Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_19

Learning Objectives

- Conduct disorder (CD) in people with intellectual disabilities
- Oppositional defiant disorder (ODD) in people with intellectual disabilities
- Intermittent explosive disorder (IED) in people with intellectual disabilities
- Stereotyped movement disorders in people with intellectual disabilities
- Other behavioural disorders with onset in childhood and adolescence
- Assessment of CD, ODD, and IED in people with intellectual disabilities

- Disruptive, impulse-control, and conduct disorders is a new category under DSM-5 classification system.
- These disorders originate in childhood and often continue into adulthood.
- There is a strong association between these disorders and intellectual disabilities (ID).
- They include conduct disorder, oppositional defiant disorder which is a less severe form of conduct disorder, and intermittent explosive disorder, which was part of impulse control disorder in the previous DSM classifications.
- By definition many of these disorders have to show an intention behind the behaviour, which is not easy to determine, particularly among those who have severe and profound ID.
- Other impulse control disorders include pyromania, kleptomania, gambling disorder, compulsive sexual behaviour disorder, trichotillomania, and excoriation disorder.
- Body-focussed repetitive behaviour, on the other hand, includes stereotyped movement disorder.
- The aetiology of these disorders is complex and often is the outcome of an interaction between internal factors within the person and external factors such as the environment.
- Therefore, the management of these disorders requires input from a multitude of professionals with relevant and specific skills to provide a person-centred assessment and management.
- The ultimate aim should be to improve the quality of life of the person with ID and their family members.

Tip

- The DSM-5 criteria are often difficult to apply to people with intellectual disabilities for conduct disorder, intermittent explosive disorder, and oppositional defiant disorder.
- Therefore, instead of making a psychiatric diagnosis as per DSM-5 criteria, it is more important to describe the behaviour which will lead to a better management.

19.1 Disruptive, Impulse-Control, and Conduct Disorders

19.1.1 Introduction

Disruptive, impulse-control, and conduct disorders (CD) are characterised by impairment in the ability to control emotions and behaviours to an extent that the resulting behaviours have a clinically significant impact on an individual and her or his interactions with others and/or society. The six specified disruptive, impulse-control, and CD are (a) antisocial personality disorder, (b) CD, (c) oppositional defiant disorder (ODD), (d) intermittent explosive disorder (IED), (e) kleptomania, and (f) pyromania. In a way ODD is considered as the less severe form of CD. In order to meet DSM-5 [1] diagnostic criteria for disruptive, impulse-control, and CD, there should be evidence that an individual present with behaviours that violate the rights of others (e.g. aggression, destruction of property) and/or bring the individual into significant conflict with societal norms or authority figures.

In the previous DSM classification such as the DSM-IV-TR [2], CD and ODD were included in the attention deficit hyperactivity

disorder (ADHD) and disruptive behaviour disorder category. In the previous version of DSM, 'Impulse-Control Disorders' included IED, kleptomania, and pyromania. These are now classified within the new DSM-5 classification as disruptive, impulse-control, and CD. Also included in this category are CD, ODD (both previously classed as Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence) and antisocial personality disorder (see ▶ Chap. 31).

Previously, trichotillomania and pathological gambling were also included in Impulse-Control Disorders Not Elsewhere Classified. However, in the DSM-5, these disorders are now included within obsessive-compulsive and related disorders and substance-related and addictive disorders respectively. Habit disorders such as finger sucking, body rocking, and bruxism are classed as stereotypic movement disorders and are included among motor disorders under the 'neurodevelopmental disorders' section of DSM-5 [1]. Antisocial personality disorder is included in DSM-5 [1] both under the 'Disruptive, Impulse-control, and CD' category as well as under the 'Personality Disorder' category.

Diagnoses of other specified or unspecified disruptive, impulse-control, and CD may be given when an individual has symptoms which are characteristic of the specific disorders listed above but do not meet the full diagnostic criteria. These diagnoses may be used for individuals with presentations in which there is insufficient information to make a more specific diagnosis.

19.1.2 Issues in the Use of Diagnosis in Intellectual Disabilities

There are a number of difficulties when using these terms in relation to people with intellectual disability (ID). These diagnostic categories are hardly used in day-to-day practice, instead a broader term such as problem (challenging) behaviour is used more widely both in clinical practice and in research. The term 'problem behaviour' is used to describe 'socially unacceptable behaviour that causes distress, harm or disadvantage to the persons themselves or to other people, and usually requires some intervention' [3] and includes behaviours such as verbal or physical aggression to others, physical aggression to property and/or self, screaming, shouting, indiscriminate wandering, objectionable personal habits including smearing of faeces and pica, etc., antisocial behaviour including taking others' possession without permission, etc., unacceptable sexual behaviours, and stereotyped movement not caused by a neurological disorder.

DSM-5 [1] reports that these disorders usually develop in childhood or adolescence. This criterion applies equally to people with ID. However, for individuals with ID there may be a higher likelihood that symptoms remain unrecognised or are misinterpreted until adulthood because of the difficulties encountered when assessing and diagnosing psychiatric and behavioural disorders in this group [4, 5], particularly among children and adolescents. For individuals with ID, before making a diagnosis one has to consider whether the behaviour is both age and developmentally appropriate as in many people with ID, developmental age does not correspond to their chronological age.

One of the reasons that diagnoses such as CD and ODD are rarely used in ID literature is that these disorders assume that the person is behaving with an intent, which is difficult to determine in most people with ID who exhibit problem behaviour. Another problem is with the DSM-5 criterion that stipulates that a diagnosis of IED cannot be made before the age 6 years. As individuals with severe and profound ID are likely to have a mental age below 6 years, this diagnosis cannot be applied to this group of people [6].

Among the general population who do not have ID, disruptive, impulse-control, and CD are known to commonly occur with each other, substance use disorders, and ADHD. This might as well be the case for people with ID. Because of these difficulties with diagnostic categories Deb and colleagues [6] suggested that a diagnosis based on a group of behaviours may be better for an appropriate formulation of management than a syndromic categorisation.

The DSM-5 [1] acknowledges that many of the behaviours associated with disruptive, impulse-control, and CD are present in the general population and that when formulating a diagnosis 'the frequency, persistence, pervasiveness across situations, and impairment associated with the behaviors…[should] be considered relative to what is normative for a person's age, gender, and culture'. For individuals with ID, attention should also be paid to what is considered normative relative to an individual's developmental level.

19.1.3 Assessment of Behaviour

As a diagnosis of disruptive, impulse-control, and CD cannot be made in most people with ID, particularly for those who have severe and profound ID, Deb and colleagues in DM-ID-2 [6] recommended that in practice, clinicians should make a diagnosis of 'problem (challenging) behaviour' outside the DSM-5 [1] framework and describe the frequency and severity of these behaviours along with severity ratings (mild, moderate, severe) and frequency ratings (low, medium, high). They recommend a multidisciplinary, person-centred assessment of the behaviours using a schema based on the assessment of the *B*ehaviour, the *P*erson showing the behaviour, *P*sychological and psychiatric factors, *M*edical and organic factors, and *S*ocial factors (BMPPS) (see ► Chap. 7 and ► https://spectrom.wixsite.com/project).

Assessment of behaviour should include the person's history of problem behaviour; baseline behaviour prior to the onset of the current behaviour; how the behaviour started, whether they appeared gradually over time or relatively abruptly, perhaps precipitated by an acute event; the frequency, severity, and duration of the behaviour; the nature, content, and context of the behaviour, as some behaviour may occur in certain circumstances/settings but not in others, associated behaviours; and the impact of the behaviour on the person's life, others' lives, and the environment. The behaviour may lead to reduced quality of life for the individual and her/his caregiver. The behaviour may lead to reduced access to services including education, day service, and employment opportunity, and may lead to a threatened or actual loss of placement in a residential setting or day placement. The behaviour may lead to reduced social activities including leisure activities, access to friends, etc.

In severe cases the individual may end up being physically restrained, inappropriately medicated, or taken to a hospital or police station. All these scenarios may subsequently have their impact on the individuals, their behaviour, and their caregivers. For example, some of these outcomes may work as perpetuating factors for the ongoing behaviour. These outcomes may be seen as inappropriate or excessive and the individuals or their caregivers may perceive them as punishments.

A risk assessment should be carried out which should include (a) risk to others, (b) risk to the individual, (c) risk to the environment, and (d) other risks. Where possible use a standardised method of risk assessment but always make a record of the assessment and review them periodically.

19.1.3.1 Assessment of Medical and Organic Factors Should Include

- Chronic physical conditions such as headache, toothache, and pain in other parts of the body.
- Medical conditions such as acid reflux, chest infections that are common in people with ID.
- Epilepsy which is common in people with ID [7].
- Neurological conditions such as cerebral palsy.
- Genetic conditions such as Prader-Willi syndrome, Fragile X syndrome, and Lesch-Nyhan syndrome which are known to be associated with problem behaviour [10].
- Hearing and visual impairments which can lead to problem behaviour form frustration.
- Sensory processing issues in people with ASD.

- Communication problems where the individual may use problem behaviour to communicate or a discrepancy between expression and comprehension.
- Physical disabilities causing frustration.
- Illicit drug and alcohol use, although this may be more of an issue in people with borderline intelligence.
- Adverse effects of prescribed medicines.

19.1.3.2 Assessment of Psychological and Psychiatric Factors

Psychiatric disorders such as mood disorders, schizophrenia, other psychoses, and anxiety-related disorders may lead to problem behaviour in people with ID [4]. ASD and ADHD are also common comorbidities resulting in higher rates of problem behaviour. It is important to investigate for these conditions as the management of the problem behaviour will depend on the management of the underlying condition.

Psychological and emotional factors such as bereavement and trauma and abuse (physical, emotional, or sexual), historical, ongoing, recurring or new, or stress and relationship difficulties may lead to loss of self-esteem and isolation, causing and perpetuating problem behaviour.

19.1.3.3 Assessment of Social Factors

Environmental factors have an important role to play as some people with ID may present with problem behaviour if they find themselves in an environment which they find too demanding or understimulating. Personalities and attitudes of others towards the person, including care givers can also affect the person with ID. Needless to say, management styles could impact on the individual too, for example confrontational attitude.

19.1.4 Conduct Disorder

The essential feature of Conduct Disorder (CD) is a repetitive and persistent pattern of behaviour that violates the basic rights of others or that breaks major age-appropriate societal norms or rules. Behaviours are grouped into four major categories: (a) aggression to people or animals, (b) destruction of property, (c) deceitfulness or theft, and (d) serious violation of rules. As with all psychiatric conditions, the presentation must cause clinically significant impairment in social, academic, or occupational functioning.

These disorders could be of (a) childhood onset where the behaviour is present before the age of 10 years or (b) adolescent onset where no symptoms are observed before the age of 10 years. Unspecified onset category applies to those for whom where there is insufficient information to determine the age of onset of symptoms.

Following are the DSM-5 [1] criteria for diagnosis of CD, none of which could be applied to those who have severe and profound ID as it is not possible to determine the underlying intention behind the behaviour. All three criteria (A, B, C) must be met in order to qualify for the diagnosis.

- **DSM-5 Diagnostic *Criteria A* [1]**

Repetitive and persistent pattern of behaviour in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of three or more of the following criteria in the past 12 months, with at least one criterion present in the past 6 months. The clinician should assess age appropriateness of the behaviour and ascertain that the individual understands societal rules and norms.

19.1.4.1 Aggression to People and Animals

- Often bullies, threatens, or intimidates others.
- Often initiates physical fights.
- Has used a weapon that can cause serious physical harm to others (e.g. bat, brick, broken bottle, knife, gun).
- Has been physically cruel to people.
- Has been physically cruel to animals.

In case of people with ID, it is important to ascertain that the individual displaying the

behaviour has understood the significance and impact of her or his actions.

19.1.4.2 Destruction of Property

- Has deliberately engaged in fire setting with the intention of causing serious damage.
- Has deliberately destroyed others' property (other than by fire setting).

In case of people with ID, clinician should assess intent behind the behaviour. Even some people with mild ID may have difficulties with communicating their thoughts and feelings. The intent is even more difficult to determine in people with severe ID.

19.1.4.3 Deceitfulness or Theft

- Has broken into someone else's house, building, or car.
- Often lies to obtain goods or favours or to avoid obligations (i.e. 'cons' others).
- Has stolen items of nontrivial value without confronting a victim (e.g. shoplifting, but without breaking and entering; forgery).

In case of people with ID, it is important to establish that the individual understands the concept of ownership.

19.1.4.4 Serious Violations of Rules

- Often stays out at night despite parental prohibitions, beginning before age 13 years.
- Has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period).
- Is often truant from school, beginning before age 13 years.

In case of ID, it is important to carefully examine the home environment and the reasons why the individual is running away. For example, if there is evidence of inadequate care, neglect, or abuse, the relevance of this behaviour to the diagnosis should be questioned. Careful examination of school environment is necessary to rule out any reasonable cause such as distress due to bullying.

- **DSM-5 Diagnostic *Criterion B* [1]**

The disturbance in behaviour causes clinically significant impairment in social, academic, or occupational functioning.

- **DSM-5 Diagnostic *Criterion C* [1]**

If the individual is 18 years or older, criteria are not met for antisocial personality disorder.

- **Severity:**

Mild: few if any conduct problems in excess of those required to make the diagnosis *and* conduct problems cause only minor harm to others.

Moderate: number of conduct problems and effect on others intermediate between 'mild' and 'severe'.

Severe: many conduct problems in excess of those required to make the diagnosis *or* conduct problems cause considerable harm to others.

It cannot be assumed that the person with ID understands the basic rights of others and appropriate social norms. The four categories of behaviours to be rated in CD cannot be viewed as equivalent in the case of people with ID. There are examples of people with ID showing aggression towards people or animals and destroying property, but there are far fewer instances of deceitfulness or serious violation of rules. The difference is in the nature of the intent. Aggression and destruction can occur when the person is frustrated and does not have any other available outlet to express their frustration. Serious violation of rules could also occur in the absence of intent, either because the person does not understand the rules or because the person does not appreciate the consequences of their actions. Deceit, however, is by definition an intended act.

Often people with ID function at a level much lower than their chronological age, which makes it difficult to determine the age appropriateness of the behaviour. When the function

of the behaviour (what the behaviour is trying to achieve) is understood, making a diagnosis of CD becomes difficult, even for those functioning at borderline levels of intelligence.

Clinicians should focus on the interaction between social environment and the individual and not assume that the responsibility lies with the individual for which it is necessary to use multiple sources of information during assessment. People with ID themselves can be essential sources of information.

Assessment should focus on obtaining the most direct information regarding current behaviours. Information on previous problem behaviour if any should be collected to determine onset, predisposing, precipitating, and perpetuating factors for the individual's behaviour. Frequency and severity of each current and past behaviours should be assessed [11] along with repetitiveness and chronicity to indicate the onset and stability over time, and developmental appropriateness.

The determination of age appropriateness depends on an understanding of both normal developmental patterns and the behavioural patterns presented by the person. For example, one might be reluctant to assign the label 'stealing' to a person for whom it is unclear whether she or he understands the concept of personal ownership.

Assessment of environment plays an important part in determining the diagnosis of CD. Behaviours that are inconsistent across settings suggest environmental influence on behaviour. The behaviours may be generated by environmental factors which would weigh against a diagnosis of CD. Importance of making assessments across multiple settings is that multiple informants are likely to be used, thus somewhat mitigating reporting bias.

19.1.5 Oppositional Defiant Disorder

The essential feature of Oppositional Defiant Disorder (ODD) is a recurrent pattern of angry, irritable mood with defiant, disobedient, and hostile vindictive behaviour towards at least one individual who is not a sibling. The behaviour must occur more frequently than would occur typically in individuals of comparable age and development and has to cause significant impairment in social, academic, or occupational functioning. All three DSM-5 [1] criteria (A, B, C) must be met in order to qualify for the diagnosis.

The DSM-5 [1] criteria could not be applied for those who have severe and profound ID and who lack communication skills but could be applied to those who have mild to moderate ID and could communicate with some caveats (see next section).

- **DSM-5 Diagnostic** *Criteria A* **[1]**

Pattern of angry/irritable mood, argumentative/defiant behaviour, or vindictiveness lasting at least 6 months, during which four or more of the following are present:

1. Often loses temper
2. Often touchy or easily annoyed
3. Often angry and resentful
4. Often argues with authority figures or, for children and adolescents, with adults
5. Often actively defies or refuses to comply with requests from authority figures or with rules
6. Often deliberately annoys others
7. Often blames others for his or her mistakes or misbehaviour
8. Spiteful or vindictive at least twice within the past 6 months

To apply this diagnosis to people with ID, the clinician must rule out any other reasons for the behaviour (see ▶ Chap. 7). The clinician also needs to carry out a language and cognitive assessment to rule out comprehension and specific cognitive difficulties that might otherwise explain the noncompliance and other associated behaviour. Assessment of both intent and developmental age is also required. Consider a criterion met only if the behaviour occurs more frequently than is typically observed in individuals of comparable age and developmental level.

- **DSM-5 Diagnostic** *Criterion B* **[1]**

The disturbance in behaviour is associated with distress in the individual or others in the

immediate social context. Further, it causes clinically significant impairment in social, academic, or occupational functioning.

DSM-5 Diagnostic *Criterion C* [1]

The behaviours do not occur exclusively during the course of a psychotic disorder, mood disorder or substance use.

Rates of problem behaviour which may or may not include CD and ODD vary widely between 2% and 60% [4, 12, 13] depending on the diagnostic criteria used and the type of population studied. The rates may also vary depending on factors like age, gender, etc. (see ► Chap. 7) [4, 14, 15]. Impairments in impulse control may be associated with aggressive behaviour in people with ID and also borderline intellectual functioning [15, 16].

Given that the locus of control in their lives is often outside their control, people with ID are more likely to feel frustrated and for this to manifest itself as insufficient self-regulation and defiance. For this reason, the clinicians have to be mindful of the danger of possible overdiagnosis of ODD in people with ID.

People with severe ID may not have the necessary language and cognitive abilities to be able to meet some of the criteria, such as argue with others, blame others, or be vindictive. It is thus incumbent on clinicians to conduct a comprehensive assessment of all relevant factors, including physical and mental health status, quality of the environment, possible sources of stress, and possible abuse and come to an accurate formulation which may point away from such a diagnosis. A diagnosis of ODD often lends the impression that the responsibility for the problem lies mainly within the individual themselves, rather than an interaction between the individual and the social environment or with other systemic factors [6].

A thorough assessment is necessary addressing the following issues in order to make the correct diagnosis and formulate an appropriate management plan.

- The nature of the behaviours must be explored in detail, including the circumstances in which they occur, including the predisposing, precipitating, and perpetuating factors.
- Assess the amount of control the individual seems to have over these behaviours.
- Make a list of all current and previous behaviours being displayed.
- Clarify the referral question.
- Determine who are affected by the behaviour, where and when do they occur?
- Define them in each area of the individual's life.
- Determine whether these behaviours are developmentally appropriate or not?
- Obtain a careful biopsychosocial history, to chart onset, course, and contributing risk factors.
- Assess the strengths and weaknesses of the individual that may have an impact on the behaviour.
- Assess the individual's cognitive, communication, occupational, and social function.
- Exclude comorbidities such as anxiety disorder, ASD, ADHD, PTSD, history of abuse that may have a bearing on the behaviour.
- How has the individual's behaviour affected the social environment and vice versa?
- What systematic factors contribute to or maintain the disruptive behaviour?
- What has the individual been referred for and by whom?
- Evaluate the reliability of the referral and informant sources.
- Gather information from as many sources as possible including the individual with ID and from direct observation of behaviour in different settings where possible.
- Consider the fact that transient oppositional behaviour may be common among preschool children and adolescents.

Emerson and Hatton [13] reported ODD among 13.3% of youth with ID compared with 2.3% in typically developing youths. In contrast Christensen and colleagues [17] reported among 5–9-year-old children, a point prevalence of ODD between 21% and 29% among the typically developing children compared with 35–44% among those who had borderline intellectual functioning and 39–48% among children who had ID. They noticed comorbidities with other disorders,

particularly ADHD, among children with ID. However, they did not find any intergroup differences in the rate of ODD according to gender, age of onset, or stability of the behaviour.

19.1.6 Intermittent Explosive Disorder

Intermittent Explosive Disorder (IED) is characterised by recurrent impulsive aggressive outbursts that are grossly out of proportion to any provocation or psychosocial stressor. Explosive episodes may be frequent and less severe (non-injurious) and less frequent but involving severe aggressive behaviour, such as destruction of property or physical assault with injury against an animal or a person. An important qualifier is that the aggressive outbursts are impulsive in nature and not premeditated or instrumental.

The recurrent aggressive outbursts cause marked distress or impairment in occupational or interpersonal functioning or are associated with social, financial, or legal consequences. The aggression in IED is characteristically more intense than what is observed in ADHD, CD, ODD, and antisocial and borderline personality disorders. IED should not be diagnosed in children younger than 6 years of age or in children aged 6–18 years if aggression occurs in the context of an adjustment disorder. This criterion makes this diagnosis invalid for people who have severe and profound ID, whose developmental age is likely to be lower than 6 years. This diagnosis may also be difficult to apply to those with less severe degree of ID (see notes in the next section).

IED should not be diagnosed in people with disruptive mood dysregulation disorder (DMDD), or whose impulsive aggressive outbursts are attributable to another medical condition or to the physiological effects of a substance or another mental disorder. All three DSM-5 [1] criteria (A, B, C) must be met in order to qualify for the diagnosis.

- **DSM-5 Diagnostic** *Criteria A* **[1]**

Pattern of angry/irritable mood, argumentative/defiant behaviour, or vindictiveness lasting at least 6 months, during which four or more of the following are present:

1. Often loses temper
2. Often touchy or easily annoyed
3. Often angry and resentful
4. Often argues with authority figures or, for children and adolescents, with adults
5. Often actively defies or refuses to comply with requests from authority figures or with rules
6. Often deliberately annoys others
7. Often blames others for his or her mistakes or misbehaviour
8. Spiteful or vindictive at least twice within the past 6 months

To apply this diagnosis to people with ID, the clinician must rule out any other reasons for the behaviour (see ▶ Chap. 7). The clinician also needs to carry out a language and cognitive assessment to rule out comprehension and specific cognitive difficulties that might otherwise explain the noncompliance and other associated behaviour. Assessment of both intent and developmental age is required. Consider a criterion met only if the behaviour occurs more frequently than is typically observed in individuals of comparable age and developmental level.

- **DSM-5 Diagnostic** *Criterion B* **[1]**

The disturbance in behaviour is associated with distress in the individual or others in the immediate social context. Further it causes clinically significant impairment in social, academic, or occupational functioning.

- **DSM-5 Diagnostic** *Criterion C* **[1]**

The behaviours do not occur exclusively during the course of a psychotic disorder, mood disorder, or substance use.

The onset of recurrent, problematic impulsive aggressive behaviour is most common in late childhood or adolescence [18]. The core

features of IED typically are persistent and continue for many years. The course of the disorder may be episodic, with recurring periods of impulsive aggressive outbursts. Coccaro and colleagues [19] reported a lifetime prevalence rate of 11% and a 1-month prevalence of 2.3% in a community sample of adults. These prevalence rates depend on the definition used for IED.

Certain factors make people with ID vulnerable to IED. For example, they may find it difficult to control their impulse compared with those who possess better psychological defence mechanism and stress management skills to deal with their inner frustration and anxiety. It may be difficult to be sure of the instrumental nature of behaviour in people with significant intellectual and communication impairment because the underlying intention could not be assumed. Other factors such as comorbid seizure disorders, developmental brain abnormalities, and environmental factors may all contribute to the behaviour (see ▶ Chap. 7). Some highlighted a role of life events as possible contributing factor to IED [20] among adults with ID, which may suggest a connection between explosive aggression and hyperarousal provoked by specific conditioned fear experiences in these individuals.

A multidisciplinary assessment is needed to confirm a diagnosis of IED in an individual with ID. The multidisciplinary team may include a psychiatrist, a psychologist or behaviour specialist, a speech and language therapist, a nurse, an occupational therapist, a social worker, and a neurologist where necessary. Caregivers including family members and other close informants such as teachers should also contribute to the discussion. Individual with ID should also take part in the discussion where necessary and appropriate.

A thorough physical and mental state examination is necessary to exclude any medical and psychiatric cause of aggressive behaviour. A neurologist may assist in the diagnosis and management of epilepsy and other neurological disorders which may be contributing to the aggressive behaviour [7–9] (see ▶ Chap. 7). The psychologist or behaviour specialist/nurse may help in gathering data on the nature, frequency, target, and impact (damage or injury) of aggression and carrying out a functional assessment of the behaviour. Finally, any history of abuse or trauma should be discussed in the context of identifying stimuli that may trigger an aggressive fear response.

Biological including genetic, developmental, psychosocial including environmental and family factors should be carefully assessed. The following conditions could be coexistent with or should be differentiated from IED.

- Disruptive mood dysregulation disorders (DMDD)
- Antisocial personality disorder or borderline personality disorder
- Delirium
- Major neurocognitive disorders
- Aggressive behaviour due to another medical condition
- Substance intoxication or substance withdrawal
- ADHD
- ODD
- CD
- ASD

19.1.7 Disruptive Mood Dysregulation Disorders

In DSM-5 [1] a new diagnostic category called 'Disruptive Mood Dysregulation Disorders (DMDD)' has been created under the overall 'Depressive disorder' category. This was done to categorise youths who display severe irritability and aggression chronically. DMDD is defined primarily by two features: (a) frequent severe temper outburst, and (b) persistent irritability evident every day for most of the day. Unlike the previous diagnosis of 'severe mood dysregulation', DMDD excludes hyperarousal (e.g. insomnia, agitation, distractibility, racing thoughts) from the essential criteria. Although theoretically DMDD is distinguishable from CD and ODD on the basis of severity, it is not so easy in practice to apply this distinction.

This causes confusion among the DMDD diagnosis and CD and ODD diagnoses. Therefore, some suggested that DMDD should be used as a specifier of ODD rather than a separate diagnosis [21]. Lochman and colleagues [21] also highlighted the danger of potential misdiagnosis of severe chronic irritability as a bipolar disorder which may lead to inappropriate use of medication.

19.1.8 Pyromania

A diagnosis of pyromania is made when a person repeatedly sets fires deliberately to relieve arousal or obtain pleasure from or relief of unpleasant tension upon watching the fire. The act is repetitive, deliberate, and for the purpose of relief of tension. This is not done for any other purpose or caused by any other mental disorder.

Only a small proportion of people with ID who set fires can be diagnosed with pyromania since most cases of fire setting occur for reasons that would exclude the diagnosis. The presence of ID particularly when severe and profound is likely to cause difficulty in assessing motivation and the presence of tension and relief of tension. In the case of severe or profound ID such assessments would be very difficult, if not impossible to carry out. Similarly, the observer of this act would have difficulty assessing whether there is a motive behind the act. DSM-5 [1] criteria also exclude a diagnosis of pyromania in the presence of impaired judgement which may be the case for many people with ID. Therefore, we do not think that this diagnosis could be applied to those who have severe and profound ID and who are unable to communicate their thoughts, feelings, and emotions.

19

DSM-5 Diagnostic Criteria [1]

A. Deliberate and purposeful fire setting on more than one occasion.
B. Tension or affective arousal before the act.
C. Fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (e.g. paraphernalia, uses, consequences).
D. Pleasure, gratification, or relief when setting fires or when witnessing or participating in their aftermath.
E. The fire setting is not done for monetary gain, as an expression of sociopolitical ideology, to conceal criminal activity, to express anger or vengeance, to improve one's living circumstances, in response to a delusion or hallucination, or as a result of impaired judgement (e.g. in major neurocognitive disorders, intellectual disabilities, substance intoxication).
F. The fire setting is not better explained by CD, a manic episode, or anti-social personality disorder.

This diagnosis has to be distinguished from abnormal rituals and interests that may be seen in a person with ASD. The clinician has to consider the difficulty in ascertaining the exact inner feelings of a person with ID.

Whereas the acts of fire setting and arson are committed by people with ID, it is not clear how many of these acts will qualify for a diagnosis of pyromania which is likely to be made of a very small subgroup of fire-setters [22–27]. Published reports identify individuals as fire setters or arsonists in a forensic setting but not in the community. It is not clear whether fire-setting is more or less prevalent among people with ID than in the general population who do not have ID. However, Jacobson [28] reported an association between the rate of fire-settings and an increasing severity of ID. Taylor and colleagues [29, 30] showed that group intervention could be effective for women with ID who set fires.

19.1.9 Kleptomania

The diagnosis requires repetitive stealing not due to the need for personal use, monetary value, anger, vengeance, or in response to delusions, hallucinations, or other mental disorders. The stealing is done to alleviate tension. It may be difficult to determine

whether these conditions are met in mild and moderate ID and it is not possible to make this diagnosis in people with severe and profound ID.

The diagnosis of kleptomania requires ascertainment of motives and the presence of tension and gratification upon stealing. Some people with ID will have difficulty describing these measures due to poor verbal skills, lack of understanding of what these measures mean, and even, inability to understand the concept of ownership and personal property.

- **A.DSM-5 Diagnostic Criteria [1]**

B. Recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value.
C. Increasing sense of tension immediately before committing the theft.
D. Pleasure, gratification, or relief at the time of committing the theft.
E. The stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination.
F. The stealing is not better explained by CD, a manic episode, or antisocial personality disorder.

In case of people with ID, it is important to assess that the individual understands the sense of ownership and normal societal rules regarding possession. The difficulty of assessing inner feelings of a person with ID should be considered.

No information is available on the development and course of this disorder. The prevalence is unknown, although stealing without meeting the criteria for kleptomania is not unusual among people with ID. This may be seen as part of mania, CD, or antisocial personality disorder. Kleptomania would severely interfere with social adaptation. No research literature concerning kleptomania in people with ID could be found except a case report in the context of naltrexone treatment. Jacobson [28] reported an increased rate of property theft associated with increased severity of ID.

19.1.10 Trichotillomania

Also known as 'hair pulling disorder', involves recurrent, irresistible urge to pull hair from scalp, eyebrows, eyelids, and other areas of the body, despite repeated attempts to stop or decrease hair pulling. In DSM-5 [1], this is classified under Obsessive Compulsive and Related Disorders.

- **DSM-5 Diagnostic Criteria [1]**

A. Recurrent pulling out of one's hair, resulting in hair loss.
B. Repeated attempts to decrease or stop hair pulling.
C. The hair pulling causes clinically significant distress or impairment in social, occupational, or other important area of functioning.
D. The hair pulling or hair loss is not attributable to another medical condition (e.g. a dermatological condition).
E. The hair pulling is not better explained by the symptoms of another mental disorder (e.g. attempts to improve a perceived defect or flaw in appearance in body dysmorphic disorder).

Hair pulling can happen in people with ID, as part of a syndrome such as Down syndrome, Prader-Willi syndrome as part of the behavioural phenotype or in people with autism and sensory issues. While they would meet Criterion A, the rest of the criteria would not be met. Pulling out hair and consuming it is a cause of bowel obstruction in people with ID [31].

19.1.11 Excoriation (Skin-Picking) Disorder

- **DSM-5 Diagnostic Criteria [1]**

A. Recurrent skin picking resulting in skin lesions.
B. Repeated attempts to decrease or stop skin picking.
C. The skin picking causes clinically significant distress or impairment in social,

occupational, or other important areas of functioning.

D. The skin picking is not attributable to the physiological effects of a substance (e.g. cocaine) or another medical condition (e.g. scabies).
E. The skin picking is not better explained by symptoms of another medical condition (e.g. tactile hallucinations or delusions in a psychotic disorder, attempts to improve a perceived defect or flaw in appearance in body dysmorphic syndrome, stereotypies in stereotypic movement disorder, or intention to harm oneself in non-suicidal self-injury).

As with hair pulling, skin picking is not uncommon, particularly in people with ID and autism and people with behavioural phenotypes such as Smith Magenis syndrome.

19.1.12 Gambling Disorder

- **DSM-5 Criteria**

A. Persistent and recurring problematic gambling behaviour leading to clinically significant impairment or distress as indicated by individual exhibiting four or more of the following in a 12-month period:
   1. Needs to gamble with increasing amounts of money in order to achieve the desired excitement.
   2. Is restless or irritable when attempting to cut down or stop gambling.
   3. Has made unsuccessful efforts to control, cut back, or stop gambling.
   4. Is often preoccupied with gambling (e.g. having persistent thoughts of reliving past gambling experiences, handicapping or planning the next venture, thinking of ways to get money with which to gamble).
   5. Often gambles when feeling distressed (e.g. helpless, guilty, anxious, depressed).
   6. After losing money gambling, often returns another day to get even (chasing one's losses)
   7. Lies to conceal the extent of involvement with gambling.
   8. Has jeopardised or lost a significant relationship, job or educational or career opportunity because of gambling.
   9. Relies on others to provide money to relieve desperate financial situations caused by gambling.
B. The gambling behaviour is not better explained by a manic episode.

Gambling disorder can be episodic or persistent and can be mild (4–5 criteria met), moderate [7, 10], or severe [11, 12].

The prevalence of gambling disorder in people with ID is not known. People with more severe degrees of ID will be supervised and may not have access to finances to gamble. It may be fair to say that there is a complex interplay of factors in people with ID. Tromans and colleagues [32] describe the association of temporal lobe epilepsy, ASD, and gambling disorder in a man with mild ID.

19.2 Secondary Impulse Control Disorders

19.2.1 Hoarding Disorder

Hoarding disorder affects both men and women. Epidemiological studies report significantly higher prevalence among men which contrasts clinical samples where women predominate. Community surveys estimate point prevalence of clinically significant hoarding to be approximately 2–6% [1]. Hoarding symptoms are three times more common in older adults, aged 55–94 years compared with younger adults.

Hoarding begins early in life, starts interfering with everyday functioning by mid-twenties and significant impairment by mid-thirties. Individuals have persistent difficulties discarding or parting with possessions, regardless of their actual value. The main reasons given are the perceived utility or the aes-

thetic value of the item or the strong sentimental attachment to the possessions. Commonly saved items include newspapers, magazines, old clothing, books, bags, mail, and paperwork, but virtually any item can be saved. Individuals experience distress when faced with the prospect of discarding them which emphasises the intentional aspect of hoarding. They accumulate large number of items which fill up and clutter living areas so that they are no longer habitable so much so that the individual may not be able to sleep on their bed or cook in their kitchen. Third parties such as family members, local authorities may have to intervene to remove clutter. Symptoms such as discarding items must cause clinically significant distress. People with hoarding disorder may show features of indecisiveness, perfectionism, avoidance, procrastination, difficulty in planning and organisation, and distractibility. Half of these people have a relative with the condition.

DSM-5 Diagnostic Criteria [1]

A. Persistent difficulty discarding or parting with possessions, regardless of their actual value.
B. This difficulty is due to a perceived need to save the items and to distress associated with discarding them.
C. The difficulty discarding possessions results in the accumulation of possessions that congest and clutter active living areas and subsequently compromises their intended use. If living areas are uncluttered, it is because of the interventions of third parties (e.g. family members, cleaners, authorities).
D. The hoarding causes clinically significant distress or impairment in social, occupational, or other important areas of functioning (including maintaining a safe environment for self and others).
E. The hoarding is not attributable to another medical condition (e.g. brain injury, cerebrovascular disease, Prader-Willi syndrome).
F. The hoarding is not better explained by the symptoms of another mental disorder (e.g. obsessions in obsessive compulsive disorder, decreased energy in major depressive disorder, delusions in schizophrenia or another psychotic disorder, cognitive deficits in major neurocognitive disorder, restricted interests in ASD).

Specify if: *with excessive acquisition:* if difficulty discarding possession is accompanied by excessive acquisition of items that are not needed or for which there is no available space.

Specify if:

with good or fair insight: The individual recognises that hoarding related beliefs and behaviours (pertaining to difficulty discarding items, clutter, or excessive acquisition) are problematic.

with poor insight: The individual is mostly convinced that hoarding-related beliefs and behaviours (pertaining to difficulty discarding items, clutter, or excessive acquisition) are not problematic despite evidence to the contrary.

with absent insight/delusional beliefs: The individual is completely convinced that hoarding related beliefs and behaviours (pertaining to difficulty discarding items, clutter, or excessive acquisition) are not problematic despite evidence to the contrary.

Although ID itself is an exclusion in the diagnosis of hoarding disorder, this behaviour occurs in people with ID. Testa and colleagues [33] found that among 61 children with ID, 16.4% exhibited hoarding as a major clinical issue. When the children with ID and hoarding were compared with age-, sex-, and IQ-matched ID participants without hoarding, hoarders exhibited a slower learning curve on word list-learning task.

Diogenes syndrome is characterised by marked self-neglect, domestic squalor, social withdrawal, and hoarding of rubbish and is named after Greek philosopher Diogenes, known for his pursuit of self-sufficiency, freedom from material possessions, and disregard for social niceties and creature comforts. Williams and colleagues [34] describe two women with mild ID who fit the criteria for Diogenes syndrome and discuss the possible differential diagnoses. Hoarding was a significant feature in both of them. One of them made a significant improvement when she returned to the care of her mother and the hoarding stopped completely but the situation continued with the second one.

Hoarding is part of the behavioural phenotype of Prader-Willi syndrome. Dykens and colleagues [35] examined the nature, severity, and correlates of non-food obsessions and compulsions in 91 people with Prader-Willi syndrome and found that 47% showed hoarding behaviour. Participants hoarded a variety of objects such as old batteries, trash, papers, pens, and toiletries. Respondents often noted that some objects were collected and stored in a specific manner, for example books or toys in a series had to be purchased and then arranged in sequential order. Many care givers noted the need for subjects to sort and arrange toys, clothing, or papers according to specific rules based on size, shape, colour, or simply until they were 'just right'. As repetitive behaviours occur in 86% of people with Williams syndrome, Royston and colleagues [36] examined the profile of behaviours, comparing them with those with Prader-Willi and Down syndromes. They administered the Repetitive Behaviour Questionnaire to care givers of adults with Williams (n = 96), Prader-Willi (n = 103), and Down (n = 78) syndromes, respectively. There were few group differences, although participants with Williams syndrome were more likely to show body stereotypies. Individuals with Williams syndrome also showed more hoarding and less tidying behaviours than those with Down syndrome.

Lane and colleagues [37] suggest that hoarding can be complicated for individuals with developmental disabilities living in congregate settings because it can interfere with staff and peer relationships and affect potential community placement. Berry and Schell [38] evaluated the effects of individualised reinforcement and item return procedures on hoarding behaviour in a multiple baseline across three persons with severe ID. Systematic preference assessment procedures identified items used in the individualised reinforcement procedures. There was a reduction in hoarding behaviour for each person when individualised treatment and where item return procedures were applied, and these reductions were maintained when direct support staff were trained to provide treatment. Kellet and colleagues [39] provided 12 cognitive behaviour therapy (CBT) sessions to 14 people with mild ID on domiciliary visits at their residential facilities in the community and followed them up 6 months later. They found no evidence of relapse or adverse events and suggest from this open label trial that CBT may be a safe intervention for people with ID who exhibit hoarding behaviour.

19.2.2 Compulsive Sexual Behaviour Disorders

Compulsive sexual behaviour disorder has been proposed for inclusion as an impulse control disorder in the ICD-11 [40]. It is characterised by a persistent pattern of failure to control intense, repetitive sexual impulses or urges, resulting in repetitive sexual behaviour over an extended period (e.g. six months or more) that causes marked distress or impairment in personal, family, social, educational, occupational, or other important areas of functioning [41].

The pattern is manifested in one or more of the following:

(a) Engaging in repetitive sexual activities has become a central focus of the person's life to the point of neglecting health and personal care or other interests, activities, and responsibilities.
(b) The person has made numerous unsuccessful efforts to control or significantly reduce repetitive sexual behaviour.
(c) The person continues to engage in repetitive sexual behaviour despite adverse consequences (e.g. repeated relationship disruption, occupational consequences, negative impact on health).
(d) The person continues to engage in repetitive sexual behaviour even when she or he derives little or no satisfaction from it [41].

Compulsive sexual disorder or sexual addiction is not recognised in the latest DSM-5 [1] classification system. It was previously included in the DSM-III-TR [42] as a descriptor under the general diagnosis of 'Sexual Disorder Not Otherwise Specified'.

Pang and Masiran [43] described a 22-year-old man referred from the genitourinary clinic where he had been treated for gonococcal urethritis. He experienced high libido from the age of 19 years, admitted to having sexual intercourse with more than one hundred different commercial sex workers in the last three years, with increase in frequency to gain satisfaction, having to widen his search of area to find sex workers, having to spend huge amounts of money on this activity which he financed by working as a shop assistant and by borrowing from relatives. There were withdrawal symptoms from abstinence and the sexual activity was carried out to the exclusion of all other activities. He has been physically abused by his father as a child. His academic functioning at school was poor, having failed examinations. He could not handle money or carry out age appropriate calculations. He is reported as meeting the criteria for compulsive sexual behaviour disorder in the context of mild ID and was treated by addiction services. Psychological work reduced his craving significantly.

Singh and Coffey [44] reported a case of a young man with mild ID, autism, OCD, and relapse of bipolar affective disorder who had developed ulcers on his penis from excessive masturbation. While an inpatient, he was treated with lithium and as his mood stabilised, so did the sexual behaviour. Nishimura and colleagues [45] also described a young woman with ID who started masturbating in public, with no other features of a mood disorder who did not respond to antipsychotics but improved with lithium treatment. Lamy and colleagues [46] describe a woman with ID who had herself been experienced sexual and physical abuse. She then perpetrated sexual abuse on her children.

Thom and colleagues [47] in their review suggested that the prevalence of inappropriate sexual behaviour in people with ID can be as high as 15–33%, but the nature tends to be inappropriate than violative. It may be associated with ID syndromes. For example, Fisher and colleagues [48] found a complex association between Klinefelter syndrome and hypersexuality, paraphilic behaviours, and gender dysphoria, which were mediated by obsessive compulsive and autistic traits. Börjeson-Forssman-Lehmann syndrome (BFLs) is an X-linked inherited disorder characterised by unusual facial features, abnormal fat distribution, and ID. Behaviour in persons with BFLs is in general friendly but can be challenging with externalising and thrill-seeking features but their social skills are good. de Winter and colleagues [49] described a group of four BFLs patients with inappropriate sexual behaviour as part of their behavioural phenotype.

Finally, as Sajith and colleague [50] point out, men with ID sometimes exhibit inappropriate sexual behaviours, which may be termed challenging behaviours or offending behaviours depending on the circumstances and whether criminal justice system is involved. Hawk and colleagues [51] have shown that the rate of sex offence charges was nearly twice as high among defendants with ID as among defendants without ID.

In conclusion, compulsive sexual behaviours can happen in people with ID for various reasons; as part of affective disorder, behavioural phenotype, due to environmental reasons, or as an entity in itself. However, it is important to explore the knowledge of the person with ID of sexual function, sexual relationship, and social norms before assuming that any socially inappropriate sexual acts on their part including sex offences are intentional.

19.3 Body-Focussed Repetitive Behaviour Disorder

19.3.1 Stereotypic Movement Disorder

- **DSM-5 Diagnostic Criteria [1]**

A. Repetitive, seemingly driven, and apparently purposeless motor behaviour (e.g. hand shaking or waving, body rocking, head banging, self-biting, hitting own body).
B. The repetitive motor behaviour interferes with social, academic, or other activities and may result in self-injury.

C. Onset is in the early developmental period.
D. The repetitive motor behaviour is not attributable to the physiological effects of a substance or neurological condition and is not better explained by another neurodevelopmental or mental disorder (e.g. trichotillomania, OCD).

- **Specify if:**

With self-injurious behaviour or behaviours that would result in an injury if preventive measures were not used.

Without self-injurious behaviour.

- **Specify if:**

Associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor (e.g. Lesch-Nyhan syndrome, ID, intrauterine alcohol exposure).

Mild, if symptoms can be suppressed by sensory stimulus or distraction; moderate, if explicit protective measures and behaviour modifications are required; and severe if continuous monitoring and protective measures are required to prevent self-injury.

Essential features of stereotypic movement disorder are that they are repetitive, seemingly driven, and apparently purposeless [1]. They are often rhythmical movements of head, hand, or body without obvious adaptive function and may not respond to effort to stop them. These may be seen in typically developing children, but they can be stopped when attention is drawn to them or when the child is distracted. The child may also demonstrate self-restraining behaviour, that is sit on their hands.

In typically developing infants, there is a predictable sequence of rhythmic motor development, which appears stereotypic and declines by 24 months of age [52]. This stereotypic, rhythmic motor behaviour may appear at later ages in children with Down syndrome and those with significant motor impairment [53, 54]. Moreover, children with significant developmental disabilities engage in relatively high rates of stereotypies as compared with typically developing infants and toddlers [54, 55]. Hoch and colleagues [56] compared two groups of young children, one with developmental delay and one without, and asked parents to complete standardised measures on the presence of stereotypies and self-injury. They found that stereotyped behaviour was reported significantly more frequently by parents of children with developmental delay than by parents of typically developing children (85.7% vs. 42.8%). Over half of the children with delay (53%) were described as having at least one stereotypy that was considered a moderate or severe problem in comparison with only 2% of the children without developmental delay on a standardised measure of repetitive behaviour.

Stereotypic behaviour is variable as each individual presents with her or his own signature behaviour. Examples of non-self-injurious stereotyped behaviour include body rocking, hands flapping, finger flicking, and head nodding. Examples of self-injurious stereotypic behaviour can be repeated head banging, face slapping, eye poking, and biting parts of the body. Frequency of occurrence of these behaviours can vary and be related to stress, excitement, boredom, fatigue, and multitude of factors specific to the person. In both humans and nonhuman primates, aberrant stereotyped behaviour including self-injury has been associated with adverse environmental circumstances and early CNS damage [57].

Stereotypic behaviours occur in a variety of neurodevelopmental conditions, particularly in people with ID and ASD. Bodfish and colleagues [58] found a prevalence of stereotypy of 60.9% and self-injury 46.6%; and compulsion when they surveyed people with severe and profound ID. Rojahn and colleagues [59] found 54% of 432 randomly selected residents from a developmental centre had stereotyped behaviour and 43%, self-injury. The determination of the functional profile of a targeted behaviour has important implications for the design of customised behavioural interventions. Medeiros and colleagues [60] investigated the relationship between the level of ID and the functional profile of aggression, stereotypy, and self-injurious behaviour. They found that individuals with mild ID tended to use self-injurious

behaviour less often for tangible rewards or to escape social demands than individuals with severe ID who tended to use them for these same purposes significantly more often. This could be helpful in devising interventions, together with language and communication training which may help people with severe ID express themselves about when they wanted a break from social demands. Research also showed that aggressive and stereotypic behaviour problems can function, regardless of the severity of ID, for the purposes of attention, sensory stimulation, pain reduction, social escape, and tangible reinforcement. A functional assessment is, therefore, an essential part of the assessment process (see Assessment section in the ► Chap. 7).

Despite their core significance in ASD, it is not clear whether there are distinct groups of stereotypic behaviours with different specificity to autism. Carcani-Rathwell and colleagues [61] found that subjects with a Pervasive Developmental Disorder (PDD) diagnosis were more likely to have repetitive stereotyped behaviours than those with only ID. Within the PDD group, those with ID had higher rates of all repetitive stereotyped behaviours. The study suggests that there may be two distinct sub-groups of repetitive behaviours whereby the sensory and motor repetitive behaviours are generally associated with lower developmental age and less specific to the autistic syndrome whereas the 'higher-order' behaviours, that is cognitive rigidity symptoms, may be a more 'autism specific' feature. Bodfish and colleagues [62] compared adults with autism with adults with ID and found that both groups had significant patterns of repetitive behaviour co-occurrence. Autistic subjects had significantly greater severity ratings for compulsions, stereotypy, and self-injury. Repetitive behaviour severity also predicted severity of autism. Pedersen and colleagues [63] found that restricted interests or repetitive behaviours significantly differentiated between children with autism and ID.

Behavioural features of children with severe ID remain difficult to disentangle from those of children with autism. Polyak and colleagues [64] suggest that current estimates of autism prevalence fail to take into account the impact of comorbidity of ID and epilepsy on autism diagnosis.

Self-injury also co-occurs in a number of syndromes associated with ID including Lesch-Nyhan, Smith Magenis, Rett, Cornelia de-Lange, Prader-Willi, and fragile X syndrome [10]. Disruption to the activity dependent neuroprotector homeobox (ADNP) gene is among the most common heterozygous gene mutation seen associated with ASD. Affected individuals have a constellation of features including autism, ID, dysmorphic features, and hypotonia. Arnett and colleagues [65] compared individuals with ADNP syndrome with those with autism due to CHD8 mutation and idiopathic autism and found that ADNP syndrome group's profile of social communication and restricted and repetitive behaviours deficits to be notably different from those of other autism subtypes. The youths with ADNP syndrome had relatively mild social communication deficits (despite impaired verbal intelligence and low expressive language abilities) coupled with stereotyped motor restricted repetitive behaviours. The social communication deficits were mild enough as to not to warrant a diagnosis of DSM-5 [1] ASD in about 30% of cases, although all of them had a diagnosis of ID. The aetiology of social communication and repetitive stereotyped behaviours in autism is not well understood. Arnett and colleagues [65] suggest that genetic subtypes of ASD may each be associated with a unique aetiology of autism trait covariance. Within the idiopathic group, it could be polygenic. However, within single gene disorder, individual differences in the location and effect of the genetic variant could have vastly different effects on protein functioning. Yet, these disparate events frequently produce a similar behavioural, physical, and/or medical phenotype, implying convergence to a common neurobiological endophenotype.

Haw and colleagues [66] carried out a study on the movement disorders seen in a cohort of 145 people with Down syndrome living both inpatient and community facilities in Surrey, UK. They found that over a third of these people experienced stereotypies and no association was found between stereotypies

and age, hospital or community placement, exposure to neuroleptics, behavioural disorder, or dementia.

For treatment of all the conditions described in ► Chaps. 11 and 12.

Key Points

- The DSM-5 criteria are often difficult to apply to people with intellectual disabilities for conduct disorder, intermittent explosive disorder, and oppositional defiant disorder.
- Therefore, instead of making a psychiatric diagnosis as per DSM-5 criteria, it is more important to describe the behaviour for a better formulation leading to a better intervention.
- Both pharmacological and non-pharmacological interventions are used but the evidence in their support is poor.
- It is, therefore, important to make a very thorough multidisciplinary assessment of these behaviours in order to achieve a successful treatment outcome.
- The ultimate goal for the intervention is to improve the quality of life of people with intellectual disabilities and their care givers.

Learning Objectives

- To learn about the definition and ascertainment of psychotic disorders in people with intellectual disabilities (ID) across the lifespan
- To become aware of differential diagnoses in people with ID
- To understand the issues around diagnosis and management at different levels of intellectual functioning
- To list treatment options and approaches to psychotic disorders in this population

20.1 Introduction

Psychosis is a severe mental disorder defined by its chronic course and the significant levels of disability that it is associated with. It is found in all parts of the world with an often reported prevalence of approximately 1% whilst incidence (median) is estimated to be 15.2/100.000 persons with a ratio for males:females of 1.4:1 [1].

The lifetime risk for psychosis is almost half of the incidence (7.2/100.000). People with psychosis have almost threefold increase in all-cause mortality, and multiple factors are implicated in its onset including urbanicity, migrant status, socio-economic status, genetic predisposition, etc. Psychotic disorders place a significant burden on individuals, their families and societies; most of the economic impact is due to use of health resources, inpatient and social care, homelessness, legal issues, and loss of productivity (these are also called direct and indirect costs). A study by Cloutier et al. [2] indicated that the annual cost was estimated at $155.7 billion at 2013 prices. The three main reasons driving expenditure were unemployment, caregiver loss of productivity, and healthcare costs.

Psychosis is a serious mental disorder with a chronic course in most cases and consequent high level of disability. It is also associated with increase in all-cause mortality, high costs for health care, low economic and decision-making autonomy as well as a considerable burden on caregivers.

20.2 Psychosis and Intellectual Disabilities

Clouston, Murray, and Bramon [3] were the first to put forward the theory of psychosis as a neurodevelopmental disorder. Kraepelin described an entity he termed 'dementia praecox' which was associated with poor prognosis and recent theorists suggest that potentially both a neurodevelopmental process and neurodegeneration may be implicated. This hypothesis suggests abnormalities have taken place in the brain early on with consequent impact in functioning including in social development [4]. However, neither hypothesis fully explains psychotic disorders with the possibility of endophenotypes existing with different aetiological background [5].

Further, recent advances in genetics suggest that genomic copy number variants may not only increase the risk of psychosis but are also associated with also associated with intellectual disability (ID), autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder, and epilepsy [6].

The causes of psychotic disorders are multiple and include neurodegenerative, neurodevelopmental, and genetic hypotheses which are supported by some evidence.

20.3 Diagnostic Criteria and Clinical Presentation

Psychosis or schizophrenia spectrum disorders are non-specific terms which include a number of conditions with both a narrow and a broader definition. These conditions may vary in duration, intensity, and course mainly clustered around clinical signs and symptoms.

Two classification manuals (the Diagnostic and Statistical Manual of Mental Disorders, DSM-5 [7] and the International Classification of Diseases, ICD-10 [8]) are mainly in use but both have adaptations for people with ID (DM-ID-2; NADD 2017 [9] and DC-LD; Royal College of Psychiatrists 2001 [10], respectively). DC-LD specifically addresses the challenges of diagnosing mental conditions in people with more severe ID. For

example, it suggests that that early signs of psychosis could be new behaviours, especially if odd/bizarre/uncharacteristic for that person or increased frequency/severity of pre-existing behaviour. It places less significance to negative symptoms than other diagnostic criteria.

In 2019, member states of the World Health Organization agreed to adopt the new (11th) revision of ICD (ICD-11; WHO 2019 [11]), whose long-text version has come out at the beginning of 2022 [12]. ICD-11 new diagnostic categories are included in ▶ Box 20.1, for comparison with the former ICD-10 and DSM-5.

Whilst ICD-10 includes a number of diagnostic sub-categories (see ▶ Box 20.2 from Sheehan, Fodor-Wynne, and Hassiotis [13]), DSM-5 does not as specific sub-types appear to have limited diagnostic stability, low reliability, and poor validity; there has been an attempt to define disorders along a spectrum with a gradient of symptoms and continuum of severity. Generally, application of diagnostic criteria appropriate to peers of average intelligence has been shown to be restrictive and may lead to the under-diagnosis of serious and treatable mental disorders in children and adults with ID. The prevalence rates of psychotic disorders according to the DSM-IV-TR [14] have been found to be lower than prevalence according to the DC-LD, suggesting that DSM is not as effective in diagnosing psychotic disorders in this patient group [15]. Usually, the criteria have to be applied in consultations with qualified practitioners who are expert in the assessment and diagnosis of people with ID.

The core symptoms of psychotic disorders – also called first rank symptoms – [17] include:

- Auditory hallucinations (indistinguishable from a normal percept but cannot be corroborated by experience)
- Thought echo (*Gedankenlautwerden*; an auditory hallucination in which the patient hears his/her thoughts spoken aloud)
- Passivity experiences (commonly delusions of being controlled by an external force or agency)
- Thought withdrawal (a belief that the patient's thoughts have been 'taken out' of the patient's mind)
- Thought insertion (thoughts, ascribed to other people, intruding into the patient's mind)
- Thought broadcasting (patient's own thoughts shared with others)
- Delusional perception (linking a normal sensory perception to a bizarre conclusion, for example, seeing an aeroplane means the patient is the president).

Delusions are fixed, false beliefs that will not be changed when patients are exposed to new, conflicting evidence. These beliefs can include a variety of themes and specifiers (e.g. grandiose, religious, persecutory). Hallucinations are sensory experiences that do not have an external stimulus. Formal thought disorder is generally observed through disorganized speech, thought blocking, derailment. For example, a patient might rapidly change topic when speaking and when asked a question, and their answer may be unrelated. This category of symptoms also includes 'catatonic behaviour' which is characterized by a marked decrease in reactivity to the environment, for example, resistance to instruction, rigid posture, lack of verbal and motor response.

Grossly disorganized or abnormal motor behaviour can manifest as unprovoked agitation, child-like behaviour, and reacting inappropriately to the environment (e.g. laughing inappropriately).

Negative symptoms are characterized by a withdrawal or lack of normal function. Two common negative symptoms are diminished emotional expression and avolition (reduction in drive to fulfill goals and activities).

Some of these core symptoms can present also in other psychiatric disorders. Catatonia in particular can occur in neurodevelopmental, affective, and organic mental disorders, or represent an unspecified diagnostic category when associated with symptoms that cannot be attributed to any mental disorder or other medical condition, as in the DSM-5 [7]. In ICD-11, catatonia is defined as 'a syndrome of primarily psychomotor disturbances that is characterized by the simultaneous occurrence of several symptoms such as stupor; catalepsy; waxy flexibility; mutism; negativism; posturing; mannerisms; stereotypies; psycho-

motor agitation; grimacing; echolalia and echopraxia', and has been split into four types based on the following characteristics: (a) occurrence in the context of specific mental disorders, including schizophrenia or other primary psychotic disorders, mood disorders, and neurodevelopmental disorders; (b) being induced by psychoactive substances, including medications; (c) being caused by a medical condition not classified under mental, behavioural, or neurodevelopmental disorders; and (d) being not otherwise specified.

The diagnosis of psychotic disorders in people with ID may be confounded by many other factors related to symptom identification and interpretation. Communication difficulties are one of the most common confounders and as yet there are no biomarkers to confirm the diagnosis of a psychotic disorder. Therefore, clinical skill is important in the ascertainment of psychosis with good reliability achieved between experienced clinicians [18]. A systematic review of the clinical presentation of psychosis in people with ID ($n = 280$) found that participants in the five included studies had an IQ range 50–81 with higher scores on scales of negative features (effect size of 1.72). Other studies indicate that people with ID show an excess of formal thought disorder and limited delusional content [19].

Psychotic disorders are characterized by a wide variety of conditions that share a cluster of clinical signs and symptoms (traditionally defined as *first-rank*) including auditory hallucinations, passivity experience, thought insertion, thought broadcasting, thought withdrawal, and delusion, often associated with disorganized behaviour and negative symptoms. It can be difficult to identify these symptoms in people with ID and/or low-functioning ASD (LF-ASD), especially in the case of severe communication difficulties, thus requiring good diagnostic skills from clinicians. The diagnostic manuals currently available for use with ID and LF-ASD are DM-ID-2 and DC-LD, which represent adaptation of the DSM-5 and ICD-10, respectively.

Box 20.1: Comparative Schema of Classification of Schizophrenia Spectrum Between ICD-10, ICD-11, and DSM-5

ICD-10		ICD-11		DSM-5
Schizophrenia, schizotypal and delusional disorders		Schizophrenia or other primary psychotic disorders		Schizophrenia and other psychotic disorders
F20 Schizophrenia		6A20 Schizophrenia		295.90 Schizophrenia
	F20.0 Paranoid schizophrenia		6A20.0 Schizophrenia, first episode	
	F20.1 Hebephrenic schizophrenia		6A20.1 Schizophrenia, multiple episodes	
	F20.2 Catatonic schizophrenia		6A20.2 Schizophrenia, continuous	

ICD-10		ICD-11		DSM-5
	F20.3 Undifferentiated schizophrenia		6A20.Y Other specified schizophrenia	
	F20.4 Post-schizophrenic depression		6A20.Z Schizophrenia unspecified	
	F20.5 Residual schizophrenia			
	F20.8 Other schizophrenia			
	F20.9 Schizophrenia, unspecified			
F21 Schizotypal disorder		6A22 Schizotypal disorder		Schizotypal (personality) disorder
F22 Persistent delusional disorder		6A24 Delusional disorder		297.1 Delusional disorder
	F22.0 Delusional disorder		6A24.0 Delusional disorder, currently symptomatic	
	F22.8 Other persistent delusional disorders		6A24.1 Delusional disorder, in partial remission	
	F22.9 Persistent delusional disorder, unspecified		6A24.2 Delusional disorder, in full remission	
			6A24.Z Delusional disorder, unspecified	
F23 Acute and transient psychotic disorders		6A23 Acute and transient psychotic disorders		298.8 Brief psychotic disorder
	F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia			

ICD-10		ICD-11		DSM-5
	F23.1 Acute polymorphic psychotic disorder with symptoms of schizophrenia			
	F23.2 Acute schizophrenia-like psychotic disorder			
	F23.3 Other acute predominantly delusional psychotic disorders			
	F23.8 Other acute and transient psychotic disorders			
	F23.9 Acute and transient psychotic disorder, unspecified			
F24 Induced delusional disorder				
F25 Schizoaffective disorders		6A21 Schizoaffective disorders		295.70 Schizoaffective disorder
	F25.0 Schizoaffective disorder, manic type		6A21.0 Schizoaffective disorders, first episode	
	F25.1 Schizoaffective disorder, depressive type		6A21.1 Schizoaffective disorders, multiple episodes	
	F25.2 Schizoaffective disorder, mixed type		6A21.2 Schizoaffective disorders, continuous	
	F25.8 Other schizoaffective disorders		6A21.Y Other specified schizoaffective disorders	
	F25.9 Schizoaffective disorder, unspecified		6A21.Z Schizoaffective disorders, unspecified	

ICD-10		ICD-11		DSM-5
F28 Other nonorganic psychotic disorders		6A2Y Other specified schizophrenia or other primary psychotic disorders		298.8 Other specified schizophrenia spectrum and other psychotic disorder
F29 Unspecified nonorganic psychosis		6A2Z Schizophrenia or other primary psychotic disorders, unspecified		298.9 Unspecified schizophrenia spectrum and other psychotic disorder
				Substance/medication-induced psychotic disorder
				Psychotic disorder due to another medical condition

Box 20.2: Schizophrenia Spectrum Disorders Defined in ICD-10

1. Schizophrenia
   Manifests as a disorder of significantly distorted thinking, perception and affect. Main symptoms include thought disorder, delusions, hallucinations, and negative symptoms. Cognitive deficits develop over time. Subtypes have been delineated by course and major features.
   - Paranoid schizophrenia
     - *The most common subtype. Paranoid or persecutory delusions and auditory hallucinations dominate.*
   - Hebephrenic schizophrenia
     - *Delusions and hallucinations are less prominent. Behaviour is grossly disorganised and emotional response is lacking or inappropriate.*
   - Catatonic schizophrenia
     - *Bizarre motor manifestations are the hallmark of catatonia. These include, but are not limited to, posturing, waxy flexibility, stupor, and mutism.*
   - Residual (and simple) schizophrenia
     - *A slow but progressive decline in functioning accompanies social withdrawal and the appearance and deepening of negative symptoms.*
2. Schizotypal disorder
   Sometimes considered a form of personality disorder, schizotypal disorder is characterised by social and interpersonal deficits. There may be suspiciousness, odd beliefs, eccentric behaviour and unusual perceptual experiences, though no single feature predominates. The disorder runs a chronic course.
3. Persistent delusional disorder
   Chronic, frequently lifelong delusions occur in the absence of other psychotic symptoms.
4. Acute and transient psychotic disorder

Psychotic symptoms develop rapidly and are not due to intoxication or an organic condition.

There is an equally rapid and usually spontaneous recovery.

5. Induced delusional disorder
Occurs when a delusional belief, and sometimes other psychotic symptoms, are shared by two or more people with close emotional links. The sufferers are typically socially or physically isolated from others. Symptoms resolve in at least one of the sufferers following geographical separation. The illness is also known by the French term folie à deux, literally 'madness of two' [16].

20.4 Incidence and Prevalence

Cooper et al. [20], found that in a Scottish epidemiological sample, the 2-year incidence of psychosis was 1.4% and for first episode of psychosis 0.5%. One of the earliest studies [21] found that incidence was higher in people with mild compared to severe ID but this may be due to inability to make a diagnosis in the latter.

A recent systematic review and meta-analysis of 25 cross-sectional studies estimated the prevalence for psychosis in people with ID to be 3.46% and the authors observed a variation in reported rates between those with mild compared to people with more severe ID (5.55% in mild vs 0.88%, respectively) [22]. Prisoners with ID are also shown to be twice as likely to suffer with psychosis compared to peers without ID [23].

20.5 Issues Related to Diagnosis in Persons with ID

Individuals with a dual diagnosis of ID and psychosis are significantly younger at first contact with mental health services compared with individuals with schizophrenia alone although the reasons for this are unclear [24]. Given the impact of untreated psychosis on the disease course, it is essential for family and paid carers to be aware of relevant symptoms that should be brought to the attention of professionals. One such example is the case of distinguishing true hallucinations from pseudohallucinations in people with ID [25]. Pseudohallucinations are defined as hallucinations where the individual is aware that their experience is in their own mind and not perceived as external stimuli. This distinction is important in terms of the therapeutic approach and advice for future management. Such diagnostic conundrums are particularly important in the diagnosis of mental disorders in people with severe ID and lack of verbal ability.

Higher levels of aggression have been found in people with ID and psychosis when compared to individuals with ID without psychosis possibly underpinned by 'impulse control, mood dysregulation and perceived threat' [26].

Bradley et al. [27] explored the association between ID and psychiatric disorders, including psychosis. The authors suggest that the symptoms of ID may sometimes be overlooked during psychiatric assessments which, they argue, may lead to inaccurate diagnosis and incorrect treatment. They argue that patients are not regularly reviewed and a patient may have a diagnosis for years when another diagnosis may better suit their symptoms. They suggest that medication is overused in this patient group and that more emphasis should be given to psychosocial therapies and good quality care. Axmon et al. [28] found that the prescription of antipsychotic medication without thorough psychiatric diagnosis is common also in older persons with ID, mainly for the management of problem behaviours.

Finally, there is a danger of misdiagnosing schizophrenia when a patient presents with positive symptoms that are caused by childhood trauma or abuse and not necessarily indicative of a psychotic disorder.

Finally, Hurley and Moore [29] suggest that cases of erotomanic type delusional disorder in adults with ID may be underreported because it is assumed to be an immature fantasy that is a product of the cognitive limitations.

Frequently reported issues in diagnosing psychotic disorders in persons with ID and LF-ASD are distinguishing hallucinations from pseudohallucinations, distinguishing other positive psychotic symptoms from symptoms caused by childhood trauma or abuse, identifying aggressive behaviour as a behavioural equivalent of one or more psychotic symptoms, and recognizing erotomanic delusion in those with assumed immature fantasy.

20.6 Aetiology

The increased comorbidity between ID and psychosis may be explained by the fact that cognitive impairment is an independent risk factor and a feature of the disorder [6, 30–35]. Evidence from epidemiological studies supports a shared genetic risk for lower IQ and schizophrenia with the strength of the genetic effect increasing with decreased IQ [36].

Very likely, the same factors that have been implicated in the onset of psychosis in the general population may play a role in people with ID too and could possibly form future research strands [36, 37]. This is an important point, as people with ID are routinely excluded from research in a variety of medical fields, and therefore, conclusions drawn from those studies cannot be fully applied to this population due to the differences in health patterns.

New advances in genetics, particularly in the study of CNVs, show that they increase the risk for other neurodevelopmental disorders [38]. In a study of 39,000 people referred to a diagnostic laboratory, about 1000 had a CNV at one of the loci identified in schizophrenia. Main clinical presentation included psychiatric disorders, developmental delay, ID, and autism-related disorders. Examples of neurodevelopmental genes implicated in schizophrenia include genes that regulate cell growth and behaviour, DISC1, NRG1, DTNBP1, KCNH2, AKT1, PAK7, and RGS4 [39, 40]. Specific genetic syndromes that have been considered as examples of the biology of psychosis include the velo-cardio-facial syndrome (VCF, also known as DiGeorge syndrome) [41, 42]. VCF syndrome is a relatively common genetic disorder (14,000) associated with ID (usually mild-moderate) and psychosis develops in about 40% of cases [43].

Other genetic syndromes linked with ID and associated with psychosis include fragile X syndrome [44], Kleinfelter syndrome [45], Prader-Willi syndrome [46, 47], Dandy Walker syndrome [48, 49], Nieman Pick disease [50], Usher syndrome [51], Williams syndrome [52], and Charlexois ARSACS [53]. A recent study reported a higher rate of psychosis in adolescents and young adults with Down's syndrome [54]. Most of the studies on syndromes are single cases of sporadic morbidity and therefore further research is needed to confirm such associations.

Imaging studies are sparse in people with ID and psychosis, but available literature appears to show that the brains of people with ID and schizophrenia are more similar to the brains of those with schizophrenia in the general population than those with ID alone suggesting a common pathophysiological process at work [55].

Multiple biochemical pathways are likely to contribute to schizophrenia so identifying a single abnormality is difficult. A number of key neurotransmitters have been linked to schizophrenia including dopamine, glutamate, serotonin, noradrenaline, and GABA. Some abnormalities in these pathways are also associated with ID [56] and ASD [57].

Another possible explanation for the increased association between ID and psychosis may be derived from the vulnerabilities conferred by cognitive deficits, for example in processing information, problem solving and planning, and emotional and social deficits [58].

Finally, whilst life events [59] and stigma [60] may be associated with psychological morbidity in people with ID there is not enough evidence from research studies to hypothesis causality in the onset of psychosis. Nevertheless, it is well established that the development of psychotic disorders is associated with aversive childhood and adulthood experiences such as bullying and trauma [61] and that individuals with neurodevelopmental disorders such as ID and ASD may be at an increased risk of victimization [62–64].

However, the impact of psychosis on people with ID was studied by Bouras et al. [65] who found that the ID group showed serious impairments in social and occupational functioning (Global Assessment of Functioning scale), compared with the non-ID group. The ID group was likely to have fewer or no friends and to have problems maintaining employment. Friedlander and Donnelly [66] found that participants with a diagnosis of psychosis not otherwise specified and moderate or severe ID were the most functionally impaired group in the study, based on the Global Assessment of Functioning scale and the Clinical Global Impression.

In a recent large prospective study carried out in Sweden, 23% of the risk for non-affective psychosis associated with urban and deprived settings at birth could be attributable to indirect effects on cognition, measured by IQ at 18 years of age [67].

Genetic factors seem to play an important role in the aetiopathogenesis of psychotic disorders in persons with ID and LF-ASD as suggested by the presence of common CNV alterations in psychotic disorders and ID/ASD, and the high prevalence of psychotic symptoms in specific genetic syndromes including ID/ASD such as DiGeorge syndrome, Prader-Willi syndrome, and Fragile X syndrome. Various neurotransmitter alterations have been identified in psychotic disorders as well as in ID and ASD. A relevant psychological vulnerability factor is represented by low coping with adverse life events, stressors, and traumas.

20.7 Differential Diagnosis

As mentioned earlier, it can be difficult to diagnose psychosis in people with an ID due to many factors, such as communication problems and variable presentation of symptoms and cultural norms. There are also several other disorders that can present with symptoms that overlap with those of psychosis. While many of these disorders are separate from schizophrenia spectrum disorders, it is important to be mindful of the fact that some could be involved in the development and course of psychosis.

Differential diagnoses to psychosis are shown in ► Box 20.3 [68].

Dementia in people with ID is more common than in the general population [69, 70]. Dementia can often present with psychotic symptoms or abnormal speech [71] and so dementia may be confused with psychotic disorders in people with ID.

Box 20.3: Differential Diagnoses

Physical illnesses including: deliriums

Epilepsy (particularly temporal lobe epilepsy)

Traumatic brain injury

Intracerebral conditions (e.g. space occupying lesion)

Sleep disorders

Infection (e.g. respiratory or urinary tract infection, meningitis)

Endocrine causes (e.g. hyper/hypothyroidism)

Hearing or visual impairment (e.g. individuals with Charles Bonnet syndrome who have a visual impairment may experience hallucinations or delusions)

Causes of pain or distress (e.g. toothache, earache, constipation, menstrual pain)

Drug or alcohol related causes including:	Delirium tremens Alcoholic hallucinations Drug-induced psychosis Sensitivity to prescribed medication
Other psychiatric illness including:	Affective illness Anxiety disorder Post-traumatic stress disorder (PTSD) Dementia (e.g. visual hallucinations in Lewy-body dementia) Autistic spectrum disorder

Other differential diagnosis (e.g. challenging *behaviour* caused by ID, or just ID itself may be diagnosed as a psychotic disorder)

20.8 Comorbidity with Autism Spectrum Disorder

A great complexity underlies the association [72, 73]. ID, psychotic disorders, and ASD may be treated as separate entities but are likely to have common underlying basis [74].

There is increasing evidence on a clinically significant degree of co-occurrence between ASD and psychotic disorders [75, 76]. Non-affective psychoses in particular are reported to be tenfold or higher in persons with ASD than in the general population [77] and childhood onset psychosis has been found to co-occur with ASD in 30–50% of common family genetic imaging findings [78]. Diagnostic confusion may also arise due to symptom overlap, for example, negative symptoms, social interaction/communication difficulties and repetitive stereotyped behaviours in people with psychosis [79] especially for those psychiatrists who have not had specific training on psychopathology in adults with neurodevelopmental disorders [73].

Waris et al. [80] investigated comorbidity between schizophrenia and pervasive developmental disorder (PDD), particularly Asperger's syndrome in adolescents. They found that 44% (n = 18) of the adolescents with schizophrenia fulfilled the diagnosis of PDD in childhood (even if they did not receive this diagnosis at the time). They conclude that patients with psychosis often have a childhood diagnosis of PDD. Palucka, Bradley, and Lunsky [81] highlight the importance of diagnosing autism in individuals with ID before making a diagnosis of psychosis. Such a process could guard against patients being given a diagnosis of psychosis when autism may better fit their presentations. Larson et al. [82] studied 116 adults with autism and psychosis; they found that age of onset had a wide range (e.g. as early as below 12 years of age and in the middle years), progress was insidious in the majority and impaired functioning. Fifty-three percent of the cohort had a diagnosis of psychosis not otherwise specified or schizophrenia with 85% reporting significant affective symptoms (the symptom categories are shown below) (Fig. 20.1).

> Psychotic disorders are frequently reported in people with ASD. These disorders are characterized by a pool of overlapping symptoms, especially negative symptoms, and social interaction/communication difficulties.

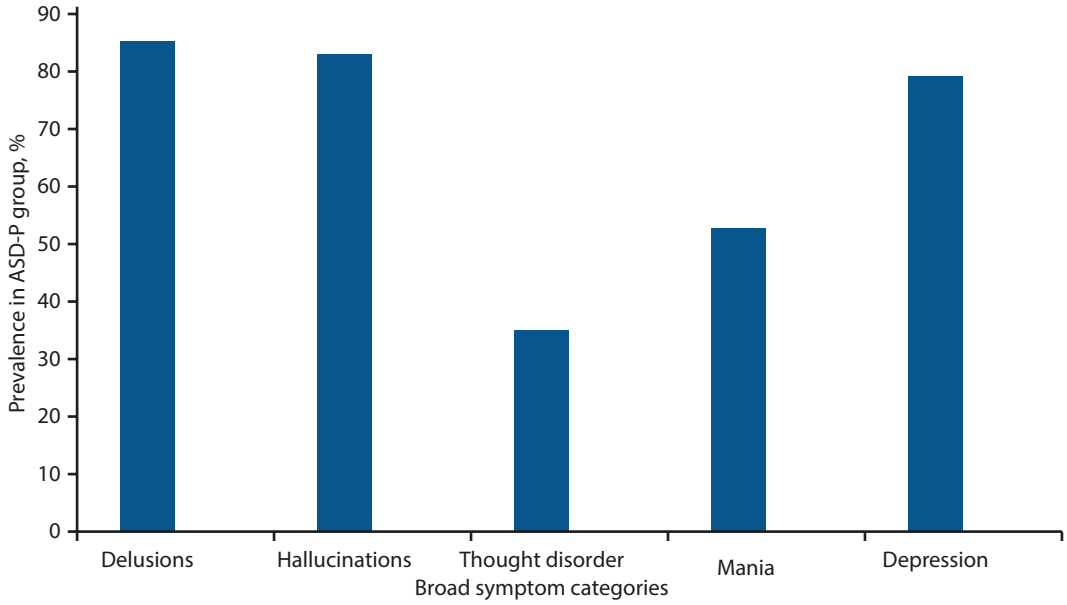

Fig. 20.1 Symptom frequencies in 116 adults with autism and psychosis [82]

20.9 Psychosis in Adults with Severe or Profound ID

Cherry et al. [83] investigated the presentation of schizophrenia in a residential sample of adults with severe ID by comparing their symptoms to symptoms that are seen in populations without ID. They concluded that the symptoms of the group scoring high on the Diagnostic Assessment for the Severely Handicapped (DASH-II) and also had a clinical diagnosis of schizophrenia were clustered around 'reality distortion and disorganization, with less evidence of negative symptoms'. However, it is possible that staff tend to report negative symptoms less as they find them less disturbing than florid symptoms. Furthermore, proxy reports of symptoms of mental disorders in people with lack of verbal ability may generally be inaccurate and further attempts to enhance individual communication is recommended [84]. It may be that interviewing several people with a good knowledge of the individual and paying close attention to changes in usual behaviour may be helpful in identifying negative symptoms that may be less salient and more difficult to identify.

Positive symptoms are generally more easily identifiable and more frequently reported in persons with severe and profound ID, probably due to the difficulties in identifying negative symptoms.

20.10 Psychosis in Children and Adolescents with ID

Psychotic disorders have an earlier onset in persons with ID than in the general population, although evidence is limited [66, 85]. The knowledge on the course of psychotic disorders in children and adolescents with ID is also restricted. Lee et al. [86] examined the development and stability of the symptoms of early-onset schizophrenia (EOS) in 10 children with ID. They found that 8 of the 10 children with a diagnosis of EOS still warranted this diagnosis 2 years later but delusions and visual hallucinations were less prominent. These children had a poor prognosis with particular impact of the disorder on cognitive ability. Of the two children not determined to have EOS at follow-up, one recovered fully and the other suffered from hypothyroidism and Tourette's syndrome. The authors argue that it is important to always gather collateral information and review symptoms at regular intervals.

A Canadian study found that three factors may improve prognosis in youths with ID and psychosis: low rates of alcohol and substance misuse, increased compliance with medication, and good psychosocial supports [66]. More longitudinal data is needed to further substantiate our understanding of outcomes in early onset psychosis in young people with ID.

Psychotic disorders seem to have an earlier onset in persons with ID than in the general population. The knowledge on course and prognosis is limited, although low rates of alcohol and substance misuse, increased compliance with medication, and good psychosocial supports have been associated with better outcomes in youths with ID.

20.11 Principles of Treatment and Management

It is evident that psychosis is a long term condition and a major cause of impairment in functioning. Prompt diagnosis and treatment are essential in managing the consequences on the individual and his/her family and social networks. Generally, medication (antipsychotics alone or in combination with mood stabilizers) and psychosocial interventions to combat persistent symptoms, lack of motivation, relapse, unemployment, and loneliness are likely to achieve best results.

Patients who are acutely unwell may require home treatment of admission to an inpatient facility. There are now fewer specialist inpatient units for people with ID and mental disorders, and therefore, it is essential that the community ID services advocate for

the individual's inclusion within generic mental health services. Risk assessment for self-harm, neglect, and harm to others is paramount and at all times the management plan must be recovery orientated with ensuring that the patient is given opportunities to express their interests and wishes. Treatment options including medications must be discussed with the patient and their family and paid carers and the patient's capacity to agree must be clearly documented.

In the UK (England and Wales) the National Institute of Health and Care Excellence and the Scottish Intercollegiate Guidelines Network (SIGN) (Scotland) have developed guidelines to drive improvements in the management of, among others, mental disorders including psychosis [87]. It is also expected that generic services will make reasonable adjustments when treating people with ID to include easy read information, longer appointments, increase in support, and advocacy to manage complex meetings and reviews. It is essential for clinicians to look for extrapyramidal and other side effects relating to antipsychotics and to ensure that patients have good access to health checks. Use of scales such as the Matson Evaluation of Drug Side-Effects Scale (MEDS) [88] or the Health of the Nation Outcome Scale-Learning Disability (HONOS-LD) [89] could be a significant aid in clinical practice.

Although there are several psychological and social interventions in the general population, there has not been an equivalent growth in people with ID. It is argued that a treatment that is effective or efficacious in people with psychosis without ID should also be available to those with ID. However, there are several issues with this argument: professionals claim to not have experience of treating people with ID, people with ID maybe unable to receive such treatments without adaptations due to cognitive difficulties or lack of knowledge as to what treatments are available. Some examples of treatments that have been delivered to people with ID and psychosis are CBT (positive improvements in symptoms and behaviour) [90] and psychoeducation [91]. Other promising areas of psychological intervention in the general population that could be beneficial in people with ID and psychosis include insight-related work, adherence therapy, family/carer work, and relapse prevention [92].

Hemmings, Underwoord, and Bouras [93] undertook a national Delphi exercise to examine professionals views and create consensus as to what services for people with ID and psychosis should provide. One hundred and thirty-nine items were included and following three rounds, over 80% agreement was reached on 18 of the routine service components, nine of the service user characteristics, and five of the more intensive service components. The authors suggest that certain elements of good care for people with ID and psychosis such as monitoring of mental state, crisis management, and support plans are already available within existing community ID services and their organizational context.

Whilst in the UK, services are more in tune with the care of people with ID and mental disorders, many parts of the world do not have specialist services or resources for this population group. It is also known that people with ID face disparities in healthcare and unequal access; therefore, global initiatives such as the WHO Mental Health GAP Action Programme (mhGAP) [94] are pivotal in improving awareness and reducing stigma of ID and mental illness.

Psychotic disorders require prompt, adequate, and long-term pharmacological and psychosocial interventions to manage the consequences on the individual, his/her family, and social networks. Although several psychological and social interventions have been developed for the general population, there has not been an equivalent growth for people with ID. Some examples of treatments that have been delivered to people with ID and psychosis are CBT and psychoeducation. Promising areas include insight related work, adherence therapy, family/carer work, and relapse prevention.

20.12 Psychopharmacology

High level evidence on the efficacy of antipsychotics in people with ID/low-functioning ASD (LF-ASD) and psychotic disorders is lacking. Most studies on psychotic disorders considered ID and LF-ASD as an exclusion criterion and specific research were hard to realize due to feasibility issues, including participant's compliance and approval by ethical committees.

Classical neuroleptics, also called first-generation antipsychotics, such as chlorpromazine, haloperidol, levomepromazine, clothiapine, and tiapride, seem to have a troublesome side effect profile, which includes a negative impact on cognitive functions and motor skills [95, 96]. Atypical neuroleptics, also called new-generation antipsychotics, such as risperidone, aripiprazole, olanzapine, quetiapine, and clozapine, show a better tolerability and safety profile with a mid and long-term efficacy comparable to that of the old-generation compounds or even higher. Most frequently reported side effects result to be weight gain and metabolic alteration, followed by sedation and more rarely extrapyramidal signs [97]. Risperidone may also determine neurological side effects, such as extrapyramidal symptoms (dyskinesia, akathisia, and parkinsonism), autonomic symptoms, and sedation [96–99]. Seizures, tachycardia, arrhythmias, and agranulocytosis are less common but more serious and require close monitoring, especially with clozapine [100].

Many combinations of antipsychotics may amplify side effects and should be carried out with great care [101].

The scientific literature suggests that new-generation antipsychotics, including clozapine, are frequently prescribed to people with ID and psychosis, although there is no systematic evidence to support its use in this population [102, 103]. Risperidone has been the most studied in aggressive behaviour, self-harm, and stereotyped behaviours, whether these behaviours were considered as determined by underlying psychotic disorders or not. Given the lack of evidence, clinicians are suggested to have an open dialogue with people with ID/LF-ASD and their caregivers as part of the discussion about informed consent for this treatment.

- High level evidence on the efficacy of antipsychotics in people with ID/LF-ASD and psychotic disorders is lacking.
- Adverse effects may be more likely than in the general population, thus potential sensitivities, monitoring issues, and medical comorbidities must be considered.
- Clozapine may be used with confirmed cases of treatment-resistant psychosis. This requires further precautions such as the patient's ability to co-operate with blood tests and other monitoring, and the consideration of epilepsy or elevated baseline cardiometabolic risk profile.

Tip

Future research should provide a more detailed picture of psychotic disorders in persons with ID and low-functioning ASD, especially in relation to age of onset, clinical presentations, disease progression, and aetiology. Also pharmacological and non-pharmacological interventions need a great deal of development supported by good level evidence.

Key Points

- Psychosis is a serious mental disorder with a chronic course associated with increase in all-cause mortality and a considerable burden on caregivers.
- The pathogenesis of psychotic disorders is currently supposed to be multifactorial and to include neurodegenerative, neurodevelopmental, and genetic causes.
- Psychotic disorders are frequently reported in persons with ID and/or ASD and are reported to have an earlier onset in persons with ID than in the general population.

- Psychotic disorders are characterized by a wide variety of conditions that share a cluster of clinical signs and symptoms that can be difficult to identify in people with ID and/or low-functioning ASD, especially in the case of severe communication difficulties. The identification of psychotic disorders in persons with ID and/or low-functioning ASD requires good diagnostic skills and the use of specific diagnostic manuals such as DC-LD and DM-ID 2.
- Patients with psychotic disorders require prompt, adequate and long-term pharmacological and psychosocial interventions to manage the consequences of the disorder on the individual, his/her family, and social networks.
- Although several psychological and social interventions have been developed for the general population, there has not been an equivalent growth for people with ID.
- High level evidence on the efficacy of antipsychotics in people with ID/low-functioning ASD and psychotic disorders is lacking.
- Adverse effects may be more likely than in the general population, thus potential sensitivities, monitoring issues, and medical comorbidities must be considered.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_21

Learning Objectives

To understand the challenges to proper diagnosis of mood disorders in persons with autism spectrum disorder (ASD) and intellectual disability (ID).

To recognize the signs and symptoms of mood disorders in persons with ASD and ID an distinguish them from behavioral problems.

To learn the treatment approaches to mood disorders in persons with ASD and ID.

21.1 Introduction

Mood disorders are common in the general population. Mood disorders include depressive disorders, and bipolar disorders historically referred to as "manic-depressive illness". These conditions cause great suffering for patients and for their families. For individuals with autism spectrum disorder (ASD) and intellectual disability (ID) the challenge of proper diagnosis as well as effective treatment presents a considerable problem. Many symptoms of mood disorders required for diagnosis depend on adequate verbal communication skills, so limitations in self-reflection and verbal reports of symptoms can make diagnosis difficult. Observable symptoms (e.g. being up all night with little need for sleep) are easily noted, but may be caused by other conditions and therefore may not be related to a mood disorder. On the other hand, many mood disorder symptoms may be mistaken for a "behaviour problems" in this population, resulting in a behavioural approach without proper psychiatric care. In this chapter, the most salient information on diagnosis and treatment of people with ID and ASD (ID/ASD) with mood disorders will be reviewed.

21.2 Diagnostic Peculiarities and Behavioural Equivalents

Before the 1980s most psychiatrists acknowledged only "behaviour" problems in people with ID/ASD. Sovner and Hurley [1] researched published case reports for patients with ID, finding 25 reports for patients with ID meeting DSM-III criteria for depression and/or mania, including nine in-patients who had ID/ASD. These reports underscored the difficulties in diagnosis. Often, the chief complaint is a challenging behaviour presented by a caregiver. This alone will invariably lead diagnosis and treatment in the wrong direction. Due to ID, the patient has difficulty answering questions in the interview. The person may also have "unusual symptoms" for someone in the general population, but these may be perfectly normal when compared to others with similar levels of ID. Lastly, the onset of a significant psychiatric illness may cause the person great distress, significantly reducing daily ability to function.

In 1986, Sovner and Hurley [2] proposed four categories of difficulty in psychiatric diagnosis for people with ID. These categories help in understanding the patient who cannot speak eloquently for themselves and supply realistic answers during the psychiatric diagnostic interview. Often, behavioural and/or unusual symptoms have led to overdiagnosis of a schizophreniform disorder rather than recognition of the more common mood disorders. The first category, *baseline exaggeration*, refers to an increase in challenging behaviour frequency and/or intensity during the course of a mental illness. For example, an individual may have a low rate of mild self-injurious behaviour, but during a time of stress or acute psychiatric disorder the frequency and intensity of this behaviour escalates to a dangerous level, prompting a mental health appointment. For some people with ID/ASD, self-injury often increases and causes significant medical risk.

The second, *intellectual distortion,* finds that the individual cannot accurately understand the questions posed by the evaluator nor assemble the correct information to respond. For example, when asked if he or she "hears voices", the individual might respond affirmatively without fully comprehending the implication in the question: the clinician

meant abnormal phantom voices, whereas the individual was thinking of ordinary voices, including the clinician's, that he or she was able to hear. This example may seem understandable, but many responses are clearly inadequate or incorrect. Much as when interviewing children, no answer can be taken at face value.

The third, *psychosocial masking,* focuses on the effects of developmental delay. The individual might present significant symptomatology that occurs within a developmental framework and would be common in a young child. For example, a manic individual with moderate intellectual disability might believe that he or she can drive a car, a skill well beyond such an individual's capability, as a manifestation of grandiosity.

Lastly, *cognitive disintegration* is a situation in which the person has become grossly disorganized, even psychotic, due to the lack of "cognitive reserve" available to cope with the illness. For example, in a major depressive episode, individuals with ID are more likely than neurotypical individuals to be severely affected and suffer mood-congruent hallucinations and delusions. Further, additional behavioural repertoires or thought patterns might be due to, or consistent with, other aspects of developmental delay. That is, they would be considered typical in a young child but would appear bizarre and abnormal in an adult.

For people with ID/ASD, symptom presentation is challenging to interpret. The idea of "behavioural equivalents" of symptoms for people with ID/ASD has been controversial (see ▶ Chap. 5). However, we believe that the format is useful in integrating the illness with symptoms of two other separate disorders that interact with the mood disorder (i.e. ID and ASD) as well as in organizing thoughts about a particular case. The DSM does not directly deal with behavioural symptoms regarding people with ID/ASD [3]. Pary and colleagues proposed a system of "equivalents" in symptoms for depression and bipolar disorder including a comparison of patients with ID and those with ID/ASD [4] (see ◘ Tables 21.1 and 21.2).

Baudewijns, Bertelli, and collaborators [7] have recently found that in persons with ID and ASD major depressive disorder tends to present with a range of aggressive behaviours (mostly self-oriented), which seems to be further differentiable by predominance of emotional symptoms (irritability, anxiety and sadness) or physical symptoms (problems with energy, eating, sleeping, and stress) [7].

With the presence of "behavioural symptoms" it is imperative that the clinician carefully consider how mood difficulties may be causing behavioural problems.

For individual with ID and ASD a proper diagnosis of mood disorders as well as an effective treatment presents considerable challenges. Baseline exaggeration, intellectual distortion, psychosocial masking, and cognitive disintegration are just some of the phenomena that can make the diagnostic process difficult in this population.

21.3 Prevalence

21.3.1 Depression

Depression takes a great toll on the suffering person, and it affects family and friends as well. When ill, physical health is affected. People with depression have alterations in sleep and appetite. They may feel a lack of energy. They also feel inadequate and can distort interactions and self-assessments, with loss of self-worth. Treatment, however, is fairly straightforward. There are many medications that can help. Psychotherapy is always recommended and there are many forms of psychotherapy to choose from. In addition, people with seasonal affective disorder (SAD) become depressed when the winter season is arriving. For this condition, the use of a Bright Light Therapy typically offers

Table 21.1 DSM-IV and DSM-5 criteria and symptoms for major depressive episode with proposed ID and ASD equivalents [4]

DSM criteria	ID equivalents	ASD equivalents
1. Depressed mood or irritable mood	Apathetic, sad or angry facial expression; lack of emotional reactivity; upset; crying; tantrums; verbal and physical aggression carefully judged for context	Irritability; crying; tantrums; verbal and physical aggression carefully judged for context
2. Markedly diminished interest or pleasure in most activities	Withdrawal; lack of reinforcers; refusal to participate in leisure activities or work; change in ability to watch TV or listen to music	Withdrawal; diminished or suddenly exclusive pursuit of fascinations and obsessions, rituals and compulsions
3. Significant weight loss; decrease or increase in appetite	Tantrums at meals; stealing food; refusing activities; hoarding food in room	Food refusal; restriction of intake to a few ritualized items; indiscriminate hyperphagia
4. Insomnia or hypersomnia	May or may not be able to self-report sleep problems; if living with others, may report being up at night; others may note going to bed quite late; if living in staffed situation, staff may note being up at night; any change in sleeping habits; tantrums or activity during sleeping hours; noted sleeping or napping during the day	May or may not be able to self- report sleep problems; if living with others, may report being up at night; others may note going to bed quite late; if living in staffed situation, staff may note being up at night; any change in sleeping habits; tantrums or activity during sleeping hours; noted sleeping or napping during the day
5. Psychomotor agitation or retardation	Pacing, hyperactivity; decreased energy, passivity; development of obsessional slowness in activities of daily living; muteness; whispering; monosyllables; increase in SIB or aggression carefully judged for context	Decreased energy, passivity; development of obsessional slowness in activities of daily living; muteness; whispering; monosyllables; increase in self-injurious behaviour or aggression, rituals and compulsions
6. Fatigue or loss of energy	Appears tired; refuses leisure activities or work; withdraws to room; loss of daily living skills; refusal to do personal care; incontinence due to lack of energy/motivation to go to bathroom; work production decreases; does not want to join activities; just watches TV, sitting for long periods of time	Appears tired; withdraws to room; loss of daily living skills; refusal to do personal care; incontinence due to lack of energy/motivation to go to bathroom
7. Feelings of worthlessness	Statements such as "I'm stupid" or "I'm bad" or "I'm not normal"	Statements such as "I'm stupid" or "I'm bad" or "I'm not normal"
8. Diminished ability to think or concentrate	Poor performance at work; change in leisure habits and hobbies; appears distracted	Poor performance at work; change in leisure habits; appears distracted
9. Recurrent thoughts of death, suicidal Behaviour or statements	Perseveration on the deaths of family members and friends; preoccupation with funerals	Perseveration on the deaths of family members and friends; preoccupation with funerals

Mental Health Aspects of Developmental Disabilities [4]
Legend: The symptoms in the left column are those described in DSM-IV [3] and DSM-5 [5]. In the second column are proposed "equivalents" to symptoms as they might appear in a person with ID as noted in case reports and research articles. The third column addresses symptom presentation in patients with ID/ASD

Table 21.2 DSM-IV and DSM-5 criteria and symptoms for manic episode with proposed ID and ASD equivalents [4]

DSM criteria	Suggested ID equivalents	Suggested ASD equivalents
1. Inflated self-esteem or grandiosity	In relationship to his/her developmental level, person believes and acts as if he/she can do more (e.g. person believes he/she is a teacher, staff member; can drive a car; can repair a broken TV; is better than peers)	In relationship to his/her developmental level, person believes and acts as if he/she can do more (e.g. able to engage in social relations successfully, overestimates likely success or comfort in a social world
2. Deceased need for sleep (e.g. feels rested after only 3 hours of sleep)	Person is up at night; is active and about the room, house; awakens early or does not get to sleep until quite late; appears energetic next day	Person is up at night; is active perhaps with rituals; awakens early or does not get to sleep until quite late; if sleep usually irregular, completely sleepless
3. More talkative than usual or pressure to keep talking	Person talks constantly, often seeking attention; cannot listen to others easily, not really conversing but espousing own thoughts	Increased frequency and/or intensity of perseverative questioning, manneristic speech
4. Flight of ideas or subjective experience that thoughts are racing	Ideas flow because of energy; topics are short, and next topic often unrelated to last; cannot respond easily to topics generated by others	Ideas flow because of energy; topics are short, and next topic often unrelated to last; rapid repetitive speech; increased vocal stereotypy
5. Distractibility (i.e. attention too easily drawn to unimportant or irrelevant external stimuli)	Compared to usual abilities to concentrate on tasks, is distracted by environment, but mainly by own internal energy; ADL tasks and work tasks completed quickly and improperly, skipping from activity to activity	Pronounced inability to concentrate on tasks; distracted by environment; skipping from activity to activity; rituals may become rapid or disorganized
6. Increase in goal-directed activity (either socially, at work, school or sexually) or psychomotor agitation	May work at ADLs or work with great speed, but little attention to detail or work quality; cannot respond to cues to slow or repeat work if sloppy; may create new tasks, take on projects, talk about new jobs and work that is not realistic; may be overactive and/or appear to be in constant motion	Overactivity; increased frequency and/or intensity of ritualistic or compulsive activities
7. Excessive involvement in pleasurable activities that have a high potential for painful consequence (e.g. engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)	Increase in obvious sexual interests; more preoccupied with hobbies or general recreational interests; intrusiveness; inhibition; inability to follow previously understood rules and limits	Increase in obvious sexual interests; more preoccupied with obsessions and fascinations; intrusiveness; disinhibitions; inability to follow previously understood rules and limits

Mental Health Aspects of Developmental Disabilities [4]

Legend: The symptoms in the left column are those described in DSM-IV [4] and DSM-5 [6]. In the second column are proposed "equivalents" to symptoms as they might appear in a person with ID as noted in case reports and research articles. The third column addresses symptom presentation in patients with ID/ASD

excellent results. For severe resistant cases of depression, electroconvulsive therapy (ECT) is another option.

Depression is a common psychiatric illness. A study of the general population of the United States utilized the World Health Organization Composite Diagnostic Interview to assess lifetime and 12-month prevalence of DSM-IV axis I disorders. Subjects were individually interviewed by trained staff. The findings for lifetime prevalence of psychiatric disorders were 16.2% of the responders, with 10.4% judged mild; 38.6% moderate; 38.0% severe; 12.9% very severe. Authors noted that only 41.9% of cases were receiving adequate treatment [8]. Premenstrual dysphoric disorder (PMDD) is reported to have a prevalence of 3–8% throughout reproductive age [9]; however, some studies suggest that up to 20% of all women of fertile age have premenstrual complaints that could be regarded as clinically relevant [10].

Smith and colleagues [11] using the UK Biobank of 172,751 individuals found lifetime prevalence rates for a single lifetime episode of major depression of 6.4%, recurrent major depression (moderate) 12.2%, probable major depression (severe) 7.2%, and probable bipolar disorder 1.3%, similar to those found in other population studies.

21.3.2 Prevalence of Depression in People with ID

The prevalence of depression and aging was investigated by Cooper [12] using ICD-10 Kettering/Leicester criteria. A comprehensive psychiatric examination and semi-structured rating scale was used for people with intellectual disability over age 65 ($n = 134$) in a defined geographic area and compared with adults ages 20–65 ($n = 73$). The rate of depression for elderly patients was 6% and 4.1% for younger individuals. In a review of depression and the DC-LD, Smiley and Cooper [13] found that a major problem in the diagnostic formulation is the presence of unusual features appearing during a depressive episode such as lability of mood, onset of challenging behaviours, reduction in speech, social withdrawal, and increase in somatic complaints. Indeed, these symptoms would be unusual for adults in the neurotypical range of intelligence.

A comprehensive set of epidemiological studies of patients with ID were conducted over several years by Cooper and her colleagues [14]. Cases were ascertained in a catchment area through extensive contacts with support agencies and medical personnel resulting in 1023 subjects. Each person was assessed using multiple measures and a standard psychiatric assessment. In addition, four diagnostic approaches were used: clinical judgement; ICD-9; DC-LD; and DSM-IV. In their study of mood disorders, the following results were obtained for unipolar depression episode: clinical judgement 4.1%; ICD-9 3.5%; DC-LD 2.8%; DSM-IV 2.0% [14]. It is important to note that clinical judgement prevailed because so many official criteria depend on self-report that can be unreliable due to intellectual disability. Many patients with intellectual disability could not self-report changes in mood time, feelings of inadequacy, or hopelessness. In addition, if challenging behaviour had developed or increased, the clinical picture was more complicated.

21.3.3 Prevalence of Depression in People with ID/ASD

Melville and colleagues also conducted an epidemiological assessment of the mental health of people with ID and ASD [13]. The larger study identified 77 adults with ASD (mean age was 37.8 years); 59 were men, 18 were women; 14 had mild ID, 14 had moderate ID, 21 severe ID, and 28 profound ID. Controls (158) were matched for sex, level of ID, and Down syndrome diagnosis. Fifty subjects had ASD and were matched to controls. Results were as follows for mood disorders: clinical judgement 5.2%; DC-LD 3.9%; DCR-ICD-10 3.9%; DSM-IV 2.6%. Overall, the incidence of mental ill health was similar to studies on people with only ID. In a second phase of the study a 2-year follow-up was conducted for

98 subjects. The recovery rate over 2 years was less for the subjects with ASD. The most common new disorders were mood disorders. There were no new episodes of mania.

Sterling and colleagues [15] investigated depression using the Autism Diagnostic Interview-Revised [16] and the Autism Diagnostic Observation Schedule (ADOS) [17] a semi-structured observation and interview administered directly to the participants, intelligence test and a psychiatric diagnostic interview. Those subjects with higher intellectual function had more symptoms of depression; 20 (43%) had depressive symptoms. Those with higher cognitive abilities showed less social impairment and were most likely to report depression. Thus people with ID/ASD may have less vulnerability to become depressed, perhaps because they are more unaware of social difficulties, or may be underdiagnosed because they cannot report or display symptoms.

Lainhart and collaborators [18] reviewed all published cases at that time of mood disorders and ASD, with a total of 17 patients. Almost all case reports were individuals with associated ID; 47% of patients were female and 50% had a family history of mood disorders. The chief complaint for 9 of 17 patients was challenging behaviour: aggression, self-injury, destructiveness, and temper outbursts. Repetitive behaviours increased in two cases, and social withdrawal and vegetative symptoms were prominent in two other cases. For all patients, however, vegetative symptoms, such as changes in sleep, were notable. However, no patients with ASD reported a change in self-attitude. For this group, four reported manic episodes only; eight had depression only; four had episodes of mania and depression. The difficulties in diagnosing related to limited self-reflection and expression of feelings are highlighted by reliance on observable behaviour.

Leyfer, Folstein, Bacalaman, and colleagues [19] conducted a study of children on the autism spectrum using the *Autism Comorbidity Interview – Present and Lifetime Version* [*Kiddie Schedule for Affective Disorders and Schizophrenia* (KSADS)] [20] modified for children and adolescents on the autism spectrum. Children were recruited from Salt Lake City and Boston resulting in 109 children ranging in age from 5 to 17 years. The diagnosis of ASD was confirmed by a senior clinician. All met DSM-III criteria as assessed with the Autism Diagnostic Interview Revised [16] and Autism Diagnostic Observation Scale [21]. A total of 109 subjects were recruited. The majority were males (94; 29%); 67.71% had IQ below 70; 57.45% verbal IQ below 70; 49% had nonverbal IQ below 70. Rates of depression were 10.1% and 13.8% for subsyndromal depression; 2.8% met criteria for depression NOS.

Henry and colleagues [22] conducted a study of mood disorder diagnoses in an outpatient sample of youth with ASD. This clinic identified 123 referred children and adolescents meeting DSM-IV-TR diagnostic criteria for autistic disorder. Mood disorder diagnoses and chief complaints along with family mood disorder history were the primary variables analysed. Four subjects (3%) presented with depressed mood. Irritability complaints were frequent ($n = 78$, 63%). Six subjects (5%) received a mood disorder diagnosis (Mood Disorder Not Otherwise Specified). No subjects received a depressive disorder diagnosis. Family history of mood disorders was common.

Regarding premenstrual dysphoric disorder, Obaydi and Puri in a systematic prospective observer-rated study on the prevalence of this disorder in women with ASD found a rate of around nine times higher than that of women of the general population (92% vs 11%) [23].

Depression is a common psychiatric disorder in persons with ID and/or ASD, even if it is not properly recognized. Many patients could not self-report changes in mood onset, feelings of inadequacy or hopelessness, and present unusual features such as onset or increase of challenging behaviours. In most cases the diagnosis is based on clinical judgement.

21.4 Criteria and Clinical Features

21.4.1 Depression

The ICD-10 uses a list of 10 depressive symptoms [24]. Key symptoms are persistent sadness, or low mood and/or loss of interest or pleasure and fatigue or low energy. One of these symptoms must be present most days, most of the time, for at least 2 weeks. In addition, other symptoms include disturbed sleep, poor concentration or indecisiveness; low self-confidence; poor or increased appetite; suicidal thoughts or acts; agitation or slowing of movement; guilt or self-blame.

These 10 symptoms define the degree of the depressive disorder. One to three symptoms present suggests the person does not have a depressive disorder. Four or more symptoms suggest mild depression; five to six symptoms suggest moderate depression; seven or more symptoms suggest severe depression which can be associated with psychotic symptoms. Lastly, the symptoms must be present for a month or more during most of the day.

In the general population, depression is fairly easy to recognize. Patients with ID and ASD cannot easily articulate symptoms or answer questions during the interview. Extra time is needed and third-party information can help establish the development of symptoms.

People with ID/ASD may present with a variety of behavioural symptoms due to the suffering of depression; however, behavioural symptoms are often difficult to interpret (see Table 21.1). Any change in behaviour, however, may be a signal of depression, or other disorder including a medical condition. Key symptoms observed may be changes such as withdrawal, changes in sleep pattern, increase in agitation, and decrease or increases in appetite. These are observable and can be tracked by caregivers. Sleep charts, changes in weight, and measures of participation in daily activities can be reported by others.

Stewart and her colleagues [25] did a literature review of depression in case reports and studies. For 15 case reports, common symptoms were regression in speech, loss of hygiene, loss of bowel and bladder control, increase in stereotypies, and self-injury. A summary of 14 studies at the time on depression and ASD found 10 of 15 studies included subjects who had ID and ASD. Those with ID and ASD had more negative life events, increased anxiety and externalizing behaviour, self-injury. Difficult symptoms associated with ASD such as obsessions may increase during a depression. Impaired verbal and nonverbal communications are barriers to the typical diagnostic interview.

Suicide and suicidal thoughts are most often linked with depression, either during a major depressive episode or in the depressive phase of bipolar disorder. Among people with ID and ASD, there is a low rate of suicide. However, reports of suicide exist. Suicide appears impulsive and generally not planned as it might be in a neurotypical person.

Several studies of suicide among people with ID alone were located. Sternlict and colleagues found a rate of nine suicide attempts per 1000 patients at a large state institution [26]. Methods used included jumping from a high place, use of a sharp instrument, and hanging/strangulation. Hardan and Sahl [27] examined the medical records of all children and adolescents assessed in a special developmental disabilities programme over a 1-year period, abstracting information reporting suicidal ideation, threats, or suicide attempts. They found that 20% of the patients made suicidal attempts. Benson [28] identified 12 patients in a large clinic for persons with ID who had made suicide attempts and ten who had suicidal ideation. In that study, ingestion of medication, cutting with sharp instruments, suffocation, and ingestion of toxic liquids were the most frequently used methods. Walters and colleagues [29] examined 90 consecutive admissions to an inpatient service for children and adolescents with intellectual disability. Ten patients had suicidal behaviour, and 60% of those acts were potentially lethal.

Lastly, Pary and colleagues [30] surveyed suicidal behaviour in persons with Down syndrome compared to a control population of persons with ID of other aetiologies using the Client Development Evaluation Report of

the California Department of Developmental Services. Of 11,277 individuals with Down syndrome, four had reports of suicidal behaviour (0.04%) compared to 1142 reports of suicidal behaviour in a total of 143,143 non-Down syndrome individuals (0.8%).

Suicide is certainly known to occur in people with Asperger's disorder and high-functioning autism. Mayes and her colleagues [31] studied the frequency of suicide ideation and attempts. They compared 791 children with autism, 35 neurotypical depressed children, and 186 neurotypical children. Mothers of children with ASD reported 14% had suicidal ideation or attempts very often, 28 times greater than neurotypical children and less than depressed children (43%). Associated diagnoses were depression and behavioural problems. The majority of children (71%) had four risk factors, such as socio-economic status. Children with high-functioning autism and low-functioning autism did not differ in suicidal ideation or attempts.

In a review of suicide and ASD, Richa and his colleagues [32] found ample evidence from 15 case studies; eight had additional ID. Precipitating events included childhood adversity, stressful life events, bullying, and physical and sexual abuse. In this way, causes of suicide are similar to the general population. Decrease in self-care was quite common. People with ASD may have more risk factors compared to neurotypical people and be more vulnerable to teasing, bullying, or abuse from others. Additional factors such as menstrual cycles can often have effects on women with ASD [33]. Some authors argue that suicide is more common in women with premenstrual dysphoric disorder, as they are more vulnerable to suicidal thoughts, plans, and attempts [34].

Any change in behaviour may be a signal of depression. Changes in sleep pattern, appetite, body weight, and participation in daily activities can represent depressive symptoms. These are observable and can be tracked by third-party information.

Suicide is not common in people with ID and low-functioning ASD.

21.4.2 Bipolar Disorder

Bipolar disorder is a serious and complex illness. Most people understand the concept of "depression" and therefore can easily understand that a severe depression would be immobilizing. It is more difficult to understand the intensity of bipolar illness: a "high" of power and feeling "on top of the world", mood swings, vast changes in typical behaviour, and physical changes such as loss or increase in appetite as well as sleep disorder. In addition, the effect of the mood (whether depressed or manic) is extreme for patients and for anyone with whom they interact. Further complexity is due to the episodic pattern. For some episodes are frequent, for others infrequent, for still others occurrence is very erratic. Because of the seriousness of this illness, people often need to be hospitalized to be safe and receive treatment. In addition, there is often a family history of the illness.

There are multiple conditions that can cause cycles of maladaptive behaviour and thus be confused with bipolar disorder in people who have ID. Pary, Levitas, and Hurley [4] describe various cyclic medical conditions, such as hay fever and inflammatory bowel diseases, which can cause great distress and resulting behavioural difficulties. A case of bipolar disorder was reported in a girl with mild ID and ASD due to menstrual difficulties resulting in acute mania [33].

Clarke and his colleagues [35] reviewed papers published with many historical cases of depression or bipolar disorder and 21 reports had ID/ASD. Clarke reported seven new cases: rapid cycling bipolar disorder; severe depressive episode with psychotic features; severe depressive episode with psychotic features; recurrent depressive disorder; bipolar affective disorder; depressive episodes; one had paranoid schizophrenia.

Matson and Smiroldo studied the mania scale of the Diagnostic Assessment for the Severely Handicapped-II (DASH-II) [36, 37]. Three groups were compared: individuals diagnosed with bipolar disorder who were currently manic, individuals with other Axis I disorders, and those with no Axis I disorders. Key symptoms of mania found were psycho-

motor agitation, decreased sleep, changes in mood, and aggression. In 2007, Matson and his colleagues further studied symptoms of mania and found psychomotor agitation and disturbed sleep were most predictive of bipolar disorder [38].

Hurley and colleagues [39] conducted a study comparing three groups of outpatients in a general psychiatry clinic: 100 neurotypical patients within normal range of intelligence; 100 patients with mild ID; 100 patients with moderate to profound ID. The chief complaint of aggression was the most common for patients with ID: Normal IQ 6; Mild ID 45; Moderate to profound ID 37. Indeed, patients had many other symptoms, but this illustrates that challenging behaviour is often the common symptom found in very distressed people with ID. Further, because challenging behaviour is seen in many conditions, in itself, this symptom has limited value as a specific indicator for a specific diagnosis.

Hurley [40] conducted an outpatient study of patient groups with ID diagnosed with depression, bipolar disorder, anxiety disorders, and patients with no psychiatric disorders seen for disability status review. Bipolar patients were significantly different from depressed patients for elevated mood, acute anger episodes, increase in verbalization, pressure of speech, talk of sexual themes, increase in appetite, and poor concentration. Challenging behaviour was most pronounced in bipolar patients.

Wozniak and collaborators [41] described a series of 66 children and adolescents with ASD. Twenty-one per cent of the children were diagnosed with bipolar disorder. Symptoms of bipolar illness were reported at similar rates for children with and without ASD. Children with mania had a high rate of irritable mood or mixed states. They were also more often described as having a chronic presentation rather than an episodic course.

21.4.3 Prevalence of Bipolar Disorder

Merikangas [42] and her colleagues investigated the 12-month prevalence of bipolar disorder as part of the National Comorbidity Survey Study utilizing the World Health Organization Composite Diagnostic Interview to assess lifetime and 12 month DSM-IV axis I disorders. Lifetime prevalence was 1% for bipolar 1, 1.1% for bipolar 2, and 2.4% for subthreshold cases. Subthreshold cases had significant impairments. Although most patients had lifetime treatment available, it was noted that many were not receiving antimanic medications, especially if seen in general medical settings.

21.4.4 Prevalence of Bipolar Disorder in People with ID

Cooper and her colleagues [14] included bipolar disorder in their epidemiological study. Point prevalence rates for bipolar disorder, currently depressed, were as follows: clinical judgement 0.5%; ICD-10 0.2%; DC-LD 0.3%; DSM-IV 0.1%. Results for mania, currently in episode: clinical judgement 0.6%; DC-LD 0.6%; CDR- ICD-10 0.6%: DSM-IV-TR 0.5%. First episode of mania: clinical judgement 2%; DC-LD 3%; ICD-10 3%; DSM-IV 4%. Bipolar disorder diagnoses occurred at about twice the estimated rate for the general public. For bipolar disorder in the depressed phase, DSM-IV-TR missed half of cases. This is thought to result from reliance on verbal self-report of depressive symptoms, whereas the outward symptoms of mania may be easier to recognize.

21.4.5 Prevalence of Bipolar Disorder in People with ID/ASD

Mellville, Cooper, and colleagues [15] epidemiological study of people with ID and ASD measuring their mental ill health was reported above. Results were as follows for mood disorders: clinical judgement 5.2%; DC-LD 3.9%; DCR-ICD-10 3.9%; DSM-IV. 2.6%. There were no episodes of mania. Given the extensive history and interviews in this study, it may be significant that there was not good

evidence of bipolar disorder as there were no reports of a manic episode.

As previously reported, Leyfer and colleagues [19] conducted a study of children with autism spectrum. The *Kiddie Schedule for Affective Disorders and Schizophrenia* (KSADS) [20] was modified for children and adolescents on the autism spectrum. Less than 2% had a manic episode or symptoms of bipolar disorder, including two with a manic episode; one cyclothymia; two bipolar-1; one bipolar-2; one hypomanic episode; two mixed bipolar episodes. This detailed study included subjects who were within a normal range of intelligence.

In persons with ID bipolar disorder diagnoses occur at about twice the estimated rate for the general population. Key symptoms of mania are psychomotor agitation, decreased sleep, changes in mood, and aggression. Challenging behaviours in general are very common and often much pronounced.

21.4.6 Other Specific Mood Disorders: Criteria and Clinical Features

There is great variability in symptomatology as well as number and length of episodes among patients. ICD-10 [24] lists the following criteria.

21.4.6.1 Mania Without Psychotic Symptoms

In manic episodes without psychotic symptoms some main psychic dimensions are characterized as following.

Affect: Elevated mood; irritability; distance; self-esteem (high); affectability; aggressiveness and hostility

Drive: Increased activity; psychomotor agitation

Vital functions: Reduced sleep needs, increased libido

Formal thinking: Flight of Ideas.

In Confused Mania confusion is caused by an extreme acceleration of thinking and speaking.

21.4.6.2 Bipolar Affective Disorder

In the mixed episodes, the symptoms of mania and depression occur in rapid alternation or are present simultaneously. The inhibition (depression) or excitation (mania) of emotional, cognitive, and psychomotor processes, which move in the same direction, are no longer present in mixed states. Thus, for example, quick thinking and talking (as in mania) can occur simultaneously with anxious-depressive mood. A mixed state is a very diverse, sometimes difficult to diagnose and treat, disorder.

21.4.6.3 Cyclothymia/Cyclothymic Disorder

Cyclothymia or cyclothymic disorder is an attenuated form of bipolar disorder. For these patients, mood variations are often observed over a period of at least 2 years, with the criteria for a depressive- or manic episode not being met in full and often occurring independently of external influences. However, the transition is very fluid, so that a bipolar (ll) disorder can often be detected in people who come to a clinic with a suspected diagnosis of cyclothymia.

21.4.6.4 Severe Depressive Episode with Psychotic Symptoms

The affected patient had at least one clearly diagnosed hypomanic, manic, or mixed affective episode and at least one further affective episode (hypomanic, manic, depressed, or mixed) in the anamnesis; in recent months and presently there is no clear disturbance of mood. Remissions during prophylactic treatment are also encoded here.

21.4.6.5 Moderate Depressive Episode

The affected patient is currently depressed, as in a mild or moderate depressive episode, and had at least one clearly diagnosed hypomanic, manic, or mixed episode in anamnesis.

21.4.6.6 Premenstrual Dysphoric Disorder

Marked affective lability, irritability, depressed mood, and anxiety represent the main symptoms. At least one of these must be present in the week leading up to menstruation together with additional possible symptoms such as decreased interest in typical activities, difficulties in concentrating, poor energy, changes in sleep or eating, feeling overwhelmed or out of control, and physical symptoms (i.e. sensation of bloating, muscle pain, etc.).

This diagnostic category has been introduced in the ICD-10 with the 2017's revision.

In ICD-11 Depressive Disorders and Bipolar Disorders are grouped together as Mood Disorders. Mood disorders are classified based on the sorts of Mood Episodes that occur and their patterns throughout time. The main types of mood episodes include Depressive Episode, Manic Episode, Mixed Episode, and Hypomanic Episode. Mood Episodes do not have their own diagnostic codes since they are not independently diagnosable entities. Mood Episodes, on the other hand, are components of Bipolar and Related Disorders, as well as Depressive Disorders. Bipolar or Related Disorders include Bipolar Type I Disorder, Bipolar Type II Disorder, Cyclothymic Disorder, and Other Specified Bipolar or Related Disorders. Depressive Disorders include Single Episode Depressive Disorder, Recurrent Depressive Disorder, Dysthymic Disorder, and Other Specified Depressive Disorders. Mixed Depressive and Anxiety Disorder is included in the section on Depressive Disorders, although it has certain characteristics in common with Anxiety or Fear-Related Disorders [43].

21.5 Aetiopathogenesis

21.5.1 Depression

Depression is one of the most common mental illnesses in the general population. Human beings experience sadness: a normal reaction to difficulties in life. Often, people report they are "depressed" about something, but these expressions are not the same as a major depressive episode.

While most common in adults, depression can occur in children and teenagers. Depression, especially in midlife or older adults, can co-occur with other serious medical illnesses, such as diabetes, cancer, heart disease, and Parkinson's disease. These conditions are often worse when depression is present. Sometimes medications taken for these physical illnesses cause side effects that cause or contribute to depression.

Causes of depression include genetic predisposition, major life changes, trauma, increase in stress, major loss of supports or friends, physical illness, disability, and medication side effects. In addition, some people are susceptible to seasonal affective disorder, becoming depressed during the fall and winter season.

Depression in people with ID/ASD can be associated with medical conditions. Autism occurs with known medical conditions in at least 10% of cases [44]. These conditions may increase the vulnerability to depression and modify its symptoms. Most notably about 30% of people with ASD have a seizure disorder [45]. Because a seizure disorder is often associated with depression in the general population, people with ASD and a seizure disorder may be more vulnerable to depression [46]. Hormonal dysregulation or sensitivity has been indicated to be involved in the pathogenesis of premenstrual dysphoric disorder, although knowledge on the origin of this condition is only in the early stages [47].

Family genetic factors play an important role in the etiology of depression in the general population, in both children and adults [48, 49]. Children with ASDs who suffer from depression are more likely to have a family history of depression [50]. Since depression does not appear to be part of the broader phenotype of autism [51] it is possible that autism with comorbid depression may form a distinct sub-group.

Life events are also known to be related to depression in the general population.

Ghaziuddin and colleagues [50] compared 11 children with ASD and depression to 11 matched controls without depression and researched unpleasant life events in the prior 12 months using a life events schedule. Nine patients with depression (82%) gave a history of having sustained recent unpleasant life events compared to five (45%) in the nondepressed group. These events consisted of the change in living arrangements, change of education programs, family illness, bereavement, and other losses.

21.5.2 Bipolar Disorder

Bipolar disorder has many possible causes. Genetic inheritance is often cited and found to be involved in many cases. It may also occur after a serious medical illness. Some medical conditions that are associated with ID and/or ASD are also associated with bipolar disorder. For example, bipolar spectrum disorder has been reported by some researchers to occur in 70% of affected individuals with velo-cardio-facial syndrome (VCFS; 22q-, 22q22.1DS) by adolescence, approaching 100% by adulthood [52]. Verhoeven [53] and colleagues identified Phelan-McDermid syndrome in two adult brothers with atypical bipolar disorder. Kerbeshian and colleagues [54] reported atypical bipolar disorder in a 33-year-old female with a deletion of 15q12. She had profound ID, was explosive, had episodes associated with insomnia, cyclical expansive mood. Mood improved markedly with lithium. Sovner and colleagues [55] reported a case of rapid cycling bipolar disorder in a man with ring chromosome 22, and 7 other cases in the literature. The patient responded well to divalproex and fluoxetine. It is currently thought that numerous ID and ASD genetic syndromes contain within their genome deletions genes associated with the endophenotypes of psychiatric disorders, possibly accounting for psychiatric comorbidity in these syndromes [56].

Medical conditions are also associated with the development of bipolar disorder. This was first reported by Krauthammer and Klerman [57] and called "secondary mania". In the general population, conditions associated with mania include degenerative neurological disorders, cerebrovascular disease, metabolic conditions, endocrine conditions, autoimmune conditions, viral or other infections, and certain cancers. There is a report of secondary mania in a patient with ID and polycystic ovary disease [58].

Causes of depression include genetic predisposition, major life changes, trauma, increase in stress, major loss of support or friends, physical illness, disability, and medication side effects. Bipolar disorder seems to be more associated with genetic inheritance and medical conditions.

21.6 Specific Assessment

Due to the complexity of patients with ID/ASD, specific assessments beyond the psychiatric diagnostic interview are essential to understand the patient, as well as monitor treatment. On a simple level, one can ask for any data held by school departments and other social services. Obtaining a properly administered IQ test is essential and hopefully assessments were conducted at least during the early school years. These will give good clinical information as to verbal abilities and other organizational abilities. When starting a new patient, best practice is to make every effort to get full medical records and school records.

Formal assessment using published instruments is helpful to diagnosis and often to assess improvement. For people with ID/ASD assessment of sensory sensitivities and stress is essential. An excellent instrument was developed by Groden and her colleagues, the *Stress Survey Schedule for Individuals with Autism and Other Pervasive Developmental Disabilities* [59]. A carer is interviewed about items commonly experienced as stressful by persons with autism spectrum disorders (e.g. "receiving hugs and affection" or "waiting in line") and rated on a 5-point scale. The items then score to important groupings for plan-

ning purposes: changes; unpleasant, (even positive) sensory-personal, food-related, social-environmental, rituals. A study of informants and self-report of persons showed modest agreement, and it is recommended that self-report is always an important factor [60]. Prior to considering a secondary mental health condition in a person with ID/ASD, a thorough evaluation of stressful events and sensory input is essential to understand complex behavioural reactions. We know that many sensory situations are experienced as aversive by people with ASD. Thus, it is essential to recognize behavioural reactions to sensory events vs. mistaking these behaviours for psychiatric disorders.

Because people with ID and ASD commonly exhibit many behavioural difficulties, assessment of behaviours is also essential. The *Reiss Screen for Maladaptive Behavior (RMB)* [61] contains 38 items rated ideally by two individuals who know the person well and the scores are averaged. This instrument can be used for all levels of ID. Items are rated on a 3-points scale for severity on eight subscales: Aggressive, Autism, Psychosis, Paranoia, Depression and Behavioural signs, Depression and Physical Signs, Dependent Personality Disorder, and Avoidant Personality Disorder. Individual items of interest not included in subscales are drug abuse, overactive, self-injury, sexual problem, suicidal, stealing. The Reiss Screen has been used in a number of studies and is popular because it is easy to complete and score and provides useful information. Although the title suggests it addresses "behaviour", it is rather an excellent instrument to assist in psychiatric diagnosis.

A more thorough and complex set of assessments are also an excellent addition to help with complex cases. The *Psychiatric Assessment Schedules for Adults with Developmental Disabilities* (*PAS-ADD*) [62] includes several measurement options. The *PAS-ADD* clinical interview [63] is the most comprehensive help with establishing a diagnosis using both ICD-10 and DSM IV. The PAS-ADD Checklist [64] is a 25-item questionnaire, designed for use primarily by care staff and families. The Mini PAS-ADD can be used by a wide range of professionals and an suggest a possible psychiatric disorder. This can be completed by interviewing a caregiver or by collecting information through chart reviews. These assessments are highly recommended for complex cases.

The direct assessment of challenging behaviours is also important. The *Aberrant Behavior Checklist* (*ABC*) [65, 66] is an informant rating scale that assesses specific behavioural problems in people with all levels of ID from ages 6–54. It has 58 items distributed on five subscales: Irritability, Lethargy, Stereotypy, Hyperactivity–Noncompliance, and Inappropriate Speech. An increase in behavioural difficulties compared to the past may signal the development of a mood disorder. A Lethargy scale high score may signal depression. An increase in hyperactivity may signal a manic episode. The ABC has excellent psychometric properties and has been used in numerous studies and is an excellent choice for patients with ASD. It can be used multiple times and is therefore useful in following a case for improvement or relapse.

Another useful instrument is the *Diagnostic Assessment for the Severely Handicapped-II (DASH-II)* [36]. The DASH is an "informant interview" scale. Because it does not rely on verbal self-report from the person being assessed, it is very useful for people with severe to profound ID and ASD. Items are rated using a 3-point scale for frequency, duration, and severity. There are 13 subscales and 7 that have direct relevance to psychiatric diagnoses: Anxiety, Depression, Mania, Schizophrenia, Stereotypies/Tics, Organic Syndromes, and Impulse Control Disorder/Miscellaneous. Additional subscales address behaviours of psychiatric importance: Self-Injurious Behaviour, Elimination Disorders, Eating Disorders, Sleep disorders, and Sexual Disorders. This instrument has been translated into Italian, Norwegian, and Spanish. The DASH-II has good psychometric properties.

An excellent instrument to assess depression, the *Mood, Interest & Pleasure Questionnaire (MIPQ),* was developed by Ross and Oliver [67, 68]. This instrument is used with people who have severe and profound ID. It is an informant rating scale with

two subscales: Mood and Interest & Pleasure, rated on a 5-point scale for being observed in the last 2 weeks. Reliability and internal consistency are good and validity was demonstrated with the ABC [65]. This instrument is useful for people with ID in moderate to profound range and also people with ASD.

The *Autism Comorbidity Interview Present and Lifetime Version* is an excellent diagnostic interview discussed above. It is used for children and young adults with ASD who may be suffering from a mood disorder [18].

On a simpler level, caretakers can track mood throughout the day over a period of time, looking for patters. The *Sovner-Hurley Bipolar Mood Tracking Sheet* [69] documents mood changes kept daily by a caregiver. The mood is rated daily so patterns may emerge linking mood to events or days, or to ascertain that a cyclic pattern is developing. Mood is rated 0 to +3 for activation (mania) and 0 to −3 scale for withdrawal daily. A similar tracking sheet, the *Sovner-Hurley Monthly Sleep Chart* [70], tracks sleep through hourly blocks. If there is no one awake at night, the chart can still be used if caretakers become aware at any time that an individual is up and active at night.

There are a number of tools that can be used to investigate the presence of a mood disorder in persons with ID. A good practice before starting the assessment should be to find medical and school records, and evaluate stress and sensory sensitivity.

21.7 Treatment

21.7.1 Depression

21.7.1.1 Psychotherapeutic Approaches

Treatment for depression in people with ID/ASD should ideally be multifaceted. It is ideal to involve the person's full circle of relationships: school, day program, family, teachers, direct support professionals, and psychologists. Medication alone is often not enough.

Increasing supports For every person with ID and ASD, the plan should begin with an increase in supports. The suffering of depression can be ameliorated by therapeutic approaches such as increasing social contact, pleasurable activities, and positive feedback. For people with ID and ASD, supports should be organized and discussed with the person's entire support team. The patient will improve most quickly if the environment and support staff can change to be as "happy" and supportive as possible. Simple interventions provide much promise. For example, offering favourite trips out, favourite foods, walks with some friends, and special music are very easy interventions to organize. Because people with ID and ASD are less able than neurotypical people to help themselves, encouraging a strong and organized support programme is essential. There are many psychotherapeutic approaches to depression, and cognitive behavioral therapy (CBT) is an excellent choice for people with ID. Patients who have bipolar disorder can also benefit from the same approaches, although active direction during a manic episode is seldom useful.

Psychotherapy There is not a large literature on psychotherapy for people with mild ID and ASD. However, there is no reason to question the same efficacy of the approaches to persons with ID and ASD who suffer from depression with as are seen in neurotypical people, modified for level of ID. CBT approaches are usually an excellent choice for patients who are within the mild to moderate range of ID. Psychotherapy should involve a great deal of education for the person and caregivers about depression itself and give hope for recovery. It is important to involve caregivers frequently in person or by telephone contact regarding active suggestions from psychotherapy sessions. For patients with ID and ASD who have bipolar disorder, when not in a manic episode, psychotherapy and supports should be organized as well.

McGillivray and her colleagues [71, 72] demonstrated that people with Asperger's Disorder or High Functioning Autism could benefit from structured CBT in structured group sessions, easing depression. In another

study, people with mild ID and depression were treated with CBT techniques assisted by staff. The programme emphasized the concepts "Think Happy, Feel Happy, Be happy" and used group sessions and typical curriculums for problems associated with depression. People in the programme showed good improvement compared to wait-list controls. There is every reason to assume that CBT approaches could be modified to help people with ID and ASD.

Psychosocial Education Another interesting approach was used by Ingram [73] who intervened with staff using psychosocial education, targeting an individual in their care who had severe ID and severe challenging behaviour. The programme exposed staff to understanding the person's history, challenges, and in some sense, "reinterpreting" their assumptions about the person. The results of attending these workshops were remarkable with dramatic drops in all challenging behaviour (e.g. incidents of physical aggression per daily interval recording when from 19 to 0, and challenging behaviour from 140 to 18). Just like family, educating support caregivers is essential in helping people with ID and ASD to fit in better with home living and day or work programme arrangements.

In persons with ID and/or ASD the treatment of depression and bipolar disorder should be multifaceted and involve the person's full circle of relationships. CBT modified approaches could be an excellent choice for people who are within mild to moderate range of ID. Providing everyone with organized support programme and psychosocial education is also very important.

21.7.1.2 Pharmacotherapy

The literature on psychopharmacotherapy for patients with ASD and mood disorder is almost exclusively geared either to patients with high-functioning autism or to the treatment of behavioural symptoms, as reviewed by Postorino and his colleagues [74], and is therefore not a guide to diagnosis-based treatment in patients with ID/ASD. There is minimal case report literature, almost all single cases; clinical experience is extensive but not reported, since patients in this population rarely meet diagnostic criteria designed for persons with more communicative ability. The pharmacotherapy of both depressive and bipolar disorders is well-known and well-established for neurotypical patients with these disorders, so that while there is no literature support for use of any particular agent, neither is there any support for a belief that they will be ineffective, and clinical experience has shown that, in fact, they are. This discussion will focus on the special considerations particular to patients with these disorders and ID/ASD.

A recent study on older persons with ID from the Swedish national registers indicates a limited use of antidepressants compared to that of other psychoactive drugs, which seems to be related to the tendency of clinicians to under-diagnose depressive disorders in favour of other psychopathological conditions, especially in the presence of problem behaviours [75]. Psychiatrists should consider antidepressants as an option in treating psychiatric disorders rather than routinely prescribe drugs with sedative effects.

Patients with ID/ASD may have quite atypical, and, as of this writing, frequently unknown atypical, neurochemistry. Responses to psychopharmaceuticals are therefore not entirely predictable, and caution should be exercised in dosing. Dosing decisions should not be based on the severity of symptom-associated behaviour, but rather based on consideration of the brain that is producing the symptoms, and by clinical response. The rubric "Start low, go slow" is good advice.

Patients with ASD, in whatever range of cognition they may function, almost always suffer from anxiety, and many have problematic gastrointestinal symptoms. Unlike older (tricyclic) antidepressants, specific serotonin reuptake inhibitors (SSRIs) offer both antidepressant and anti-anxiety effects and have (usually) minimal gastrointestinal effects, making them the logical first choice for pharmacotherapy of depression in this population. All SSRIs take 4–6 weeks for their full effects to unfold; dose increases should therefore take place at 1-month intervals,

with monitoring for activation and increased anxiety. Neuromodulation via SSRIs has also been suggested for the treatment of premenstrual dysphoric disorder, together with ovulation suppression through various contraceptive and hormonal preparations. Unlike traditional depression therapy, the treatment of premenstrual dysphoric disorder does not require SSRIs to be used every day; they can be used cyclically, only during the luteal phase, or also for the duration of the monthly symptoms) [76, 77].

Serotonin/noreprinephrine reuptake inhibitors (SNRIs) may also be effective, but affect two neurotransmitters, making assessment of possible side effects problematic, and perhaps more likely than with SSRIs.

It has long been thought that antidepressant medication may be tapered a year after remission in first episodes, with a 50% recurrence rate in neurotypical populations, a year after remission after a second episode with a 90% recurrence rate; after a third episode recurrence rate after cessation of antidepressant medication is 100%. The recurrence rate in persons with ID, ASDs, and ID/ASD is unknown. Further, one is often unable to determine if a patient has had previous episodes. Tapering of effective antidepressant pharmacotherapy is therefore, unfortunately, very problematic in this population.

21.7.1.3 Mania and Mixed Mood Episodes

Mood stabilizing medications are numerous. The antiepileptic mood stabilizers (valproate, carbamazepine, oxycarbazepine, topiramate, and sometimes lamotrigine) can offer advantages in a population with a high rate of comorbid seizure disorder. Lithium can be difficult to manage in this population; individuals with ID/ASD may have unreliable fluid intake (especially in regimented settings, where they may not have free access to fluids), presenting risk of Lithium toxicity.

All the antiepileptic mood stabilizers, and Lithium, require blood monitoring of various kinds to detect and avoid possible toxicity, which can present problems in patients averse to venipuncture. Supportive measures to reduce anxiety until venipuncture becomes routine may be necessary. This is especially necessary in a patient population which may lack the ability to report side effects. Toxicity may not be apparent until observed by carers in patients lacking the ability to communicate internal experiences. Lamotrigine does not require blood monitoring, but presents the risk of the potentially fatal Stevens-Johnson Syndrome (SJS) in a person who may lack the verbal ability or sensitivity to pain to report the first signs of rash and mucous membrane involvement.

Antipsychotic medications may have to be added to mood stabilizers as adjuncts, or used as mood stabilizers, if the antiepileptic medications and Lithium are ineffective or poorly tolerated. However, these medications present the well-known disadvantages of appetite increase and weight gain, insulin-resistance and hyperlipidemia, in a population already burdened with food rituals and obsessive food preferences, plus the risk of movement disorders. They should not be the medications of first choice to treat mania.

21.7.1.4 Light Therapy

Seasonal affective disorder may be fairly common in the general population and should be considered when helping people with ID/ASD. Changes in a person's behaviour during the fall and remitting in the spring are key symptoms. For seasonal affective disorder, the use of a qualified Bright Light Box can be very effective [78]. Typically, the Bright Light Box is used in the morning daily from late fall and winter months for 30 minutes to an hour. The person sits near it but does not look directly at the light box. Most bright light boxes deliver 10,000 LUX. For people with ID and/or ASD, caregivers typically will be in charge of turning on the box, supporting the person personally while in use, and in limiting time with the light.

Several reports address the use of Bright Light Therapy for people with ID/ASD. Hermans and colleagues [79] treated 14 patients with ID/ASD for depression using Bright Light Therapy. All patients were rated on the depressive mood subscale of the ADAMS (Anxiety, Depression and Mood Scale) [80]. Subjects' levels of ID were: 3 mod-

erate; 3 severe; and 8 profound. Subjects were treated for 2 weeks sitting near the light box for 30–60 minutes. Considerable accommodations were needed to engage the individuals due to their schedules, medical needs, and some difficulty sitting near the light box for a long time. However, most participants showed reduction in symptoms of depression, and six showed remarkable change.

Altabet and colleagues [81] described three people with profound intellectual disability who exhibited signs of depression. Each patient was treated in a special room and a Bright Light Box using 10,000 LUX. Patients were supervised to sit a bit away at an angle to not look at the light. Measurements taken included: ABC Irritability and Lethargy Scale; the DASH depression scale; a sleep record; and a mood chart. Patients were females age 42, female age 61, and female age 68. All improved significantly in standard measures. In all three cases, decreases in depression, irritability, or lethargy attained during treatment remained stable for 3 weeks, but continued to decrease after 8 weeks.

Cooke and Thompson [82] treated two patients with ID using Bright Light Therapy. These patients manifested seasonal cycles in mood and behaviour. The first patient in adolescence displayed significant periods of overactivity, elation, and for example, dancing for hours followed by a period of withdrawal, loss of interest. He was diagnosed with bipolar disorder and treated with medications including lithium. At the age of 40, his depression became more frequent and occurred in winter. He was treated with 10,000 LUX lamp. He became very stable, did not become depressed that winter, and was subsequently maintained on Lithium. The second patient was a 9-year-old boy with severe ID/ASD. At the age of 6, he had very difficult behaviours, which seemed to have a cyclical presentation. At the beginning of October, he was treated with 10,000 LUX lamp. He appeared happier, was much less anxious, and did not have problems of aggression or hyperactivity. Unfortunately, sleep itself did not improve. No structured assessments were used.

Tsiouris [83] used light therapy for four patients. He chose 5000 LUX to assure that there would not be light too intense for patients. One patient had Down syndrome and a seasonal pattern of depression in the fall and winter months. His parents administered the Bright Light Therapy at home which was successful and his fluvoxamine was reduced. The second patient was a female with severe ID, a seizure disorder, traumatic brain injury, and major depression. In childhood, she had a right-side lobectomy for severe aggression. Psychiatric medications alone did not help her depression, which seemed worse in winter months. Bright Light Therapy was used for 30 minutes in the morning. Within 1 week, all symptoms of depression and challenging behaviour were reduced and eliminated. Thereafter, she began Bright Light Therapy each September. The third patient was 45 years old and had severe ID/ASD, Tourette disorder, and was also diagnosed with bipolar II disorder. Her symptoms of depression were reversed with Bright Light Therapy conducted during the winter months. The last patient was a 44-year-old female with ASD, spastic diplegia, and rapid cycling bipolar II disorder. After light therapy, she was much less depressed and treatment continued from September through April annually.

21.7.1.5 Electroconvulsive Therapy (ECT)

It is impossible to review treatment of mood disorders without mention of ECT. There are several reviews of the use of ECT in persons with ID [84–86], and many case reports of its use with patients with ID and mood disorders [87] and many of its use in patients with ASDs and a variety of behavioural issues and diagnoses [88]. Only two case studies of patients with ID/ASD and a mood disorder could be located. Wachtel and colleagues [88] and Siegel and colleagues [89] both describe single cases of patients with ID/ASD and cycling mood disorders refractory to medication and responsive to ECT. There are no controlled studies, and patients all remained on their existing medication regimens to which ECT was added.

Several of these studies, notably Reinblatt and colleagues [84], refer to the difficulties in obtaining informed consent in this popula-

tion, without detailing the reasons. Beyond the obvious issues presented by cognitive limitations, one must consider the scepticism among the general public about ECT, magnified by the scepticism in many parents and guardians of persons with ASDs about psychiatric medication.

Anxiety is bound to be an issue in experiencing ECT for persons who become anxious at far less anxiety-producing medical procedures. The known effects of ECT on memory and cognition may be equally anxiety-producing, and patients with limited or no language would be unable to communicate these adverse experiences. While ECT must remain an alternative where food, fluid, and medication refusal, medication intolerance or ineffectiveness, is an issue, there is insufficient evidence or experience to advocate it as a first-line approach to mood disorder in this population.

Psychiatrists should consider antidepressants as an option in treating psychiatric disorders rather than routinely prescribe drugs with sedative effects.

Patients with ID and/or ASD may have quite atypical neurochemistry, and therefore great caution is required in dosing antidepressant and mood stabilizers. SSRIs represent the first choice for moderate depressive episodes, while antiepileptic mood stabilizers can offer advantages to treat mania.

Several reports address the use of Bright Light Therapy to treat seasonal affective disorder and ECT as an alternative treatment in very specific conditions.

21.8 Prognosis

The prognosis for people with ID and ASD who suffer from mood disorders will be improved by diagnosing the correct condition. In the past, many individuals with ID and ASD were not diagnosed with psychiatric disorders and were treated only for having challenging behaviour. We must be sensitive to the mood of individuals we support and treat. Families and caregivers, who often speak for these individuals in appointments, must be educated so that they do not give prejudiced information. For example, in a staffed home, the carers may have little or no training in mental health issues. Thus, information is framed from a certain point of view, often as a behavioural problem. This makes it essential that formal assessment tools be used so that extensive background information and records are reviewed when we see a patient for the first time. Understanding the person's mood state, psychiatric symptoms, and medical issues is essential [90].

Depression must be treated with kindness and consideration. As previously suggested, family and caregivers can help by increasing pleasurable activities. Just as we might treat someone suffering from cancer with soothing and supportive caring, we must see depression as a serious illness that can be helped by positive environments. Bipolar disorder must be carefully followed and monitored for switches in mood. Medications must be closely monitored with timely laboratory information.

Bipolar disorder requires medication, perhaps multiple medications, and possible hospitalizations. The most effective mediations require laboratory tests, which may be a problem for some individuals. It is important to organize ways to make these tests go smoothly if patients are afraid or object. Sometimes, simple anaesthetic ointment and support may suffice. Ideally, patients with bipolar disorder will have a stable team of support staff, psychotherapists, psychiatrists, and primary care clinicians to care for them.

As of this writing there are no extant studies of the prognosis for treatment of mood disorders in persons with ID/ASD. It is only relatively recently that it was recognized that these disorders could be diagnosed and treated in these populations; studies of prognosis were confined to treatment of behaviours, not comorbid disorders. Case report literature (cited above) is replete with reports of successful treatment of depressive episodes and manic episodes, but studies of long

term antimanic and antidepressant prophylaxis are lacking. If it is ever done, comparison would have to be made with such studies in neurotypical patients with these disorders, with the provision that no expectation should be held that mood stabilization will improve the underlying ASD or ID, only the mood disorder.

Clinical experience so far suggests that prognosis will be comparable. Individual episodes of mania and depression are responsive to antimanic and antidepressant medication much as they are in the neuroptypical population. Recurrence of depression or of manic cycling can be expected if medication is not maintained. The same issues of long-term medication tolerance are encountered as in the neurotypical population (e.g. bone marrow effects, hyponatremia with carbamazepine and valproate; nephrogenic diabetes insipidus and hypothyroidism with Lithium). Breakthrough episodes, especially of bipolar disorder, can be expected to occur, with the necessity for adjunctive medication so familiar in the treatment of neurotypical patients with mood disorders. Whether or not these are more frequent in persons with ASD and ID is at present unknown, but any studies would have to take into account the fact that most of these patients, unlike neurotypical patients with mood disorders, will be in the care of systems that ensure their compliance with their medication regimen, in contrast with the noncompliance often encountered in neurotypical patients. Selection of comparison groups for such studies, and interpretation of results, may prove difficult.

For the moment, lacking any information to the contrary, we must treat with the agents that we have or that become available and do what is clinically indicated to maintain mood stability, much as is done with neurotypical patients with mood disorders.

The prognosis for people with ID and/or ASD who suffer from mood disorders will be improved by diagnosing the correct condition.

Studies of long-term antimanic and antidepressant prophylaxes are lacking, but recurrence of mood disorders can be expected if medication is not maintained.

Tip

Mood disorders in people with ID and ASD deserve increasing research interest and continued acquisition of up-to-date knowledge by clinicians.

Key Points

- Depression and bipolar disorder are common psychiatric disorders in persons with ID and/or ASD, even if they are not properly recognized.
- For individuals with ID and ASD proper diagnosis and effective treatment of mood disorders present considerable challenges.
- In persons with ID and/or ASD changes in sleep pattern, appetite, body weight, and participation in daily activities can represent symptoms of mood disorders.
- Reduction in speech, social withdrawal, and increase in somatic complaints occur more frequently in depression, while psychomotor agitation, decreased sleep, changes in mood, and aggression occur in mania.
- Causes of depression include genetic predisposition, major life changes, trauma, increase in stress, major loss of support or friends, physical illness, disability, and medications, while bipolar disorder seems to be more associated with genetic inheritance and medical conditions.
- In persons with ID and/or ASD the treatment of depression and bipolar disorder should be multifaceted, com-

bining psychotherapy and medications, and including organized support programme and psychosocial education.
- Specific serotonin reuptake inhibitors (SSRIs) represent the first choice for moderate depressive episodes, while antiepileptic mood stabilizers can offer advantages to treat mania.
- In persons with ID and/or ASD the prognosis of mood disorders can be significantly improved by diagnosing the correct condition. Evidence on long-term antimanic and antidepressant prophylaxes are lacking, but recurrence of mood disorders can be expected if medication is withdrawn.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_22

Learning Points

- Anxiety disorders and related disorders are common in persons with intellectual disability/disorders of intellectual development (ID/DID) and frequently missed due to inherent limitations in cognitive function and communication difficulties, described elsewhere in this book.
- The clinical utility of the classificatory systems such as the ICD and the DSM could be adapted and modified as relevant by placing equal emphasis on reliably observed components (signs) as well as symptoms (reported).
- In those with more severe ID/DID, anxiety disorders may present as problem behaviours.
- Accurate diagnosis underpins access to appropriate interventions maximizing optimum quality of life.
- Management includes psychological and pharmacological treatment adapted or extrapolated from the general population since there is overall a dearth of empirical evidence specific to persons with ID/DID.

22.1 Introduction

Anxiety is a ubiquitous emotional state that lies on a continuum between fear-related responses and those characterized by a diffuse sense of dread, unease, and worry/misery. Fear-related anxiety affects cognitive, emotional, and behavioural responses to danger or imminent threat. In fear, the cues are usually external in most anxiety states; they eventually generalize and respond to learned (conditioned) cues. Fear also manifests as freezing and flight (escape and avoidance) or fight behaviours (defensive aggression). These states involve activation of the sympathetic nervous, endocrine (increased cortisol) and neuro-immunological (cytokine release) components of the stress response system [1, 2].

Non-fear-related anxiety arises in response to anticipated threat, worry, and other negative affective states. Physiological arousal and anxiety-related behaviours resemble scaled-down versions of fear-related responses to non-life threatening, diffuse threats. Panic disorder (fear-related anxiety) frequently spawns anticipatory and avoidance behaviours (agoraphobia) to multiple layers of generalized fear-conditioned stimuli. Many of these responses bear only a faint resemblance to the original fear experiences. In summary, anxiety lies along a spectrum of negative affective states that range from acute fear to worries about illness, physical appearance, social acceptance or what might happen in the future.

Anxiety disorders (ADs) can be roughly divided into two overlapping domains: (1) fear-related anxiety which includes phobias, panic disorder (with/without agoraphobia), trauma-related disorder, and social anxiety disorder (performance anxiety) and secondary forms (traumatic brain injury, seizure with fear at onset). Each involves variations on fear response, fear conditioning, avoidance behaviours, and risk for excessive generalization, transformation, and problems with extinction. (2) The second subtype involves excessive worry/distress-related anxiety disorder that includes social anxiety (generalization of social avoidance), generalized anxiety disorder, and related mood-anxiety disorder and dysthymia. In each of these syndromes, the threat is more diffuse, and behavioural responses are mediated by higher levels of cognitive processes, cortical modulation, and executive functions [3–6].

ADs are defined in the DSM-5 [7] as "The apprehensive anticipation of future danger or misfortune accompanied by a feeling of worry, distress, and/or somatic symptoms of tension. The focus of anticipated danger may be internal or external". Anxiety refers to the "anticipation" of future threat while fear is "the emotional response to real or perceived imminent threat". Worry is defined as "apprehensive expectation". The DSM-5 also includes severity as a qualifier for diagnosis in that the anxiety must be of sufficient degree to interfere significantly with the person's social, occupational, or global functioning. In ADs,

the intensity or duration of anxiety is disproportionate to the potential for harm, or in the absence of recognizable threat to the individual. It involves increased levels of arousal, resulting in disorganizing rather than facilitating an individual's performance.

Persons with intellectual disability/disorders of intellectual development (PWID/DID) are a heterogeneous group, which share significant cognitive and communication impairments with physical as well as mental comorbidities and poor social functioning in varying degrees. Consequently, in common with all other psychiatric disorders, ADs are often not diagnosed in this vulnerable population, resulting in poor access to appropriate treatment which further limits quality of life.

Overall, there is a paucity of high-quality evidence specific to AD as is the case in all mental disorders in PWID/DID due to difficulties in carrying out good quality research [8]. Given these limitations, evidence derived from empirical studies in the mainstream population has been adapted, extrapolated, or modified within the context of the individual's psychological, biological, and social circumstances.

This chapter provides an overview of anxiety and related disorders including, generalized anxiety disorder, panic disorder, agoraphobia, specific phobia, social anxiety disorder, separation anxiety disorder, selective mutism, health-related anxiety, and post-traumatic stress disorder (PTSD) as well as obsessive-compulsive disorder (OCD) categorized separately in DSM-5. It covers classification and diagnosis, clinical features, epidemiology, aetiology, pathophysiology, risk factors, treatment, and prognosis within the context of available evidence.

Anxiety disorders refer to negative emotional states ranging from acute fear to worry about something that significantly interferes with the person's global functioning. In persons with ID/DID, anxiety disorders are often not diagnosed, resulting in poor access to appropriate treatment which diminishes quality of life.

22.2 Classification and Diagnosis

The DSM-5 [7] identifies eleven disorders in the anxiety category all of which use the term fear, worry, and anxiety; the exception being selective mutism. It also separates OCD from AD. The ICD-11 [9] describes anxiety and fear-related disorders as being "characterized by excessive fear and anxiety and related behavioural disturbances, with symptoms that are severe enough to result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning. A key differentiating feature amongst the anxiety and fear-related disorders is disorder-specific foci of apprehension, that is, the stimulus or situation that triggers the fear or anxiety. The clinical presentation of anxiety and fear-related disorders typically includes specific associated cognitions that can assist in differentiating amongst the disorders by clarifying the focus of apprehension".

Kogan et al. [10] have outlined the changes in the organization and diagnostic guidelines for anxiety and fear-related disorders proposed by the ICD-11 Working Group on the Classification of Mood and Anxiety Disorders and the rationale and evidence base for the proposals. The ICD-11 [9] contains nine types of conditions defined as follows- (substance/medication-induced AD and anxiety due to another medical condition categorized in DSM-5 have been excluded).

1. Generalized Anxiety Disorder (GAD)

GAD is characterized by marked symptoms of anxiety of least several months duration, for more days than not, manifested by either general apprehension (i.e. "free-floating anxiety") or excessive worry focused on multiple everyday events, most often concerning family, health, finances, and school or work, together with additional symptoms such as muscular tension or motor restlessness, sympathetic autonomic overactivity, subjective experience of nervousness, difficulty maintaining concentration, irritability,

or sleep disturbance. The symptoms result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning.

2. Panic Disorder

Panic disorder is characterized by recurrent unexpected panic attacks that are not restricted to particular stimuli or situations. Panic attacks consist of discrete episodes of intense fear or apprehension accompanied by the rapid and concurrent onset of several characteristic symptoms (e.g. palpitations or increased heart rate, sweating, trembling, shortness of breath, chest pain, dizziness or lightheadedness, chills, hot flushes, fear of imminent death). In addition, panic disorder is characterized by persistent concern about the recurrence or significance of panic attacks, or behaviours intended to avoid their recurrence, that results in significant impairment in personal, family, social, educational, occupational, or other important areas of functioning.

3. Agoraphobia

Agoraphobia is described as marked and excessive fear or anxiety that occurs in response to multiple situations where escape might be difficult or help might not be available, such as using public transportation, being in crowds, being outside the home alone (e.g. in shops, theatres, standing in line). The individual is consistently anxious about these situations due to a fear of specific negative outcomes (e.g. panic attacks, other incapacitating or embarrassing physical symptoms). The situations are actively avoided, entered only under specific circumstances such as in the presence of a trusted companion, or endured with intense fear or anxiety. The symptoms persist for at least several months and are sufficiently severe to result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning [9].

4. Specific Phobia

Specific phobia is characterized by a marked and excessive fear or anxiety that consistently occurs when exposed to one or more specific objects or situations (e.g. proximity to certain animals, flying, heights, closed spaces, sight of blood or injury) and that is out of proportion to actual danger. The phobic objects or situations are avoided or else endured with intense fear or anxiety. Symptoms persist for at least several months and are sufficiently severe to result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning (simple phobia, claustrophobia). Approximately, 75% of individuals diagnosed with specific phobia fear more than one object. When this occurs, more than one diagnosis is given.

5. Social Anxiety Disorder

Social anxiety disorder signifies marked and excessive fear or anxiety that consistently occurs in one or more social situations such as social interactions (e.g. having a conversation), being observed (e.g. eating or drinking), or performing in front of others (e.g. giving a speech). The individual is concerned that he or she will act in a way, or show anxiety symptoms, that will be negatively evaluated by others. The social situations are consistently avoided or else endured with intense fear or anxiety. The symptoms persist for at least several months and are sufficiently severe to result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning.

6. Separation Anxiety Disorder

Separation anxiety disorder is characterized by marked and excessive fear or anxiety about separation from specific attachment figures. In children, separation anxiety typically focuses on caregivers, parents, or other family members; in adults, it is typically a romantic partner or children. Manifestations of separation anxiety may include thoughts of harm or

untoward events befalling the attachment figure, reluctance to go to school or work, recurrent excessive distress upon separation, reluctance or refusal to sleep away from the attachment figure, and recurrent nightmares about separation. The symptoms persist for at least several months and are sufficiently severe to result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of function.

7. Selective Mutism

Selective mutism manifests as a consistent failure to speak in specific social situations in which there is an expectation for speaking (e.g. at school or work) despite speaking in other situations. The disturbance interferes with educational or occupational achievement or with social communication, and the duration of the disturbance is at least 1 month. The failure to speak is not due to the lack of knowledge of, or comfort with, the spoken language required in the social situation. The disturbance is not better accounted for by a communication disorder (e.g. childhood-onset fluency disorder) and does not occur exclusively during the course of autism spectrum disorder, schizophrenia, or another psychotic disorder [7].

8. Other Specified Anxiety or Fear-Related Disorders

Despite not fulfilling all the requisite criteria, for a particular anxiety disorder, if the anxiety symptoms cause significant distress or impairment, the condition may be noted under this category.

9. Anxiety or Fear-Related Disorders, Unspecified

This category is used when anxiety-like symptoms that cause significant distress or impaired functioning is manifest with insufficient information to determine the particular type of anxiety disorder. For example, emergency situations, where a complete history and full psychiatric evaluation are not always feasible.

The DSM-5 [7] classifies ADs into 11 sub-categories, broadly similar to the above with the additional inclusion of substance/medication-induced anxiety disorder and anxiety disorder due to another medical condition. Panic disorder also has a panic attack specifier.

■ Obsessive-Compulsive Disorder (OCD)

NB: OCD is separate from ADs and categorized under obsessive-compulsive and related disorders in DSM-5 [7] and ICD-11 [9].

OCD is characterized by uncontrollable, recurring thoughts (obsessions) and behaviours (compulsions) that the person feels the urge to repeat over and over again which tends to follow a chronic course. Commonly occurring obsessions include fear of contamination, need for order or symmetry, obsessive doubts, excessive conscientiousness (need to do the right thing, fear of committing a transgression, often religious), and unwanted, intrusive sexual/aggressive thoughts. Commonly occurring compulsions consist of hoarding, arranging, and rearranging objects, reassurance seeking, list making, cleaning/washing rituals, counting/repeating actions a certain number of times or until it "feels right" and checking (e.g. locks, cooker, safety of family members).

OCD is a heterogeneous condition [11] and generally follows a chronic long-lasting course, with peaks and troughs, having significant comorbidity with other mental disorders with major depression, anxiety, as well as tic disorder [12, 13]. Lifetime and 12-month prevalence estimates for DSM-IV OCD are reported as 2.3% (0.3) and 1.2% (0.3) [14]. The differential diagnosis of OCD includes obsessive-compulsive personality disorder (OCPD). OCPD typically emerges in early adulthood and refers to individuals who are preoccupied with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency.

A small study carried out on patients with mild to profound ID/DID by Vitiello

[15], reported that 3.5% of the sample presented with compulsive behaviour that significantly interfered with their daily functioning. Compulsions occurred in the context of obvious cerebral dysfunction and in the absence of anxiety or "ego-dystonic" qualities. They concluded that the emphasis should be on the behavioural, externally observable components of the disorder rather than the cognitive elements of inner conflicts and anxiety.

OCD also occurs as behavioural phenotypes of specific disorders in PWID/DID such as Down syndrome [16] and Prader-Willi syndrome [17]. The presence of compulsions is helpful in distinguishing this disorder from other ADs as well as depression.

Post-traumatic Stress Disorder (PTSD)

NB: PTSD is categorized separately from ADs in DSM-5 [7], coming under trauma- and stressor-related disorders in DSM-5. The upcoming ICD-11 [9] proposes the inclusion of an additional category of complex post-traumatic stress disorder (CPTSD). This is a condition that results from chronic or long-term exposure to emotional trauma over which a victim has little or no control and from which there is little or no hope of escape, such as in cases of: domestic emotional, physical or sexual abuse, long-term imprisonment and torture, exposure to crisis conditions, etc. [18].

PTSD involves a history of exposure to a traumatic event that results in symptoms from each of four symptom clusters, namely, intrusion, avoidance, negative alterations in cognitions and mood, and alterations in arousal and reactivity. Other requisites for a diagnosis concern symptom duration and non-attribution of symptoms to a substance or comorbid medical condition. The individual initially responds with intense fear, helplessness, or horror to the traumatic exposure, later developing a response characterized by persistently re-experiencing the event, with resultant symptoms of numbness, avoidance, and hyperarousal causing clinically significant distress or functional impairment [19]. Although a substantial minority of PTSD cases remits within months after onset, mean symptom duration is considerably longer than previously recognized [20].

People with disorders of intellectual development (PWDID) appear to have a predisposition to develop PTSD [21] but with differences in manifestation when compared with the general population. These may consist of the expression of symptoms, and the interpretation of distressing experiences, as the manifestation of possible PTSD seems to vary with the level of severity of ID.

Although there is evidence to suggest that PWID/DID are likely to suffer from PTSD, reviews of the evidence base and the potential consequences of this contention are sparse or absent. Some support was found for the notion that PWID/DID have a predisposition to the development of PTSD. Differences in comparison with the general population may consist of the expression of symptoms, and the interpretation of distressing experiences, as the manifestation of possible PTSD seems to vary with the level of ID. In the absence of reliable and valid instruments for assessing PTSD in this, there is no prevalence data on PTSD amongst PWID/DID while Nine papers described treatment of PTSD in people with ID/DID. Interventions reported involve those aimed to establish environmental change, the use of medication, and psychological treatments (i.e. cognitive-behavioural therapy, Eye Movement Desensitization and Reprocessing - EMDR, and psychodynamic-based treatments). Case reports suggest positive treatment effects for various treatment methods. Development of diagnostic instruments for assessment of PTSD symptomatology in this population is required, as it could facilitate further research on its prevalence and treatment.

The DSM-5 classifies anxiety disorders into 11 sub-categories. All disorders are characterized by the presence of excessive fear, worry, and behavioural disturbances for at least several months, sufficiently severe to result in significant distress or impairment in personal, family, social,

educational, occupational, or other important areas of functioning. OCD and PTSD are separated from anxiety disorders, and both conditions occur frequently in persons with ID/DID causing alterations in arousal and behavioural changes.

22.2.1 ICD/DSM Diagnostic Criteria for Anxiety Disorders and PWID/DID

PWID/DID constitute a significantly heterogeneous population where chronological age and developmental level (mental age) are by definition discrepant. The phenomenon described by Reiss [22] as diagnostic overshadowing, where clinicians overlook symptoms of mental illness attributing them to ID/DID, may also contribute to difficulties experienced by clinicians in diagnosing ADs in this population. The presence of a co-occurring autism spectrum disorder (ASD), which is rather frequent in persons with more severe ID, further complicates the situation, compromising traditional diagnostic techniques and processes [23]. When applying ICD or DSM diagnostic criteria for ADs to individuals with PWID/DID, efforts must be made to seek the presence of signs and symptoms using developmentally appropriate methods of investigation and appropriate adaptations that take note of the different levels of ID [24, 25]. Such methods should include the ascertainment of "signs" of disorder that are observable, or those that are reported by parents or others familiar with the person.

All the criteria for ADs in ICD/DSM can be applied validly and reliably in people with mild-to-moderate PWDID [24–27]. A study by Sternlicht [28] on children with moderate ID/DID suggested that the developmental trend of fears that appear in normal children appears in PWID/DID as well, and these fears follow Piaget's level of cognitive development, proceeding from egocentric perceptions of causality to realistic cause and effect thinking. People with more severe degrees of ID/DID experience difficulties in articulating key diagnostic concepts of anxiety particularly with relation to more complex subjective cognitive phenomena and may manifest as problem behaviours [29–31]. However, behaviours may also be a reflection of other triggers in the environment, and it is therefore important to distinguish behaviours due to ADs from behaviours due to other causes. In diagnosing anxiety, Khreim and Mikkelson [32] emphasized the relevance of phenomena such as agitation, screaming, crying, withdrawal, regressive/clingy behaviour, or freezing, which could be interpreted as manifestations of fear in PWID/DID.

In persons with severe ID/DID and/or ASD, diagnosis is therefore reliant on caregiver feedback or completion of questionnaires. Caregivers are asked to interpret the behaviour of the person with ID/DID and/or ASD and accurately report this back. However, there are research findings on caregivers often failing to identify physiological markers in those they care for, making reporting anxiety-related behaviours and therefore diagnosis difficult [33]. The most reliable diagnostic process has been reported to be multimodal; that is, multiple informants, multiple assessment techniques (clinical interview, observation, physiological assessment), in addition to ID/DID and/or ASD appropriate standardized measurement tools [34]. A number of guidelines and diagnostic tools consisting of informant and self-report assessment instruments of psychopathology have been developed specifically for use in PWID/DID involving the DSM/ICD classificatory systems [35, 36]. These include the Psychopathology Instrument for Mentally Retarded Adults (PIMRA) [37] and Diagnostic Assessment for the Severely Handicapped (DASH) [38]. Scale, both based on the DSM-III-R [39] and ICD-10 [40]; the Anxiety, Depression, and Mood Scale (ADAMS) [41] developed using DSM-IV-TR criteria [42]; and the Psychiatric Assessment Schedule for Adults with Developmental Disability (PAS–ADD) [43]. Masi and colleagues [26] evaluated the concurrent validity of different informant and self-report assessment instruments of

psychopathology based on DSM-IV criteria (both general and specific for anxiety and/or depression), in adolescents with ID/DID, and concluded that anxiety measures were positively correlated with PIMRA [37] and Child Behavior Checklist (CBCL) [38] total scores, as well as with the internalizing score of the CBCL. However, the reliability of these instruments was found to be variable. Costello [44] reported that the anxiety element in the PAS-ADD instrument had poorer reliability when compared with the rest of the mental health disorders.

Comprehensive and helpful guidelines have been published in the Diagnostic Manual – Intellectual Disability (DM-ID) [25] and the Diagnostic Criteria for Psychiatric Disorders for use with adults with Learning Disability (DC-LD) [45] to facilitate the diagnostic process in this population. The latter renamed as DC-DID (Diagnostic Criteria for Psychiatric Disorders for use with adults with Disorders of Intellectual Development) is being revised updated within the context of the upcoming ICD-11 [9].

The Glasgow Anxiety Scale for People with an Intellectual Disability (GAS-ID) [46] appears to offer a psychometrically robust and pragmatic (5–10 min) approach to the appraisal of anxiety in people with mild ID/DID.

In the absence of robust empirical evidence, the clinical consensus supports the view that in PWID/DID functioning at lower moderate, severe, and profound levels, the likelihood of eliciting the cognitive elements of ADs is unlikely. Instead, alternative adaptations to the DSM-5 Criteria placing greater emphasis on reported symptoms have been proposed [47].

> The identification of anxiety disorders in people with more severe degrees of ID/DID is particularly difficult and frequently missed by carers and clinicians. Adaptations of the current classification systems (DM-ID, DC-LD) and other psychopathology instruments (PIMRA, DASH, ADAMS, PAS-ADD, CBCL, GAS-ID) could facilitate the diagnostic process in this population.

22.3 Comorbidity

ADs exhibit high levels of lifetime comorbidity with one another to such an extent that it is unlikely for an individual to experience a single anxiety disorder in isolation [48]. They are known to commonly coexist in individuals, both with other ADs and with mental disorders from other groupings, such as affective disorders [49]. The prevalence of having a current comorbid mental disorder is estimated at 50%, with ADs and depressive disorders being the most prevalent comorbid disorders [50, 51]. A population study based on three Swedish national registers over 11 years found that amongst older persons with ID, those with at least one anxiety diagnosis had an occurrence of psychiatric comorbidities approximately 11 times higher than the general population, and the most common comorbidities were specific personality disorders, unspecified nonorganic psychosis, and other mental disorders due to brain damage and dysfunction and to physical disease [52].

Whereas anxiety/anxiety comorbidity occurs earlier in onset and follows a more chronic course, anxiety/depressive comorbidity results in greater functional impairment, even more severity, and a poorer outcome [53]. From a clinical perspective, it is important to diagnose and treat comorbidity amongst ADs since it is associated with higher severity and greater chronicity.

22.4 Epidemiology

The World Health Organisation study of the Life Time prevalence of Mental Health Disorders in a global mental health survey concluded that ADs constitute the most prevalent of mental disorders in the general population [54] and have a significant impact on morbidity, mortality, and global burden of disease [55]. Occurring early in onset, they tend to be chronic conditions with high social and economic costs [55, 56]. Despite the availability of effective psychological and pharmacological treatments, a large proportion of affected individuals do not contact health services, remaining undiagnosed or do not receive correct

treatment [57]. According to large scale epidemiological surveys, ADs are the most prevalent of the psychiatric disorders with a lifetime morbidity risk of 41.7% [58, 59]. Around 80% of consultations for mental health problems in primary care are for anxiety and depression with the highest prevalence occurring during midlife [60]. ADs are more common in women [61]. Prevalence rates have remained unchanged in the past years with variations found in different countries and cultures possibly due to methodological differences rather than culture-specific factors. High comorbidity is found amongst the ADs and between the ADs and other mental disorders, respectively [62].

There have been numerous studies reporting that PWID/DID suffer from ADs [63] at rates at least equal to the general population [64, 65]. ADs have also been reported as one of the most common forms of psychological distress for persons with ID/DID and or ASD [64, 66] with a significantly higher prevalence rate than in typically developing (TD) populations [65]. Individuals with co-occurring ASD in particular are exposed to specific sources of anxiety such as changes in routine, anticipation of change, or environmental stimuli, which are hard to be diagnostically interpreted, as they describe both common experiences in ASD and ADs.

Due to communication and cognitive impairments, ADs are likely to be underreported, especially in persons with severe ID and/or co-occurring ASD [67]. Borthwick-Duffy [68] and Deb and collaborators [64] reported the prevalence of ADs amongst PWID/DID of around 5–10%. Bailey and Andrews [69] concluded that many studies fail to make a definitive diagnosis of AD and report only the prevalence of anxiety symptoms, which range from 6% [70] to 31% [71]. The point prevalence of ADs in PWID/DID is estimated to be 3.8% with GAD being most common (1.7%), followed by agoraphobia (0.7%) [72]. There is evidence to suggest that in persons with ID/IDD, older age, co-occurrence of ASD, and hearing impairments are associated with higher rates of GAD and other ADs [72, 73].

ADs were identified as more prevalent in individuals with ID/DID and co-occurring self-injurious behaviour than in those without such behaviour [43]. A study cohort comparing PWID/DID with the general population revealed significantly higher rates of phobic disorder in the former [64]. Hermans and colleagues [74] reported that older people with ID/DID reported more symptoms of anxiety when compared with older people with average intelligence.

The available evidence from studies carried out on children with ID/DID suggest high levels of ADs vary from 8.7% [75] to 21.98% [76]. The prevalence rate of ADs is also reported to vary according to the different subtypes of ADs [77]. A study by Catani and Sosalla [78] revealed that child abuse in the family to be the only significant independent predictor of PTSD symptom severity in this population of PWID/DID.

The correlation between rates of ADs and chronic physical health conditions has been found to be higher in persons with ID/IDD and ASD than in the general population [73], which might indicate a higher expression of the interconnected nature of mental and physical health.

Anxiety disorders are very common in persons with ID/DID and are often found in comorbidity with other psychiatric disorders, particularly mood disorders. The prevalence rate varies according to the different subtypes of anxiety disorders and depending on the background characteristics (age, level of DID) of the study sample.

22.5 Clinical Features

The clinical features of anxiety include cognitive, physiological, psychological, and behavioural elements. The cognitive components consist of irritability, fearful anticipation, concentration/memory problems, repetitive worrying thoughts, and fear, and when extreme, these may manifest as full-blown panic states. The physiological manifestations include flushing, sweating, pallor, dry mouth, difficulty in swallowing, palpitations, tremor, hyperventilation, pains/tightness in the chest, and other bodily aches and pains such as head/

backache, fatigue, muscle tension, diarrhoea, increased urinary frequency, paraesthesia, heightened startle response, and insomnia. Avoidance is a common behavioural manifestation of anxiety. Chronologically, anxiety can be episodic, continuous, or stress related.

In terms of how young people with mild ID/DID understand anxiety, Wilson and colleagues [79] reported that PWID/DID did not discuss their understanding of mental health issues in abstract terms but tended to use descriptive terms often linked to unpleasant emotional and physical sensation. They used words like "temper", "frightened", "fed up", and "things wrong to me" and described the physiological symptoms of anxiety and depression, such as sweaty palms and hyperventilation. Sometimes they used phrases that seemed to have been picked up from others, like "mood swings" and "in a huff".

While the DSM/ICD diagnostic criteria for anxiety and related disorders could be applied without adaptation to those with mild to moderate levels of impairment, there is no empirical evidence on their application to those with more severe degrees of impairment and/or co-occurrence of ASD [24, 46]. However, available research reports note that in these persons the manifestation of anxiety can be observed rather than subjectively reported and that cognitive symptoms of anxiety are less useful for diagnosing ADs than physiological symptoms [23]. Consequently, the clinical diagnosis relies on observable signs such as dry mouth, increased pulse and heart rate, pallor, flushing, facial expressions, crying, freezing, failure to speak in social occasions, as well as problem behaviours. The DM-ID 2 [25] provides succinct guidelines which elaborates these issues in greater detail.

Further peculiarities of clinical presentation with respect to individuals with ID/DID and ASD compared to those with ID/DID or ASD alone have been identified by research [80–84] and are reported in ◘ Table 22.1.

The clinical features of anxiety include cognitive, physiological, psychological, and behavioural elements. For people with more severe degrees of cognitive and communication impairment, manifestation of anxiety can be observed (i.e. pallor, flushing, facial expressions, crying, freezing, problem behaviours) rather than subjectively reported.

◘ **Table 22.1** Anxiety in ID/DID and ASD compared to ID/DID or ASD alone

Manifestation	ID/DID+ASD	ID/DID alone	ASD alone
Repetitive behaviours	More likely to be a result of anxiety than for sensory seeking purposes More likely during transitions between tasks	More likely to be for sensory seeking purposes than a result of anxiety Less likely during transitions between tasks	More likely to be a result of anxiety than for sensory seeking purposes More likely during transitions between tasks
Sensory experiences	Higher sensitivity and avoidance	Lower sensitivity and avoidance	Higher sensitivity and avoidance
Stress levels	Higher	Lower	Lower
Hyperactivity	Higher	Lower	Lower
Problem behaviours	Higher	Varying	Varying
Communication of symptoms	Lower	Varying	Higher
Cognitive symptoms	Lower	Varying	Higher

Tip

Future research should further explore the correlates and behavioural patterns of anxiety for persons with more severe ID and/or co-occurrence of autism spectrum disorder. The development of an anxiety measure that takes into account the specific behaviours and changes in presentation over time of these persons could result in more reliable identification and diagnosis.

Future studies are also hoped to address the relationship between stress, physical health, and anxiety across the lifespan and particularly during transition phases.

22.6 Aetiology and Risk Factors

In common with many mental disorders, the development of ADs is probably best perceived as an interaction between several different biopsychosocial factors. Currently, the definitive risk factors for ADs remain unclear. However, it is probable that a combination of multiple factors including genetics, environmental, psychological and developmental are likely to be involved [85–87]. For example, ADs tend to run in families, which suggest that a combination of genes and environmental stresses may produce these disorders. The candidate genes relating to ADs are largely the same across diagnoses and tend to be genes whose products regulate the hypothalamic-pituitary-adrenal (HPA) axis and monoaminergic signalling [88]. The impact of individual diagnosis-specific genetic risk factors may vary over time, depending on the developmental stage and previous experience of each subject.

When attempting to identify the genetic contribution towards susceptibility for psychopathology, similarities, however, do not preclude important clinical distinctions between diagnostic classes within ADs or between ADs and major depressive disorders (MDD). Some genetic factors are nonspecific but influence the risk for psychopathology in general; others are diagnosis specific.

There is a large body of evidence which concludes that panic disorder, GAD, phobias, and OCD all have significant familial aggregation and genes largely explain these phenomena. Gottschalk and Domschke [92] concluded from a comprehensive study that GAD is a heritable condition with a moderate genetic risk and heritability of approximately 30%. Within the anxiety spectrum, GAD was seen to be closely related to childhood separation anxiety, social phobia, and panic. A shared genetic origin with other internalizing disorders, especially MDD, became apparent during later developmental stages. Hettema and colleagues [48] reported that in ADs, certain genes predispose to two broad groups of disorders dichotomized as panic-generalized-agoraphobic anxiety versus the specific phobias.

A large population-based study undertaken by Kessler and colleagues [89] concluded that all types of mental disorder, including ADs, reduce in frequency with increasing educational level. Some genetic causes of ID/DID are associated with ADs. For example, Fragile X syndrome is associated with social anxiety disorder; Rubinstein–Taybi and Prader–Willi syndromes are associated with OCD [90]. Williams syndrome appears to be associated with ADs [91] and phobias [92]. Significantly high compulsive behaviour was noted in Cornelia de Lange syndrome [93].

Studies on types of fear reported in persons with ID/DID reported similarities between children and adults of equivalent mental age, highlighting the developmental perspective [28, 94, 95]. For example, individuals with moderate ID/DID experience fears of animals, thunder and ghosts (preoperational thinking), and physical injuries (concrete operational), mirroring normal Piagetian transition in non-learning-disabled children. It is however noteworthy that anxieties and phobias might also occur as transient phenomena in children of average intelligence which is integral to normal early development.

PWID/DID are also more likely to experience child abuse as well as other forms of traumatic or negative events later in life compared to the general population. Bradley and colleagues [96] noted that PWID/DID frequently encounter adversity and stressful life events as well as other trigger risk factors such as poor

coping skills and inadequate social supports which are known to increase vulnerability for anxiety and related disorders.

Multiple factors including genetics, environmental, psychological, and developmental are likely to be involved in the genesis of anxiety disorders. Some genetic syndromes, familial aggregation, low educational level, and stressful life events can increase the vulnerability for anxiety and related disorders.

22.7 Pathophysiology

The symptoms of anxiety and mood disorders are thought to result in part from disruption in the balance of activity in the emotional centres of the brain rather than in the higher cognitive centres [97]. Anxiety is a ubiquitous emotional state that represents an interrelationship between mammalian and primate stress response systems, and more recent expansion of the human neocortex. This expansion signalled the emergence of increasingly complex top-down regulation of limbic-subcortical responses, as well as an enhanced adaptability associated with developing executive functions. These changes which also include a hierarchically organized perceptual, processing, and response system is involved in modulating fear responses, enhanced adaptability, and neurocognitive skills necessary for dealing with uncertainty of increasingly complex social relationships and social/technological ecology [1, 2].

The inherent neuroplasticity of this infrastructure is maintained throughout our prolonged childhood. But development is not a linear process, but one governed by stage-specific time and stage changes in genetic activity, neuronal maturation, and myelination. There are critical periods during this developmental journey that suggest that this developmental flexibility also carries risks, prolonged periods of increased vulnerability, and potential insults that may derail these [2, 98, 99]. This is the essence of neurodevelopmental disorders such as ID/DID. Similar developmental insults (i.e. genetic vulnerability) also derail the developmental trajectory of the stress response system and more complex substrate for ADs. The co-occurrence of ADs with ASD and ID/DID further complicates the atypical neurodevelopmental trajectories of all three conditions and partially explains the nearly twofold increase in the prevalence rates of anxiety and ADs in this population [100–102].

The experience of anxiety undergoes many changes during the life cycle, including developmental processes outlined above. Derailment of this developmental process helps explain why some children may not successfully negotiate and master these challenges [103–105], neurotypical children developmental anxieties related to typical life issues that reflect changing expectations, cognitive development, and mastery of developmental crises. The likelihood of mastering these developmental challenges is profoundly influenced by temperament, patterns of attachment, and the capacity of caregivers to help the child negotiate these challenges.

Pathological anxiety represents an atypical pattern of experiencing and expressing anxiety during development. Left unchecked, pathological anxiety can serve as a source of functional impairment, as well as a potential risk factor for ADs. In genetically and biopsychosocially vulnerable individual, pathological anxiety may also represent either a prodromal phase or a subclinical expression of later developing ADs. These subclinical forms of ADs progress to full syndrome ADs in nearly 40–50% of affected patients [3, 97, 106, 107].

The developmental trajectory of each stage of ADs is complicated by a second pattern of divergence – developmental changes that are homotypic and heterotypic. An example of homotypic development is present when panic attacks (e.g. school phobia) appear during childhood that emerges as panic disorder in late adolescence. The fear-related reactions persist largely unchanged. Childhood school avoidance behaviour without overt fear-related arousal, but associated harm avoidance of behavioural inhibition, may evolve in generalized anxiety disorder, social anxiety (generalized type), or mood disorder. This

form of separation anxiety fits into the heterotypic category scenario [3, 5, 6, 108].

Genetic vulnerability (heritability), puberty, and psychosocial factors (including gene-environment interactions) help shape both homotypic and heterotypic courses [109]. Both pathways are transactional processes that arise from the complex entanglement of anxiety as a neurodevelopmental phenomenon, gene-environment interactions, and psychosocial factors. The presence of ASD, DID, or ASD+DID can strongly influence these developmental trajectories [110–112].

Developmental insults (e.g. heritability, puberty, psychosocial factors) can derail the developmental trajectory of the stress response system, creating a condition of vulnerability for the development of anxiety. The presence of ASD, ID/DID, or ASD+ID/DID can strongly influence these developmental trajectories, increasing the prevalence rate of anxiety disorders in this population.

22.8 Aetiopathogenic Models

Amongst neurotypical patients, a number of functional magnetic resonance imaging (fMRI) studies suggest a relationship between subtypes of anxiety disorders and amygdala hyper-reactivity, reduced integration between prefrontal cortex (PFC), anterior cingulate gyrus, bed nucleus of the stria terminalis, and association cortices with subcortical regions [113, 114].

These studies also suggest the involvement of aberrant processing of fearful faces (inferior temporal cortex), threat perception, vulnerability to fear conditioning and amygdala/hippocampal activity, and dysregulation of frontal-limbic networks that integrate and regulate input and output between these networks [4, 5, 115, 116]. As a general rule, the temporal-parietal and cortical, fronto-limbic, and fronto-subcortical linkages are critical for neuromodulation and top down affect regulation and impulse control as well as other executive functions. There are multiple studies addressing the role of the medial PFC and ventral-medial PFC in fear conditioning and extinction [2, 117].

These circuits are foundational to associative and instrumental conditioning. Applying these findings may enhance our understanding of the neurobiological foundations of fear conditioning, generalization, extinction, and the mechanisms for behavioural and pharmacological interventions [97, 118, 119]. But applying these principles to the pathophysiology of anxiety and ADs in patients with ID/DID will require a deeper understanding of their interrelationships between their underlying neurobiology, these learning models, and atypical cognitive development. One of our greatest challenges is to upgrade our current thinking about the bio-psycho-sociology of specific biomarker and the emergence of neurodevelopmental anxieties, pathological anxiety, and ultimately, ADs. Since ID/DID is a heterogeneous syndrome, this process will require fine tuning subsets of pathological anxiety and ADs. One of the key steps in this process will be the application of specific genetic and other biomarkers, pre-existing medical, neurological, and neurodevelopmental disorders, rather depending on descriptive criteria. Rather than listing biopsychosocial factors, we need to take the next step and explore how and why they influence the developmental trajectory of these endophenotypes. [2, 4, 99, 118, 119]

Recent developments in molecular genetics have suggested complex interaction between decreased activity in serotonin reuptake receptors (SCL6A4, 5-HTTPLR polymorphisms) and reduced activity amongst corticotrophin receptors, dysregulation of corticotrophin releasing factor, and responses to social and environmental stressors [2, 119]. It is unclear how these affect individuals with DI/DID, especially in the context of an increased lifetime risk for psychological, physical, and sexual abuse. For many, the boundary between PTSD and other trauma-related disorders, mood and anxiety disorders, and externalizing disorders is difficult to establish. Epigenetic changes in response to trauma have lifelong implications for anxiety, self-injurious behavior (SIB), aggression, explosive emotional reactivity, and other disruptive/destructive behaviours. These data

may enhance our understanding of trauma-related disorders and the long consequences of trauma on treatment refractory anxiety and mood disorders [120, 121].

Once these changes are underway, epigenetic forces alter the patterns of gene activation that can have lifelong implications. Yet, the effects of these same gene markers can be overridden by a nurturing mother (rat models this involves maternal licking of rat pups). However, those rat pups who do not receive this nurturing are vulnerable to the epigenetic changes that can increase the risk for subsequent traumatization. In humans, similar forms of deprivation can contribute to higher rates of chronic, treatment refractory mood and anxiety disorders [107, 122]. Once these changes are underway, epigenetic forces alter the patterns of gene activation that can have lifelong implications.

In summary, in common with other neurodevelopmental disorders, ID/DID is a complex condition associated with significant clinical diversity. Nevertheless, they do all seem to share a neurophysiological imbalance between dysfunctional excitatory (bottom-up limbic/brain stem) and a dysfunctional inhibitory network (top-down cortico-striatal). This imbalance may explain why panic attacks, phobic reactions, and other fear-related anxiety present as aggression, SIB, or destructive behaviours. For this patient's defensive aggression, SIB and other escape-motivated behaviours reflect deficits in self-regulating negative affective states and a greater vulnerability to automatic/pre-potent fear-conditioned responses. Those prone to approaching negative events and externalizing behaviours may express these in terms of disruptive or aggressive/destructive behaviours. Internalizers may be prone to avoidance and escape behaviours. Both are goal directed in terms of either obtaining relief or escaping affective states. In chronic traumatic or stressful settings, these conditioned avoidance behaviours persist (maintenance-phase) but can morph in vulnerable patients through a combination of sensitization (kindling-like phenomena) and progression to habit-/addiction-like behaviours. Consequently, some individuals are prone to engage in the behaviours independent of their previous trigger stimuli and replace their goal directed behaviours. Once these behaviours become habits, the connection between key stimuli and behavioural responses becomes less clear-cut [120–125].

Research is ongoing into how these variations affect individuals with severe to profound ID/DID, especially in the context of an increased lifetime risk for psychological, physical, and sexual abuse. For many, the boundary between PTSD and other trauma-related disorders, mood and ADs, and externalizing disorders is difficult to establish. Epigenetic changes in response to trauma have lifelong implications for anxiety, SIB, aggression, explosive emotional reactivity, and other disruptive/destructive behaviours [2, 123, 124, 126].

This section on pathophysiology is a synthesis of both conceptual models that moved away from a diagnostic approach that relied primarily on our current descriptive/categorical phenomenological diagnostic criteria. Combining these two models may provide a more comprehensive platform for understanding the relationships between anxiety disorders, ID/DID and ASD. In addition, genetic studies suggest that clinically relevant polymorphisms are associated with secondary and tertiary messenger systems, intracellular ion release and the regulation of synapse formation and stabilization, neuroplasticity and learning, and memory and extinction. Brain maturation involves the maturation, integration, and hierarchical organization of each of these processes [2, 99, 124, 127, 128]. The use of more sophisticated, higher resolution functional neuroimaging and neurophysiological techniques will help map these changes. Combining and integrating these technologies will help us to better understand the pathophysiology of AD, but coping with the heterogeneity associated with ASD/AD remains a work in progress.

The pathophysiology of anxiety disorders in persons with ID/DID remains unclear. Some etiopathogenetic models have been considered, including the interaction between decreased activity in serotonin reuptake receptors and reduced activity amongst corticotrophin receptors, the dysregulation of corticotrophin releasing factor, and the

responses to social and environmental stressors. Epigenetic changes in response to trauma seem to have lifelong implications for anxiety, self-injurious behaviours, aggression, explosive emotional reactivity, and other disruptive/destructive behaviours.

22.9 Neurobiology

A myriad of neuroendocrine, neurotransmitter, and neuroanatomical disruptions in the limbic, brain stem, and higher cortical brain areas appear to be implicated in ADs. The differences remain elusive in view of complexities within this system and the high degree interconnectivity between neurotransmitter- and neuropeptide-containing circuits in limbic, brain stem, and higher cortical brain areas. A primary alteration in brain structure or function or in neurotransmitter signalling may result from environmental experiences and underlying genetic predisposition which can increase the risk for psychopathology [97].

The neurotransmitters that are mainly implicated in the symptoms of anxiety disorders within the central nervous system are noradrenaline, serotonin, dopamine, and gamma-aminobutyric acid (GABA). Others that may possibly play a role include corticotropin-releasing factor and peptides.

Many of the symptoms of the symptoms of ADs are mediated peripherally by the autonomic nervous system, in particular, the sympathetic nervous system [129].

A study by Katerndahl and colleagues [130] using positron emission tomography (PET) scanning demonstrated an increased flow in the right parahippocampal region and reduced serotonin type 1A receptor binding in the anterior and posterior cingulate and raphe of patients with panic disorder. Vythilingam's [131] study using magnetic resonance imaging (MRI) demonstrated smaller temporal lobe volume in patients when compared with healthy subjects with normal hippocampal volumes in both patients and controls. The cerebrospinal fluid (CSF) in studies in humans with panic disorder show elevated levels of hypocretin, thought to play an important role in the pathogenesis of panic in rat models [130].

Obsessive-Compulsive Disorder

The current research and treatment trials suggest that abnormalities in serotonin (5-HT and in some cases, dopamine) neurotransmission in the brain are involved in OCD. The efficacy of serotonin reuptake inhibitors (SSRIs) in the treatment of this condition strongly endorses this contention. Emerging evidence from a genetic perspective support the view that OCD co-varies in conditions such as Tourette's syndrome and multiple chronic tics in an autosomal dominant pattern. Bloch [132] reported that symptoms of OCD in such individuals respond preferentially to a combination therapy of SSRIs and antipsychotics.

Attention has also been focused on glutamatergic abnormalities and possible glutamatergic treatments for OCD. Although modulated by serotonin and other neurotransmitters, the synapses in the cortico-striato-thalamo-cortical circuits thought to be centrally involved in the pathology of OCD principally employ the neurotransmitters glutamate and GABA.

The imaging studies in OCD such as magnetic resonance imaging (MRI) and PET scanning have demonstrated increases in blood flow and metabolic activity in the orbitofrontal cortex, limbic structures, caudate, and thalamus, with a trend towards right-sided predominance in OCD. Some studies report that these areas of overactivity have been shown to normalize following successful treatment with either SSRIs or cognitive-behavioural therapy (CBT) [133]. This supports the hypothesis that symptoms of OCD are a consequence of impaired intracortical inhibition of specific orbitofrontal-subcortical circuitry that mediates strong emotions and the autonomic responses to those emotions. It is noteworthy that cingulotomy, sometimes used for severe and treatment-resistant OCD, interrupts this circuit.

Some neuroendocrine, neuroanatomical, and neurotransmitter alterations appear to be implicated in anxiety disorders. It is well established that abnormalities in serotonin neurotransmission are involved in obses-

sive-compulsive disorder, and the efficacy of serotonin reuptake inhibitors in the treatment of this condition strongly endorses this contention. Attention has also been focused on glutamatergic abnormalities and possible glutamatergic treatments for obsessive-compulsive disorder.

22.10 Management and Treatment

Empirically based studies on treatment of ADs are sparse in PWDID and limited to a handful. However, the full range of strategies utilized in the general population including effective psychological interventions are available [134]. Cognitive behaviour therapy (CBT), dialectical behaviour therapy (DBT), reassurance, and counselling have been successfully used as have anxiety management techniques such as relaxation training, mindfulness, anger management, and self-help techniques [135]. Behaviour therapies such as desensitization and exposure therapy are effective management strategies in OCD and social phobia.

The need for treatment for ADs is influenced by the intensity and duration of illness and the impact of symptoms on everyday life [136]. The NICE Guidelines [137, 138] recommended evidence-based psychological interventions as a first-line intervention with pharmacological therapy as a second choice.

Some studies in the general population support the contention that optimum results are achieved by combination of psychological and pharmacological interventions [139], such as the combination of CBT with SSRIs [140]. Behavioural therapy and cognitive therapy alone or in combination have demonstrated clear evidence of efficacy in the treatment of ADs [140, 141]. The involvement of patients in their treatment by using comprehensible and clear communication is reported to improve outcomes [142].

Psychotherapy, such as exposure therapy, cognitive therapy, and cognitive-behavioural therapy (CBT), has consistent evidence of efficacy in the treatment of ADs [143, 144]. The efficacy of psychological and pharmacological approaches is broadly similar in the acute treatment of ADs.

Evidence based on case studies in people with mild or borderline ID/DID and ADs have demonstrated the effectiveness of CBT [145–147]. However, the core principles of CBT may require modification to meet individual abilities. Overall, currently available empirical evidence with regards the efficacy of CBT for treatment of ADs in persons with ID/DID is weak. A range of psychological interventions [147, 148] including reassurance, counselling, exposure-based approaches, anxiety management such as relaxation training, anger management, and self-help are being found to be effective and useful in this population [134, 147].

The aim of behavioural interventions is to modify any behaviour that is unhelpful or harmful. Commonly used behavioural interventions include relaxation which appears to be effective in reducing anxiety as well as improving cognitive performance amongst those with mild, moderate, and severe DID. Relaxation behavioural training has been found to be effective in the treatment of generalized anxiety in persons with ID/DID. Lindsay et al. studied anxiety treatments for adults who have moderate and severe ID/DID by undertaking a study based on the simplification of a technique called progressive relaxation, which demonstrated that behavioural relaxation training is an effective treatment modality [145, 149, 150].

Studies on psychological interventions of anxiety disorders in persons with ID/DID are scarce and limited. Evidence based on case studies indicates effectiveness of cognitive-behavioural therapy, although it may require variation based on individual skills. Other psychological interventions including reassurance, counselling, relaxation training, anger management, and self-help have been found to be effective in this population.

22.11 Pharmacological Treatment

In the general population, four broad categories of psychotropic medications are used in adults with anxiety syndrome: (1)

antidepressants, (2) benzodiazepines, (3) other medications (e.g. Buspirone), and (4) antipsychotics for severe debilitating symptoms. In GAD, OCD, panic disorder, PTSD, and social phobia, SSRIs (selective serotonin reuptake inhibitors) may be used as first-line treatment. The SNRIs (serotonin noradrenaline reuptake inhibitors) duloxetine and venlafaxine have proven efficacy in short-term and long-term treatment of GAD [151]. Venlafaxine is also efficacious in the acute treatment and relapse prevention of panic disorder [152]. With the exception of social phobia, tricyclics may be used as second-line intervention for all of these conditions. Other pharmacological treatments such as buspirone (GAD, OCD) and antipsychotics (quetiapine or risperidone) as an augmentation for OCD have a weaker evidence base or are less well tolerated.

Despite the widespread belief that antidepressants can lower the seizure threshold, systematic review of data from placebo-controlled trials indicates that the frequency of seizures is significantly lower with psychotropic drugs than with placebo [153].

Benzodiazepines should be considered only for short-term (up to 4 weeks) treatment of acute, disabling anxiety which is causing significant distress, while longer-term strategies are instituted in view of potentially adverse effects. Nevertheless, a minority with intractable anxiety may benefit from long-term treatment, with benzodiazepines which should not be denied [154, 155].

Follow up of anxiety symptom severity after initial treatment is reported to be lower with CBT than with other forms of psychological treatment: but the comparative efficacy of pharmacological and psychological approaches over the long term is not established [156]. It is probable that the combination of pharmacological and psychological treatment is superior to psychological approaches or medication, when either is given alone [136].

In persons with ID/DID and/or ASD, excess prescriptions of anxiolytics, antidepressants, and GABA agonists in comparison with the general population are reported, especially older individuals [157]. Empirical evidence is not available on the pharmacological efficacy of specific anxiolytic medications for discrete types of ADs. As such, current treatment is guided by consensus expert opinion extrapolated from the general population. Anti-anxiety medications should only be undertaken following a comprehensive and meticulous evaluation of the person to exclude medical, psychiatric, behavioural, and environmental precipitants of the anxiety symptom/s. The therapeutic goal for treating ADs is maximum reduction of symptoms or elimination of symptoms as described by the patient and or caregiver or as measured by behavioural monitoring. Whereas in persons with milder degrees of ID/DID the individuals are able to self-report, the clinician is dependent on behavioural symptoms to determine the efficacy of treatment in individuals with more severe degrees of ID/DID. The behavioural monitoring requires consistent measurements over a minimum period of several days of observation.

The pharmacological management of anxiety and related disorders in PWID/DID must be undertaken within the context of a comprehensive physical, psychosocial, and environmental assessment. The treatment aim is targeted at achieving maximum gains with minimum harm the lowest effective dose. PWID/DID need careful and frequent monitoring since they may not be able to report adverse effects. The possibility of drug interactions, lower doses, and the risk of worsening any pre-existing cognitive impairment, particularly from medications with sedative effects, should also be borne in mind [158]. In the patients with ID/DID, consensus expert opinion recommends second-generation, selective serotonin reuptake inhibitor (SSRI) medications as treatment of first choice for ADs. Expert clinical consensus favours the short-term use of anxiolytics in some instances to enable those individuals who are deemed too anxious to engage in psychological interventions to facilitate the process.

▪ OCD

Remission of OCD spontaneously without treatment is unusual. The treatment of choice is CBT modified as relevant with SSRIs as second choice. Most improve significantly

with treatment, but around 15% have symptoms which worsen with functional impairment over time. A minority of approximately 5% reportedly have complete remission of symptoms between episodes of exacerbation. OCD symptoms can worsen with stress; however, stress does not appear to be an aetiological factor.

PTSD

There is robust evidence supporting the efficacy of SSRIs and SNRIs in the acute treatment of PTSD continuing for at least 12 months after response [136]. All PTSD sufferers should be offered a course of trauma-focused psychological treatment (CBT) or eye movement desensitization and reprocessing (EMDR) which is safe and effective [144] preferably on an individual outpatient basis. When evidence-based psychological or pharmacological treatments fail, combination therapy may be considered. There is limited evidence in support of combination therapy with paroxetine and exposure therapy.

Ultimately, the treatment choice should be a consequence of the assessment process and shared decision-making, with a strong emphasis on safety, tolerability, and the patient's preferences within the context of best available evidence.

The pharmacological management of anxiety disorders in persons with ID/DID must be undertaken within the context of a comprehensive physical, psychosocial, and environmental assessment. Selective serotonin reuptake inhibitors may be used as a first-line treatment, while anxiolytics should be used in the short term and only in special cases. Persons with ID/DID need careful and frequent monitoring since they may not be able to report adverse effects.

22.12 Prognosis

In general, maintenance of pharmacological treatment is recommended in anxiety and related disorders where effective, since discontinuation frequently precipitates relapse. Successful completion of CBT may bring about enduring relief following treatment. Evidence also suggests that "extending/top up" CBT may further improve the outcome. Some patients may have treatment-resistant CBT requiring multiple trials of medication. An even smaller proportion with intractable and disabling symptoms may benefit from neurosurgical interventions. OCD sufferers improve significantly with appropriate treatment including CBT and, often, medication.

Tip

Anxiety disorders in people with ID/IDD deserve increasing research interest and continued acquisition of up-to-date knowledge by clinicians, especially in reference to persons with more severe degrees of cognitive and/or communication impairment.

Key Points

- Anxiety disorders in persons with ID/DID are common, but often not diagnosed, resulting in poor access to appropriate treatment which lowers quality of life.
- The identification of anxiety disorders in people with more severe degrees of ID/DID is particularly difficult and frequently missed by carers and clinicians. Adaptations of the current classification systems (DM-ID, DC-LD) and psychopathology assessment tools (PIMRA, DASH, ADAMS, PAS-ADD, CBCL, GAS-ID) can facilitate the diagnostic process in this population.
- The clinical features of anxiety include cognitive, physiological, psychological, and behavioural elements. For people with more severe degrees of communication impairment, manifestation of these features can be observed rather than subjectively reported.
- The management and treatment of anxiety disorders in persons with ID/DID must be undertaken within a multidimensional assessment. Psychological interventions including cognitive-

behavioural therapy and behavioural therapy are been found to be effective in this population. Pharmacological treatment has also proved effective, and SSRIs are recommended as a first-line drug treatment.

Learning Objectives

The key objectives of this chapter are to describe:

- The presenting symptoms and phenomenology of specific somatic symptom and related disorders in persons with intellectual disability and autism spectrum disorder with high support needs.
- The differential diagnosis and factors which contribute to the development of these disorders.
- The multimodal approach to their management.

23.1 Introduction

Somatic symptom and related disorders (SSRD) are a group of conditions characterized by persistent, distressing and excessive thoughts, emotions and behaviours regarding somatic symptoms. These somatic symptoms, which are substantially more severe than expected from underlying pathology or have no medical explanation, and the accompanying excessive thoughts, emotions and behaviours impair and disrupt personal functioning and adjustment [1].

In persons with intellectual disability (ID) and low-functioning autism spectrum disorder (ASD), SSRD are often overlooked, especially in primary care and regarded as a medical disorder or as emotional and behavioural difficulties directly due to the ID. Therefore, it is likely that persons with ID and/or ASD who suffer from an SSRD remain undiagnosed and do not receive specific mental health treatment and support.

In persons with neurodevelopmental disorders, mind-body interactions and their influence on mental and physical health seem to be stronger than in the general population, which has been associated with cognitive issues and difficulties in identifying and managing personal emotions and psychological suffering. Features of alexithymia, defined as the inability to differentiate, describe and label one's own emotions [2] and repeatedly associated in the general population with a high risk of SSRD [3, 4], have been found in persons with neurodevelopmental disorders and related to difficulties in identifying and distinguishing between feelings and bodily sensations [5–7]. According to a developmental perspective, these difficulties and the consequent expression of somatic symptoms may be reinforced or weakened by particular life experiences, relationships and psychological assets across childhood, adolescence and early adulthood.

23.2 Somatic Symptom and Related Disorders

SSRD, classified in the DSM-5 [1], are a group of conditions in which the person experiences excessive and persistent somatic symptoms causing distress which adversely affects and disrupts daily life. This group of disorders comprises somatic symptom disorder, illness anxiety disorder, conversion disorder (functional neurological symptom disorder), psychological factors affecting other medical conditions, factitious disorder, other specified somatic symptom and related disorder and unspecified somatic symptom and related disorder.

23.2.1 Prevalence

Somatic symptoms seem to be more frequent in persons with ID than in the general population across the lifespan from early childhood to the elderly. Troublesome somatic symptoms are reported in 12–14% of children and adolescents, decreasing to around 10% in adults [8–12]. These symptoms are more prevalent in females than in males and are associated with increased levels of overall emotional and behavioural disturbance [9–12].

It is well established that children with ASD have a relatively increased risk of gastrointestinal symptoms compared to typically developing (TD) children [13, 14]. A meta-analysis of literature demonstrated an increased odds (4.42 OR) of gastrointestinal symptoms in children with ASD compared to TD children [15]. The likelihood of

gastrointestinal symptoms is also greater in children with ASD compared to those with developmental delay (1.74 OR) [13]. These studies on reported gastrointestinal symptoms have not specifically diagnosed what proportion have SSRD compared to other likely organic causes of symptoms such as ulcerative colitis or gluten enteropathy. There is limited information available on the specific prevalence of SSRD in those with ID who also have ASD. One study of a range of somatic symptoms in children with ASD and ID (N = 118) found an increased likelihood (1.5 OR) of somatic symptoms compared to other children with ID (N = 590) [12]. Clearly further research is required on the phenomenology of SSRD in persons with ID who also have ASD across the lifespan.

23.2.2 Aetiopathogenesis

There is a lack of research regarding the aetiology of somatic symptom disorders in people with ID. To date, a multifactorial origin, biological, psychological and environmental, is the most valued hypothesis, as for most psychiatric disorders in persons with and without neurodevelopmental disorders [16].

23.2.2.1 Biological Factors

The higher rates of chronic physical illness such as gastrointestinal disease and epilepsy in persons with ID [17, 18] and their excessive use of tobacco [19] and caffeine [20] might either create anxiety in relation to somatic symptoms or provide a rewarding experience of care and knowledge of illness, thus predisposing the individual to a somatic symptom disorder. Somatic symptoms are also associated with the behavioural phenotype of some genetic disorders. For example, conversion disorders are associated with Fragile X syndrome and its pre-mutation form [21]. Young people with Williams syndrome are three times more likely than others with ID to have somatic symptoms probably associated with high levels of anxiety [12, 22] and somatic symptoms are commonly associated with Prader–Willi syndrome [23]. Young people with Down syndrome perhaps as a reflection of their generally low level of emotional and behavioural disturbance are four times less likely than others with ID to have somatic symptoms [12, 24].

23.2.2.2 Psychological and Environmental Factors

The increased likelihood that persons with ID will experience adverse life events, stigma, abuse and social adversity might increase the risk of somatic complaints [25], but these symptoms are likely to also be associated with anxiety or depressive illness [8, 26].

Overall emotional and behavioural disturbances have been associated with increased rate of somatic symptoms [9, 11, 12, 19].

According to the authors' clinical experience, the co-occurrence of ID and ASD and the experience of anxiety may increase the probability to develop an SSRD. The inability to express emotions verbally and the impoverished fantasy and imaginal life, which characterize the ASD, are associated with difficulty in distinguishing emotional states from bodily sensations. Furthermore, persons with ASD may experience pain in unusual ways and have considerable difficulties with pain awareness and communication, ending up in a vicious circle that causes great distress [27].

Somatic symptoms seems to be more frequent in persons with ID, and particularly ID comorbid with ASD, than in the general population across the lifespan from early childhood to the elderly. Aetiology is uncertain with multifactorial origin, biological, psychological and environmental, being the most valued hypothesis.

23.3 Somatic Symptom Disorder

23.3.1 Criteria and Clinical Features

Somatic symptom disorder (SSD) presents with persistent, distressing and excessive thoughts, emotions and behaviours regarding somatic symptoms. These somatic symptoms

and the accompanying excessive thoughts, emotions and behaviours impair and disrupt daily life and adjustment. The somatic symptoms may be medically unexplained but might also be associated with a medical condition, but in both instances the critical aspect of the diagnosis is the presence of disproportionate and excessive thoughts, emotions and behaviours regarding these somatic symptoms. Therefore, the task of the clinician, regardless of whether or not the somatic symptoms have a medical explanation, is to undertake a comprehensive biopsychosocial assessment in order to determine if the psychological symptoms are excessive and persistent. Diagnosis therefore requires medical experience or at least clinical consultation. In the DSM-5 [1] field trials, the diagnosis of SSD was found to be highly reliable, identifying more cases than the previous DSM-IV criteria which required that the symptoms had to be medically unexplained [28]. These studies also indicated that the diagnosis of SSD has better predictive validity of psychological functioning at 1 year follow-up than the previous DSM-IV criteria [29, 30]. The DSM-5 [1] criteria also means that chronic pain associated with medical illness and injury is a qualifier of SSD provided that it is associated with excessive and disproportionate thoughts, feelings and behaviours. Therefore, people with chronic pain who, because of a complex interaction of biopsychosocial factors, also experience disabling psychological symptoms can now have this identified and treated as an SSD without the previous stigma which inferred that there was no physical basis to their problems or that their difficulties were a fabrication of their mind.

Diagnosis of SSD requires that the somatic symptoms are distressing and cause significant impairment in daily functioning and adjustment (Criterion A). The number or nature of the somatic symptoms may vary, but symptoms are persistent (Criterion C). Symptoms may be specific such as a chest pain or nonspecific such as fatigue. Individuals with an SSD also experience excessive and persistent thoughts, emotions and behaviours associated with the somatic symptoms (Criterion B). For example, individuals might spend considerable time worrying about the seriousness of their somatic symptoms and are anxiously preoccupied about their health. They often give exaggerated and inconsistent accounts of their illness concerns and frequently seek advice from a range of health and alternative medical treatment practitioners leading to multiple medical and alternative treatments. Normal physical sensations and bodily functions are erroneously thought to be due to physical illness, and physical activity might become more limited due to a fear of injury and time is spent examining the body for abnormalities. The presentation in children is usually less complex with concern focused on one symptom.

Medical illness is the main differential diagnosis, but the presence of excessive and distressing thoughts, feelings and behaviour is necessary to make the diagnosis of SSD in obvious medical conditions such as ulcerative colitis and diabetes. Somatic symptoms can also occur in anxiety disorder, depressive disorder, conversion disorder (functional neurological symptom disorder), delusional disorder and body dysmorphic disorder. A differentiation is made between SSD and obsessive–compulsive disorder in which the compulsive behaviours are an attempt to relieve the anxiety of intrusive, obsessional thoughts. SSD can also be comorbid with other psychopathological conditions, particularly anxiety disorders and depressive disorders, for example, in the elderly. Cultural factors might influence the type of symptoms, understanding of causation and approaches to treatment.

The critical aspect of the diagnosis of somatic symptom disorder is the presence of disproportionate and excessive thoughts, emotions and behaviours regarding persistent somatic symptoms.

23

23.3.2 Diagnosis of SSD in Persons with Intellectual Disability

A diagnosis requires that the person is able to talk about their symptoms and reflect on their emotions and thoughts. Therefore, the diagnosis of SSD in a person with moderate or more severe levels of ID who do not have language ability can only be at best inferred through their behaviour. For example, changes in previous behaviour such as posture, the use of limbs and apparent loss of sensation or focus on a specific part of the body might indicate pain or evidence of dysfunction, and other behaviours indicate excessive distress and preoccupation, such as psychomotor agitation, distractibility, irritability or aggressivity. A full adaptation to ID of the DSM-5 diagnostic criteria has recently been produced by Bertelli, Tonge and Brereton [16].

Clearly a careful history and routine observation by caregivers is a necessary component of assessment and management. Persons with ID who possess some verbal skills are more likely to give an inconsistent and medically naive account of their symptoms requiring a supporting history from a caregiver to confirm the diagnosis. Because people with ID are more likely to have more limited access to medical services [31] and general medical practitioners often lack experience in the medical care of people with ID [32], somatic symptoms might be regarded as a medical disorder and any emotional and behavioural difficulties are regarded simply as a consequence of the ID. Therefore, it is likely that persons with ID who suffer from an SSD remain undiagnosed and do not receive specific mental health treatment and support.

The diagnosis of SSD requires that the symptoms impair the person's functioning in daily life. Therefore, for a person with ID, it is necessary to gather information from caregivers, employers and day programme staff to determine that the symptoms have interrupted usual day time activities such as their participation in domestic and community activities.

In people with ID who have limited or no language ability, it is likely to be difficult if not impossible to differentiate the presenting behavioural symptoms from another mental disorder. For example, behavioural symptoms such as psychomotor retardation, loss of interest in usual activities and changes in appetite are useful in the diagnosis of a mood disorder, but these symptoms might also be present in SSD. Somatic symptoms of anxiety including sweating, shaking and agitation can be reliably diagnosed in individuals with ID [33, 34]. Altered sensory responsiveness such as hypo- or hypersensitivity to pain is also experienced in persons with ID who also have ASD [35, 36]. The behavioural phenotypes of Prader–Willi syndrome [23] and velocardiofacial syndrome [37] are likely to include somatization symptoms indicating a genetic predisposition. Therefore, in the absence of the ability of a person with ID to report on their symptoms and emotions and the necessary reliance on the observation of behaviours to infer somatic symptoms and differentiate SSD from other mental disorders or neurodevelopment conditions, making the diagnosis of SSD is difficult if not impossible.

In the diagnosis of SSD, it is necessary to determine that the somatic symptom such as pain is "not intentionally produced or feigned" for some gain such as assuming a sick role, obtaining medical attention or receiving a reward such as avoiding a duty. Therefore, care must be taken in the diagnosis of SSD in a person with ID to be sure that a somatic symptom such as vomiting did not initially occur in a context such as a community residential unit where this symptom has led to repeated secondary gain such as the avoidance of a specific disliked community activity. Traumatic and stressful life events are risk factors for SSD but are also associated with a range of other mental health problems such as anxiety disorders, post-traumatic stress disorder and conversion disorder. Compared to the general community, a person with ID is at increased risk of experiencing stressful and traumatic life events, denigration and physical, emotional or sexual abuse [38] and homelessness [39]. Therefore, it is essential that the clinician gathers historical and current information from the person with ID if possible

and from caregivers regarding their experience of trauma and psychological stress. Environmental changes and unexpected events are also likely to be stressful to a person with ID [38] acting as a precipitating risk factor for SSD. For example, sudden changes in the routine of a day programme or the loss of a regular caregiver can cause stress, highlighting the need for an assessment of the person's historical and current response to change as part of the diagnostic assessment for SSD [40]. In persons with ID, the likelihood of comorbidity of SSD with anxiety and depression reflects findings from the general community in which somatic symptoms and comorbid depression and anxiety are predicted by recent stress, increased use of health services and chronic medical conditions [41].

The diagnosis and treatment of an anxiety or a mood disorder takes precedence over the diagnosis of SSD. In situations of diagnostic uncertainty, particularly in persons with more severe levels of ID and poor communication skills, it is appropriate to make a diagnosis of a mood or anxiety disorder instead of an SSD if the observed behaviours and history of behavioural change suggests a mood or an anxiety disorder. Systematic follow-up of behavioural response to treatment can help to confirm diagnosis or indicate a comorbid SSD.

There are older case study reports in the literature which probably meet criteria for SSD such as a man with moderate ID and somatic symptoms of globus pharyngeus [42]. Carer or parent report checklists of emotional and behavioural symptoms in persons with ID are a reliable and valid means of detecting somatic symptoms. For example, the Psychopathology Inventory for Mentally Retarded Adults (PIMRA) [43] has a Somatoform Disorder Scale [44] and the Developmental Behaviour Checklist (DBC) for children and adolescents [45] or adults [46] records somatic symptoms. However, the likelihood that somatic symptoms recorded by these checklists will be associated with higher rates of other symptoms indicates the likelihood of another diagnosis such as depression or anxiety.

In persons with ID, somatic symptom disorder is often overlooked. Somatic symptom might be regarded as a medical disorder and emotional and behavioural difficulties simply as a consequence of the ID. In those with moderate-to-severe ID, changes in posture, the use of limbs and apparent loss of sensation or focus on a specific part of the body might indicate pain or evidence of dysfunction, and other behavioural alterations might express excessive distress and preoccupation, such as psychomotor agitation, distractibility, irritability or aggressivity.

23.4 Illness Anxiety Disorder

23.4.1 Criteria and Clinical Features

Illness anxiety disorder (IAD) is manifest by functional impairment due to anxiety about health that is not better explained by an anxiety disorder such as generalized anxiety.

The person has fearful preoccupying thoughts that they have a serious illness and misinterpret minor bodily symptoms (Criterion A). Somatic symptoms, if present at all, are mild (Criterion B) and significant anxiety about health is experienced (Criterion C). Concern about illness is a consuming preoccupation to the extent that they repeatedly examine themselves, seek information about their imagined condition and persistently seek advice from family, friends and multiple medical services (Criterion D) which do not reassure them [1].

23.4.2 Diagnosis of Illness Anxiety Disorder in Persons with Intellectual Disability

Persons with ID who are able to communicate are likely to have a naïve understanding of illness and therefore have difficulty realizing that the fear of illness is unjustified. The diagnosis of IAD is usually not possible in those with more severe levels of ID who cannot use language. An episode of distressing illness in a person with ID might sensitize them to an

excessive emotional response to a subsequent reminder of this illness, and if this response persists, the diagnosis of an IAD might be considered. Therefore, a comprehensive history of previous illness and their response assists diagnosis. Two case studies of hypochondriasis (which has been replaced by IAD) in adult men with ID report hypochondriacal delusions [47, 48] which better meet diagnostic criteria for a delusional disorder rather than IAD. IAD is thought to be rare in children and has its onset in early to middle adult life [1].

The main differential diagnosis is a medical condition, although diagnosis of IAD is not excluded if preoccupying anxiety and fear regarding the medical illness are excessive and unreasonable. Individuals with generalized anxiety can have concerns of illness, but they are not persistent and preoccupying. Sufferers of an obsessive–compulsive disorder can have obsessional thoughts about developing an illness but are not focused on anxiety about a current illness. Depressive disorder, SSD and adjustment disorder are other differential diagnoses. Illness delusions can be present in a psychotic disorder but are not credible which differentiates them from IAD. Associated comorbid conditions are not well described but are most probably SSD and personality disorders [1].

One or more episodes of distressing illness might sensitize person with ID to an excessive emotional response to a subsequent reminder of this illness, and if this response persists, the diagnosis of an IAD might be considered. Therefore, a comprehensive history of previous illnesses and their response assists diagnosis.

23.5 Conversion Disorder (Functional Neurological Symptom Disorder)

23.5.1 Criteria and Clinical Features

Conversion disorder (functional neurological symptom disorder) (CD/FNSD) present with at least one pseudo-neurological symptom of abnormal sensory or voluntary motor function (Criterion A) that is inconsistent with a known neurological or medical disorder (Criterion B) [1]. The symptom is not better explained by another medical or mental illness (Criterion C) and causes significant distress or impairment in daily life (Criterion D). CD/FNSD can present with a range of symptoms including abnormal gait, motor weakness, paralysis, altered or absent skin sensitivity, hearing and sight. These abnormalities must be incompatible with the symptoms, signs and investigative findings of known neurological disorders. Symptoms such as depersonalization and amnesia and stressful experiences are common antecedents. It is not necessary to unequivocally determine that the symptom is not feigned for secondary gain, unless it is clearly evident, in which case the alternative diagnosis of factitious disorder would be made.

23.5.2 Diagnosis of Conversion Disorder (Functional Neurological Symptom Disorder) in Persons with Intellectual Disability

A comprehensive developmental and clinical history from parents or carers, neurological examination and indicated investigations are necessary to confirm the diagnosis, particularly in individuals with more severe ID and limited or no language, when the application of modified diagnostic criteria for use in ID such as the Diagnostic Manual-Intellectual Disability (DM-ID-2) [49] are helpful.

Neurological conditions, SSD, factitious disorder, dissociative disorder, body dysmorphic disorder, depressive and panic disorder are differential diagnoses. However, comorbidity occurs with neurological disorders, SSD, anxiety and depressive disorders and personality disorders but less commonly with substance use and psychosis. For people with ID, differentiation of epilepsy from non-epileptic seizures (NES) is a challenge. The risk of having refractory and recurrent epileptic seizures together with NES is increased in

individuals with ID [25, 50, 51]. Psychosocial stress and cultural influences also increase the likelihood of NES [25, 51, 52]. Abnormal activation of frontal inhibitory brain function might also have a genetic basis manifest as an increased risk of conversion disorder and NES in Fragile X syndrome [21]. A study in Bangladesh of 44 children with NES found that 77% had a conversion disorder and 23% of these also had ID [51]. There are some reported case studies of children with ID who might have a CD/FNSD presenting with pseudo-seizures in the context of a normal EEG, but the possibility of secondary gain from attention challenges the diagnosis [53]. The DSM-5 suggests that the prognosis for children is better than for adolescents and adults [1].

A comprehensive developmental and clinical history from parents or carers, neurological examination and indicated investigations are necessary to confirm the diagnosis, particularly in persons with more severe ID and limited or no language.

23.6 Psychological Factors Affecting Other Medical Conditions

23.6.1 Criteria and Clinical Features

Psychological factors affecting other medical conditions (PFAMC) is a disorder where a medical (not mental) illness is present (Criterion A) which is adversely affected by emotional and behavioural factors (Criterion B) that influence the course and/or treatment, that create additional health risks and/or that adversely influence the illness process necessitating treatment and may even be life threatening. These psychological or behavioural factors are not due to another mental illness such as depression, anxiety or Posttraumatic stress disorder (PTSD) [1].

The impact of the psychological factors on the medical condition can vary from a mild increase in medical risk to severe and life threatening such as ignoring the symptoms of an acute bowel obstruction. It can occur at any age and be acute or chronic, related to stress, anxiety, denial, personality, relationship difficulties and cultural context. If the emotional or behavioural problems develop as a consequence of the medical illness, then they are diagnosed as an adjustment disorder. An SSD which has maladaptive thoughts and feelings or an IAD with high illness anxiety and no associated medical illness are differential diagnoses.

23.6.2 Diagnosis of Psychological Factors Affecting Other Medical Conditions in Persons with Intellectual Disability

There is little literature regarding the phenomenology of PFAMC in people with ID. It could be argued that ID itself, particularly when more severe and where there is limited or no language, is a factor that can adversely affect a medical condition. Persons with ID have an increased risk of suffering chronic medical conditions such as osteoporosis and musculoskeletal disorders (MSDs), chronic dental disease and gastrointestinal problems including constipation and reflux and may not be able to adequately report their symptoms [17, 54, 55]. As a consequence, the medical risk is increased. Persons with ASD [1] often have sensory sensitivities which may include reduced sensitivity to pain leading to injuries such as bone fractures or medical conditions such as dental caries or peptic ulcers being unrecognized and deteriorating. Differential diagnoses include a mental illness due to a medical condition, an adjustment disorder where psychological symptoms develop in response to a medical condition, SSD where excessive thoughts and feelings are in response to somatic symptoms and IAD with high anxiety with minimal somatic symptoms. The assessment of PFAMC in children requires a history and observation from parents and teachers.

23

23.7 Factitious Disorders

23.7.1 Criteria and Clinical Features

Factitious disorders (FD) are induced falsified symptoms or signs of injury or disease or psychological disorder associated with intent to deceive (Criterion A). The individual presents themselves or is presented by another, as ill, impaired or injured (Criterion B) not necessarily to achieve an obvious reward (Criterion C). The FD is not better explained by a psychotic disorder or mental illness (Criterion D) [1]. There are two types: one imposed on the self and the second imposed on another. A wide range of presentations include producing physical injury, cutting to obtain blood to put in urine or faeces to mimic a disease, talking nonsense, claiming hallucinations, appearing to be forgetful or in tears to indicate a mental illness or claiming symptoms of a medical illness such as stomach pain (which is referred to as Munchausen syndrome after an eighteenth-century German Baron who fabricated stories of his exploits). A factitious disorder imposed on another (Munchausen syndrome by Proxy) occurs when the diagnosed individual intentionally causes illness, for example, by administering insulin, or reports fictitious symptoms in someone they care for such as a child, an elderly person or someone with an ID. The presentation to medical services is often dramatic with an overelaboration and inconsistent history given (pseudologia fantastica). If challenged, they leave but usually travel to present at many other medical facilities.

23.7.2 Diagnosis of Factitious Disorders in Persons with Intellectual Disability

Persons with ID are likely to be medically naïve and produce more obviously fabricated signs or inconsistent symptoms perhaps copied from others or the media. It is essential to the diagnosis to determine that the intentional production of signs and symptoms is in the absence of any obvious reward such as care and attention. Therefore, a clear account from an independent carer of the context and history of the symptoms is necessary to exclude the likelihood of external reward such as avoiding a noisy shopping mall in a person with ID and autism with sound sensitivity and social anxiety, in which case the individual would be malingering. There are reports of FD imposed on the self in persons with mild ID [56, 57], but this is not likely to occur in people with more severe levels of ID as they would not be able to plan and instigate the signs or symptoms. There is a case report of a person who did not have ID who feigned symptoms of ID, depression and psychosis [58]. There is no evidence in the literature that self-injurious behaviour (SIB) occurring in ID has the intent to deceive although some instances might be to gain care and attention [59]. There is no evidence regarding the presentation of self-induced FD in children or adolescents.

> Persons with ID and ID comorbid with ASD with high support need are likely to be medically naïve and produce more obviously fabricated signs or inconsistent symptoms than persons of the general population. Thus, it is essential for the diagnosis to determine that the intentional production of signs and symptoms is in the absence of any obvious reward such as care, attention or avoidance of annoying stimuli.

23.8 Other Specified (or Unspecified) Somatic Symptoms and Related Disorders

23.8.1 Criteria and Clinical Features

These diagnostic categories are used when there are some symptoms of SSRD causing impairment and distress which do not fulfil the criteria for SSRD. A woman who believes she is pregnant when this is not physiologically

so ("pseudocyesis") might be diagnosed in this category and has been described as occurring in women with mild ID. In general, these categories should be avoided, particularly the one on unspecified somatic symptoms, which is suggested by the DSM-5 [1] to be used with caution also towards the general population. However, the lack of a sufficient and comprehensive history and information from carers and limited language ability in persons with ID might make this diagnostic category the only feasible one in a person with more severe levels of ID who have at least sufficient communication ability to indicate somatic symptoms [44].

23.9 Treatment

There is a lack of specific literature on the treatment of SSRD in ID, but the approaches to their treatment in the general population are likely to be relevant provided the cognitive and communication difficulties inherent in ID, the general health and effects of any known genetic causes of the ID, the environment of care and the social, cultural and educational/daily activity context are taken into account.

The first and essential component of management is a comprehensive biopsychosocial assessment including a medical assessment as indicated and symptom history and observations from parents or carers. As far as possible, the patient needs to experience that they are being taken seriously and their distress and symptoms are understood. The social, cultural and environmental context of symptoms must be clear including a history of stressful life events and social and economic adversity. If possible, and using appropriate communication methods such as visual aids, the link between symptoms and psychosocial or medical illness experiences as well as the experience of anxiety should be explained. Reassurance is therapeutic particularly if symptoms are tackled early in the course of the disorder.

Parents and carers need to be included in the treatment and understand the link between symptoms and medical illness and environmental factors. Management skills training, support and respite care services and treatment of any mental health problem in the parent that contributes might be necessary. Consultation with the network and system of services will inform others and support their care of the individual. Any underlying medical problem such as dental pain or gastric reflux requires treatment. Support and changes in the environment that might reduce anxiety, reward adaptive behaviour and improve positive social engagement and daily occupation are therapeutic and help the individual to cope with their situation. Treatment of anxiety using modified cognitive approaches such a picture-based health education, positive behaviour scripts, behavioural strategies using rewards and relaxation exercises adapted to suit the individual's level of understanding may be therapeutic [60, 61]. These strategies require observation and understanding of the context and antecedents and consequences of the symptom. There is a single case report of a man with ID who was successfully treated for symptoms of excessive medical complaints that were consistent with the diagnosis of an FD using non-contingent rewards [62]. Medication should only be used if symptom profiles are consistent with their indicated use, for example, a trial of an antidepressant if there are symptoms of a comorbid depressive illness [61]. For the treatment of anxiety and depression, tricyclics and selective serotonin reuptake inhibitors (SSRIs) might be of therapeutic benefit but using initially low doses as sensitivity to side effects can be prominent [63]. Benzodiazepines should only be used briefly and with caution given tolerance. Propranolol can be useful in highly aroused patients. Analgesics should remain simple and non-addictive, such as paracetamol, given that chronic pain is generally unresponsive to analgesics where the treatment focus needs to be on rehabilitation and behavioural management.

Early intervention is the key because the prognosis for chronic SSD is generally poor, in which case the focus must be on limiting further deterioration and prevention of medical complications, psychiatric comorbidity and avoidable side effects of psychotropic

medication. Response to a management plan is best documented in a systematic way using behavioural checklists sensitive to change and for use in people with ID such as the developmental behaviour checklist for children and adolescents [45] or adults [46].

Tip

Early multimodal intervention has to be favoured, including individual and family psychoeducation, environmental support and changes, tailored cognitive and behavioural strategies. Medication should only be used if symptom profiles are consistent with their indicated use, for example, in case of unmanageable anxiety or depression.

23.10 Case Example

"Sarah" a 26-year-old woman with moderate ID due to Williams syndrome (WS: loquacious but poor comprehension and gross/fine motor skills deficits) fell off a placid horse when on a day programme group activity. A number of young men in the group laughed at her. She suffered bruising and swelling of her right forearm but emergency room examination and detailed X-rays revealed no fractures. A cold compress and sling were applied and she was returned home to the care of her single parent mother. Over the next 6 weeks, she became increasingly fearful and distressed, constantly stating that her arm was "broken" and that it was "so bad" that it would have to be "chopped off". She refused to attend her day programme, isolated herself in her room, her longstanding insomnia (related to her WS) worsened, she cried frequently in distress and refused to use her right arm and hand claiming that her "fingers wouldn't work" necessitating spoon feeding by her increasingly worried mother. Sarah frequently demanded to see her general practitioner or "go back to hospital". General practitioner review and repeated X-rays failed to demonstrate a fracture and the bruising had resolved. A diagnosis of SSD was made taking into account the behavioural phenotype of WS with its risk of phobias and anxiety.

Treatment which was successful included helping the mother develop strategies to manage her daughter's behaviour and manage her own stress and the provision of periods of daily in-home respite care. Sarah received coaching in modified relaxation exercises; a reward programme of her favourite small figurines for a graded removal of the sling and increasing arm and finger movements supported by a detailed picture script; a picture account of the events surrounding the accident, the visit to hospital and the normal X-ray, and recovery of her arm and return to normal activities; a get-well card from her day programme group indicating that they missed her and the promise of tickets to see her favourite pop group when she was better and had her arm and fingers moving again.

Key Points

- Somatic symptoms which adversely impact daily life are common affecting around 10% of adults and 14% of children with ID.
- Somatic symptoms are often a feature of anxiety, depression and acute stress reactions in persons with ID but can also occur independently as the prime symptom of several specific disorders defined in the DSM-5.
- SSD has somatic symptoms associated with persistent and distressing thoughts and emotions related to the symptoms.
- IAD presents as incapacitating anxiety about health concerns and fears that a serious illness will develop.
- CD presents with neurological symptoms that are inconsistent with any neurological disorder.
- PFAMC presents with an abnormal or excessive psychological response to a medical condition that then adversely affects the outcome of that condition.
- FD presents with fabricated symptoms that intend to deceive others.

- Diagnosis of these conditions in individuals with ID becomes more problematic if not impossible as communication skills decrease with more severe levels of ID.
- Behavioural observation, history from parents or carers, medical, cognitive, cause of ID, environmental, social and cultural context assessment are necessary to inform diagnosis and management.
- Early intervention promises the best prognosis.
- Management is usually multimodal including environmental adjustment, modified cognitive (e.g. psychoeducation) and behavioural strategies with examination of antecedents and consequences of the somatic symptom (e.g. relaxation exercises, contingent and non-contingent rewards), anxiety reduction strategies (e.g. reassurance, modified psychological treatments), anxiolytic medication, treatment of any comorbid mental illness, such as depression, parent/carer support, education and skills training, and wider system consultation.
- Systematic follow-up and review of response to treatment are recommended.

Leaning Objectives

Recent neuroscientific research in genetics, neurophysiology, functional neuroimaging, and neuropharmacology are broadening our understanding of the complex pathophysiology of OCRD. These new findings are also providing new insights into the complex interrelationships between OCRD, ASD, ID, and other neurodevelopmental disorders. In this chapter, the focus is on the synthesis of new research into OCRD with our growing knowledge about the psychopathology in the context of neurodevelopmental disorders. One approach to this problem involves searching for neurobiological endophenotypes to define various subtypes of OCRD. These subtypes can specify more focused treatment algorithms.

Upon completion of this chapter, the reader should be able to demonstrate the following:

1. Discuss the relationship between OCRD and ASD, ID and other developmental disorders, and the application of this knowledge to treatment planning.
2. An understanding of the basic neuropharmacology of OCD and its psychiatric comorbidities and applying these ideas to treatment decision-making.
3. The use of subtypes of OC-related behaviors to aid the differential diagnosis and treatment of stereotypies, complex tics, self-injury, and ritualized behaviors.
4. A working knowledge of alternative treatments for treatment refractory OCRD.
5. An enhanced ability to recognize, differentially diagnose, and treat patients with OCRD plus ASD and ID.

24.1 Introduction

Obsessive-compulsive disorder (OCD) is a heterogeneous syndrome characterized by (1) intrusive ego-alien thoughts or experiences, (2) varying degrees of insight, and (3) a relatively limited repertoire of avoidance behaviors (compulsions) [1–4]. Behaviorists conceptualize this phenotype in terms of avoidance responses (compulsions) to aversive thoughts and emotional preoccupations (obsessions).

The capacity of these behaviors to reduce anxiety or distress in turn negatively reinforces their continued utility [5–9]. In some patients, the long-term repetition of the stimulus response cycles metamorphose into nongoal-directed behaviors commonly labeled as habits [3, 4, 6].

The publication of the DSM-5 (2013) and the DM-ID-2 (2016) replaced OCD as an anxiety disorder and established a free-standing category of obsessive-compulsive and related disorders (OCRD), which has been adopted also by the last edition of ICD-11 [94]. This step expanded the scope of OCD to include an addition group of complex repetitive cognitive and behavior disorders. These disorders differ from anxiety-driven OCD in terms of motivational state, semiology of repetitive behaviors, and a different set of co-occurring psychiatric disorders [2, 6, 10].

These changes fell short of making significant revisions in the descriptive/categorical approach to diagnosis and shifting the focus of diagnostic criteria to incorporate pathophysiology and aetiopathogenesis. This leaves us with the problems of overlapping of gene markers, biomarkers, clinical symptomatology, and boundaries issues between OCRD, intellectual disability (ID), autism spectrum disorder (ASD), and ASD +ID [6, 10, 95, 96]. The goals for this chapter center on trying to improve our understanding of the effects of such interrelatedness on the predisposition, precipitation, and perpetuation of OCRD. To explore these issues, we need to modify our conceptual model of OCRD that treats OCRD, ASD, and ID as three discrete disorders following separate clinical trajectories and focus instead on them as a mosaic of entangled neurodevelopmental disorders that change throughout the life cycle. As a result, treatment planning and implementation need to focus not only OCRD as a psychiatric disorder but how the presence of ASD and ID influence the interventions. Our goal is to look carefully at the high rates of incomplete treatment responses and tease out how co-occurring ASD and ID influence these outcomes.

This process is a step toward synthesizing a model for personalized treatment and improving treatment outcomes for nearly 30% of patients with OCRD.

24.2 Diagnostic Criteria

The process begins with an exploration of our current descriptive/categorical diagnostic criteria outlined in the DSM-5 [1] and DM-ID-2 [10]. The following criteria are required:

A. Presence of obsession, compulsions, or both Obsessions defined by 1 and 2,
   1. Intrusive, unwanted, and distressing recurrent thoughts, urges, images
   2. Attempt to ignore or suppress or to neutralize them with some other thought or image and Compulsions defined by 1 and 2:
      1. Repetitive behaviors (handwashing, ordering, checking) or mental acts (praying, counting, repeating words silently) that the individual feels is driven to perform to an obsession according to the rules that must be applied rigidly.
      2. The function of these behaviors or mental acts involves eliminating or at least reducing anxiety or distress, preventing some dreaded event or situation; the actions are not connected in any realistic way to what they are intended to neutralize or prevent.

B. Obsessions and compulsions are time consuming (>1 h per day) or cause significant distress or impairment in important areas of functioning.

C. Not attributed to physiological effects of substance of abuse, medication, or other medical conditions.

D. Not better explained by symptom of another mental disorders; this includes other OC-related disorders, paraphilias, substance use disorders, impulse control and conduct disorder, mood or schizophrenia spectrum disorders.

Also in the ICD-11, essential diagnostic features are represented by persistent obsessions and/or compulsions. Obsessions are defined as "repetitive and persistent thoughts, images, or impulses/urges that are experienced as intrusive and unwanted, and are commonly associated with anxiety. The individual typically attempts to ignore or suppress obsessions or to neutralize them by performing compulsions." Compulsions are described as "repetitive behaviours or rituals, including repetitive mental acts, that the individual feels driven to perform in response to an obsession, according to rigid rules, or to achieve a sense of 'completeness'. Examples of overt behaviours include repetitive washing, checking, and ordering of objects. Examples of analogous mental acts include mentally repeating specific phrases in order to prevent negative outcomes, reviewing a memory to make sure that one has caused no harm, and mentally counting objects. Compulsions are either not connected in a realistic way to the feared event or are clearly excessive" [94].

Specifiers

Specifiers are a major part of the DSM-5 criteria for OCRD. They define two phenomenological endophenotypes characterized by the presence or absence of both insight and the presence of tics/tic disorders. According to the ICD-11, "individuals with OCD vary in the degree of insight they have about the accuracy of the beliefs that underlie their obsessive-compulsive symptoms. Although many can acknowledge that their thoughts or behaviours are untrue or excessive, some cannot, and the beliefs of a small minority of individuals with OCD may at times appear to be delusional in the degree of conviction or fixity with which these beliefs are held. Insight may vary substantially even over short periods of time, for example depending on the level of current anxiety or distress, and should be assessed with respect to a time period that is sufficient to allow for such fluctuation (e.g., a few days or a week)." [94]. Hence, insight is a requirement for OCD although developmental studies suggest that children with early-onset OCD frequently lack both self-awareness or the ability to perceive obsessions and compulsions as ego dystonic.

Unfortunately, many adult patients also lack insight or ego dystonicity. This discrepancy creates a potential boundary problem

with delusional thoughts. Resolving this issue requires a more detailed investigation into the tenacity and rigidity of these beliefs, their resistance to contradictory evidence, and relationship to psychosis [1, 6, 10]. Yet these distinctions are not absolute since the co-occurrence of OCD, delusional disorders, and schizophrenia is well established. The presence of ASD creates a similar quandary. It can be difficult to distinguish OCRD from the core features of ASD and ID-repetitive and restrictive interests, cognitive rigidity, intolerance of change, and egocentricity due to subtle deficits in theory of mind skills [1, 6, 10].

The presence of tic disorders creates a second subgroup of OCRD that overlaps both the phenomenology of OCD and the relationship between tics and OCD-related disorders. Both specifiers address basic differences in clinical phenomenology as well as neurobiology and responses to psychotropic medications [6, 11, 97, 98, 99]. These relationships are subject to more careful scrutiny later in this chapter.

There are three basic components to the differential diagnosis of OCRD. These function mainly as rule-outs:

1. The persistence of rituals is well past their normal neurodevelopmental time frame. This refers to childhood preoccupations and ritualized behaviors [1] (see section on OCRD as a neurodevelopmental disorder).
2. OCRD is comorbid with the following neuropsychiatric disorders: anxiety disorders, major depressive disorder, trauma-and-stressor-related disorders, eating disorders, tics, stereotypic movements, psychotic disorders, ASD, and substance use disorder. The neurobiology of these relationship varies in part along the lines of anxiety-related and nonanxiety-related subsets of OCRD.
3. OC-like symptoms are associated with a wide range of medical, neurological, metabolic, genetic, neuroimmunological/autoimmune disorders, traumatic brain injury, and other acquired brain disorders. The secondary forms of OC-like symptoms involve the many interconnections within the corticostriate and corticolimbic neurocircuitries.

OC behaviors in patients with tic disorders frequently have more in common with OCRD, in which intrusive and disturbing experiences differ from the doubts and intolerance of uncertainty and fears of contamination associated with anxiety-related OCD. In many cases, there are no specific obsessions nor compulsions that allow the individual to avoid the adverse outcomes associated with the patient's noncompliance with the rituals. In tic-related OC symptoms, there are differences in the motivational state that are oriented more toward approach/appetitive behaviors in which interference with the ritual leads to an intensification of the drive to complete it. There is more frustration than anxiety.

In addition, "feeling right" rather than less distressed may serve as the terminating event for the repetitive motor or cognitive actions [1, 26].

In addition, there are subtypes of OCRD associated with stimulant abuse, traumatic brain injury, autoimmune (systemic lupus and PANDAS), neurodegenerative and other movement disorders (Parkinson's and Huntington's disease), genetic/metabolic disorders (neuroacanthocytosis and Wilson's disease), more recently co-occurring with abnormal movements associated with anti-neuronal antibody syndromes, and mitochondrial disorders. The semiology of these secondary forms of OC-like behaviors may also lack obsessions, insight, or dystonicity [6, 28, 29, 30].

Patients with a history of traumatic brain injury during infancy display a global pattern of deficits that can resemble ID, but less so for ASD. These adult patients also present with neuropsychological deficits that can complicate the diagnosis of OCRD. Perhaps the most dramatic include environmental dependency (echopraxia, echolalia, and catatonic-like imitative behaviors), perseveration, negative affective reactions to environmental changes (intolerance of change), hyperactivity, irritability and impulsivity, lack of insight, relative intolerance for change, catastrophic anxiety/cognitive disintegration, memory and working memory deficits, and a range of fixed responses and behavior (executive deficits).

Unfortunately, this group may be the most vulnerable to dysfunctional family systems,

ongoing psychological trauma, and disorganized living environments and poorly structured daily routines. Individuals with co-occuring neurodegenerative disorders commonly display neurocognitve decline in conjunction with progressive changes in repetitive behaviors. When the decline is subtle, extended longitudinal follow-up may give the clinician an opportunity to observe progressive ongoing deterioration. Many frontotemporal dementias may present with increases in perseverative behaviors than be overlooked in the face of preexisting patterns of repetitive behaviors. The loss of daily living skills or progressive apathy may require time to emerge [3, 62, 63].

Many early onset psychiatric disorders are associated with neurodevelopmental comorbidities. Both influence the actively developing brain. Like ASD/ID, many of these disorders influence neuroplasticity, neuronal migration, and the development of cortical specialization and coherence. For example, repeated trauma can increase the risk of sensitization and epigenetic changes during critical periods of emerging neurocircuitry. Once these epigenetic changes in promoter regions are methylated and switched off, the likelihood of spontaneously reversals lessens, as does their impact on future interactive specialization and brain maturation [3, 63, 64, 100].

Many "organic forms" of OC behaviors resemble impulsive-compulsive behaviors that include addiction-like behaviors. These include disorders of excessive grooming, repetitive counting, arranging, organizing, need for symmetry and intrusive images, or thoughts involving sex, violence, and destructive behaviors [1, 6]. These appear analogous to another group of automatic (habits) repetitive behaviors that resemble addiction behaviors and tic-related and ASD repetitive behaviors (classified as nonsubstance-related disorders) [1, 4]. These expanded phenocopies interface with personality disorders, bipolar disorder, ASD, other movement disorders, and stereotypic movement disorder (stereotypies and self-injurious behaviors) [6, 11].

Lastly, OCRD also include: type unspecified (subsyndromal), body dysmorphic disorder, hoarding, excoriation (skin picking) disorder, and trichotillomania (hair pulling) in both primary and secondary forms. The secondary disorders include substance-induced and OCRD associated with medical, neurological, immunological, metabolic, and neurodegenerative disorders [1] (Table 24.1).

OCRD also includes other specified OCRD that consist of body dysmorphic disorder (BDD), nail, and cheek biting and differentiate these behaviors from other forms of high-frequency/low-intensity forms of compulsive self-injury. This group also includes obsessional jealousy and several culture-specific disorders. Unspecified OCRD is analogous to a subsyndromal condition that does not meet the criteria threshold for OCRD. Nevertheless, approximately 50% of patients classified as unspecified OCRD will progress to the full syndrome. Each of these subtypes share an increased risk for comorbid mood and anxiety disorders [1, 6, 10].

This section on diagnostic criteria reviews the updated version of the diagnostic criteria spelled out in the DSM-5 and Diagnostic Manual Intellectual Disability-2 (DM-ID-2). The reader should be alert to the implications of a shift from anxiety disorders to a free-standing category, obsessive-compulsive and related disorders. The second change involves the addition of repetitive behaviors that differ from traditional doubting/checking and contamination/cleansing rituals in terms of their relationship to obsessions, motivation, and functional states.

24.3 The Relationship Between OCRD, Repetitive/Stereotypic, and Addiction Behaviors

The DSM-5 and DM-ID-2 classify a variety of repetitive behaviors among the nonsubstance-related disorders or stereotypic movement disorder. As we shall see, complex tics and some forms of stereotypies/self-injury may lie midway between OCD and habits. Habits are automatic behaviors that may no longer appear directly linked to a subjective sense of pleasure or reward [5, 6]. The

Table 24.1 OCRD-related disorders includes

Diagnostic criteria	Body dysmorphic disorder [38–40]	Hoarding disorder [41]	Trichotillomania TTM [44]	Excoriation disorder [101]	Substance/medication-induced [1]	OCRD due to other medical condition [42]
A.	Preoccupation with one or more perceived flaws or defects-not observable by others	Persistent difficulty discarding or parting with possessions, regardless of actual value	Recurrent pulling of one's hair, resulting in hair loss	Recurrent skin picking, causing skin lesions	OCRD-core symptoms	OCRD-core symptoms
B.	Repetitive checking, grooming, skin picking, reassurance seeking, mental acts, comparison with others	Need to save the items and distress associated with discarding them	Repeated attempts to decrease or stop hair pulling	Repeated attempt decreases or stops	Evidence of substance use/abuse temporally associated with symptoms	Evidence of medical/neurological condition directly related to symptoms
C.	Creates significant distress, impairment of social function	Accumulate possessions, congest or clutter living areas, compromises their intended use	Causes significant distress; impairment of social, occupation, or other areas of functioning	Causes significant distress, impairment of social occupational activities	Not better explained by OCRD, delirium, functional impairment	Not better explained by OCRD, delirium
D.	Not better explained by eating disorders	Significant distress. Not attributed to other medical condition; not related to ASD or other psychiatric disorders	Not attributed to medical or other mental conditions	Not due to substance abuse or other medical and mental disorders	Specify: – specific drug; – onset during intoxication, withdrawal; – onset after medication use	Specify type of disorder
E.	Specify: – with muscle dysmorphia; – with fair to good, poor, and absence of delusional beliefs	Specify: – with excessive accumulation; – insight				

boundary between habitual and addiction behaviors can be confusing. Addiction behaviors are repetitive behaviors characterized by increasing urges to carry out a ritual without signicant anxiety or avoidance behaviors. Once the repetitive behavior is completed, the urge temporarily subsides. The initial sense of relief wanes and the urge returns.

Some patients cannot escape the cycle and seem bound to repeating self-defeating or self-destructive behaviors. Several key features of this subgroup arise longstanding re-enactments and repetition:

1. Sensitization of neuronal circuits in a process analogous to kindling of stimulus-induced seizures.
2. Because of the potentially self-defeating properties, some patients experience a sense of guilt or dysphoria associated with gratifying the urge and in some patients, a sense of psychological withdrawal.
3. The cycle of dysphoria and a return of the motivational state contribute to the persistence of these repetitive behaviors. From a functional behavioral model, the original triggers may generalize to include multiple specific and context-related cues as well as internal affective states that can continue in spite of severe adverse consequences [2, 3, 4].

These repetitive behaviors differ from other of nonsubstance-related disorders in terms comorbidity. Many related disorders are less likely to present with comorbid anxiety disorders (and OCD). For example, nonsubstance-related disorders are more likely to occur in the context of dysfunctional impulse control or substance use disorders [6, 10].

Differentiating these subgroups of repetitive behaviors from other stereotypic movement disorders can be challenging especially in patients with co-occurring ID or ASD [6, 10]. This problem seems most obvious for mannerisms and stereotypies associated with the core features of ASD/ID. Similar difficulties arise when the clinician confronts patients with ASD/ID and co-occurring complex tics, hoarding behaviors, and in some cases, perseveration associated with other neurocognitive disorders.

There is a larger subset of repetitive thoughts and behaviors that are germane to our understanding of the relationship between OCRD and autism spectrum disorders (ASD) and intellectual disability (ID). These differences overlap motivational states (goal-directed behaviors) and underlying neurobiology. These subtypes may partly explain the variability in both behavioral and psychopharmacological treatments.

24.4 Boundary Problems Created by Co-occurring Neurodevelopmental Disorders

In many settings, clinicians may overlook the fact that many psychiatric are complex genetic-neurodevelopmental disorders. This combination creates some challenges. For example, familial ASD (multiplex families) is a highly heritable, polygenic disorder. Symptomatic ASD on the other hand is more likely to be associated with multiple genetic, neurological, metabolic, early infectious, and toxin-related conditions. This latter group is also more likely to co-occur with ID. The origins of both subtypes occur during critical developmental periods (embryological and early postnatal insults) that effect very early brain organization and maturation. Many of the genes linked to ASD also affect synaptogenesis, neuroplastic changes in the neuropil, stabilization of these new synaptic connections, and interconnections between newly developing cortical-subcortical/limbic and striatal networks. These changes seem to guide future attachment, temperament, neurocognitive, emotional, and social development [7, 61, 65, 67].

However, most psychiatric disorders emerge during later stages of brain development. For example, trauma-related insults during early childhood disrupt the entrainment of the stress-response system as well as later episodes of neuroplasticity, neurogenesis, myelination, interactive specialization, and the development of hierarchically organized frontal-striatal and fronto-limbic

neuronal networks. During early childhood, these insults may not result in ASD or ID but may adversely affect the emergence of affect regulation, attention, executive functions, and other higher cortical functions [16, 37, 61, 73, 74]. A close look at the neuropsychology and neurobiology of OCRD reveal a mean age of onset around age 10, as well as neurocognitive deficits in spatial orientation, information processing, and decision-making and executive functions (including working memory) [6, 11, 15, 102].

Neurotypical children express transient rituals, repetitive behaviors, and developmental, age-dependent magical thought. The typology of early OCRD differs from the typical childhood worries and rituals. However, some children fail to resolve these worries but never develop OCRD. Children with mild ID are likely to fit into this group. Recent evidence suggests that the childhood precursors of OCRD usually differ from the beginning. The worries and behaviors among children with OCD belong to a more restricted repertoire of concerns and behaviors. In addition, children with early onset OCRD may lack insight, display more compulsions than obsessions, and may present with comorbid externalizing and internalizing disorders [6]. Neurotypical and children with OC symptoms differ from those with ASD in terms of complexity, persistent of need for sameness/reduced tolerance of change and limits on the richness of imagination, social communication, and shared, social expression (imaginative social play or age-related fiction) [6, 11, 15].

As alluded to earlier, there is a subgroup of preschool males who present with transient motor and/or vocal tics alongside ASD, ID, and other neurodevelopmental disorders [6, 18, 19]. These young males present OC symptoms characterized by fewer obsessions, limited insight, and a cluster of arranging, ordering, counting, and symmetry rituals. These OC behaviors give way to tic disorders in between 20% and 40% of the original cohort. Others may present with both tics and OC symptoms at the outset. This group will also experience fewer obsessions, less anxiety, fewer avoidance behaviors, and later onset problems associated with changing typologies of tics. A smaller percentage develops Tourette disorder (TD) in which both motor and vocal tics are present.

Within the first 5 years after TD onset, nearly 50% develop intrusive thoughts, urges, and sensory experiences that are relieved by ticqueing. These children may also develop sequences of multiple tics that terminate when the urge or sensation abates ("feels right"). At this stage, the boundary between tics and OCRD becomes more difficult to establish. Careful factor analytics offer some help. These studies suggest that complex tics differ from compulsive behaviors in anxiety-mediated OCD. In contrast to fears of contamination/cleaning and doubting/checking, tic-related, repetitive behaviors include touching, arranging, organizing, counting, and need for symmetry. Tic-related OCRD also display different patterns of impulse regulation and comorbidity with other neuropsychiatric disorders [11, 20–22].

Similar patterns of tic-related repetitive behaviors also occur in patients with ASD and ID. The higher prevalence rates for tic disorders in ASD and ID than in the general population underscore the significance of these data [11]. The entanglement of boundaries between OCRD, tic disorders, and ASD/ID phenotype confounds attempts to track their clinical trajectories. In addition, the severity of OCRD and TD tend to worsen during periods of increased stress, and wax and wane over time. This inherent variability challenges attempts to monitor diagnostic fidelity and treatment efficacy. To do so, requires ongoing assessment. However, it can be difficult to sort out these variables, and this process may take repeated examinations over an extended period of time [23–28].

In general, childhood onset OCRD with and without tics may differ in terms of intrusive sensory experiences, sexual, and violent images, as well as urges and cravings. Embedded in this group, however, are patients with OC-like repetitive behaviors that are difficult to characterize. This in part is due to a relative absence of readily discernable patterns of contingency-driven behaviors (avoidant/escape behaviors), less overt anxiety, and tendency toward negative affective or behavioral

displays in response to limits. These problems appear more habit-related behaviors, and tend to occur without readily discernable reinforcers [4, 6, 11]. Unfortunately, the enhanced hedonic drive associated with these behaviors can give way to an addiction-like pattern that continues in spite of significant negative consequences (e.g., some forms of severe self-injury). Their waxing and waning course may also increase the chances of a bipolar disorder diagnosis [6, 26, 28].

Even with this subtype analyses, there are still important issues that shape the boundaries between OCRD and repetitive/ritualized behaviors. Our next step is to delve into issues linking OCRD to more complex neurodevelopmental disorders such as (Autism, ID, ADHD) and other neuropsychiatric disorders (tic disorders, other medical/neurological syndromes). The central theme in this analysis is to explore the effects atypical development in the mergence and presentation of OCRD.

24.5 Neuroethology of OCRD

Tip

Neuroethological models suggest a relationship between conflict mediated behaviors in animals and many human repetitive behaviors. Think of the neurobiological similarities between OCRD in humans and ritualized behaviors in animals.

Our current understanding of the transformations from stereotypies, into self-defeating, habitual behaviors remains a work in progress. Neuroimaging studies of these habit-related behaviors suggest a pattern of overlapping, dysfunctional fronto-striatal (caudate), ventral striatal, palladial, thalamocortical ensembles substrates [4, 6, 11, 29, 103]. These networks differ from the ancient fear/anxiety-aversion conditioned behaviors that underlie OCD and other anxiety disorders. Studies of the anxiety-conditioned group suggest involvement of the basal-lateral amygdala, basal striatum, hippocampus, limbic and insular, brainstem, and several orbitofrontal regions. This network also underlies trauma- related anxiety disorders [32–34]. The fear pathway is highly conserved in evolutionary terms. However, mammals, and especially primates (especially humans), have a more complicated fear/anxiety network that is interconnected with several late evolving, cortical networks. These pathways involve higher-level processing and interpreting cortical input that plays a role in regulating and planning cognitive and behavioral responses [6, 32, 35].

Humans are also social primates who evolved an elaborate, finely tuned, social brain that remains highly adaptable to social contexts. The prolongation of neuroplasticity, neurogenesis, and ongoing myelination in modern humans permit ongoing modifications of late-developing networks that underlie language, social communication, abstract thought, more complex social behaviors, and a new range of executive functions (interactive specialization). ID and ASD may represent complex patterns of dysfunctional maturation in these developmental lines [6, 32, 35].

OCRD may represent more system-specific malfunctions that release mammalian patterns of ritualized social behaviors. Neuroethologists and evolutionary biologists take this approach. They expand the ideas to humans in order to link OCRD to "fixed action patterns" with species-specific, trigger stimuli ("innate releasing mechanisms") in ambiguous or conflictual, social situations. In humans, the enhanced top-down regulation provided by fronto-cortical expansion overrides automatic responses associated with instinctual behaviors. Metaphorically, OCRD is a dysregulated remnant (disconnection syndrome) that permits the expression of these attenuated species-specific behaviors (fear, fear-conditioned influence). In addition, dominance hierarchies may underlie social anxieties and perhaps some disorders of excessive grooming [6, 36–38, 62].

Although neglected in most diagnostic models, neuroethological principles provide observational social data to the assessment. This information is useful in the study of disorders excessive grooming, ritualized social defeat behaviors associated with OCRD and social anxiety. In animal models, these social

behaviors occur in socially ambiguous situations that relate to conflicts over behavioral expectations, dominance, territorial, and courtship rituals. Of course, these animal models are only analogs of OCRD. Nearly six million years of primate evolution separate us from our closest relative, the chimpanzee. During that time, humans evolved a much more sophisticated brain that exercises greater cortical regulation of rituals and automatic behavior. From an evolutionary biology perspective, OCRD may represent dysfunctional top-down neocortical regulation. Developing a more expansive understanding, its neurophysiology and neuropharmacology can provide additional insights into OCRD [6, 49, 50, 51].

An understanding of neuroethology can provide insights into how we may adapt current findings in the developmental neuroscience to the broader concepts of diagnoses in terms of hypothesis testing. The neuroethological model has obvious limitations but may provide useful tools for understanding OCRD in individuals with severe developmental disorders.

24.6 Neurophysiological Models: Search for Biomarkers and Endophenotypes

For many years, our understanding of OCD focused almost exclusively on psychoanalytic concepts such as ego dystonic, anxiety disorder, and preserved insight. A major change to this approach began with the Research Diagnostic Criteria and the DSM-III. Since that time, the authors of DSM-5 and then the DM-ID-2 expanded this model in two ways. The first involved creating a separate category (OCRD) and the second was to graft other repetitive behavioral disorders onto anxiety-related OCD. This new category includes disorders of dysfunctional grooming behaviors (body dysmorphic disorder, trichotillomania), aberrant attachment behaviors, working memory deficits, intolerance of change/insistence on sameness (hoarding), and a group of minor self-injurious behaviors (skin picking, nail biting) [6, 40, 44, 45].

OCRD excludes nonsubstance abuse disorders such as gambling, compulsive shopping, sexual behaviors, and Internet use. These behaviors resemble addiction behaviors and other habit-related disorders. They differ from other OC behaviors in terms of clinical semiology, patterns of increased arousal (skin conductance), and regional changes in activation related, functional neuroimaging [47–50]. This group also includes patients with complex tic disorders that may wax and wane in repetitive cycles that are occasionally confused with bipolar disorder [4, 6, 11, 21, 46].

The clinical application of these pathophysiological findings leads us to modify assessment and treatment by specifying a mechanism of action (pathophysiology), identification of particular genetic and physiological features (biomarkers) rather than relying exclusively on syndromal psychiatric disorders (Phenomenological phenotypes). There is growing research interest in dissecting syndromes into component parts, and adding biomarkers with pharmacogenomics to diminish this frustration. In addition, applying both drug-specific pharmacokinetics and pharmacodynamics can assist in designing a more personalized plan of care. Accomplishing this goal requires matching more specific medication regimen-based features such as threshold for arousal, intensity of negative affective states, and level of stress tolerance, impulse dyscontrol, and the degree of sympathetic arousal needed to initiate and sustain avoidance behaviors into the treatment of OCRD [51, 52].

In summary, these subgroups of OCRD represent variations in approach/avoidance, learning models (types of conditioned stimuli), vulnerability to overgeneralization of avoidance behaviors, and the metamorphosis of some goal-directed repetitive behaviors into habits [6, 11, 32]. A comparison between contamination-motivated handwashing and trichotillomania or skin picking reinforces these differences. Close factor analysis reveals not only differences in overt behaviors but also variations in genetic risk factors, functional neuroimaging, relationship to ID/ASD, sensitivity and response to selective serotonin reuptake inhibitors (SSRIs), and efficacy of

CBT-exposure-response prevention/habit-reversal therapies [52, 53]. Differentiating subsets of OCRD in this fashion can result in a treatment plan that more closely matches to individual patient needs.

24.7 The Use of Research Domain and Intermediate Endophenoytypes

The heterogeneity of OCRD, ASD, ID, and ASD/ID creates many problems for assessment and treatment. Most of our existing diagnostic protocols depend on descriptive/phenomenology and do not address issues related to aetiopathogenesis. This section provides brief description of the genetic, neurobiological, neuroimaging, and neuropharmacological underpinnings of neurodevelopmental disorders in clinical/research settings.

The following bullets outline an attempt to pull together some of the many data sets from recent neuroscience. This algorithm may be useful in organizing data:

1. Syncretize the expression of clinical subtypes with temperamental style such as harm avoidance, low novelty seeking, adaptability [2, 6] with the complex social ecology of a family, and social environment. These factors influence the age of recognition, nature and severity of symptoms, predictability of clinical course and treatment response, as well as the entangled biopsychosociology of co-occurring OCRD, ID, and ASD.
2. Address clinical subtypes of OCRD in terms of neuropsychological data. These data focus on conflict and error monitoring; response inhibition; integration and regulation of motor output; task switching and reversal, assessment of risk, coping with uncertainty; reward processing and impaired shifting, inhibition of intrusive thoughts, experiences and urges (input gating), impaired decision-making (require too much evidence to act); working memory issues; and other executive functions. Each of these traits is associated in some way with an OCRD phenotype [18, 27, 28, 33].
3. Apply data from neuroimaging studies that help define anatomical and functional changes in the corticostriate and limbic networks. The patterns observed in OCRD suggest a disconnection between the regulatory functions of the medial prefrontal, orbitofrontal, cingulate, and reward pathways in goal-directed behaviors. The transition from goal or contingency directed to habit formation centers on the role of the caudate in this process [17, 25, 90, 91].
4. Address the role of multiple neuropharmacological systems involved (especially relevant for treatment-resistant cases):
   (a) Neurotransmitters, neuropeptides (oxytocin, vasopressin), glutamate, gamma aminobutyric acid (GABA), and patterns of neuronal firing. These may increase limbic activity that disrupts the normal homeostatic mechanisms linked to top-down regulation of excitatory/inhibitory networks [11, 12, 14, 92].
   (b) The foundation for these dysfunctional circuits arises is associated with aberrant brain interconnections related to several gene polymorphisms that involve serotonin reuptake (serotonin-transporter-linked promoter region; 5HTTPLR) [11, 53, 65, 104].
   (c) Catechol-0-methyltransferase (COMT) and the whole dopamine metabolism in the frontal cortex play an indirect role in both the direct and indirect dopamine systems (fronto-striate, substantia nigari/globus pallidus (exterior and interior), subthalamic and thalamic nuclei, and their interaction with pathways in the limbic system. The latter may be significant in OCRD-related tic disorders [11, 67].
   (d) Brain-derived neurotrophic factor (BDNF) that is involved in neurogenesis, synaptogenesis, neurophysiological changes in the cortical-striatal; amygdala-hippocampal, cingulate and supplemental motor regions that influence generalization, and extinction of conditioned responses. SSRIs may liberate promoters that increase the production of this nerve growth factor.

This may apply for neuropsychological, behavioral, and pathophysiological models for OCRD and ASD/ID. More effective treatment agents may provide an important contribution to new treatment models [27, 32].

24.8 Neuropsychological and Neurobehavioral Models

Although relevant, the author did not expand upon OCRD and ASD/ID as disconnection syndromes. ASD and ID present challenges to early prenatal development, especially the organizational phases of the eventual hierarchical organization of the sensory, processing, and integrative motor activity. These organizational disruptions arise from neurogenesis, synaptogenesis, axonal growth, myelination, and the effects of ongoing environmental events on brain maturation. Many of these events occur during critical periods of brain development and maturation in which external and internal insults disrupt sequential gene-environment interactions. These affect both interactive specialization and emerging cortical interconnections (coherence).

Later many of these gene-environmental interactions influence the ongoing transformation of many repetitive behaviors (including OCRD) from goal-directed compulsive behaviors (e.g., OC behaviors that permit escape from aversive stimuli, reducing overarousal or coping with understimulation) into a group of habitual behaviors that represent automatic responses to specific cues. This group encompasses OC symptom related to tic disorders and addiction-like stereotypic repetitive behaviors (severe self-injurious behaviors (SIB) and milder forms of impulsive control disorders). These habit disorders are not directly involved with activation of reward pathways [7, 14, 17, 25]. This group differs from OCD/anxiety-driven disorders in several ways. These include treatment responses to SSRIs and cognitive behavior therapy-exposure and response prevention therapy (CBT-ERP), and greater clinical improvement with habit-reversal therapy (HRT) and augmented pharmacotherapies [2, 21].

Other sequential transformations enhance generalization of cue-stimuli (defective pattern separation) and limit extinction learning as a means of overriding these conditioned behaviors. As in kindling studies in induced seizure activity, repeated activation of these pathways influences long-term potentiation (LTP) and depression (LTD). Glutamate evolved as a key player in synaptic spine changes involved in laying down new learning and memory formation. Extinction also involves new learning in the medial prefrontal regions that help override previous dysfunctional conditioned experiences [32, 58, 61, 62, 64, 72]. The role of glutamate in resistant OCRD is an important step in our understating of ASD, OCD-related disorders, and disorders in which extinction and generalization are major players. Unfortunately, many treatment protocols that address the imbalance between excitatory and inhibitory circuits (dopamine, GABA, and glutamate) are not as helpful as anticipated. This small step opens the doorway for a new array of potential pharmacological treatment approaches. The increased use of repetitive transcranial magnetic stimulation (rTMS) and direct current stimulation protocols may prove helpful. The use of opioid antagonists, partial agonists for glutamate, n-acetyl cysteine, oxytocin, and other neuropeptides may have indirect benefit, especially by restoring homeostasis in excitatory/inhibitory dysfunction and facilitating synaptic plasticity necessary for extinction learning and memory [6, 11, 67, 72].

The relationship between brain dysfunction, neurodevelopment, and psychiatric disorders is a complex process that evolves during childhood. The concept of endophenotypes involves looking for core traits that co-occur with many other behavioral/psychiatric disorders. The application of endophenotypes can narrow the heterogeneity gap while at the same time leads clinicians to consider psychiatric and neurodevelopmental disorders as complex genetic disorders. These complex phenotypes appear to represent final common pathways involving multiple genetic and neurobiological factors (endophenotypes).

The overlap between the syndromes suggests that a high degree transdiagnostic relatedness may partly explain the relatively low rates of remission in many current treatments.

24.9 Gaps Between Diagnosis and Treatment Planning

We will review three approaches to the treatment of OCRD in patients with ID and ASD. These basic therapies are psychopharmacological, behavioral, and neuromodulation therapies. Behavioral, cognitive-behavioral, habit-reversal, and pharmacotherapies are more familiar to most clinicians. Neuromodulation therapies include deep brain stimulation, transcranial direct current and magnetic stimulation, and neurosurgical tractotomies. Intervention studies remind clinicians that treatment response rates for most therapies hover around 60–70%, whereas remission rates are in 30% range. Among the incomplete nonresponders, 20% have partial or marginal improvement whereas around 10% continue to worsen. We need novel approaches to close this treatment-nonresponse gap. Currently our best tools are polypharmacy (augmentation strategies), combinations of pharmacological and behavioral therapies interventions, alternative therapies/neuromodulation, and combinations of all three. Unfortunately, the response rates to combined therapies are not dramatically better than monotherapies [8, 16, 19, 37].

Until recently, demonstrating treatment nonresponse was the best way to access neuromodulation therapies. As a result, it is not surprising, however, that a significant number of patients also fail these new treatments. For a select few, deep brain stimulation (DBS; stereoscopic implantations of electrodes) and tractotomies (sectioning key circuits) are useful neurosurgical interventions. Although effective in many cases, these procedures carry significant risks for adverse neurosurgical outcomes [55]. Unfortunately, few patients with ASD or ID receive these neuromodulatory treatments.

As alluded earlier, the treatment approaches to subtypes of OCRD differ based on the following:

1. The presence of anxiety-related with obsessions-compulsions versus habit-related, nonanxiety forms of repetitive behaviors.
2. OC behaviors associated with tic disorders.
3. Secondary OC behaviors related to neurobiological, genetic, metabolic, and neurological disorders.
4. Comorbidity with ADHD (hyperactivity, impulsivity), presence of chronic pain, level of ID, and the presence of other neuropsychiatric disorders.

Each of these subtypes differs in terms of their sensitivity to available therapies. For example, the response rates of CBT-ERP vary based on severity of OC symptoms, co-occurrence with neurodevelopmental disorders like ID, age of onset, and the presence of comorbid major depressive/anxiety disorder and schizophrenia spectrum disorders [52]. Anxiety-related OCRD are most responsive to SSRIs and CBT-ERP. Neuromodulation therapies appear more for patients with complicated OCRD. Nevertheless, there is a rub. The improvement in OCRD relates to improvement in depressive disorders rather than selective benefits for repetitive thoughts and behaviors. Patients with OCRD plus Tourette syndrome are less likely to benefit from SSRIs and/or CBT-ERP but more likely to improve with neuromodulation, neuroleptic/benzodiazepine/SSRIs combinations and habit-reversal therapy (HRT) [35, 52, 55]. The Tic-related group also creates diagnostic problems due to their confusing mixture of sensory and premonitory tics and differentiating involuntary from voluntary movements.

There is gender difference in phenotypic expression of both OCRD and tic disorders. Perhaps the most confusing findings arise from population genetics studies, which demonstrate evidence for a greater level of genetic loading among symptomatic females with TD, but also a female gender bias toward phenotypic expression of OCD rather than tics. The presence of both OC behaviors and Tourette's

disorder appears to represent a more severe form of both disorders regardless of gender. Modifications in treatment are also frequently necessary, but there are limited data about gender differences in response to specific therapies [6, 11, 12, 21]. The prevalence rates of tic disorders tend to be much higher in ASD and ID patients than in neurotypicals [6, 11]. As in other neurodevelopmental disorders, there tends to be a male bias toward ASD without ID, TD, and tic-related compulsions. Each may bias the treatment of OCRD toward combination therapies.

High rates of repetitive behavior such as self-injurious behaviors in patients with ASD occur in the presence of ADHD-like overactivity/impulse dyscontrol. Other factors include the relationship of self-injurious behaviors (SIB), ASD, presence of severe ID, and severity of repetitive-restrictive behaviors. In patients with severe ASD/ID, medical issues (pain) and gastrointestinal distress also increase rates of SIB. This population is less well studied, but it remains uncertain if HRT or CBT-ERP are truly ineffective or is there a selection bias toward behavioral modification techniques or pharmacotherapies overshadow consideration of these therapies. Current data suggest that their cognitive demands pose a barrier to even modified therapies [6, 10].

A second source of diagnostic relates to uncertainties in differential diagnosis. Relative absence of insight and the intrusive nature of aversive images, urges, and emotional/affective states suggest the presence of OCRD + tics. However, by adulthood, tics may no longer be observable or confused with tardive dyskinesia or masked by long-term use of neuroleptic. Many complications are the result of the widespread use of second- and third-generation neuroleptics for aggressive behavior, rage outbursts, property destruction, and SIB. In addition, the presence of trauma-related alterations in stress-response networks and the entanglement of ASD, severe ID, and tics + hyperactivity/impulsivity confound the clinician trying to differentiate OCRD from other forms of repetitive and self-injurious behavior. Each of these conditions can accentuate surges in these target symptoms during periods of psychosocial stress (an example of baseline exaggeration; for a description of the concept of baseline exaggeration see ▶ Chap. 5) [6, 10, 55–58]. In this context, matching treatment options with data from a behavioral analysis or detailed diagnostic workup and diagnosis can be a very challenging task [57, 58].

Additional problems arise with the inclusion of skin picking (e.g., Prader-Willi syndrome), body dysmorphic disorder (with SIB), hoarding (in ASD), trichotillomania (high-frequency/low-intensity, mild SIB), or partial expression of OCRD (specified and unspecified OCRD). Many of these behaviors resemble nonsyndromal self-injury, self-stimulation, and repetitive behaviors associated with ASD and ID [1, 2, 6, 59]. Perhaps the best sources of data are a psychiatric assessment and comprehensive functional behavioral analyses combined with the use of standardized rating instruments. The functional behavioral analysis addresses setting events, antecedents, operationalized description of repetitive behaviors, and a sense of what trigger and maintain these challenging behaviors. There are drawbacks. Most relate to difficulties integrating these divergent treatment models into a comprehensive and coherent intervention.

In summary, diagnoses are hypotheses based on "symptoms" and findings from various examinations [11, 60]. However, OCRD is a complex group of disorders with a wide range of behavioral manifestations. It is also comorbid with other behavioral and psychiatric disorders. Yet connecting the dots between psychiatric assessment and behavioral data can be a challenge. Although discussed elsewhere in this chapter, ethological data can be very helpful at this point. This ethological approach adds social or group observational data to the assessment. For many patients with severe ID/ASD, behaviors are the means of communicating distress, expressing emotional states, dealing with disrupted attachments, and even territorial or dominance issues within stable social groups. Unfortunately, systematic ethological assessment is not a routine part of most evaluations. In the future, clinicians may combine ethological data with information about tempera-

ment variability, specific biologic markers, and available biomarkers for social behavior to enhance treatment planning, implementation, and monitoring [6, 50].

24.10 Cognitive-Behavioral, Exposure-Response Prevention, and Habit-Reversal Therapies

The introduction of cognitive behavioral, exposure-response prevention, and habit-reversal therapies revolutionized the psychotherapy of OCRD. In many clinical settings, CBT-ERP is a frontline treatment choice based on high rates of clinical improvement and a low risk of adverse effects [2, 4, 15, 105]. CBT addresses the top-down regulation of automatic thoughts that serve as setting events and limit potentially effective solutions. The basic technique focuses on overriding and replacing these automatic thoughts and the anxiety associated with new forms of thinking and behaving. The patient rehearses and then challenges the cognitive distortions (inaccurate risk assessment) and substitutes more adaptive cognitions and behaviors, as well as means of defusing and de-catastrophizing uncertainty rather than simply avoiding anxiety. CBT relies upon the integrity of frontal and cortical networks that regulate subcortical and limbic input in a top-down fashion. The role of language and thought process in behavioral regulation is to override associatively conditioned automatic linking of negative affective states to previously neutral experiences [3, 5, 64, 65].

ERP on the other hand focuses on the extinction of chains of these conditioned responses [2, 80, 90]. The basic components of ERP arise from a mixture of associative and instrumental learning. The mechanics of ERP involve breaking the linkages between unconditioned (aversive or distressing affective state) and generalizable conditioned stimuli (CS-neutral stimuli) that trigger a pattern of escape/avoidance behaviors (compulsions) that provide temporary relief. OCD represents a narrow group of triggers and repetitive behaviors. For example, performing a handwashing ritual (specific compulsive behavior) provides temporary relief from anxiety-provoking stimuli (dirt and fear of contamination) [8, 52].

The therapeutic technique of CBT-ERP focuses on a form of exposure based on a graduated schedule of affective intensity associated with systematic desensitization. This process includes hierarchically organizing threat cues or context-specific antecedents; then preventing the overlearned pattern of responding. OCD has a limited number of categories (doubt/checking; contamination/cleaning), whereas the "related disorders" have a broader sweep of triggers and symptoms. The ERP therapist tries to help regulate setting events (anxiety or threat level) and establish some degree of stimulus control. Once these techniques are in place, the therapist gradually increases the intensity of the exposure phase while desensitizing the patient to graduated levels of uncertainty and anxiety [52, 62, 66, 80, 90].

In some treatment-resistant patients, the combination of psychotropic medications with CBT-ERP provides additional therapeutic benefit. Combined therapy is useful for response maintenance, although many patients are able to tolerate a reduction and possible discontinuation of their psychotropic medications. Ongoing CBT-ERP can also be an effective relapse prevention technique. Thus far, adapted forms of CBT-ERP are effective for selected patients with mild ID/ASD but uncertainties about the risk of relapse, value of booster sessions, or the continued benefit over time remain [8, 16, 52].

Nevertheless, CBT-ERP is not a panacea. Data suggest that nearly 30% of patients do not achieve long-term positive outcomes. Remission is less frequent. CBT-ERP is constantly readapting to cope with treatment nonresponders. One approach addresses the differences between focuses on "in therapy" versus "out of therapy" responses working on the patient's compulsive use of exposure and response prevention but never focusing on the underlying anxieties associated with uncertainty and unpredictability [80, 90]. Interestingly, these response data are similar

outcomes for pharmacotherapy, but they may not represent the same 30% [2, 66]. Many of the same negative outcome predictors apply to both treatments, but neuroimaging suggest that there may be biological differences among CBT-ERP nonresponders. These include early onset OCD (children under age 10), chronic, severe OCD, high rates of psychiatric comorbidity (including tic disorders), significant psychosocial/family dysfunction, and in some impulsive/compulsive behaviors, habitual behaviors, and fronto-striatal disconnections that resemble some addiction-like behaviors [52, 63]. Other markers for nonresponse include comorbid psychiatric and neuropsychiatric conditions, poor insight, greater symptom severity, and specific clinical subtypes of OCRD (hoarding, sexual and religious preoccupation, and in some cases co-occurring tic and other movement disorders) [2, 8, 16, 52].

Habits, addiction, and tic-related repetitive subtypes are generally more resistant to CBT-ERP. Many of these patients do not respond to with anxiety but struggle instead with urges or intrusive images that crescendo until satisfied (or feel right). There are also differences in the typology of their repetitive behaviors, patterns of neuropsychological deficits, and basic neurobiology/neuropharmacology. This group is also more etiologically diverse. The focus of HRT is on recognition of the motivational factors associated with tic-related, compulsive behaviors combined with attempts to find alternative activities that may relieve the urges associated with tics and socially unacceptable behaviors [2, 10, 22, 58, 62].

At a deeper level, nonresponse to CBT-ERP parallels unsuccessful pharmacotherapies. Combined CBT-ERP and SSRIs may compensate for incomplete changes in neurophysiology and imbalanced excitatory/inhibitory brain functions. Functional neuroimaging (fMRI) suggests a failure to override a metabolically hyperactive caudate and medial prefrontal cortex. Correcting these faulty circuits may aid in behavioral and extinction protocols. Our understanding of the regulation of neuroplasticity is limited, but the role of several polymorphisms of the genes that regulate the production of brain-derived nerve growth factor, FMR1 protein, and metabotropic glutamate receptors and micro-RNA control of synaptic protein transcription are offering tantalizing clues for possible pharmacological interventions in this process. These may alter the course of learning, extinction, and deficits in neuroplasticity associated with OCRD and other neurodevelopmental disorders such as ID and ASD. Integrating these with CBT-ERP and HRT may be a useful strategy in patients with early-onset, chronic, and recurring OCRD [62–68].

CBT-ERP and HRT require modifications for patients with ASD or ID. There is little evidence that these techniques are applicable for patients with severe-to-profound ID. Children with ASD and ID are more vulnerable to the effects of trauma-related stresses (toxic childhood) and ongoing family dysfunction on psychopathology. Disentangling the effects of dysfunctional, family system dynamics on epigenetic changes is a subject of intense interest. Reversing these changes may require manipulating epigenetic tools (acetylation, blocking de-acetylation, blocking methylation, and enhancing the methylation to reverse some of the damage done during critical periods in development and restore neuroplasticity) [35, 58, 62, 64, 65, 68].

> The use of manualized behavioral psychotherapies is a very effective intervention for OCRD. For many patients, these interventions are better tolerated and more effective that other biological interventions. The do require some modifications for individuals with ASD and ID.

24.11 Psychopharmacology

This discussion will shy away from dealing with specific drugs, doses, variability in metabolism, or a restatement of evidenced evidence-based data on efficacy. Instead, the emphasis is on patterns of response-partial response, nonresponse, and or continued worsening in spite of our best efforts. The philosophy behind this approach centers on the premise that in an era of evidenced-based medicine, we may be able to learn more about

OCRD among patients with ASD/ID from nonresponders than from responders. This decision, in part, was an outgrowth of an observation that the psychopharmacological treatment of OCRD appears in a state of flux as several new trends are emerging. The use of pharmacogenomic profiles is one of these. There are multiple cytochrome P450 polymorphisms that influence drug metabolism. Some psychotropics are metabolized by multiple P450 pathways, glucouronidases, enolases, or are renally excreted largely unchanged. In addition to these enzymatic steps, the degree of protein binding, p-glycoprotein impact on the blood brain and cellular extrusion also influence pharmacokinetic variability [2, 32, 37].

Additional pharmacogenomic studies focus on pharmacodynamics, mostly mechanism of action and what drugs actually do within the cell. Ironically in recent years, there is growing interest not just on neurons, but drug effects on astrocytes, microglia (inflammatory peptides), local rRNA translation, and gene expression [32, 46]. Additional studies focus on differences on second and third messenger networks, differences between specific neurotransmitter or channel sites (ionotropic or metabotropic receptors), autoreceptor modulations, allosteric modulation, intracellular effects on calcium release and activity, phosphoinositol pathways, and gene activation that underlie drug response. These downstream effects constitute elements of the pharmacodynamics of various classes of psychotropics [32, 46].

Recent evidence suggests that OCRD shares at least some neurobiological, neuropsychological, neurophysiological, and genetic markers with a larger group of spectrum of clinical phenotypes. These include ADHD, ASD, ID, and tic disorders [2, 12, 32, 56, 67]. It can be difficult to disentangle these relationships based solely on descriptive/categorical phenomenology. For example, OCRD comprises at least five subgroups: anxiety-related OCD, nonanxiety-related compulsive behaviors, OC behaviors with tics, addiction-like behaviors, and OC behaviors related to other medical, neurological, metabolic, and neurodegenerative disorders [20, 42, 43, 67].

Although psychotropic drugs can influence the neurobiology of developmental disorders at many levels, mental health clinicians and psychopharmacologists tend to focus on diagnosing and treating syndromes (psychiatric disorders). The measurement of treatment response is largely based on symptomatic improvement. In this chapter, we face a different set of needs. As clinicians, we focus on a broad spectrum of repetitive behaviors and OCRD and monitor changes in these states. However, even our most effective treatments do not eliminate ASD or ID. Most controlled studies compare treatment with nontreatment (placebo). Lest we forget, ASD and ID consist of multiple subtypes. Perhaps it would be more useful to compare changes in specific temperamental or neurophysiological states in patients with ASD or ID with and without OCRD (control population). But even this level of analysis leaves us to cope with a heterogeneous sample. ASD and ID are complex genetic disorders with both Mendelian and polygenic patterns of inheritance and multiple etiologies. The most reasonable approach may be to accept that at this point we cannot eliminate the effects of ASD or ID on OCRD, but we can narrow our focus and address shared biomarkers and combine phenomenological and neurobiological endophenotypes [32, 50, 70].

One example of such an approach involves addressing the effects of psychotropic drugs on observable phenomena like temperament differences in neurophysiological arousal, behavioral inhibition, harm avoidance, neuroticism and new neuropharmacological studies of fear/anxiety conditioning, sensitization, generalization, and resistance to extinction learning. Each of these traits may help tease out a specific treatment approach to the different subgroups of OCRD. This is a slightly more refined treatment model than just focusing on OCRD. This approach is a step toward a behavioral pharmacology of intermediate endophenotypes rather than focusing treatment exclusively on DSM-5/DM-ID-2 diagnostic categories [16, 70, 75].

More powerful functional neuroimaging and electrophysiological tools are slowly exposing drug-induced changes in specific

neuronal ensembles, sensory processing networks, and downstream effects associated with default mode, selective attention, and the interconnections between innumerable brain networks (coherence). These new developments shed additional light on aberrant cognitions and behaviors associated with ASD/ID and are likely to influence the course of research on future treatments for OCRD.

At a deeper level, such analyses define differences in temperamental vulnerabilities such as threshold intensity and extent of fear/anxiety conditioning, excessive generalization, and deficits in extinction. These intermediate endophenotypes arise from underlying developmental neurobiological, neurophysiological, differences in functional neuroimaging, and behavioral neuropharmacological strata. The most complicated step in this process may be addressing the role of biomarkers shared by subgroups of patients with OCRD and subtypes of ASD/ID. This would be a step in the direction of more personalized care, but unfortunately, we must leave most of these complex issues unexplored and definitely unresolved.

Realistically this level of analysis is beyond the scope of practice for most practitioners. We rely on evidenced-based studies or best practices models to provide guidance and reassurance. Unfortunately, many of our current evidenced-based treatments do not require this level of data-driven diagnostic precision. Many of our current psychotropics were developed to affect a relatively small collection of neurotransmitter systems. The mechanism of action generally includes reuptake blockade to increase neurotransmitter bioavailability. More recently, an expanded understanding of their mechanisms of action includes up/down regulation of autoreceptors, and postsynaptic receptors, allosteric modulation by means of neuropeptides, nitric oxide (NO)/carbon monoxide (CO), and cytokine activity. On the horizon, there are immune modulators, anti-inflammatory biologicals, and treatments designed to modulate or reverse epigenetic changes; metabotropic glutamate receptors that help regulate local protein transcription [53, 60, 65].

Most clinicians successfully grapple with the pharmacological treatment of OCRD at the syndromal level with or without comorbidities. For the most part, these pharmacological strategies are effective for a large number of patients. Many patients are resistant to available evidence-based and best practices treatment recommendations. The underresponding patients either only partially respond, or worsen in spite of treatment. This effectiveness gap in neurotypical populations suggests the need to look nonresponders at different perspectives. This strategy is especially true for patients with OCRD+ ASD+ ID. For example, many clinic referrals are not limited to primary OCRD [69, 71, 76, 77]. Most patients present with coexisting static encephalopathy, epilepsy, or medical conditions that influence their mental health. The process of teasing out OCRD is not always straightforward. For many, side effects from medical treatments can exacerbate baseline repetitive or OC behaviors. Resolving these usually requires close collaboration with medical colleagues in an attempt to avoid misattributing these changes in symptoms to ineffective treatment of OCRD. In other situations, the OCRD is misdiagnosed and the decision to treat with an SSRI and/or a neuroleptic may increase the likelihood of treatment nonresponse, or worsening of the original, presenting symptoms [2, 6, 11, 21, 29].

Is improvement with SSRIs related to a specific anti-obsessional effect or a reduction in comorbid anxiety or depression or adverse effects from antipsychotics, mood stabilizers, or SSRI dosing patterns? We could answer "yes" to each. Comparison studies of pharmacotherapies suggest interesting differences between antidepressant and anti-OCRD effects. These differences include a longer latency of treatment response in OCD; higher dosing needs for OCD; different responses to tryptophan depletion; and a more selective response to SSRIs than to noradrenergic specific tricyclic antidepressants. The tricyclic clomipramine is effective for OCD (stronger serotonin reuptake inhibition) but its metabolite is not (inhibits norepinephrine reuptake). The data about the relationship between OCRD and depression, bipolar disorder, and schizophrenia are equally nuanced and warrant close attention [6, 12, 14, 41].

Many prescribers do not factor in the prolonged latency of response or dosing needs for patients with OCRD who also have ASD/ID. This problem has two faces: the dosing requirements for OCRD and the heightened sensitivities to side effects among patients with ASD/ID. The latter problem relates to the complex neuropharmacology and apparent pharmacodynamic variability associated with ASD and ID. In addition, SSRIs do more than block serotonin reuptake. They display a prolonged latency of response that is due in part to a delayed effect on brain-derived neurotrophic factor synthesis, release and activation, related effects on synaptic plasticity, receptor up/down regulation, reduction in cytokines and inflammatory peptides, and increased neuro-steroid activity. Many of these complex biological responses are not specific to OCRD, but may represent shared traits with other mood-anxiety disorders, as well as temperamental traits like irritability, pain responses and some forms of affective aggression. These multiple pathways are sensitive to SSRIs/selective norepinephrine reuptake inhibitors (SNRIs) and support the generalilzed nature of SSRIs response [34, 51, 53, 69, 70, 106].

A third factor involves a complex response to tryptophan depletion (lowering serotonin levels). The effects are most dramatic in patients who are SSRIs responders. Patient response to serotonin-depletion differs between patients with major depression, ASD, and anxiety-related OCRD. Those with OCD require months to relapse if at all. Patients with depression experience a rapid downturn in mood and hedonic drive. Those with ASD also experience a rapid increase in irritability and other challenging behaviors. This pattern of serotonin effects suggests that ASD and mood disorders are sensitive to this technique while patients with anxiety-related OCRD are not. It may also indicate a subtle difference between OCD (anxiety disorder) and the other subtypes of OCRD that may be relevant to treatment response. The symptoms that seem most resistant to SSRIs include a need for symmetry, arranging, organizing, and counting with obsessions or overt anxiety. Many of the compulsive behavior resemble complex tics and some symptoms of ASD [37, 69, 71, 75, 76].

Many patients with OCRD remain are at increased risk for developing other psychiatric disorders [20–22, 32]. Many also present with early-onset OCRD and co-occurring ADHD-like symptoms. For these patients, SSRIs can be less than optimal. For children with OCRD, minor tics, and ADHD, many clinicians avoid the use of stimulants due to uncertainties about the safety of stimulants, the risk of "causing" or exacerbating tics, or worsening repetitive behaviors. These worries may be unfounded for many patients, but multiple alternatives are available [2, 21]. These include alpha agonists, N-acetyl cysteine, omega-3 fatty acids, second-generation antipsychotic drugs plus SSRIs, and stimulants for younger children. Older children and adolescents are treated with SSRIs/SNRIs and, if necessary, adjunctive buspirone, benzodiazepines (clonazepam in particular), and, in recent years, partial glutamate agonists, antagonists, anti-inflammatory agents, probiotics, and neuromodulation [2, 6, 11, 21].

The response to alternative SSRIs, SNRIs, and clomipramine is more variable in the population with coexisting tic disorders. This group may require augmentation in order to better stabilize their obsessive-compulsive features. The need for augmentation with first- or second-generation antipsychotic drugs, clonazepam, and in some cases N-acetyl cysteine suggests that the relationship between serotonin, dopamine, excitatory amino acids (glutamate), and other neurotransmitter networks is far more complex than originally proposed. Older studies suggest differences in cerebrospinal fluid (CSF) levels of vasopressin and males with tic disorders and oxytocin in females with OCD. The broad range of targets for these two hormones suggests a more complex problem [12, 32]. In addition, some patients worsen on naltrexone, whereas those with related symptoms (trichotillomania) may improve. Cannabinoids may improve tics but have little or no benefit for OCRD. In the

last 10 years, the introduction of glutamate antagonists, opiate antagonists, both benzodiazepine type A and B receptor agonists, N-acetylcysteine, and inositol have demonstrated limited efficacy [32, 51, 53].

Of course, the heterogeneity of ASD and ID challenges the validity of this pharmacological model for OCRD. Many patients are receiving complex multidrug regimens that target OCRD, but on closer inspection, they do not meet the diagnostic criteria for OCRD. In addition, many of these patients have their repetitive-restrictive behaviors (rituals, stereotypies and self-injury) misattributed to OCRD. This challenge is particularly difficult in patients with severe ASD/ID. There is a tendency to label repetitive behaviors as treatment-resistant OCRD rather than focusing on the presence of co-occurring tic, neurogenetic, and other neuropsychiatric disorders [37, 69, 71].

As noted earlier, many patients will experience symptoms of OCRD for years before seeking treatment. The emergence of depression, however, prompts the decision to seek treatment [2, 6]. In many, the successful treatment of depressive symptoms leads to an improvement in OC symptoms but usually not remission. As we shall see later, studies of neuromodulatory treatments suggest that their antidepressant effects may actually mediate their positive effects on treatment-resistant OCRD.

Tip

Neuropharmacology involves genetics (pharmacogenetics), complex mechanisms of action (pharmacodynamics), and modifications of multiple neuronal systems that are more complex than simple drug effects on specific neurotransmitters. Treatment response involves many biopsychosocial factors as well. The entanglement between neuropharmacological and biopsychosocial factors are major contributors to clinically observed low remission rates and high rates of treatment unresponsiveness.

24.12 Rationale for Combined Therapies

There is ample clinical evidence that SSRIs are helpful for 60–70% of individuals with OCRD. The remaining 30–40% points to several gaps in our treatment models [37, 69, 71]. Treatment response depends upon an appropriate dose and sufficient patience to endure the long latency of treatment response. This type of nonresponse is frequently due to disregarding these caveats. However, nonresponse is also traceable to pharmacokinetic differences in rate of absorption and the functional dynamics of presynaptic drug transport receptors (5-HT transporter protein).

Pharmacogenomic studies suggest that variability in drug response is also due to the gene effects on the regulation of postsynaptic receptor activity, intracellular activity such as effects on second messenger systems, and gene regulation of neuroplastic changes and neuronal interconnectivity [6, 28, 73–75, 77]. In addition, we may focus our attention solely on serotonin and overlook the fact that it may not be the only neurotransmitter involved. There are multiple systems interfacing the dysregulated serotonin system we observe clinically such as dopaminergic, glutamatergic, neuropeptidergic, neuroendocrine, neuroimmune (anti-neuronal antibodies) and inflammatory (cytokine), and diffusible neuromodulators. It turns out that the bigger challenges may be determining which interface is involved, matching a particular interface with our OCRD subtypes, and then describing how ASD/ID influences both [3, 6, 16, 51, 74, 77].

In neurotypical patients, treatment resistance in OCRD relates to the presence of comorbid tic disorders [21, 77]; co-occurring impulse control disorders and addiction behaviors [1, 4]; trauma-related, mood and anxiety disorders; and other neuropsychiatric disorders. These insights may not clearly apply to OCRD co-occurring with ASD, ID, and ASD+ID. All too frequently, we lump these heterogeneous phenotypes and not dissect ASD or ID into its many subtypes. For example, clinicians may have difficulty differ-

entiating OC behaviors from complex rituals, stereotypies, self- injury, and other repetitive behaviors associated with ASD and ID [53, 75, 78]. The limited effectiveness of pharmacotherapy is frequently the result of mismatching psychotropic drug to problem behavior. A second problem area is due to a lower threshold for troublesome side effects. For example, akathisia is a sense of inner restlessness and dysphoria that accompany a dysphoric affective state that can exacerbate insomnia, stereotypies, aggression, self-injury, and other psychiatric symptoms. It is generally associated with antipsychotic-related extrapyramidal side effects but can also occur in response to higher doses of SSRIs. Unless clearly recognized and appropriately treated, akathisia becomes a contributor to high dose polypharmacy [69, 71].

Other medical conditions are frequently associated with OCRD and other disorders of repetitive behavior. This list is a familiar one in this chapter and includes a variety of medical/neurological disorders and trauma and stress-related disorders. OC-like symptoms in these cases may not respond to standard anti-OCRD treatments. Polypharmacy may also contribute to delirium and further complicate treatment [32, 37, 55, 59, 67, 79].

In keeping with the philosophy of this chapter, adopting a behavioral pharmacological approach can help focus the assessment on the search for a neuropharmacological basis for the intermediate endophenotypes of temperament. This approach is also a step towards linking sympathetic/parasympathetic imbalance, and disruption of excitatory/inhibitory networks with the neuropharmacological foundations of learning theory. This linkage appears to underlie not only conditioned response but also their generalization of conditioned stimuli-response learning, neuroplastic changes associated with sensitization of specific experiences, and the stability of memory storage and retrieval of this information. Each of these phenomena contribute to the extinction of maladaptive conditioned learning and the capacity for new learning of alternative patterns of behavior [6, 46, 64, 66, 77]. These techniques would match temperamental traits routinely with selective or combined pharmacotherapy and behavioral or CBT-ERP [5, 17, 28, 80, 81]. One intriguing strategy involves pretherapy treatment with glutamate partial agonist (d-cycloserine) to enhance memory during extinction training [2, 6, 18, 25, 26, 32]. The combination of novel pharmacotherapies for addictions with habit-reversal therapy depends on a different set of neuropsychopharmacological and behavioral strategies. Many of these interventions are useful in the treatment of chronic substance use disorders. But neither augmentation strategies are panaceas. They do however open the doorway to novel treatment ideas and future research [52, 63].

In summary, the definition of treatment resistance remains a fluid one. In recent years, combination therapies and nonpharmacological interventions are gaining ground.

This is especially true in light of the 30% of patients who may fail combined pharmacotherapy and cognitive-behavioral, exposure-response/habit-reversal therapies. There is growing evidence from functional neuroimaging to suggest not only brain changes arising from psychotherapies that overlap drug effects. These studies also demonstrate that CBT-ERP/HRT nonresponders fail to show similar reversals in the Caudate/ventral orbitofrontal cortex dysfunctional activity [21, 22, 32, 52, 55, 62]. For some nonresponders, there is growing use of neuromodulation (transcranial magnetic and electrical stimulation), deep brain stimulations, and neurosurgical interventions for severe, treatment refractory OCRD [25, 54].

There are many factors related to incomplete treatment response to standard psychotherapies and pharmacotherapies. Keep in mind that response takes proper dosing, sufficient time, and methods of monitoring clinical response. In some situations, treatment augmentation and combined psychotherapies can be helpful.

24.13 Neuromodulation and Neurophysiology

Neurobiological research into OCRD consistently points to dysfunctional connections between supplemental motor, medial prefron-

tal; orbitofrontal, caudate dorsal and ventral striatum, putamen, globus pallidus, subthalamic nucleus, thalamus, greater amygdala and hippocampus, and temporal-parietal association cortices [11, 14, 25, 54, 82, 83].

The behavioral expression of functional neuroanatomical connections is influenced by co-occurring ASD and other neurodevelopmental disorders, Tourette syndrome, schizophrenia spectrum, mood, ID, and most neuropsychiatric disorders. Our ability to measure brain activity with neurophysiological probes, magneto-encephalography (MEG), and diffusion tensor imaging (white matter tracts) allows researchers and clinicians to better define the relationship with higher cortical functions. Functional neuroimaging adds to our capacity to study both resting and activation states. These studies expand our knowledge base in areas such as a lack of coherence between functional circuits, dysregulation of default mode cognition, attention and sensory processing and integration, and cognitive-behavioral processing and motor expression [2, 6, 15, 36, 58, 84, 93].

Transcranial direct current stimulation and transcranial magnetic stimulation are noninvasive technologies that use electromagnetic current and fields to not only mapping neuronal activity within these circuits but as effective treatment strategy for mood disorders and anxiety disorders [25, 26, 54]. Transcranial direct current stimulation (tDCS) delivers a low-intensity electrical current that influences both immediate and distant neuronal activity. It affects the interconnections within and between neuronal populations. tDCS may influence the synchronous firing rates of neurons within a circuit. There are short- and long-range effects that may induce neuroplastic changes over time [54, 89].

The treatment effects on the neurophysiology of brain functioning with seizure induction (ECT) and without (tDCS) suggest that tDCS may become a reliable treatment for disorders like OCRD, and perhaps augmentation of other interventions for patients with ASD and other neurodevelopmental disorders [24, 36, 46, 58, 68, 81, 85, 107].

TMS uses magnetic fields to alter regional cortical activity. Low frequency (1–2 Hz) stimulation has an inhibitory effect on overexcited neuronal activity. These changes raise the threshold for activation of various neuronal pathways and reduce their rates of firing. Higher frequencies (10 Hz) may stimulate similar pathways, especially those in the premotor cortex. The clinical effects of both may depend on lateralization, selection of neuroanatomical sites, nature of the circuits under study, and the relationship between over and reduced activity on the circuits involved [84, 85, 86].

For rTMS, lower frequency probes provide additional information about thalamocortical and corticostriatal and limbic regulation. Many of these inputs are excitatory but they synapse onto inhibitory subcortical substrates and fine-tune sensory gating, attention, emotional perception, and responses, prepotent responses. OCRD, tic disorders, traumatic experiences, and primary psychiatric disorders result from various disconnections within these circuits. The high-low frequency probes are useful for regional mapping studies as well as treatment of mood/anxiety and tic disorders, and reduce auditory hallucinations in some patients with treatment refractory schizophrenia [54, 84, 85, 86, 108]. tDCS may influence the synchronous firing rates of neurons within a circuit. There are short- and long-range effects that may induce neuroplastic changes over time [54, 89].

Deep brain stimulation (DBS) involves neurosurgical implantation of electrodes that deliver programmed electrical activity directly within fronto-striatal networks. Although DBS is frequently more effective for treatment refractory OCRD, it does carry surgical risks [82, 87]. Currently clinical research suggests that electrode place in the brain circuits connecting the ventral striatum, palladium, and corticostriate pathways. The exact mechanism of action for DBS remains unsettled, but in all likelihood, it influences the imbalance between excitatory and inhibitory activity in several corticostriate pathways. For many patients, ablation neurosurgical intervention can be most effective when directed toward disconnecting dysfunctional circuits between the ventral basal ganglia, limbic, and other cortical regions [54, 85, 86, 87, 88, 89].

However, there are limitations to these strategies. The risk treatment refractory OCRD emerges in context of comorbid mood/anxiety disorders, early age of onset, chronic illness, comorbid tics, ASD/ID and other neurodevelopmental disorders. Some of these can decrease the efficacy of rTMS [16, 26, 37]. For example, ECT can be an extremely effective treatment for severe depression but has little or no efficacy for patients with OCRD. The response rates for ECT, however, vary relative to the number of previously unsuccessful medication trials. This also may apply to rTMS and suggests a change in the neurophysiology of depression with repeated episodes, early onset, and long duration of the disorder.

Nevertheless, rTMS does have a positive effect on depression—especially newer strategies that combine high and low frequencies to reflect bifrontal activation. Improvement in OCRD may be indirect, reminding clinicians that many demoralized patients with refractory OCRD go on to develop depressive disorders. rTMS may have a direct effect on mood and an indirect one on the level of functional impairment in which many patients feel less overwhelmed by their OCD. The problem of comorbidity means that we still must disentangle the positive effects of rTMS and ECT on comorbid mood and anxiety disorders from their effects on OCRD [35, 36, 46, 54, 82, 84, 92].

To date it is unclear if tDCS or DBS differs in this regard. This may require additional studies about age of onset, duration of symptoms, and past treatment failures; alternative placement arrays, combination of high and low frequencies for direct current and magnetic field probes, or more research into better electromagnetic access to critical nodes within and between these complex circuitries [19, 37, 53, 65].

Unfortunately, patients with treatment-resistant OCRD, ASD, and ID are not participants in many of these studies. In ASD, the aberrant functional neuroanatomical and imbalanced neurophysiological-neuropharmacological networks relate to a risk increase of stereotypies, rituals, and other repetitive and restrictive patterns of cognition, emotions, and behaviors [1, 13, 37, 59]. The insistence on sameness and reactions to change may underlie some of these rituals. The boundaries between these repetitive behaviors and OCRD can be confusing [55–57]. Many ritualized behaviors in ASD seem to become habitual over and more difficult to pinpoint specific triggers, typologies, or reinforcing properties. In this sense, patients with ASD may have more in common with tic disorders, the related disorders spectrum of OCRD, hoarding, and impulsive-stereotypic movement disorders than from current knowledge [13, 17, 23, 62]. Clinicians are less apt to find classic OCD (obsessions, contamination cleaning or avoiding, and doubting-checking symptoms) in patients with ID/ASD [6, 37, 59]. Our understanding of OCRD in patients with ID/ASD may require a dissection of habit-related (reactions to social ambiguity, unexpected noises, broken routines, or environmental changes) from those anxieties related to anxiety/misery/worry dimensions, dysphoric affective responses, high harm avoidance [6, 15, 17, 80, 62].

In both ASD and ID, the use of these exploratory neuromodulation may be helpful in dissecting aberrant interconnections between localized and distal neurocircuitries that underlie ASD and ASD + ID. These studies can provide additional data on the patterns of atypical neuronal development and maturation that most closely link to ASD and OCRD. In addition, they may provide a better understanding of gender dimorphism in ASD, tic disorders and mood/anxiety disorders. As a rule, males are more vulnerable to primary ASD (polygenic inheritance, higher familial occurrence), ADHD, and many other neurodevelopmental disorders and tic disorders. The male:female ratio is significantly larger than those found in late onset OCRD are. A similar shift in gender ratios occur in secondary ASD (associated with neurological and metabolic disorders) [2, 21, 23, 37]. These studies will hopefully provide a better understanding of the role played by serotonin, glutamate, dopamine, and oxytocin/vasopressin and may offer new insights into different patterns of drug response [32, 37, 92].

As noted earlier, rTMS and tDCS technologies are very useful for mapping out the neu-

rophysiology and functional neuroanatomy of OCRD. More detailed functional probing and mapping will continue to provide insights into the neurocircuitry of fronto-striatal ensembles and their role in top-down regulation and overly zealous subcortical/limbic activation [3, 7, 24, 36]. The second positive impact involves developing deeper insights into the interconnections between excitatory/inhibitory circuitries at a local level of neuronal activity and their regional influences on distal activation and coherence. These distal connections may heighten our understanding of top-down regulation of sympathetic/parasympathetic, neuroendocrine, and neuroinflammatory functions [21, 24, 26, 27]. Lastly, these technologies may help refine our understanding of the neurodevelopmental underpinnings of ASD and ID on the emergence of coherence, default mode cognitions and neurocognitive and neurobehavioral substrates.

Mapping the neurophysiological differences with OCRD can be combined with studies of aberrant patterns of white matter tracts (diffusion tensor imaging; DTI) to gain a deeper understanding of excitatory/inhibitory balance, top-down regulation, and long-term interconnections in ASD that may differ from OCRD [23, 25, 26, 37, 92]. The impact of ID on these neuropsychological and cognitive traits of ASD and OCRD may improve the quality of current treatment approaches. In many cases, such combined studies may help reduce considerable phenomenological and pathophysiological heterogeneity that make studies so difficult to extrapolate and interpret. These new methodologies may help to better define phenotypic variability within ID (including specific behavioral phenotypes) that may help differentiate stereotypies and some treatment-resistant forms of self-injury [10].

More recently, alternative biological treatments using direct brain stimulation are becoming more acceptable for individuals with high levels or treatment refractory OCRD. In general, there is limited application of these technologies for individuals with co-occurring ID and ASD. Less-invasive strategies such as various iterations of rTMS are gaining interest.

24.14 Summary and Conclusions: How Pathophysiology Guides Treatment

The DSM-5 and the DM-ID-2 bring together obsessive-compulsive disorder and other repetitive behavioral syndromes into obsessive-compulsive and related disorders (OCRD). In this chapter, the author expanded beyond diagnostic criteria, and focused instead on deconstructing OCRD. The goal of this deconstruction project was to sort out as much diversity as possible and create a framework for understanding the complex interrelationships between OCRD and ASD and ID. The mechanics of this process involved dissecting specific temperamental features and behavior clusters down to their basic pathophysiology. This included their basic neuropharmacology, neurophysiology, and ultimately gene regulation and expression.

Throughout, the explicit goal was to augment the categorical, descriptive definition of OCRD with data from the neurosciences on biological and neuropharmacological endophenotypes. In doing so, the search was on for interconnections between OCRD, mood and anxiety disorders, impulse control and addiction-related disorders, and ASD/ID. A second goal focused on the exploration of behavioral (learning models), neuroethological, and behavioral psychopharmacological subtypes of OCRD. Many behavioral programs focus on challenging behaviors rather than specific syndromes. Functional behavioral data guide an analysis of variables associated with the precipitation, maintenance, and treatment of repetitive behaviors and OCRD as a subset of ID/ASD. From this perspective, clinicians are tasked with understanding mutually interacting systems rather than three distinct, co-occurring syndromes. The level of syndromal and biological entanglement may push researchers and clinicians to consider strategies that focus on the behavioral pharmacology of OCRD subtypes within the framework of ASD and ID.

The last segment of this chapter concentrated on three treatment models: exposure-response prevention/CBT and habit-reversal

therapy, psychopharmacology, and neuromodulatory/neurosurgical interventions. A review of psychopharmacological interventions suggests that our best treatment approaches fall short of clinical remission for as many as 70% of those treated for OCRD [2, 7, 51, 66]. A similar observation holds for CBT/ERP, habit-reversal therapy (HRT), and combinations of CBT/ERP and psychotropic medications. Neuromodulatory and neurosurgical treatment currently apply to the most severe, treatment-resistant forms of OCRD. This is unfortunate since direct current neurostimulation, rTMS, and even neurosurgical interventions may be more effective earlier in the treatment selection process. The problem with each of these new technologies involves how to apply them to patients with ASD and ID.

In the final analysis, clinicians must deal with the sense of frustration with our current treatment approaches to OCRD. Although we are making significant gains, persistently high rates of treatment resistance still plagues clinicians. Part of the problem lies in the often overwhelming heterogeneity of OCRD patients with ASD and ID. We are dealing with three entangled neurodevelopmental disorders that present as final common pathways to three species of complex genetic disorders. They converge along many nodal points and breakthrough as subtypes along a OCRD-ASD/ID continuum. Further developments in the neurosciences may eventually help us improve outcomes by designing more personalized treatment approaches.

Of course, the ideas expressed in this chapter will need additional revision as new data emerges. The application of pathophysiological model will be contingent on these data, but there are new models such as Research Domain Criteria (RDoC) [47] and the Intermediate Phenotyping [49] that will play a major role in this transformation. New technologies will help to look beyond our current fixation on specific neurotransmitters and mechanism of drug action. However, there are dangers in any paradigm shift, especially when we reduce complex patterns of human behavior and emotional life down to a molecular level.

However, these are not simple challenges. These many models addressed in this chapter make this abundantly clear. It is easy to become discouraged or get bogged down in the details and lose ourselves in the forest while concentrating on the microscopic structure of molecular biology. Any hope of success hinges on our capacity to translate the neuroscience explosion into manageable chunks, which are applicable to clinical problems. Hopefully, this chapter is at least one step in that direction, and a bequeathal for our students, residents, and trainees who will struggle after us.

To date, we have no cures or magical silver bullets, but as new discoveries trickle down from the neurosciences, new diagnostic and treatment models will follow. The brain and disorders of brain functioning share more in common with a complex ecosystem than discrete lesions or single neurotransmitters.

Key Points

- Obsessive-compulsive disorder is a complex polygenic and heterogeneous neuropsychiatric disorder.
- The DSM-5 and DM-ID-2 recategorized OCD from an anxiety disorder to obsessive-compulsive and related disorders. This step expanded OCD to include other patterns of repetitive behaviors.
- OCD frequently co-occurs with anxiety and mood disorders. Psychotic disorders, ADHD and other impulse control disorders, stereotypic and tic disorders, and neurodevelopmental disorders such as autism spectrum and intellectual developmental disorder.
- The neurobiology of OCRD involves elements of the fronto-striato-thalamic networks that are involved in sensory gating, and top-down regulation of multiple reciprocating subcortical connections.

- The boundaries between the core features of OCD overlap ASD, tic disorders, and other movement disorders, as well as other neuropsychiatric disorders, OCD, and other.
- Manualized psychotherapies (cognitive-behavioral), exposure-response prevention, and habit-reversal therapies are considered frontline treatment in many settings. The presence of ASD and ID require modifications.
- Primary psychopharmacological treatments focus on modifying serotonin networks. The presence of other comorbid conditions impacts the nature and clinical course of OCD as well as the effectiveness of these treatments.
- Both psychotherapy and pharmacotherapy lead to significant improvement in the majority of patients. The co-occurrence of ASD and ID can be effective, but may require modifications of these techniques.
- Remission is rather uncommon even with combination therapies. A substantial minority does not respond and requires more complicated treatment protocols.
- Treatment-resistant, severe OCD may require transcranial direct current or magnetic stimulation, as well as neurosurgical interventions such as lesioning connecting tracts or implantation for direct brain stimulation.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_25

Learning Objectives

- To understand why feeding and eating disorders (FEEDs) are among the least studied psychiatric disorders in persons with ID/ASD.
- To define what FEEDs are and outline their main psychopathological, physical and nutritional features in adults with ID and ASD.
- To clarify the prevalence, types and aetiological associations of the different FEEDs in adults with ID and ASD.
- To discuss screening, diagnosis, clinical assessment and management of FEEDs in adults with ID and ASD.
- To consider the personal psychological meaning of FEEDs for individual adults with ID and ASD.
- To suggest future clinical, research and service development directions.
- To understand implications of FEEDs for individuals with ID, their families/carers and care service providers.

25.1 Introduction

Eating disorders (EDs) in the 'mainstream' (non-ID) population are serious frequently persistent and complex mental disorders that usually involve young adolescent and adult females. The burden of such 'mainstream' EDs (anorexia nervosa, bulimia nervosa and binge eating disorder) for healthcare systems is high. The prevalence of such mainstream EDs (especially binge eating disorder) seems to have increased in the last decades [1, 2]. Little is known about these 'mainstream EDs' when they occur among adults with intellectual disability (ID). This has been partly explained by the obviously lower levels of communication and conceptualizing skills demonstrated by most adults with ID, making it challenging to adequately clinically assess and diagnose such complex EDs in them [3].

Moreover, little attention was paid to these diagnostic issues by clinicians and researchers, with few contributions evaluating the complex relationships between feeding and eating disorders (FEEDs) and ID [4]. Therefore, more studies were and still are needed to further clarify the prevalence, clinical and service impacts and personal meaning of FEEDs in adults with ID [5] and autism spectrum disorder (ASD) [6].

Little is known about clinical and service impact, and personal meaning of FEEDs in adults with ID/ASD.

25.2 Recent Classifications of FEEDs

ICD-10 [7] and ICD-10 MR [8] will still be in widespread use for several years awaiting full role out and adoption of the new online ICD-11 beta version available for field trials since 2015 [9]. In the UK, DC-LD [10] is still widely used despite the availability of DSM-5 [11] and DM-ID [12]. Evaluation of DM-ID [13] is awaited before adoption can be considered.

Table 25.1 compares the DC-LD, DSM-5, DM-ID and current field trial ICD-11 diagnostic classifications for FEEDs. The FEEDs have included: classical 'mainstream' eating disorders best known in adolescent/young adult females without ID, that is, anorexia nervosa, bulimia nervosa and binge eating disorder; feeding disorders most commonly seen in developmentally less mature children and adults with ID and ASD, that is, pica, rumination/regurgitation disorder, food faddiness/refusal aka avoidant and restrictive food intake disorder (ARFID); previous psychogenic stress related loss of appetite, overeating and vomiting EDs; some less common EDs such as night bingeing syndrome and newer EDs disorders including orthorexia [15–17] and muscle dystopic syndrome ('bigorexia') [18, 19].

Mainstream EDs are severe and chronic syndromes that in most cases involve young women affecting their personality development and their physical health [20]. EDs are sustained by socio-cultural, psychological and biological factors [21].

Table 25.1 Comparison of ICD-10, DC-LD, ICD-11, DSM-5 and DM-ID-2 diagnostic classifications for FEEDs

Eating disorder	ICD-10	DC-LD	ICD-11	DSM-5	DM-ID-2
Pica	Not present as a specific category	Pica	Pica	Pica	Pica
	Coded as a category of 'Other behavioural and emotional disorders with onset usually occurring in childhood and adolescence' or included within 'Other eating disorders' for adults	–	–	Different codes for children and adults, within the same category	Excluding people with severe or profound ID just being unable to differentiate between prepared and unprepared, raw or discarded food
Avoidant/restrictive food intake disorder	Not present as a specific category	Food faddiness/food refusal disorder	Avoidant-restrictive food intake disorder	Avoidant/restrictive food intake disorder	Avoidant/restrictive food intake disorder
	Partially included in 'Feeding disorder of infancy and childhood'	–	–	Specifier for 'in remission'	Including atypical manifestations such as food refusal, turning away of the head or keeping lips sealed while being fed, vomiting during or after the meal. Excluding inadequate diet or insufficient care
Rumination disorder	Not present as a specific category	Food rumination/ regurgitation disorder	Rumination-regurgitation disorder	Rumination disorder	Rumination disorder

	Rumination disorder of infancy, within 'Feeding disorder of infancy and childhood', part of the chapter 'Other behavioural and emotional disorders with onset usually occurring in childhood and adolescence'	'Excessive chewing/ spitting out food disorder' as a separate category	Does not include 'Adult rumination syndrome' (under chapter 13 - Diseases of the digestive system) and 'Nausea or vomiting' (under chapter 21 - Symptoms, signs or clinical findings, not elsewhere classified)	Specifier for 'in remission'	Excluding inadequate diet or insufficient care
Anorexia nervosa	Anorexia nervosa	Anorexia nervosa	Anorexia nervosa	Anorexia nervosa	Anorexia nervosa
	'Atypical anorexia nervosa' as a separate category	–	Specifiers for 'with significantly low body weight'; 'with dangerously low body weight'; 'in recovery with normal body weight'; 'other specified'; and 'unspecified'	Subtypes: binge-eating/purging; restricting. Specifiers for 'in partial' or 'in complete remission'. Specifiers for severity	Including additional observations from caregivers and family members for persons with moderate to profound ID
Psychogenic loss of appetite disorder	Not present as a specific category	Psychogenic loss of appetite disorder	Not present	Not present	Not present
	Included in 'Other Specified Feeding or Eating Disorder'	Specifiers for 'currently in episode' or 'currently in remission'	–	–	–
Psychogenic vomiting disorder	Vomiting associated with other psychological disturbances	Psychogenic vomiting disorder	Not present	Not present	Not present
	–	Specifiers for 'currently in episode' or 'currently in remission'	–	–	–

(continued)

Table 25.1 (continued)

Eating disorder	ICD-10	DC-LD	ICD-11	DSM-5	DM-ID-2
Bulimia nervosa	Bulimia nervosa	Bulimia nervosa	Bulimia nervosa	Bulimia nervosa	Bulimia nervosa
	Atypical bulimia nervosa as a separate category	–	–	Specifiers for 'in partial' or 'in complete remission'. Specifiers for severity	–
Binge-eating disorder	Overeating associated with other psychological disturbances	'Binge-eating disorder' and 'psychogenic overeating disorder'	Binge-eating disorder	Binge-eating disorder	Binge-eating disorder
	Includes: overeating due to stressful events; Psychogenic overeating	'Psychogenic over-eating disorder' has specifiers for 'currently in episode' or 'currently in remission'	–	Specifiers for 'in partial' or 'in complete remission'. Specifiers for severity	–
Other Specified Feeding or Eating Disorder	Other eating disorders	Not present	Other specified Feeding or eating disorders	Other specified feeding or eating disorder	Other specified feeding or eating disorders
	Includes: Pica in adults; psychogenic loss of appetite	–	–	–	–
Unspecified feeding or eating disorder	Eating disorder, unspecified	Not present	Feeding or eating disorders, unspecified	Unspecified feeding or eating disorder	Unspecified feeding or eating disorder
	–	–	–	–	–

25.2.1 DSM-5 Criteria for Feeding and Eating Disorders

In the DSM-5, EDs are in a new chapter called *Feeding and Eating Disorders*. This category encompasses different psychopathological conditions such as anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and 3 FEEDs disorders previously described in the *Feeding and Eating Disorders of Infancy or Early Childhood* chapter in DSM-IV-TR, that is pica, rumination disorder (RD), avoidant/restrictive food intake disorder (ARFID) [11].

Feeding disorders are defined as a set of symptoms and behaviours related to an inadequate quantity of food intake that does not satisfy nutritional needs and causes quantitative and/or qualitative alterations of nutritional status. The main difference between feeding disorders and EDs is the absence of body shape and weight concerns or disturbance of body image as a main feature in the development of feeding disorders. Consequently, in these psychiatric conditions the eating behaviour is not enacted with the aim to control body weight or shape.

According to the DSM-5 criteria, AN is characterized by a persistent restriction of food intake leading to a very low body weight; an intense fear of gaining weight or of becoming fat, or a persistent behaviour that interferes with weight gain even though the body weight is significantly low; an altered experience of body weight and shape, an excessive influence of body shape and weight on self-evaluation, a persistent lack of recognition of the severity of the current underweight. In DSM-5 classification, two subtypes of AN are included: restricting type, based on a persistent restriction of food intake in order to control the body weight and shape; binge-purging type, characterized by restriction of food intake associated with episodes of binge eating and compensatory behaviours [11].

The diagnosis of BN is made when patient's recurrent episodes of binge eating are associated with the use of inappropriate compensatory behaviour to avoid weight gain, and their self-evaluation is influenced by body shape and weight.

An episode of binge eating has two main features: eating, in a defined period of time (e.g. 2 h), an amount of food significantly larger than most people would eat in the same period and in similar circumstances and a sense of lack of control over eating during the binge eating episode. People with BN use recurrent compensatory behaviours to prevent weight gain such as self-induced vomiting, use of laxatives, diuretics or other medications, fasting or excessive exercise. Furthermore, in BN binge eating episodes and compensatory behaviours must occur at least once a week for 3 months, and not exclusively during an episode of AN.

Unlike DSM-IV [22] and DSM-IV-TR [23], DSM-5 officially recognizes binge-eating disorder (BED) as a formal diagnosis. BED is characterized by the presence of binge eating episodes that must be associated with at least three of the following features: eating more rapidly than normal; eating until feeling uncomfortably full; eating a large amount of food when not hungry; eating alone because of feeling embarrassed by how much one is eating; feeling disgusted with oneself, depressed or guilty after the episode.

Unlike BN, in BED the binge eating episode is not associated with any compensatory behaviour and this is the reason why patients with BED are often overweight or obese. As in BD, a diagnosis of BED is made when the episodes of binge eating have a frequency of at least once a week for the last 3 months [11].

AN, BN and BED share the concern about body shape and weight, which leads these patients to dysfunctional eating behaviours in order to try to modify or control their body. In the same chapter of these eating disorders, the DSM-5 also includes pica, rumination and ARFID, which are distinguished from EDs mainly by the absence of fear of gaining weight or concern about body shape/weight.

The term pica originates from the specific Latin epithet of the Eurasian magpie 'corvus pica', introduced by Linnaeus in the second half of the eighteenth century [24] in reference to bird characterized by appetite for a diversity of objects, including inedible objects [25]. The DSM-5 describes pica as a persistent craving and eating of non-food substances. This behaviour has to be judged as inappropriate to the developmental level of the person (includ-

ing persons with ID/ASD), not part of a cultural practice, and severe enough to deserve specific clinical attention when occurring during the course of other health or clinical conditions such as pregnancy [26, 27], psychotic disorders [28, 29], obsessive-compulsive disorder [30, 31], some forms of masked depression [32] or ID and ASD themselves. In order to fulfil the DSM-5 criteria, this behaviour must last longer than a month. Various substances may be craved, including cigarette butts, clay, raw starch, paint, paper, string, clothes, dirt, dust, plastic, hair, metal, rocks, foliage and faeces. Ingestion of clay (geophagia), raw starch (amylophagia), faeces (coprophagia) and ice (pagophagia) are reported to be the most common types of pica [33–35].

Rumination disorder (RD) is defined as the presence for at least 1 month of repeated regurgitation of food that may be re-chewed, re-swallowed or spit-out, not due to a medical condition nor in the presence of other EDs. When RD occurs in patients with other mental disorder, it has to be severe enough to warrant clinical attention.

Finally, avoidant/restrictive food intake disorder (ARFID) is described as a persistent inability to fulfil appropriate nutritional needs, associated with one of the following: nutritional deficiency, loss of weight, dependence on oral nutritional supplements or enteral feeding and inference with psychosocial functioning. This behaviour is not associated with lack of available food and is not part of a cultural practice. Furthermore, it does not occur in the presence of other EDs and is not associated with disturbance of experience of body shape and weight. When ARFID manifests in patients with other medical conditions, it has to be more severe than the eating symptoms typically associated with that medical condition, and, therefore, warrants clinical attention [11].

25.3 Prevalence of Feeding and Eating Disorders

The lifetime prevalence of EDs is estimated to be up to 4% for AN, 2% for BN and 2% for BED [36]. In recent decades EDs seem to have become more common, except for BN. The reason for this increase remains unclear, although it is suggested that it may be due to better detection by clinicians [2]. As for feeding disorders, there is a lack of prevalence data among general population and also among people with ID/ASD. Indeed, the prevalence of pica in the general population is unclear and clinical studies are lacking also among people without ID or ASD. In individuals with ID, prevalence of pica seems to increase with the severity of the ID [11]. The prevalence of RD is 'unclear' according to the DSM-5 criteria. Moreover, diagnosis of RD cannot be made in the presence of another ED, but there is evidence of the presence of rumination behaviour in individuals with other EDs [37]. To date, ARFID has not been the subject of any large-scale epidemiological study, therefore, the prevalence of ARFID among the general population remains unknown [38], and the same applies to its prevalence among individuals with ID/ASD.

Studies have documented higher incidence of eating and feeding problems in people with ID and ASD [39, 40] than in the general population. A range of 3–42% of adults with ID living in congregate residential settings and 1–19% of those living more independently in the community have diagnosable EDs [4, 10]. More generally, a variety of problems with eating have been estimated to prevail in about one third of people with ID [41, 42] and up to 80% in those with more severe impairment, problem behaviours and co-occurring ASD [41–45].

Nevertheless, as for other psychiatric disorders, the real prevalence of FEEDs in people with ID is probably underestimated because most of these patients do not present symptoms as described in the DSM and ICD diagnostic criteria for the general population and their psychopathological co-occurrence is not identified (see Chap. 9).

A variety of problems with eating have been estimated to prevail in about one-third of people with ID and even more in those with higher severity of cognitive impairment, problem behaviours and co-occurring ASD.

25.4 Aetiopathogenesis of FEEDs

Thousands of studies have attempted to specify exactly what causes eating and feeding disorders. The current consensual approach to integrating the various factors that contribute to these conditions is the 'biopsychosocial' model, which has the advantage of taking into account several factors that are associated with an increased risk, ranging from the broadly cultural to the narrowly biological, and stopping along the way for relational, personality and other psychological factors [46, 47].

As from the DSM-5 criteria reported above, all EDs are characterized by a loss of physiological meaning of nutrition. Food loses its value of nourishment and pleasure and it assumes a negative connotation. Consequently, in EDs we find that feeling of hunger and satiety are no longer determinant upon the power supply, that appears qualitatively and quantitatively based on arbitrary parameters such as rigid rules or concept of control. All EDs are defined by pathological behaviours such as dieting, vomiting, avoiding specific foods, binge eating combined in different patterns and resulting in specific medical complications including weight loss, obesity, heart or kidneys failures and blood changes. Moreover, EDs are frequently associated with several psychiatric comorbidities, such as anxiety and mood disorders, or personality disorders, which makes the long-term outcome poor [48]. Longitudinal studies indicate that most patients migrate among diagnoses over time, mostly among AN, BN and BED [20, 49] without a substantial change in fundamental psychopathological features [48, 50, 51]. This evidence points towards a common psychopathological core of EDs.

Because of the tendency to migrate among ED diagnoses and the relevant overlap between ED symptoms and different medical and psychiatric conditions (e.g. obesity, obsessive compulsive disorder, autism spectrum disorders, depression, substance abuse, personality disorders), many researchers focused on the different behavioural patterns, rather than the full syndrome [52].

This tendency leads to create a new clinical perspective which is expressed in the concept of 'spectrum'. As for ASD and other clinical conditions within psychiatry, the term 'spectrum' has been used to refer to etiologically related clinical features; eating disorders spectrum involves core, atypical and subclinical symptoms and signs, personality and behavioural traits that belong to a group of psychiatric syndromes related to eating disorders. The 'spectrum approach' may be useful to identify subjects with vulnerability to EDs that do not meet criteria for a clear diagnosis, or individuals with prodromes to a full-blown disorder or with sequelae of a previous disorder [53].

In the DSM-5, EDs are defined as 'characterized by persistent disturbance of eating or eating-related behavior that results in the altered consumption or absorption of food and that significantly impairs health or psychosocial functioning' [11]. Considering the three main ED diagnoses, AN, BN and BED, the dysfunction of eating behaviours can be considered as the clinical expression of specific cognitive and emotional disturbance [20, 54, 55], including the overestimation of the body shape and weight concerns, and personal identity [56].

Persons with EDs have a tendency to overvalue their body shape and weight [20], and to evaluate themselves on the basis of their ability to control their body weight and shape, instead of valuing themselves on the basis of work performances or relationships, as people without EDs are supposed to do. Consequently, we may better describe EDs as a psychiatric condition based on a disturbance of subjective perception of body and personal identity; in particular, it has been suggested that the main characteristic of EDs patients is suffering from a specific disorder of lived altered reality contributing to an abnormal constitution of one's identity [57].

To better understand the overvaluation of body shape and weight in EDs patients, it is important to introduce the concept of 'lived body'. This concept comes from phenomenology that distinguishes between lived body (or body subject) and physical body (or body

object) [58]. 'Lived body' is the primitive experience of body in the first-person perspective, the cenesthetic self-awareness of one's own body not mediated by reflection [57, 59]. On other hand, the physical body, or body object, is the body studied by natural sciences, as anatomy and physiology, that can be manipulated (e.g. by surgery), in the third-person perspective [58, 59].

The lived body is the centre of three main dimensions of experience [60]: the experience of oneself (self-awareness); the object-experience; and the experience of other people. First of all, the primitive self-awareness is based on personal experiences, such as emotions or perceptions, as well as on actions and thoughts. It is not a conceptual representation, neither an object-awareness coming from the observation of oneself. We can use the term 'ipseity', created by Henry [61], to explain this primitive form of self-awareness that is immediate, non-observational and pre-reflexive. Ipseity has two main features: self-ownership, which is the awareness that I am the one who is living an experience, and self-agency, which is the consciousness that I am the one who is taking an action. These two characteristics allow the differentiation between me and the object I perceive, and between my representation of the object and the object itself. It is the lived body that provides the 'ipseity', the immediate self-awareness that allows the engagement with the environment [59].

Secondly, according to Husserl, lived body is the protagonist of the making experience of objects just as I perceive them intuitively. Consequently, a modification of the lived body causes an alteration in the perception of the external world. The lived body is at the same time the responsible of perceptions and the place of their integration. We can consider it as the instrument that allows the relationship with the world itself, notably by perceiving objects as a part of a context in which the individual is engaged. In this view, human beings understand environment as long as they live it, thanks to the constant projection of their body into it, and their knowledge of objects does not require a merely theoretical cognitive act, but rather a concept which manipulates things and allows the use of them [62].

Moreover, the lived body has been proposed to be the centre of intersubjectivity, that is, the experience of other people, based on the immediate and pre-cognitive perception of the linkage between my own and other's body, by transferring the corporeal schema to another human being. This process, which allows to recognize others as similar to myself, is defined 'intercorporeality' and is considered the basis of intersubjectivity [63]. Intercorporeality is the fundamental of all interactions based on behaviour and it is present ahead of explicit communication. Proprioception seems to be involved in this process by promoting the understanding of other persons' perspectives through immediate body-to-body attunement.

An interesting integration to Husserl's dimensions of corporeality (body subject and body object) has been introduced by Sartre [64], who suggested that individuals can know their own body also from the observation of it by another person ('lived body-for-other'). According to this view, the realization that one's own body can be looked at by another person would favour its perception as an object and the extremization of this process would lead to a progressive loss of the autonomous consciousness of one's own body, up to the belief that it can be modified by the gaze of others.

Persons with EDs often have difficulties in distinguishing their emotions [65–68] as well as in having a first-perspective perception of their own body and a sense of themselves as embodied agents, which implicates unstable sense of identity and awareness of feelings, that is, what one likes or dislikes [69]. People with EDs feel a sense of extraneity from their own body and they often try to get back in touch with their physical dimension through starvation or other objectified aspects [57]. They experience their own body as an object for other people's senses and feelings, rather than the result of their own somato-kinaesthetic perceptions and emotions, and tend to construct their self-identity basing on the way they feel looked at by others (see Fig. 25.1).

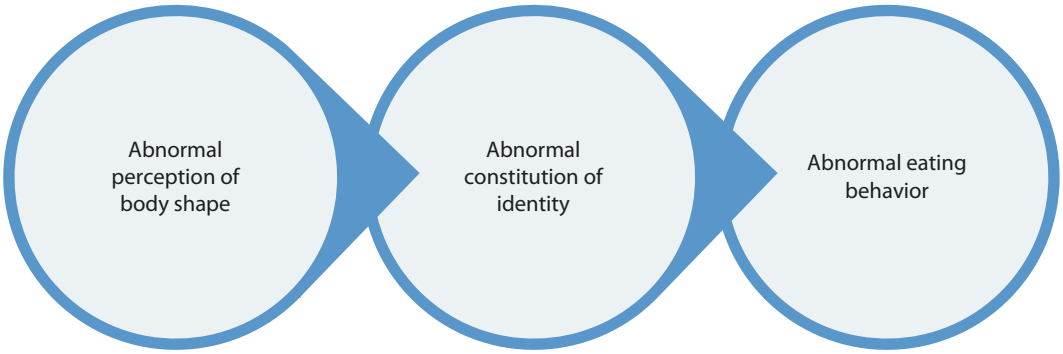

Fig. 25.1 The relationship between body image, self-identity and eating disorder

Individuals with EDs experience a disturbance of the body image that causes an alteration of the process of shaping their personal identity. In EDs patients, the identity disorder is considered as a maintaining factor of the eating disorder mostly through two main features: perfectionism and low self-esteem [70]. In addition to the control of body shape and weight, patients with EDs show perfectionism in almost all the areas where performance is required (work, sport), and are concerned with achieving unattainable ideals or unrealistic goals, which often lead to an aggravation of underlying low self-esteem.

These hypotheses are supported by the data collected by using a self-reported questionnaire called IDEA (IDentity and EAting disorders), aimed at identifying psychological vulnerability factors in persons with abnormal eating habits [69]. This questionnaire assumes that most pathological eating behaviours and features are a consequence of the severity of abnormal bodily experiences and identity disorders, and it is focused on the phenomenological areas explained above: (1) feeling oneself through the gaze of the other, (2) defining oneself through the evaluation of the other, (3) feeling oneself through objective measures, (4) feeling extraneous from one's own body, (5) feeling oneself through starvation, (6) defining one's identity through one's own body, (7) feeling oneself through physical activity and fatigue [69].

The IDEA was tested in a population of individuals who did not suffer from EDs, in which it resulted to be able to identify vulnerability factors in persons with abnormal eating patterns and significantly higher identity alterations in those with clinically evident EDs than in those without a full-blown pattern of symptoms [57]. When used among obese patients, the IDEA test confirmed that abnormal body experience may represent a key risk factor for developing an eating disorder [71].

The IDEA test explores mainly two phenomena: abnormal corporeality and difficulties in defining self-identity. These results support previous clinical impressions that specific dysfunction of lived corporeality, namely experiencing one's own body as an object being looked at by another (rather than from a first-person perspective), and of personal identity, namely defining one's own self by the way one feels being looked at by others and through one's ability to control one's shape and weight (rather than through other kinds of personal quality), are supposedly core features of ED psychopathology.

The main difference between eating and feeding disorders is the absence of body shape concern and/or weight phobia in individuals with feeding disorders.

25.4.1 Physical, Sexual Abuse and Neglect in Individuals with Intellectual Disability: Potential Risk Factors for Eating Disorders

Emotional and physical abuse represents important risk factor for the development of EDs, especially when occurring during child-

hood. In reference to the general population recent meta-analyses [72, 73] show a strong association between childhood abuse (i.e. physical, sexual and emotional abuse and neglect) and prevalence, severity and early onset of EDs, especially BN, BED and AN binge purging subtype [73]. Persons with ID and/or ASD are significantly more exposed to different kinds of abuse than peers with other types of disability and peers without disability, with prevalence rates ranging from 7% to 34% [74–81]. More specifically, sexual abuse is reported to occur in 14–32% of children with ID and 7–34% of adults, physical abuse in 22–26.8% of children, and emotional abuse in 17.5–26.7% of children [74, 75, 80]. Victims of sexual abuse have been found to be mostly females, aged between 11 and 20 years, and living with their parents [82]. The abuse usually takes place in victim's house and is perpetrated by someone known by the victim [82].

Causes of maltreatment are complex, involving stressors of various kinds that interact with family, parent and child characteristics. Environmental stressors include poverty, educational deprivation, low socio-economic status and unemployment. Family and parent factors include social isolation, problems in attachment or interaction between parent and child, parental substance abuse, mental illness or neurodevelopmental disability, and parents' own experience of childhood abuse. Increased parental stress and a lack of social supports are associated with increased aversive, coercive and inconsistent discipline. Child factors include temperament, personality, physical characteristics, co-occurrence of attention deficit-hyperactivity disorder, problem behaviours, age-inappropriate sexual behaviour as well as obviously emotional and cognitive immaturity [80, 83–85].

Within child maltreatment, sexual abuse represents the main risk factor for the development of all EDs [86–88], especially BN [88]. In some cases, this relationship between a history of sexual abuse and EDs, especially BN, seems to be mediated by dissociative experiences, which in fact are reported to be more common among bulimic women overall and particularly in those who experienced sexual abuse during childhood. Some authors have argued that dissociation would allow the bulimic to shift (more or less episodically) to a lower level of consciousness in order to be able to binge and purge, while other authors suggested that binge-eating behaviour (with or without purging) might develop as a means of inducing dissociation or reduced levels of self-awareness [89–92].

However, dissociation is widespread across many different psychiatric disorders, not exclusively in EDs [93] and is challenging to identify in persons with ID and low-functioning ASD, mostly due to their insight and communication difficulties. Furthermore, in these persons neither the role of dissociation in the development of binge eating behaviour nor BN itself appear to be measurable.

In addition to abuse, the scientific literature indicates that many other negative life events are associated with the onset of EDs across the life span [73, 94]. In the general population some eating behaviours have been found to be instrumental in shunning or avoiding trauma-related emotions or thoughts [94], and it is probable that this type of reaction to trauma also happens in people with ID/ASD. Addressing this issue in future research could significantly improve our understanding of psychological mechanism underlying FEEDs in individuals with ID/ASD, and improve standards of care both for eating symptoms and trauma-related manifestations.

Emotional and physical abuse represents important risk factor for the development of EDs, especially when occurring during childhood, and persons with ID and/or ASD are significantly more exposed to different kinds of abuse than peers with other types of disability and peers without disability.

Tip

The role of dissociation in determining specific presentation of EDs in persons with ID/ASD and the pathogenic contribution of negative life events deserve high attention in future research and clinical practice.

25.4.2 Aetiology and Pathogenesis of Specific FEEDs in Persons with ID and Low-Functioning ASD

25.4.2.1 Anorexia Nervosa

In adults with ID, anorexia nervosa has been found to be associated with previous dieting, identity problems, sexual issues, bereavement, regression, family conflicts and history of psychopathology in family members [4].

Scientific literature includes reports of anorexia nervosa in persons with Down syndrome [95–98], also in association with depression [99–101] as well as in persons with Prader-Willi syndrome [102–104] and to a lesser extent in those with phenylketonuria [105].

25.4.2.2 Bulimia Nervosa and Binge-Eating Disorder

Very little is known on possible causes of bulimia nervosa and binge-eating disorder in persons with ID and or low functioning-ASD. Hyperphagia, including gorging, pica, food hoarding, and polydipsia, has been found to associate with distress in persons with hyperphagic short stature syndrome, a condition sharing many signs and symptoms with Prader-Willi syndrome but having slightly lower IQ reduction, normal or low body mass index and different aetiology [106, 107].

25.4.2.3 Avoidant/Restrictive Food Intake Disorder

Feeding difficulties including apparent lack of interest in food and food refusal have been reported in persons with Down syndrome [108], Joubert syndrome, Lesch-Nyhan syndrome, Smith-Lemli-Opitz syndrome, Sotos syndrome and Willem Bueren syndrome, mainly during childhood. Similar feeding difficulties also occur in Prader-Willi syndrome and Costello syndrome but only in the very first months of life [109–111].

Some features associated with ID and ASD such as the difficulty to identify and express one's feelings or specific sensory sensitivities may contribute to restrictive eating.

Persons who received supplementary feeding in the form of beverages or smoothies for a long time often show food refusal and gagging when only or mainly textured food is offered, especially during childhood.

Other factors associated with persistent lack of interest in food and food refusal are experiences of abuse or neglect as well as high level of anxiety, expressed emotion and psychopathology among family members and/or other significant caregivers [112].

25.4.2.4 Rumination Disorder

Within persons with ID, RD occurs more frequently in males, in those with more severe IQ impairment and in case of co-occurrence of ASD, anxiety disorders and other FEEDs [113]. No specific genetic syndromes have been associated with RD.

Persons with ID may begin to engage in ruminating behaviour due to an exacerbation of dysphagia, gastroesophageal reflux disease or pyloric stenosis. Other gastric sensory and motor dysfunction may also represent contributing factors [114]. As for other FEEDs, high level of anxiety, expressed emotion and psychopathology among family members and/or other significant caregivers may represent contributing or precipitating factors [113].

25.4.2.5 Pica

In persons with ID, prevalence rate of pica has been reported to be higher in persons with more severe IQ impairment, co-occurrence of ASD, depressive disorder, ADHD, anxiety disorders and personality disorders as well as in males, children, adolescents and younger adults, and those with weight problems [4, 25, 35, 110].

High occurrence of pica in persons with Prader-Willi syndrome [115, 116] and Kleine-Levin syndrome [117] has been reported.

Some researchers have associated pica with problems with impulse control and the broad spectrum of the obsessive-compulsive disorder. In some cases, this association was supported by the finding of decreased serotonin metabolite concentration in cerebral spinal fluid and frontal lobe hypoactivity on

SPECT (single photon emission computed tomography) [4, 30, 118–120].

Pica is sometimes found in conjunction with vitamin, minerals or oligoelements deficiencies, although the direction of this relationship is not well understood. Some researchers have suggested that pica may represent an instinctive attempt to replenish low micronutrients levels from non-food substances, which could be effective in some cases and non-adaptive in others. Conversely, other researchers suggested that micronutrients deficiencies could be a consequence of pica, as pica materials may limit absorption and metabolism of specific minerals or oligoelements [121]. In general, there is no clear evidence of correlation between low level of specific nutrients and the onset of pica as well as the type of non-food ingested [25, 121].

Addiction to specific substances may play a role in specific forms of pica, such as nicotine addiction in cigarette butts pica [4].

Psychosocial theories on pica have described an association with poverty, environmental deprivation, family stress and small social support network [4, 122, 123].

25.5 Diagnosing Issues in Persons with ID and Low Functioning ASD

As explained above, the psychopathological core of EDs, especially AN, BN and BED, implicates disturbance of body image and body perceptions, low self-esteem, difficulties in self-definition and identity impairment, which adults with ID especially of severe degree are unlikely to be able to articulate [4]. Consequently, the clinical evaluation of the psychopathological core of these disorders remains challenging.

Some have tried to investigate body image among people with ID [124, 125]. One of these studies underlines that people with ID tend to underestimate their body weight [125]. In this study, researchers use the 'Stunkard Figure Rating Scale' (SFRS, [126]) to assess body dissatisfaction and body perception. The SFRS scale is based on drawings of nine male and nine female figures ranging in size from underweight to obese; participants have to indicate the figure associated to overweight, underweight and healthy weight by their point of view. They are also required to indicate which figure they see as more similar to their own body [125].

The results of this study [125] suggest that most individuals with ID have a correct general conceptualization of appropriate weight, but they do not apply this concept to themselves. This could be one of the reasons of the high prevalence of overweight (BMI 25.1–30 kg/m^2) and obesity (BMI > 30 kg/m^2) among these persons, with rate ranges of 28–71% and 17–43%, respectively [127]. Similar rates have been found in adolescents with ID, with overweight varying between 11% and 24.5% and obesity between 7% and 36% [128, 129]. It is possible that the underestimation of body weight underlying these alterations is based on a wrong transposition of what observed on other persons to themselves as well as to inability to contextualize general rules and concepts [125].

Others studies addressed the relationship between body perception and EDs in persons with ID [124, 125]. A recent review suggests that both social context or experiences and social identity may contribute to a negative body image and subsequent ED [124]. Persons with ID were found to present higher vulnerability for AN and higher association with relational factors than those described for the general population. For example, Dymek and le Grange described a girl with mild ID and AN, who used her weight loss as a 'strategy' for gaining attention from her caregivers [130]. Difficulties in interpreting beliefs, attitudes and behaviours of other persons, especially peers and significantly others, may represent and adjunctive vulnerability factor. Cottrell and Crisp reported on a person with Down syndrome and moderate ID who developed AN after having long heard her caregivers to associate weight losing and physical attractiveness [96].

Studying and managing EDs in persons with ID and low-functioning ASD is challenging not only because of the difficulty in identifying alterations of body image, self-

Table 25.2 The multiaxial structure of DC-LD

Cooper et al. [14]

esteem, identity or other core aspects of EDs, but more generally for the atypical presentation and course of the full range of symptoms and the peculiarities of risk and pathogenic factors [131]. As mentioned, diagnostic criteria developed for the general population, including DSM and ICD criteria, need to be adapted to be used with persons with ID and/or low-functioning ASD. Even the dimensional approach, as proposed by the latest edition of the DSM, has limitations, as it does not allow the establishment of abnormal eating behaviour and what associated alterations of weight and mental or social functioning should be considered as constituents of a core feeding or eating disorder [4].

25.5.1 Specific Diagnostic Approaches for FEEDs in People with ID

To overcome these diagnostic problems, adaptations of the diagnostic criteria for the general population to persons with ID were developed. The adaptation to ICD-10 criteria was produced by the Royal College of Psychiatrists in 2001 with the name of 'Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning Disabilities/Mental Retardation – DC-LD' [10], while those to DSM-IV-TR and DSM-5 were realized by the National Association on Dual Diagnosis (NADD, United States of America) with the name of Diagnostic Manual – Intellectual Disability (DM-ID [12]) and Diagnostic Manual – Intellectual Disability 2 (DM-ID 2 [13]), respectively (see ▶ Chap. 5).

The DC-LD are based on a multiaxial and hierarchical differential diagnostic approach that allows to clinically describe problem behaviours in adults with ID and to classify them as a manifestation of ID itself, co-occurrence of ASD, psychiatric disorder, personality disorder or none of these (see Table 25.2) [14]. The application of this hierarchical and multiaxial approach to eating behaviour makes the differential diagnosis between abnormal eating behaviours and EDs possible, and allows multiple diagnoses [5].

DC-LD also allows the evaluation of symptoms and signs of EDs in persons with ID basing on the information provided by their caregivers and other significant proxies (see Fig. 25.2). DC-LD includes data about type, frequency and duration of abnormal

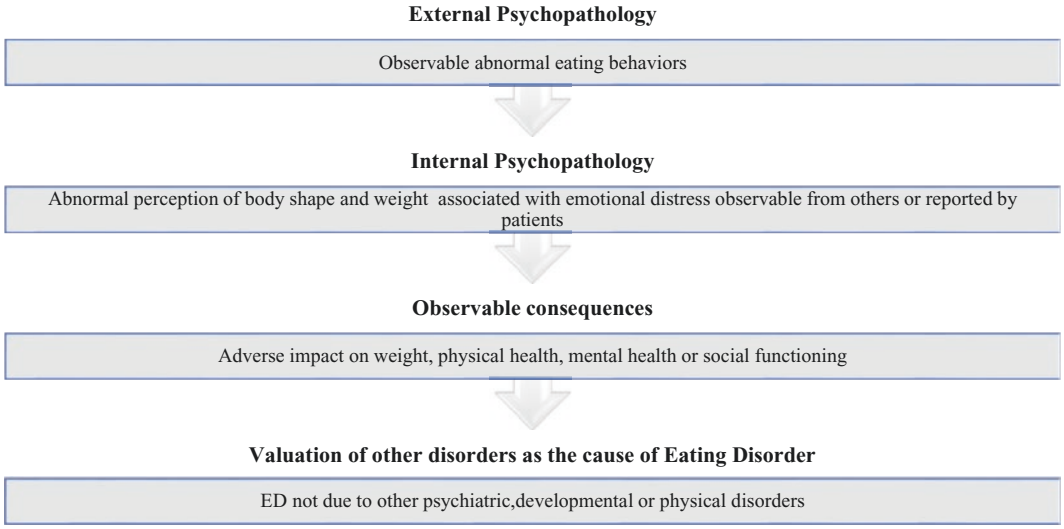

Fig. 25.2 The DC-LD model for eating disorders in adults with ID. (From Gravestock [5])

eating behaviours as well as their impact on weight, and physical and mental health, all of which represent useful information for making a diagnosis of specific EDs [5].

In addition, this multiaxial approach provides clinical case formulations useful for the assessment and differential diagnosis of abnormal eating behaviours and EDs. Published data show encouraging results in using DC-LD criteria to achieve a more accurate description of psychiatric disorders and problem behaviours in adults with ID [14, 132], but further studies are needed to address the limitations of these criteria in reference to EDs, especially among adults with more severe ID and/or co-occurrence of ASD.

DM-ID 2 encompasses seven types of applications of the DSM-5 criteria to persons with ID, which includes addition of symptom equivalents, omission of symptoms (not existing or not identifiable in persons with ID), changes in symptom count, modification of symptom duration, modification of age requirements, addition of explanatory notes and exclusion of criteria sets (not applying to persons with ID). Unlike the DSM system, DM-ID 2 does not rely on self-report and its criteria subsets are principally concerned with observational or behavioural symptoms and signs [13].

The DM-ID 2 criteria for FEEDs are presented with two columns: one column lists the DSM-5 criteria and the other one lists the adapted criteria for the full range of severity of ID. Other diagnostic chapters have three columns, with the middle column referring to mild-to-moderate ID and the right-hand one to severe-to-profound ID [13].

Despite recent advances, also due to the use of these adapted criteria, many issues of FEEDs diagnosis in persons with ID are still far from being solved, starting from the definition of a boundary between abnormal eating behaviours and EDs.

25.6 Presentation and Clinical Issues of FEEDs in Intellectual Disability

25.6.1 Abnormal Eating Behaviours: Clinical Features and Hypothetical Meanings

Abnormal eating behaviours may have different impacts and meanings in subjects with ID and/or low functioning ASD. Apart from nutritional consequences, some studies underline that eating behaviour seems to assume a more communicative/relational function for people with ID in comparison with the general popula-

tion [133, 134]. This hypothesis is partially supported by some data which show that people with moderate-to-severe ID and physical illness that makes it difficult for them to both eat and communicate, are more likely to have eating dysfunctions [135]. The same study reported an interesting association between dysfunctional eating behaviour and aggressive behaviour, which would deserve further investigation.

Kuhn et al. [133] evaluated the possible relationship between rumination and social skills in persons with ID. They found that these persons show significant deficits in social skills (e.g. participating in leisure or occupational activities with others) when compared with non-ruminant persons with ID [133]. This result confirms previous data about the association between lower level of social adaptive skills and stereotypies [134]. Researchers have hypothesized that stereotypic behaviour such as rumination may develop in the absence of environmental/relational stimuli as a kind of compensatory sensory self-stimulation, and get to structure progressively until it becomes the only possible relational modality [108, 133, 136]. Rapid eating has also been associated with relational difficulties, especially with preventing one from contacting the reinforcers associated with eating with others and sitting down over a period of time [112].

Tip

The compensatory role of rumination for lack of environmental/relational stimuli in persons with ID/ASD represents an interesting field of research that could also lead to new therapeutic strategies aimed at improving dysfunctional eating behaviour by increasing social skills.

25.6.2 Key Aspects of Clinical Presentation and Differential Diagnosis of Specific FEEDs

25.6.2.1 Anorexia Nervosa

Cognitive symptoms such as fear of gaining weight and distorted body image can be difficult to assess, especially in persons with more severe ID and communication impairment. The presence of persistent behaviour that interferes with weight gain has to be considered the most important symptom and needs accurate assessment through additional observation from family members and other significant caregivers. The use of pictures may also be helpful to evaluate self-perception of body image.

Food refusal may present with atypical symptoms and problem behaviours such as temper tantrums, keeping lips sealed, turning the head away, spitting, throwing cutlery, self-injury (up to self-mutilation), vomiting in the face of caregivers, masturbation, compulsive singing, compulsive laughing and apathy [113].

In persons with ID/low functioning-ASD, anorexia nervosa has to be carefully differentiated from physical illnesses and other psychiatric disorders, especially depression, ADHD, obsessive compulsive disorder, psychotic disorders (delusions of poisoning) and anxiety disorders. In fact, as aforementioned, understanding the reasons of food refusal may be challenging as well as identifying cognitive symptoms of anorexia nervosa. Clinicians should also consider that anorexia nervosa may co-occur with other psychiatric disorders, especially anxiety disorders, mood disorders and ADHD [113, 137].

25.6.2.2 Bulimia Nervosa

As for anorexia nervosa, cognitive and self-reported symptoms can be difficult to observe and to elicit. Furthermore, careful assessment and comprehensive information is needed to ascertain secretive inappropriate behaviours.

25.6.2.3 Binge Eating Disorder

Feelings of self-disgust, sadness or guilt after binges may be difficult to identify. The presence and frequency of binge eating episodes should be defined at the light of availability of food, which can be excessive in many living contexts of person with ID/ASD.

25.6.2.4 Avoidant/Restrictive Food Intake Disorder

As general food refusal, also selective food refusal may present with atypical symptoms and problem behaviours, especially in persons

with major cognitive and communication difficulties, who cannot communicate which aspects of food are aversive. Inability to identify and express one's feelings may also contribute to restrictive eating as a means of internalizing distress [138].

The sensory peculiarities often present in persons with ID and ASD can lead to refusal of some or many foods, as the colour, texture or smell may result unpleasant. In this case a diagnosis of co-occurrent ARFID should be made with caution, only if the food restriction cannot be explained by the specific manifestations of the ASD.

Food refusal can also be a component of a co-occurrent anxiety disorder or ADHD. Loss of appetite is a common response to anxiety and stress, due to the activation of the sympathetic nervous system and the other changes the body makes as part of the fight-or-flight response. ADHD can affect eating behaviour because of distractibility, lack of interest in eating and high levels of arousal at mealtimes [137, 139]. Even in these cases and in those of other psychopathological co-occurrences, the issue of differential or adjunctive diagnosis of ARFID must be carefully considered.

25.6.2.5 Rumination Disorder

In individuals with ID and/or low functioning-ASD, regurgitation could be due to self-stimulatory or self-soothing behaviours. It could also be associated with physical problems that individuals are not able to describe, such as dysphagia, gastroesophageal reflux disease, pyloric stenosis or gastroparesis. Careful history taking and specific testing such as high-resolution oesophageal manometry with pH impedance are key to an effective differential diagnosis.

The occurrence of regurgitation in the context of an anxiety disorder, especially a generalized anxiety disorder, should also be excluded.

25.6.2.6 Pica

Persistent eating of non-nutritive, non-food substances should be distinguished from the inability of many persons with ID and/or low functioning-ASD to control hunger and to differentiate between food and non-food substances as well as prepared and unprepared or discarded food [113].

There is a strong correlation between pica and other mental illnesses, including ADHD, depressive disorders, anxiety disorders, post-traumatic stress disorder, obsessive compulsive disorder and other FEEDs. In all these cases, the issue of differential or adjunctive diagnosis of pica must be carefully considered.

25.6.3 Feeding Disorders: Quantitative and Qualitative Medical Implications

As described above, feeding disorder is characterized by inadequate quantity of food intake that does not satisfy nutritional needs and causes quantitative and/or qualitative alterations of nutritional status. Persons with ID/ASD often have overweight and obesity as consequences of abnormal eating behaviours, poor education about dietary habits, healthy life styles and nutritional potential of food, as well as low physical activity, due in turn to frequent pain, fatigue, athletic inability and limited mobility [4, 140–142]. Research has found that sex and age can also increase the risk of obesity, with females and adults showing higher rates than males and adolescents [143, 144]. Obesity appeared also significantly associated with some genetic syndromes, such as Down syndrome [145] and Prader-Willi syndrome [146]. Persons with Prader-Willi syndrome report compulsive eating and binge eating probably because of their hypothalamic and endocrine abnormalities which are responsible of an impairment of the food satiety response [147].

On the other hand, low weight (BMI < 18 kg/m^2) also represents a frequent quantitative alteration of nutritional status in individuals with ID, with rates ranging from 5% to 43% [4] and generally higher than those of the general population [148], although much less attention has been paid to this condition than to overweight and obesity.

There are a number of factors associated with ID that increase the risk of becoming underweight such as abnormal eating behav-

iours, avoidant/restricted intake of food, food refusal and food selectivity. Neuromotor alterations of the upper gastrointestinal tract (i.e. chewing problems, dysphagia, regurgitation, gastroesophageal reflux, cyclic vomiting) and consequent dehydration, aspiration and asphyxiation, and upper respiratory infection are frequent and may also contribute to nutritional deficiency [149].

The causal contribution to low weight of sex-related factors is not clear, as is the sex ratio of low weight prevalence. Hove found it to be higher in men with ID (9%) than in women (7%), while Emerson did not find any difference in reference to any age [148].

In summary, overweight/obesity and low weight in people with ID/ASD can be defined as a multifactorial manifestation of their complex mental and physical vulnerability. Both conditions determine a high risk of further serious health problems. Low weight is associated with increased susceptibility to infections, anaemia, osteoporosis, fertility issues, persistent fatigue and several dermatological problems, while obesity increases the risk of coronary heart disease, ischemic stroke, type II diabetes, osteoarthritis and cancers of the breast, colon, prostate, endometrium, kidney and gallbladder [7].

In persons with ID and/or ASD, overweight and obesity are the most common medical consequences of abnormal eating behaviours, although underweight is also rather frequent.

Rapid eating and low mastication also present threats to one's safety and health, in both the short- and long term. Immediate risks include the possibility of choking or aspiration, vomiting, acid reflux and poor digestion, whereas more long-term risks include overweight, obesity, insulin resistance, type 2 diabetes and metabolic syndrome [150–153]. Rapid eating has also been found to decrease the taste and smell sensory stimulation by food and determine lower satisfaction with food. Fast eaters tend to rate their meals as less pleasant and to eat more food to compensate, compared with slow eaters [154].

Table 25.3 Potential complication of pica

Toxicity	Hypokalemia or hyperkalemia, poisoning, deficiency of vitamins and iron
Obstruction	Intestinal obstruction with possible perforation, peritonitis, and death
Excessive caloric intake	As a consequence of the craving for food items such as carbohydrate and fats
Nutritional deficit	Failure to thrive, achlorhydria
Other	Dental injury, infections, infestations

Adapted from Sayetta [122] and Rose et al. [77, 155]

Rapid eating is a relatively understudied behaviour that also falls under the broad group of FEEDs, although it does not easily fit into either the skills deficit or behavioural excess categories since the alteration refers to the amount of time between one bite of food and another, which is too short and does not allow adequate chewing.

FEEDs can also have serious negative implications on qualitative nutritional status and consequently on general health. Among FEEDs, pica which represents the most common condition determining qualitative alteration of nutritional status in person with ID, with prevalence rates ranging from 4% to 26% [4]. Pica has numerous medical complications that have been gathered in five groups: inherent toxicity, obstruction, excessive calorie intake, nutritional deprivation and other complications [155] (see Table 25.3). Complications depend on the substance ingested. Iron deficiency anaemia is particularly common in persons with geophagia and pagophagia, while lead intoxication is more frequently associated with ingestion of flaking paint or plaster. Parasitic infestation (e.g. toxocariasis, toxoplasmosis, ascariasis, giardiasis, cysticercosis) often follows the ingestion of soil contaminated with the excreta of dog, cat and pork [35].

Definition and clinical characteristics of pica have been provided in the ▶ Sect. 25.2.1 of this chapter.

Rumination, another frequent feeding/eating disorder determining qualitative alteration of nutritional status, may also cause considerable health issues such as halitosis, lethargy, irritability, malnutrition, dehydration, electrolyte abnormalities, renal damage, parotid swelling, dental erosion and aspiration pneumonia, which can be lethal in 12–20% of chase, if not treated [4]. Also definition and clinical characteristics of rumination disorder have been provided in ▶ Sect. 25.2.1 of this chapter.

ARFID encompasses clinical conditions previous categorized by GOS (Great Ormond Street) classification system in: food avoidant emotional disorder (significant food intake restriction in absence of body and shape concerns), selective eating (selectivity based on food non nutritional characteristics such as taste, colour, temperature, texture, and smell), and functional dysphagia (fear of swallowing, vomiting or choking that cause anxiety) [156]. GOS developed this classification in order to distinguish different clinical patterns that encompass in the DSM-IV group of Eating Disorders not Otherwise Specified (EDNOS) [22].

Very little is known about ARFID prevalence and its medical consequences, with some exception for malnutrition and low body weigh that often necessitate hospitalization and tube feeding [157].

In summary, we can affirm that abnormal eating behaviours and feeding disorders in individuals with ID/ASD cause serious medical problems as a result of quantitative and qualitative alterations of nutritional status. FEEDs also complicate the management of all other health, social and educational needs of persons with ID/ASD, especially during infancy and childhood and in presence of more severe cognitive and relational impairment [41, 158]. Furthermore, these conditions have a strong negative impact on the quality of life of persons with ID and their caregivers.

These data indicate the need for clinicians and other professional operators to pay more attention to risk factors, early warning signs and symptoms of FEEDs in order to achieve timely diagnosis, prevention of complications and treatment. Standardized assessment tools can assist clinicians and the whole multidisciplinary team in the systematic identification of problems to be targeted for further clinical assessment. Beside generic screening tools for any psychiatric disorder (including FEEDs), few specific tools for FEEDs have been produced such as the STEP (Screening Tool of Feeding Problems; [42]).

25.7 Anorexia Nervosa and Autism Spectrum Disorder

A large body of literature considering the association between ASD and EDs, especially AN, has been published over the years since 1983, when Gillberg identified some similarities in the cognitive profiles of the two conditions [159, 160] and proposed an empathy defect to be a core feature of AN and its pathogenesis [53]. Some communalities between AN and ASD pointed out by the scientific literature refer to impairments of theory of mind (the ability to impute independent mental state in other individuals), central coherence (the ability to have a global prospective instead of focusing on details) and set shifting (the ability to shift from one action to another fluently, with no difficulty) [161]. Other similarities concern rigid attitudes and behaviours, especially towards food, and excessive focus on self. This tendency to an extreme self-attention can be interpreted as a consequence of the difficulty to empathize with other persons and associated psychopathological features such as anhedonia, deficit of emotional intelligence and alexithymia, which have been reported for both AN and ASD [162].

In ED populations, ASD prevalence is reported at rates of around 23–30%, especially among female individuals and in reference to anorexia nervosa [161, 163, 164]. Furthermore, it has been suggested that autistic traits in childhood increase the risk

of developing an ED during adolescence and adulthood, especially AN [165]. Conversely, eating problems and food selectivity are frequent in individuals with ASD, especially during childhood and adolescence [166].

ASD has been identified as a possible non-specific familiar risk factor for AN and a family history of AN has been associated with a risk increase of ASD [167].

Nevertheless, it is not clear whether ASD aspects in EDs represent psychopathological dimensions (quantitative variations along a continuum) that can be found also in other psychiatric disorders or they really describe the coexistence of the two nosographic categories (qualitative differences from other psychiatric disorders). In fact, beside the above-mentioned aspects in common, AN and ASD show main differences such as later age of onset of AN, higher prevalence in females for AN and in males for ASD, and more heterogeneous IQ levels for ASD than for AN [168].

Tchanturia et al. [169] found ASD aspects not to correlate with the core physical symptoms of AN, such as low BMI, malnutrition or starvation, suggesting that the link between ASD and AN could go through mental dysfunctions rather than their physical consequences. Moreover, the same authors showed that in persons with ASD, AN presents with more severe symptoms, higher association with depressive symptoms and poorer social functioning than in the general population.

Some researchers and clinicians indicated that persons with ASD may require longer and more intensive treatments for AN than other patients without ASD, suggesting that the presence of ASD can contribute to treatment resistance to conventional therapies [169]. AN patients with ASD-related social cognitive difficulties have been reported to have lower engagement in family-based treatment and other main psychotherapeutic interventions [169]. Nevertheless, no clear evidence have been provided to date on the impact of ASD traits on treatment outcomes of patients with AN.

Tip

The main similarities between AN and ASD are some cognitive and behavioural patterns: restricted interest and activities, difficulties in social interaction and communication, repetitive behaviours.

25.8 Treatment

FEEDs include a host of heterogeneous problems that vary in nature and it is highly unlikely that one or two therapeutic interventions can be effective in all instances. Multi/interdisciplinary and tailored therapy is key, based on the complex interactions among individual and disease characteristics, including type of behaviour, frequency, intensity, chronicity and cause.

Clinical management of FEEDs implies continuous risk monitoring for medical complications and the need for hospitalization, including monitoring of vital signs (e.g. heart rate < 40 bpm), weight status (e.g. extremely low body mass index), severe blood abnormalities (e.g. severe anaemia or electrolyte imbalances), treatment fails (e.g. decline in oral intake or family and caregivers support) and other psychiatric conditions (e.g. suicide risk) [170].

Normalization of nutritional status and dietary patterns are central features of the treatment of many FEEDs, especially anorexia nervosa, bulimia and avoidant/restrictive food intake disorder. As far as possible, oral-enteral nutrition should be favoured over parenteral nutrition, which should only be used as a last option. When appropriate, nutritional supplements should also be considered, including phosphate, thiamine, zinc, potassium and vitamins [170].

Psychotherapy is deemed as a central part of the treatment of all FEEDs, with behavioural therapy being the most evidence-based approach in persons with ID and/or ASD [112]. Several researchers have found antecedent interventions to be effective in altering the

aversive characteristics of the feeding context and/or non-preferred food as well as increasing the value of reinforcement for food consumption, and reducing the response effort for engaging in the target behaviour [112]. Examples of antecedent procedures are represented by simultaneous presentation, high-probability instructional sequence, food texture manipulation, presentation of bites of food and fading of bites demand. Simultaneous presentation involves the provision of non-preferred foods at the same time as preferred foods and the association of specific preferred tastes or stimuli (e.g. preferred condiments) to non-preferred foods [171, 172], while the high-probability instructional sequence consists in presenting 2–3 responses which the individual has a high probability of complying with, just before the non-preferred food [173–175].

Reinforcement and extinction procedures, especially differential reinforcement of alternative behaviour and escape extinction, have also received considerable attention in research and practice on treatment of FEEDs. Several kinds of reinforcers such as attention, favourite objects and/or preferred foods have been provided contingent upon food consumption and not at any other time [176–178]. Two of the most utilized extinction procedures include non-removal of the spoon and physical guidance [179, 180].

Some specific behavioural treatments have been practiced and studied for specific FEEDs. Rapid eating has been treated through reinforcement of pauses between bites of food, shaping of longer pauses and prevention of attempts to eat rapidly by prompting the person to wait [181], while some cases of rumination disorder have been improved by use of modelling and reinforcement in diaphragmatic breathing training and/or behavioural relaxation training [182]. Pica has been addressed mainly through behavioural treatments involving reinforcement and response reduction, with and without aversive components. Most studied aversive stimuli methods are lemon juice, food aversion and water mist [183, 184], while overcorrection has been the most considered of the work and effort methods, although it is now largely out of favour and replaced by other methods such as negative practice, habit reversal and response effort. In general, current clinical practice is drifting away from aversive techniques and relying more on positive procedures such as environmental enrichment, reinforcement schedules and eclectic methods [184].

Family-based therapy is increasingly being recommended for younger neurotypical patients [185] and could be of some utility also for many persons with ID and/or ASD but evidence on practicability and effectiveness is still lacking.

Research on pharmacological treatments of FEEDs in persons with ID and/or ASD is scarce. Antidepressants represent the most used class of drugs, specifically the SSRI (selective serotonin reuptake inhibitor) fluoxetine for the treatment of bulimia nervosa and co-occurrence of depressive disorders in anorexia nervosa, albeit with several restrictions and in combination with psychotherapy whenever possible. Selective serotonin reuptake inhibitors seem to be useful also for those cases of pica that seem to lie within the obsessive-compulsive spectrum [30].

Topiramate has been shown to have some efficacy on bulimia and binge eating disorder, although reports are limited and contradictory [186–188]. Orlistat and liraglutide could be of some utility for weight loss in these conditions and obesity [189–191].

Baclofen, a γ-aminobutyric acid agonist with antispasmodic activity, has been used for rumination disorder. It increases post prandial LES (lower oesophageal sphincter) pressure and reduces the number of its transient relaxation episodes. Another pharmacological therapy that has shown some benefit for rumination disorder is the antipsychotic levosulpiride, a selective dopamine D2-receptor antagonist with prokinetic activity.

Surgical treatment represents an extreme therapeutic ratio for rumination syndrome, in particular patients with low basal LES pressure on HREM (high-resolution oesophageal manometry) with evidence of GERD (gastroesophageal reflux disease) based on 24-h pH impedance testing may benefit from Nissen fundoplication refractory to behavioural and pharmacological therapy [192].

Key Points

In this chapter, we focused our attention on the clinical manifestations and the impact of eating and feeding disorders for individuals with ID. It appears that there is still a lot to study in order to clarify the role of these clinical syndromes in people with ID and other developmental disorders. This topic could be crucial for the development of a new management of eating symptoms in people with ID.

The main key points of this chapter are the following:

- With respect to people with ID it is challenging to investigate their disturbance of body image, one of the most important elements in the development of EDs. This issue limits the knowledge about prevalence data, psychopathological and clinical features of EDs in adults with ID.
- Subjects with ID are often victims of physical, sexual and psychological abuse. The role of abuse in the aetiopathogenesis of EDs, well known in adults without ID, could be a key element and should be evaluated also in ID population.
- People with ID often demonstrate serious medical consequences of feeding disorders and/or abnormal eating behaviour such as overweight and obesity, most frequently.
- Autism spectrum disorder and anorexia nervosa demonstrate to have some clinical features in common. The relationship between these two psychiatric conditions needs further studies.

Learning Objectives

- To understand the biological, genetic, and psychosocial risk factors for the development of sleep abnormalities in individuals with intellectual disability and/or low-functioning autism spectrum disorder.
- To understand how sleep disorders in the ID/ASD population can be diagnosed especially when there are comorbid conditions such as seizure activity, medical conditions, problems behaviours, and neurodegenerative and psychiatric disorders.
- To understand the issues around diagnosis and management at different levels of intellectual functioning.
- To discuss treatment options and approaches to sleep disorders in this population.

26.1 Introduction

Sleep disturbance is a common problem in people with intellectual disability (ID) and/or autism spectrum disorder (ASD) due to their biological (including genetic) and psychosocial risk factors that predispose them to sleep abnormalities [1, 2].

Sleep is a dynamic state that is essential for human physical and mental health, including cognitive performance and emotional reactivity. Experimental sleep deprivation has been shown to negatively impact on all the human body communication systems (nervous, endocrine, and immune) and determines a wide range of negative effects on mood, cognitive, and psychomotor performance, glycogen sensitivity, lipid metabolism, immune responses to endotoxins, and many other physiological set points, also suggesting that persistent sleep restriction may accelerate some processes of ageing [3–9].

From a neurophysiological point of view, two main types of sleep can be distinguished: desynchronized sleep or sleep with rapid eye movements (REM), which is often associated with vivid dreams and intense brain activity, and synchronized sleep also known as sleep without rapid eye movements (non-rapid eye movements, NREM), which is associated with reduced brain activity. According to Rechtschaffen and Kales' model, which is meant as a reference method for sleep analysis and scoring, NREM sleep accounts for 75–80% of total sleep time in adults and can be split into four stages [10].

REM and the four NREM stages make up the sleep macrostructure, in which brain electrical activity occurs in coordinated and repeated cycles, normally four to six cycles per night. The initial cycle lasts 70 to 100 minutes while the following cycles are longer, 90–120 minutes each, with the amount of REM also increasing over the cycles up to 30% in the later cycle of the night [3, 11].

The average individual's sleep episode begins in NREM stage 1, which usually lasts 1–7 minutes in the initial cycle, constituting 2–8% of total sleep, and is easily interrupted by disruptive noise. In this stage brain electrical activity [as detectable through the electroencephalogram (EEG)] varies from rhythmic alpha waves to low-voltage, mixed-frequency waves. Alpha waves are associated with a wakeful relaxation state and are characterized by a frequency of 8–13 cycles per second. Stage 1 sleep may also play a transitional role in sleep-stage cycling [3].

Stage 2 sleep lasts approximately 10–25 minutes in the initial cycle and lengthens with successive cycles, constituting between 45% and 55% of the total sleep episode. To awaken from this stage of sleep, a person needs more intense stimulation than in stage 1. Brain electrical activity shows relatively low-voltage and mixed-frequency waves, with characteristic sleep spindles and K-complexes. It has been hypothesized that sleep spindles and K-complex are important for memory consolidation because of their high presence in individuals who learn a new task. K-complex has also been suggested to have other relevant functions such as the maintenance of interruption of sleep when encountered with a stimulus that the brain evaluates as harmless or potentially dangerous, respectively, and the maintenance of synapse homeostasis, which would be exerted by

determining a sort of "reboot" for the neural connections [3, 12].

Stage 3 lasts only a few minutes and constitutes about 3–8% of sleep while stage 4 lasts approximately 20–40 minutes in the first cycle and makes up about 10–15% of sleep. Stage 4 presents the highest arousal threshold of all NREM stages. Because of the increased amount of high-voltage and slow-wave activity on the EEG (i.e. delta waves), stages 3 and 4 are collectively referred to as slow-wave sleep, most of which occurs during the first third of the whole sleep episode [3].

In the last 20 years, Rechtschaffen and Kales' description of sleep processes and associated scoring rules have increasingly been criticized [13] and alternative guidelines have been developed such as those by the American Academy of Sleep Medicine, in which sleep stages S1–S4 are referred to as N1, N2, and N3, with N3 merging S3 and S4; stage REM is referred to as stage R [14]. Other approaches have also been employed for the automated categorization of sleep stages using modern multi-channel EEG [15–17].

Sleep structure and sleep propensity derive from the interactions of circadian and sleep-wake-dependent oscillatory processes developed by a hierarchy of tissue-specific structures located throughout the body and coordinated by the suprachiasmatic nucleus (SCN) of the hypothalamus [18]. These tissue-specific rhythms are based on light input from the outside world and cortisol release during daytime and by melatonin secretion during the dark hours. Damage to the SCN eliminates the circadian rhythms of many behaviours, including sleep [19]. The melatonin secretion pathway extends from the SCN to the paraventricular nucleus (PVN) of the hypothalamus, the upper thoracic spinal cord, superior cervical ganglion, and the pineal gland [20]. Cortisol level is reduced during slow-wave sleep while it rises rapidly in the middle of the night and peaks during the biological morning. Cortisol pathway projects from the SCN to the subparaventricular zone of the hypothalamus, the dorsomedial nucleus, and the medial parvocellular part of the PVN. The latter stimulates the release of corticotropin releasing factor, which has also been implicated in the control of sleep-wake rhythm as well as in the promotion of REM sleep [21].

The sleep phase is regulated by neural structures that switch off the brain's arousal systems, allowing it to fall asleep. The preoptic region of the hypothalamus contains a large number of these neurons but the sleep system is also heavily influenced by inputs from other parts of the brain such as the emotional and cognitive areas of the forebrain as well as the lower brainstem, which relay information about the state of the body (e.g. a full stomach makes it easier to fall asleep). The sleep-generating system also involves neurons in the pons, which regulate the transitions from NREM to REM phases during the night. These neurons transmit signals to the lower brainstem and spinal cord, resulting in muscle atonia, rapid eye movements, and erratic autonomic activity, all of which are hallmarks of REM sleep [3]. NREM sleep is controlled mostly by the thalamus and the cerebral cortex, although other structures like the basal forebrain, anterior hypothalamus, cerebellum, caudal brain stem, spinal cord, and peripheral nerves contribute to its regulation and modulation [22]. REM sleep is activated by the brainstem, particularly the pons and adjacent portions of the midbrain, and deactivated by the dorsal nuclei of the raphe, the locus coeruleus, and the deep mesencephalic reticular nucleus [23, 24].

The major pathways of the ascending arousal influence originate in the upper brainstem. One of these arises from cholinergic neurons in the upper pons, which stimulates portions of the thalamus that are responsible for preserving sensory input delivery to the cerebral cortex. Another pathway starts from monoamine neurotransmitter-containing cell groups in the upper brainstem and joins the hypothalamus rather than the thalamus, where it receives input from nerve cells containing peptides such as orexin and melanin-concentrating hormone. These signals then travel to the basal forebrain, where they receive additional information by acetylcholine and gamma-aminobutyric acid-containing cells, before entering the cerebral cortex to provide a diffuse activation and

preparation for the interpretation and analysis of sensory data [3].

Sleep is induced and maintained by the activity of acetylcholine, gamma aminobutyric acid, serotonin, norepinephrine, and a number of cytokines, hormones, nucleosides, and prostaglandins, while waking is more associated with glutamate, dopamine, hypocretin, and histaminergic systems, although many of these and other neurotransmitters and neuromodulators are involved in both states [25].

Insomnia and other sleep disturbances are common in mental disorders, especially depression and anxiety disorders, and many researchers have proposed a causal interplay between sleep and psychopathological conditions, which has been largely supported by contemporary neurobiology studies [26]. This association appears to be even stronger in persons with ID, ASD, attention deficit hyperactivity disorder, and other neurodevelopmental disorders than in the general population, with repeated findings of very high co-occurrence of sleep issues, problem behaviours, and psychiatric disorders [27–30].

The most common theory describes disturbed sleep as a causal mechanism for other psychiatric problems, which seems to be supported by the common observation that treating insomnia reduces the occurrence of other mental health issues. Common causes for sleep and mental disorders have also been proposed to explain this high coexistence and interrelation [31].

In persons with ID and/or ASD these difficulties of differential diagnosis and other diagnostic issues are even greater than in neurotypical persons since the peculiarities of clinical presentation and consequent overshadowing with common comorbid conditions such as epilepsy, respiratory illnesses, problem behaviours, neurodegenerative, and psychiatric disorders.

26.2 Prevalence

Sleep problems are commonly reported complaints of individuals with ID, with an estimated prevalence exceeding that reported for individuals in the general population [32–34]. According to the literature, the prevalence of sleep disorders in children with ID ranged from 25.5% to 36.2% with an average duration of between 6 and 9 years [35]. In adults with ID, the prevalence seems to vary between 8.5% and 34.1% and in the most severe forms, it reaches 9.2% [29]. However, when actigraphy has been used to evaluate insomnia, 72% of a large community sample of people with ID was found to suffer from sleep problems [36]. It is important to notice that the majority of the available studies on sleep disorders in people with ID concentrate on insomnia. The sleep-wake rhythm of adults with ID has been reported less stable, fragmented, and with a lower relative amplitude [37]. Furthermore, the evidence indicates that individuals with higher severity or comorbid disabilities are at an increased risk of developing sleep difficulties [38]. The factors that have been most frequently associated with the presence of sleep disorders are problem behaviours, respiratory disease, vision problems, psychiatric disorders, and intake of psychotropic drugs, especially anti-epileptics [28, 29]. Fragmented sleep has also been associated with lower physical activity, dementia, epilepsy, sensory impairments, and spasticity [37]. Sleep disorders have been reported more commonly in the case of difficult temperament, anxious or disorganized attachment behaviours, parental exhaustion, inexperience, psychosocial stressors and anxieties, conflicts over sleeping arrangements. Particularly, in the case of family psychopathology, the condition of maternal depression has been observed to lead to a higher chance of transferring to the child genetic risk factors for sleep and mental disorders [39–41]. Moreover, depending on the changes during the lifetime, sleep disorders may be treated as part of developmental disorders. Indeed, it is well established that the prevalence of sleep disorders varies depending on brain maturation and development and with the modification of environmental expectations and demands. At the molecular level, the timing of gene-environmental interactions changes across the lifespan and is regulated by the modifications of the environment previously stated [42, 43]. Finally, it has been observed that different rapid eye movement

(REM) characteristics are typical of different psychiatric situations and could concur to define endophenotypes specific for the considered disorder. For example, depression has been found to be characterized by a decreased REM sleep latency and an increased REM density. In schizophrenia, on the other hand, electrophysiological, pharmacological, and neurochemical activities have all been found to be encountered during REM sleep. Similarly, in ID and dementia-specific REM sleep disturbances have been reported [44].

Sleep problems are frequent in people with ID, with an estimated prevalence higher than that of the general population. These disturbances are common in both children and adults, especially in individuals with higher severity or comorbidities.

26.3 Development and Maturation of Physiological Sleep Timing

The sleep in infancy is marked by the circadian biological rhythms that correspond to zeitgebers, which is the night-day cycle, and in this case, can be identified as the night sleep and day attentiveness [45–48].

Most of the sleeping processes are learned and not innate, as it is commonly believed. Indeed, during early infancy, the schemas of sleep are characterized by "active sleep", which has short inactivity to REM-like activity, except for some characteristics of the REM phase such as atonia and muscle paralysis.

The period between 3 and 6 months of the child is characterized by non-REM sleep. In fact, the majority of the sleep cycle is characterized by the sleep spindles, K complexes, and slow wave activity.

On the other hand, the older infants' sleep cycle is dominated by the slow wave, as the non-REM activity is present for 50% of the time during sleep [45–48].

Finally, as the age progresses, there are changes in REM latency and density, sleep efficiency deteriorates as it becomes more desynchronized and less restorative. Indeed, there are some physiological changes such as the reduction of melatonin production and the decline in access and sensitivity to light and other zeitgebers.

26.4 Etiopathogenesis of Sleep Abnormalities in Neurodevelopmental Disorders

26.4.1 Biological Factors

The incorrect function of melatonin activity has been found to have effects on sleep phase disorders and also to affect psychopathology. Specifically, the production of melatonin is found to be dysfunctional in people with ASD and ID [49, 50]. Indeed, in these populations, sleep is fragmented, erratic, and the transition between cycles can be challenging to identify. Besides, people with ASD or people who are visually impaired are more likely to have an irregular sleep-wake cycle that is not regulated by light, as they have a desynchronized sleep rhythm with zeitgebers that lead them to depend on social cues to have a regular sleep [51, 52].

However, there is no evidence that poor levels of melatonin are the cause of disruptive behaviour in the ID population despite it is clear that subjects with severe/profound ID, ASD, and visual impairments do not produce enough melatonin, they may secrete it during the day instead of at night, or they metabolize it promptly. These characteristics can explain the reason why these people may not respond to melatonin.

Hypersomnia may be caused by another sleep disorder (e.g. narcolepsy or sleep apnoea), dysfunction of the autonomic nervous system, or drug or alcohol abuse. In some cases, it results from a psychopathological condition such as depression, a neurological problem such as multiple sclerosis, epilepsy, encephalitis, a tumour, head trauma, or injury to the central nervous system, or other physical health issues such as obesity. Certain medications, or medicine withdrawal, may also cause hypersomnia. Some people appear to

have a genetic predisposition to hypersomnia; in others, there is no known cause.

Narcolepsy-cataplexy is most commonly caused by a loss of hypocretin-producing cells in the lateral hypothalamus. Hypocretin is a neuropeptide vital for the regulation of the sleep-wake cycle by its influence on the histaminergic, nonadrenergic, serotonergic, and cholinergic systems. Low cerebrospinal fluid hypocretin levels are found in the wide majority (90–95%) of patients with narcolepsy and typical cataplexy and can be used to diagnose the conditions, while they are present in only 10–30% of cases of narcolepsy without cataplexy. Narcolepsy-cataplexy is tightly associated with a specific human leukocyte antigen (HLA)-allele, namely HLA-DQB1*0602, suggesting an autoimmune process to underlie the destruction of hypocretin-producing neurons [53].

For parasomnias, a link between a delayed maturational process of sleep associated with a greater amount of slow wave sleep (SWS) in adulthood has been postulated, which would be confirmed by the high prevalence of these group of sleep disorders in persons with ASD, ID, and other neurodevelopmental conditions [54].

26.4.2 Genetic Factors

People with ASD and Smith-Magenis syndrome can exhibit a switch in melatonin synthesis and release [49]. Besides, people with Angelman's syndrome and complex epilepsy can have an interrupted sleep caused by anticonvulsants, dysfunctional GABA receptors, arousal problems, and nocturnal seizures [2, 55]. Indeed, nocturnal frontal lobe seizures are related to nicotinic cholinergic receptors, and for this reason, they have to be distinguished from parasomnias and REM-sleep related behaviours [56, 57].

Moreover, some physical changes can be related to sleep problems. Indeed, the changes of the facial morphology that are present in Down syndrome and Fragile X syndrome and the obesity that characterizes Prader-Willi syndrome are associated with breathing disorders which can lead to obstructive sleep apnoea syndrome (OSAS) [58, 59]. Owing to midface and maxillary hypoplasia as well as relative macroglossia and glossoptosis, persons with Down syndrome have a narrower bony dimension of the upper airway with superficially positioned tonsils, relative tonsillar and adenoidal encroachment, and increased secretions. Furthermore, they show generalized hypotonia and increased risk of hypothyroidism and obesity, which are also risk factors for OSAS [1, 58–60]. Main predisposing factors of persons with Fragile X syndrome are represented by high arched palate and generalized hypotonia [2]. Many persons with Prader-Willi syndrome show altered hypocretin levels in the cerebrospinal fluid that are associated with hypersomnia, and cataplexy, but only one-third of these cases possess the above-mentioned HLA-DQB1*0602 haplotype [2].

Diverse behavioural phenotypes have been recognized in people with ID, such as the presence of polysomnographic phenotypes [61], while people with ASD, Down, and Fragile X syndromes have problems in sleep architecture [2, 62]. Persons with Williams syndrome show an increase of non-rapid eye movement percentage, slow-wave sleep, number of leg movements, irregular sleep cycles, respiratory-related arousals, and slow-wave sleep, while rapid eye movement sleep percentage is reported to be significantly decreased [63, 64]. Rett syndrome is characterized by frequent night-time awakenings, bruxism, and difficulty falling asleep, although these issues show an age-related decreased across the life-span. Night screaming and night laughing in particular are strongly related to large deletions in MECP2 [2].

Moreover, a link has been found between the level of ID and total sleep time, frequency of awakenings, eye movements during REM-sleep, and stability in sleep architecture [65]. In addition, the Smith-Magenis syndrome presents a sleep disorder as the main symptom, which in part is correlated with the inverted process of melatonin production [66].

26.4.3 Psychosocial Factors

Nowadays, there are some lifestyle and habit changes within the society that can lead to sleep disorders or insufficient sleep. These are high-stress levels that can be due to work or academic demands, time spent in natural and artificial light, use of computers in late evenings, TV and other electronic devices, obesity, fixed bedtimes, use of pharmaceuticals, and other psychosocial or cultural factors [67].

Mainly, the same psychosocial and environmental issues affect normal population as well as neurotypical and people with ID. However, their impact on people with ID can be different depending on the level of ID and the presence of other risk factors for disrupted sleep. Besides, the adverse effects of relative insufficient sleep can negatively affect the quality of life of people with ID and increase the rates of disruptive and destructive behaviours [50]. Indeed, children and several adults with ID, when they experience insufficient sleep, instead of fatigue and sleepiness, may show hyperactivity, disruptive or stereotypic behaviours, irritability, and self-injurious or aggressive behaviour [68].

26.4.4 Developmental Factors Through the Lifespan

There is still little information on the developmental trajectory of brain "ageing" in several subpopulations with ID. Indeed, despite the neuroimaging and post-mortem studies made to gain data on the brain ageing and dementia in people with Down syndrome [69], there is a general lack of information on the remaining and more heterogeneous ID population. Currently, some investigators are addressing the link between emerging tauopathies, synucleopathies, cerebrovascular disease, and REM parasomnias in people with ID.

In persons with ID and/or ASD non-organic sleep disorders can be caused by various biological, psychological, and environmental factors, including genetic anomalies, alterations in the melatonergic system, psychiatric problems, distress, medications, and ageing.

26.5 Criteria and Clinical Features

There are many distinct sleep disorders, but the majority of them are characterized by one of the following symptoms: "excessive daytime sleepiness, difficulties initiating or maintaining sleep, or abnormal movements, behaviours, and sensations occurring during sleep".

DSM-5 [70] offers the classification of ten main sleep-wake disorders (eight main groups), conditions that are manifested by disturbed sleep that cause both distress and impaired functioning during the daytime:

1. Insomnia disorder. It is the most frequent sleep disorder. The diagnostic criteria include problems falling asleep, difficulties maintaining major sleep, and difficulties with daytime attention, concentration, memory, and executive function.
2. Hypersomnolence disorder. It is characterized by daytime sleepiness.
3. Narcolepsy. It is characterized by periods of sleep attacks, rapid eye movements, sleep paralysis, and in some cases episodes of cataplexy (partial or total loss of muscle control, often triggered by a strong emotion such as laughter).
4. Breathing-related sleep disorders. They are associated with daytime sleepiness and fatigue and include the following:
   - Obstructive sleep apnoea-hypopnoea. It is characterized by repetitive episodes of airflow reduction (hypopnoea) or cessation (apnoea) due to upper airway collapse during sleep.
   - Central sleep apnoea. It is characterized by a lack of drive to breathe during sleep, resulting in repetitive periods of insufficient ventilation and compromised gas exchange.
   - Sleep-related hypoventilation. It is characterized by an abnormal increase in partial pressure of carbon dioxide ($PaCO_2$) and a decrease in PaO_2 during sleep.
5. Circadian rhythm sleep disorders, including:
   - Advanced sleep phase syndrome. It is a disorder in which the major sleep episode is advanced in relation to the

desired clock time that results in symptoms of compelling evening sleepiness an early sleep onset, and an awakening that is earlier than desired.
   - Irregular sleep-wake type. It is characterized by numerous naps throughout the 24-hour period, no main night-time sleep episode, and irregularity from day to day.
   - Non-24-hour sleep-wake type. It is defined as comprising daily delays in sleep onset and wake times.
6. Parasomnias, characterized by abnormal behavioural, experiential, or physiological events that occur during sleep, specific sleep stages, or sleep-wake transitions, including the following:
   - Non-REM (NREM) sleep arousal disorders. They are recurrent episodes of incomplete awakening from sleep. During these episodes, patients may experience sleepwalking or sleep terrors. Sleepwalking can be associated with sleep-related eating or sleep-related sexual behaviour (sexsomnia).
   - Nightmare disorder. It involves repeated severe anxiety dreams during REM sleep.
   - REM sleep behaviour disorder. It involves abnormal behaviour during the sleep phase with REM sleep.
7. Restless legs syndrome. It is characterized by an unpleasant tickling or twitching sensation in the leg muscles when sitting or lying down, relieved only by moving the legs.
8. Substance- or medication-induced sleep disorder. It is the diagnostic name for insomnia and other sleep problems which are caused by the use of alcohol, drugs, or certain medications.

The ICD-10's [71] categorization of sleep disorders was based on the now-outdated distinction between organic and non-organic illnesses, resulting in the inclusion of "non-organic" sleep disorders in the ICD-10's [71] mental and behavioural disorders chapter, and "organic" sleep disorders in other chapters (i.e. diseases of the nervous system, diseases of the respiratory system, and endocrine, nutritional, and metabolic disorders). In ICD-11, a distinct chapter for sleep-wake disorders has been formed, which includes all pertinent sleep-related illnesses, regardless of whether they are more or less biological or psychological in nature, as following: [72]

- Insomnia disorders
- Hypersomnolence disorders
- Sleep-related breathing disorders
- Circadian rhythm sleep-wake disorders
- Sleep-related movement disorders
- Parasomnia disorders
- Other specified sleep-wake disorders
- Sleep-wake disorders, unspecified

Sleep-related movement disorders are characterized by basic, often stereotyped movements that disrupt sleep or its onset, and include restless legs syndrome, periodic limb movement disorder, sleep-related leg cramps, sleep-related bruxism, sleep-related rhythmic movement disorder, benign sleep myoclonus of infancy, propriospinal myoclonus at sleep onset, sleep-related movement disorder due to a medical condition, and sleep-related movement disorder due to a medication or substance. Unlike other sleep-related movement disorders, restless legs syndrome is mainly characterized by a waking, sensorimotor experience, but it has been included in this group of disorders because it almost always also includes periodic limb movements during sleep.

Parasomnias include disorders of arousal from non-REM sleep, parasomnias related to REM sleep, and other parasomnias. In the ICD-11 [72] the articulation of disorders of arousal from non-REM sleep is somewhat different from that of the DSM-5 [70] and includes confusional arousals, sleepwalking disorder, sleep terrors, and sleep-related eating disorder. Confusional arousals are marked by mental confusion or disturbed behaviour (e.g. disorientation, becoming unresponsive, slurred or slow speech, poor memory) during partial arousal from deep sleep. Like in all other disorders of arousal from non-REM sleep, partial or complete amnesia for the event can be present as well as inappropriate

or absent responsiveness to efforts by others to intervene or redirect the person during the episode.

The category "other parasomnias" includes hypnagogic exploding head syndrome, sleep-related hallucinations, and parasomnia disorder due to a medical condition. The impression of a sudden, loud noise, or a sensation of a violent explosion in the head is the main symptom of the hypnagogic exploding head syndrome, which usually happens while the person is falling asleep but episodes may also occur with awakening during the night. Sleep-related hallucinations are hallucinatory events that occur during the falling asleep phase (hypnagogic hallucinations) or while awakening from sleep (hypnopompic hallucinations). Visual hallucinations are the most common, but they may also involve auditory, tactile, or kinaesthetic experiences.

Sleep disorders in the population with ID can be the consequence of decreased adaptability, an attachment disorder, and poor sleep-related hygiene, combined with immature or dysfunctional sleep networks, primary psychiatric disorders, visual impairments, and psychosocial factors [68].

Most people with severe ID generate wrongly timed or insufficient melatonin production and sleep-induced peptides to initiate sleep. In contrast, others are unable to suppress the production of melatonin during daylight hours, which disturbs the circadian cycle and sometimes leads to behavioural disturbance [73].

Most people with ID show aberrant sleep rhythms, such as slow wave/REM, sleep fragmentation, restless legs syndrome, sensitivity to medication side effects, nocturnal epilepsy, or other physiological problems associated with sleep onset. Indeed, it has been stated by Kaplan and colleagues [74] that people with Rett, Down, Prader-Willi, Smith-Magenis, and Cornelia de Lange syndromes, along with those with orofacial and upper airway anomalies, are more likely to have obstructive sleep apnoea and disrupted sleep [65, 75]. In this case, these people are more likely to develop irritability, hyperactivity, and increased aggression or self-injurious behaviour (SIB) instead of excessive daytime somnolence. A correlation has been established between regressive subtype of ASD and REM-related parasomnias [76]. REM may bring to the integration of the cortical, mesencephalic, and pontine management of motor generators and maybe to the rise of atypical cortical neurones and head circumference associated with these syndromes [77, 78].

Moreover, it has been established that sleep disruption and fragmentation are extremely common in people with ID. Shibagaki, Kiyono, and Mastruno [79] carried out a study on 79 children with ID that suggested an increased rate of abnormal sleep physiology in people with ID and cerebral palsy. Besides, the majority of sleep dysfunctions are common pathways for several excitatory or inhibitory brain networks.

Also, Okawa and colleagues [80] studied four congenitally blind children with ID and stated that the relationship between social deficits and severe ID inhibited the use of alternative zeitgebers.

Several other studies identified sleep problems in children with autism [81–83], sleep-related breathing disorders in adults with Down syndrome [84], and a more complex correlation between insomnia and ID [29], suggesting that different sleep disorders can be associated with specific genetic disorders. Besides, more complex genetic disorders along with neuropsychiatric disorders imply a multidirectional correlation between primary and secondary sleep disorders.

26.5.1 Children with Intellectual Disability

Brain maturation and the interaction between neurones related to sleep mechanism drive sleep physiology. It has been stated that many sleep disorders are developmental, such as primary non-REM parasomnias, which are more likely to occur along with stressors or medical or psychiatric disorders in adulthood [42, 85, 86]. There are other disorders that are

highly heritable such as restless legs syndrome and periodic limb movements [87, 88].

However, the majority of sleep disorders come from the interaction between genes and the environment and the boundaries between syndromes are semi-permeable. In children, the supremacy of slow wave sleep overlaps with the emergence of non-REM parasomnias. In addition, the rate of nightmares is influenced by sleep phase instability and traumatic experiences in childhood, while, during adolescence, they grow less but are replaced by sleep phase delay, narcolepsy, persistent enuresis, chronic sleep deprivation, insomnia, substance use, and increase in psychiatric disorders [86, 89].

Finally, insomnia, irregular sleep-wake cycles, fragmentation of sleep, and REM-related parasomnias are common in children with ASD and ID [50, 90, 91].

26.5.2 Adults with Intellectual Disabilities

Sleep difficulties are a lifelong condition in ID population, continuing to persist into adolescence [92] and adulthood [93, 94].

Insomnia is frequent in adults with ID, ASD, and other neurodevelopmental disorders, comorbid psychiatric or neurological disorders, post-traumatic stress disorder [95], and in certain behavioural phenotypes [65]. Nevertheless, people with severe ID, ASD, and insomnia can also have other sleep dysfunctions that remain unidentified or misunderstood with seizure activity or severe psychiatric disorder [51, 96].

Also, the prevalence of sleep-related breathing, central and hypoventilation disorders, REM, periodic limb movements, declines in vision and hearing, and less sensitivity to the light (zeitgebers) usually increase with age. Besides, blindness and severe visual problems are more frequently related to irregular sleep-wake cycle disorder. On the other hand, non-24-hour sleep wake cycle disorder has been observed in adult patients with ID and/or ASD, sensory impairments and mood disorders. Fragmented sleep has also been found to be common in people with ASD, traumatic brain injury, and dementias. Furthermore, REM-related movement disorder has a link with the neurodegenerative disorders and progressive supranuclear palsy (synucleopathies), dementias, and vascular disorders.

Insomnia, irregular sleep-wake cycles, fragmentation of sleep, and other sleep difficulties represent frequent life-long conditions in persons with ID and/or ASD, with onset in infancy and continuous course across adolescence, adulthood, and old age.

26.6 Specific Assessment

26.6.1 Issues Related to Diagnosis in People with Neurodevelopmental Disorders

In order to diagnose sleep disorder in people with ID it is necessary to analyse the available sleep-related evidence, identify the link between sleep changes and daytime behaviours, and complete the assessment and differential diagnosis. However, several aspects need more in-depth investigations. Indeed, people with ID insufficiently report or cannot report their own sleep disorders. Besides, clinicians do not always have the most up-to-date in-depth knowledge of the links among sleep physiology, atypical brain development, and the different phenotypes of sleep disorders. Furthermore, the steps for allowing reasonable adjustments to make sense of the information gathered from people with varied levels of severity of ID can be difficult [32]. Finally, there can be some training deficits as clinicians belong to different schools that give importance to different aspects. For example, some of them do not collect the sleep history of the patient, while others do not use direct observations.

Boyle and colleagues [28], in an epidemiological review of sleep-related disorders, argued that the prevalence rate can be

overestimated in some published literature. However, the effect of some health pertinent changes that can be correlated with the level of severity of ID and the co-occurrence with some health, psychological and behavioural disorders, can represent exceptions.

Generally, available studies often have design flaws such as a small sample size and selection bias. However, there is an urgent need for further research on the correlation between sleep disorder and the level of severity of ID [97].

26.6.2 Differential Diagnosis

In order to diagnose a sleep disorder in a patient, it is fundamental to know the individual's history and carry out an appropriate medical evaluation. Indeed, the changes in the physical and chemical processes involved in sleep in people with ID can lead to difficulties in the interpretation of polysomnography data because of the instability of the phasic shifts during sleep. Besides, difficulty in diagnosing sleep disorders can vary depending on the level of the ID, because of some people's limited ability to self-express and controlling for the confounding factors such as the higher prevalence of comorbid medical, neurological, and psychiatric disorders. These aspects should raise a high index of doubt and an efficient investigation for sleep disorders.

The two rating instruments to measure sleep disorders in the population with ID are the Stanford Sleepiness Scale [98] and the Sleep Disturbance Questionnaire [99, 100].

High rates of co-occurrence of primary sleep disorders have been reported to date, as well as a significant permeability in the boundaries between different subtypes of sleep disorders. Moreover, elevated levels of comorbidity with other neurodevelopmental, metabolic, genetic, medical, and neurological factors have been found in people with ID with sleep disorders. These data imply that the physiology and the reasons that lower the threshold for sleep disorders in people with ID need further investigation.

Subjects with ASD have several sleep disorders. These disorders can be exclusive to the neurophysiology of the ASD or also present problems for people with ASD, such as high rates of insomnia seem to be related to sleep hygiene and psychophysiological conditioning.

Finally, the high prevalence of psychiatric disorders, trauma, neurodegenerative disorders, and psychosocial stressors, makes it difficult to tease apart some primary sleep disorders from sleep disorders secondary to an underlying cause [101].

To diagnose sleep disorder in people with ID and/or ASD, it is necessary to analyse the available sleep related evidence, identify the link between sleep changes and daytime behaviours, review the medical history, and carry out appropriate medical evaluation.

Difficulties in diagnosing sleep disorders can vary depending on the level of the ID, because of some people's limited ability to self-express, and controlling for the confounding factors such as the higher prevalence of comorbid medical, neurological, and psychiatric disorders.

26.7 Functional Consequences

Sleep-phase shifts, restless legs syndrome, sleep-related breathing disorders, and parasomnias are related to insomnias. The restless legs syndrome is similar to the neuroleptic effect, akathisia; both of them can be difficult to detect in people with severe ID and problems in sleep initiation [68].

Besides, adults with ID can react to sleep deprivation with an increase in irritability, hyperactivity, aggression, and self-injurious behaviour (SIB), while the normal adult population feels fatigue or excessive daytime sleepiness [90, 102, 103]. Finally, it has to be considered that sleep in people with ID and ASD can also be susceptible to cyclical and seasonal changes, with a particular sensitivity to rapidly changing photoperiods and to sunlight on longer rhythms.

26.8 Treatment

Most studies on treatment strategies for sleep disturbances and sleep disorders have been carried out in children and younger adolescents. There is little research assessing sleep in very young children, older adolescents, or adults with developmental disabilities [32]. Indeed, there is limited evidence on intervention strategies for adults with ID experiencing sleep problems, and many studies have serious risk of bias [97]. Most research concentrates on the pharmacological treatment of sleep problems. However, current evidence primarily supports the use of non-pharmacological interventions [29]. Psychosocial intervention is the first-line treatment of sleep problems in the general population [104], with evidence of effectiveness. In studies of diverse ID, there is also strong evidence that behavioural and sleep hygiene measures should be the first line approach [105]. Sleep hygiene focuses on lifestyle and environmental factors such as reducing the consumption of caffeine, exercising regularly, avoiding daytime naps, and managing stress to promote sleep [106].

Most common cognitive-behavioural interventions include bedtime fading, extinction, distancing/desensitization, sleep-wake scheduling, multicomponent behaviour plan based on the function of sleep disrupting behaviour [29, 107, 108], and stimulus control, which aims to generate in a person's mind and body a strong association between going to bed and sleeping [109]. Other interventions that may be effective in the adult population include optimal scheduling of sleep, light therapy, and relaxation [97].

Furthermore, a combination of individualized behavioural therapy and medication has been proven effective [91, 110]. Educational training for staff supporting adults with ID has demonstrated improvements in sleep efficiency, declines in time in bed, and daytime napping [111]. A study by Gunning and Espie [109] assessed the effects of behavioural sleep management on adults with ID, finding that such management may improve behavioural sleep patterns or sleep-related functioning in the majority of adults with ID who are experiencing sleep problems.

Pharmacological treatments of sleep disorders include benzodiazepines, anticonvulsants, antidepressants, atypical antipsychotics, and agomelatine [33]. In general, psychopharmacological treatments are reported to be associated with longer sleep duration and better sleep efficiency [36].

Benzodiazepines act on γ-aminobutyric acid (GABA) neuroreceptors and have far less overdose danger and abuse potential than previous medications used for sleep disorders such as barbiturates [112]. Nevertheless, they can also cause some side effects, resulting in impaired sleep quality, residual sedation, drowsiness, dizziness, memory and cognitive impairment increased risk of falls, reduction of reflexes, or rebound insomnia. Paradoxical reactions to benzodiazepines are also possible, although relatively uncommon (less than 1% of patients), and may include increased talkativeness, emotional release, excitement, excessive movement, and aggression [113, 114]. Long-term benzodiazepine use may determine dose escalation, tolerance, dependence, and withdrawal issues. Physiological tolerance and dependency have both been linked to an increase in the negative effects of benzodiazepines [115].

The newer non-benzodiazepine agents zopiclone, zolpidem, and zaleplon have a hypnotic action comparable with that of benzodiazepines, but they display specific pharmacokinetic and pharmacodynamic properties. These three "Z" agents all share a short plasma half-life and limited duration of action as well as a selective interaction with omega (1) receptors (responsible for sedative effect), whereas benzodiazepines also interact with omega (2) receptors (responsible for some adverse effects such as memory and cognitive reduction) [116, 117].

Antipsychotics are usually prescribed for psychotic and mood comorbidities but also for the management of problem behaviours [118–120] and secondarily have a beneficial effect on sleep, although there are reports of specific prescription for sleep disturbances,

both in children and adults [121–123]. When used for the treatment of schizophrenia or bipolar disorder, the positive effects of atypical antipsychotic medications on sleep architecture are well documented [124–128]. Typical antipsychotics, including haloperidol, chlorpromazine, fluphenazine, and thioridazine, are associated with higher incidence of extrapyramidal side effects and daytime somnolence. Newer, second-generation antipsychotics, including clozapine, risperidone, olanzapine, quetiapine, and aripiprazole, have a lower propensity for extrapyramidal side effects and are generally less sedating (with the exception of clozapine, which can cause significant sedation, particularly during the initiation of treatment). Few studies examining the effect on sleep architecture have shown that slow wave sleep is increased by olanzapine, ziprasidone, and risperidone, whereas REM suppression is greatest for ziprasidone and risperidone [124, 126, 127, 129]. These agents are prescribed off label for the treatment of insomnia or the management of sedation, and are not recommended to be prescribed routinely for this indication, especially as a first-line pharmacotherapeutic agent [125, 130–132].

Limited data exist regarding use and efficacy of sedating antidepressants, selective serotonin reuptake inhibitors (SSRI), and tricyclic antidepressants (TCA) for treatment of sleep disturbances in people with ID/ASD. Sedating antidepressant such as mirtazapine and trazodone may be beneficial in case of co-occurrent depression [133–135]. In the general population the off-label use of trazodone for insomnia has surpassed its usage as an antidepressant [135]. The doses used for the treatment of insomnia are generally lower compared to those used for the treatment of mood disorders. Amongst TCAs, amitriptyline, imipramine, and doxepin are the most sedating and the most used for the treatment of insomnia in adults [136].

Agomelatine, an antidepressant analogue of melatonin and agonist of melatonergic MT1 and MT2 receptors, is reported to be effective and well tolerated for treating insomnia and sleep-wake alterations in adults with neurodevelopmental disorders [137]. Agomelatine produces both subjective and objective improvements in sleep quality and continuity, with increased slow-wave sleep and no effect on REM sleep [138].

Even anticonvulsants have little research on their use in the treatment of sleep disturbances in people with ID/ASD. The agents that have commonly been used in this category include valproate, lamotrigine, gabapentin, and carbamazepine [97].

In neurotypical persons with epilepsy, valproic acid has been shown to decrease REM activity and increase delta activity, although clear definitive evidence is lacking [139–142]. For lamotrigine, a minority of studies in epileptic patients indicate slight improvements in sleep duration and/or quality while many others show no effect on total sleep time, sleep efficiency, sleep latency or REM latency, and NREM duration [139, 143]. Lamotrigine has been reported to even cause insomnia, in a dose-dependent manner [144]. Gabapentin seems to shorten sleep latency, reduces awakenings and fast-wave sleep, enhances slow-wave sleep, and improves overall sleep quality and duration. Nevertheless, these effects have been reported in persons with sleep disorders secondary to various neurological or psychiatric conditions and effectiveness for primary and sleep disorders remains to be verified [141, 145]. Carbamazepine has been associated with decreased sleep fragmentation, increased delta NREM sleep, and increased total sleep time when used to treat bipolar disorders or epilepsy. Nevertheless, these effects have not been reported in other conditions and appear to be time-limited [141, 142].

Melatonin as both a dietary supplement and a drug (at a higher dose and/or prolonged release) has been shown to reduce sleep onset latency in primary insomnia and to regulate sleep-wake patterns in the neurotypical population. However, evidence is insufficient and controversial about long-term utility and safety as well as effects on sleep quality and duration, although slightly higher agreement exists on effectiveness in older people, who may be deficient in the hormone and present mitochondrial dysfunction [146, 147].

Specific studies, including open-label data, controlled trials, and meta-analysis, have been

conducted in people with ID/ASD, indicating melatonin to be effective on sleep onset latency, sleep duration, and sleep-wake alteration. Night awakenings have also been reported to improve, although some controversial findings, especially in persons with ASD [73, 97, 148, 149], who also showed higher rates of rather rapid loss (within a few weeks of treatment starting) of melatonin general efficacy, due to low genetically determined (single nucleotide polymorphism) metabolic activity of cytochrome P450 CYP1A2 [150]. Other differences in treatment response can be attributed to individual variations in receptor sensitivity [151]. Melatonin has also been used to treat severe sleep problems associated with various genetic syndromes such as Angelman syndrome, tuberous sclerosis complex, Rett syndrome, Smith-Magenis syndrome, and Sanfilippo syndrome [2, 152]. Except for tuberous sclerosis [153, 154], all other genetic syndromes reported significant decrease in sleep onset latency and other sleep improvements [155].

Most studies of melatonin involving people with ID and/or ASD have reported no adverse effects, although agitation, aggression, and restlessness have been described in a small number of cases, mostly when melatonin has been used in combination with other drugs [73, 148, 156–159].

The most used dosage in studies and clinical reports is between 1 and 2 mg in children/adolescents and between 1 and 5 mg in adults/elderlies, administered 30 minutes before bedtime [160–162]. Controlled-release formulations are likely to be more appropriate for those individuals who have issues with sleep maintenance and night awakes while immediate-release may be more appropriate for those with sleep onset delay [32, 162].

The implementation of evidence-based sleep intervention strategies can also help to reduce some of the short-term and long-term health and behavioural consequences of poor sleep [163–165].

Excessive daytime sleepiness can benefit from behavioural treatments aimed at extending total time asleep and supporting sleep onset. Medication to support sleep can also be considered [33]. Excessive daytime sleepiness associated with narcolepsy, idiopathic hypersomnia, and other forms of hypersomnias can be treated with amphetamine-like central nervous system stimulants or modafinil and its R-enantiomer, armodafinil, and wake-promoting compounds unrelated to amphetamines. Methylphenidate is the most commonly prescribed amphetamine-like stimulant and is reported to be quite efficacious and well tolerated by most narcoleptic patients. For excessive daytime sleepiness associated with narcolepsy, modafinil is considered a first-line treatment, also due to its safety and low side-effect profile. These compounds, however, lack efficacy for cataplexy and dissociated manifestations of REM sleep, so antidepressants, especially selective norepinephrine, and serotonin reuptake inhibitors are additionally prescribed to treat these issues. Sodium oxybate, a salt of gamma-hydroxybutyrate (GHB), is indicated as the most effective drug for the treatment of cataplexy, but its prescription status is limited in many countries across the world since the high risk of serious side effects, craving, and physical dependence [166, 167].

The treatment of obstructive sleep apnoea-hypopnea syndrome includes weight loss and exercise, positive airway pressure, continuous electrical stimulation, and surgical enlargement of the upper airway. Continuous positive airway pressure (CPAP) is the standard treatment for moderate to severe OSAS and can be selectively used also for mild OSAS. For persons with intolerance to CPAP, bilevel positive airway pressure (BPAP) can represent a valid alternative since the lower pressure is exerted during exhalation. Other alternative treatments are represented by positional therapy, mandibular advancement devices, continuous transcutaneous electrical stimulation, and hypoglossal nerve stimulation. Surgical treatments include nasal surgery, oral/palate surgery, hypopharyngeal surgery, and other operations, such as orthognathic surgery, tracheostomy, and multi-lateral surgery. There are currently no effective pharmacological therapies, although corticosteroids and leukotriene receptor antagonists have been reported to have some efficacy on mild OSAS in children [168, 169].

There is little high-level evidence for the treatment of parasomnias, especially in adults [170]. Priorities include avoiding potential triggers such as scary movies, caffeine, alcohol, or late-night meals, as well as maintaining a consistent and healthy sleep-wake pattern. It is also critical to adopt behavioural techniques and environmental measures to protect the patient, bedmate, nearby youngsters, and other fragile persons, such as closing windows, bolting doors, removing any sharp objects or furniture near the bed area, and sleeping on the bottom floor [108, 170–172]. Cognitive-behavioural therapy seems to be effective for most parasomnias and further progress is expected in the near future [172]. In particular, schedule awakening, a behavioural intervention based on the involvement of briefly awakening the patient approximately 15–30 minutes prior to the expected episode, has been reported to provide good results in sleepwalking, sleep terrors, and confusional arousal, while nightmare disorder seems to benefit more from imagery rehearsal therapy, exposure relaxation and rescription therapy, imagery rescripting and exposure therapy, self-exposure, lucid dreaming treatment, and eye movement desensitization reprocessing therapy [172].

Benzodiazepines, especially clonazepam, are the mainstay of pharmacological management for most persisting parasomnia, although imipramine, pramipexole, levodopa, and melatonin have also been used in the past with some efficacy [108, 170, 171, 173, 174]. Clonazepam has to be used with caution in patients with dementia, disorders of gait or balance, or concomitant OSAS [108].

Restless leg syndrome can benefit from dopaminergic therapies such as pramipexole, ropinirole, and rotigotine, both for sleep disturbance and daytime symptoms. Alternative treatments include α2δ ligands, opioids, and iron preparations, although no iron preparations have received regulatory approval. Oxycodone and naloxone are indicated for severe restless legs but, due to the commonly occurring adverse effects, they should be used exclusively as second-line therapy [175].

Nightmare disorder and other parasomnias have been reported to be triggered or worsened by many psychoactive compounds, including SSRIs (especially paroxetine), cholinesterase inhibitors, beta-blockers, levodopa, lamotrigine, and following withdrawal from antidepressants [108].

Current evidence primary supports the use of a combination of individualized behavioural (including sleep hygiene) and pharmacological therapies to treat sleep disorders in persons with ID and/or ASD. For insomnia, pharmacological treatments include benzodiazepines, anticonvulsants, antidepressants, atypical antipsychotics, and agomelatine. Melatonin has also been shown to have some efficacy.

Tip

Sleep disorders are a quite common comorbidity in people with ID, and their presence further compromises physical, cognitive, and behavioural functioning. New models of testing, using new technology, will allow researchers and clinicians to collect precise data on sleep while patients go about their daily lives in their normal environment.

Key Points

- Aetiology and pathogenesis of sleep disorders in ID is multifactorial. There are biological, genetic, and psychosocial risk factors for developmental of sleep abnormalities.
- There are several comorbid conditions which are associated with sleep disorders in ID. One must be able to evaluate comorbid disorders to make a differential diagnosis.
- Sleep disorders are important because they may affect the person's quality of life, lead to subsequent problem behaviours, and cause both distress and impaired functioning during the daytime.
- The diagnosis of sleep abnormalities in persons with ID is complex due to the

limited ability of people with ID to report their own sleep disorders. Besides, the changes in the physical and chemical processes of sleep in people with ID can lead to difficulties in the interpretation of polysomnography because of the instability of the phasic shifts during sleep.

- The diagnosis could be facilitated by collecting sleep history and identifying the link between sleep changes and daytime behaviours.
- Most effective treatment is based on a combination of individualized behavioural and pharmacological therapies. Benzodiazepines, anticonvulsants, antidepressants, atypical antipsychotics, and agomelatine represent the most studied drugs.
- Effects of exogenous melatonin have been widely investigated, with indications of effectiveness on sleep onset latency, sleep duration, and sleep-wake alteration.

Learning Objectives

- To learn about the definition of sexual health and sexuality.
- To learn about the definition and ascertainment of sexual dysfunctions in people with ID and/or ASD.
- To know how much the issue around sexual health in the ID and or ASD population can be underestimated.
- To learn the peculiar presentation of sexual dysfunction in persons with ID/ASD and how to diagnose them.
- To know the course and treatment of the sexual health issues in people with ID and/or ASD.

27.1 Introduction

Several definitions of sexual health have been provided across time, the most recent of which have built upon the essential elements provided in the original definition of the World Health Organization (WHO) [1] but have added concepts of mental health, responsibility, and sexual rights [2].

According to the current working definition of the WHO, sexual health is "…a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence. For sexual health to be attained and maintained, the sexual rights of all persons must be respected, protected and fulfilled" [3, 4].

The WHO specifies that sexual health cannot be understood and made operational without a broad consideration of sexuality, which is defined as "…a central aspect of being human throughout life" and "encompasses sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction". "Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles and relationships", and "is influenced by the interaction of biological, psychological, social, economic, political, cultural, legal, historical, religious and spiritual factors" [3, 4].

The fulfilment of sexual health is tied to the extent to which sexual rights are respected, protected, and complied. In their position statement on the sexuality of persons with intellectual disabilities and developmental disabilities, the American Association on Intellectual and Developmental Disabilities (AAIDD) and The Arc [5] denounce that for a long-time persons with intellectual disability (ID) "have been thought to be asexual, having no need for loving and fulfilling relationships with others. Individual rights to sexuality, which is essential to human health and well-being, have been denied. This loss has negatively affected people with ID in gender identity, friendships, self-esteem, body image and awareness, emotional growth, and social behaviour. People with ID frequently lack access to appropriate sex education in schools and other settings. At the same time, some individuals may engage in sexual activity as a result of poor options, manipulation, loneliness or physical force rather than as an expression of their sexuality". The same AAIDD and The Arc, in alignment with the United Nations Convention on the Rights of Persons with Disabilities [6] and the WHO framework for an operational approach to sexual health [7], state that the presence of ID, regardless of severity, does not justify the loss of rights related to sexual health and sexuality, which include safe and pleasurable experiences, equality, privacy, marriage, choice around reproduction, information or education, opinion, and expression [5].

The aforementioned framework for an operational approach to sexual health that has been recently produced by the WHO in partnership with the Gender and Rights Advisory Panel (GAP) of the UNDP/UNFPA/UNICEF/WHO/World Bank Special Programme of Research and the Development and Research Training in Human Reproduction (HRP) identifies six crucial, cross-cutting principles to be incorporated into the design of all sexual health (and reproductive health) interventions and which can also serve as evaluation criteria against

which these interventions should be assessed. These principles are the following: (1) holistic approach to sexual health; (2) linked nature of sexual health and reproductive health; (3) respect, protection, and fulfilment of human rights; (4) multilevel influences on sexual health; (5) diversity of needs across life course and populations; and (6) evidence-based, respectful and positive approach. The fifth principle has particular relevance for persons with intellectual and developmental disabilities since it states that "sexual health exists on a dynamic continuum, with needs that …vary depending on a complex mix of individual characteristics, as well as the cultural, socioeconomic, geopolitical and legal environment. Particular combinations of these factors can create vulnerabilities … that may increase susceptibility to ill health and/or hinder access to health care. For example, certain sexual health interventions may not be available because they are not culturally acceptable or legally permissible; available sexual health interventions may be difficult to access for a range of reasons; and the sexual health needs of some individuals, populations or age groups may not be recognized or acknowledged. Sexual health programming and research must therefore be inclusive of the diversity of needs among individuals at various points across the life course and in various settings or circumstances" [7].

In the last decades, the interest in the sexual health and sexuality of persons with ID has increased. Nevertheless, there has been a tendency to focus on sexual rights and societal attitudes, while less attention has been paid to sexual health [8, 9].

Very little information is available on sexual problems in people with ID, but it is known that they have more vulnerability factors than the general population to mental and physical ill-health, including sexual dysfunctions. Furthermore, some genetic syndromes including ID and/or autism spectrum disorder (ASD) also include fertility issues [10, 11].

Sexual dysfunctions are a set of clinical conditions characterised, in both genders, by the significant difficulty to respond sexually or to experience sexual pleasure, that regard different behavioural aspects, including the psycho-physiological functioning profile. With the exception of substance/medication-induced sexual dysfunctions, they must be present for at least 6 months and be associated with individual distress [12]. The lack of sexual education, low-grade support systems, negative social attitudes, mental and physical health problems, life events, and medications seem to represent significant aetiological factors for the development of sexual dysfunctions in people with ID and/or ASD [13].

27.2 Prevalence

The epidemiological studies on sexual dysfunctions in ID are very limited [13]. There are different reasons that can account for this finding such as the lack of interest in this comorbidity, the difficulty in assessing the sexual functioning in this population, and the methodological difficulties in conducting research in this area.

Expert opinion reports and interesting summaries are available to date, but no systematic reviews of the literature [14–19].

The only prevalence data available indicate that 35% of men with severe to borderline ID and epilepsy had never experienced spontaneous erections while awake, 44% had never had an orgasm, and 21% had never had intercourse [15]. Furthermore, it is possible to forecast that some sexual dysfunctions could accentuate with ageing.

People with ID and/or ASD have more vulnerability factors than the general population to develop specific comorbidities, including sexual dysfunctions. Nevertheless, scientific evidence on these health issues is limited.

27.3 Aetiopathogenesis

The aetiology of sexual dysfunctions in persons with ID/ASD is probably similar to that of the general population, and it comprises biological, genetic, psychosocial, developmental, and cultural factors and various life events.

27.3.1 Biological Factors

One or more psychotropic medications are prescribed to the wide majority of persons with ID/ASD across their life span, especially in order to prevent and treat problem behaviours. These treatments include antipsychotics, antidepressants, mood stabilisers, and anxiolytics [20, 21], most of which can cause sexual dysfunction even though some of the most recent antipsychotics are found to have less impact on sexual functioning. Moreover, some people with ID/ASD are administered androgen-depleting drugs as a consequence of inappropriate sexual behaviour [22]. For the high prevalence of many physical health issues, persons with ID/ASD also receive many other non-psychopharmacological treatments and are often exposed to polypharmacy [23, 24]. Because of this high rate of use of psychotropic and not psychotropic drugs, persons with ID/ASD are more likely to develop a substance/medication-induced sexual and endocrine dysfunction, including erectile dysfunction, ejaculation disorder, and priapism in males and vaginismus, inadequate lubrication, anorgasmia, dyspareunia, and menstrual disorder in women, along with hyperprolactinaemia, weight gain, and movement disorders in both genders.

In addition, a higher rate of psychiatric disorders is found in people with epilepsy, and epilepsy is common in people with ID/ASD [25]. Anti-epileptic drugs (AEDs) are also used as mood stabilisers in people with ID/ASD. Seizures and AEDs can affect hypothalamic-pituitary-gonadal axis, causing changes in hormones production and, thus, sexuality [26, 27].

Furthermore, these people might encounter decreased sexual activities, listlessness, and depression as a consequence of the sedative effects of the AEDs. Besides, AEDs are also linked to hypo-sexuality, abnormal morphology, low sperm count and androgen, and elevated oestrogen, testosterone, and sex hormone-binding globulin [26].

Other neurological conditions can be linked to sexual dysfunctions in people with ID/ASD. Parkinson's disease may be responsible for affect arousal, orgasm, and sexual desire in women and erectile dysfunction, sexual dissatisfaction, and premature ejaculation in men [19].

In multiple sclerosis, the sexual dysfunctions may be due to pain or physical fatigue or movement disorders or the body self-image. Similar problems are caused by spinal cord injuries [19].

27.3.2 Genetic Factors

People with ID tend to have genetic syndromes that can be associated with sexual dysfunction. Downs syndrome, for example, is related to hypogonadism. The Prader-Willi syndrome is linked to small penis-size, hypogonadism in males, and delayed puberty in females [28]. The Klinefelter syndrome, which is characterised by having 47 XXY or more than one X chromosome in males, is related to hypergonadotropic hypogonadism, reduced body hair, small testes, decreased libido, and increased breast tissue [29]. Turner syndrome (45 X) is linked to hypogonadism, delayed puberty, amenorrhoea, lack of breast tissue, and infertility [30]. Finally, Fragile X syndrome is related to macroorchidism and premature menopause [31].

27.3.3 Psychosocial Factors

Services can influence sexuality in various ways. Most of them are restrictive, aversive, and do not help people with ID and/or ASD in their free expression or privacy. Indeed, there is a general fear that talking about sexuality could lead them to abusive conducts or to sexually offensive behaviours [32]. Besides, there is less support for lesbian, gay, bisexual, and transgender (LGBT)-related issues [33] or masturbation. Because people with ID have limited privacy, education, economic independence, social skills, and environmental mastery, they are at higher risk for abuse [34, 35], more exposed to an unplanned pregnancy [36] and sexually transmitted disease, and for some because of lack of communication skills, they are unable to express their experiences, needs, and desires. Given appropriate opportunities and support, many people with

ID and/or ASD are likely to develop an intimate relationship and sexual interactions, but the misconceptions about sexuality in the ID/ASD population still represent social barriers for them to develop such relationships.

27.3.4 Developmental Factors Through the Lifespan

The social, emotional, and psychosexual development of people with ID and/or ASD often do not synchronise with that of the general population. People with ID and/or low-functioning ASD may not have age-appropriate sexual knowledge and often be unable to determine whether they have sexual dysfunctions [25, 37, 38]. Indeed, people with ID would need support from their family or carers with their understanding of the sexual knowledge as well as finding potential partners and spending time alone with them. On the contrary, in the past, people with ID often were desexualised and prevented from having sexual intercourse by punishing them and suppressing that behaviour. Even today, many adults with ID/ASD are still likely to be viewed as childlike and asexual by their families and service workers [39].

27.4 Criteria and Clinical Features

The assessment of sexual dysfunctions in people with ID and/or ASD presents many problems. First of all, the inability of these people to recognise and communicate their own health and sexual needs, thus failing to ask for help leading to appropriate diagnosis and necessary treatment [40]. The social stigma and the attitude of some familiars and caregivers may hinder the sexual experience, the sexual identity development, and the identification of dysfunctions [14].

Furthermore, in this population, although the physical growth may follow the normal stages, the development of cognitive, emotional, and social aspects is generally atypical and asynchronous.

The clinicians need to be aware to include important issues in assessing sexual dysfunctions in ID and/or ASD. These are, for example, societal attitudes and sexual education of people with ID/ASD; the influence of family and care-staff in the expression of individual sexual needs and behaviours; the frequent use of medications; the presence of many mental health problems, genetic syndromes, and neurological disorders; and the lack of opportunity for the person to experience their own sexuality and to share with others.

In relation to clinical issues, it is very difficult to determine the criterion of distress, which is very important for making a diagnosis. In fact, in this population it is difficult to establish how the distress is experienced and shown. Indeed, often the distress could be hidden or expressed with unspecific irritability.

Therefore, a longer and deeper assessment is required in people with ID to explore their self-knowledge of sexuality and sexual needs, their gender identity and sexual orientation, and their medication history [33, 41, 42].

The diagnosis of sexual dysfunction in persons with ID/ASD is very complex due to the developmental, educational, and functional peculiarities and the lack of a specific diagnostic methodology.

▪ Delayed Ejaculation

This disorder is characterised by the inability or considerable delay in reaching ejaculation during sexual intercourse with the partner for at least 6 months. The exact prevalence of this disorder in the ID population is unknown. Indeed, it increases with age and the relation between delayed ejaculation and medical causes still needs to be investigated in-depth, such as the role of medications and substances. Moreover, the psychological factors related to delayed ejaculation also need further investigation to understand if there are specific circumstances that can promote healthy ejaculation.

▪ Erectile Disorder

This disorder is characterised by experiencing at least one of three following symptoms for no less than 6 months: (a) having difficulty with achieving or (b) maintaining erections

during sexual activity and (c) a considerable decrease in erectile rigidity.

As for many other sexual dysfunctions, the prevalence of this disorder is unknown, although there are reports of an increase with age [4]. However, there is evidence that erectile disorder is related to having sexual intercourse with an unknown partner, substance abuse, and peer pressure. The erectile disorder can also be associated with medical conditions and comorbid mental illnesses [43–45].

Female Orgasmic Disorder

The female orgasmic disorder is characterised by the absence, considerable delay, infrequency, or reduced intensity of the orgasmic sensations. The symptoms must be present for at least 6 months in order to meet the diagnostic criteria. The prevalence of the female orgasmic disorder in the general population is 10–42% [46]. However, these data do not take into account distress as a causative factor leading to fewer women reaching the diagnostic criteria. Besides, it has been calculated that 10% of women in the general population never reach an orgasm in their lifetime [47]. The female orgasmic disorder may be related to psychological factors such as feelings of inadequacy or guilt as well as relationship problems and cultural factors. Moreover, there is a link between female orgasmic disorder and vulvovaginal atrophy and mental health problems, especially anxiety and depressive disorders [48, 49].

Female Sexual Interest/Arousal Disorder

The disorder is characterised by having at least three of the following criteria for at least 6 months: (a) a decline or absence of interest in sexual activities; (b) a reduction or lack of sexual thoughts and fantasy; (c) a reduction or loss of desire to take the initiative for the sexual intercourse or a negative response to the partner's initiative; (d) a decline or loss of sexual pleasure or excitement during sexual activities; (e) a decline or absence in sexual desire or arousal to stimuli that are related to sexual activities; and (f) a reduction or lack of sensations during the sexual intercourse. The prevalence of this disorder in the ID population is still unknown. Moreover, this disorder can be associated with depression, anxiety, urinary incontinence, thyroid problems, arthritis, and irritable bowel syndrome [49–51].

Genito-pelvic Pain/Penetration Disorder

The disorder consists of having difficulties with vaginal penetration, pain in the vulvovaginal or pelvic area when trying to penetrate or during the sexual act, and fear and anxiety that is related to the pain and tense pelvic floor muscles upon attempted penetration, for no less than 6 months. Besides, while the diagnosis can be made based on one symptom dimension, all four aspects should be assessed. The peculiarity of this disorder is that it can take place with a partner (during sexual intercourse) or even during medical examinations or while inserting a tampon. The prevalence of this disorder is unknown, but in North America, nearly 15% of women in the general population noted recurrent pain during the sexual act. The genito-pelvic pain/penetration disorder can occur along with other sexual dysfunctions leading to the exclusion of sexual activities or intimate situations. However, both physical and sexual abuse and cultural factors have been considered predictors of this disorder, as evidence leads to believe that there is possibly a higher prevalence in non-Western countries [52, 53]. The disorder can be also anticipated by vaginal infection, which can persist even when the symptoms are treated. Although the DSM-5 [12] diagnoses it only in women, there are shreds of evidence that men can feel genito-pelvic pain as well [54]. A common cause in men is represented by pelvic floor overactivity, which is encountered in up to 50% of chronic prostatitis and/or chronic pelvic pain syndrome and characterised by persistent muscle pain that can also affect the bowel and bladder [55].

Male Hypoactive Sexual Desire Disorder

The prevalence of this disorder is still unknown, and it is characterised by a decline or absence of sexual fantasy or desire for sexual intercourse for a minimum of 6 months. However, these difficulties can be preferential or associated with other sexual dysfunctions such as difficulties in erection or ejaculation.

Besides, as for previous sexual disorders, there is a relation between age and fantasy or desire. Moreover, it is related to mental health problems, such as depression, anxiety, and alcohol abuse. Endocrinologic factors, such as hyperprolactinaemia and hypogonadism, should also be considered as aetiologies [45, 56].

Premature (Early) Ejaculation

Premature ejaculation is characterised by ejaculation within 1 minute of penetration. This fact is consistent and undesired and has to be present for at least 6 months. It seems to be only applicable for vaginal penetration, as there are not specific duration criteria indicated for the manual stimulation, oral and anal sex, and other activities. Nevertheless, the DSM-5 [12] states that this diagnosis can be applied to individuals who engage in non-vaginal sexual activities. Based on two separate observational, cross-sectional surveys the overall prevalence of the of premature ejaculation is founded to be 19.8% and 25.80% with a lifelong rates of 2.3% and 3.2% [57]. Besides, there could be a correlation among anxiety disorder, self-esteem, and premature ejaculation, while cultural and religious factors still need to be assessed [46, 58].

Substance-/Medication-Induced Sexual Dysfunction

Because of the lack of reports on treatment-emergent sexual side effects, the prevalence of these dysfunctions in persons with ID and/or ASD is unclear. A relation between psychotropic medications, such as antidepressants, opioids, and antipsychotics, and sexual dysfunction has been reported [5, 45, 56].

The disorder is characterised by problems in sexual activity that are due to substance or medication. The problem can appear before or after the substance misuse, after stopping the substance or following the introduction of medications.

27.5 Treatment

Treatment of sexual dysfunctions must take into account underlying problems or problems that are causing the dysfunction. If the cause is physical, medication and mechanical aids should be considered, while counselling, psychotherapy, behaviour modification, and education may work in presence of prevalently psychological causes [59].

When a medication is the cause of the dysfunction, a change in the medication may help. Hormone therapy, both local and systemic, can be considered for men and women with hormone deficiencies. In men, sexual function may be improved with phosphodiesterase-5 inhibitors such as sildenafil, tadalafil, vardenafil, and avanafil by increasing blood flow to the penis [60, 61]. For women, hormonal options such as oestrogen and testosterone can be used, although specific approval is lacking [62]. In premenopausal women, flibanserin and bremelanotide have been used (and approved by some agencies) to treat low desire [62].

A good quality health and sex education presented in an accessible format describing body parts and relationship using pictures, role-play, guided practice, corrective feedback, modelling, or reinforcement is a good start in addressing the problem of sexual disorders in adults with ID [63, 64].

People with ID should see a sex therapist in order to present the concerns that are related to their particular disability. However, most of the readings and written homework that is an essential/intrinsic part of sex therapy are complicated/problematic/challenging to these people because of their intellectual impairments. Moreover, the therapist should be cautious in the use of body-awareness and touching exercises that can be seen as humiliating by these people that have in general a negative self-image. It is also essential, for those individuals who are not able to have a sexual intercourse, to pay attention to masturbation, as it may offer an outlet and a way to experience sexuality [65]. Once a person with ID or a couple finds their way into the sex therapist's office, he/she or they can present treatment concerns unique to their particular disabilities. Many couples who were referred to this kind of therapy were experiencing some level of relational or family issues, exacerbated by poor communication. In this case, the interplay between the relational and sex-

ual difficulties requires that the focus of treatment should include working with issues of intimacy and communication as well as with the specific sexual dysfunctions [18].

Since professional caregivers may play a key role in the development and management of sexual dysfunctions in persons with ID and/or ASD, it can be useful for those of them who have difficulties in approaching sexuality and sexual issues of their clients with ID/ASD, to receive specific training on these topics [33, 66]. Chou and collaborators found that workers of a service for people with ID who participated in an intervention programme aimed at fostering positive attitudes towards the sexual identities, health, and rights of people with ID changed their perception of sexual behaviours of their clients with ID from problematic to normal. Parents, who participated in the same study, were also found to shift their approach to the sexual needs of their children with ID from prohibition to communication and support [67].

27.6 Course and Prognosis

The lack of sexual knowledge and the absence of appropriate sexual models with which to compare people with ID and the attitudes of carers can delay or hinder the recognition of problems. It is also probable that people with cognitive, communicative, and relational impairment have limited skills to understand and express needs, feelings, and difficulties as well as behavioural issues related to sexual life [65]. Furthermore, people with ID may have fewer interpersonal experiences and present various problems regarding finding, entering, and maintaining sexual friendships and relationships [68].

In the meantime, people may develop a childlike self-image or compensate for their sexual problems and dissatisfaction developing psychological problems and challenging or stereotypical or compensative behaviours. Typically, it's possible to note aggression, criminal acts, compulsive masturbation, exhibitionism, sexual victimisation, etc. [13].

Accordingly, the prevalent sexual activity in this group of ID is masturbation, but in most cases the person needs support to ensure proper execution of this act. In fact, the frequent problem in people with severe ID is excessive masturbation or unsuitable behaviours towards others, often in an inappropriate context.

Finally, persons with ID who are also LGBT sexual may have much more difficulties establishing intimate and sexual relationships with others [33, 42].

Educational intervention should be very useful in promoting knowledge of the parts of one's body and their functions, pubertal changes, and interpersonal, relational, and life context adequacy as well as acquiring personal hygiene skills and self-protective behaviours.

This chapter does not consider issues related to the sexuality of persons with ID/ASD that have not been included in the group of sexual dysfunctions and disorders as defined by the DSM-5 or the ICD-11. Nevertheless, readers have to be aware that some of these untreated issues such as masturbation in public, touching others inappropriately, or sexual offending are frequently encountered in persons with ID/ASD and would deserve specific coverage. An emerging area of interest is related to the psychological implications of having a homosexual relationship because of the lack of opportunity for a heterosexual relationship.

> The diagnosis of sexual dysfunctions becomes possible later in the life of persons with ID compared with the general population. During the developmental period, people may develop a distorted self-image or compensate for the sexual dissatisfaction developing psychological and behavioural problems.
>
> Psychotherapy and psychoeducation can help these people to improve their sexual health and sexuality.

Tip

Sexual health is an important element in the functioning of people with ID. The scientific community has long neglected the study of sexuality in these persons, probably due to the cultural attitude and the clinical difficulty posed by the condition of ID itself. Early diagnosis and treatment of sexual dysfunctions can promote quality of life and discourage other physical, psychological, and relationship problems.

Key Points

- Data on the prevalence of sexual dysfunctions in persons with ID and/or low-functioning ASD are lacking.
- Aetiopathogenesis of sexual dysfunctions in ID/ASD seems to be multifactorial, although knowledge is limited.
- Assessment of sexual dysfunctions in persons with ID/ASD is complex, for different reasons, ranging from individual communication deficits to social stigma.
- Diagnostic criteria of sexual dysfunction in persons with ID/ASD are the same as those used for the general population. There is not available specific adaptation.
- Treatment should be approached at a multidimensional level, with early affective-sexual education having a significant role. Programmes to develop specific skills in relation to specific sexual dysfunction may be particularly effective.

Dementia in People with Intellectual Disabilities

Shoumitro (Shoumi) Deb, André Strydom, Rosalyn Hithersay, Tiziano Gomiero, Luc Pieter De Vreese, Matthew P. Janicki, Nancy S. Jokinen, and Kathryn P. Service

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_28

Learning Objectives

- Rate of dementia in people with intellectual disabilities.
- Rate of dementia in people with Down syndrome.
- Neuropathology of dementia in intellectual disabilities.
- Clinical features of dementia in people with intellectual disabilities.
- Assessment of dementia in intellectual disabilities.
- Differential diagnosis of dementia in intellectual disabilities.
- Investigations for dementia in intellectual disabilities.
- Rating scales for dementia in intellectual disabilities.
- Pharmacological treatment of dementia in intellectual disabilities.
- Non-pharmacological intervention for dementia in intellectual disabilities.
- Service needs for people with intellectual disabilities and dementia.

- The rate of dementia is higher among people with intellectual disabilities than the general population who do not have intellectual disabilities.
- The rate (particularly of Alzheimer's disease) is even higher among people with Down syndrome with an earlier age of onset compared with the general population and people with intellectual disabilities who do not have Down syndrome.
- Early diagnosis of dementia in people with intellectual disabilities may be difficult, and a combination of informant-rated instrument and direct examination of the person with intellectual disabilities is desirable.
- Loss of memory of recent events in the context of intact distant memory which is common in early-stage dementia among people who do not have intellectual disabilities seems to be the early manifestation of dementia in people with mild to moderate intellectual disabilities.
- Skill loss, on the other hand, seems to be an early sign of dementia in people with severe intellectual disabilities.
- Features of frontal lobe dysfunction including apathy and other behavioural changes seem to be common in early stages of dementia diagnosis in people with intellectual disabilities.
- Regular yearly assessment from an early age (30–35 years) is recommended to compare disease onset with a pre-determined baseline.
- Screening instruments used for the general population are often not useful in people with intellectual disabilities.
- In the absence of any convincing randomised controlled trial (RCT)-based evidence in intellectual disabilities, the treatment recommendations for dementia in people with intellectual disabilities should be based on evidence based on that for the general population who do not have intellectual disabilities.

Tip

- Dementia is more prevalent in people with intellectual disabilities and more so in people with Down syndrome who are affected early in their lives.
- Dementia at its early stage may be difficult to diagnose in people with intellectual disabilities.

28.1 Introduction

Life expectancy of people with intellectual disabilities (ID), perhaps with exception of those with profound ID, has increased considerably in the last five decades [1]. Although this is very good news this also means that people with ID are exposed more to the risks of developing medical conditions that affect people in older age such as neurodegenerative disorders including Alzheimer's disease (AD) and other dementias. In this chapter,

we discuss dementia in people with ID in general and Down syndrome (DS) in particular.

28.1.1 Dementia in Persons with Intellectual Disabilities Who Do Not Have Down Syndrome

Studies of dementia in people with non-DS ID have reported an increased prevalence of dementia compared with the non-ID general population. Cooper reported dementia in 21.6% of 134 adults with ID aged 65 years and above [2]. In a cross-sectional study involving adults with non-DS ID (aged >60 years), AD was found to be the most common subtype (prevalence of 8.6%), followed by Lewy body, frontotemporal and vascular dementia [3]. Strydom and colleagues found an increased prevalence (18.3%) of dementia in 284 adults (≥65 years) with non-DS ID. This prevalence was not affected by the severity of ID [4]. The study confirmed a downward shift in age-associated risk, with an earlier age of dementia onset in this population compared with the general population. In contrast, Zigman and colleagues reported the prevalence of AD in 2.7% of adults with the non-DS ID of age 65 and over, and 4.1% in adults aged 75 years and older [5]. These rates are comparable with or lower than the expected rates in the general population. Patel and colleagues found a prevalence of dementia of 11.4% among 105 adults with ID aged 50 years and older [6]. The incidence rates were also higher compared with the general population [7]. Between 31% and 78% of non-DS adults with ID show AD neuropathology, whereas almost all people with DS over age 50 are known to develop AD neuropathology [8].

Autopsy examinations on 60 brains of individuals with ID of whom 15 had DS and 29 were aged 40 years and over showed a variety of acquired neuropathological changes, the most common being AD pathology with or without cerebrovascular disease (CVBD) (n = 8) followed by CVBD alone (n = 6) and Parkinson disease (n = 3) [8]. Of note, four brains showed neurofibrillary tangles (NFTs) confined to entorhinal cortex, compatible with the concept of primary age-related tauopathy (see ◘ Fig. 28.1).

A number of non-DS ID genetic syndromes are shown to be associated with increased prevalence of dementia [1]. These include Fragile X-associated tremor/ataxia syndrome (FXTAS), Cockayne syndrome (CS), Williams syndrome (WS), Prader-Willi syndrome (PWS), mucopolysaccharidosis type III (MPS III), Angelman syndrome (AS), and untreated phenylketonuria (PKU). It is not always clear whether this clinical presentation is due to premature neurodegeneration associated with specific syndromes as dementia neuropathology could not always be confirmed.

The CGG repeat size has been shown to be an independent risk factor for the FXTAS dementia [9]. Neuropathological characteristics are heterogeneous ranging from AD pathology to Lewy bodies in cortical and brainstem dopaminergic neurons, white matter disease, and astrocytic pathology [10].

In mildly affected people with CS, the course is slower, resulting in survival into adulthood with the development of dementia. Neuropathological examination discloses profound microencephaly, basal ganglia calcification, white-matter atrophy due to severe patchy myelin loss (tigroid leukodystrophy) with string vessels (i.e. thin connective tissue strands, remnants of capillaries, with no endothelial cells and no blood flow), and severe CVBD [11].

A few people with WS and premature 'senile dementia' have been reported, but neuropathological post-mortem examinations are lacking. However, people with WS may be considered to be at risk for developing both AD and vascular dementia, due to the high prevalence of hypertension and a high incidence rate of glucose intolerance or type 2 diabetes mellitus [12].

Also, in people with PWS, some cases of early-onset dementia have been reported but, again, without autopsy confirmation [13]. Maternal uniparental disomy (mUPD) with female sex and a history of psychosis appear to increase the risk for dementia [14].

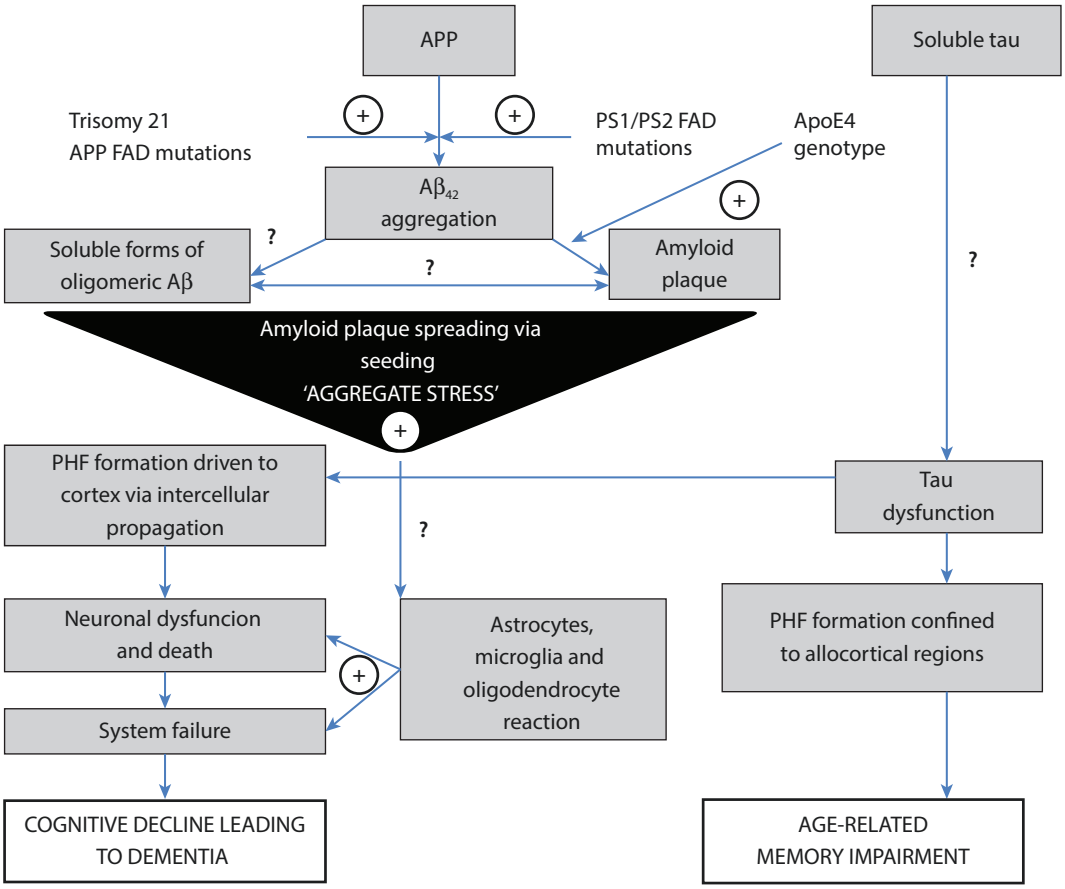

Fig. 28.1 Amyloid Cascade Hypothesis: current state of knowledge. APP amyloid precursor protein, FAD familial Alzheimer 's disease, PS presenilin, ApoE4 apolipoprotein epsilon4, Aβ amyloid beta, Tau tubulin-associated unit. (Modified from Karran & De Strooper (2016) [84])

MPS IIIB, also known as Sanfilippo syndrome, although associated with premature death, a number of less severe cases have been described to be living into late adulthood (age 30s to 60s) [15]. To the best of our knowledge, there is only one case report of an early-onset dementia in a female patient with MPS IIIB with a history of autistic-like features [16].

AS, albeit being a severe form of ID, may be compatible with long life (72–75 years) [1, 17]. There are, however, no published case reports of AS with dementia apart from a report on a 75-year-old male with a reduced cerebral circulation compatible with 'organic dementia' [17].

Untreated PKU although is typically associated with severe neurological dysfunction beginning in early childhood; there is one case report of a 57-year-old woman with mild ID who manifested four years of progressive spastic paraparesis and dementia with only partial (motor) improvement after protein-restricted diet [18].

Although there is an improved life expectancy in individuals with Rubinstein-Taybi syndrome and Cornelia de Lange syndrome [1], no case report of dementia could be found in the literature involving these syndromes.

28.1.2 Dementia in Persons with Down Syndrome

Among people with DS not only is AD much more common, but the age of onset of dementia is much earlier than in the non-ID general population [19].

Reported average ages of diagnosis vary between 50 and 56 years, with median survival times of 45 to 84 months [20–22]. Despite near universal AD neuropathology in DS, there is great inter-individual variability in dementia presentation. Studies using information from medical records, informant report, and direct assessment of cognitive abilities show ages of diagnosis range from 35 to 74 years (◘ Figs. 28.2 and 28.3), with some individuals showing barely any signs of decline over the age of 65 [22, 23].

Before the age of 40, less than 5% of the DS population show dementia. However, the prevalence over age 40 increases steeply with age. The prevalence of dementia in DS was reported to be between 10% and 25% in the 40 to 49 years age group, 20% and 50% in the 50 to 59 years age group, and 30% and 75% in those older than 60 years [24–29]. This diversity in the prevalence rates may be caused by difficulty in diagnosing dementia in people with DS since their baseline cognitive abilities can vary considerably. The incidence similarly increases with age. ◘ Table 28.1 shows dementia incidence from a study of 506 adults with DS in the Netherlands [29]. A 20-year longitudinal study of 77 women with DS found all but two had developed dementia [21]. From these data, the calculated cumulative risk for developing dementia increased from 23.38% at 50 years of age to 88% at age 65.

The average prevalence of dementia in DS is about 15% at age 45 compared with 13% among individuals with non-DS ID at age 60 and over, and less than 12% for AD at age 65 in the non-ID general population [30]. Thereafter, the rate of dementia doubles with each 5-year interval in both groups with DS and non-DS ID (see ◘ Fig. 28.3) [31]. A recent publication of a cross-sectional study of 388 individuals with DS from Barcelona, Spain, and Cambridge, UK, have reported prodromal AD at a median age of 50.2 years (IQR 47·5–54·1), and AD at 53.7 years (49·5–57·2). The prevalence of clinically confirmed AD increased with age, reaching 90–100% in the seventh decade of life [32].

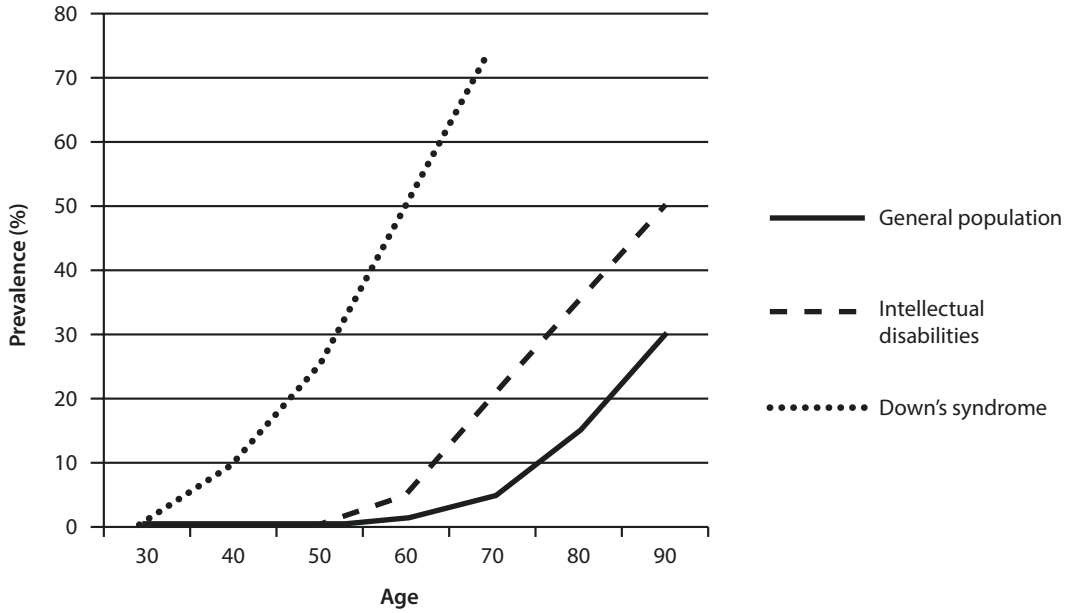

Fig. 28.3 Comparison of dementia prevalence rates by age in different populations [145]

Table 28.1 Incidence per 100 person years from Coppus et al. (2006) [29]

Age (years)	Incidence per 100 person years
<50	2.53
50–54	2.82
55–59	4.88
≥60	13.31

28.1.3 Diagnostic Criteria

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) replaced criteria for 'dementia' with 'mild or major neurocognitive disorder', with specifiers indicating the likely underlying cause (e.g. AD, vascular disease) [33, 34]. While previous diagnostic criteria framed dementia primarily as a disorder of impaired memory, these new criteria view decline in any one of six cognitive domains (learning and memory, language, executive function, complex attention, perceptual-motor skills, and social cognition) as a key feature. This must not occur exclusively in the context of a delirium or be better explained by another mental disorder. In mild neurocognitive disorder, the decline would be modest and ability to live independently would not be affected. In major neurocognitive disorder, the decline would be significant, and the individual would require assistance in, at the very least, more complex instrumental activities of daily living, such as managing their bills or medication. A mild neurocognitive disorder has to be backed up by an objective neuropsychological test, which remains difficult to achieve in a number of individuals with ID, particularly those with severe and profound ID. A similar problem exists in determining the effect of cognitive impairment on everyday activities as often in the case for more severe ID these activities are dependent on external support. The ICD-10 criteria for dementia view dementia as a chronic or progressive disturbance of memory as well as other higher cortical functions, together with deterioration in emotional control, social behaviour, and motivation [35].

Both ICD-10 and DSM-IV dementia criteria were found to be reliable in individuals with ID, but when used in individuals with more severe ID and sensory deficits, predictive validity was less good than in the general

population [36]. It was noted that the ICD-10 criteria were more specific but less sensitive than the DSM-IV criteria. The ICD-10 criteria are more demanding to apply because they are more dependent on reliable information from informants. The ICD-10 and the Diagnostic Criteria for Learning Disabilities (DC-LD) criteria [37] require behavioural and emotional changes to make the diagnosis, but the DSM-IV does not. ICD-10 dementia criteria have also been shown to be reliable in DS, but a clinical diagnosis of dementia following comprehensive assessment in DS may identify cases before ICD or DSM-IV criteria for dementia is met [38].

28.1.4 Diagnosis of Dementia in Persons with Intellectual Disabilities and Down Syndrome

Making a diagnosis of dementia in individuals with ID could be difficult for various reasons [19]. For example, (a) the main criterion for making a diagnosis in the general population is the gradual deterioration in memory and other cognitive functions. However, many people with ID have a pre-existing cognitive impairment, therefore, creating a floor effect for cognitive assessment. Therefore, in many cases, the only way to assess a cognitive impairment will be to compare current state with a pre-morbid baseline of cognitive skills. (b) The level of cognitive abilities varies widely among people with ID. On one end, people with mild ID may have fairly intact cognitive skills to start with and may live independently in the community with minimum support. On the other end, people with severe/profound ID have a very poor cognitive skill and are almost totally dependent on others for their day-to-day needs. Therefore, it is difficult, if not impossible, to use the same diagnostic method for people with different levels of severity of ID. (c) There is also difficulty in obtaining reliable baseline levels of cognitive functioning from which to measure change. Therefore, it remains difficult to accurately identify when the cognitive decline begins. (d) Many people with ID will not have enough communication skills to express the symptoms associated with dementia. (e) For a diagnosis of dementia in the general population, it is important to establish that cognitive impairment has affected the person's functional abilities, but in case of people with severe ID, functional abilities are poor to start with, therefore, making it difficult to assess the impact of any cognitive decline on their day-to-day functioning [19].

Studies that have mapped out cognitive decline among adults with ID (both with and without DS) using prospective designs show a trend of relatively greater decline in verbal abilities compared with non-verbal abilities that has been the case in the non-ID general population [39, 40]. Krinsky-McHale and colleagues [41] observed changes in both the storage and retrieval of information using a modified Selective Reminding Task [42] several years prior to the diagnosis of AD. Urv and colleagues, on the other hand, showed evidence of behaviour change prior to the onset of dementia [43]. However, none of these symptoms are definite markers of future dementia. The validity of mild neurocognitive disorder as a definite diagnostic category among people with ID remains questionable at this stage. Also, the exact features associated with normal ageing and their overlap with dementia symptoms have never been properly studied among individuals with ID.

28.1.5 Clinical Features of Dementia in Intellectual Disabilities and Down Syndrome

There is an ongoing debate as to whether the presentation of AD in DS/ID population is similar to that in the non-ID general population. Many factors such as age, level of ID, pre-morbid personality, state of physical and mental health, and the individual's circumstances are likely to influence the pattern of clinical presentation of dementia in this population. The level of ID may also modify and in some cases mask the early manifestation of dementia. Both typical and atypical pre-

sentations of dementia have been reported in people with ID/DS [44]. The main clinical features of dementia in individuals with ID are presented in ► Box 28.1.

Dementia in people with DS and non-DS ID, as in the general population, is characterised by progressive decline in cognitive abilities and everyday skills (see ► Case study 28.1). Behavioural and psychological symptoms of dementia (BPSD), such as apathy, aggression, and sleep disturbances are equally noted, and in some adults with DS may occur a few years before dementia is clinically diagnosed [45, 46]. Many memory measures are insufficiently sensitive to assess the decline in lower functioning participants; [46] however, with sensitive tests, it has been shown that memory changes may occur earlier than the decline in executive function, similar to AD in the general population [47]. Caregivers are also more likely to respond to excessive behaviour (problem behaviour such as aggres-

Box 28.1: The Main Clinical Features of Dementia Among Individuals with ID

- Forgetfulness
- Confusion
- Apraxic symptoms: e.g. putting on clothes the wrong way round, doing up buttons the wrong way
- Speech and language problems: e.g. difficulty instigating a conversation, lack of expression and flattening of the tone of voice, repetitive questioning, and problems with understanding
- Slowness
- Loss of skills
- Problems with socialising
- Lack of confidence
- Obsessional behaviour
- Paranoia/suspiciousness
- Sleep problems: early morning waking, wandering at night
- Change in appetite, often weight loss
- Balance problems: unsteady gait, fearful of kerbs, leaning to one side, shuffling
- Taking a big step over a crack or uneven surface or pattern on the floor
- Emotional problems: crying episodes, easily upset and frustrated
- Shouting and screaming
- Agitation/restlessness
- Aggression (verbal and physical)
- Hallucinations, delusions, and illusions
- Loss of interest/apathy
- Covering up/confabulating
- Seizures

Case Study 28.1: Molly

Every Saturday morning, Molly takes the 439 bus across town to visit her 'little' brother, Harry. On the way, she usually stops in the local shop to buy a magazine for her nephew, Tommy.

But today, Molly was late, and Harry was annoyed. Harry reminded Molly last night about leaving before 11 am to take Tommy to his friend's birthday party, but at 12 pm, Molly was still not there. When Molly finally arrived at 6 pm, it was courtesy of the local police. She had been spotted by a member of the public on a country lane 10 miles from home, clearly lost and distressed. Molly had taken the wrong bus. Normally, she would call Harry if anything went wrong, but she had forgotten to bring her mobile phone. Harry was concerned – Molly had been taking that same bus route for years.

As Harry reflected over the past few months, several other moments sprang to mind. This year in particular, Harry is realising how much older Molly seems.

She remembered the time Molly shouted at Tommy, because he was sat in 'her' place. At other times, she seemed withdrawn. Harry remembered the tins of beans in the freezer and wondering at the time why Molly would have put them there, and she realised that she hadn't seen the diary that Molly religiously carried with her for several months. These were so out-of-character – Molly was usually calm, meticulously well organised, and outgoing. Harry had heard about people with Down syndrome being at risk of developing dementia, but Molly had only just turned 43, surely she was too young?

sion) than behavioural deficits (cognitive and functional impairment) [48], which may mean subtle early changes that cause no disruption are missed. Adults with DS who live with their families receive dementia diagnoses 4 years earlier on average than those in other settings, further highlighting how differences in sensitivity to change may influence diagnosis [22]. Gender does not appear to influence the age of onset [22, 29]; however, earlier onset follows early menopause in women with DS [49].

Using the Severe Impairment Battery, Dick and colleagues found similar neuropsychological profiles among 59 individuals with AD when compared with 51 non-ID individuals with moderate to severe AD [31]. However, overall it appears that in most people with mild to moderate ID, the early presentation is similar to that in the non-ID general population. In that, it seems that an impairment of recent episodic memory in the context of relatively intact distant memory is an early manifestation, whereas, in severe ID loss of skills, neurological symptoms such as seizures and possible problem behaviours seem to be the early manifestation. The first appearance of epilepsy in later life could be a sign of dementia in DS. There is a bimodal distribution of epilepsy in the DS population, with early-onset epilepsy (primarily infantile spasms which may or may not lead to Lennox-Gastaut syndrome) occurring in about 10% of children and a late-onset epilepsy associated with dementia [50]. The presence of seizures is a poor prognostic feature being associated with death within 3 to 5 years [51]. Occasionally, late-onset progressive myoclonic epilepsy may develop [52]. This is of interest as the gene for Unverricht-Lundborg myoclonic epilepsy has been identified adjacent to the critical site for DS on chromosome 21 [53].

Deb and colleagues gathered unconstrained information by interviewing caregivers of 24 individuals with DS and dementia regarding the symptoms, particularly the early symptoms of dementia using a qualitative methodology [54]. Findings show that many 'frontal lobe'-related symptoms such as lack of motivation, apathy, inability to socialise, general slowness, and lack of interest in life in general that are usually manifested later in the process of AD in the general population were common at an early stage of dementia among individuals with DS. Loss of interest in activities and problems with speech and language are also common in the early stage. Caregivers reported general confusion, physical and mental slowness, deterioration in pre-existing skills, and emotional and behavioural problems in the early stage of dementia in individuals with DS, whereas these symptoms tend to appear later in the course of AD in the general population. Some caregivers reported, although not frequently, early symptoms such as illusions (e.g. thinking a cat is rubbing against them, while in fact, the cat is sitting still in the room at a distance), visual agnosia (e.g. picking things out of the air), and tactile hallucinations (e.g. feeling of touch sensation that is not there). Change in personality in the form of aggression was rarely manifested in early stages, but personality change in the form of apathy and social withdrawal were not uncommon in early stages of dementia in people with DS.

Some had problems in following more than one instruction at one given time. One example of such a problem given by the caregivers is that a person would pick up all the knives or all the forks when she/he was asked to pick up a knife and a fork from a drawer in the next room. An early symptom of dementia in people with DS was evidence of slowness that affects almost all aspects of their functioning such as walking slowly, eating slowly, speaking slowly, particularly failing to initiate conversations, and slowness in the overall body movement. Some caregivers reported that the individual with DS they cared for would stop in the middle of a task such as eating or drinking.

Caregivers reported that many individuals with DS at an early stage of dementia showed speech and language problems in the form of tardiness in instigating a conversation, lack of expression and flattening of the tone of voice, and repetitive questioning, which was not present prior to the development of dementia. Other examples included speech becoming slow and difficult to understand (which was not the case before). Sleep problems in the form of early morning wakening and wandering at night were reported as early prominent features of dementia in individuals with DS in a number of cases. Some reported evidence of

catnapping during the day at the expense of less and less sleep at night.

Loss of self-help skills could be an early symptom of dementia among individuals with DS. In the beginning, the caregivers often reported that the person with DS needed more and more prompts to carry out simple self-help chores such as wiping face with a flannel or brushing teeth or drinking from a cup. Eventually, individuals with DS lost these skills altogether and could not carry them out even with a lot of prompts. Many caregivers reported that the individuals with DS took part in fewer socialisation activities and withdrew from other people around them and also did not show interest in activities that they used to enjoy before the onset of dementia. Another prominent feature of dementia in people with DS was unsteady gait. Some people tended to lean to one side while walking while others took a big step over a crack on the surface or an uneven surface, including kerbs and uneven patterns in the carpet. One unusual symptom such as 'pica' (eating/mouthing inedible substances) was reported by one caregiver.

There are two possible explanations for prominent features of 'frontal lobe' dysfunction early in dementia among adults with DS. First, even before developing dementia individuals with DS show structural brain abnormalities in the frontal and the temporal lobes, and are, therefore, vulnerable to loss of frontal and temporal lobe functions early if there is any brain insult. Second, it is often not possible to detect dementia in its early stage among individuals with DS. Therefore, dementia tends only to be diagnosed in these individuals once the disease has already progressed to its middle or late stage. This is also evident from the shorter period of time that is clinically observed between making the diagnosis of dementia and death among individuals with DS compared with the general population who do not have ID. The features of 'frontal lobe' dysfunction are not uncommon in the later stage dementia in the general population; therefore, it is not surprising to detect these features fairly early in the diagnosis among individuals with DS, given that these individuals are probably already in an advanced stage of dementia by the time a diagnosis is made [55]. Spatial disorientation was a frequently reported symptom and was present in both individuals with moderate and severe ID.

Prasher's study of common early symptoms of dementia among people with DS included mental deterioration, slowing, confusion, reduced output of speech, and deterioration in gait and personality change [56]. Evenhuis, on the other hand, described apathy and withdrawal symptoms as the most common early features of dementia among people with both moderate and severe ID [57]. Prasher described late features of dementia in individuals with ID as severe intellectual deterioration, marked change in personality and mood, loss of sphincter control, onset of epileptic seizures, loss of mobility with increased muscle tone, and eventual complete loss of all self-help skills [58]. Holland and colleagues found in an 18-month follow-up study that in the initial assessment, caregivers reported changes predominantly in behaviour and personality in individuals with DS who later developed dementia [27]. According to Holland and colleagues, the frontal-like dementia was more prevalent, particularly among the younger groups [27]. On the basis of their findings, the authors hypothesised that the frontal lobe functions are the first to be compromised with the progressive development of Alzheimer-like neuropathology in individuals with DS. Crayton and colleagues [59] in another 4-year follow-up study found that those individuals with DS who developed dementia at the follow-up showed evidence of impaired orientation and visuospatial memory at the beginning of the study, but language function and praxis deteriorated later. The progression of dementia in people with DS has been reported to be more rapid than in the general population, one of the reasons being a late diagnosis in this population [60].

28.2 Etiopathogenesis

DS initially described by J. Langdon Down in 1866 [61] is the most common highly variable developmental genetic condition that primarily (≅95%) arises from an additional copy of an entire chromosome 21 (Hsa21) [62]. Other genetic errors associated with DS

are Robertsonian translocations (i.e. some genetic material from Hsa21, most often from the long arm, is translocated to Hsa14 or 22, or from the long to the short arm of Hsa21) and mosaicism (i.e. the whole Hsa21 is triplicated in only a proportion of cells with other cells being euploid), accounting for 1–5% and 1–2% of DS cases respectively [63, 64]. Exceptionally, DS can also occur with partial trisomy 21 (i.e. duplication of only a delimited segment of Hsa21) [65]. These multiple individual differences in DS genetics need to be taken into account when discussing the aetiopathogenesis of DS-related AD [66].

28.2.1 Down Syndrome-Related Alzheimer's Dementia Neuropathology

The neuropathology observed almost universally among aged individuals with DS is almost identical to those found in people with AD in the general population. The two major hallmarks of this neuropathology are extracellular amyloid plaques (see Fig. 28.4) and intra-cellular neurofibrillary tangles (see Fig. 28.5) composed of amyloid β (Aβ) and phosphorylated tubulin-associated unit (tau) protein, respectively [67]. The mechanisms behind this are thought to be overexpression of amyloid precursor protein (APP), locus for which is found on chromosome 21 that leads to overproduction of Aβ [68] as well as overexpression of Dyrk1A (dual specificity tyrosine phosphorylation-regulated kinase 1A) and RCAN1 (regulator of calcineurin 1) also located on chromosome 21 which are both involved in hyperphosphorylation of tau [69–72]. Neuropathological changes begin many years before clinical symptoms [73]. Positron emission tomography (PET) studies showed that both tau and amyloid binding in vivo are related to age and cognitive status [74, 75]. There is evidence of elevated levels of total-tau (t-tau) [72], and markers of oxidative stress and amyloid deposition in blood and cerebrospinal fluid may be of particular value; however, further research is needed and as yet, there are no biomarkers that allow clear predictions of future clinical course on an individual basis [44].

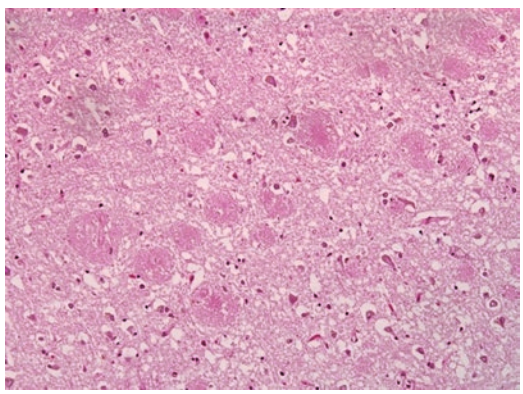

Fig. 28.4 Amyloid plaques, Alzheimer's disease, HE stain

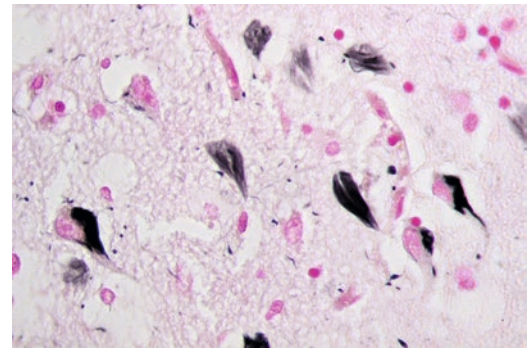

Fig. 28.5 Neurofibrillary tangles, Alzheimer's disease, Gallyas silver stain

There have been at least three seminal events in AD research: (a) the identification of the gene located on Hsa21 coding for the APP [76]; (b) the discovery of a missense mutation in the APP gene causing autosomal dominant familiar AD (FAD) in typically developing people [77]; and (c) the subsequent articulation of the amyloid cascade hypothesis (ACH) by John Hardy and Gerry Higgins [78] which posited that the extracellular deposition of the aggregated amyloid-β (Aβ) peptide – the major constituent of amyloid and neuritic (when associated with dystrophic and degenerating neurons) plaques in the brain parenchyma, initiates a sequence of events that ultimately lead to AD dementia (Fig. 28.1). Apart from the ACH and tau mechanisms, neuroinflammation is another important hypothesis in relation to AD which is relevant to DS as amyloid plaques lead to the production of neurotoxic pro-inflammatory cytokines [79]. Additionally, relevant to DS neuropathology, some other genes on Hsa21 include SOD-1 (superoxide

dismutase 1) and SLC5A3 (Solute Carrier Family 5 Member 3) [80, 81]. Mitochondrial dysfunction in neurons and astrocytes could also be involved, either independently or via altered APP metabolism [81–83].

28.2.2 The Amyloid Cascade Hypothesis and Down Syndrome-Related Alzheimer's Dementia

There is still a significant number of gaps in the ACH (see Fig. 28.1), among which at least three are fundamental. For example, we do not know (a) whether neurotoxicity and/or synaptotoxicity are caused by abnormal Aβ species as intracellular accumulations, or as extracellular free-soluble Aβ monomers, insoluble amyloid fibrils, and plaques or rather by the increase in the ratio of the longer (Aβ42) to the shorter forms (Aβ40) of the Aβ peptide; (b) how deposited Aβ triggers or accelerates the formation of neurofibrillary tangles (NFTs); and (c) what initiates ultimately the neuronal cell death that accompanies AD? The earlier outlined deficiencies in the ACH fostered in recent years the postulation of alternative hypotheses [84, 85], supported by the failure of multiple clinical trials targeting amyloid [86]. Yet, the ACH accommodates a wide range of data that we have on the aetiopathogenesis of DS-AD into a coherent hypothesis.

28.2.3 The Pathophysiology of Down Syndrome-Alzheimer's Dementia

Although our understanding of genetic and pathogenetic features in DS-AD has dramatically evolved in the last decade, some issues still remain unanswered [87, 88]. For example, besides the *APP* gene, approximately 13 protein-coding genes on HSa21 and four non-Hsa21 genes are thought to play a direct or indirect role in amyloidogenic *APP* processing and Aβ clearance, and in tau phosphorylation [88]. There are at least another 12 Hsa21 genes that are strongly implicated in neuro-inflammation, and oxidative stress deemed to be relevant in neuronal dysfunction and death according to the ACH [89]. Another 11 Hsa21-encoded genes and a five-cluster microRNAs flanking the *APP* gene are assumed to be involved in far-reaching epigenetic mechanisms [45, 64].

Also, the mechanisms underlying the wide variability in the onset of dementia in DS ranging from very early (<40 years) to very late (>70 years) onset remain largely unknown. Indeed, DS with trisomy 21 presents with many individual differences at the genome, single gene, epigenetic, cellular, neuro-developmental, cognitive, behavioural, and environmental levels, attesting the hypothesis that DS-AD may be considered a 'developmental disease' across the lifespan [66] so that, if individuals with DS live long enough, the development of clinical features associated with AD pathology appears almost inescapable as recently illustrated by McCarron and colleagues [21] who showed a prevalence of virtually 100% of dementia in 77 females at the end of a 20-year follow-up period.

28.3 Risk Factors and Biomarkers

An appropriate management would be helped by an understanding of the important risk factors for dementia in individuals with ID. Increasing age, a positive family history of AD, genetic factors, low educational level, sedentary lifestyle, history of head trauma, dyslipidaemia, diabetes mellitus, hypertension/hypotension, obesity, sleep apnoea, insomnia, depression, sensory impairments, periodontal disease, osteoporosis, chronic anticholinergic medication use, heavy smoking and drinking of alcohol, and cardiovascular disease have been identified as risk factors for AD and cerebrovascular dementia in the non-ID general population [90]. The use of non-steroidal anti-inflammatory drugs, antioxidants, and a high educational level may act as protective factors. There are likely to be similarities in the risk factors associated with AD in individuals with DS and the general population [19].

The Healthy Ageing in ID study involving 980 people with ID with a mean age of

61.5 years (range 50–93), of whom 861 had a diagnosis of DS, found that hypertension (53%), diabetes mellitus (14%), and metabolic syndrome (45%) were present similarly as in the general Dutch population matched for age [91]. Moreover, 50% of the people with hypertension had not been previously diagnosed with this condition. There is robust evidence that effective management of vascular risk factors delay the onset of AD in the general population [92], which is consistent with increasing research data that AD and cerebrovascular dementia have shared pathophysiology and neuropathological substrates [93].

Whereas the presence of trisomy 21 is a major risk factor for majority of people with DS, there is evidence that adults with DS who have atypical karyotypes including translocations, partial trisomies, and mosaicism have an improved survival and decreased rates of AD [94]. The presence of Apolipoprotein E allele 4 (ApoE e4) on chromosome 19 is shown to be a risk factor for AD in the general population, and there is some evidence that it may act as a risk factor for individuals with DS [95]. Some studies [96], though not all [95], have suggested that ApoE status, particularly the presence of the ApoE ε4 allele, affects the age of onset of dementia in people with DS. It is also suggested that ApoE status may influence the age of death [97]. Apart from the APP, there are other genes located on Hsa21 that may mitigate the occurrence of AD in individuals with DS [98, 99].

Mothers under 35 years of age of children with DS show a greater susceptibility to aneuploidy and trisomy 21 non-disjunction and have a five-fold increased risk for AD later in life compared with older mothers of a child with DS, to all fathers of a child with DS, or to the general population [100]. Low levels of oestrogen and an early-onset menopause may bring forward the age of onset of dementia in women with DS [101].

The cognitive reserve hypothesis has been proposed to explain how adults with similar brain insults may present with different clinical pictures [102]. The hypothesis proposes that there is a critical threshold of reserve capacity that needs to be breached by pathological processes before symptoms and signs develop. Individuals with DS will have reduced cognitive reserve due to their underlying decreased cognitive function and the likelihood that they will have had less education and may have resided in environmentally impoverished institutions. The cognitive reserve hypothesis predicts that adults with ID should be at risk for dementia and that they will be at risk of developing dementia at a younger age. There is a need for further research into this hypothesis to clearly elucidate its possible effects on individuals with DS.

There are controversial findings in the literature regarding whether or not the severity of ID acts as a risk factor for dementia [103]. Age, however, is the strongest risk factor for AD and in the case of individuals with DS, the effect of age is independent of severity of ID and gender [4]. Multiple vascular risk factors influence risk for AD and may act by increasing cerebrovascular pathology or also through a direct effect on AD pathology [104]. Coppus and colleagues showed that in individuals with DS, higher levels of plasma Aβ40 and Aβ42 were associated with increased risk of dementia [105]. Adjusted risk of dementia was increased in people with higher level of anti-fibril antibodies. Others have failed to show this association with dementia but showed Aβ40 level to be associated with cognitive decline in people with DS [106]. On the other hand, Matsuoka and colleagues showed that the ratio of Aβ42 to Aβ40 rather than absolute levels of the peptides is important to the pathophysiology of AD in genetically vulnerable population such as people with DS [107]. For example, a recent biomarker study of 388 adults with DS found that the Aβ1-42/1-40 ratio in the cerebrospinal fluid (CSF) and neurofilament light chain (NFL) values in the plasma changed among the participants as early as the third decade of life, and amyloid PET uptake changed in the fourth decade [18].F-fluorodeoxyglucose PET and CSF p-tau changes occurred later in the fourth decade of life, followed by hippocampal atrophy and changes in cognition in the fifth decade of life [32].

Other factors such as the raised mean corpuscular volume (MCV) of red blood cells (RBC) [108], impaired balance between

excitatory and inhibitory neurotransmitter system, particularly involving GABAA system [109] and higher levels of macrophage inflammatory protein-1α (MIP-1α) [110] have been implicated as risk factors, but further proof is required to confirm these findings. Triggering receptor expressed in myeloid cells 2 (TREM2) genetic variants are risk factors for AD and other neurodegenerative diseases. Plasma-soluble TREM2 (sTREM2) and other inflammatory markers are raised in adults with DS and dementia [111, 112].

The use of certain medications particularly with anticholinergic properties may enhance the expression of the neurocognitive disorder. A number of medication classes have been reported to be associated with possible worsening of cognitive function in people with dementia. These include antihistamines, especially first generation (diphenhydramine, hydroxyzine, promethazine), bladder agents (oxybutynin, tolterodine), certain pain medications (meperidine, propoxyphene), tricyclic anti-depressants, certain antipsychotics (chlorpromazine, clozapine, pimozide), and benzodiazepines [113].

There are also a number of psychological risk factors for dementia in individuals with ID. Esbensen and colleagues found that higher initial maternal and paternal levels of depressive symptoms and lower initial levels of paternal relationship quality were significant predictors of a higher likelihood of a dementia diagnosis in individuals with DS 10 years later [100]. Furthermore, lower initial levels of maternal positive psychological well-being predicted a higher likelihood of developing dementia in individuals with DS 10 years later, but the effect was only marginally significant.

Poorer overall physical health and depression are shown to be associated with an increased rate of dementia in individuals with ID [114]. However, it is not clear to what extent other known risk factors for dementia in the non-ID general population such as lack of engagement in mentally stimulating leisure and social activities, poor educational achievement, emotional trauma and associated post-traumatic stress disorder, poor diet and lack of exercise, also have a role to play in individuals with DS.

28.4 Diagnostic or Screening Instruments

Two main approaches have been taken for screening or making a diagnosis of dementia in individuals with ID with and without DS. These include instruments completed by caregivers of individuals with ID (informant-rated questionnaire) (see ◘ Table 28.2) or face-to-face interviews and examination, primarily including neuropsychological tests (see ◘ Table 28.3). There are pros and cons for each of these approaches. For example, direct cognitive assessment is impossible in people with severe ID and may be unreliable in people with even moderate to mild ID. On the other hand, different informants may provide different information on the information-rated scales. However, to counter this problem, most scales have assessed inter-informant reliability scores and found them to be good. The second problem is that many informants may not have known the person with ID since before the time of developing dementia, therefore, being unable to compare pre- with post-dementia symptoms. It is, therefore, recommended that both informant-rated and face-to-face cognitive tests should be administered periodically from age 30/35 years onwards in order to establish a pre-dementia baseline score. Zellinger and colleagues recently published a systematic review of assessment instruments for dementia in people with ID [115]. They found 35 instruments that are used for face-to-face cognitive testing in individuals with ID and dementia. They have also found 15 informant-rated scales that have been used either as a diagnostic tool or a screening tool for dementia in individuals with ID and/or DS. There are other recent reviews on rating scales for the detection of dementia in ID/DS [116, 117].

The face-to-face cognitive tests available involve assessment of various aspects of memory, language, executive function, orientation in time, place and person, attention, abstract thinking, visuospatial abilities, apraxia/dyspraxia, fine motor skills, dexterity, agnosia, etc. The informant-rated scales include assessment of behaviour and memory including adap-

Table 28.2 Informant-rated dementia rating scales

Domain assessed	Names of the instrument
Behaviour and memory	Assessment for Adults with Developmental Disabilities (AADS) [206]
Adaptive behaviour	Adaptive Behaviour Dementia Questionnaire (ABDQ) [131]
Cognitive functions	InterRAI-ID-cognitive performance test (InterRAI-ID-CPS) [207]
Cognitive function	Cognitive Scale for Down Syndrome (CS-DS) [208]
Dementia symptoms related	Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID) [125]
Dementia symptoms related	National Task Group-Early Detection Screen for Dementia (NTG-EDSD; adapted from DSQIID) [130]
Dementia symptoms related	Dementia Scale for DS (DSDS) [138]
Dementia symptoms related	Plymouth Dementia Screening Checklist (Plymouth-DSC) [209]
Behaviour and function test based	Dementia Questionnaire for People with Learning Disabilities (DLD) [123]
Behaviour and function test based	Multidimensional Observation Scale for Elderly Subjects-adapted for persons with DS (MOSES-DS) [129]
Behaviour and function test based	Behavior and Function Test (BFT) [210]
Behaviour and function test based	CAMDEX informant interview-DS [120]
Behaviour and function test based	Johanson interview from Johanson Test Battery [211]
Global outcome scale	Clinical Global Impression (CGI) [212]

tive behaviour, cognitive functions, but some are related to dementia-related symptoms. A global outcome scale has also been adapted for dementia screening in individuals with ID (see Table 28.2). A number of test batteries have also been developed (see Table 28.4).

The original CAMDEX (Cambridge Examination for Mental Disorders of the Elderly) was developed by Roth and colleagues [118] and revised in 1998 [119]. The full schedule includes an informant interview, an interview with the participant, an objective examination of cognitive function (CAMCOG) (Cambridge Cognitive Examination), and a physical examination and information on laboratory investigations. The original CAMDEX has been adapted for use in individuals with DS (CAMDEX-DS) (now updated as CAMDEX-DS-II) [120]. This is an informant-rated scale which has been combined with an adaptation of the CAMCOG as CAMCOG-DS (now updated as CAMCOG-DS-II) for use in individuals with DS, which is a direct cognitive assessment of individuals with DS [27]. Therefore, this battery combines an informant-rated interview with cognitive testing. Hon and colleagues [121] and Beacher and colleagues [122] found that the difficulty level of the CAMCOG led to exclusion of participants and limits the degree to which the results can be generalised to the DS population as a whole.

28.4.1 Informant-Rated Scales

Some of the early symptoms of dementia may be subtle or may present as an exacerbation of the existing behavioural traits or manifest differently in people with DS than they do in people who do not have ID. Only caregivers will notice these early and sometimes, unusual changes in the individual's behaviour and only by asking caregivers we can ensure that such symptoms are included in any case detection instrument. Therefore, an informant-rated instrument is ideal for screening or diagnostic purposes among individuals with ID and DS.

Table 28.3 Face-to-face neuropsychological assessment scales

Domains assessed	Names of the instrument
Cognitive function	Modified MMSE [140, 213]
Visuospatial function	Spatial Recognition Test (SRT) [214]
Delayed and immediate memory	Buschke Verbal Selective Reminding Task (4–6-year version) (SRT) [42]
Digit and sentence recall	McCarthy Scales of Children's Abilities (MSCA) [135]; Modified Boston Naming Test [215]
Memory for sentences, object and picture; delayed object memory	Rivermead Behavioral Memory Test (RBMT-C) [216]; Peabody Picture Vocabulary Test-revised (PPVT-III) [217]; The Fuld Object Memory Evaluation [218]; Modified Fuld [219]
Shoebox memory task, and delayed match-to-sample task	(Devenny et al., 2002) [220]
Verbal and semantic fluency	Controlled Oral Word Association Test (COWAT) [221]; Semantic verbal fluency [222]
Nonverbal reasoning/mental status	Leiter International Performance Scale (LIPS) [223]; Bayley Scales of Infant Development [224]; Test of Severe Impairment-Modified (TSI-M) [225, 226]
Visual perception, visual-motor integration and precision, spatial recognition span	Developmental NEuroPSYchological Assessment-II (NEPSY-II) [227]
Fine/perceptual motor skills	Modified Purdue Pegboard [143]
Dyspraxia, praxis	Dyspraxia Scale for Adults with Down Syndrome called the Brief Praxis Test (BPT) [228]
Executive function	Modified version of the Tower of London Test [3]
Language	British Picture Vocabulary Scale (BPVS) [229]
Not all tests mentioned in the above Table are specific for ID and AD [230]	

Table 28.4 Cognitive batteries used for detection of dementia in people with DS

Domains assessed	Names of the test battery
Cognitive function	CAMCOG-DS (part of the CAMDEX-DS) [120, 121]
Cognitive function	Cambridge Neuropsychological Test Automated Battery (CANTAB®), Cambridge Cognition Ltd., Cambridge, UK. 2016.
Cognitive function	Cognitive Assessment System (CAS) [231]
Memory, language, picture and object naming and identification	Neuropsychological assessment of dementia in individuals with intellectual disability (NAIID) [59, 232]
Memory, orientation, language, praxis, calculation	Prudhoe Cognitive Function Test (PCFT) (one long and two short Forms) [233]
Memory, language, executive functioning, motor performance, new learning	Rapid Assessment for Developmental Disabilities (RADD) [234]
Memory, orientation, language, attention, perception, construction, praxis, social interaction	SIB (Severe Impairment Battery) [235]

The Dementia Questionnaire for people with Learning Disabilities (DLD) [123] (formerly the Dementia Questionnaire for people with Mental Retardation; DMR [124]) and the Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID) [125] are perhaps the two most widely used informant-rated scales.

The DLD/DMR has 50 questions that have been divided up into the categories of 'short-term memory', 'long-term memory', 'spatial and temporal orientation' (making up the sum of cognitive scores; SCS), 'speech', 'practical skills', 'mood', 'activity and interest', and behavioural disturbance (making up the sum of social skills score; SOS). Each of the behaviours is rated as present either 'normally yes' (0), 'sometimes' (1), or 'normally no' (2). The overall score is calculated under two headings, namely, the 'sum of cognitive scores' (SCS) and the 'sum of social scores' (SOS). The cut-off scores for screening positive for dementia are different for individuals who have mild, moderate, or severe ID, respectively. The main problem with the scale is that it has shown low reliability when completed by caregivers [114]. Another practical problem is to determine accurately the severity of an individual's ID, which is required to determine cut-off scores for dementia.

Visser and colleagues followed up adults who had DS in a Dutch Institution with the Early Signs of Dementia Checklist (ESDC) [126], and Dalton and co-workers have used the Multi-dimensional Observation Scale for Elderly Subjects (MOSES) [127]. Neither has been properly validated for use in individuals with ID. Some studies have used the Adaptive Behaviour Scale [128] to estimate the rate of decline in adaptive behaviours in individuals with DS over a period of time [129]. The Adaptive Behaviour Dementia Questionnaire (ABDQ) is a 15-item questionnaire used to detect changes in adaptive behaviour and can be used as a screening tool [129]. However, it is not clear whether an assessment of the decline in adaptive behaviour alone is sufficient to make a diagnosis or screen for dementia, although adaptive behaviours are likely to be affected by dementia.

The DSQIID is unique in many ways [125]. Whereas most scales used professionals' views in developing the scales, a 'bottom-up' approach incorporating the views of caregivers regarding the symptoms of dementia was adopted for the DSQIID. Whereas almost all the scales included an inadequate number of participants with dementia to validate their scales, the DSQIID is the only scale that recruited an adequate number of participants with dementia for its validation. Unlike the other scales, the DSQIID avoids floor effect by comparing the current symptoms with a pre-morbid baseline. Also, unlike many other scales, the DSQIID is based purely on dementia symptoms rather than cognition-related items. The DSQIID has shown very good psychometric properties and factor structure. The DSQIID is a screening instrument and not a diagnostic tool and should not be used as such. In a clinical setting, the DSQIID is best used to explore each item with the caregiver in more detail in order to build up a clinical picture. If the DSQIID is used in a prospective manner, certain items may show floor effect as dementia progresses thus giving a lower total score as time progresses. Also, it is worth keeping in mind that there are certain physical and psychological conditions that may affect the scoring of certain items. For example, a cerebral stroke may affect scoring on items on 'walking and gait' and 'speech'.

The DSQIID has been translated into more than 16 languages for use worldwide, and in the USA, the National Task Group-Early Detection Screen for Dementia (NTG-EDSD) [130] has adapted the DSQIID and incorporated it into the NTG-EDSD [130], an early detection and screening tool. Validation of a Chinese (DSQIID-CV) [131], an Italian (DSQIID-I) [132], a Taiwanese [133], a German [134], and a Japanese version [72] have been published in peer-reviewed journals. Both the DSQIID-CV [131] and the DSQIID-I [132] have shown very good psychometric properties and good factor structure. Although in the original UK version Deb and colleagues found 20 as the best fit for specificity and sensitivity [125], in a subsequent recent study of the Japanese version of DSQIID (DSQIID-J), the

authors found a lower screening score of 10/11 [135]. Also, a recent independent validation of DSQIID items in the US NTG-EDSD an even lower score of 5 was seen to best fit the specificity and sensitivity for screening [136]. However, both the latter studies have shown good psychometric properties of DSQIID [135, 136]. A very recent study of the French version of DSQIID (DSQIID-F) has shown good psychometric properties and best fit between specificity and sensitivity at a total score of 19 [137]. However, as a screening instrument it may be better to use a lower cut-off score at the expense of detecting some false negatives, which could be excluded when a full clinical assessment is carried out at a later stage to confirm the diagnosis of dementia.

28.4.2 Neuropsychological Tests

Deb and Braganza highlighted the difficulty of using direct neuropsychological tests on people with ID [138]. The authors compared clinicians' diagnosis of dementia using Dementia Scale for Down Syndrome (DSDS) [139], DMR [124], and Mini-Mental State Examination (MMSE) [140] scores among 36 adults with DS without dementia and 26 adults with DS and dementia. DSDS and DMR scores correlated with each other and also with the clinicians' diagnosis (possibly because the same clinicians rated the DSDS and the DMR, and also have made the clinical diagnosis). It was only possible to administer the MMSE to 34 of the 62 (55%) participants. Thirty of these 34 adults (95%) had a score below 24 (the usual cut-off score for possible dementia diagnosis), but 23 (67.64%) of these had no diagnosis of dementia according to either DSDS or DMR or the clinicians' diagnosis.

Adult versions of neuropsychological tests are usually amended, or children's versions are used when testing adults who have ID. However, both these approaches carry the risk of losing the psychometric properties of the original scales. The 'McCarthy Verbal Fluency' Test [141], designed originally for children with normal cognitive function, has also been used for adults with ID. This test requires the individual to name as many words as possible within four specific categories, namely, 'food', 'animals', 'things to wear', and 'things to ride'. The initial simpler items of the 'Boston Naming Test' [142] can also be used to test language. The 'Purdue Pegboard modified' [143] tests constructional and psychomotor skills and requires the individual to place as many round pegs in round holes as possible in 30 seconds. The 'Brief Praxis Test' was developed by Dalton and co-workers [144] specifically to screen for early features of dementia in adults with ID. In this test, the individual is asked to carry out simple motor tasks such as raising an arm, shaking hands, and unscrewing the top of a jar.

Despite the use of all the above tests, their validity for use among adults who have ID still remains questionable. Perhaps an important strategy is to use these tests alongside an informant-rated behaviour questionnaire on a prospective basis.

28.5 Differential Diagnosis/ Co-morbidities

While making a diagnosis of dementia in individuals with DS, it is important to consider all the factors that may lead to cognitive impairment or give a picture similar to that of dementia. Sensory impairments, such as difficulty with hearing and vision, are not uncommon among people with DS, and they may lead to symptoms similar to that of dementia. There are a wide variety of potential causes for the decline in function in the ageing population with ID, many of whom have DS that are listed in ▶ Box 28.2 [113, 145].

Alongside their elevated AD risk, adults with DS experience higher rates of other common age-related issues, including sensory impairments and musculoskeletal disorders, than the general population and people with non-DS ID [146]. The development of dementia is further associated with higher levels of specific co-morbidities, including depression, hypothyroidism, epilepsy, and sleep disturbances [29, 147]. Capone and O'Neill [148] discussed other physical problems commonly associated with people with DS that may have

Box 28.2: Differential Diagnosis of Dementia/Decline in Function

- Depression
- Decline secondary to sensory impairment (visual and hearing)
- Endocrine disorders such as hypothyroidism
- Delirium
- Vascular disease: multi-infarct dementia
- Physical brain damage: tumour, head injury, epilepsy
- High-dose antipsychotics, medications with anti-cholinergic adverse effects, anti-epileptic drugs, and multiple medications
- Degenerative disorders: Parkinson's disease
- Infections: encephalitis, meningitis, Creutzfeldt-Jakob disease
- Anaemia, chronic infection, nutritional deficiency: vitamin B12, folate
- Impact of life events (bereavement, change in environment, move from home, loss of day activities, etc.)
- Physical and emotional abuse

an impact on dementia. Some of these include extrapyramidal symptoms, cervical spondylosis, atlanto-axial instability, feeding/swallowing problem, sleep apnoea, cardiac valve disease, peripheral vascular disease and atherosclerosis, autonomic dysfunction, the problem with bone metabolism, and early menopause. Individuals with the non-DS ID may also present with a range of physical health co-morbidities, including sensory deficits [149].

Assessment for, and treatment of, such co-morbidities should form an essential part of diagnostic procedures for individuals with suspected dementia. Thyroid disorders, depression, and sleep apnoea, in particular, could lead to misdiagnosis of dementia, as each can cause impairments in cognitive and/or adaptive functioning that could be reversed with appropriate treatment [150–152].

Thyroid Disorders

Thyroid disorders are more common in DS and non-DS ID than the general population and more common in older people with DS than younger [153, 154]. Prevalence of thyroid disorders is not directly related to dementia status in DS [147, 155]; however, thyroid disorders may be more common in those with end-stage than early-stage dementia [147]. Both hypo- and hyperthyroidism can impair cognitive abilities [150], thus given the increased risk, thyroid disorders must be first ruled out when assessing suspected dementia. Subclinical hypothyroidism (high basal level of thyroid-stimulating hormone (TSH) and low total or free T4) is present in approximately one third, and anti-thyroid antibodies are present in 18% of adults with DS compared with 6% of matched healthy control subjects [156]. The presence of anti-thyroid antibodies makes individuals with DS vulnerable to develop clinical hypothyroidism, and this must be differentiated from other causes of dementia as clinical hypothyroidism could be treated with supplementary thyroxine.

Depression

Depression can be both a co-morbid condition and a confounder of dementia (see ▶ Case study 28.2) [21, 155]. Some authors have reported a higher prevalence of depression among adults with DS, compared with adults who have non-DS ID [157], whilst others have not confirmed this [158]. There may be an overlap between the clinical expression of depression and dementia, which is important to distinguish, as most cases of depression are treatable. Untreated depression may exacerbate the cognitive decline in DS or ID, and cognitive abilities following extended periods of decline in these cases can recover upon appropriate treatment [159]. In adults with DS, treatment with anti-depressants regardless of the existence of depression has been reportedly associated with delayed onset of dementia and increased longevity, though this was not a randomised trial [152]. However, the previous history of depression and treatment with anti-depressants were both found to increase the likelihood of dementia in a longitudinal study conducted in the Netherlands [29].

Epilepsy

Epilepsy is strongly associated with dementia in the DS population [160, 161]. Between

Case Study 28.2: Vignette 2: Jerome

It had been 6 months since Jerome moved in to the care home. Jerome had lived in his family home for the previous 60 years, however when his mother passed away, with no other family to support him, Jerome had to move.

When he first arrived, Jerome was withdrawn and often tearful. He spoke very little with the other residents and required help from staff to get ready in the morning and make his own food and drinks. When staff took Jerome out, he would often try to go 'home' to his family home. The staff thought perhaps he kept forgetting that he had moved.

One member of staff had known Jerome as a younger man, when he attended a day centre that they were working in. They were surprised to see Jerome needing so much help. While Jerome had always required some support with shopping and travelling, he would always dress and clean himself and enjoyed helping to prepare lunch for everyone at the day centre. Being aware of the risk of dementia in this population, and knowing Jerome was now in his 60s, the staff arranged a review with a psychiatrist.

While Jerome's age and apparent deterioration could well be indicative of the beginnings of dementia, the psychiatrist was also mindful of the major bereavement and change in living circumstances Jerome was experiencing, so suggested a course of anti-depressants. Three months later, the staff reported a marked improvement in Jerome. He was managing his own self-care and chatting readily with the people he lived with, although he was sometimes getting his words mixed up. He was more settled in the home, although found it difficult to remember new staff member's names and would occasionally forget where things belonged.

40% and 77% of those who develop dementia will also have seizures [29, 147, 162]. For the majority, these seizures will be late onset, starting after the age of 35. Retrospective patient data showed a median time of seizure onset of 2 years following the dementia diagnosis, with generalised tonic-clonic seizures being the most frequently reported type [162]. However, in a recent clinical-video-EEG study of 22 adults with DS, Vignoli and colleagues [163] found focal seizures among nine (41%), late-onset myoclonic epilepsy among nine (41%), and unclassified type among four (18%) remaining participants. Indeed, some suggested that many generalised seizures observed in people with ID are focal seizures secondarily generalised, which could be wrongly classified in the absence of an appropriate investigation [50, 51]. The presence of seizures is associated with more severe cognitive decline, highlighting the importance of seizure management in this group [164].

Neurological complications, including extra-pyramidal symptoms, incontinence, and mobility issues are also common features of dementia in individuals with ID, particularly in later stages [165].

28.6 Assessment

In the USA the National Task Group (NTG) on ID and Dementia Practices [113] and in the UK the British Psychological Society and the Royal College of Psychiatrists jointly [145] produced consensus recommendations for the evaluation and management of dementia in adults with ID. The US guideline recommends the following steps for assessment: (a) Gather a pertinent medical and psychiatric history. (b) Obtain a historical description of baseline functioning. (c) Obtain a description of current functioning and compare with baseline. (d) Perform a focused review of systems. (e) Review the medication list thoroughly (see the earlier Section on 'risk factors' in this chapter). (f) Obtain a pertinent family history. (g) Assess for other psychological issues or changes. (h) Review social history, living environment, and level of support. (i) Synthesise the information. (j) Carry out a physical examination. (k) Carry out a mental state examination including cognitive assessment. In addition, the UK guidelines recommend certain relevant investigations (see ► Box 28.3).

Box 28.3: Schema for the Diagnosis of Dementia in a Person Who Has Intellectual Disability

- History from the person
- History from an observer/carer
- Examination of the person
  - Test for sensory impairments such as hearing and vision
  - Check for physical disorders, particularly hypothyroidism
  - Check for other psychiatric disorders such as depression
  - Check for epilepsy
  - Check for associated drug treatment
- Laboratory investigations (for differential diagnosis and cause of dementia; FBC, Vitamin B12 etc.)
- Neuroimaging (structural to exclude space-occupying lesion, etc.; functional to help with the differential diagnosis)
- Longitudinal use of neuropsychological tests and observer-rated questionnaire including an assessment of adaptive function

The assessment of an individual with DS suspected of dementia should start with a history from the individual and their caregivers. A mental state and physical examination of the individual with DS is imperative in order to make a diagnosis. Mental state examination should be used to exclude specifically the presence of depression, delirium, sleep problem, and anxiety (https://spectrom.wixsite.com/project) disorder. The issue of so-called diagnostic overshadowing is worth keeping in mind in which symptoms of dementia may be mistakenly attributed to the effect of ID in individuals with ID/DS. Physical examination includes assessment of all bodily systems including neurological examination for focal neurological signs and cardiovascular system including high blood pressure, and importantly assessment of sensory modalities such as hearing and vision. Neurological examination should also emphasise on language assessment and gait and motor coordination. Special emphasis should be placed in excluding hypothyroidism and anaemia. Standard laboratory tests should include vitamin B12 and folate levels, thyroid function test, full blood count (FBC), serum glucose/HbA1c, lipid profile, urea and electrolytes, renal function test, and liver function test.

An electroencephalograph (EEG) will be useful for those who have seizures and for whom anti-cholinesterase treatment is being considered an electrocardiogram (ECG) is necessary. There are differing views on the usefulness of neuroimaging in the work-up of the individual. Structural neuroimaging is widely considered to be useful to exclude space-occupying lesions, and it may also have a role in early diagnosis of dementia. An MRI study in individuals with DS found reduced medial temporal and striatal volume as a marker of AD [121]. These grey matter changes can be seen before the onset of clinical dementia [166, 167]. Functional neuroimaging such as Single Proton Emission Computed Tomography (SPECT) [168] and Positron Emission Tomography (PET) [169] have been used in individuals with DS and dementia [167, 170].

Recent advances in PET using new ligands have enabled researchers to show deposition of cerebral amyloid and tau in the brains of individuals with DS and dementia. Both [^{18}F] FDDNP and carbon 11-labeled Pittsburgh Compound B ([^{11}C] PiB) have been used to measure cerebral beta-amyloid [171, 172]. 11-PiB is used for amyloid and FDDNP for both amyloid plaques and neurofibrillary tangles [170]. Amyloid deposition, particularly in the posterior cingulate gyrus, has been detected using 11PiB before the clinical onset of dementia. Some showed a different distribution of amyloid deposition in the brains of people with DS compared with people with AD in the general population, in that the first deposition is shown in the striatum at around age 40 years, which some suggested could be the precursor of dementia. The FDG-PET showed hypo-metabolism of glucose in the posterior cingulate and other relevant brain areas even before the onset of dementia in

people with DS [166, 173]. Although paradoxically in some adults with DS who did not develop clinical dementia, hyper-metabolism was also observed. This may be a possible compensatory mechanism before manifestation of hypometabolism [167].

Diffusion Tensor Imaging (DTI) studies showed impaired integrity in frontal tracts in people with DS and dementia compared with people with DS who did not have dementia [174, 175]. Increased white matter damage in-PiB positive subjects with DS, predominantly in the posterior tracts has also been reported [167, 176].

However, neuroimaging requires informed consent which will require accessible information to be given to the individual and also possibly an assessment of capacity to consent to the procedure. The procedures are often long and complex requiring the co-operation of the individual, and this is often difficult in this population. The British Psychological Society guideline [145] concluded that neuroimaging is not an essential investigation but that it may be of value where other brain lesions or vascular dementia are suspected.

Therefore, for regular prospective screening, an informant-rated dementia symptom-based scale such as the DSQIID/NTG-EDSD [125, 130] along with neuropsychological screening if appropriate could be used. A more detailed diagnostic battery such as the CAMDEX-DS [120] could be used if the decline is noted or if the diagnosis is unclear. An assessment of environmental factors is also mandatory. Ageing individuals with DS are likely to face many changes in their lives. For example, there could be a change in their living environment as their parents may not be available any longer to support them. Similarly, there may be a change in care staff or residents in the community home where they live. Many of these individuals are also likely to see the death of parents or other close family members. There may be a change in occupational status, leisure activities, or in friend circle. Given the limited coping skills, individuals with DS are likely to be affected at times quite profoundly by these life events which would have an effect on their cognition and functional skills. Therefore, these issues have to be considered carefully before a definitive diagnosis of dementia is made.

28.7 Management Options

28.7.1 Pharmacological and Medical Interventions

Two classes of medication are currently licenced for the treatment of dementia, particularly AD. Acetylcholinesterase inhibitors such as donepezil, galantamine, and rivastigmine are used for mild to moderate dementia. Adverse effects may include dose-related cholinergic effects such as nausea, vomiting, hallucination, sleep disturbance, dizziness, and agitation. Available evidence suggests that acetylcholinesterase inhibitors are well tolerated by individuals with DS/ID, although lower doses may be required due to bradycardia which is common in DS [177]. Therefore, it is advisable to carry out an ECG prior to initiation of treatment and monitor pulse rate regularly thereafter. Memantine is a glutamate receptor antagonist often used in severe dementia. Adverse effects include constipation, headache, dizziness, and hypertension.

A recent Cochrane review on the efficacy of drugs in improving cognition in people with DS included nine randomised controlled trials (RCTs) [178]. Of these, four studies were on donepezil, two on memantine, and one each on simvastatin, anti-oxidants, and acetyl-L-carnitine (a dietary supplement). Four of these studies included participants below age 30, before the age of expected onset of clinical dementia in this population. Only simvastatin had shown some positive difference on cognition when compared with the placebo group but given the very small number of participants whose data were analysed ($n = 13$) [179], this finding is of very limited value. Donepezil group showed a statistically significant higher rate of adverse effects when compared with placebo group (Odds ratio: 0.32). However, no significant inter-group differences were observed with other active interventions. Authors concluded that due to the low qual-

ity of the body of evidence synthesised, it was not possible to draw any definitive conclusion about the efficacy of any medication in the management of cognitive decline in people with DS. However, a recent practice-based cohort study of 310 adults with DS and AD in the South of England in the UK showed a statistically significant longer median survival time among those who were prescribed anti-dementia drugs (primarily acetylcholinesterase inhibitors) (5.9 years; 95% CI: 4.67–6.67; n = 145) compared with those who were not (3.45 years; 95% CI: 2.91–4.13; n = 165) during the period of 2000 and 2013 [180].

Current guidance suggests that medication for dementia in individuals with ID should be initiated by specialists [145]. Once started, treatment should be carefully monitored to assess benefit and adverse effects and may need to be stopped if not tolerated as dementia progresses. Medical management is generally supportive. Common issues include sleep problems with reversal of sleep-wake cycle, which can be associated with problem behaviour, but sleep apnoea, which is a common co-morbidity in DS, has to be excluded first. Sleep-wake problems can be managed using simple interventions such as reinforcing the cycle, and melatonin may be useful [177]. In the early stages of dementia, additional functional gains can be made by managing sensory impairments such as hearing and vision problems. Respiratory and other infections that are common in individuals with dementia should be treated early. In the case of dementia-related seizures, a partial or complete response to treatment with anti-epileptic medication, particularly levetiracetam, has been described [162].

Eventually, dementia will progress with increasing complications, including problems with eating and drinking and incontinence, myoclonus or seizures, increased risk of infections, and mobility issues. The person may become bed-ridden and need 24-hour support. Palliative and end-of-life care should be instigated in a timely manner with the aim to support quality of life, addressing both psychological needs and symptom management. Areas that may require particular attention towards the end of life include swallowing assessments and eating and drinking guidelines to avoid aspiration, pain relief, and posture.

28.7.2 Non-pharmacological Management

There is a range of non-pharmacological management that may be used to promote quality of life, potentially avert or respond to symptomatic issues, and/or support family and other caregivers [181]. Guidelines for the care and treatment of persons with and without ID affected by dementia recommend the use of non-pharmacological therapeutics over pharmacological options as a first approach in addressing issues that arise in dementia care [182]. Table 28.5 identifies an assortment of non-pharmacological therapeutic interventions commonly found in practice. Research on specific therapeutic interventions used with persons with ID experiencing dementia or aiding their caregivers is sparse [183], although the literature offers some evidence of the utility of select interventions. Dodd and colleagues [184] noted that these include developing an understanding of dementia [185], anxiety and stress reduction [186], life story work [187], reminiscence [188], validation techniques [189], and helping peers to understand dementia [190]. The use of support groups for persons with ID and dementia which employ various strategies (e.g. information and education using visual aids, role-playing) has its benefits [191, 192]. A range of other generic therapeutic approaches may also be effective with people with ID and dementia, including music therapy [193, 194], aromatherapy, sensory stimulation (including Snoezelen), touch, and the use of electronic devices, domotica (smart homes), and entertainment. Generally, the most commonly used approaches for people with ID are the same as those used in the general population; however, some applications may need to be adapted contingent on the innate level of ID [181]. Their utility will be stage- and function-based; the efficacy of each approach needs should be individually monitored and evaluated [195]. Family caregivers and paid-staff

Table 28.5 Possible applications of non-pharmacological management strategies

Therapeutics	Examples	Rationale
Counselling and group support	Individual, family, and significant others	Address psychosocial/emotional needs of individual affected and caregivers
Culture and arts based and other therapies	Dance/movement, music/music therapy, art, pet, massage	Enhance quality of life, maintain interests/abilities, address behaviours
Reminiscence	Life story work, review of photos and memories	Keep long-term memory active and permitting favourable memories to come forth
Education and skills training for caregivers	Dementia information, communication strategies, other specific interventions	Modify caregivers' interactions, reduce behavioural reactions/stress
Health discussions	Physical exercise, dining strategies, personal reviews of physical factors	Maintain health and improve diet, nutrition, and hydration of person
Multisensory approaches	Snoezelen, Montessori	Stimulate yet calm the individual
Advanced dementia physical care	Bathing, voice modulation and facial expressions, massages, sensorimotor activities (such as 'twiddle muffs'), aromatherapy, scented lotions, use of durable medical equipment, help with swallowing and breathing	Prevent skin breakdown, provide physical and sensory stimulation Maintain relationships

Source: Jokinen, 2014 [181]

should be given information, instruction, and receive follow-up to effectively incorporate non-pharmacological therapeutics into a person's daily or weekly routine.

The most recent systematic review on non-pharmacological interventions for people with dementia in the general population who do not have ID has shown that person-centred training, communication skills training, and adapted dementia care mapping decreased symptomatic and severe agitation in care homes immediately (Standardised Effect Size; SES range 0.3–1.8) and for up to 6 months afterwards (SES range 0.2–2.2). Activities and music therapy by protocol (SES range 0.5–0.6) decreased overall agitation, and sensory intervention decreased clinically significant agitation immediately. However, aromatherapy and light therapy did not demonstrate efficacy [196]. A recent Cochrane review has shown a decreased need for antipsychotic use among patients with dementia in the general population when psychosocial interventions including staff training were introduced [197, 198]. However no such evidence exists involving people with ID.

28.8 Service Needs

An ideal service for people with ID and dementia should ensure that (a) periodic, but regular and planned, reviews are undertaken of the person's programme/care plan to identify significant changes in health, function, and quality of life, and adjustments are made in activities and care practices to ensure that the person continues to receive quality person-centred care; (b) early identification of behavioural and psychological symptoms of dementia occurs and reviews of care practices and supports are undertaken when such symptoms are present; (c) support is offered to caregivers throughout the course of the condition, from both specialist and mainstream services, and there is a continuing provision of information; and (d) quality of life is evaluated at regular intervals from both the perspective of the person with ID and caregivers, across the course of the person's journey.

Generally, dementia-related care is stage-based and in Table 28.6 [182] we offer a structure for stage-based activities and

Table 28.6 Pre-and post-diagnostic supports for community care

Pre-diagnostic stage	*Recommended actions:* Make provisions for the ongoing information needs of individuals, friends, and families as well as staff training to better understand the diagnostic process and progressive nature of dementia Use a detection/screening tool on a regular basis to capture early warning signs that may or may not indicate dementia Assess for medication-induced adverse drug reactions or other conditions mimicking, exacerbating, or masking dementia Dialogue with a healthcare professional or clinician about the screening tool results and, if the suspicions appear supported, seek a referral for a formal health assessment Advocate that trained professionals familiar with assessment and diagnosis of adults with ID and cognitive/functional decline become involved Have a person familiar with the adult with an ID and his or her history and communication method always accompany the adult to the assessment appointment(s) Hold meetings with the individual, family members, and others important to the person, if a diagnosis of dementia is obtained, to explain the diagnosis, prognosis, and begin to map out priorities for future support
Post-diagnostic stages	
Early stage: Mild dementia	*Recommended actions:* Engage the individual and their family, and/or other caregivers or guardians in advance care planning (and prepare advance directives) consistent with state or other requirements Identify and plan to remediate the environmental challenges to help maintain community living Establish a daily regime that provides for purposeful engagement based on individual needs and preferences yet is organised so as not to cause anxiety and confusion Provide ongoing clinical support to address behavioural and psychological symptoms associated with dementia Redesign day activities and programmes so that participation in valued activities and opportunities for interaction with others continues and respite for families and other caregivers is possible
Mid-stage: Moderate dementia	*Recommended actions* Provide increased assistance with personal care and hygiene when needed Secure appropriate residential supports and consider housing options to accommodate increasing losses in independent functioning Continue surveillance and periodic assessments to determine extent of change and progressive dysfunction as well as the possible development of co-morbid conditions Monitor any medications being taken to prevent adverse drug reactions Enhance training of staff and family as well as consultation to caregivers around coping with behaviours and adapting routines Provide caregivers information about potential complications, and how to prevent these, including falls (footwear), swallowing issues (choking/coughing during eating, which needs rapid assessment), sleep issues, risk for infections, etc. Institute planning for long-term services and supports Ensure protections are in place to preclude abuse or harm in both formal and informal settings
Late stage: Advanced dementia	*Recommended actions* Reorganise care management towards non-ambulatory care Identify eating/drinking/swallowing issues, also infections, aspiration pneumonia, etc. Reassign staff to activities more structured around nursing and personal care including the support of family caregivers who wish to maintain the person at home Obtain support from palliative care or hospice specialists Institute procedures to maintain dignity, comfort, and address pain and symptom management Organise end-of-life supports and post-death arrangements

Source: Jokinen et al., 2013 [182]

adaptation in care practices as dementia-related decline runs its course. As noted in the pre-diagnostic stage, preliminary activities are designed to identify or validate the presence of mild cognitive impairment or early-stage dementia. In the post-diagnostic stages, activities and care practices are progressively more focused on coping with and management of gradually deteriorating function. Early-stage practices tend towards personal supports and enabling the person to remain-in-place. With the deterioration of function, the focus of mid-stage practices shifts to greater levels of supports as well as introducing various environmental adaptations. In structured settings, this stage often calls for more enhanced staffing and supervision, while providing personal supports to maintain the integrity of the person's function and skills. For more detailed information and recommendations related to stage-based care, we recommend sourcing the following International Summit on Intellectual Disability and Dementia statements: for general post-diagnostic supports (PDS) issues [184], for advanced dementia [199], for family supports [200], and for end-of-life care and dementia [145, 201].

A multi-disciplinary/multi-professional approach to assessment and service provision in which General Practitioners/Family Physicians, Psychiatrists, Neurologists, Nurses, Psychologists, Physiotherapists, Social workers, and Occupational Therapists are involved, is vital in order to lessen the burden of care. Watchman [202] suggests a need for increased awareness and training for professionals in primary care. She also suggests that one professional should take responsibility for sharing the diagnosis with the individual and their caregivers.

In terms of accommodation, the best practice is to facilitate ageing and caring in the same home where they have lived in if possible, to do so. Moving home at the time of increased confusion may be detrimental and hasten their decline and increases the chances of emerging problem behaviour. However, if a move away from family home really becomes inevitable, then relocation to a model service specifically designed to care for people with DS and dementia as suggested in De Vreese and colleagues' paper [203] would be ideal. In the late stage of the disease, a co-ordinated service from Health, Social, Voluntary, and Private sector may be required because in the majority of cases these individuals may have to be transferred away from their home settings and looked after within one of the services mentioned earlier in the text. It is important to ensure that caregivers are fully involved in the formulation and provision of care. Other important areas to assess are the organisational settings, systems, and processes in place to support the person with ID and dementia and their caregivers, and the need to address the possible absence of adequate support.

28.8.1 Cross-Cutting Management Issues

Abuse and neglect. With diminished capacity, adults affected by dementia become vulnerable to different kinds of abuse or mistreatment, which can take varied forms, such as emotional, physical/sexual, and financial. Neglect, a form of abuse, is the refusal or failure to fulfil caregivers' obligations or duties to a person under their care. Self-neglect, also a form of abuse, occurs when an adult with dementia who lives alone loses the ability to care for him or herself, lacks support resources, and poses a threat to his or her health, safety, and well-being. Whatever the source, abuse, mistreatment, and neglect should not be tolerated, and any instances immediately reported to the appropriate authorities [204].

Nutrition. Weight loss and under-nutrition are common complications that occur with dementia. Under-nutrition adversely affects an individual's functional abilities, resistance to infections, and general overall health status and independence. As dementia progresses, the person increasingly becomes more dependent on caregivers to adapt meals and meet nutritional needs. Malnutrition is preventable and can be addressed; early intervention strategies should be set up and management of emerging nutritional problems dealt with rapidly.

Relationships. In person-centred care for dementia, Kitwood [205] has related person-

hood to the relationship and social being. In the context of relationships, life stories can be used to nurture a sense of history and selfhood with people with dementia. Assisting caregivers to understand behaviours and offering them tools to connect with and 'be in the present' with the person 'as is' can enhance well-being for both the person with dementia and the caregivers. PDS also involves aiding families and paid care staff, to deal with emotions, such as grief (for multiple losses), guilt, and self-doubt which can colour interactions, and to receive education and counselling.

The shift in philosophy. In many cultures, the overall focus for people with ID is based upon fostering skill building, along with increasing independence and autonomy. Goals and strategies that value and promote skill maintenance and overall well-being ('being not doing') in dementia care should be employed that recognise and promote greater systems change.

Education and training. Best practice would dictate the exposure of staff or other workers to information about dementia and its effects. Education should include an understanding of best practices for providing day-to-day specialised dementia supports; a familiarity with adaptations and modifications to the physical and social environments, as well as to activities to promote active engagement; and exposure to a range of models for providing community-based dementia care and supports. Training should also lead to a familiarity with the range of resources available to help support people with dementia and their families [204].

28.9 Conclusion

A case could be made to make caregivers aware of the main themes of expression of dementia in individuals with ID so that the caregivers could raise suspicion at an early stage about the condition and an appropriate referral could be made to specialist services for confirmation of diagnosis. Whereas an early and accurate diagnosis of dementia in individuals with ID is necessary for timely management, it is equally important to bear in mind that a false positive diagnosis of dementia may cause unnecessary anxiety to the individuals and their families and lead to wrong management of the problem. A multi-disciplinary, person-centred approach to diagnosis is, therefore, recommended in which a baseline is established at a stage before dementia is likely to occur. Use of screening instruments followed by a full work-up by an appropriately qualified professional or a group of professionals when dementia is suspected is likely to provide the best yield in terms of diagnosis. A longitudinal approach to diagnosis would be desirable, where the intervals between assessments decrease in proportion to increase in age and subsequent amplification of risk. The effect of medical, psychological, social, and environmental factors on cognition of individuals with ID has to be carefully assessed. It would be desirable for local services to set up a register of adults with ID/DS in order to carry out a baseline assessment of cognitive and adaptive functioning which should be further assessed at regular intervals in a prospective manner. It is also desirable that each service should develop specialist skills in this area and offer training to other professionals, front line staff and caregivers. Caregivers and health professionals need more information on behavioural and cognitive changes in early stage of dementia so that an earlier and more effective referral to specialist services can be made. In terms of accommodation, the best practice is to facilitate ageing and caring in the same home where the individuals with ID have lived in if possible to do so. Moving home at the time of increased confusion may be detrimental and hasten their decline, although this may become unavoidable as the disease progresses to an advanced stage.

Key Points

- Dementia is more prevalent in people with intellectual disabilities and more so in people with Down syndrome.
- Onset of dementia in people with Down syndrome is earlier in their lives com-

pared with the general population who do not have intellectual disabilities.
- Dementia at its early stage may be difficult to diagnose in people with intellectual disabilities.
- A combination of caregiver-rated questionnaire and direct examination of the person with intellectual disabilities is necessary to reach a clinical diagnosis of dementia.
- Usually loss of recent memory in the context of intact distant memory as is the case in the general population is an early symptom of dementia in people with mild to moderate intellectual disabilities.
- Usually loss of skills is the early symptom of dementia in people with severe and profound intellectual disabilities.
- There is no cure for dementia, but the medication used for treating symptoms of dementia in the general population who do not have intellectual disabilities should also be used to treat people with intellectual disabilities.

Learning Objectives

- Concept and definition of organic mental disorders (other than dementia and mild neurocognitive disorder)
- Symptomatic similarity between organic and nonorganic mental disorders in persons with intellectual disability (ID) and/or autism spectrum disorder (ASD)
- Prevalence of organic mental disorders in persons with ID and ASD
- Relationship of organic mental disorders and some etiologically defined forms of ID and/or ASD
- Relevance of thorough and comprehensive physical assessments
- Bias that may limit the epidemiological estimate of epilepsy in people with ID and ASD
- Factors correlated with epilepsy that may determine adjunctive cognitive dysfunction
- Factors to be considered in choosing antiepileptic drugs
- Importance of multi-/interdisciplinary approach in diagnosis and treatment of organic mental disorders and epilepsy in persons with ID and/or ASD

29.1 Introduction

Besides dementia or mild neurocognitive disorders, there are other mental disorders caused by brain dysfunctions or brain damage. Brain dysfunctions may be a consequence of a primary cerebral disease (e.g., encephalitis) or a systemic somatic disease including endocrine disorders (e.g., hypothyroidism) secondarily affecting the brain, and of exogenous toxic substances disturbing the brain function. Because such disorders are based on identifiable organic changes of the brain (primary brain involvement) or of the body (physical disease) secondarily affecting the brain function (secondary brain involvement), they are often called *organic mental disorders*. Organically caused mental disorders are able to imitate nearly all "non-organic" mental disorders (e.g., schizophrenia or affective disorder). In other words, the psychopathological features of the syndrome itself do not expose the "organic" nature. A thorough physical assessment has to be part of diagnostic procedures, particularly in persons with a first manifestation of a mental disorder, because clinical manifestations of organic mental disorders may resemble – or are identical with – those of disorders not regarded as "organic."

The ICD-11 [1] terms this group of disorders as "secondary mental or behavioural syndromes associated with disorders or diseases classified elsewhere" and includes "syndromes characterised by the presence of prominent psychological or behavioural symptoms judged to be direct pathophysiological consequences of a medical condition not classified under mental and behavioural disorders, based on evidence from the history, physical examination, or laboratory findings." ICD-11 [1] also specifies that symptoms of this group of disorders "are not accounted for by delirium or by another mental and behavioral disorder and are not a psychologically mediated response to a severe medical condition (e.g., adjustment disorder or anxiety symptoms in response to being diagnosed with a life-threatening illness)." The diagnostic categories included in this meta-structure "should be used in addition to the diagnosis for the presumed underlying disorder or disease when the psychological and behavioural symptoms are sufficiently severe to warrant specific clinical attention" [1].

In accordance with current ICD diagnostic criteria [2], a clinical syndrome is to be diagnosed as an "organic" mental disorder if the following conditions are met:

(a) Evidence of cerebral disease, damage, or dysfunction or of systemic physical disease, known to be associated with one of the clinical syndromes.
(b) Temporal relationship between the development of the underlying disease and the onset of the mental symptoms.
(c) Recovery from the mental disorder following removal or improvement of the presumed underlying cause.
(d) Absence of evidence to suggest an alternative cause of the mental syndrome (e.g., family history or precipitating stress).

Criteria (a) and (b) already justify a provisional diagnosis of organic mental disorder. The certainty of diagnosis is significantly increased in the case that all four criteria (a–d) are met.

Various clinical conditions and factors may result in an increased risk of organic mental disorders: for example, epilepsies, head trauma, brain damage due to hypoxia, infectious and parasitic brain diseases, brain tumors or brain metastases, cerebrovascular diseases, endocrine diseases, metabolic disorders, some nonpsychotropic drugs (e.g., propranolol, levodopa, methyldopa, steroids, antihypertensives, antimalarials).

Persons with intellectual disability (ID) or autism spectrum disorder (ASD) are particularly exposed to such diseases or clinical conditions due to the high rate of physical health problems, which is more than double that of the general population [3–5]. Furthermore, some etiologically defined forms of ID and/or ASD are associated with specific risks for certain physical disorders that often determine organic mental disorders. Examples are represented by the elevated prevalence of hypothyroidism in trisomy 21 [6] and the high risk of renal insufficiency in tuberous sclerosis [7].

Epilepsy is also much more common in persons with ID and/or ASD than in the general population and shows higher association with secondary mental or behavioral problems, less favorable prognosis, and consequent more complex diagnosis and management [8–13].

Persons with ID and/or ASD are particularly exposed to mental or behavioral syndromes secondary to physical diseases, due to the high rate of physical health problems in general and the frequent link between specific genetic alterations and specific physical disorders determining psychopathology.

29.2 Specific Clinical Disorders

The general descriptions of organic mental disorders in the following rubrics are guided by the description of the ICD-10 [2].

29.2.1 Organic Hallucinosis

General Description

An organic hallucinosis is characterized by recurrent or persistent visual or auditory hallucinations, occurring in clear consciousness. The hallucinations may or may not be recognized as such by the subject. Delusional elaboration of the hallucinations may exist, but insight is not infrequently preserved.

Organic hallucinations may occur in alcohol dependence [14], in cocaine dependence [15], in tumors or other lesions of the temporal lobe [16–18], or in Parkinson's disease [19]. In addition, anticholinergic or dopaminergic substances may result in organic hallucinations [20]. The relation of hallucinations to epilepsy is highly complex and the administration of neuroleptics in epilepsy-related hallucinations should be handled with care [21, 22].

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

Dravet syndrome [23] is a rare encephalopathy due to a gene mutation in most cases. Myoclonic seizures (starting in the first year of life) are the prominent symptoms. Many affected children develop an ID. Persons with Dravet syndrome very often show hallucinations. Martin and collaborators [24] detected hallucinations in 10 out of 41 patients with this syndrome. In some other cases, they assumed the presence of hallucinations basing only on their behavioral and observable aspects.

The 22q11.2 deletion syndrome (synonyms: velo-cardio-facial syndrome, DiGeorge syndrome, Shprintzen syndrome) [25] is associated with ID and with a broad spectrum of physical and psychiatric manifestations [26]. Biswas and Furniss [27] assumed that some of the cognitive difficulties in persons with this syndrome represent risk factors for hallucinations and paranoid delusions often emerging in these persons.

Homocystinuria, a very rare genetic disorder, comprises various forms with different clinical signs and genetic causes. Frequent symptoms are ectopia lentis, myopia, skel-

etal anomalies, and thromboembolic events [28]. Sometimes, homocystinuria includes ID. Acute psychosis is a rare symptom in this disease. Colafrancesco and collaborators described an affected 17-year-old girl presenting visual hallucinations, behavioral perseverance, psychomotor hyperactivity, and affective inappropriateness [29].

17q24.2 microdeletions are a rare genetic condition, which presents with ID, delayed speech development, truncal obesity, epileptic seizures, hearing loss, and a particular physiognomy. Vergult and collaborators [30] reported hallucinations and mood swings in two out of four persons with this condition.

Malm and colleagues [31] described a group of persons with alpha-mannosidosis, a very rare genetic syndrome [32], with psychiatric symptoms including hallucinations.

Organic hallucinations have been reported in some genetic syndromes including ID such as Dravet syndrome, DiGeorge syndrome, homocystinuria, 17q24.2 microdeletion syndrome, and alpha-mannosidosis. In persons with ID and/or ASD, organic hallucinations may also occur in case of substance dependence, tumors or other lesions of the temporal lobe, Parkinson's disease, epilepsy, and anticholinergic or dopaminergic treatments.

29.2.2 Organic Catatonic Disorder

General Description

The main features of organic catatonic disorder are represented by diminished or increased psychomotor activities and catatonic symptoms (e.g., stereotypies, waxy flexibility, and impulsive acts). The extremes of psychomotor disturbance may alternate. Other catatonic phenomena, such as stereotypies, waxy flexibility, or impulsive acts, increase confidence in the diagnosis of this disorder.

There is some terminological confusion between the terms catatonia or catatonic syndrome and catatonic symptoms in the scientific literature. However, to date organic catatonic disorder or catatonic symptomatology is recognized to occur with a broad spectrum of medical and psychiatric illnesses [33]. Infectious, paraneoplastic, or autoimmune encephalitis and carbon monoxide poisoning may be etiological factors of catatonic symptoms [34, 35]. In addition, metabolic disorders, endocrine conditions, and intoxications may result in an organic catatonic disorder [36, 37]. In most cases, catatonic symptoms are part of a broader array of psychiatric symptoms.

Kiani and colleagues [38] published two cases of anti-N-methyl-d-aspartate (NMDA) receptor encephalitis presenting with neuropsychiatric symptoms of catatonia and neuroleptic malignant syndrome in two patients with ID and ASD.

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

In a study on the aspects of catatonia through the copy number variation analysis, Breckpot and collaborators [39] investigated persons with ID and catatonic symptoms. Psychiatric diagnoses in these patients were ASD, psychotic or mood disorders. The authors identified copy number variants, 22q13.3 deletions and 14q11.2 duplications, as relevant causes.

Serret and collaborators [40] presented two patients with a similar psychiatric and genetic diagnosis as well as similar histories and evolutions. They were diagnosed with ASD in childhood and showed regression with catatonic features and behavioral disorders after stressful events during adolescence. Both patients had mutations or microdeletions of the SHANK3 gene. Only lithium therapy reversed clinical regression, whereas other psychopharmacological therapies failed. These observations emphasize the relevance of genetic investigations with respect to effective therapeutic options.

Catatonia has also been described in a female adolescent with velo-cardio-facial syndrome (VCFS). The authors indicate catatonia to be relatively common in persons with VCFS and treatment-refractory psychiatric manifestations [41].

Winarni and collaborators published a case report on a 25-year-old fragile X syndrome premutation carrier who developed ASD, psychosis, and catatonia [42].

Organic catatonic disorder has been reported in persons with velo-cardio-facial syndrome and fragile X syndrome as well as in persons with copy number variations of 22q13.3, 14q11.2, and SHANK3 genes. In persons with ID and/or ASD, organic catatonic disorder or catatonic symptoms may also occur in the course of infectious, paraneoplastic, or autoimmune encephalitis as well as metabolic disorders, endocrine conditions, and intoxications.

29.2.3 Organic Delusional [Schizophrenia-Like] Disorder

29

General Description

Persistent or recurrent delusions dominate the clinical picture of the organic delusional disorder. Hallucinations may accompany the delusions. However, the delusions are not confined to the content of the hallucinations. Schizophrenia-like symptoms, such as bizarre delusions, hallucinations, catatonic symptoms, or thought disorders, may also be present.

Organic delusional disorders share some etiological factors with organic catatonic disorders. Therefore, delusions are often part of a broader spectrum of mental symptoms in medical conditions. Cocaine, alcohol, amphetamines, mechanical trauma, and inflammatory cerebral disease may lead to organic delusional disorders; temporal lobe epilepsies are also often associated with organic delusional disorders [37].

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

Prader-Willi syndrome (PWS) is a condition caused by the lack of expression of genes on the paternally inherited chromosome 15q11.2-q13 region [43]. There are three genetic subtypes: paternal 15q11-q13 deletion, maternal uniparental disomy 15, and imprinting defect. Young adults with PWS show high rates of physical diseases and psychiatric disorders, which include delusions [44].

The 2q37 microdeletion syndrome is a complex genetic disorder consisting of diverse mental (including ID and ASD) and somatic symptoms [45]. Lally and collaborators described a 21-year-old woman with moderate ID showing nihilistic delusions, incessant pressure of speech, and worsening of sleep and eating [46]. Other authors reported on a person with 2q37 microdeletion syndrome presenting schizophrenic psychosis including delusion, in line with previous findings of an association between schizophrenia susceptibility and unknown genes within the chromosomal region 2q37 [47].

Recent genetic studies are increasingly indicating vulnerability to psychotic disorders to have a polygenic origin, with a complex array of contributing risk loci across the allelic frequency spectrum that are shared with ID and ASD as well as bipolar disorder and major depressive disorder [48, 49].

Organic delusional disorder has been reported in Prader-Willi syndrome and 2q37 microdeletion syndrome. Cocaine, alcohol, amphetamines, mechanical trauma, temporal lobe epilepsies, and inflammatory cerebral disease may also lead to organic delusional disorders. Delusions are often part of a broader spectrum of mental symptoms in many medical conditions.

29.2.4 Organic Mood [Affective] Disorder

General Description

Organic mood disorders or organic affective disorders are characterized by changes in mood (depressed or elevated), usually accompanied by changes in the level of activity (increased or decreased). Organic mood disorders are often triggered due to endocrine disorders like hypothyroidism, hyperthyroidism, Cushing's syndrome, and Addison's disease [50]. Some drugs (e.g., clonidine, reserpine, beta-blockers, or antibiotics) may act as causes of organic depres-

sions, whereas other medications (e.g., corticosteroids, levodopa) used to treat cerebrovascular disorders, cerebral tumors, or hyperglycemic states in diabetes mellitus may result in organic mania [37].

Rundell and Wise [51] analyzed the records of 755 patients seen by consultation-liaison psychiatrists in a general hospital and found that 87% of manic patients and 38% of depressed patients had organic mood disorders. The most frequent precipitants of organic mania were corticosteroids, HIV infection, and epilepsy, while the most frequent precipitants of organic depression were stroke, Parkinson's disease, and HIV infection.

▪ Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

There are many studies describing affective disorders in persons with ID in general. However, convincing studies on etiologically specific syndromes are very scarce. Rodriguez-Revenga and collaborators found fragile-X premutation carrying mothers of children with fragile X syndrome to have a higher tendency to depression than mothers of children with ID but without fragile X syndrome and mothers from the general population. The authors conclude that this premutation could represent a genetic risk factor for mood disorders, both primary and secondary to physical disorders or diseases [52].

- Organic mood disorders can be determined by endocrine disorders like hypo- or hyperthyroidism, Cushing's syndrome, Addison's disease, and hyperglycemic states in diabetes mellitus. A broad spectrum of drugs, cerebrovascular disorders, and cerebral tumors are other frequent causes.

- High vulnerability to primary and secondary depressive disorders has been found in fragile-X premutation carrying mothers of children with fragile X syndrome.

29.2.5 Organic Anxiety Disorder

▪ General Description

The organic anxiety disorder is characterized by the essential features of a generalized anxiety disorder or a panic disorder or a combination of both, but arising as a consequence of an organic disorder capable of causing cerebral dysfunction (e.g., temporal lobe epilepsy, thyrotoxicosis, or pheochromocytoma) [53]. Organic anxiety disorder and organic affective disorder share many clinical aspects and represent the most common organic mental disorders [37]. Wise and Rundell emphasized the frequent occurrence of pathological anxiety in neurological diseases [54].

▪ Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

The prevalence of anxiety disorders in persons with ID and/or ASD is high, with generalized anxiety disorder being the most common, followed by agoraphobia [55].

Fragile X syndrome is a clinical condition caused by mutations in the FMR1 gene of the X chromosome, which includes ID, ASD, and many physical problems [56]. Cordeiro and collaborators assessed the prevalence of anxiety disorders in 58 males and 39 females with fragile X syndrome. Despite a high rate of psychopharmacological treatment, 86.2% of males and 76.9% of females showed anxiety disorder, particularly social phobia and specific phobia. The authors concluded that the mutation of the FMR1 gene is associated with a high risk of anxiety disorders [57]. The importance of anxiety disorders in the complex physical and mental vulnerability of persons with fragile X syndrome has been identified or emphasized also by other researchers [58, 59].

Women with FMR1 premutation who are mothers of children with fragile X syndrome have also been found to present high rate of pathological anxiety associated with early ovarian aging and predicted in severity by polymorphisms of the corticotropin releasing

hormone receptor 1 (CRHR1) gene, which associate with differences in hypothalamic-pituitary-adrenal (HPA) axis function [60, 61].

Persons with 7q11.23 duplication syndrome show ID, ASD, distinctive physiognomic features, cardiovascular disease, hypotonia, adventitious movements, gait abnormalities, speech sound disorders, behavioral problems, anxiety disorders, selective mutism, attention-deficit/hyperactivity disorders, oppositional disorders, and physically aggressive behavior [62]. In children with 7q11.23 duplication syndrome, anxiety disorders are common, especially social phobia, specific phobia, selective mutism, and separation anxiety disorder.

Williams syndrome is a microdeletion syndrome due to deletion of genetic material from the region q11.23 of one of the two chromosomes 7. The clinical pictures are characterized by a broad spectrum of mental and physical features. Anxiety and specific phobias are common symptoms in Williams syndrome [63]. The data from a systematic literature review on Williams syndrome [64] revealed that the affected individuals were four times more likely to experience anxiety than individuals with ID due to other causes.

Rett syndrome [65] is a rare genetic syndrome, occurring almost exclusively in girls. The Rett syndrome affects the daily activities. Repetitive hand movements are typical behavioral symptoms of Rett syndrome. Based on comprehensive investigations of anxious behavior in 74 girls with Rett syndrome, Barnes and colleagues [66] interpreted anxiety-like behavior as a prominent component of the behavioral phenotype in Rett syndrome, affecting predominantly children with less severe neurologic impairment.

Treadwell-Deering and collaborators [67] found in the majority of patients with Potocki-Lupski syndrome (duplication 17p11.2) [68] besides ID, many behavioral difficulties such as withdrawal, anxiety, and inattention. Many patients presented autistic symptoms.

Organic anxiety disorder has been reported in some genetic syndromes including ID and/or ASD such as fragile X syndrome, 7q11.23 duplication syndrome, Williams syndrome, and Rett syndrome. In persons with ID and/or ASD, organic anxiety disorder may also occur in the case of temporal lobe epilepsy, thyrotoxicosis, or pheochromocytoma.

29.2.6 Organic Dissociative Disorder

General Description

The organic dissociative disorder has to meet the criteria for one of the conversion disorders. In addition, general criteria for organic etiology are also fulfilled. This diagnostic category is very seldom used. In addition, its nosological position is controversial.

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

There is no information in the scientific literature regarding the occurrence of organic dissociative disorders in persons with ID and/or ASD.

29.2.7 Organic Emotionally Labile [Asthenic] Disorder

General Description

Organic emotionally labile disorder (alternatively: organic asthenic disorder) is characterized by marked and persistent emotional incontinence or lability, fatigability, or a variety of unpleasant physical sensations (e.g., dizziness) and pains regarded as being due to the presence of an organic disorder. Various etiological factors may play a role, for example, cerebrovascular diseases, trauma, and encephalitis [37].

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

The literature contains no information concerning specific occurrence of organic emotionally labile disorder in persons with intellectual disability and/or autism spectrum disorder.

29.2.8 Organic Personality Disorder

General Description

Organic personality disorder is characterized by significant alterations of the habitual patterns compared with the premorbid behavior. In particular, the emotions, needs, and impulses are affected. In addition, cognitive functions in the areas of planning and anticipating probable personal and social consequences may be influenced, for example, in the so-called frontal lobe syndrome. There is a spectrum of etiological factors, mainly primary brain damages or dysfunctions. In Parkinson's disease or in multiple sclerosis, organic personality changes may occur, too [37, 69].

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

There is no specific literature on organic personality disorders in persons with intellectual disability and/or autism spectrum disorders. Of course, some aspects of behavior in persons with intellectual disability due to brain lesions could be interpreted as components of an organic personality disorder.

29.2.9 Postencephalitic Syndrome

General Description

The etiological basis of the postencephalitic syndrome is an inflammatory disease of the brain. Infectious agents cause most cases. The disorder includes residual behavioral change after recovery from encephalitis. The spectrum of nonspecific symptoms depends on the infectious agent, on individual dispositions, and on the age of the individual at the time of infection. Unlike the organic personality disorder, the postencephalitic syndrome is often reversible.

With respect to this syndrome, two aspects are important. First, encephalitis during childhood may be a relatively rare cause of intellectual disability or autism spectrum disorder. Any person can get an encephalitis. Of course, persons with intellectual disability and autism can be affected too.

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

There are no relevant reports on postencephalitic syndromes in intellectual disability or autism spectrum disorders.

29.2.10 Post-Concussion Syndrome

General Description

The post-concussion syndrome is caused by mechanical brain trauma, for example, in traffic accidents or by a fall during an epileptic seizure. Its clinical phenomenology is heterogeneous. It may consist of a number of symptoms and complaints such as headache, dizziness, fatigue, irritability, concentration problems, difficulty in performing mental tasks, memory impairment, insomnia, reduced stress tolerance, emotional excitement, or alcohol. Sometimes, these symptoms and complaints are accompanied by depression or anxiety, resulting from the loss of self-esteem and fear of permanent brain damage. With respect to the last-mentioned symptoms, organic as well as psychological factors may play a role.

Of course, brain trauma are accidental events without any specific relation to intellectual disability or autism.

Reports on Persons with Intellectual Disability and/or Autism Spectrum Disorders

There is no significant literature regarding post-concussion syndrome in intellectual disability or autism spectrum disorder.

29.3 Conclusive Considerations

The field of organic mental disorders is highly complex and connected with many open questions. Some aspects, especially aspects of epidemiology or the relations between certain

clinical pictures and specific etiogical factors, are unclear. In principle, persons with ID and/or ASD are confronted with a higher risk for organic mental disorders than the general population. Moreover, for some specific etiological conditions, specific risks of organic mental disorders are known and can be identified. Mainly genetically caused syndromes play an outstanding role in this field. It is to be expected that knowledge in this area will increase over the next years and decades.

29.4 Prognosis

The prognosis for organic mental disorders is not determined by the specific psychiatric manifestation, but by the underlying mechanism, its natural and therapeutically modified course.

29.5 Therapy

The therapeutic options are twofold. The most important option is the so-called causal therapy, adequately treating the underlying medical condition, if possible. Should the causal treatment of the underlying medical condition be impossible or insufficient, a symptomatic therapy of mental symptoms by psychotropics (e.g., neuroleptics, antidepressant, and anxiolytics) is necessary. Particularly in the case of epilepsy-related organic mental disorders, certain psychotropic medications (e.g., certain neuroleptics or antidepressants) may be contraindicated. Some organic hallucinations can represent an adverse event of anticholinergic or dopaminergic substances. Therefore, options of targeted antiepileptic treatment are to be considered. In other cases, the recognition of the genetic background of mental symptoms may be helpful for an adequate therapeutic decision.

For organic hallucinations, treatment with antiepileptic drugs is often the first choice.

Due to multimorbidity and frailty, persons with and/or ASD are confronted with a higher risk for organic mental disorders than the general population. Some specific genetic syndromes are associated with specific risks.

The most important therapeutic option is the treatment of underlying medical condition, when impossible or insufficient, a symptomatic therapy of mental symptoms by psychotropic drugs is necessary.

29.6 Epilepsy in Intellectual Disability and Autism Spectrum Disorder

29.6.1 Introduction

Approximately 50 million people worldwide are estimated to suffer from epilepsy [70]. The average incidence rate of unprovoked recurrent epileptic seizures in children has been reported from 35/100,000/year [71] to 88.8/100,000/year [72]. The cumulative incidence rate of epilepsy by the age of 15 years is about 0.8% [73]. The average prevalence in developed countries is between 3.5 and 5 per 1000 children; the incidence and prevalence of epilepsy are higher in developing countries [74]. Comorbidities, defined as disorders coexisting with or preceding epilepsy, or else compounded or directly attributed to epilepsy or to its treatment, are common, especially parasitic and infectious diseases (44%), somatic comorbidities (37%), and psychiatric/psychosocial problems (19%), of which neurocysticercosis, head trauma, malnutrition, and stroke are the most frequently studied worldwide [75].

According to the most recent Classification of the Epilepsies proposed by the International League Against Epilepsy (ILAE), seizure types, epilepsy types (focal, generalized, combined generalized and focal, unknown), and epilepsy syndromes should be defined at a diagnostic level. Furthermore, an etiologic diagnosis should be considered, taking in count at least six different groups: structural, genetic, infectious, metabolic, immune, and unknown causes [76].

Prognosis for patients with epilepsy is usually good, but up to 30% of them present are drug-resistant to adequate treatments with antiepileptic drugs [77]. Furthermore, co-occurrence of epilepsy with intellectual disability (ID) or autism spectrum disorder (ASD) makes prognosis less favorable.

29.6.2 Epilepsy and ID

There are several biases that limit the epidemiological estimate of epilepsy in the population of patients with ID: difficulties in reporting their seizures; sensory impairments, which may restrict communication and, thus, self-report of seizures; changing of caretakers over time, thereby creating communication problems; different inclusion criteria which may select different subpopulations; occurrence of subclinical seizures or nonepileptic events.

However, in the "institutional group" of subjects with ID, the prevalence of epilepsy has been estimated as 33.1%, and in the "community group" 16.1% [11]. Other authors reported even higher prevalence rates, from 32% [8], to 40% [10], or 65% [9], in institutional settings.

The prevalence of epilepsy seems not to be constant over the life span and varies with etiology: it increases from age 20 to >60 years for those without ID and for those with Down syndrome or ASD; the prevalence of epilepsy declines for other adults with ID, cerebral palsy, or a combination of these comorbidities [78].

In a meta-analysis by Robertson and colleagues [79], in general samples of people with ID, the pooled estimate from 38 studies was 22.2%. Prevalence increased with increasing level of ID.

The relationship between epilepsy and cognition is hypothesized as a two-way condition in which cognitive factors and epilepsy interact, by influencing the individual's development [80]. Some studies report cognitive impairments prior to the onset of seizures that could, along with the onset of epilepsy, be explained by a common factor determining both conditions [81, 82].

Many factors correlated with epilepsy may determine cognitive dysfunction, such as etiology, seizure activity (onset, type, duration, and frequency), type of electroencephalogram (EEG) abnormalities, neurological side effects of antiepileptic drugs (AEDs), concomitant disability and neurophysiological impairment, environmental factors and parental attitudes, emotional and personality characteristics [83, 84].

The age of onset. Several authors agree that epilepsy severity depends on early seizure onset [85–88].

A longer duration of seizures (longer disease/epilepsy duration) leads to increased probabilities of developing cognitive deficits [89–91]; vice versa, the effects of active persistent seizures do not appear completely clear [92].

Seizure frequency represents an increased risk of developing cognitive problems, too [93–95].

As for memory processes, nonhomogeneous results were found in the comparison studies between "Localization vs generalized" [96–98].

The effects of intercritical EEGraphic activity (EEG findings: focal, generalized, normal) on cognitive development are the subject of debate [99, 100]. Japaridze and colleagues [101] compared two groups of patients with and without ID, both with pathologic intercritical EEGraphic activity. The study did not show significant neuropsychological impacts either on the two groups, or on the control group, except for an increased difficulty in the ID sample with regard to reaction times, selective attention, and cognitive flexibility.

Furthermore, the use of a large number of AEDs is a significant predictor of cognitive performance in samples of children with epilepsy [95]. Thompson and collaborators [102] underlined how the side effects of AEDs are often underestimated in populations with ID and epilepsy. According to Kerr and colleagues [103], most of this population has difficulty in self-reporting their health and quality of life, and in fact the most significant side effects (such as vomiting and weight loss) are reported by caregivers. Studies – performed in English until 2017 – on the impact of AEDs and side effects in adults with ID

and epilepsy have been collected in a review by Copeland and colleagues [104]. The authors concluded that it is more complex to evaluate AEDs' side effects in people with ID because they present with greater comorbidities (e.g., ASD) and it is more difficult to get feedback directly from patients. In order to assess the efficacy of AEDs in this population, Kerr and colleagues [103], while drafting the guidelines for the management of adults with epilepsy and ID, underline that both standardized cognitive and behavioral assessment procedures are needed in baseline as well as in postpharmacological treatment.

Furthermore, there are some specific childhood epileptic conditions, classified as epileptic encephalopathies, usually resistant to antiepileptic treatment, in which the epileptiform abnormalities may contribute to progressive neuropsychological dysfunction and ID: early myoclonic encephalopathy, Ohtahara syndrome, West syndrome, Dravet syndrome (previously known as severe myoclonic epilepsy in infancy), myoclonic status in nonprogressive encephalopathies, Lennox-Gastaut syndrome, Landau-Kleffner syndrome, and epilepsy with continuous spike-waves during slow-wave sleep [105–109].

For these reasons, and on the basis of our experience, diagnostic workup of patients with ID and epilepsy should have a multidisciplinary approach based on the clinical history, with an emphasis on witness description of seizures; physical and neurological examinations; dysmorphology evaluation; assessment of the individual's level of ability; psychiatric examination and tests; video-EEG or ambulatory EEG; MRI, often with sedation or general anesthesia, because subjects with ID may have difficulties in cooperating; blood AED monitoring; metabolic investigations; genetic analyses (i.e., karyotype, FISH, MLPA, array-CGH, gene sequencing, next-generation sequencing, and whole exome sequencing); and other specific investigations.

Moreover, the assessment of cognitive and neuropsychological processes is very important, through the use of appropriate scales such as Wechsler, Leiter, Nepsy, etc., as well as the detection of social and practical adaptive-conceptual skills by means of scales like Vineland or Adaptive Behavior Assessment System (ABAS).

Prognosis of epilepsy in patients with ID appears obviously correlated with the underlying etiology [110, 111]. However, some studies have demonstrated that outcome in this special population is not so unfavorable as one can believe. In a residential group of 215 subjects with ID and epilepsy, over a 5-year period, 18% became seizure-free on one or two drugs; of these, 60% were on monotherapy; of the group remaining uncontrolled, most were improved and only 8% required three drugs to get optimal control. Twenty-two percent of subjects were followed without recurrence once off medication for intervals between 1 and 20 years [9].

29.6.3 Epilepsy, ID, and Psychopathology

The connection between epilepsy and psychiatric disorders is complex and still not fully clarified, determining frequent issues of overlapping symptoms and mistaken diagnoses in clinical practice, especially in persons with ID and/or ASD. Some symptoms of seizures, especially focal seizure, such as altered consciousness or feeling of unreality, are also frequently found in some psychiatric disorders, conversely some psychiatric symptoms may also resemble epilepsy and some psychopathological conditions (e.g., conversion disorder) can produce symptoms that are quite similar to those of generalized seizures that are called psychogenic nonepileptic seizures (PNES). Furthermore, persons with true epilepsy may also have PNES, especially persons with ID and/or ASD [112]. Diagnostic errors between epilepsy and PNES need careful consideration also when reviewing studies showing associations between psychiatric disorders and epilepsy or indicating lower need of seizure control in epileptic patients with co-occurrence of psychiatric conditions [113]. A history of emotional disturbance or a pattern of inadequate coping may help in making the distinction, although continuous electroencephalogram (EEG) and video

monitoring are the best methods to achieve a correct diagnosis.

In the general population, 20–30% of people with epilepsy have psychopathological symptoms that require treatment, especially in pharmacoresistant cases [114–116]. Anxiety, especially agoraphobia, and depression are the most common conditions, with an important role in the premature mortality evidenced in epileptic patients, which includes suicide rate that is reported to be four-to-five times higher than in healthy population [117]. Adults with a history of seizures are two-to-three times more likely than average to develop a psychotic disorder and a history of attention deficit hyperactivity disorder is two and one-half times more common than average in children with seizures [118–120].

A continuum between emotional reaction to persistent seizures and psychopathological features is observable in many clinical cases. For example, long-lasting frustration and discouragement can lead to depression as well as increasing fear of having a seizure in public can give rise to agoraphobia. Nevertheless, there is also evidence that brain alterations and dysfunctions determining seizures are also responsible for significant changes of psychic functioning, especially of mood and thought. Two psychopathological conditions called interictal dysphoric disorder and interictal behavior syndrome occur in some patients with epilepsy [121, 122]. The former includes depression (or more rarely euphoria), lack of energy, pain, irritability, anxiety, and fear, while the latter comprises sadness, humorlessness, interest reduction (including sex), obsession with details, compulsive writing or scribbling, anger, and social withdrawal [123, 124].

The chronological relationship between psychiatric disorders and epilepsy is yet to be cleared, although some findings indicating unprovoked seizures (not caused by brain disease or injury) to follow psychiatric conditions, especially major depressive disorder. Through the twentieth century, many researchers in the field of psychiatry described an "epileptic personality," with a specific reference to affective viscosity (the tendency to prolong interactions with others), slowness in thinking and acting, and dramatic features, including PNES, as a way to gain others' attention [125, 126]. Within ICD-11, this condition is comprised in the chapter of secondary personality change, which refers to "syndromes characterized by a persistent personality disturbance that represents a change from the individual's previous characteristic personality pattern" and "is judged to be a direct pathophysiological consequence of a health condition not classified under mental and behavioral disorders, based on evidence from the history, physical examination, or laboratory findings." "This category should be used in addition to the diagnosis for the presumed underlying disorder or disease when the personality symptoms are sufficiently severe to warrant specific clinical attention" [1].

Besides, many psychoactive drugs are prescribed for both epilepsy and psychiatric disorders. For example, antiepileptic drugs are used in the treatment of mood disorders and benzodiazepines are used for anxiety disorders. Comorbidity between psychiatric disorders and epilepsy is particularly frequent and complex in persons with ID [127–133]. The question of whether individuals with epilepsy and ID have a higher rate of psychopathological comorbidity than people with only epilepsy or ID has been examined in several studies. The results of such researches have highlighted conflicting data.

Some results indicate that the most severe forms of epilepsy, including generalized seizures characterized by higher severity, frequency, and number of episodes, represent risk factors for the development of behavioral problems and psychopathological disorders [134–136].

A significant association between the level of ID severity and the presence of psychiatric disorders, especially ASD and psychosis, in subjects with epilepsy has been identified [129–136]. In particular, the level of ID seems to be linked to the presence of behavioral problems, the more severe the ID, the more the behavioral problems that people with epilepsy show [134, 137]. In contrast, other authors have found no differences regarding the presence of psychological disorders between people presenting only with epilepsy or ID, or affected by both conditions [138, 139].

The results of a review conducted by Jans and collaborators [140] show that the presence of epilepsy does not represent a clear determinant of neuropsychiatric comorbidities in patients with ID, although a tendency toward negative mood symptoms is identified. Other studies found epilepsy to represent a risk factor for self-injurious behavior, either at short- or long-term follow-up [141, 142].

29.6.4 Epilepsy and ASD

A great amount of epidemiological data has been produced on association between ASD and epilepsy. Prevalence of epilepsy in the population of patients with ASD varies from approximately 2.4–46% in different studies [143–145]. These variable figures substantially depend on several factors, such as the study design (i.e., retrospective or prospective), the clinical setting (i.e., primary, secondary, or tertiary centers), the definition of autism which changed over time according to the editions of DSM, the inclusion criteria for epilepsy (i.e., one single seizure, two seizures, febrile or nonfebrile), the age at the recruitment, and the presence of ID or other comorbidities (i.e., cerebral palsy).

The prevalence of epilepsy in the different forms of autistic syndromes, as classified at the time of DSM-IV TR [146], has been estimated: more than one third of cases in autistic disorder, 5–10% in Asperger syndrome, about 31% in pervasive developmental disorders not otherwise specified, 70% in childhood disintegrative disorder, and 90% in Rett syndrome [147].

On the other hand, the prevalence of ASD in populations of patients with epilepsy has been reported from 5% to 21% [129, 148]. The reported rates of epilepsy in all of these studies are greater than general population prevalence estimates and raise the possibility of a direct association between epilepsy and ASD [149].

Familiarity for epilepsy is associated with an increased risk to present epilepsy in subjects with ASD [150]. Furthermore, the analysis of multiplex ASD families showed an epilepsy rate of 12.8% in children with ASD versus a rate of 2.3% in the siblings without ASD. This would suggest a genetic predisposition not only for ASD, but also for epilepsy [151].

The risk to present epilepsy in subjects with ASD seems higher in females than in males (respectively, 34.5% and 18.5%) [152, 153]. On the other hand, some studies did not find any difference between gender and epilepsy prevalence [144, 154, 155].

Other studies showed that people with idiopathic ASD seem to have a lower risk of developing epilepsy than those with syndromic ASD or concomitant neurological conditions [156, 157].

Another relevant risk factor for epilepsy is represented by ID. In fact, prevalence of epilepsy is 21.4% in patients with ASD and ID, and 8% in those with only ASD [153].

Epileptiform abnormalities are also reported as most likely in children with low-functioning autism [158] or with more severe forms of autism [159, 160].

A meta-analysis performed in 2012, including sole follow-up studies, reported rates of 23.7% in patients with ASD and ID, and 8% in patients with ASD without ID [161], while little is known about the relationship between epilepsy and ASD in the absence of ID [162].

The age at onset of seizures has a bimodal distribution in ASD, with a first peak during childhood and a second during adolescence. However, approximately 20% of patients with ASD present their first seizure after the age of 20 [163].

Evaluation and classification of seizures in ASD may become difficult, because avoiding of eye contact, or motor block, typical of ASD, may be confused with absences, and generalized or segmental stereotyped movements may be interpreted as motor features of focal and generalized seizures. In a continuous video-EEG telemetry study performed at a tertiary care referral center, 32 children with ASD were monitored. Of these patients, 22 were primarily referred for seizure evaluation and 15 of them had recorded events which were nonepileptic seizures; the other 7 patients had no recorded events. Interestingly, 11 (73%) of the 15 patients with nonepileptic events had interictal epileptiform EEG abnormalities [164]. There are not peculiar epileptic seizures or syndromes which are

prevalent in the population of patients with ASD [152]. Focal seizures with unawareness are more frequent of the generalized ones (respectively, 73% and 27%) [165]. Among the special epileptic syndromes which have been reported in association with ASD, there are febrile seizures, benign childhood epilepsy with centro-temporal spikes, West syndrome, Lennox-Gastaut syndrome, and Landau-Kleffner syndrome [166]. Recently, typical behavioral characteristics of ASD have been described in 18/30 patients (60%) with Dravet syndrome [167].

Also, interictal EEG pattern is not homogeneous in ASD. Paroxysmal abnormalities are mostly focal, more frequently localized over the frontal, temporal, or centro-temporal regions [166].

The presence of epilepsy in people with ASD may be determined by several structural alterations, genetic conditions, or metabolic dysfunctions, known to play a role in the emergence of both epilepsy and autism. Genetic etiologies include isodicentric chromosome 15 syndrome, Phelan-McDermid syndrome, fragile X syndrome, tuberous sclerosis complex, Rett syndrome, encephalopathies due to mutations of PTEN, CDKL5, FOXG1, MEF2C, CASK, and SCN2A genes [168, 169]. Metabolic conditions, such as mitochondrial diseases, abnormalities in cerebral folate metabolism, disorders of creatine, cholesterol, pyridoxine, biotin, carnitine, γ-aminobutyric acid, purine, pyrimidine, and amino acid metabolism and urea cycle disorders, have also been associated with ASD and epilepsy [170].

The pathophysiology of epilepsy in ASD has not been completely clarified. Three theories, not mutually exclusive, have been proposed to explain the relationships between brain development, epilepsy, and ASD. First, ASD and epilepsy might represent distinct conditions without causal relationship. Second, a common neurobiological dysfunction might lead to abnormal brain development that results in both epilepsy and ASD. Third, epilepsy could lead to ASD or conversely, abnormal brain circuitry underlying ASD could predispose the brain to seizures [171]. More recently, on the basis of neurophysiological and neuroimaging studies (diffusion MRI), the "underconnectivity" model has been proposed, hypothesizing that ASD and epilepsy might be the result of a diffuse dysfunction of neural networks involving different cortical and subcortical regions [172].

Concerning the diagnostic workup for epilepsy, the same recommendations formulated for patients with ID are valid also for those with ASD (see above).

We would like to stress here the importance of video-EEG and sleep EEG for a correct interpretation and classification of interictal and ictal events. Recording a good quality EEG is often an arduous task in patients with ASD who may not tolerate the procedure, and sometimes drug sedation (i.e., with promazine) is needed to minimize artifacts arising from movement in these patients.

According to a meta-analysis, in the absence of clinical seizures, children with ASD and developmental regression have EEG findings similar to those with nonregressive autism. Therefore, no evidence suggests to perform an EEG to rule out underlying subclinical epilepsy in a child with ASD and developmental regression without clinical seizures [173].

As for the consequences of epilepsy on the functioning of people with ASD, the DSM-5 [174], points out that in this population, the presence of epilepsy is associated with a higher severity of ID and a lower verbal communication skill.

In 2015, Shubrata and collaborators observed that subjects with ASD and epilepsy presented with a more severe form of ASD [175].

In a study carried out by Matson and colleagues [176], children with seizure disorders achieved significantly lower scores in the cognitive, personal-social, and communication areas than children without convulsive disorders.

Greater deficits in adaptive functioning and social skills in people with ASD and epilepsy have also been reported, compared to those with only ASD [158, 176–179].

Other studies have not shown differences in behaviors or severity of autistic characteristics in individuals with ASD and epileptiform abnormalities, although they have been found

in subjects with ASD and convulsions, major behavioral disorders, stereotypies, hyperactivity and irritability, sleep disorders, and attention deficit [159, 180, 181].

In a study performed by Smith and Matson [178], it was found that the adult ASD group showed a higher number of self-injurious behaviors than those with ID, and the additional diagnosis of epilepsy did not add to this. Those with ASD and epilepsy were more impaired on measures of disruptive behavior than those with ID alone, ASD alone, or epilepsy alone.

These results suggest that most of the effects of epilepsy on the behavioral phenotype of people with ASD are due to the presence of ID [182, 183].

Ko and collaborators [184], using the Social Responsiveness Scale (SRS), showed that ASD participants with epilepsy were significantly more impaired than ASD participants on some measures of social functioning such as social awareness and social communication. Participants were more impaired than ASD participants on social security measures.

Also for subjects with ASD, the outcome of epilepsy strictly depends on the related etiology; however, in the cases of epilepsy without demonstrable etiology prognosis can be rather favorable [152]. Data about epilepsy outcome are not univocal. While some studies have reported a good control of seizures with one or two AEDs [163, 185], others have observed pharmacoresistance in about a third of cases [186, 187].

The association between subclinical epileptiform EEG abnormalities and autistic regression is not significant, except for some epileptic encephalopathies, such as electric status epilepticus in sleep or Landau-Kleffner syndrome, which may determine psychomotor and behavioral regression [166, 188].

However, there are clear evidences, based on long-term analyses, that epilepsy has a relevant impact on behavioral, psychomotor, and cognitive outcome of subjects with ASD, determining disturbances in gross and fine motor skills, in daily life activities, and in many autistic behaviors [177].

The prevalence of epilepsy is higher in people with ID and/or ASD. Etiology is a very relevant factor for prognosis and treatment of epilepsy in these special populations. Epileptic encephalopathies strongly influence cognitive functions and adaptive behavior in persons with ID and/or ASD.

29.6.5 Pharmacological Treatment for ID and ASD

The right choice of an AED for the patients with ID or ASD and epilepsy often represents a serious challenge. Evidence-based recommendations or guidelines concerning the antiepileptic treatment in this special population are not yet available. When the treatment has been started, the EEG, clinical, and neuropsychological picture of the patient should be periodically reevaluated [189].

The choice of the most appropriate AED is driven by the type of epilepsy and tolerability, which cannot be expected a priori, and should be evaluated case by case. Some AEDs, such as phenobarbitone, ethosuximide, and vigabatrin, may worsen the behavioral disturbances. Other AEDs may present negative pharmacokinetic or pharmacodynamic interactions with the psychotropic drugs used for the behavioral disturbances often presented by subjects with ID or ASD. Regarding pharmacokinetic interactions, carbamazepine reduces plasma concentrations of clozapine, olanzapine, risperidone, quetiapine, and ziprasidone; valproic acid reduces the plasma concentration of aripiprazole, and increases that of quetiapine; phenobarbitone and phenytoin, respectively, reduce plasma levels of clozapine and quetiapine [190]. An important pharmacodynamic interaction occurs between carbamazepine and clozapine, potentiating hematologic side effects, such as thrombocythemia; the associations valproate-clozapine or valproate-olanzapine may show additive side effects, such as weight increase, sedation, and neurotoxicity; carbamazepine and lithium may determine neurotoxicity; valproate and lithium may cause weight increase,

sedation, tremor, and gastrointestinal disturbances [166].

In an open observational add-on study design carried out on 46 patients with severe drug-resistant epilepsy and different degrees of ID, levetiracetam became an effective and generally well-tolerated drug [191]. In another retrospective evaluation of 32 inpatients with drug-resistant epilepsy and ID, pregabalin was only moderately effective [192].

Furthermore, some AEDs have a psychotropic activity and are helpful in the management of behavioral disturbances: valproic acid [193], topiramate [194], and lamotrigine [195].

In a series of 85 patients out of a resident population with epilepsy and ID, an attempt was made to taper barbiturates in order to improve the cognitive and psychological state, and to reduce polypharmacy while avoiding seizure exacerbation. The number of barbiturate drugs has been considerably reduced, but only in one out of four patients barbiturate side effects have been relieved [196].

Patients with ID or ASD who show pharmacoresistance may undergo surgical treatment, should they present a focal epileptogenic lesion at the presurgical evaluation. Vagus nerve stimulation (VNS) may result in an alternative option for subjects who are not candidate to surgery, reducing seizure frequency and consequently improving the quality of life [197].

29.6.6 Psychosocial Treatment for ID and ASD

The clinical management of epilepsy in people with ID is complex; compared to the general population, in this population seizures are unpredictable, atypical, more frequent, and often drug resistant. A reduced epilepsy control can have a significant effect on the quality of life and mortality. However, even when epilepsy is well controlled by drugs, many people with ID and their caregivers report difficulties in managing the disease and a negative impact on well-being [198].

Kerr and collaborators [103] believe that the management of epilepsy in people with an ID demands high professional standards across a range of clinical domains.

On the whole, the guidelines highlight the need for people with epilepsy and ID to receive appropriate information and training in order to increase their capacity to manage their condition [199, 200].

However, there is a lack of appropriate training and support activities for people with ID and their caregivers, as well as a lack of easily accessible information [198]. It is not clear how many interventions exist, which are their characteristics and their impact. In fact, there are no methodologically "relevant" studies aimed at assessing the quality of the intervention [201]. However, specific trainings addressed to the professionals involved in the care of these patients [201], caregivers [201] (and the same persons with ID [202]) are needed, being considered as important factors for a positive outcome.

The treatment of the child with ASD and epilepsy should aim not only at reducing seizures but also at improving cognitive and social development [203]. Interventions in seizure management, along with the development of cognitive and social skills, are probably the best solution to maximize the outcomes of neuropsychological development in children with ASD and epilepsy.

Although the effectiveness of the interventions aimed at enhancing social cognition skills in children with ASD and epilepsy has been underestimated [204, 205], there is, however, clear evidence that interventions aimed at increasing social cognition skills can improve cognitive functioning, adaptive behavior, and social behavior, with results maintained for at least 2 years after the intervention [206–208]. Rodenburg and colleagues [209] believe that parents can benefit from parent-training programs in order to receive psychological support and improve coping strategies for the management of their children both in childhood and adolescence. Early interventions applied by parents to their children with epilepsy at risk of ASD have not only produced improvements in social behavior, but may also have an impact on epilepsy [210].

On the basis of our experience, the rehabilitative work with patients with ID or ASD and epilepsy should have a multidisciplinary

approach based on a multidimensional vision that requires the involvement of different operators, family members, and caregivers specially trained in the management of these complex clinical conditions.

Pharmacokinetic or pharmacodynamic interactions of AEDs with the psychotropic drugs used in people with ID and/or ASD are important factors which could determine behavioral impairments. On the other hand, some AEDs show a psychotropic action and could be helpful in the management of behavioral disturbances. Specific trainings for persons with ID and/or ASD, professionals, or caregivers are needed, being considered as important factors for a positive outcome. Interventions aimed at increasing social cognition skills could improve cognitive functioning, adaptive and social behavior.

29

Tip

- There are several biases that limit the epidemiological estimate of epilepsy in people with ID or ASD: sensory impairments, which may reduce self-report of seizures; changing of caretakers over time, creating communication problems; different inclusion criteria; occurrence of subclinical seizures or nonepileptic events.
- Many factors correlated with epilepsy may determine cognitive dysfunction, such as etiology, seizure activity, type of EEG abnormalities, neurological side effects of AEDs, concomitant disability or neurophysiological impairment, environmental factors and parental attitudes, emotional and personality characteristics.
- The choice of the most appropriate AED is driven by the type of epilepsy and tolerability which cannot be expected a priori and should be evaluated case by case.
- The multidimensional nature of epilepsy, ID, and ASD needs a multidisciplinary approach in the field of diagnosis and treatment.

Key Point

- Persons with ID and/or ASD are particularly exposed to mental or behavioral syndromes secondary to physical diseases, due to the high rate of physical health problems in general and the frequent link between specific genetic alterations and specific physical disorders determining psychopathology.
- Organic anxiety disorder and organic affective disorder share many clinical aspects and represent the most common organic mental disorders.
- The most important therapeutic option for organic mental disorders is the treatment of underlying medical condition, when impossible or insufficient, a symptomatic therapy of mental symptoms by psychotropic drugs is necessary.
- Prevalence of epilepsy is higher in the population with ID and/or ASD than in general population.
- Clinical management of epilepsy in people with ID and/or ASD is complex; compared to the general population seizures are unpredictable, atypical, more frequent, and often drug resistant.
- Action of AEDs on behavioral disturbances is strictly correlated with their pharmacokinetic or pharmacodynamic interactions with psychotropic drugs used in people with ID and/or ASD.
- Rehabilitative work with patients with ID or ASD and epilepsy should have a multidisciplinary approach requiring the involvement of different operators, family members, and caregivers specially trained in the management of these complex clinical conditions.

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_30

Learning Objectives

The primary objective of this chapter is to raise awareness on the extent of problematic substance consumption in people with ID, a neglected issue in both research and clinical practice. This chapter is developed in order to resume current epidemiological data and to explore the specific diagnostic issues and clinical characteristics of SAD in ID people. Finally, assessment options and treatment approaches for SAD in ID population will be discussed.

30.1 Introduction

Substance use (SU), substance use disorders (SUD), and substance-related and addictive disorders (SAD) among people with intellectual disability (ID) are some of the less investigated issues both from a clinical and from a research point of view. Thus, the main purpose of the first part of this chapter is to clarify the terminology related to this area. Then, an overview of available epidemiologic and clinical data will follow. Some awareness on this topic has been raised over the past two decades with an increasing amount of literature, especially regarding prevalence rates and risk factors [1], whereas there is a substantial paucity of studies regarding treatment strategies. The generalizability of such data to the overall ID population is limited. That is why, the appropriate interpretation of such heterogeneous data requires a foreword regarding the limitations of research methodologies.

30.1.1 Terminology

There is a great variety of terms regarding SU and SUD (e.g., abuse, misuse, dependence), which creates confusion. As regards the term "abuse" for example, the World Health Organization (WHO) defines it as a "persistent or sporadic excessive drug use inconsistent with or unrelated to medical practice" but the employment of the term is not recommended because of its perceived negative meaning [2]; the US Food and Drug Administration (FDA) definition stresses that the substance, regardless of the type, is taken specifically for the positive psychoactive effects produced, "to get high" [3]; and the Diagnostic and Statistical Manual of Mental Disorders in its second-last edition (DSM-IV-TR) defined abuse as "a maladaptive pattern of substance use leading to clinically significant impairment or distress," a residual diagnosis when dependence criteria are not met [4]. The International Classification of Diseases (ICD) counterpart diagnosis is "harmful use" of substances [5], in both its tenth (ICD-10) [5] and eleventh (ICD-11) [6] editions. The term "misuse" instead, according to the WHO definition describes "the use of a substance for a purpose not consistent with legal or medical guidelines, as in the non-medical use of prescription medications" [2]. In this meaning, it is frequently used in the literature on SUD in ID as interchangeable with "abuse." Other definitions of misuse are more restrictive: FDA, for example, considers "misuse" exclusively as the use of medications outside prescription or guide of a healthcare practitioner. This includes patients using a drug for a condition different from that for which it has been prescribed, patients having higher dosages or more frequent assumptions than those prescribed, and persons using medications not prescribed for them [3]. DSM too attributes a similar meaning to misuse. Talking about the use of the term "dependence," it is usually associated to chronic and regular use of the substance. It should be noted that it includes both physical and psychological dependence. There is wide agreement among different international classifications on the definition of "physical dependence" as a cluster of physiological, behavioral, and cognitive symptoms related to the substance withdrawal or to the development of tolerance [3, 5, 7]. Whereas, the "psychological dependence" includes different characteristics ranging from the compulsive assumption of the substance, the experience of impaired control over drug use to the emotional state of craving [2, 5, 7]. The term "craving" has been introduced as a diagnostic criterion in the DSM-5 and it is described as "an intense desire or urge for the drug that may occur at any time but is more likely when in an environment where the drug

previously was obtained or used. Craving has also been shown to involve classical conditioning" [7].

The definition of "craving" by the WHO adds that craving may be also provoked by any kind of physiological arousal state resembling withdrawal symptoms [2]. Finally, the term "addiction" is not used as a classificatory label. It may have different meanings and can be used to comprehend all the abovementioned terms. Indeed, it includes the compulsive use of the substance in spite of the awareness of potential or present harm and negative consequences, the concept of SUD as a chronic illness involving impaired control, craving, and genetic, psychosocial and environmental factors and implying specific neurobiological dysfunctions [8]. The term "Substance-related and Addictive Disorders" (SAD) has been introduced by the DSM-5 to define a new chapter including substance use disorders and the behavioural addiction of gambling disorder [7]. The ICD-11 followed suit, with a name that is extremely similar: Disorders due to substance use or addictive behaviours [6].

30.1.2 Research Limitations

In ID research also, there is a great variability of terms which causes inconsistencies in the application of diagnostic terminology. This, in research settings, makes difficult to compare findings from different studies impeding clear prevalence estimations [9]. In fact, not surprisingly, prevalence rates across studies are broad-ranged. For example, a recent Iranian study in non-ID people, compared DSM and ICD diagnostic criteria finding good levels of consistency among dependence diagnoses (0.81), but very low levels of consistency for abuse and harmful use (0.41) [10]. This is a source of heterogeneity among different studies and may affect the generalizability of results together with other methodological issues. Moreover, this specific population presents peculiar limitations intrinsic to the condition of ID. Factors that contribute to the paucity of scientific and reliable data include the following:

1. ID patients are usually excluded from SUD studies, because of possible atypical manifestations considered as a confounding factor or milder forms of intellectual impairment, as borderline intellectual functioning (BIF), may be overlooked in non-vocational settings [9]. Furthermore, in those studies including ID patients, there are concerns about how ID has been appropriately assessed and scored, and this, in turn, could impair the validity and generalizability of the results.
2. Large epidemiological studies and surveys, for example, those examining utilization and attitudes toward substances among students, often use self-administered tools. In ID people, the limitations in cognitive skills may weaken the validity of collected data [11].
3. ID population is quite heterogeneous by itself for several biological, genetic, psychosocial, and psychiatric reasons. For example, it is well known that brain circuits presiding to different cognitive and executive skills may be variously involved in different genetic syndromes: such a variance may imply different behavioral patterns and a discrepancy in the vulnerability to develop SUD. Even the presence of specific psychiatric comorbidities may influence the proneness to SUD, for example, attention deficit/hyperactivity disorder (ADHD) [12]. In this perspective, a more rigorous identification of clinical phenotypes may allow a better understanding of the problem.
4. Variations in prevalence rates over time may contribute to increase heterogeneity as well as cultural, policy, and social differences across countries [1, 13].
5. The probability to develop SUD according to different ID degree is partly linked to point 3 and partly related to the complex interaction with psychosocial risk factors. In fact, most of the studies on SUD in ID included people with BIF or mild ID. This is comprehensible considering the higher chances for these subpopulations to meet substances, especially in the last two decades after the empowerment of social inclusion policies [1, 14]. However, it could be argued that lower functioning individu-

als might have even higher biological and psychopathological predisposing factors to addiction. From a merely clinical perspective, it is not infrequent to identify behaviors resembling SAD in moderate-to-severe ID patients, such as overeating or misuse and dependence from medications, behavioral dependences, and others [14]. However, until now, the awareness toward alternative addictive behaviors in lower functioning individuals who do not have access to the majority of substances of abuse, is very poor.

Based on these limitations, data on prevalence rates should be critically interpreted, keeping in mind that they should be considered exploratory and that they cannot be generalized to the overall ID population.

The research about addiction and substance use in ID persons is very limited and both epidemiological, clinical, and treatment data have to be interpreted carefully. The validity and reliability of results are influenced by the exclusion of ID persons from most studies about SUD, the large use of self-assessment tools in this field, great heterogeneity of ID persons and across different countries, and different possibility to access drugs according to different ID levels.

30.2 Prevalence and Risk Factors

There are very few good and methodologically strong prevalence estimations for substance use and SUD among ID population [1, 15]. The methodological quality of most articles on this topic has been described as poor or moderate concerning reliability, description of procedures, and designs [16, 17]. Currently available literature, recruiting mainly BIF or mild ID patients, suggests a trend of lower overall licit and illicit drug consumption compared to general population, but an increased risk to develop SUD [9, 18–22] and other negative consequences on functioning [19, 23–25] among ID. Current literature reports a prevalence of total substance-related problems in ID population ranging from 0.5% [26] to 21% [20]. Such a variability could be related to the factors discussed above, particularly the sample characteristics and the studies' setting. For example, in a large population-based survey including almost 10,000 people, 2.6% of the sample met criteria for both ID and substance-related problems [27]. The ID prevalence among treatment-seeking SUD patients ranged from 5.2% to 6.2% [22, 28], two- to three-fold higher than in general population. However, these data are not conclusive. VanDerNagel and colleagues [28] found SUD to co-occur with ID in 4% of the cases as measured in vocational facilities for ID, whereas the prevalence of ID among patients receiving treatments in addiction services was 5.2%. Via capture-recapture analysis, they demonstrated a substantial underestimation of the overall prevalence due to a minimal overlap between the two subsamples. In another study, Cooper and colleagues reported differential prevalence rates according to ID level and gender. As expected, they found alcohol and substance use disorders to be more common in mild ID men (2.5%), whereas the prevalence in moderate-to-profound ID patients was 0.5% (0.8% in men, 0% in women) [29]. Another more recent research found even higher prevalence rates of SUD and indicated tobacco as the most commonly used and abused substance among intellectually disabled persons living independently [15]. Almost half of the 123 study partecipants with mild-to-moderate ID was found to use substances (48% tobacco and 45.5% alcohol) [15]. The authors of the paper also provided data regarding different patterns of substances' use, reporting that 32.2% of the sample showed tobacco-use related problems. As regards alcohol use, 17.8% of the probands reported hazardous drinking, 4.4% harmful drinking, and 11.1% alcohol dependence. These results are in line with previous evidence by Taggart and colleagues [30] who found that 75% of BIF and mild ID patients living independently were at risk of alcohol misuse over a 5-year period.

Therefore, higher cognitive level, ranging from mild ID to BIF, seems to be one of the main risk factors for the development of SUD [15, 29–32]. As for the general population,

young age, and male gender are considered independent risk factors for substance use and SUD [1, 21, 29–33]. Moreover, early onset of substance use may predict a later development of substance-related problems even in ID people. Other risk factors are independent community living [15, 30], poor socio-economic status, and living in the poorest neighborhood [31]. A forensic history is biunivocally related to SUD in ID population, both representing a risk factor and a consequence. In fact, ID people more commonly than normal peers, commit offending behaviors under the influence of alcohol or drugs [34, 35], particularly when substance use takes the form of SUD such as continuous or heavy substance use [36]. On the contrary, ID people with a history of offending behaviors and criminal records have higher rates of SUD than their peers [37]. Finally, psychiatric comorbidity may play a role in increasing the risk of developing SUD [13, 38]. The prevalence of overall psychiatric disorders in patients with co-occurring ID and SUD ranges from 42% to 79% [28]. In a recent study, Lin and colleagues [31] estimated anxiety disorders to be the most common psychiatric comorbidities among ID-SUD patients with a 68% prevalence rate. Affective illness and psychotic disorders followed with prevalence rates of 45% and 36% respectively; more specifically 35.2% of the sample had a diagnosis of depressive disorder, 25.2% of bipolar disorder, and 30.5% of schizophrenia spectrum disorder. Almost a quarter of the sample also had a personality disorder. Moreover, SUD may also be associated with emotional dysregulation and behavioral issues such as aggression [19] and ADHD [12]. In general, psychiatric vulnerability seems to be associated with substance consumption irrespective of the actual development of SUD and substance-related problems [32], but any specific disorder may impact differently on the vulnerability to develop SUD. For example, autism spectrum disorders are inversely associated to both occasional and continuous/heavy substance use, whereas schizophrenia spectrum disorders are strong predictors for substance use and SUD [36]. The presence of personality disorders, other than increasing the risk of SUD, may produce a seven-fold increase of the risk to have had criminal justice system contacts and an 11-fold higher risk for conviction [37].

Substance use and abuse may have similar consequences in people with ID and in general population, although ID population seems to be more vulnerable to negative substance effects [32]. Beyond the already mentioned increased risk to be involved with the justice system, affective instability and unpredictable mood changes, interpersonal conflicts, both verbal and physical aggressiveness toward others, suicidal ideation, poorer mental and physical health, and greater likelihood to hospitalization are common consequences of substance consumption in ID [19, 23, 24, 26, 30, 32]. As expected, the more severe the substance utilization, the more severe are the consequences. In fact, substance abuse impacts more than substance use, particularly on daily functioning and interpersonal relationships [32].

Tobacco Studies on lifetime prevalence of tobacco use in ID found that rates range from 2.6% [39] to 77.2% [15]. The majority of studies showed a prevalence of 15–30% [1, 33, 40–42] with fewer surveys reporting rates lower than 10% [43, 44]. Differences in sampling may account for variable rates. For example, those studies including students with ID reported smoking rates of 23–27% [33, 40, 45]. Higher rates have been detected in people with dual diagnosis (ID plus a psychiatric disorder), reaching over 30%, with the highest rate in those patients with mild ID and BIF [41, 42, 44]. The co-occurrence of alcohol abuse may further increase cigarette smoking [20]. The comparison of different living arrangements confirmed a larger daily consumption of cigarettes in people living independently in group homes (8.5 ± 14.1), with similar lower levels for those living in residential facilities or at home with relatives (1.4 ± 4.4 and 2.2 ± 8.4, respectively) [44].

Alcohol According to some studies, alcohol would be, together with tobacco, the most frequently used substance in ID people. The rate of alcohol use varies largely across studies reaching 77.9% in a study by To and colleagues which includes mild-to-severe ID individuals

[32]. Other studies reported lower but similar prevalence rates: a study including BIF and mild ID people found a 66.1% rate [28] and two studies regarding mild and moderate ID probands found 21% [20] and 45.5% [15] respectively. A recent French survey involving 700 disabled students compared to more than 7000 neurotypical junior high school students, examined the attitude toward drugs through self-administered questionnaires; 62.9% of disabled students reported using alcohol; alcohol use was more common in males, and 16.4% had experienced being drunk: similar rates were found in non-disabled students [33]. Alcohol misuse or abuse rate was about 20% [15, 20, 39]. Compared to other substances, alcohol consumption resulted to be significantly more associated with abuse and use-related problems among people with mild-to-moderate ID and with higher skills to live independently [32]. Similarly, in a sample of 123 individuals with mild-to-moderate ID living independently, prevalence rates for hazardous drinking, harmful drinking, and alcohol dependence resulted to be 17.8%, 4.4%, and 11.1% respectively [15]. These findings confirmed the observation that in people with ID, the line between use and abuse/misuse is fine: indeed, ID people often show lower tolerance to alcohol than non-ID peers with easy-to-appear changes in behavior, mood and attitude, reduced control over the substance, and possibly higher proneness to develop addiction [22]. Prevalence rates may vary according to the level of ID in a case-registered study involving 411 ID-mental health patients, SUD rate was estimated as 12.2% in mild ID, 5.3% in moderate ID, and 2.9% in severe ID [37]. The use of alcohol, particularly in people with BIF and mild ID, is associated with the use of other substances, mostly cannabis: almost half of both samples included in the studies by VanDerNagel et al. and To et al. abused cannabis [28, 32].

Illicit Drugs As regard other substances of abuse in ID literature, cannabis, cocaine, and opiates are the most investigated, whereas data about amphetamines and derivatives, hallucinogens, and inhalants are limited and not fully reliable. Nevertheless, rates for drugs' use in ID patients are apparently higher than in general population and vary between 14.5%–15% [1, 36] and more than 50% [28].

Cannabis Cannabis emerged as one of the most frequently used and abused substance. Data regarding cannabis use in ID people are heterogeneous across studies. Four studies examined cannabis consumption among disabled high-school students finding rates ranging from 9.1% to 26% [33, 40, 45, 46]. The large ACHA-NCHA II biannual survey included 60,940 college students across the United States: authors found that 44.2–49.5% of disabled students (not only ID but also physical and social disability) reported having used cannabis in the previous 30 days, with an odds ratio of 1.36–1.67 compared to non-disabled students [47]. Curiously, antipodal data emerged from two other samples, similar in their compositions (they both included mild-to-severe ID), examined by Chaplin et al. and by To et al. [32, 37], who found 8.8% and 39.4% cannabis use prevalence rates, respectively. Interestingly, in the study by To et al., more than half of cannabis users also developed misuse/abuse conducts, 31.3% of the sample consumed cannabis on a daily basis, and 80% had used it for more than 5 years [32]. When considering the subpopulation of people with mild ID or BIF even a higher rate emerge: VanDerNagel and colleagues found in fact that 8% of the sample used cannabis exclusively, whereas 34.8% used it in combination with alcohol [28]. Finally, the highest rates of cannabis consumption have been measured in ID prisoners reaching 51.2% in a 2011 survey. Comparing to their average IQ peers, ID probands were more prone to develop cannabis dependence (51.2% vs. 42.1%, $p = 0.01$) and the co-occurrence of ID and cannabis dependence doubled the risk of psychosis [48]. Moreover, 52.9% of incarcerated ID individuals used cannabis in the 12 months prior to commit the crime and imprisonment [49].

Cocaine Cocaine resulted to be used by a percentage of 2.7–12.5% of ID people living in the community [15, 20, 32, 37]. It is probable that more than 60% of cocaine users develop addiction and cocaine-related problems [32]. The studies regarding ID people with an involve-

ment with the criminal justice system showed a higher but similar cocaine use rate (12.6%) [49] with a 6% prevalence of misuse/abuse [50]. Prevalence seems to be lower among ID students (3%) [40].

Opiates According to available data, the use of heroin and other opiates seems to be lower than those of other drugs, with rates of 1.2–1.6% [15, 28] to 9.6% [32] in ID and BIF individuals living in the community and 11–17.9% in ID criminal offenders [49, 50]. The rates of abuse, dependence, and opiates-related problems are similar to those found for cocaine [32]. For example, a large cross-sectional clinical study including Medicaid care data of about 9484 ID patients with a comorbid SUD diagnosis, highlighted a prevalence of opiate dependence of 16.4%. Furthermore, as in general population, ID people would misuse opiate replacement medications prescribed for the treatment of opioid addiction. For example, referring to the 5 patients treated with methadone or buprenorphine in the sample by To et al., 80% of them misused the medication [32]. Given the small dimension of this subsample, this result is not generalizable but interesting anyway. In 180 ID individuals evaluated for substance consumption and adherence to programs for the treatment of addiction during their conviction, 30% abused opiates, 3% reported the misuse of methadone in the year prior the arrest, and 47% was treated with buprenorphine in prison [51].

Amphetamines The use of amphetamines and derivatives in ID has been less extensively explored and precise prevalence data are substantially lacking because most studies combined amphetamines' rates together with rates of other substances and abused stimulant medications. For example, Chaplin and colleagues reported an overall rate of 3.2% including opiate, solvents, and amphetamines use [37]. Mild-to-moderate ID subjects who live independently reported a lifetime use of amphetamines in 4.1% of the cases [15] whereas, in a study including severe ID also, the prevalence was 2.9% with two third of the users also showing problems related to amphetamine abuse [32]. In another study on substance and medication use and abuse, 4.7% of the overall sample composed of 86 mild ID and BIF individuals was prescribed with stimulants; the rate of misuse was 15.1% for the entire sample, 23.8% for BIF, and 6.8% for mild ID [28]. The authors did not specify whether the category "stimulants" included only medications (e.g., mixed salts of amphetamines, methylphenidate) or not. Plant and colleagues reported similar rates in a forensic sample (8%) [50]. The co-occurrence of ADHD may favor misuse and diversion of prescribed stimulant medications [52].

Sedatives To our knowledge, there are no systematic data regarding sedative misuse and dependence in ID people even though sedatives especially benzodiazepines (BDZ) are extensively prescribed in clinical practice to treat both psychiatric and neurological conditions frequently co-occurring in this population. In fact, the abuse of BDZ could be clinically relevant given the easy accessibility also to people with higher severity of ID. Further, it has to be taken into account that BDZ use in ID patients is associated with behavioral side effects more frequently than in general population, thus prescribing BDZ requires caution [53].

Food and Drinks Caffeine and other beverages or food with abuse potential (e.g., tea and derivatives) would require similar considerations. In clinical practice, it is not rare to meet ID individuals who show compulsive assumption and addiction-related behaviors, independently of IQ level.

Summarizing risk factors for substance use and SUD in ID, young age, male gender, and milder severity degrees of ID are quite unanimously reputed to be factors independently associated to SUD in ID population [15, 28, 30, 32, 36, 54]. Other factors associated to the development of SUD are the earlier age of first substance use [30], hazardous drinking in the previous 5 years [1, 30], and a diagnosis of conduct disorders, ADHD, and antisocial personality disorders during adolescence [12, 55]. More in general, the co-occurrence of mental illness, particularly mood and psychotic disorders may represent a ground for SUD and

related behavioral complications [19, 30–32, 36, 54]. Moreover, also specific temperamental and personality traits have been reported to be associated with SUD in ID population similarly to what happens in people with an average IQ: difficulties in emotional control [19], negative thinking, impulsivity, and sensation seeking [38] are considered predisposing factors. Even environmental factors may play a role: living independently with low levels of supervision [1, 15, 28, 31, 32, 55], poor socio-economic status including scarce educational and employment opportunities, living in a poor neighborhood, belonging to ethnic minority groups, and isolation. All of these are well-known risk factors in general population, however, few data are available for ID people [31]. Finally, also negative life events are frequently reported (history of trauma and physical or sexual abuse in childhood and/or adulthood) as risk factors [1].

30.3 Criteria and Clinical Features

The Diagnostic Manual for Intellectual Disability, Second edition, (DM-ID-2) [56] provides suggestions and revisions to adapt DSM criteria to people with ID. Such adaptations were highly needed considering that the clinical presentation of psychiatric disorders in ID patients often shows atypical features making the diagnostic process difficult. This, in turn, often leads to under- or misdiagnosis with a negative impact on therapeutic interventions. With regard to substance-related and addictive disorders (SAD) according to DSM-5 description [7], DM-ID-2 does not provide particular suggestions for adaptations of criteria. This is probably related to the relatively low-to-moderate quality of the evidence currently available, as already discussed. In this perspective, it is possible that individuals with mild-to-moderate ID and BIF could satisfy SUD criteria, whereas "it is almost impossible to apply the diagnostic criteria for substance abuse to individuals with severe-to-profound degrees of ID" [57].

DSM-5 SAD category includes several diagnoses that have in common the excessive use of a psychoactive substance. Ten classes of substances have been identified (e.g., alcohol, caffeine, cannabis, hallucinogens, inhalants, opioids, sedatives, hypnotics and anxiolytics, stimulants including amphetamine-type substances, cocaine and other stimulants, tobacco, and other or unknown substances). The excessive use of such substances causes a direct activation of the brain reward system, so intense that normal activities may result impaired: the assumption of the substance may produce feelings of pleasure as a result of the initial activation of the reward system usually described as "to be/get high." Individuals with congenital or acquired impairment of inhibitory brain mechanisms, as some intellectually disabled are, are considered at higher risk to develop a substance-related disorder. SAD are divided in the two major groups: *Substance Use Disorders* and *Substance-Induced Disorders*. The last two decades of research on addiction has disclosed that a pathological activation of reward/motivation brain circuits similar to that provoked by substances of abuse, may be also caused by a range of behaviors that are not pathological in their nature but they become it, assuming an "addictive" quality. In this regard, DSM-5 and, subsequently, DM-ID-2 have separately included in SAD section also gambling disorder, moving it from impulse control disorders where it is located in DSM-IV-TR. Other excessive, repetitive, and impairing behaviors labeled as *behavioral addictions,* such as sex addiction, exercise addiction, and shopping addiction have not been included since current evidence is not sufficient to establish valid and reliable diagnostic criteria, psychopathological, and course descriptions [7], in spite of their clinical relevance in some cases. Internet gaming has raised clinical interest in the last few years hence it has been included in the DSM-5 "Conditions for further study" section.

Substance Use Disorders Regarding SUD, the pathological pattern of *substance use* is defined by four major symptomatic areas: impaired control over quantity and duration of substance use, social impairment caused by substance use, risky use of the substance, and pharmacological indicators. The impaired control over the sub-

stance use is described by the first four criteria: (1) Use of larger amount of substance or for a larger period than how desired. (2) Persistent unsuccessful desire to discontinue or reduce the use of the substance. (3) Great deal of time spent to obtain or use the substance or to recover from their effects. (4) Craving. Social impairment is explored by the following three criteria: (1) Failure to fulfil important activities at school, work, or home caused by the substance use. (2) The use of the substance persists even after the evidence of continuous or recurrent social or interpersonal problems caused or exacerbated by substance effects. (3) Using the substance causes the drop out or reduction of important social, occupational, or recreational activities. Risky use is described by two criteria referring to the use in physically hazardous situations and the persistence in use despite knowing that the substance impacts on physical or mental health, evidenced by continuous or recurrent physical or psychological disturbances. Finally, pharmacological criteria encompass tolerance and withdrawal symptoms. Tolerance is described as the need to markedly increase the dose of the substance to obtain the desired effect, or markedly reduced effects when the usual dose is consumed; whereas withdrawal refers to blood and tissue substance concentration decline causing a constellation of symptoms, different for each class of substances, after a heavy and continuous use. During withdrawal, the consumption of the substance or an agonist may reduce or completely relieve symptoms. DSM-5 provides also the diagnosis of SUD in presence of tolerance and withdrawal symptoms in the context of medical treatment (e.g., opioid analgesics, sedatives, and stimulants), only if prescribed medications are used inappropriately as demonstrated by SUD criteria fulfilment. To make a diagnosis of SUD, at least two of the above-mentioned criteria must be present (Table 30.1). There are some minor differences between substance categories. For example, withdrawal criterion is not present in the list of symptoms for tobacco use disorder [7].

Further, DSM-5 provides some course and severity specifiers. In particular, course specifiers include "in early remission" and "in sus-

Table 30.1 Summary of DSM-5 Criterion A for substance use disorder (adapted from DSM-5 and DM-ID-2) [7, 56]

A problematic pattern of substance use: at least two of the following within a 12-month period		
Impaired control over the substance		**Description of the symptom and adaptation for ID**
1	Use of larger amount of substance or for a larger period than how desired	–√
2	Persistent unsuccessful desire to discontinue or reduce the use of the substance	Poorly applicable in individuals with severe-to-profound ID due to self-control and language/communication impairment
3	Great deal of time spent to obtain or use the substance or to recover from their effects	Reliable in severe-to-profound ID as it is observable. Behavioral equivalents may include repetitiveness and compulsivity with reduced involvement and focus on usual and pleasant activities
4	Craving	Strong desire or urge of the substance provoked by environmental and inner stimuli, even those resembling withdrawal. Difficult to be explored in patients with low verbal abilities. Behavioral equivalents might include problematic and challenging behavior chronologically related to abstinence, stressful events, and places/moments of the day when/where they were used to consume the substance

(continued)

Table 30.1 (continued)

A problematic pattern of substance use: at least two of the following within a 12-month period		
Social impairment		
5	Important activities at school, work, or home failure caused by the substance use	Minor adaptations have to be made to correspond to the individual's functioning level and with respect to premorbid functioning, variations have to be detected. Behavioral equivalents may include refuse to participate or reduced involvement in usual activities in individuals with more severe degrees of ID due to the search or consumption of the substance
6	Continuous or recurrent social or interpersonal problems caused or exacerbated by substance effects	–√
7	Drop out/reduction of important social, occupational, and recreational activities	Reliable in severe-to-profound ID as it is observable
Risky use		
8	Use in physically hazardous situations	Poorly reliable in people with severe-to-profound ID spending much time under surveillance and with basically reduced sense of danger and poor inhibitory control
9	Use despite knowledge of continuous or recurrent physical or psychological disturbances caused by the substance	Only moderately reliable in people with severe-to-profound ID because cognitive difficulties may severely reduce self-awareness of psychological state as well as difficulties to understand the consequential relationship between substance consumption and physical problems
Pharmacological		
10	Tolerance	Need to markedly increase the dose of the substance to obtain the desired effect, or markedly reduced effects when the usual dose is consumed. Reliable as it is observable, for example, through the reduction of the span of time between one consumption and the following
11	Withdrawal	Blood and tissue substance concentration decline causing a constellation of symptoms, different for each class of substances, after a heavy and continuous use. Symptoms are observable (e.g. psychomotor agitation or problem behaviors) and chronologically correlated to abstinence

tained remission" according to the period of abstinence, lasting for at least 3 months but less than or more than 12 months, respectively. An additional specifier for remission (in a controlled environment) is used for those individuals living in an environment with restricted access to the substance. The three severity specifiers depend on the number of diagnostic criteria fulfilled: mild for 2–3 criteria, moderate for 4–5 criteria, and severe for 6 or more criteria).

A dissertation regarding the specific features of each category of SUD and the effects of each substance goes beyond the purpose of this chapter. In fact, considering BIF and mild-to-moderate ID, the physiological effects of substances, the development, and course of SUD is usually comparable to those in non-ID patients. We will limit to describe general and associated features peculiar to ID.

Epidemiological findings showed substance use to begin in early-to-late adoles-

cence in ID individuals as in non-ID peers [1]. Substance use rate is higher in non-ID than in ID population: the main reason could be the easier access to substances for average IQ individuals. However, ID people using substances showed increased risk to develop SUD comparing the non-ID people [9, 26, 36]. Moreover, substance use seems to impact more negatively on both mental and physical health in ID compared to non-ID population [32, 58]. In spite of expectations, all types of substances are used by individuals with ID [28, 32], alcohol [1, 13, 30, 59], and tobacco [15] being the most frequently used, at least in people with mild ID and BIF. There are no systematic data regarding readily accessible substances such as caffeine, medications, food, and beverages, which could have even higher abuse rates. Finally, there is no agreement regarding poly-use to be more common than single substance use [15, 28, 32, 36], however, poly-users are usually younger than 30 years [28].

SUD and its complications might be considered as risk factors for needing specialist treatments in psychiatric, addiction, and more in general, medical services earlier in life. In this vein, in a large survey considering Medicaid records in US [54], ID substance users were younger compared to ID-only individuals seeking treatment for a variety of medical conditions. For example, the survey evidenced that ID people suffering from SUD might be more vulnerable to develop organic substance-related conditions with an earlier onset: ID-SUD patients treated for alcoholic liver diseases were on average in their mid-30s, at least 10 years younger than both their ID without SUD and average IQ-SUD counterparts. As it concerns both mental and physical health, it has to be taken into account that also direct physiological effects of substances may be amplified or paradoxical in ID. Additional cognitive deficits [60], induction or precipitation of seizures [14, 30], worsening of gross motor function [21], confusion, sedation, and coma, especially when medications are associated [61], are common neurological effects. The negative impact on pre-existing somatic problems is also frequent, for example, cardiovascular, respiratory, and gastrointestinal illnesses [14, 60]. It is possible that the sum of these factors may increase the mortality risk in ID compared to average IQ substance users [61]. Moreover, substance use may cause psychopathological states with acute and sub-chronic development and course, such as affective instability, mood dysregulation, inappropriate emotional responses, extreme anxiety and panic attacks, depressive symptoms and despair, suicidal ideation, odd or paranoid thinking, and bizarre behaviors [17, 19, 24, 32, 54]. Usually, in spite of similar effects on mental states and substance-induced altered behaviors, heavy disturbance on functioning in different life domains are related to SUD more than to occasional substance use and intensification of affective instability, unpredictable mood changes, and the appearance of suicidal ideation would be specifically related to SUD [32] and may represent indices of greater severity. The relationship between SUD and psychiatric disorders is biunivocal. Interpreting data from current literature, it can be hypothesized that psychiatric illness is a risk and anticipating factor for the development of a SUD in ID as well as in average IQ population [62, 63]. On the other hand, SUD might represent a trigger or causal factor for some psychiatric diagnoses. Epidemiological data demonstrated that mental health problems are the most common additional diagnosis in ID-SUD patients, with five-fold increase of the relative risk to have any psychiatric diagnosis comparing to ID people without SUD [54]. On the other hand, Pezzoni and colleagues found that in 40 mild ID patients referring to psychiatric services and screened for alcohol abuse, about 20% presented alcohol abuse, 87% of them have had also a lifetime psychiatric illness, and 75% were also smokers [14]. Depressive and bipolar disorders resulted together the most frequent co-occurring diagnosis, with 35% and 25% prevalence rates respectively. Anxiety also is frequently associated with SUD in ID people [19, 31]. Psychotic and personality disorders are common too (30% and 23% prevalence, respectively) [31]. Finally, schizophrenia spectrum disorders are associated to continuous and heavy substance use [36] whereas the impact of co-occurrent

autism spectrum disorder on substance use and development of SUD still needs to be clarified [36]. A recent review explored epidemiology and risk factors associated to SUD in autism spectrum disorder. This subpopulation shares most risk and protective factors for SUD of ID persons such as co-occurrence of externalizing, mood and anxiety disorders, perceived social deficits, peculiar social motivation, psychological distress, weak executive functioning and maladaptive coping styles, familial history of SUD, and poor social conditions. Autism spectrum disorder seems to be related to higher risk for the development of SUD and greater consumption [64].

Risky behaviors, loss of cooperativeness, poor social judgment, hostility, and aggressiveness ranging from being argumentative and confrontational to physical aggressions are the most common behavioral disturbances, and usually, represent the main cause for interpersonal, familial, and daily functioning impairment, or for vulnerability to exploitation and involvement with justice systems [1, 12, 17, 24, 30, 32, 36]. Some authors suggested that SUD would have a particularly relevant role in offending behaviors committed by ID individuals, in fact many of those referred to specialist services or convicted for criminal acts had committed offending behaviors under the influence of alcohol or substances [12, 34–36]. Hassiotis and colleagues recently found a significant correlation among psychosis, cannabis dependence, and attempted suicide in ID offenders [48]. In this study, cannabis use resulted a probable mediator between ID and psychosis.

The course of SUD in ID population is usually alike to that in general population with an early onset usually in late adolescence, even if DM-ID-2 underlines that in ID individuals the age of first substance consumption could be delayed compared to average IQ peers [56]. This delay could be related to the parents and teachers' higher "vigilance" on ID adolescents during their school years. In fact, the period following the end of the studies, especially when specific services and employment integration plans are not provided, should be considered as the most critical time with the highest level of vulnerability. SUD has often a chronic and recurring course as the persistent use of the substance may induce enduring physiological modifications in the motivation/reward, inhibitory control, and salience interrelated brain systems. Such changes may last for years even after the suspension of the substance use making reason for relapses. In ID substance users, two factors may worsen this aspect: pre-existing neurological and cognitive deficits basically reducing self-control and inhibition capacities can accelerate the transition from substance use to SUD and severe addiction [56]. However, it has not been conclusively ascertained whether or not and what kind of specific cognitive and executive deficits would be mediators between ID, addiction, and its development. In fact, a Dutch group investigating on this topic in the last 5 years did not confirm previous speculations regarding the involvement of attentional bias toward the substance and alterations in working memory and inhibitory control [65–67]. Secondly, cognitive deficits may also interfere with capacity to understand and participate in standard rehabilitative programs. In this perspective, it has to be taken into account that addiction services are often poorly accessible for ID addicted people and special informative and rehabilitative programs are not available. This last point will be more extensively discussed in the Treatment section.

Substance-Induced Disorders These include intoxication, withdrawal, and substance/medication-induced mental disorders. Intoxication is generally characterized by the development of a substance-specific syndrome linked to the recent consumption of the substance. The appearing symptoms must have a causal physiological relationship to the substance. Intoxication criteria are not available only for tobacco. Given that each substance induces a specific symptomatic pattern, more common intoxication symptoms include "disturbances in perception, wakefulness, attention, thinking, judgment, psychomotor, and interpersonal behavior" [7]. It is likely that the diagnosis of substance intoxication of mild severity or with chronic course in ID individuals may be more complicated than in neurotypical peers, as most of them may have some degree of impairment

in cognitive and executive functions with some overlapping features (overshadowing phenomenon; see ▶ chapter 5): mild intoxication symptoms, for example, might be attributed to the underlying neurodevelopmental condition. Also, withdrawal syndrome may assume substance-specific features, being the strict link between onset of symptoms and blood levels' decrease of the substance in long-term users the common denominator. Withdrawal criteria are not available for hallucinogens and inhalants.

There are ten *Substance-Induced Mental Disorders* according to DSM-5: psychotic disorder, depressive bipolar and related disorders, anxiety, obsessive-compulsive and related disorders, sleep disorders, sexual dysfunction, delirium, and neurocognitive disorder. A chronological and causal relationship with substance intoxication or withdrawal has to be established based on history, laboratory findings, and physical examination (Criterion B). A diagnosis of substance-induced mental disorder instead of a diagnosis of substance-induced disorder only can be formulated when the syndromic presentation of one of the ten above disorders is clinically relevant and needs independent attention (Criterion A). Obviously, the presence of another mental disorder justifying the symptomatology has to be excluded (Criterion C). Moreover, this criterion indicates as an exclusionary condition the persistence of the symptoms for a long time after the cessation of acute intoxication, withdrawal or the exposure to the substance. In fact, the course of substance-induced mental disorders, by definition, should be transitional and would resolve after the cessation of the causal factor, usually improving within 1 month. However, some disorders, mostly substance-induced neurocognitive disorders or hallucinogen persisting perception disorder may continue as the result of permanent brain damage. An interesting example in ID patients would be alcohol-induced neurocognitive disorder, given the high prevalence of alcohol abuse in this population. Unfortunately, studies specifically addressing this topic are lacking. When the constellation of symptoms (e.g., hallucinations, anxiety, and rapid mood shifts) occurs in the context of delirium, for example, the correct diagnosis should be delirium only. DSM-5 provides also some generalizations regarding the predictability of substance-specific syndromes: it is expected that more sedating compounds (e.g., sedatives, hypnotics or anxiolytics, and alcohol) produce prominently depressive disorders or confusion states during intoxication; on the other hand, intoxication due to excitatory drugs such as stimulants, amphetamines, and cocaine may cause a variety of conditions ranging from anxiety to mania and psychosis [7]. These elements must be weighed when considering ID individuals; this population indeed, as children and elderly, may present paradoxical reactions to substances and medications in the measure that, for example, mild-to-moderate sedatives' intoxication may occur with anxiety, psychomotor agitation, and manic symptoms.

Gambling disorder (GD) is the only behavioral addiction included among SAD in DSM-5 [7]. The diagnosis was moved to this category from impulse-control disorders where it was placed in DSM-IV-TR. GD Criterion A describes nine symptoms or pathological behaviors that cause clinically significant impairment or distress during a 12-month period. At least four of them must be fulfilled to make a diagnosis of GD. ◘ Table 30.2 summarizes GD Criterion A. The second criterion requires that gambling behavior has not to be exclusively present in or explained by a manic episode. Specifiers are the same as for SUD, with two additional ones regarding the *episodic* or *persistent* course of disorder. DM-ID-2 do not provide adaptations but only suggestions regarding the limitations that ID people may show to access money, resources, and treatments [56]. These limitations, similar to those described for the access to substances, may mislead the clinician to underestimate the relevance and the severity of gambling behavior, sometimes overlooking the diagnosis. GD literature in ID is scarce. A 2% prevalence rate of GD in mild-to-moderate ID and BIF people was found and was similar to that of general population. It has also been estimated that an additional 6% may meet criteria

Table 30.2 DSM-5 Criterion A for gambling disorder [7]

Problematic gambling behavior: at least four of the following within a 12-month period	
1	Needs to gamble with increasing amounts of money in order to achieve the desired excitement
2	Is restless or irritable when attempting to cut down or stop gambling
3	Has made repeated unsuccessful efforts to control, cut back, or stop gambling
4	Is often preoccupied with gambling (e.g., having persistent thoughts of reliving past gambling experiences, handicapping or planning the next venture, thinking of ways to get money with which to gamble)
5	Often gambles when feeling distressed (e.g., helpless, guilty, anxious, and depressed)
6	After losing money gambling, often returns another day to get even ("chasing" one's losses)
7	Lies to conceal the extent of involvement with gambling
8	Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
9	Relies on others to provide money to relieve desperate financial situations caused by gambling

for problematic gambling. Furthermore, GD seems to be associated to living independently and co-occurring anxiety and mood disorders [68]. Unfortunately, reliable studies regarding development, course, and prognosis of GD in ID are lacking.

The textbooks aimed to give descriptions of mental disorders in ID and based on DSM-5 and ICD-10 do not provide significant adaptations for SAD. Thus, diagnostic criteria are the same as for the general population. This raises some issues, especially that hypothetically the diagnosis of SAD would be limited to only BIF and mild ID persons as it is not probable that lower functioning persons may present and communicate symptoms in a way that is similar to that of the general population. Furthermore, in persons with ID the boundaries of addiction should be enlarged to cover any kind of behavioral addictions.

30.4 Specific Assessment

The assessment of SUD requires a multidisciplinary evaluation regarding substance consumption, physical, and mental health and psychosocial factors associated to the illness. Current guidelines [69] indicate as a priority a correct anamnestic assessment on substance use accounting for historical and recent patterns of substance use. Obtaining collateral information and the use of diaries may add objective data to the history and may be used as monitoring instruments. A correct framework of the clinical picture is very important to set up appropriate treatment and the estimation of the severity of the substance use is required: the clinician should collect information and observations regarding the modality, circumstances, and the amount of substance consumed. Consequences in terms of behavioral alterations and emergence of psychiatric symptoms have to be evaluated. The identification of dependence and withdrawal symptoms is crucial to provide adequate pharmacological management. A complete physical examination and appropriate supporting tests are due to identify pre-existing or substance-related physical illness or problems. Checking cardiovascular, liver, and renal functioning, a variety of hematic parameters as full blood count and electrolytes, nutritional state, and eventual infectious illnesses (e.g., hepatitis B and C viruses and HIV) would be performed. Moreover, toxicological blood and urinary tests may help to monitor substance consumption and actual abstinence. A psychiatric diagnostic process to detect mental illness is equally indispensable as the presence of an unbalanced psychiatric disorder, apart from representing a risk factor for the development and retention in substance abuse, may cause failure of all the other interventions. The assessment would include psychological and social problems, as

they represent important targets of intervention and rehabilitation. At the beginning of taking charge of the patient, where not available, the clinician should plan a basal cognitive evaluation with multiple aims: the confirmation of ID and its staging, and the evaluation of specific cognitive dysfunction useful to choose the most appropriate intervention strategy. This is also useful as a baseline parameter to compare with further cognitive evaluation to monitor any positive change related to abstinence or, conversely, any worsening of deficits caused by SUD. Finally, the evaluation of motivation to change and quit the substance or addictive behavior is required. Overall, the diagnostic and follow-up process may be helped by the use of specific assessing tools.

In this regard, a variety of assessing tools for the screening and diagnosis of substance use, SUD, and tools specific for alcohol or other substances are available for the general population. Unfortunately, assessment instruments adjusted for ID are lacking [13]. Adaptations, especially regarding self-administered questionnaire should consist of simplifications of questions and, eventually, visual supports to overcome cognitive and communicative difficulties. The lack of specific assessment tools for ID is a matter of concern since this can lead to the under-identification of SUD in ID population.

Below a brief list of some tools commonly used in research and clinical practice for the general population:

1. The Alcohol Use Disorders Identification Test (AUDIT) is the screening tool for alcohol use and abuse developed by the WHO [70, 71]. It is a 10-item questionnaire exploring alcohol consumption, drinking behaviors, and problems related to alcohol. It is available in the clinician-administered and the self-report versions. AUDIT is based on the quantitative evaluation of drinking habits to differentiate drinking problems, hazardous and harmful alcohol use, or dependence. AUDIT has not been specifically validated for ID population, but its simplicity could make it suitable also for BIF and mild ID.

   The Drug Use Disorders Identification Test (DUDIT) is the screening tool version for substances complementary to AUDIT [72]. It has similar structure and approach to explore substance consumption and related problems. There is also an extended version (DUDIT-E) with additional questions about consequences of substance abuse and treatment readiness [73].

   The strength of AUDIT and DUDIT seems to be the use of familial language and free from criticism: the information obtained can be the starting point for the clinician to further explore substance use and attitudes of the patient. The main weakness is that they are self-administered and, especially with higher degrees of ID, results could not be completely valid and reliable.
2. CAGE is another simple screening test to detect lifetime excessive alcohol consumption and related problems. CAGE-AID is the version adapted to explore also problematic drug use. The acronym CAGE refers to the first four fundamental questions of the test (need to Cut down drinking/drugs, Annoyed by people's critiques on drinking/substance use, feeling of Guilt about drinking/drug use, Eye-opener as the need to drink or assume drugs soon in the morning to avoid hangover). The test is positive when at least one answer is "yes." This tool has several limitations because, even if specific, it is not completely sensitive because questions are interpretable and this is particularly true in ID population [74].
3. The Michigan Alcoholism Screening Test (MAST) is a 25-item questionnaire developed to rapidly screen lifetime problematic drinking and alcohol-related consequences, being able to provide a gross estimation of the severity of the disorder. It is available both as self-questionnaire and clinical interview [75]. In ID people, it is recommended that the clinician administer the test in order to ensure the correct understanding of the questions.

One example of a tool adapted to ID is the Substance Use and Misuse in Intellectual Disability Questionnaire (SumID-Q) developed and validated by VanDerNagel and colleagues of the Dutch SumID group [76]. It is

a structured interview specifically developed for mild ID and BIF individuals to assess risk factors for SUD, substance use, and their consequences. Adaptations consisted in the use of a simplified language and pictures in order to facilitate the proband to understand questions. It can be used to assess lifetime, last month, and current use of a variety of substances including tobacco, alcohol, cannabis, and stimulants. This allows a complete overview on alcohol and substance use across the life and can also be used as a follow-up instrument.

Assessing tools for SAD specifically addressed to ID people are lacking; instruments used for the general population are usually employed also for ID individuals. It has to be remembered that addictive behavior has to be carefully explored and the diagnosis requires a multidisciplinary and complex evaluation.

30.5 Treatment

Available literature points out the lack of treatment options and services for substance-related problems specifically addressed to the ID population [1, 13, 26, 27, 77, 78]. There are several reasons explaining the low access to treatments for SUD and the consequent reduced development of high-standard care measures for ID people. In the past, it was estimated that one third of community treatment services for addiction did not provide specific treatments for patients with ID, and one fifth of services overtly did not accept ID people in their treatment programs [79]. More recent surveys demonstrate not so discouraging data. For example, some research in forensic settings enlightened that ID individuals received treatment for drug addiction and drug education even if significantly less compared to their average IQ counterparts during conviction period [48].

A discussion about social and health policies in this field goes beyond the purpose of this chapter (for more details cfr. [27, 61, 80]): we will limit to mention the main issues preventing ID-SUD population to access adequate interventions. For example, the analysis of Medicaid records by Slayter [80] showed that young individuals with ID and SUD, compared to those with SUD only, had fewer opportunities to access and engage specific treatments and presented higher rates of dropout. As suggested by the author, a variety of factors may influence access and retention rates such as inefficiency of transports, fragmentation of health services for ID, SUD and mental illness, physical, language and communication barriers, and the lack of treatment programs entailed to meet special needs of ID people [80]. The inappropriate framework for these patients, due to deficiency of adapted and reliable diagnostic criteria and the substantial lack of screening and assessing tools, would be considered the primary link of a chain of clinical, organizational, and structural issues. Moreover, in addiction treatment services, professionals are usually not trained for the implications that ID have on clinical course, adherence, and response to treatment, outcome, and specific multi-professional interventions recommended. This shortcoming may affect professionals' capability to receive, interact, and manage ID patients and, more in general, the suitability of the overall service for them. Furthermore, it has to be taken into account that ID individuals admitted to addiction treatment programs have cognitive impairments usually associated to poor verbal skills, memory limitations with scarce capacity to learn treatment information, and behavioral strategies besides discrimination difficulties [18]. These limitations preclude the full inclusion and participation to standard programs, the beneficial use of counseling procedures, and self-help groups.

There are few data regarding treatment strategies for alcohol and tobacco use in ID, and the few available regard only BIF and mild ID subjects. No data are available on the treatment of other drugs abuse [17]. Experts in this field agree that there is a need to develop specialized and integrated treatment approaches. Current literature reported the use of psychoeducation, motivational interviewing, and cognitive behavioral strategies with the aim to reduce substance consumption [17]. Interventions have to be adapted, for example, through the use of simplified

language and clearly understood concepts, pictorial stimuli, and role playing [16–18]. Motivational interviews are aimed to implement motivation to engage and adhere to treatment and to deal with ambivalence using cyclical model encompassing pros and cons of substance consumption and treatment; this is very helpful in anticipating relapsing and in increasing self-efficacy and determination to change substance-related problem behavior [69]. A variety of cognitive-behavioral techniques have been employed in addiction settings with the target of quitting the use of substances (e.g., stimulus control strategies) [13, 16, 18]. Interpersonal abilities, implicated in the development of SUD in ID, might be an intervention approach in some cases through the use of verbal rehearsal strategies, social skills, relaxation, and problem-solving skills training [18]. Educational interventions are aimed to expand the patient's knowledge about short- and long-term substance adverse effects on physical and mental health, possible legal consequences, and motivations for substance consumption. Psychoeducation is usually performed in small groups and, beyond the adaptation of communication techniques, it could be useful to deliver a higher number of short duration sessions [16, 17]. Psychoeducation has been found to be effective in reducing substance consumption in a small proportion of the cases [13] and it could be more effective in primary prevention programs. Some authors suggested that educational approaches would be less effective than contingency contracting and close supervision [22]. Otherwise, it is possible that a multimodal treatment including different strategies might result more effective but, to our knowledge, experimental confirmations are not currently available. More recent findings indicate that abstinence through restriction would be the best choice compared to rewarding behavioral strategies [28, 32]. Restriction is a well-known paradigm in addiction services for non-ID substance users and its application even for ID patients makes sense considering that living independently, isolation, and lack of supervision are among the most important independent risk factors for the development of SUD in this population. However, such an approach opens some ethical and practical concerns because the safeguard of self-determination and empowerment represent fundamental objectives in developing rehabilitative projects in ID services [61]. The conflicts of the two opposite paradigms may result in low cooperation between ID and addiction services with potential harmful consequences on the health of ID addicted patients [32]. Another important issue is the treatment of co-occurring psychiatric disorders, particularly mood disorders: achieving the psycho-affective balance can be in some cases the fundamental prerequisite to proceed to further treatment steps. The emerging perspective of individualized and personalized medicine is going in this direction and could represent the happy medium in clinical practice: in fact, when a correct framework of the clinical picture has been performed, a hierarchical approach can be adopted independently from IQ. Further, methodologically well-conducted studies are needed to identify risk and prognostic factors and treatment outcomes to correctly stratify interventions.

The aim of treatment may vary considerably depending on the type of substance (licit or illicit) and the severity of abuse. For example, in presence of mild severity alcohol use without significant comorbidities, reducing the consumption of alcohol to more acceptable levels can be considered an adequate and feasible goal. On the other hand, the diagnosis of dependence and/or the co-occurrence of relevant physical or psychiatric disorders or severe complications would require to rapidly achieve abstinence [69]. Similar considerations are also valid for the majority of other substances. Current management guidelines for ID, following guidelines for average IQ substance users, identified a range of good practices. Brief verbal support must be the first step with the double aim to inform the patient and his caregivers and to obtain more in-depth information regarding the quantity, modality, and duration of substance consumptions and eventual consequences. When a SUD has been identified, the patient should be evaluated and followed in specific addiction services and a cooperation should be estab-

lished. To achieve abstinence, it is very important to manage withdrawal. Mild withdrawal may not require medical interventions but only monitoring and support, whereas severe withdrawal needs high and complex medical examination and care. For example, it has to be remembered that alcohol withdrawal may cause death in the 8% of people hospitalized for a withdrawal syndrome [81]. Emerging complications as well as seizures should be monitored or better prevented via the administration of anticonvulsants. The identification and treatment of emerging psychiatric symptoms (as insomnia, anxiety, depressive mood, etc.) or comorbid mental illness are considered an essential step. The treatment of co-occurring ADHD represents a particularly great management challenge, requiring a multidisciplinary evaluation and intensive monitoring. All these recommendations, valid for any person suffering from SUD, are even much relevant for ID population considering their particular neurovegetative, neurological, and physical vulnerability. Some medications used to treat acute withdrawal may be useful in the long-term to reduce craving and secondary abstinence. Unfortunately, substitute medications are not available for all the substances: benzodiazepine, gamma hydroxybutyric acid, and acamprosate are currently used to manage withdrawal and both primary and secondary alcohol abstinence. Similarly, the opioid agonist methadone and the partial agonist buprenorphine (with or without the addition of naloxone) are successfully employed to treat opioids and particularly heroin addiction. It has to be taken into account that the scarce control of craving may lead all other treatment strategies to fail. On the other hand, a careful risk-benefit analysis and the adaptation of standard dosages of medications are needed as ID patients are at higher risk to develop side effects. Adversative agents, such as disulfiram, acamprosate, and anticonvulsants in alcohol dependence, or naltrexone and naloxone in opioids dependence, are often used in average IQ cooperative patients to increase the motivation to abstinence and reduce the perceived effects of the substance of abuse. In ID patients, all these should be valid options, except for disulfiram, that is not recommended. Disulfiram mechanism of action and effectiveness require full cooperativeness and a complete understanding that all alcohol must be avoided. No studies are available regarding psychopharmacological treatment outcomes of specific categories of SUD in ID population.

Cognitive limitations often preclude the full inclusion, participation, and adherence to standard treatment programs. There is a paucity of studies on treatment strategies specifically addressed to ID persons. Psychoeducation, motivational interviewing, and cognitive behavioral strategies with the aim to reduce substance consumption are the most studied. They require adaptations. Results are promising but not conclusive. Psychopharmacology would help as in the general population. Unfortunately, no studies relative to this field are available.

30.6 Future Perspectives and Conclusion

SUD is a chronic and often severely impairing illness, with a relapsing course. This trend is mostly linked to the neurobiological general modifications commonly shared by all the substances of abuse and even behavioral dependence, regardless of the pharmacodynamic characteristics of each substance. Addiction involves the disruption of those neural circuitries implicated in reward, motivation, inhibitory control, and other executive functioning [82] such as limbic system, prefrontal, temporal, and cerebellar cortices [83–85]. As shown by epidemiological data, the prevalence of substance-related and addictive disorders is lower in ID population compared to the general one. However, considering only those ID patients with easier access to substances, the risk to develop a full-blown SUD after substance use is far higher than for average IQ substance user. These findings highlight that the presence of ID has to be considered an important vulnerability factor for SUD. It is probable that the neurobiological correlates of ID in single individuals with basic impairment of specific brain networks and cognitive functions may be

responsible of such a vulnerability (e.g., basic hypofrontality may be related to poor inhibition control, impulsivity, attentional biases). This aspect of addiction is of great interest in the field of ID. In fact, studies found that SUD involve in most cases individuals with BIF and mild-to-moderate ID. The analysis of risk factors suggests that this is, at least in part, due to the higher accessibility to substances that people with some independence and with lower cognitive and pragmatic impairments have. However, considering the neurobiological basis of addiction, it is possible to hypothesize that even those with higher severity degrees of ID may develop addictive behaviors. This consideration could be supported by neuroimaging and neurofunctional studies that have demonstrated that the alterations of brain networks commonly found in "classical" addictions are found even in other pathological conditions. This is the example of uncontrolled eating and obesity. There is a great vulnerability and neural disruption overlap between SUD and uncontrolled eating similarly involving dopaminergic modulation of dorsal and ventral striatum, and the above-mentioned brain regions, specifically anterior cingulum, supplementary motor area, medial orbito-frontal cortex, hippocampus, and parahippocampal gyrus. Inborn or acquired alterations impair top-down control that is necessary for self-regulation [86–88]. Indeed, uncontrolled eating also shows wide overlapping clinical areas, especially considering behavioral profiles of affected persons. It is also possible that addiction may manifest in severely ID individuals in an atypical way including a wide variety of behaviors and behavioral equivalents of craving would be the most important parameter to make diagnosis of addiction in ID population. In this perspective, addiction could be more frequent than expected in ID people.

SUD is not an outlying issue in ID psychiatry because, when co-occurring, it has a destroying impact on cognitive, health, behavioral, and functional outcome. By now, in both clinical and research fields, this issue has been neglected with negative consequences on the validity and reliability of diagnosis and interventions for this vulnerable subpopulation. Further studies in this direction are needed.

Tip

The evaluation of addiction in ID as well as in average IQ persons should also include a full psychopathological evaluation. Co-occurring psychiatric disorders or psychopathological dimensions may increase the vulnerability to SUD, the difficulties to treat the SUD and relapses of SUD. Specific interventions should have double purposes and should consider multiple outcomes not only to ameliorate the general mental health but also to indirectly reduce and contain the substance consumption and more in general addiction.

Key Points

1. Substance-related and addictive disorders have been reported to reach 20% prevalence rate in ID population, with the highest rates in BIF and mild ID.
2. ID people seem to be particularly vulnerable to develop substance-related and addictive disorders and severe physical, mental health, and behavioral consequences after substance consumption.
3. The co-occurrence of psychiatric disorders may increase the risk, severity, and chronicity of substance-related and addictive disorders in this population.
4. Currently, there is a wide fragmentation of ID, addiction, and psychiatric services. Often, ID substance users do not receive a correct diagnosis neither correct interventions for substance-related and addictive disorders.
5. Assessing tools and treatment strategies for substance-related and addictive disorders should be adapted to meet the needs of ID population.

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_31

Learning Objectives

1. Personality disorders (PDs) are important moderators of mental state and physical disorders, with significant impact on psycho-social functioning and ability to live productive lives in the community.
2. The diagnosis of PDs in persons with intellectual disability (PwID) or persons with intellectual disability and autism spectrum disorder (PwID-ASD) is important because it may affect the person's acceptance into community placements, predict subsequent psychiatric disorders, determine the rate of referrals to psychiatric services, and significantly influence the mode of management.
3. The diagnosis of PDs in PwID or those PwID-ASD is complex due to difficulties in teasing out maladaptive patterns of cognition, emotion and behaviour from those which are integral to the intellectual disability or autism.
4. The diagnosis can be facilitated by greater use of behavioural observation together with informant information.
5. In spite of a growing evidence base, there is a dearth of good quality studies in this area. Treatment strategies are still largely derived from the research evidence in the general population.

31.1 Introduction

Personality is characterised as the set of habitual behaviours, cognitions and emotional patterns that evolve from biological and environmental factors and so define an individual [1]. Due to wide variation in these factors, an individual's personality is unique and cannot be adequately summarised by any classification system. As a consequence, all systems are found wanting in some way. This is even more of an issue in people with intellectual disability (PwID) or those with both intellectual disability and autism spectrum disorder (PwID-ASD).

Personality disorder (PD) is usually defined as an enduring and pervasive disturbance in how individuals experience and interpret themselves, others and the world, that results in maladaptive patterns of cognition, emotional experience, emotional expression and behaviour. These maladaptive patterns are relatively inflexible and are associated with significant problems in psychosocial functioning, which are particularly evident in interpersonal relationships. The disturbance is manifest across a range of personal and social situations and is thought of as being of long duration, typically lasting at least several years. Its features are usually shown first in adolescence but may appear later in life [2].

In the last two decades, the utility of the categorical diagnosis for PD has been debated at length, sometimes quite robustly. Thus, the DSM-5 while retaining the categorical approach to diagnosing personality disorders also proposes an alternative diagnostic system based on a dimensional approach and organised into four stages [3]. The first two stages consist of identification and severity assessment of the deficits in self (identity and self-direction) and interpersonal functioning (empathy and intimacy). The third stage compares the personality traits of the person under evaluation with those of six PD types (antisocial, borderline, narcissistic, schizotypal, avoidant and obsessive-compulsive), which have been retained from the original ten in DSM-IV for the highest availability of research data. The fourth stage includes the identification of maladaptive personality traits, which differ from symptoms for far less fluctuation across time and for continuity with healthy and adaptive characteristics of personality. A trait is considered maladaptive to the extent it interferes with individual functioning and wellbeing, which may depend on cultural and societal factors. Nonetheless, research has consistently validated and replicated five broad personality domains, sometimes called 'The Big Five' Model of personality [4]. The heritability estimates of these Big Five personality traits based on common genetic variants have been described [5], and their pathological aspect has been adopted by the DSM-5 task force for the identification of PD maladaptive traits (see Table 31.1).

Table 31.1 Pathological personality traits

Healthy polarity	Pathological polarity	Pathological facets
Emotional stability	Negative affect	Emotional lability Anxiousness Separation anxiety Submissiveness Hostility Perseveration
Extraversion	Detachment	Withdrawal Intimacy avoidance Anhedonia (lack of enjoyment) Depressivity Restricted affect (limited emotional range) suspiciousness
Agreeableness	Antagonism	Manipulativeness Deceitfulness Grandiosity Attention seeking Callousness Hostility
Conscientiousness	Disinhibition	Irresponsibility Impulsivity Distractibility Risk taking Rigid perfectionism
Lucidity	Psychoticism	Unusual beliefs and experiences Eccentricity Cognitive and perceptual dysregulation

Utilising recent advances in molecular biology and epigenetics, Svrakic and Cloninger [7] proposed a simpler definition of personality disorders as 'maladaptive syndromes developed through person-environment interaction' whereby maladaptation is a failure of integrative functions of personality (i.e. those that carry out adaptive processes) caused by strong biogenetic dispositions or by pathological environmental effects, or both. However, no biomarkers of any sort have been linked clearly to personality status. Despite being common and universal in all medical settings, and an important moderator of mental state and physical disorders, with high societal costs [8, 9], personality disorders often remain undetected or ignored in clinical practice [2, 10, 11].

Knowledge about personality disorders in PwID is sparse, significantly hampered by methodological shortcomings and poor-quality data. This reflects the lack of conceptual clarity relating to the fundamental validity of constructs of PD in intellectual disability (ID) [6, 12]. Teasing out which of the 'maladaptive patterns' of cognition, emotion and behaviour are those of personality disorder and which are of ID is a challenge that has not been met satisfactorily by any classification. Torr [6] concluded that there is 'a lack of conceptual clarity about the fundamental constructs of personality disorder in ID and the blurring of the boundaries between personality, psychiatric and behaviour disorders'.

The current research available on the impact of PD in PwID or PwID-ASD suggests

that its effects are likely to be wide ranging and significant. A community-based study carried out by Lidher et al. [13] demonstrated that compared with controls, intellectually disabled people with a PD were significantly more likely to have a maladaptive pattern of cognition, emotion and behaviour.

31.2 Diagnosis and Classification

As is evident from the preceding discussion, the classification of personality disorder is complex. A key issue, perhaps not unique in clinical psychiatry, relates to the diagnosis of a long-term condition in the absence of biological markers. Further, while a categorical classificatory system provides clear, vivid descriptions of discrete personality types, these categories are seldom 'pure' and most patients in real life clinical practice have elements of several personality disorder categories. Finally, personality evolves with time and requires longitudinal evaluation. All these make clear why the diagnosis of a PD is one of the most difficult tasks in clinical practice [2].

In PwID or PwID-ASD, the diagnosis and classification of PD becomes even more challenging and complex. Unlike those with average ability, where lasting personality characteristics develop by adolescence, the personality development phase in PwID can be prolonged. It is recommended that a diagnosis of PD should not be made before the age of 21 years in this population [14]. Nonetheless, many aspects of a person's personality structure are obvious during the developmental period, and therefore, in the proposed ICD-11 classification, the diagnosis of 'PD in development' can be made in childhood or adolescence.

In people without ID, the diagnosis of PD requires subjective information about thoughts and emotions and therefore demands an ability to communicate adequately. Such information is difficult to elicit in those with severe ID. Physical and sensory problems may compound this difficulty [15]. Consequently, a particular pattern of behaviour diagnosed as 'personality disorder' in those with mild or moderate ID could be perceived as a 'behavioural disorder' in those with severe or profound disability [12]. Guidance specific to ID emphasises that the diagnosis of personality disorders is unlikely to be accurate in those with severe or profound ID [14]. In a comparative study of ICD-10 and ICD-11 personality status in PwID, those with challenging behaviour were more likely to be diagnosed as having personality disorder than others [16].

PwID or PwID-ASD often display other behaviours that overlap with features of personality disorder (see Table 31.2). Zigler and Burack [17] noted that personality development in PwID mirrors the general population, but negative life experiences common to this group can lead to the development of personality traits such as dependency on others, fear of failure and 'outer-directed' problem-solving styles, considered among the several features of PD. PwID also experience numerous failures and negative self-worth compared with their non-disabled peers. It is this which led to Zigler and colleagues to suggest seven personality dimensions, based on motivation to interact with the environment for PwID: positive reaction tendency (a heightened motivation to both interact with and be dependent upon a supportive adult), negative reaction tendency (initial wariness shown when interacting with strange adults), expectancy of success (the degree to which one expects to succeed or fail when presented with a new task), outer directedness (tendency to look to others for the cues to solutions of difficult or ambiguous tasks), effectance motivation (the pleasure derived from tackling and solving difficult problems), obedience (individual follows directions) and curiosity/creativity.

Furthermore, the psychiatric diagnostic manuals specific for ID give only partial indications on the phenomenology of PD, and generally they lack adaptation of the diagnostic criteria for the general population. A recent development in this regard is the Diagnostic Manual–Intellectual Disability (DM-ID-2) which contains notes that help professionals to consider some important variables at the time of diagnosis and the differentiation

Table 31.2 PwID/PwID-ASD and PD: overlapping features

Symptoms	Characteristics often associated with ID/ID-ASD	PD	DSM-5 alternative model for PD
Suspiciousness and/or inhibition and/or restricted range of expressions in relationships	Consequence of the many restrictions, exclusions and frustrations to which many persons with ID are exposed in daily life	Paranoid Schizoid Schizotypal Antisocial Avoidant	Negative affectivity (hostility) Detachment (suspiciousness)
Fear or avoidance of certain situations	Emotional vulnerability 'Outer directed' problem-solving styles Repeated negative experiences Learned helplessness	Avoidant Dependent	Negative affectivity (separation insecurity)
Lack of empathic skills or difficulties in understanding societal rules, indifference, or lack of repentance	Specific form of ID and severity levels Co-occurrence of ASD	Schizoid Antisocial	Negative affectivity (hostility) Detachment (withdrawal; intimacy avoidance; suspiciousness) Antagonism (callousness) Psychoticism (eccentricity)
Dependency on others	Inability to do things independently Poor assumption of personal responsibility Lack of practise and experience in planning and decision-making Overestimation of the level of intimacy of a relationship, connected to a lack of awareness of the type of relationship and of the real emotional investment by the other person. Highly negative impact of the end of an important relationship, because of narrowness of the circle of friendships	Dependent Borderline	Negative affectivity (submissiveness; separation insecurity; submissiveness)
Self-harm or accesses of anger, rancour and aggression	Communication difficulties Poor introspection Low levels of Theory of Mind development Alteration of executive functions, such as inhibition	Antisocial Borderline	Negative affectivity (emotional lability; hostility) Detachment (depressivity) Antagonism (callousness) Disinhibition (impulsivity)
Anomalies of form and content in verbal and non-verbal communication	Very particular, and idiosyncratic communication style Atypical development of language Tendency to exaggerate or underestimate one's talents and results due to deficits of self-assessment, self-awareness and metacognition	Schizotypal Histrionic Narcissistic	Psychoticism (eccentricity) Antagonism (grandiosity; attention seeking)

between personality traits and characteristics attributable to cognitive and relational disability [18]. A list of behavioural and observable symptoms for the three PD clusters has been developed by Bertelli as part of a wider system to help clinicians in the psychopathological diagnostic screening [19, 20]. The main items of this list are reported in Table 31.3.

Alexander and Cooray [12] summarised the problems pertaining to the diagnosis of PD in PwID. These include differences between ICD-10 [21] and DSM-IV classifications [22], the confusion of definitions and different personality theories [23], the difficulties in distinguishing personality disorders from late effects of childhood psychosis [24],

Table 31.3 Main behavioural and observable symptoms of cluster A, B and C personality disorders in PwID or PwID-ASD

PD cluster	Main characteristics/pervasive patterns of behaviour
A. Odd/eccentric Paranoid Schizoid Schizotypal	Absence of adequate reactions to people's suffering or to the emotional climate of the environment Lack of interactive attitudes albeit in a socially adequate environment Aggressive and other non-aggressive but nonetheless harmful behaviour Avoidance or escape from specific objects, people or situations. Excessive self-esteem, belief of being capable of extraordinary performance compared to the real possibilities Distrust of others and/or supporters of unjustified hostility Limited emotional responses from the previous level Expiration of abstraction and logic skills No manifestation of pleasure for the activity or objects previously appreciated Irritation, opposition or fear in circumstances that do not justify such reactions Act as if she/he was another person or an object
B. Dramatic/erratic Antisocial/dissocial Borderline/emotionally unstable Histrionic Narcissistic	Irritation, opposition or fear in circumstances that do not justify such reactions Aggressive and other non-aggressive but nonetheless harmful behaviour Self-injurious or self-mutilating behaviours Decline of logical skills Loss of confidence with the known environment associated with fear or agitation Excessive self-esteem, belief of being capable of extraordinary performances compared to real possibilities Behaviours potentially capable of causing own death Absence of adequate reactions to the suffering of people or to the emotional climate of the environment Pervasive tendency to irritability Only temporary signs of satisfaction in relation to gratification Continuous requests Limited emotional responses from the previous level Interactions aimed primarily at deriving a secondary advantage The same confidence with all people Binge eating Act as if she/he was another person or an object
C. Anxious/fearful Avoidant/anxious Obsessive-compulsive Dependent	Irritation, opposition or fear in circumstances that do not justify such reactions Reduction in frequency or determination in moving away from habitual residence Avoidance or escape from certain objects, people or situations Limited emotional responses, lack of interactive attitudes albeit in a socially adequate environment Excessive indecision in choices and rigidity with respect to the placement of objects or the way of doing things

and the concern about adding another potentially stigmatising label of personality disorder to an already marginalised group cannot be overstated too. Alexander and Cooray [12] advocated strongly for the greater use of behavioural observation together with informant information when making a diagnosis of PD. The limited research available on PwID or PwID-ASD suggests that PD has broad and serious maladaptive patterns of cognition, emotion and behaviour [13, 25]. Despite the difficulties outlined, diagnosis is still significant because it may affect the patient's acceptance into community placements [15], predict subsequent psychiatric disorders [25], determine the rate of referrals to psychiatric services [15] and significantly influence the mode of management [26–30].

Making a diagnosis of PD in PwID or PwID-ASD is more difficult than in the general population. There are many reasons for this including sensory and communication difficulties, psychiatric illnesses, autism spectrum disorder, overlapping clinical features and a prolonged developmental phase for personality characteristics. Taking these, and the particular life experiences of the person, can aid in making a diagnosis.

31.3 Epidemiology

31.3.1 Prevalence

A screening survey in the general population carried out in 2009 across 13 countries by the World Health Organization using DSM-IV criteria yielded an estimated prevalence of around 6% for personality disorders [31]. Demographic and social factors were noted to influence the rate in some instances. Functional impairment was partially explained by comorbid mental disorders. A UK-based national epidemiological study utilising DSM-5 criteria reported that a majority of the study population showed some degree of personality 'difficulties' short of the diagnostic threshold. The estimated prevalence of the most complex and severe cases (including meeting criteria for multiple diagnoses in different clusters) was 1.3%. Personality symptoms even at low levels were noted to be associated with functional problems. In the new ICD-11 classification, the prevalence of personality disorder may be somewhat higher [32].

Research findings on the prevalence of PD in PwID or PwID-ASD can be contradictory. They are limited by the lack of large-scale studies with several works indicating different rates depending on the samples that were studied and the assessment tools that were used [33]. Goldberg and colleagues [23] observed the presence of PD in 90% of 384 Canadians with ID living in the community and in residential facilities, while previous and more recent studies indicate lower rates, between 0.7 and 35% [34, 35]. In a literature review, Alexander and Cooray [12] listed the wide-ranging prevalence rates in community and inpatient settings (1–91% and 22–92%, respectively) and commented that this difference was too large to be attributable to true variability. They highlighted the importance of utilising consensus diagnostic criteria based on developmental level, such as those outlined by the Royal College of Psychiatrists [14], though such criteria currently lack published studies on validity or reliability. Cooper et al. [36] identified PD using four approaches in a population sample of 1023 PwID. The prevalence rates were 1% using a clinical diagnosis, 0.8% using diagnostic criteria-learning disability (DC-LD), 0.7% using ICD-10 diagnostic criteria for research (DCR) and 0.7% using DSM-IV-TR criteria. Tyrer et al. [37] found a prevalence of 35% among 38 persons with borderline to severe ID living in the community. Kiani et al. [38] reported a prevalence of 2% in urban areas and 1.1% in rural areas, in reference to a sample of 2713 persons with mild to profound ID. Tsiouris and colleagues [39] found a prevalence of around 8% in a sample of 4069 persons attending specialised services for ID. Lindsay et al. [40] evaluated the internal consistency and factor structure of PD in PwID, analysing 164 males with ID from three forensic settings who were diag-

nosed with PD using DSM-III criteria. The overall prevalence of PD in this sample was 39.3%. The reliability data for each PD was acceptable, with the exception of schizotypal PD. Within forensic settings, Hogue and colleagues [41] showed that 55% of persons from high secure settings 10% in medium/low secure settings met ICD-10 criteria for PD, while Alexander and colleagues found that up to 50% of those in low and medium secure settings met the diagnostic criteria [29, 42]. The higher prevalence of PD has been noted not just in those with ID, but also in those with borderline intellectual functioning, with a prevalence rate up to 52.8% [43].

- In persons with ID and ID-ASD, the reported rates of PD show a wide range, both in community (1% to 91%) and inpatient settings (22% to 92%). This is perceived as too great to be attributable to true variability.

- A valid diagnosis implies the use of consensus diagnostic criteria based on developmental level, such as those outlined by the Royal College of Psychiatrists, though such criteria currently lack published studies on validity or reliability.

31.3.2 Prevalence of Specific Personality Disorders

The state of knowledge on the prevalence of specific PD is even more uncertain than that of PD overall. In the studies by Lindsay and collaborators in forensic settings [40, 41, 44] and through the use of DSM-IV criteria and the Standardised Assessment of Personality (SAP), antisocial PD was the most frequent PD (22.1 and 62.8%) followed by PD not otherwise specified (NOS) (9.8 and 30.6%), schizotypal (8.6%), paranoid (7.6%), schizoid (7.6%), borderline (7.6%), narcissistic (7.6%), histrionic (3.8%) and avoidant (3.3%). The preponderance of antisocial PD was confirmed by an ICD 10-DCR study on a sample of 430 persons, which found a prevalence of 59%, followed by emotionally unstable PD (28%), a combination of antisocial and emotionally unstable PD (10%) and anxious PD (3%) [45]. On the contrary, a previous study on a community sample using ICD-10 criteria and the SAP [46, 47] found antisocial PD to be one of the less common PD (3%), preceded by schizoid (10%), impulsive (7%) and paranoid (5%), and followed only by dependent (3%), histrionic (1%), anankastic (1%) and anxious 1% [15]. Another relevant DSM-IV-TR study by Wieland and collaborators [43] found PD NOS to be the most commonly diagnosed PD (19.1%), followed by borderline PD (8.7%), which represents together with antisocial PD the most complex PD within the DSM cluster of dramatic PD, also known as cluster B [3]. A higher prevalence of cluster B (antisocial, borderline, histrionic and narcissistic) PD in comparison to cluster A (paranoid, schizoid and schizotypal) and cluster C (avoidant, dependent and obsessive-compulsive) PD has been reported also by Bertelli and collaborators, with rates of 24.0, 18.01 and 15.5 per cent, respectively [19]. With specific reference to mild ID, Wieland and collaborators found cluster B PD to be the most common PD (9.2%) (antisocial 0%, borderline 7.9%, histrionic 0.7%, narcissistic 0.7%), but cluster A to be not diagnosed at all. Cluster C rate stood at 2.6% (avoidant 2.0%, dependent 0.7%, obsessive-compulsive 0%) and PD NOS at 21.7% [43]. In persons with ID and severe challenging behaviours assessed with the SAP, cluster A PD was the most common, followed by cluster B. Specific rates were found as follows: paranoid for 64%, schizoid 50%, dissocial 53%, emotionally unstable 50%, histrionic 33%, anankastic 22%, avoidant 50% and dependent 28% [48]. In persons with borderline intellectual functioning, PD NOS have been identified as the most common diagnosis of PD (28.1%), followed by cluster B (17.4%) (antisocial 1.7%, borderline 15.3%, histrionic 0%, narcissistic 1.3%) and cluster C (8.1%) (avoidant 2.6%, dependent 4.7%, obsessive-compulsive 1.3%), while cluster A PD was not diagnosed at all [43].

As is clear from the account above, there have been a number of contradictory findings in terms of how often the various PD are diagnosed. From a practising clinician's viewpoint,

cluster A PD often overlaps with other developmental conditions like ASD and cluster C PD overlaps with the realistic dependency needs that are often found in PwID. Therefore, it is the recognition and diagnosis of a cluster B PD which often has the most potential to affect treatment plans and therefore have the most clinical utility [45].

Most studies report cluster B PD to be the most common PD in persons with ID, followed by cluster C PD, although the state of knowledge on the prevalence of specific PD in this population is still uncertain. For the practising clinician, the diagnosis of cluster B PD often appears to be the one with most clinical utility.

31.4 Comorbidity

There is ample evidence that in the general population, personality disorders are commonly concurrent with a wide range of other mental disorders, usually impairing both function and outcome [29, 30, 48, 49, 50–52]. A meta-analysis conducted by Friborg et al. [53] to identify the proportions of comorbid PD in the mood disorders, bipolar disorders (BD), major depressive disorders (MDD) and dysthymic disorders (DYS) concluded that the risk of having at least one comorbid PD was high across all three mood disorders (BD = .42, MDD = .45), but highest in dysthymic disorders.

31.5 Assessment/Research Instruments Used in People with ID

A number of assessment instruments have been used in studies of personality disorders in PwID and are described as follows:

Standardised Assessment of Personality (SAP) – The SAP relies on an informant account to establish a diagnosis of personality disorder [25, 46–48, 54, 55]. The presence of three or more durable criteria establishes a personality trait. The diagnosis of personality disorder is established if this causes significant personal distress, or occupational or social impairment.

Reiss screen and Psychopathology Inventory for Mentally Retarded Adults (PIMRA) – The Reiss screen [56] is a screening tool for the detection of psychopathology in mental retardation. For those scoring above a threshold, the PIMRA [57], a checklist of psychopathological behaviour based on DSM-III, is administered.

Temporal-Lobe Personality Behaviour Inventory – This instrument is utilised in identification of abnormal personalities specifically associated with epilepsy [58].

'Clinical' diagnosis based on ICD [21] and DSM [22] – Most studies carried out on PwID have used 'clinical' diagnoses based on either the ICD or DSM systems to identify personality disorders. The standard categories within these classificatory systems have sometimes been supplemented with extra items, for example, immature and impulsive [24].

The International Personality Disorder Examination (IPDE) – The IPDE is a semi-structured clinical interview [59] that is compatible with the ICD and DSM systems. Its manual makes clear that it is not validated for PwID. However, it has been used in PwID [60], particularly when the degree of ID is quite mild.

Diagnostic Criteria in Learning Disability (DC-LD) [14] – The DC-LD which provides operationalised criteria for psychiatric disorders in PwID adopts a multi-axial, hierarchical approach to diagnosis. It suggests that the ICD-10 category of organic PD should not be used purely on the grounds that a person has ID, or a syndrome with an associated behavioural phenotype or epilepsy. It proposes a higher age threshold (over 21 years) for diagnosing PD and does not recommend using the categories of schizoid, dependent and anxious/avoidant PD. It emphasises that the diagnosis of PD in severe or profound ID is likely to be problematic. Initial diagnosis using the criteria for personality disorder-unspecified is suggested and if these are met, further sub-classification should be consid-

ered. It has been used in some studies that compare the prevalence rates based on different diagnostic criteria [36].

The Diagnostic Manual Intellectual Disability 2 (DM-ID-2), [18] which draws on diagnostic criteria from the DSM, allows clinicians to understand the variations in the way diagnostic criteria of the various PDs differ in PwID. It also sets out the alternate dimensional approach to personality disorders. There are few published studies using the DM-ID 2 criteria for PD.

A number of assessment instruments have been used in studies of personality disorders in PwID/PwID-ASD. The main ones are Standardised Assessment of Personality, Reiss screen, Psychopathology Inventory for Mentally Retarded Adults, International Personality Disorder Examination and Clinical Interviews based on standardised classificatory systems.

31.6 Aetiology and Risk Factors

There is no conclusive evidence about the aetiology of PD. As is the case with other psychiatric diagnoses, PDs have a complex aetiology involving genetic and environmental factors and gene-environment interactions. A number of possible causes and known risk factors have been suggested, which vary depending on the disorder, the individual and the circumstances. Flynn et al. [48] found preliminary evidence that the diagnosis is associated with abuse in childhood. Ferguson [61] conducted a meta-analytic review of evidence from behavioural genetics, which supports the conclusion that a significant amount of the variance in antisocial personality and behaviour is due to genetic contributions. Roy et al. [62] studied the factors that shape personality and concluded that understanding how early-life experience and current-life situations give rise to personality traits and taking a developmental perspective, for example, mental age, could clarify the clinical presentation in PwID.

31.7 Treatment

The evidence base relating to the treatment of PD in PwID, though growing, is still rather limited. Johnstone [63] described a four-stage treatment process consisting of (i) assessment and motivational work, (ii) interventions including foundation treatments, offence-specific treatments and personality disorder symptom reduction treatments, (iii) consolidation or relapse prevention and (iv) discharge. This process became the basis for the framework of a comprehensive, multi-disciplinary, ten-point treatment programme [64–67] that could be used both within hospital and community settings (See ► Box 31.1).

Box 31.1 The Ten-Point Treatment Programme

1. A multi-axial diagnostic assessment
   - Degree of learning disability
   - Cause of learning disability
   - Pervasive developmental disorders (autism spectrum disorder)
   - Other developmental disorders (e.g. ADHD)
   - Personality disorders
   - Mental illness
   - Alcohol and/or illicit drug use
   - Physical health conditions
   - Psycho-social disadvantage (e.g. experience of trauma)
   - Types of challenging behaviour
2. A collaboratively developed psychological formulation
3. A behaviour support plan
4. Risk assessments
5. Pharmacotherapy
6. Individual and group psychotherapy
7. Offence-specific therapies, if relevant
8. Education, skills acquisition and occupational/vocational rehabilitation
9. Increasing community participation
10. Preparation for transition and discharge

The treatment of PD in PwID follows the same premise as the general population, with psychological treatment the mainstay of treatment. Most treatments are relatively prolonged and involve group and individual therapy modes, and there is little evidence that any one is superior to another [11]. Dialectical behaviour therapy, mentalisation-based therapy and cognitive behaviour therapy are the most commonly used, but almost all are indicated for borderline personality disorder [68]. Other therapies include person-centred therapy, group treatments and behavioural management strategies. None of these treatments have a robust evidence base in PwID and there is a compelling need for more research to establish whether these benefits extend to the ID population. Past objections have been replaced by innovation to accommodate the needs of people who have ID (see: Commissioning Team for the Faculties for Intellectual Disabilities of the Royal College of Psychiatrists and the Division of Clinical Psychology of the British Psychological Society, 2016) [69]. We list below the highlights regarding some treatment modalities and treatment outcomes.

31.7.1 Dialectical Behaviour Therapy

There are a limited number of studies on Dialectical Behaviour Therapy (DBT) with rather small sample sizes. Sakdalan, Shaw and Collier [70] described a 13-week programme for six patients and reported significant improvements on dynamic risk assessment scores. Morrissey and Ingamells [71] developed a 60-session programme for six people, four of whom showed some improvements.

31.7.2 Schema Therapy

Schema therapy (ST) is an approach deriving from cognitive behavioural therapy but which also has a parenting aspect. It has been used for the management of antisocial and borderline personality problems. ST integrates elements of existing models and techniques into a consistent case conceptualisation as the foundation for understanding and changing coping behaviours that are maladaptive.

31.7.3 Therapeutic Community

Morrissey and Taylor [72] have successfully applied therapeutic community treatment models resulting in significant reductions in antisocial, schizoid and paranoid traits and in schemas relating to entitlement, defectiveness, emotional inhibition and vulnerability in a forensic unit for people with mild IDs within a high secure psychiatric service. However, no randomised studies have been carried out.

31.7.4 Nidotherapy

Nidotherapy is an environmental form of management that systematically analyses the physical, social and personal environment of a patient and collaboratively makes changes that create a better fit [73]. It has been tested in two randomised controlled trials, in people with severe mental illness (schizophrenia with comorbid PD and substance misuse) and PwID and challenging behaviour. Benefits were shown for nidotherapy in symptom reduction, social function and cost in the first trial [74, 75] and in reducing challenging behaviour in the second cluster randomised trial [76]. Nidotherapy is well accepted by patients and can be given by relatively inexperienced practitioners. It may have particular value in PwID who also have PD [77].

31.7.5 Education and Occupational/ Vocational Rehabilitation

Smith and colleagues [78] have described a work-based learning programme designed for patients within a forensic hospital for PwID. They describe the partnership between the hospital, a work place and a further education college which became a crucial part of the patient's treatment programme.

31.7.6 Pharmacotherapy

People with PD receive psychotropic medications much more frequently than any other diagnostic group despite a poor evidence base and the absence of a clear understanding of the neurobiological underpinnings of personality. Most of the available evidence focuses on borderline [79] and schizotypal PD, with some additional evidence concerning the treatment of avoidant and antisocial PD. In general, the evidence supporting pharmacotherapy is weak and the National Institute for Clinical Excellence (NICE) guidelines does not recommend drug treatment except in a crisis, after which the drugs should be stopped [80]. This conclusion has been challenged by Leib et al. [81] who concluded that the evidence from randomised controlled trials suggests that drug treatment, especially with mood stabilisers and second-generation antipsychotics, may be effective for treating a number of core symptoms and associated psychopathology.

In PwID and PD, it is important to have a careful diagnostic evaluation which will clarify the presence of any mental illnesses, many of which may present atypically. This will avoid the risk of diagnostic overshadowing and ensure adequate treatment of comorbid mental illnesses [82]. If clinically indicated, short-term treatment to target four predominant symptom clusters – behaviour dyscontrol, affective dysregulation, anxiety symptoms and psychotic symptoms – has been described. This should be subject to strict monitoring of the following standards: (a) recording all the diagnoses, (b) initiating medication only as part of a multidisciplinary treatment package, (c) clearly identifying the predominant symptom complexes being targeted, (d) identifying and recording in consultation with the patient the expected improvements and behavioural targets, (e) discussing and recording the rationale, effects and potential side effects of the proposed treatment, (f) having regular follow-up appointments to monitor progress on the expected changes and (g) specifying a length of time that the person will be tried on medication with the plan to stop if there is no improvement [64, 83–85]. The development of rational pharmacotherapy necessitates increased understanding of the neurobiological underpinnings of personality disorders and their component dimensions as a prerequisite. Translating personality theory and social cognitive neuroscience into increasingly specific neurobiological substrates may provide more effective targets for pharmacotherapy in the future [86].

31.7.7 Long-Term Treatment Outcomes

There are a limited number of longer term treatment outcome studies. While there are many clinical anecdotes about particular difficulties in this group and suggestions that treatment may need to be more prolonged than in those with average intelligence [87], there is no evidence to show that treatment outcomes are poorer. Alexander et al. [29] reported no significant differences in the clinical outcome of those with a PD treated within a forensic ID hospital. Later in a study comparing three distinct groups within forensic hospitals in the UK [30] (those with ID alone, those with ID and PD and those with PD alone), they found that the ID group and the ID-PD group tended to stay longer in hospital than the PD group, but once discharged into the community had better long-term outcomes in terms of violent re-offending.

Tip

While there is a growing evidence base about treatments and treatment outcomes for PD in PwID, there is a compelling need for methodologically sound research projects to establish whether the benefits identified in the general population can be extended to this group too.

Key Points

- The diagnosis of personality disorders in PwID or PwID-ASD can be complex, but it is clinically relevant for a number of reasons.
- It would be prudent to limit the diagnosis to those with mild rather than severe degrees of intellectual disability.
- The recognition and diagnosis of a cluster B PD (borderline or antisocial) has the most potential to affect treatment plans and therefore the most clinical utility in this group.
- Diagnosis relies on a combination of patient and informant interviews as well as behavioural observations.
- Treatment approaches have to start with a comprehensive diagnostic assessment and psychological formulation and can include a range of psychological and pharmacological interventions, many adapted from those used in the general population.
- While there are many clinical anecdotes about particular difficulties in this group, there is no evidence to show that treatment outcomes are poorer.

Learning Objectives

The primary objective of this chapter is to provide a detailed description of the differential diagnosis processes among intellectual disability (ID) and/or autism spectrum disorder (ASD) and psychiatric disorders. This chapter also provides the examination of the current categorical and dimensional approaches to diagnosis and a discussion of the neurodevelopmental perspective as a theoretical framework linking ID, ASD, and psychiatric disorders.

Introduction

The identification, co-occurrence, and differentiation of borderline intellectual functioning (BIF), mild intellectual disability (ID), and autism spectrum disorder (ASD) in adulthood represents a diagnostic challenge for several reasons: (1) the diagnosis has to be formulated in part on behavioral data that are commonly more complicated to be measured compared to the presence/absence of genetic or biochemical data; (2) behavioral manifestation can evolve over time, meaning that the phenomena to be observed could need a time span ranging from infancy to adulthood to fully tackle the entire symptomatology; and (3) the possibility of comorbidity with other psychiatric or neurological conditions could "mask" the clinical background of the patient especially in adult individuals.

32.1 Differential Diagnosis

32.1.1 Issues Specific to ASD

Although studies regarding the clinical course in adults with ASD are still few compared to the ones performed during the last 25 years in children and adolescents [1], it is widely recognized by the scientific community that a first-time diagnosis of ASD in adulthood is frequently characterized by a more subtle presentation, a higher verbal competence compared to the individuals diagnosed during childhood, and a general good or high level of psychosocial functioning [1]. Indeed, the most prominent impairments in first-diagnosed adults with ASD appear to be in non-verbal communication and in some aspects of social reciprocity [2], with less evident repetitive behaviors or stereotyped interests. Accordingly, studies have shown that of all ASD symptoms, repetitive behaviors are the clinical manifestations that tend to decline most strongly with age [3]. To mention other confounding factors that may complicate an ASD diagnosis in adults are the comorbidities often carried by those individuals, considering that several studies have shown that 50–70% of adults receiving a first-time diagnosis of ASD also have or develop a comorbid anxiety disorder, depression, or other psychiatric disorders [1, 4, 5]. Therefore, the differential diagnosis for ASD in adulthood is broad and subtle, encompassing first of all anxiety and mood disorders, personality disorders, psychotic disorders, but also ID and BIF.

In summary, diagnosing ASD in adulthood often represents a challenge in clinical practice due to several aspects linked to the presentation of the symptoms of the condition, to the coping strategies of the individual and to the possible comorbid psychiatric manifestations that risk masking some aspects of the disorder.

32.1.2 Issues Specific to ID and ASD

Both ID and ASD are metasyndromic groups including several and different clinical conditions [6]. The difficulties in defining the diagnostic boundaries between ASD and ID are largely documented [7–9]. Some studies report that a 30–40% of people with ID present also pervasive autistic traits [10–12], whereas a 70% of patients with ASD are also affected by ID [13–19]. The boundaries between ID, ASD, and schizophrenia spectrum disorders (SSD) (i.e., schizoid and schizotypal personality disorders and schizophrenia) are also more difficult to define, and they constitute an important issue considering the high co-occurrence of schizophrenia and ASD [20, 21], especially in people with ID [12, 22]. Such complexity has been associated to their broad phenotypes that overlap over the spectra [23], the similar cognitive dysfunctions [24, 25], alterations of brain regions [26], dysregulated neurotransmission [27, 28] and shared genetic factors [29–31].

Interestingly, both ASD and schizophrenia have been described as common-sense disorders [32, 33]. Specifically, Minkowsky made a distinction between "autisme riche" and "autisme pauvre," indicating with the former an intensive attempt to find meanings in the environment that is also peculiar of what is defined as productive schizophrenia, whereas the latter refers to a prevalent lack of contacts with the external world and that is closest to the current concept of autism.

There is evidence of the higher rate of psychotic disorders in adults with ID in respect with the general population, with some studies reporting a rate of 3% for schizophrenia in ID in comparison to the 1% in people without ID [12, 34, 35], and others suggested a comorbid SSD in 4.4% of people with ID [12].

However, in a context of a dual diagnosis (i.e., a developmental disorder such as ASD or ID and psychiatric disorder), there is evidence of a general tendency to underestimate ASD in people with ID in presence of a diagnosis of schizophrenia [9, 36, 37]. Research showed that about 40% of the items which examined a potential psychosis obtained a high score in presence of autism [38]. Interestingly, in a 20-year follow-up study, authors found that in 20 adults who received as children a diagnosis of "childhood schizophrenia" (infantile autism), their symptoms did not change over time [39]. Moreover, although none of them met Schneider's criteria for schizophrenia (i.e., "first rank" symptoms), they all met Feighner's criteria for schizophrenia [40], which coincide with Kraepelin's dementia praecox, Crow's type II schizophrenia (defect state) and DSM III [41] residual schizophrenia [39].

Data collected from a survey conducted by the National Institute of Mental Health on a sample of subjects with childhood-onset schizophrenia found that a 21% of participants presented a lifetime diagnosis of ASD-not otherwise specified [42, 43], and some authors found that a 26% of adults psychiatric patients had undiagnosed ASD and received instead a diagnosis of schizophrenia [44]. It has been also described a subset of patients affected by a complex neurodevelopmental disorder characterized by impairments crossing the diagnostic categories that received the name of "autism-plus" disorder [45].

It is important to note that the complex diagnosis in people with ASD and ID is essential also in areas where there are concerns about mental-health and the management of psychiatric comorbidity.

It is well known that individuals with ID are at greater risk of hospitalization for behavioral and mental distress, and this has been associated to the difficulties in recognizing co-occurrent ASD or other psychiatric disorders [46]. Problem behaviors (PBs) and autism have been found as the strongest predictors of hospital admission [47, 48], and they resulted frequently associated with mood disorders and aggressive behaviors. [49]

Therefore, there is a considerable amount of data confirming the extreme complexity in the detection of psychiatric illness because of the problematic distinction of psychiatric symptoms from the autism core symptoms and ID [22, 50, 51].

It is now clear that the assessment of mental health problems in individuals with ID and ASD raises several theoretical questions and methodological dilemmas, and this is due to the definition and classification of mental health problems and to the nature of psychiatric assessment [52, 53], in consideration that the mental illness presentation in ID and ASD is often atypical [9].

Data from literature showed that mood disorders [54], anxiety disorders, [55] SSD, and impulse control disorders [56–59] are the most frequent psychiatric conditions in people with ASD and ID, and teens with autism and ID seem to present increased rates of inattention, hyperactivity, and impulsivity compared with people affected by ID alone [60]. Moreover, people with both autism and ID resulted more vulnerable to anxiety, mood, sleep problems, organic syndrome, stereotypies, and tics [56].

In this scenario, the investigation of behavioral phenotypes may help to clarify mental-health issues in some developmental conditions. For example, genetic studies found a statistically significant comorbidity between Fragile X syndrome and ASD, with a prevalence rate ranging from 7% to 25% [61–64]. However, neither the particular

psychiatric features of Fragile X syndrome nor correlations with age or genetics have been investigated. The increased occurrence of psychiatric disorders in individuals with Fragile X syndrome has been confirmed also by the research group of the Weinberg Centre for Child Development at Tel Hashomer in Israel [65]. Indeed, findings showed an occurrence of specific phobias and vocal tics in about half of participants, whereas the criteria for autistic symptoms and schizoid personality were met by one third of them.

It is evident how a more accurate assessment process of both ASD and ID could provide a better understanding of the "psychiatric" presentation and of the associated mental distress [7, 9, 54, 66].

A first-time diagnosis of ASD in adulthood can be challenging, since it is frequently characterized by a more subtle presentation and a general good or high level of psychosocial functioning. The difficulties in defining the diagnostic boundaries between ASD and ID are also largely documented, and the boundaries between ID, ASD, and psychiatric disorders can be even more challenging because of the problematic distinction of psychiatric symptoms from the autism core symptoms and ID.

32.1.3 Issues Specific to ASD and Schizophrenia

Schizophrenia is characterized by both positive and negative symptoms. Positive symptoms include thought content not based on reality, such as paranoid delusions, and perceptual disturbances, such as auditory and visual hallucinations. Therefore, positive symptoms are considered as the expressions of a loss of ability to participate with other people in a shared sense of reality. Negative symptoms include, among others, avolition, or loss of motivation, and blunted affect, or loss of emotional expressivity in facial expressions, gestures, and tone of voice. Negative symptoms are not overtly psychotic. They are evidence of the loss of aspects of the sense of self. A given individual with schizophrenia can display any combination of symptoms – predominantly positive, predominantly negative, or a fairly balanced mix of both.

The presentation of schizophrenia with predominantly negative symptoms can appear similar to ASD. Negative symptoms can be described in a variety of ways, and there is a large body of research devoted to how to best characterize them. According to the most recent National Institute of Mental Health consensus statement in 2005, negative symptoms are most accurately categorized into five symptom domains: blunted affect, alogia (or poverty of speech), asociality (social withdrawal), anhedonia (loss of pleasure in activities), and avolition (loss of motivation) [67]. Studies have shown that although ASD and schizophrenia have different developmental trajectories, their clinical presentations at any given time can overlap [68, 69]. In particular, individuals with schizophrenia with predominantly negative symptoms show many of the same social deficits as individuals with ASD [68].

There are a few approaches that may be taken in trying to differentiate these two diagnoses. For a person to be diagnosed with schizophrenia, at least one of the following symptoms must have persisted for a considerable period of time for at least one month: delusions, hallucinations, or disorganized speech (e.g., "frequent derailment or incoherence") [70]. Delusions or hallucinations persisting for this amount of time do not typically appear in ASD. The disorganized speech in schizophrenia is qualitatively different from the stereotyped and repetitive or idiosyncratic use of language in ASD. If a patient with schizophrenia, however, presents during a period of time when negative symptoms are predominant and the patient's only history of positive symptoms is disorganized speech, it may be difficult to tease out by history-taking the presence of disorganized speech if only alogia, or poverty of speech, is present at the time of the examination. If, however, a clear history of disorganized speech can be provided by a family member or close friend, this information can help to point toward a diagnosis of schizophrenia and not ASD. Of course, it is important, as in every case, to take as detailed

as possible a history of childhood development because a patient with schizophrenia will not display prodromal symptoms as early as the patterns of ASD will appear in a child.

Although ASD and schizophrenia have different developmental trajectories, their clinical presentations at any given time can overlap and in particular, individuals with schizophrenia with predominantly negative symptoms show many of the same social deficits as individuals with ASD. In terms of differential diagnosis, SSD and ASD can be distinguished mainly by the interest toward others, the level of understanding others' meaning and emotions, the manifestation of positive symptoms, and the deficits in global cognition.

32.1.4 Issues Specific to Schizophrenia Spectrum Disorders and ASD in ID

A reliable diagnosis requires a great knowledge of target symptoms and a considerable attention to the details of differential diagnosis. Basically, ID is characterized by significant impairments in cognition, social, and adaptive behavior [71–77] and by the frequent presence of stereotypies, challenging behaviors, and autistic symptoms [78, 79].

The core symptomatology characterizing ASD consists of impairments in social interaction (e.g., inadequate eye contact, inappropriate peer relationships, lack of emotional reciprocity), impaired verbal and nonverbal communication (e.g., language delay, poor conversation skills, inability to play imaginatively), and a pattern of repetitive behaviors and restricted interests (e.g., repetitive motor movements, intense attraction to particular objects or parts of objects) [80–88]. However, some of these difficulties are also found in ID [17, 78].

As mentioned before, there is an increased risk to receive a diagnosis of schizophrenia spectrum and other psychotic disorders in this kind of population, and there is evidence showing that a first diagnosis of schizophrenia or psychosis tends to be confirmed over time [7–9, 89].

In order to provide a reliable and robust diagnosis of a psychotic disorder in individuals with ID, it is of extreme relevance the evaluation of the impact that the ID itself (e.g., cognitive fragmentation associated with stressful life events) and a possible coexisting ASD exert on the individual's clinical presentation [9, 90, 91], even with the consideration of the context in which the psychotic-like symptoms appear [92].

It is important to emphasize that some psychotic-like behaviors such as talking to one's self, regression, as well particular postures that may be assumed in response to stressful events, can be part of the ID symptomatology, also without ASD [93, 94]. Even some particular ways of experiencing the world in ASD that may result in a specific symptomatology, such as bizarre expression or fantastic thinking, may be confused with psychotic symptoms [37].

In this challenging situation, the careful evaluation of the individual's developmental history, the prodromes, the onset, and the course of the condition, the presence of positive symptoms has a central role for determining whether the clinical manifestations belong to the autistic or schizophrenic spectra or are the result of their comorbidity [95, 96].

Data documenting neurological and social development from infancy are of great value, in consideration that the abnormalities in social cognition typically present in ASD can be detected in the first year of age; conversely, in schizophrenia, they are evident at 7–8 years old and more frequently in teenage years.

In terms of differential diagnosis, it has been reported that SSD and ASD can be distinguished by the interest toward others, [97] the level of understanding others' meaning and emotions, the manifestation of positive symptoms, and the deficits in global cognition. As Crespi and Badcock [98] reported, individuals with ASD are characterized by an unusual disinterest in shared sense and others' thought, whereas those with schizophrenia try to interpret the other's thought and intentions, and such effort in understanding can become even an obsession. Furthermore, evidence shows that people with ASD generally lack of contact with other persons from the

infancy, and usually this can be evident in the first years of life; conversely, a progressive loss of contact appears to characterize individuals affected by schizophrenia [99].

According to literature, social cognition refers to a number of abilities encompassing the detection of biological motion, the identification of facial affect and metacognitive skills such as the theory of mind and the attribution of mental states [100]. The impairments in social cognition characterizing people with ASD adversely affect face processing, emotion recognition, eye gaze processing, face scanning processing, biological motion perception, dynamic social interactions, and interpretation of emotionally charged situations [100–107]. It is noteworthy that similar deficits, for example, impaired perception of emotions, theory of mind, perception of social cues, complex social judgments, face scanning processing, and biological motion, have been also reported in people with schizophrenia [108–113].

However, there is evidence that these two conditions can be differentiated considering the strategies that people affected use for evaluating events characterized by social and emotional contents. In fact, in individuals with schizophrenia, it has been described the so-called "jumping to conclusions" bias, when they have to evaluate emotional information [114]; instead, in people with ASD, a poor perceptual integration has been considered the cause of a dysfunctional decoding strategy [115]. Consequently, it has been elaborated a new theory conceptualizing ASD as an hyposocial disorder and schizophrenia as the opposite, because it is characterized by an hyper, even though dysfunctional, development of social attitude [98, 116].

In contrast with what is usually described regarding ASD, in ID social cognition appear less compromised in respect to the general intellectual capacity, and this pattern tends to remain stable during the lifespan. On the other hand, impairments in cognitive and social abilities that characterize schizophrenia appear to gradually increase over time and may present an exacerbation in early adulthood after the first psychotic episode [117]. In addition, delusions and hallucinations are typical symptoms of schizophrenia and generally are not present in ID as well in ASD [9]. Nevertheless, approximately 90% of children with autism have abnormalities in sensory perception affecting smell, taste, and also vision [118], and they can be mistaken for hallucinations. Also the presence of pretend/imaginary friends, relationships with a "transitional object" (when a toy is treated as a real friend), stereotypic preoccupations, concrete externalization of thoughts or conscience and pseudo-hallucinations should not be confused with hallucinations and delusions [119]. Other features that can help to differentiate autism and schizophrenia are the typical lack of flexibility and the disturbance in response to routine changes characterizing autism [97] and the bizarre behavior including stereotypical speech, echolalia, posturing, grimacing, and rigidity characterizing the catatonia spectrum. However, mild forms of catatonia may also occur in autism, since they have been observed in approximately 17% of adolescents and young adults affected [120].

In consideration of the current classification systems, it is very likely that the disorganized subtype of schizophrenia can be confused with autism, because of its core symptomatology represented by disorganized speech and behaviors, and flattened affect. This can be also the case for the residual type, because of the persisting negative symptoms after the psychotic episode [95].

It is possible to observe a mixed form of catatonia, autism and psychosis, when none of the single diagnoses could explain better the clinical presentation. If a single diagnosis is given, such as "schizophrenia," the standard pharmacological interventions usually do not produce the expected response [121].

A recent study revealed the presence of a relationship between autistic symptomatology and schizotypal traits, and interestingly autism symptoms resulted associated with negative, disorganized, and positive schizotypal ones [122]. It is noteworthy that individuals with an ASD diagnosis present some schizophrenia spectrum traits during the years of adolescence, and such overlap includes not only the negative schizotypal symptomatology, but also the disorganized and positive symptoms [123].

There is an increased risk to receive a diagnosis of SSD in the ID population. In order to provide a reliable diagnosis of a psychotic condition in individuals with ID, it is of extreme relevance the evaluation of the impact that the ID itself (e.g., cognitive fragmentation associated with stressful life events) and a possible coexisting ASD exert on the individual's clinical presentation, with the consideration of the context in which the psychotic-like symptoms appear. Indeed, some psychotic-like behaviors (e.g., talking to one's self, regression, as well particular postures that may be assumed in response to stressful events) can be part of the core ID symptomatology, also without ASD.

32.1.5 Issues Specific to ASD and Social Anxiety Disorder

Social withdrawal and poor socializing in public situations are behaviors that may be exhibited by adults with ASD but also by individuals with social anxiety disorder, and these manifestations may represent the primary reasons for which the diagnosis of either ASD or social anxiety disorder may be missed or delayed [124].

It has to be remembered that social anxiety disorder is characterized by the fear of the judgment by third parts, accompanied by the preoccupation to have an embarrassing or humiliating behavior in social contexts. Accordingly, those individuals choose to avoid personal encounters in order to circumvent intense physical and emotional discomfort frequently correlated to social stressful situations (e.g., fear, trouble concentrating, avoiding eye contact, trembling, sweating, and heart racing) [125]. Nevertheless, in one-on-one settings, the signs and symptoms of social anxiety are expected to abate to a major degree in individuals with social anxiety disorder compared to individuals with ASD, considering also that people with ASD do not always display all the physical signs (e.g., sweating and blushing) of anxiety in social situations that individuals with social anxiety disorder present. Another key point for differential diagnosis is the presence of sensitiveness to verbal and nonverbal signs of judgment that can guide the clinician to consider the presence of social anxiety instead of ASD since interpreting social cues is one of the main areas of deficit in individuals with ASD.

Behaviors that may be exhibited both by adults with ASD and individuals with social anxiety disorder are social withdrawal and poor socializing in public situations. Nevertheless, people with ASD do not always display all the physical signs (e.g., sweating and blushing) of anxiety in social situations that individuals with social anxiety disorder present. Moreover, the interpretation of social cues is more deficient in individuals with ASD compared to the ones that have only a social anxiety disorder.

32.1.6 Issues Specific to ASD and Major Depressive Disorder

Neurovegetative symptoms (changes in sleep, appetite, and energy) together with psychomotor agitation or retardation and lack of mood reactivity with a specific loss of pleasure in almost all activities (anhedonia) typically characterize the presentation of severe depression [70]. As a result, the individual may experience an evident personal and social impairment that resembles the characteristic behavior of individuals with ASD. Indeed, the presence of anhedonia can appear through behavioral conducts such as poor modulation of facial expression, lack of research of social interactions, lack of interests, absence of spontaneous seeking to share personal activities, and all of these manifestations resemble typical conducts of individuals with ASD. Moreover, psychomotor agitation or slowing can be found also in ASD individuals. Nevertheless, depressive illnesses are expected to have a definite time-frame and can be characterized by acute phases and remitting phases. As a consequence, in the differential diagnostic process, also the general functioning profile is expected to have an abrupt

decline linked to the acute phase of the illness, whereas functioning in ASD individuals is almost constant, except for the presence of a psychiatric comorbidity.

Evident personal and social impairment (e.g., poor modulation of facial expression, lack of research of social interactions, lack of interests, psychomotor disturbances) can be present in individuals with ASD and individuals with mood disorders. In the differential diagnosis process, the time-frame of symptom presentation and the general functioning profile are key elements to differentiate ASD from mood disorders presentations.

32.1.7 Issues Specific to ASD and Obsessive-Compulsive Disorder

Differential diagnosis between the presence of an obsessive-compulsive disorder (OCD) and ASD with the typical restricted and repetitive patterns of behavior, interests, and activities can be extremely difficult and lead to overdiagnosis of OCD in people with ASD.

OCD is characterized by the presence of obsessions and compulsions. Obsessions are defined as intrusive and recurrent thoughts or impulses causing severe anxiety, comprising obsession of contamination, ordering/counting, symmetry, intruding forbidden thoughts, harm. Compulsions are defined as rigid ritualistic and repetitive behaviors typically acted in order to relieve obsession-induced anxiety [70]. Such patterns of behavior, when observed by the clinician, may closely resemble the rituals, stereotypes, and adherence to routines of adult individuals with ASD [126]. In the differential diagnostic process, the key to proceed can be found mainly in analyzing the function of the obsessive-compulsive behavior and the emotional valence of thoughts and the compulsions. Indeed, restricted and repetitive behaviors represent pleasurable experiences in ASD individuals, intrinsically motivating and reinforcing the repetition [1]. First of all, generally the actions in ASD individuals lack the "neutralizing" character of true compulsions [127]. Moreover, those experiences are emotionally considered as "ego-syntonic" in this population, meaning that the individual lives the experience in a positive and not conflicting way when generating the behavioral conduct. On the other hand, individuals with OCD live the experiences related to the illness in an "ego-dystonic" manner, admitting that both thoughts and behaviors are irrational and without the possibility to stop them and not wanting to experience them anymore [128]. Finally, social cognition and empathy are mainly preserved in individuals with OCD, making therefore always suitable to explore the general functioning profile of the individual when considering a differential diagnosis with ASD.

There is a trend toward overdiagnosing OCD in individuals with ASD, since both conditions share restricted and repetitive patterns of behavior, interests, and activities. Key elements to proceed in the differential diagnosis procedures can be found mainly in analyzing the function of the obsessive-compulsive behavior and the emotional valence of thoughts and compulsions.

32.1.8 Issues Specific to ASD and Obsessive-Compulsive Personality Disorder

The differential diagnosis of ASD includes also personality disorders. For the case of obsessive-compulsive personality disorder (OCPD), repetitive and rigid patterns of behavior may resemble stereotypies of individuals with ASD. The differential diagnosis is even more complicated since OCPD individuals, unlike OCD ones, have impaired empathy and social cognition and often experience their compulsions in an ego-syntonic way [129]. Moreover, OCPD patients tend to not report the content of their thoughts as intrusive or upsetting [130]. Indeed, OCPD is described in the DSM-5 [70] as a condition involving impairments in self-functioning due

to a rigid obsession with productivity, morality, or other personal or social codes. For these individuals, self-imposed rules are believed to be the best way of behaving and they present lack of flexibility accompanied by a consequent perseverating pattern of conduct with rigid perfectionism [70].

Therefore, adults presenting rigid behaviors, lack in empathy, and social impairment should be necessarily considered by the clinician in the view of a differential diagnostic process between ASD and OCPD, with special attention to be given to the age of onset (adolescence or adulthood in OCPD, childhood in ASD).

Interestingly, researchers have stressed the presence of a significantly increased ability to delay gratification in individuals with OCPD, with people with OCPD exhibiting a hypercapacity for self-inhibition [130], while individuals with ASD tend to show a significantly reduced ability to delay gratification and exercise effortful control [131]. Consequently, as a second step, clinicians may perform tests of effortful control and reward delay to pursue the differential diagnosis, with high performances in these tasks suggesting the presence of OCPD.

Finally, impairments in social functioning confined to intimate or familial context with a well-preserved community general functioning may again suggest the presence of OCPD instead of ASD [132].

32.1.9 Issues Specific to ASD and Avoidant Personality Disorder

Avoidant personality disorder and ASD share similarities in their presentation particularly in the field of social impairment. Avoidant personality disorder is described as a "pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts" [70]. Moreover, a diagnosis of avoidant personality disorder in people with generalized social anxiety disorder represents a marker of severity of the condition [133] with "emotional guardedness," assessed primarily by response to the Structured Clinical Interview for the DSM (SCID) [134] scale item of "difficulty being open even with people you are close to," most consistently differentiating avoidant personality disorder symptoms in patients with generalized social anxiety disorder [133]. Starting from these premises, it appears that people with avoidant personality disorder may share with ASD individuals even more features than patients with social anxiety alone.

Apart from the individual report during the clinical interview, it would be of primary importance to observe patients' nonverbal communication in order to find behaviors more likely suggesting the presence of ASD or avoidant personality disorder. In the differential diagnostic process, age of onset of the impairments (adolescence or early adulthood), the absence of stereotyped or idiosyncratic language, and the presence of a certain attitude to social cues with suffering in interpersonal relationship would suggest the presence of the personality disorder instead of ASD.

32.1.10 Issues Specific to ASD and Schizotypal Personality Disorder

ASD and SSD have been at the center of a scientific controversy since Leo Kanner borrowed the term "autism" from Swiss psychiatrist Eugen Bleuler, who had previously coined to describe the socially withdrawn behaviors of individuals with schizophrenia [135]. Over the past years, many researchers have argued about the boundaries between the two diagnostic categories. Studies in the 1970s for the most part suggested that ASD and SSD were mutually exclusive categorical diagnoses with distinct developmental trajectories [123]. More recently, however, studies have shown empirical evidence for conceptual and phenotypic overlap [5, 123, 136].

In clinical practice, when considering personality disorders of the above-mentioned spectrum, severe difficulties emerge in the process of the differential diagnosis. Behaviors

performed by ASD individuals frequently overlap with schizotypal ones [137, 138], with data showing that 40% of ASD subjects can meet formal criteria for schizotypal personality disorder [122].

By definition, schizotypal personality disorder is described as "a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior" [70]. Criteria for the disorder include odd or eccentric thinking, speech, and behavior, as well as "excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self." Nevertheless, criteria also include nondelusional ideas of reference, "odd beliefs or magical thinking that is inconsistent with subcultural norms," and suspiciousness or paranoid ideation and the exploration of these dimensions is critical in the differential diagnostic process, since ASD individuals generally do not show paranoid ideation or nondelusional ideas of reference. Indeed, individuals with ASD show impairments in the ability to conceptualize the mental state of other people and therefore might be defined as "hypo-mentalizers," while individuals with schizotypal personality disorder tend to overinterpret the mental state of others in a suspicious or paranoid way and might be called "hyper-mentalizers" [1, 122]. Apart from the presence of an interpretative way of thinking, as with all personality disorder, it will obviously help in differentiating patients with ASD from those with schizotypal personality disorder the exploration of the time-frame in which symptoms emerge, respectively, childhood or adolescence/early adulthood [1].

32.1.11 Issues Specific to ASD and Schizoid Personality Disorder

The term "schizoid," like the term "autism," was coined by Swiss psychiatrist Eugen Bleuler, who first used it in 1908 to describe an individual's exaggerated tendency to direct attention toward his inner life and away from the outside world. However, the existence of schizoid personality disorder as a discrete entity has been controversial since then, with the rising of the hypothesis that it could be seen as a personality trait rather than a personality disorder [139].

By definition, schizoid personality disorder manifests itself as "a pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts" [70]. Criteria for the diagnosis include "neither desires nor enjoys close relationships, including being part of a family"; "almost always chooses solitary activities"; "takes pleasure in few, if any, activities"; and "appears indifferent to the praise or criticism of others". Interestingly, schizoid personality disorder "should not be diagnosed if the pattern of behavior occurs exclusively during the course of schizophrenia, a bipolar or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder" [70].

Consequently, a subject cannot have a diagnosis of both ASD and schizoid personality disorder because the schizoid symptoms are considered to be etiologically rooted in ASD and not a personality disorder. Nevertheless, as with schizotypal personality disorder, studies have showed overlap between schizoid and ASD behavioral traits [137, 138]. In clinical practice, it must be noted that the lack of a paranoid dimension in individuals with schizoid personality disorder represents the main obstacle in the differential diagnostic process. Therefore, the first and principal step in considering the two diagnostic options is to obtain a detailed childhood developmental history of the subject, since behaviors raising during adolescence or early adulthood will be suggestive of the presence a personality disorder rather than ASD.

The differential diagnosis of ASD includes also personality disorders. Particularly, in the differential diagnosis process, it has to be paid special attention to the age of onset of the symptoms (adolescence or adulthood in personality disorders, childhood

in ASD) and the general functioning profile of the individual. Particularly, a subject cannot have a diagnosis of both ASD and schizoid personality disorder because the schizoid symptoms are considered to be etiologically rooted in ASD and not a personality disorder.

32.2 Categorical and Dimensional Approaches

The DSM-5 introduces an integration of a dimensional approach to diagnosis and classification together with the DSM-IV-TR [140] categorical approach [70].

Previous editions of DSM used a categorical model requiring a clinician to determine that a disorder was present or absent. The dimensional approach allows a clinician more possibilities to assess the severity of a condition and does not imply a real threshold from low-functioning forms to forms with very high general skills. All the psychiatric disorders in DSM-5 remain in specific categories, while measures indicating the degree of severity have been added to several combined diagnoses. Indeed, the DSM-5 combines four different categorical disorders in the ASD diagnosis and conceptualizes them as occurring along a single spectrum characterized by dysfunctional social communication and restricted, repetitive behaviors or interests. Using DSM-IV [141], people with such symptoms could be diagnosed with four separate disorders: autistic disorder, Asperger's disorder, childhood disintegrative disorder, or Pervasive Developmental Disorder-Not Otherwise Specified.

Given the phenotypic heterogeneity of this condition, the DSM-5 introduced the concept of neurodevelopmental disorders that include a range of disorders associated with learning difficulties, skills impairment, high reduction in logical-deductive intelligence, and significant difficulty in sharing emotional content [70]. The disorders included in this new metastructure are not primarily associated with a debut in infancy and adolescence, as described in previous classification systems, but from etiopathogenetic, risk, and clinical factors, such as the neuro-evolutive genetic phenotype, neural circuit anomalies, cognitive, learning, communicative and behavioral deficits, early onset, lifelong persistence, and the high mutual comorbidity [142].

The categorical approach and the dimensional approach both present advantages and disadvantages. The categorical approach is based on the kraepelinian and neo-kraepelinian perspective and refers to the process of dividing mental disorders into discrete entities, whereas the dimensional concept of spectrum, often used interchangeably to that of the continuum, includes a set of clinical forms that show a similar appearance or are thought to be caused by the same underlying etiological mechanism, differentiated according to increasing severity. The principal disadvantage of the categorical model is its tendency to encourage a "discrete entity" view of the psychiatric disorders. Conversely, dimensional approach introduces quantitative variation and graded transition between different forms of the disorder, as well as between normality and pathology [143].

Since 2009, a dimensional approach to neural circuits and their connections with psychopathology was promoted. The National Institute of Mental Health (NIMH) instituted the Research Domain Criteria (RDoC) project to develop a research classification system for psychopathology based on neurobiology and observable behavior.

The RDoC is based on three assumptions. First, the RDoC framework conceptualizes the mental illnesses as disorders of brain. While neurological disorders show identifiable lesions, mental disorders were considered as disorders of brain circuits. Second, RDoC assumes that the dysfunction in neural circuits can be detected by some screening and diagnostic tools employed in neuroscience, such as the fMRI. Third, the RDoC framework assumes that data from genetics research and clinical neuroscience will yield biosignatures that will augment clinical symptoms and signs for clinical management. RDoC is intended to support research toward a new classification that encourages investigators to approach to the study of the genetic, neural, and behavioral features of mental disorders [144–146].

In this context, advances in knowledge of early brain development highlighted the role of the neurodevelopmental perspective in theorizing about the etiology of disorders. Distinctive types of psychopathology may have early onset, features in common, and different time courses in symptoms depending on the variations of the same underlying disposition.

The categorical approach to diagnosis and classification of disorders is based on the kraepelinian and neo-kraepelinian perspective and refers to the process of dividing mental disorders into discrete entities, whereas the dimensional concept of spectrum, often used interchangeably to that of the continuum, includes a set of clinical forms that show a similar appearance or are thought to be caused by the same underlying etiological mechanism, differentiated according to increasing severity.

32

32.3 The Neurodevelopmental Perspective

Advances in the development of dimensional models and approaches to research on psychopathology made possible to find that behavioral, cognitive, social, and emotional competencies share common neurobiological bases, evolve across the brain development, and vary across individuals in different traits, abilities, or mental disorders [147].

Research in ASD and other neurodevelopmental disorders is in progress. How a damage in one system may lead to deficit in another or how different brain regions develop and interact with others remain largely unknown. Indeed, disruptions in specific cerebro-cerebellar circuits in ASD might interfere with the specialization of cortical regions involved in motor control, memory, attention, language, and social interaction, leading to deficit in these domains. Extensive connections within the brain provide an anatomical substrate for the broad range of clinical presentations of ASD and others neurodevelopmental disorders [148]. Genetic, anatomical, and functional imaging studies in ASD found an atypical organization of subcortical and cortical areas related to autistic symptoms. A damage occurring early in the brain development may induce a cascade of more complex deficits. Furthermore, neuronal circuits interact with others across the different brain regions. The cumulative consequences of these interactions among complex biological and also environmental systems can alter the course of brain development. Indeed, the international scientific community considers the extreme variability of symptoms as a polymorphism due to a complexity of different causal factors, both biological and environmental. Among the biological factors, genetic type has a predominant role. Association studies on the entire human genome (genome-wide) show that variations in the number of gene copies characterizing some syndromes including ID are also present in many forms of ASD and other major psychiatric disorders such as schizophrenia, bipolar, and major depressive disorder. A recent review conducted by Torres and colleagues [149] found that CNVs of 1q21.1, 3q29, 15q11.2, 15q13.3, 16p11.2, 16p13.1, and 22q11 chromosomal regions result in a wide phenotypic spectrum, ranging from normal development to learning problems, including ID, ASD, and SSD. Waltereit [150] and collaborators also analyzed the functions of genes mutated in these three disorders and selected some shared mechanisms in neurodevelopmental pathways, finding some similarities.

To note, emerging evidence suggests that ID, ASD, and also SSD are part of a single group of neurodevelopmental disorders [151]. Etiologically all the three syndromes are considered to result from the overlap between different combination of specific causative factors, both genetic and environmental that influence brain growth and maturation with subsequent effects on general and specific impairments of cognitive functioning [152].

In summary, the neurodevelopmental perspective is currently recognized as the most valid theoretical framework to explain the relationships between systems and to support multidimensional, transnosographic, interdisciplinary approaches, referring to the whole life, more useful to the understanding of the etiopathogenesis of mental health problems

and the identification of the best interventions [142, 153].

In fact, this perspective, which draws on the tradition of psychology and developmental psychobiology, and that has been enriched by evolutionary and cognitive neuroscience, localizes positive and pathological adaptation in the transactional relationships between the biological mechanisms of the brain, their psychological functions, and the external environment. Moreover, it represents a dimensional approach able to grasp the complexity of the differences between individuals, their evolution over time, the relations between mind and behavior, and the declinations of personal functioning in a better way than the categorical approaches and the relative quantitative diagnostic references.

Indeed, one of the most important advances linked to this perspective is to have recognized that psychopathological conditions traditionally considered distinct share common etiological and risk factors, and they occur simultaneously in the same person or at different times of life (sequential comorbidity), representing changes related to the age of the underlying common provisions.

Also dementia and other disorders traditionally considered to be neurodegenerative in nature – and that are often present in some genetic syndromes including ID – have also been suggested as conditions of late-onset neurodevelopment, as evidenced by an increasing number of genetic and neurobiological studies [154, 155]. Accordingly, a group of American researchers from the University of Wisconsin and Indiana recently found high levels of the beta-amyloid precursor protein, known so far only for its implications in the pathogenesis of Alzheimer's dementia, in people with Fragile X syndrome and with ASD [156].

While the prospect of neurodevelopment could contribute to a better understanding of the multifactorial etiopathogenetic mechanisms underlying many psychiatric and cognitive disorders and provide new intervention strategies, on the other hand it could lead to the premature abandonment of traditional nosology and the emergence of broad spectrum covering the full range of current psychopathology. For example, the trend of recent years to increasingly broaden the number of psychiatric aspects included in the autism spectrum [157–159] should be more appropriately evaluated in relation to the potential negative impact on research and clinical resources dedicated to the autistic syndromes closest to the descriptions of Kanner or associated with ID. In many countries, the ever increasing identification of ASD has been associated with a proportional reduction of ID diagnoses, with significant epidemiological, social, cultural, and economic implications [160]. Research on the differentiation criteria is desirable to undergo a progressive development, including new semeiological references, such as sensory-perceptual or motor disorders, and limiting the spread of conditions of uncertain nosographic validity, such as the high-functioning autistic disorder, the semantic-pragmatic disorder, the evolutionary disorder of the right hemisphere or the multidimensional impairment disorder.

Some members of the Psychiatry Section of the ID of the World Association of Psychiatry (WPA-SPID) have recently proposed a contribution in this sense, with the aim of achieving a better definition of the diagnostic borders between ID, ASD, and SSD; particular attention has been paid to the differentiation of ASD and SSD in people with ID [161].

The prospect of neurodevelopment has also provided the theoretical framework for the recent process of redefining ID, which is abandoning the reduction of the IQ, the deficits in adaptation, and the age of onset as the main diagnostic references. ID is not considered either as a disease or as a handicap, but as a metasyndromic group of health conditions associated with a variety of specific etiologies, which have in common a deficit in cognitive development prior to the acquisition of skills through learning and that significantly interfere with the activities and skills of participation [162]. Although many clinical conditions including ID can be diagnosed before birth or during the neonatal period, other syndromes may occur much later, in adolescence or even in early adulthood. Continuous adaptation throughout life and cognitive skills can develop sequentially over time, especially when optimal environmental supports and

stimuli exist [163, 164]. Much has been done to identify the periods in which the effect of experience has the greatest impact on brain development and the evidence collected shows interesting specificities for language, attachment, and behavioral pattern [165].

The introduction of an evolutionary and longitudinal perspective therefore seems to be able to improve the understanding of how the different presentations of ID and low-functioning ASD, with or without a known etiology, can change and evolve over time and how the different genotypes can determine specific cognitive behaviors and profiles in the different ages of life. For example, children with Down syndrome show better abilities in receptive language earlier than expressive ones [166, 167], while boys with Fragile X syndrome tend to acquire more skills in simultaneous processing with respect to sequential processing during development [168].

Further advances in this research area would allow to deepen the understanding of the dynamics of cognitive development and how to enhance the effectiveness of educational, therapeutic, and rehabilitative interventions, by better regulating their structure and chronology.

The model of intelligence, based on the measurement of IQ, appears to be of limited use compared to the definition of ID recently proposed in the DSM-5 [70] and in the eleventh edition of the ICD [162, 169]; people with ID present in fact an extreme variability of specific cognitive dysfunctions, even with IQ parity, strongly correlated to various bio-psycho-social factors and to the equally wide range of adaptive skills [170]. These impairments of a single cognitive function, or some, may have the effect of a neuropsychological overtone and determine low scores in complex executive performance. People with Down syndrome, for example, usually have deficits in specific areas of language, long-term memory, and motor performance [171], whereas in those with Williams syndrome, areas are more compromised of attention, visuo-spatial construction, short-term memory, and planning [172].

There is much evidence on how the limits in functioning, behavioral problems, and various alterations of instrumental examinations of the central nervous system correlate more with deficits in specific cognitive functions than with IQ or its complex subdivisions [173, 174].

In the literature on ID, the most investigated cognitive functions were the associative memory, the working memory, the orientation response, and the attention switch. Although there is not yet a conceptual map or hierarchy of relevant cognitive functions and domains in ID, some of these are compromised more often and more markedly, such as perceptual reasoning, operational memory, processing speed, and verbal comprehension [170].

The ICF [175] already considers intelligence as a generic concept, which includes cognitive functions, adaptive behavior, and learning and which depends on age and cultural standards. Also the DSM-5 [70] has abandoned part of the over-reliance traditionally placed on the IQ in favor of the expression of executive functions in everyday life, suggesting that the determination of levels of gravity of intellectual functioning, previously based only on the reduction of IQ, should have as main reference the level of adaptive functioning, assessed through conceptual, social, and practical skills [70, 176].

In the perspective of neurodevelopment, the impairment of cognition should be evaluated with the highest possible level of specificity, to precisely identify the dysfunctions that have the greatest impact on individual behavior, skills, adaptation, autonomy, and quality of life, during all of life [176]. It is desirable that specific neuropsychological investigative tools are progressively adapted to all levels of ID severity, spread rapidly in clinical practice and favor the establishment of a new concept of "functional neurocaracterization" [176].

Also, the neurodevelopment perspective offers the condition defined BIF, not yet codified in the ICD, a new consideration by the international scientific community and a large space in the debate on the reconceptualization of the ID. The term BIF refers to a very slight impairment of preschool onset cognitive abilities, characterized by an IQ between 70 and 85 points, with very high prevalence rates, up to 1 in 8 people [177]. The connotation of an

element of continuity between the ID and the normality that is frequently attributed to this condition must be reconsidered in the light of recent research: In fact many more commonalities have been found with people with IQ clearly below 70 than with the general population, for example, the high rates of psychiatric disorders and psychopharmacological treatments, the greater tendency to substance abuse, being more easily victims of exploitation or abuse, the type of communication and social support [177, 178].

On the one hand, in most countries of the world, people with ID still face great difficulties to access mental health services and to receive adequate assessment and treatment, on the other hand the prospect of neurodevelopment is arousing increasing interest among neuroscientists for psychiatry in this sector, both for clinical and research aspects. In recent years, there has been an increase in the production and dissemination of data on epidemiology, symptomatology, therapeutic interventions, and habilitation, even in countries with medium and low income.

Finally, the neurodevelopmental perspective has also favored a multidimensional and polysemic approach to the new classification of ID, which distinguishes between clinical metasyndromes and their declension in terms of dysfunction or disability, with different applications and implications for health and social policies. According to the first WHO ICD-11 working group, the first dimension should find an adequate place in the ICD, with the term "intellectual development disorders," while the second should be included in the International Classification of Operation, of disability and health (ICF) [175], with the term "intellectual disability," already in use for some time in the international scientific community [162]. The proposal of some researchers and clinicians to use the word "disability" also in systems of classification of disorders and diseases could have extremely negative implications for the health needs of people with this condition: The social connotation of the term could in fact offer the opportunities for healthcare providers and organizers to steal resources, already severely limited [6, 162].

The neurodevelopmental approach is currently recognized as the most valid theoretical framework to explain the relationships between genetic and environmental factors that influence brain growth and maturation with subsequent effects on general and specific impairments of functioning and to support multidimensional, transnosographic, interdisciplinary approaches to the study and treatment of neurodevelopmental disorders and psychiatric disorders.

Tip

A systematic approach to differential diagnosis involves a thorough consideration of all candidate diagnoses to yield the most accurate classification, with attention to be primarily given to the age of presentation of symptoms. As a second general step, the most prominent symptom should guide the clinician in the process of considering the possible differential diagnoses. Finally, an accurate evaluation of the general functioning profile of the individual has always to be taken into account.

Key Points

- Symptoms of ASD and/or ID overlap significantly with a wide range of psychiatric conditions and in particular the recognition of ASD across the lifespan represents a clinical challenge. The diagnosis of ASD in clinical practice is often made difficult by the preponderance of differential diagnoses that should be considered, such as neurodevelopmental, anxiety, mood, psychotic, and personality disorders.
- Given the numerous overlapping symptoms among ID, ASD, and psychiatric conditions, it has to be considered that the DSM-5 has introduced an integration of a dimensional approach to diagnosis and classification together with the DSM-IV-TR categorical approach. Indeed, previous editions of the DSM used a categorical model requiring a cli-

nician to determine that a disorder was present or absent. The dimensional approach allows a clinician more possibilities to assess the severity of a condition and does not imply a real threshold from low-functioning forms to forms with very high general skills.

- Advances in the development of dimensional models and approaches to research on psychopathology made possible to find that behavioral, cognitive, social, and emotional competencies share common neurobiological bases, evolve across the brain development, and vary across individuals in different traits, abilities, or mental disorders. In this context, the neurodevelopmental perspective is gaining a central role in theorizing about the etiology of disorders. Indeed, distinctive types of psychopathology may have early onset, features in common, and different time courses in symptoms depending on the variations of the same underlying disposition.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_33

Learning Objectives

- To become aware of the high prevalence of hearing, visual and dual sensory impairments in the population of people with intellectual disabilities (ID).
- To learn about adequate assessment methods.
- To learn to differentiate key phenomena of autism in people with ID and sensory impairments.
- To learn to consider communication difficulties as possible reasons for challenging behaviour in people with ID and sensory impairments and to differentiate from mental health disorders, especially in deaf individuals who use sign language.
- To learn how to improve environmental conditions with respect to the specific needs of people with hearing, visual and dual sensory impairments and ID.
- To learn how to avoid unnecessary stress for people with sensory impairments by using proper announcement and information strategies.
- To learn to acquire a responsive communication style and knowledge about different communication modes like sign language and tactile communication.
- To learn how to improve communication abilities in individuals with ID and sensory impairments and in all people who are part of their social network like family members, peers and professionals.

33.1 Introduction

Impairments of sensory functions in people with intellectual and multiple disabilities stay frequently unrecognised. Abnormalities and delays in information processing and behaviour are frequently attributed to cognitive dysfunctions only. This 'overshadowing' leaves sensory impairments undiagnosed.

This chapter aims to give an overview on prevalence rates of the combination of sensory impairments and intellectual disabilities. Assessment methods and therapeutic consequences, especially with respect to improving communication, will be highlighted. Challenging behaviour and autism spectrum disorders occurring in people with sensory impairment and intellectual disabilities will be discussed. Practical aspects regarding the design of environments in ways that accommodate the needs of people with sensory impairments and intellectual disabilities will be pointed out. Furthermore, the chapter will close with practical aspects focusing on the improvement of communication.

33.2 Definition and Epidemiology

Various studies have investigated the prevalence rates of sensory impairments and intellectual disabilities in the past. The rates vary depending on the methodology (assessment or questionnaire) and the definition used for sensory impairments. Studies collecting data from questionnaires might be influenced by the subjective information given by staff or family members and, therefore, may not be completely accurate [1].

33.2.1 Visual Impairment and Intellectual Disability

Definition of Visual Impairment

The WHO defines visual impairment as a visual acuity of less than 0.30 but more than 0.05 and/or visual fields less than 30° around a central fixation point. Blindness is defined as a visual acuity of less than 0.05 and/or visual fields of less than 10° [2].

Prevalence of Visual Impairments

Globally, 0.48% of the population is blind, 2.95% are moderately to severely visually impaired, and 2.57% have a mild visual impairment [3].

Prevalence rates of visual impairments in people with intellectual disabilities are varying according to different methodologies used in studies. A study conducted by Warburg in 1994 showed that there was only consensus in 32% of the cases when estimates of caregivers and clinical assessments were compared [4].

A study in Copenhagen, Denmark, looked at a representative group of 778 people, attending therapeutic working programs and day structures. It showed that after the assessment of the visual function, 20% of the participants were attested with a visual impairment. After they received adequate visual aids, 10% of them were still permanently visually impaired. The most common causes identified were excessive myopia, cortical visual impairment, optic atrophy, cataract and keratoconus. The study concludes that the prevalence rate for visual impairment in adults with intellectual disabilities is 10 times higher than would be expected when compared to a sample of the general population [4, 5].

In the Netherlands, a large-scale epidemiological study including 1598 adults with intellectual disabilities was conducted in order to gain more information on the prevalence of visual and hearing impairments within this population. Even though the results found in this study cannot be extrapolated to the entire adult population with intellectual disabilities in the Netherlands, it can still be assumed that a large number of participants portray a reliable reflection of this population. The results show that visual impairments were present in 13.5% and blindness in 5.7% of the study population. Visual impairment had been newly diagnosed in 42.6% and blindness was not diagnosed in 35.9% prior to this study. In total, in 40.6% of the cases, the visual impairment had not been diagnosed before. These results are in line with the numbers other studies have found in the same group of population and are partly traced back to the overshadowing effect [6].

A study conducted in Austria had the aim to investigate the proportion of previously undiagnosed deafblindness in a large sample (224 participants with available data) of persons with intellectual disabilities living in congregate settings. All participants were enrolled at a facility called 'Hartheim', which offers high standard care for people with profound, severe and moderate intellectual disabilities. All people living in this facility are seen by a general practitioner prior to admission, and medical check-ups are done regularly. For this study, all participants had their vision re-assessed. The assessment identified 21.4% of the total sample with a previously undiagnosed visual impairment (see Table 33.1). It was apparent that ophthalmic pathology was more often diagnosed compared to hearing impairment. This could also be observed in the Dutch sample [7].

The Metropolitan Atlanta Developmental Disabilities Surveillance Program (MADDSP) was established in 1991 and the main goal is to estimate the prevalence of children in the metropolitan Atlanta area with one or more

Table 33.1 Visual impairments previously and newly detected by severity of impairment in 224 residents with intellectual disability [7]

	Before assessment *n* (%)	Newly detected *n* (%)	Total after assessment *n* (%)
Visual impairment			
Severe/profound (VA < 0.1)	20 (71.4%)	8 (28.6%)	28 (12.5%)
Moderate (0.1 ≤ VA < 0.3)	18 (31.0%)	40 (69.0%)	58 (25.9%)
Total	38 (17% of 224)	48 (21.4%)	86 (38.4%)

developmental disabilities. The disabilities looked at included cerebral palsy, hearing loss, intellectual disability and vision impairment. In 1996, autism spectrum disorder was added to the list. The method that is used is called 'active record review' and means that, every other year, trained staff get information from various health and educational sources. From the years 1991 to 1994, children between the ages of 3 and 10 were included. Starting in the year 2000, only 8-year-old children were included. By that age, it is assumed that most children with developmental disabilities have been identified for services [8]. This large study found that intellectual disability was the most common co-occurring developmental disability in people with visual impairment, present in 55% of visually impaired people. The prevalence rate was stable between 1991 and 2010 [9].

Van den Broek reported in line with other studies higher prevalence of visual impairments in people with more severe degrees of intellectual disabilities [10].

Evenhuis et al. investigated whether visual impairment causes impact on adaptive skills in people with intellectual disabilities. Research shows that, in the general population, visual impairment causes problems with daily activities. This study found that with an increase in intellectual disabilities and an increase in visual impairment, adaptive behaviour decreases. The study had five hypotheses. Firstly, they hypothesised that independent of the severity of intellectual disability, lower vision was associated with a decrease in independent living skills. Further, they assumed that lower vision increased the difficulties in communication. Thirdly, they associated lower vision with more insecure movements. Additionally, visual impairment was associated with more self-absorbed and withdrawn behaviour. Finally, it was assumed that lower vision was associated with less antisocial and disruptive behaviour. This study finds that, generally, the effects caused by intellectual disability are larger than the effects of the visual impairment. Independent living skills, communication and social skills are mainly affected by the intellectual disability, but as expected, visual impairment does add to this. The study found that, contrary to their hypothesis, visual impairment is not related to a more self-absorbed behaviour. In the subgroup of people with severe intellectual disability, lower vision was associated with less anxiety. The last hypothesis was also not confirmed, disruptive and antisocial behaviour did not decrease with lower vision [11].

Dijkhuizen et al. investigated the impact of visual impairment on the ability to perform daily living activities in a sample of 240 people with intellectual disabilities. The Barthel index was used to measure the ability to perform daily activities and the locomotor functioning was operationalised through measuring the comfortable walking speed. The outcome of the study is in line with the study by Evenhuis et al. and shows that, in people with intellectual disabilities, visual impairment only slightly affects the ability to perform daily activities [12].

Assessment Methods and Refractory Correction

People with intellectual disabilities may have difficulties communicating a worsening of their sensory abilities due to language deficits. Therefore, sensory impairments often become evident when behaviour changes, which in many cases is misinterpreted as the person being non-cooperative [13].

Generally, in this population it is recommended that visual functions are regularly evaluated by the use of more than one assessment method. This increases the reliability of visual acuity measurement [6, 14].

The assessment of visual function often proves to be more difficult in people with intellectual disabilities due to problems in communication and understanding. The assessments rely on subjective responses, which might be difficult to elicit. For the assessment of the visual acuity in people with mild-to-moderate intellectual disabilities, a high-contrast logMAR letter or symbol acuity charts are suitable [15]. For people with more severe intellectual disabilities, the Teller Acuity Cards [16], which are grating cards with contrasting stripes, can be used. This test makes use of a

forced choice procedure based on the tendency of people to preferentially look for contrast. The assessment includes the observation of the patient's direction of gaze. The stripes become progressively narrower, with the size of the smallest stripes seen determining the visual angle and, thus, the visual acuity [7]. The Pacific Acuity Test, originally a test to measure recognition of visual acuities in preverbal children, has also proven to be suitable to use for people with intellectual disabilities [17]. If people are not familiar with letters or shapes, objects that are known from daily life can be used [15].

Restrictions of the visual field might explain certain behaviours or the failure to do certain activities. Usually, it is difficult to do an automated static visual field assessment in people with intellectual disabilities; therefore, modified confrontation testing, such as the Stycar graded balls test, is well suited [18]. Additionally, attention should be put on eye movement and head turns towards peripheral targets [15].

If possible, subjective refraction measurement can be performed, if the intellectual level of the person does not allow this, then retinoscopy should be done to measure the refractive error of the person's eye. In the last part of the assessment, the doctor looks at the ocular health. This can be particularly challenging in people with intellectual disabilities. Due to difficulties in sitting still, it is important to use portable equipment [15].

Findings regarding the treatment were as alarming as the high prevalence rate of undiagnosed visual impairments. In many cases, individuals did not wear glasses. It has been observed that people with intellectual disabilities receive less eye care compared to the general population [13]. Previous studies have also found that the prescription rate for glasses is much lower in people with intellectual disability [19]. It is difficult to predict how a person with intellectual disability will respond to wearing glasses and how big the benefit of it would be, nevertheless, doctors should not decide about the appropriateness basing only on the presenting behaviour, but ideally trial the effectiveness of the glasses and then observe the behaviour [15]. There are various reasons found in the literature to explain this, one of them highlights the misconception that people with intellectual disabilities have less visual demands. It is often argued that people with profound intellectual disabilities do not participate in activities that would require good vision and, therefore, it is said that glasses would be of little use. It is important though to look at this phenomenon the other way around. Could it be possible that the visual impairment is the reason for disengagement? Another explanation could be that physicians are sometimes facing challenges such as limited specialised training, difficulties in communication, inadequate information prior to the assessment and eventual presence of challenging behaviour in persons with intellectual disabilities. The Functional Vision Assessment (FVA) for people with learning disabilities [20] can help to evaluate different aspects of visually related symptoms and behaviour. There are checklists for seven domains: appearance of the eyes, behaviour, central vision, peripheral vision, sensitivity to light, colour vision and contrast sensitivity and poor vision in one eye. These checklists can support the history taking with the patient and, furthermore, can sensitise the carers to look out for visual and ocular health [15].

- About 35% of individuals with intellectual disability have visual impairments.
- Severity of intellectual disability correlates with severity of visual impairment.
- Half of the co-existing visual impairments stay undetected without proper assessments, which should lead to correction of refractive errors.
- Assessment methods that make use of the tendency to preferentially look for contrast are beneficial

33.2.2 Hearing Impairment and Intellectual Disability

Definition of Hearing Impairment

Hearing loss can be categorised into four different groups. Mild hearing loss is present from 20 to 30 dB, and moderate hearing loss is

up to 69 dB. Within this definition, severe hearing loss is up to 94 dB and profound hearing loss is higher than 95 dB [13]. People suffering from mild to severe hearing loss are also referred to as hard of hearing. The World Health Organization uses the definition of disabling hearing loss if the hearing loss is greater than 40 dB in the better ear. Hearing loss can be either due to congenital causes or acquired causes. Congenital means that the hearing loss is already present or acquired soon after birth. Globally, the most prevalent reasons for hearing loss are maternal rubella, low birthweight and birth asphyxia. Acquired hearing loss can occur at any age and the most prevalent factors include infectious diseases (meningitis, measles and mumps), chronic ear infections, excessive noise, and ageing. Among children, chronic otitis media is a common cause of hearing loss [21].

Prevalence of Hearing Impairment

According to the Metropolitan Atlanta registry between the years 1991 and 2010, the prevalence rate of moderate-to-profound hearing loss was 1.4 per 1000 children with an average change of 0.93% per year. Forty-seven per cent of the children have moderate hearing loss, 23% have severe hearing loss and 31% have a profound hearing loss. The prevalence rate was stable throughout the years across all severity levels. The most common co-occurring developmental disability was intellectual disability, present in 23% of the children. Looking at it the other way around, 3% of all 8-year-old children with an intellectual disability have a co-occurring hearing loss. A significant increase could be found for the years 1991 and 2010. The increase ranged from 0.02 to 0.03 per 1000 children, with an average yearly increase of 2.4% [9].

The prevalence rate of hearing impairments in adults with intellectual disabilities varies depending on the methodology of the studies. A Dutch study which investigated visual impairments in 1598 adults with intellectual disabilities also investigated the prevalence of hearing impairments in this population. The results show that 35.8% of the study population have a hearing impairment, and 47.6% out of them did not have a diagnosis prior to the study. There was no significant relationship between the degree of intellectual disability and the hearing impairment. The re-weighted prevalence of hearing impairment to the total population with intellectual disability was 30.3%, which is almost twice as high as the prevalence in the general population (16–17%). The important message of this study is that almost half of the hearing impairments have not been diagnosed before structured assessment [22].

The previously mentioned Austrian study conducted in Hartheim ($N = 224$) found that 46% of the individuals with intellectual disability have a hearing impairment. Prior to the study 72.8% (75 of 103) did not have a diagnosis of hearing impairment (see Table 33.2) [7]. This high number of undiagnosed hearing impairment, both in this and in the study from the Netherlands, shows the importance of proper assessment in populations with intellectual disabilities.

A study by Timehin et al. found a prevalence rate of 9.2% of hearing impairment in people with learning disabilities. Only 12 people out of 50 have ongoing assessments and hearing aid maintenance. Further, only three-quarters of the participants have their hearing checked at some point in their life [23].

Assessment Methods and Hearing Aids

Checking the otoacoustic emissions proves to be an ideal screening method for people with intellectual disability, after cleaning the external auditory canal from cerumen (in many cases necessary) [24, 25]. Depending on compliance, behavioural audiometry, puretone audiometry and speech audiometry can be used. If the target population does not show compliance, the last step in the diagnostic process is brain stem audiometry, which requires general anaesthesia.

Once the diagnosis of hearing impairment is made, hearing aids should be fitted. However, in people with intellectual disabilities, the use of hearing aids is often not tried, or fails. This is because it is assumed that they

Table 33.2 Hearing impairments previously and newly detected by severity of impairment in 224 residents with intellectual disability [7]

	Before assessment *n* (%)	Newly detected *n* (%)	Total after assessment *n* (%)
Hearing impairment			
Profound: hearing loss ≥90 dB	10 (90.9%)	1 (9.1%)	11 (4.9%)
Severe: 70 dB ≤ hearing loss <90 dB	6 (46.1%)	7 (53.9%)	13 (5.8%)
Moderate: 40 dB ≤ hearing loss <70 dB	10 (16.9%)	49 (83.1%)	59 (26.3%)
Mild:25 dB ≤ hearing loss <40 dB	2 (10%)	18 (90%)	20 (8.9%)
Total	28 (12.5% od 224)	75 (33.5% of 224)	103 (46% of 224)

would not easily accept hearing aids [26]. A constant effort and careful process of adaption are needed to encourage people with intellectual disability to use hearing aids [27]. In a study with 16 people with mild-to-moderate intellectual disability, the acceptance of hearing aids was tested. The participants were interviewed before and 6 months after fitting with hearing aids. The questions asked evolved around the topics of benefit, cosmetics and self-image, sound quality/acoustics, comfort and ease of use and service. Most of the participants were aware of their hearing impairment and understood why they were fitted with hearing aids. Furthermore, similar as in the general population, the perceived benefits of hearing aids played an important role in the acceptance. The authors concluded that the people with mild-to-moderate intellectual disability are able to express their opinion and experience with hearing aids, given that they are asked simple questions [28].

The fitting with hearing aids is only one important aspect; central issues such as communication and environment will be discussed in the last chapter 'practical issues'.

- About 40% of individuals with intellectual disability have hearing impairments, and about 75% do not have diagnosis prior to systematic assessment.
- Severity of intellectual disability does not correlate with severity of hearing impairment.
- Otoacoustic emissions are a proper screening method.
- The use of hearing aids requires constant efforts.

33.2.3 Dual Sensory Impairment and Intellectual Disability

Prevalence of Combined Visual and Hearing Impairment (Deafblindness)

In the year 2004, the European Parliament classified 'deafblindness as a distinct disability, that is a combination of both sight and hearing impairments, which results in difficulties having access to information, communication and mobility' [29].

It is important that this declaration not only uses the word 'deafblind' but that it also includes people with moderate impairments of vision and hearing. This takes into consideration that a dual sensory impairment causes a greater degree of impairment than the sum of each impairment individually, which not only affects the communicative and social development but also the quality of life [30]. A person is considered deafblind when the hearing loss in the better ear is more than 35 dB and the vision

is less than 0.3. Evenhuis suggests a more conservative definition of hearing loss greater than 25 dB in people with intellectual disability [25].

The Dutch cross-sectional study, which also included a high number of people with mild intellectual disabilities, identified 5% with a visual and hearing impairment, of which 2.9% were younger than 50 years of age. A specific risk factor identified was Trisomy 21. The more severe the intellectual disability, the more often deafblindness was present [31].

The Austrian study that focused on the detection of deafblindness in people with intellectual disabilities identified 21.4% of the participants with a combined visual and hearing impairment (see Table 33.3) [7]. This number is close to the prevalence rate of 20% that was found in 2001 in a large Dutch Institution in a group of people with severe and profound intellectual disabilities [32]. More severe forms of deafblindness were more likely to be detected. There was no correlation between the severity of deafblindness and the level of intellectual disability. But more severe intellectual disability was related to a higher prevalence of combined sensory impairment. Failure to identify the various degrees of deafblindness is common among those with intellectual disability and is most common in those with profound intellectual disability. This emphasises the need for awareness training for staff members as well as appropriate assessment methods [7].

In this study [7] as well as in a Danish prevalence study [33], Trisomy 21 was identified as a further risk factor.

- Deafblindness is a distinct disability and is defined as a combination of both sight and hearing impairments.
- About 20% of individuals with intellectual disability have dual sensory impairments.
- More severe intellectual disability is related to higher prevalence of dual sensory impairments.
- Especially individuals with Trisomy 21 are at risk for acquiring dual sensory impairments; regular assessments are needed.

33.3 Intellectual Disability, Sensory Impairment and Autism

Prevalence of autism spectrum disorder in people with intellectual disabilities is much higher compared to the normal population. Similarly, the prevalence rates of autism spectrum disorders in people with sensory impairments are also much higher, but there are no studies that give exact numbers. Existing literature suggests two different explanations. Firstly, a relationship between autism spectrum disorder and sensory impairment and intellectual disabilities is

Table 33.3 Hearing impairments and visual impairments previously and newly detected by severity of impairment in 224 residents with intellectual disability [7]

Category of deafblindness	Known before assessment	Newly detected	All deafblind	% newly detected residents
Profound/severe hearing & visual impairment	4	1	5	20%
Moderate hearing & profound/severe visual impairment	2	14	16	87.5%
Profound/severe hearing & moderate visual impairment	1	9	10	90%
Moderate hearing & visual impairment	1	16	17	94.1%
Total n (%)	8 (3.6% of 224)	40 (17.9% of 224)	48 (21.4% of 224)	83.3%

assumed. The second thesis postulates an overlap of symptoms, which lead to false-positive diagnoses, which subsequently are the reason for the high prevalence rate in this population. The risk that autism spectrum disorder is missed or unjustly diagnosed in people with intellectual disabilities and sensory impairments is often due to the similarities in behaviour. The importance of a correct diagnosis cannot be highlighted enough, when thinking of the right treatment plans that differ greatly whether an autism spectrum disorder is the cause or not. Even though the ICD-11 criteria for autism spectrum disorder include qualitative impairment in social interaction, qualitative impairment in communication and restricted patterns of behaviour, interests and activities, these aspects can also be found in people with intellectual and sensory disability, although they are usually expressed in a different way.

Difficulties in the following areas, reciprocity and peer relationships, verbal and non-verbal social behaviours, joint attention and theory of mind, making conversations, language, imitation and make belief or symbolic play, stereotyped use of objects and self-stimulation, occur in people with autism spectrum disorder as well as in people with intellectual disabilities and sensory impairments. The origins differ depending on the impairment. It is important to focus on the small differences in the way the symptoms are expressed in order to make the right diagnosis and decide for the correct treatment. The lack of suitable instruments to diagnose autism spectrum disorder in people with multiple impairments adds to the difficulties to differentiate between all the overlapping symptoms [34].

Deafblindness and Intellectual Disabilities and Autism

Research shows a positive correlation among dual sensory impairments, intellectual disabilities and autism [1, 35, 36]. It is, therefore, assumed that deafblind people have a higher risk for autism spectrum disorder. The same risk of overdiagnosis that appears to be present in people with single sensory impairments also seems to be present in people who have dual sensory impairments [37].

All three of the components of autism mentioned above can also be found in non-autistic people with sensory and intellectual disabilities [34].

People who are deafblind often show similar behaviours with regards to social interaction as people with autism spectrum disorder. In deafblind people, their lack of social interaction is often a result of their dependency on others to start the initiative. For them these situations are often frightening because they miss out on important context-relevant information. Qualitative impairments in communication can also be found in people who are deafblind. They, similar to people who are autistic, have problems with identifying and understanding non-verbal communication. Many people with autism spectrum disorder show a delay or lack of spoken language. In people who are deafblind, spoken language is often absent due to their hearing impairment. Further, they can only communicate to people who are trained in tactile sign language, which restricts the size of their social environment. Both people with autism spectrum disorder as well as deafblind people can show stereotyped and repetitive behaviour. In the latter, the behaviour will decrease with age and with an increase in opportunities to communicate [37].

Differential Diagnosis

The important question that has to be asked is whether the observed behaviour is caused by autism spectrum disorder or by the sensory impairment. For example, when looking at repetitive behaviour, it is assumed that in people with deafblindness it is caused by sensory and social deprivation, whereas in people with autism spectrum disorder it is considered as a way of coping with overstimulation. The different causes of the symptoms highlight the importance of the right diagnosis in order to make the correct treatment plan [37].

Until 2009, it was difficult to differentiate between characteristics in clinical practice because existing tests were not validated or reliable to use with people with deafblindness.

Hoevenaars-van den Boom et al. designed an instrument called 'Observation of characteristics of autism in persons with deafblindness' (O-ADB), which is a semi-standardised observation instrument adapted to identify the competencies and skills of deafblind people. The instrument scores the quality and the frequency of the target behaviours [37].

The instrument was used in a study with 10 deafblind people with intellectual disabilities and with and without autism spectrum disorder. The results showed that the instrument was suitable for the differentiation between deafblind people with and without autism, especially in the domains 'openness for contact', reciprocity in contact including 'joint attention' and 'communicative functions'. The participants with autism were rated significantly lower than the participants without autism. No differences were found in exploration, play and problem-solving behaviour. The same applies for stereotyped behaviour. These categories are not well suited to differentiate because baseline levels are too high, meaning that the prevalence is also very high in people with sensory impairments without autism [37].

- In people with intellectual disability, autism spectrum disorder and dual sensory impairments have overlapping symptoms.
- To differentiate between autism and deafblindness, it is necessary to implement proper treatments.
- The domains 'openness for contact', reciprocity in contact including 'joint attention' and 'communicative functions' are most suitable to establish a proper diagnosis.

33.4 Intellectual Disability, Sensory Impairment and Challenging Behaviour

Limited understanding was associated with the highest relative risk for aggressive-destructive behaviour (RR:3.8 [1.7–8.5]) in a study including the total population of people with intellectual disability in Jersey, UK [38].

A meta-analysis by McClintock identified risk markers associated with challenging behaviour in people with developmental disabilities. Problems in both receptive and expressive communication were significantly correlated with self-injury. Difficulties in expressive communication were additionally significantly linked with aggression towards others [39].

These findings indirectly address the problems of individuals with intellectual disabilities and sensory impairments (especially when hearing is affected), who frequently suffer from communication problems.

Challenging Behaviour in People with Disabilities and Hearing Impairments

In their review with the title 'Risk factors leading to behavioural problems in individuals with hearing impairments and intellectual disabilities', Buskermolen et al. complain about the scarcity of studies on challenging behaviour in people with both hearing impairment and intellectual disability and mention that they found only Timehins' publication to give a prevalence rate [40].

Timehin et al. showed in a sample of 543 residents of homes affiliated to the learning disability trust (Lifecare NHS Trust, locality 4) that 9.2% of the sample had a hearing impairment and 42% out of them were profoundly deaf. The prevalence rate of challenging behaviour was 62% within the sample. Thirty-four per cent of the people showed self-injurious behaviour. They also point out that hearing impairments in people with intellectual disabilities are not always identified and that challenging behaviour can be seen as a form of communication for people with limited language abilities. Therefore, they emphasise the importance of paying attention to the link between a possible undiagnosed hearing impairment and challenging behaviour [23].

Buskermolen et al. designed a new assessment instrument called the 'Individual Behaviour Observation and Recording Scale' to assess challenging behaviour in people with intellectual disability and hearing impairment. After they did a review of the existing instruments, they decided that none of them

were adequate for the target population. Taking into account that every behaviour should be considered as some form of communication, it was important for them to create a scale with an emphasis on non-verbal signals. The authors set the following requirements for the observation and recording scale: 'A variety of non-verbal behavioural aspects must be measureable. There must be room for individual behavioural descriptions. The severity of problem behaviour must be measurable. There should be room for several records per day. It should be filled in by professional carers. It must be efficient and easy to use for every carer' [41 p. 33].

The scale consists of five different levels of behaviour (relaxation, slight restlessness, tension, threat and loss of control) and eight different dimensions of behaviour (making sounds, locomotion, facial expression, object manipulation, body manipulation, concentration, expressive communication and receptive communication). A total of 40 individual behavioural descriptions are needed to fill in the scale. Emphasis was put on the recording of individual behaviour [41].

Buskermolen et al. (2016) used the questionnaire in a sample of 21 people with intellectual disabilities and hearing impairments. The cognitive level of the participants was given in developmental age and ranged from 1.3 years to 8.1 years. The hearing loss was measured with the Fletcher Index and the measurements were between 40 and 110 dB. Furthermore, 10 of the participants were diagnosed with autism spectrum disorder. Additionally, the communication abilities and the level of social independence were measured. During the 1-year period of the study, all participants experienced challenging behaviour at some point of time. In the person showing the least challenging behaviour, it was recorded in 1.8% of the time, and the person with the most challenging behaviour showed it in 75.4% of the time. The average was 28.9%. The authors could find a significant negative correlation among challenging behaviour, age, level of social independence and communicative development. This means that people who were socially more independent and who had higher levels of communication showed challenging behaviour on fewer occasions. Further, autism spectrum disorder as a comorbidity had a significant influence on challenging behaviour and was, therefore, identified as an important risk factor [42].

Challenging Behaviour in People with Intellectual Disabilities and Visual Impairments

In a systematic review on challenging behaviour in people with physical and intellectual disabilities, de Winter found a significant correlation between challenging behaviour and visual impairment. Visual impairments were significantly associated with self-injurious behaviour but not with aggressive behaviour. The three studies that looked at sensory impairment and challenging behaviour were of varying quality. The first study by Evenhuis et al. [11] investigating visual impairment and challenging behaviour did not find a significant relationship. The second study by Wieseler et al. [43] found that people with self-injurious behaviour were more often diagnosed with visual and hearing impairment. The last study also investigated self-injurious behaviour and found a high prevalence of visual impairment in eye-poking children. These children often also experience other self-injurious behaviours [44].

In a large Scottish cohort study, Cooper et al. looked at factors that influence the prevalence of self-injurious behaviour in 1023 people with intellectual disability and found a prevalence rate of 4.9% and a significant association with visual impairments [45].

However, these correlations cannot establish causation. Visual impairment might be the reason for the self-harming behaviour, or the other way around that the tissue damage causes the visual impairment [45, 46].

Challenging Behaviour in People with Intellectual Disabilities and Dual Sensory Impairments

Carvill stated in a narrative review that people with intellectual disabilities combined with sensory impairments are often more at risk for developing behavioural problems/challenging behaviour and mental health problems [1]. In 2002, Carvill conducted a case

series with 18 people with intellectual disabilities and sensory impairments in order to investigate behaviour disorders within this population. Most of the participants had dual sensory impairments due to maternal rubella infections during pregnancy and only a few of them had a single sensory impairment. It was evident that the majority of them got referred because of self-injurious behaviour and aggression. In 10 out of the 18 patients, an ICD-10 diagnosis could not be made. This was either due to the unusual behavioural presentation or their degree of intellectual disability. In 15 cases, pervasive developmental disorders were identified. One of the conclusions of the study was that the assessment of psychiatric disorders in people with intellectual disabilities and sensory impairments is problematic, and the difficulties increase with the degree of intellectual disability. It was recommended to gather detailed information from various sources. For behavioural problems in this population, diagnostic overshadowing was highlighted as a reason for long delays in getting proper diagnoses and treatments [47].

Dammeyer showed that within a group of 95 deafblind people, 75% have a psychiatric or behavioural diagnosis [48].

In order to adequately address the needs of people with intellectual disability and sensory impairments who show challenging behaviour, Carvill [49] and Fellinger et al. [7] mention the importance of secured communication as well as experience with people with sensory impairment and intellectual disability in order to identify even small anomalies. Further, the sensitive usage of external sources of information is emphasised.

- Challenging behaviour is frequently associated with communication problems.
- High rates of challenging behaviour in people with intellectual disability and sensory impairments are reported.
- Mental state examination in signing prelingually deaf individuals requires specific experience.

33.5 Intellectual Disability, Sensory Impairment and Psychiatric Disorders

While it is important to consider challenging behaviour as a consequence of communication problems, as well as a number of associated psychological and/or environmental factors, it is also essential to assess their possible nature of symptoms of psychiatric disorder. Especially in prelingually deaf individuals with language deficiency, a mental state examination is difficult, particularly for clinicians with little experience with signing deaf people [50]. Table 33.4 summarises important aspects of a mental state examination in deaf individuals.

Having detected psychopathology in a deaf person with intellectual disability, the treatment plan has to consider the specific communication needs by involving signing experts or sign language interpreters. Support by professional deaf staff is highly recommended also in deaf psychiatric patients with limited sign language skills [50].

When it comes to medication, one has to be specifically cautious with respect to extrapyramidal side effects that might impact vision or hamper communication in sign language ([52] pp. 249–251). In some countries, psychiatric units for deaf people are also accessible for deaf people with intellectual disability including those who need forensic settings [53].

Studies that indicate whether there are higher prevalence rates for specific psychiatric disorders in individuals with intellectual disability and sensory impairments are scarce and hardly population based.

From studies in deaf populations without intellectual disability, one can deduce that increased rates of depression and somatoform disorders can also be expected in deaf individuals with intellectual disability [51]. As far as psychotic disorders are concerned, especially in individuals with congenital rubella, the likelihood to suffer from non-affective psychosis was reported to be five times higher than healthy controls. Brown could also show in his mixed deaf and hearing sample with normal

Table 33.4 Mental state examination of deaf individuals ideally undertaken by signing specialist

Appearance	Deaf people using visual communication modes (sign language and gestures) might give a misleading impression of being agitated. Nevertheless, some seem to be withdrawn or anxious, potentially because of a reaction to the inability to communicate with medical staff and so this can be a result of the situation and not a symptom of a mental health disorder
Affect	In sign language, facial expressions not only represent emotions but also have specific linguistic functions. Some problems such as low drive can be made clear by the clinician imitating the symptoms – for example, looking listless and apathetic. Judgement of whether the patient shows affect appropriate to the topic being discussed could be hindered by poor communication
Thought	Language dysfluency might be wrongly believed to be a result of thought disorder. There is evidence that thought disorder often manifests itself in sign language in a bizarre quality and a meaningless repetition of signs. Signing to oneself might be a symptom of psychosis
Cognition	Many deaf people have reduced access to information. Poor knowledge should never be attributed to low intelligence without proper assessment. In many cases, information from external sources about behavioural and language functions is helpful, but such outside information should not prevent the patient from being able to express himself or herself [51]

Taken from Fellinger et al. 2012 [51]

IQ and congenital rubella that the fact of infection and not deafness itself was the main factor contributing to these high prevalence rates [54].

Besides rubella infections during the first trimenon causing dual sensory impairment, Usher syndrome is one of the most prevalent genetic etiologies, with prevalence rates of 3–5 per 100,000 in the general population. Different subtypes are characterised by retinitis pigmentosa and sensorineural hearing loss and problems in balance. Hallgren reported an association of Usher syndrome and psychosis in 23% [55], whereas more recent studies suggest prevalence rates of about 4%. This is still four times higher compared to the general population [56–58].

In other syndromes with deafblindness like CHARGE syndrome[1] and Wolfram syndrome,[2] a high likelihood of co-occurring mood disorders and/or psychotic symptoms is also reported.

With respect to specific psychopathology in people with intellectual disability, who are blind, no prevalence studies could be found. Visual hallucinatory symptoms due to sensory deprivation are attributed as Charles Bonet syndrome as long as there is no evidence for persistent paranoid ideation.

33.6 Practical Conclusions

As mentioned above people with intellectual disability and sensory impairments are highly vulnerable to stress with communication problems as a specific risk factor. In the following, measures to reduce unnecessary stress and to improve communication are introduced. It is realistic to suspect sensory impairments in a high number of individuals with intellectual disability. Therefore, all of the following recommendations can be of general value.

33.6.1 Structured Time and Environment

- **Announcement Strategies and Structured Schedules**

Lack of information in advance for people with visual and hearing impairments has to be

1 CHARGE syndrome: C – coloboma of the eye, central nercous system anomalies; H – heart defects; A – atresia of the choanae; R – retardation of growth and/or development; G – genital and/or urinary defects; E – ear anomalies and/or deafness.

2 Wolfram syndrome: diabetes insipidus, childhood-onset diabetes mellitus, a gradual loss of vision caused by optic atrophy and deafness.

acknowledged as a relevant source of distress [59]. Therefore, appropriate announcement targeting the functional senses (for deafblind people, e.g. vibration or draft) is crucial to prevent surprise by external stimuli. Picture boards, if necessary with haptic elements (e.g. magnetic boards), depicting the daily routine, can give an accessible structure and contribute to reducing unnecessary stress reactions. People with intellectual disabilities and sensory impairments can use them independently to plan upcoming events or to deal with challenging activities in advance. In congregate settings, the use of picture cards (haptic symbols) of staff who is on duty has proven to be helpful. Just as important as preparing for future activities is dealing with past events by creating, for example, a visual (haptic) personal diary.

An appropriate design of the environment according to the needs of individuals with sensory impairments is a crucial precondition not only for quality of life but also for stress reduction, communication and mobility.

Acoustical Design of the Environment

Background noise reduction makes the target sound more accessible for people with intellectual disability and sensory impairments. Visits to congregate settings for people with multiple disabilities as well as congregate settings for the elderly have shown that often there is a lot of unnecessary background noise polluting the auditory environment. It is important to explain the consequences of background noise on the communicative atmosphere to the staff and find ways to keep radios and TVs switched off. It might be a good idea to mention in the house rules that undirected constant sonication should be refrained from. Room acoustics are particularly important. For reverberant rooms (glass surface, smooth walls and hard floors), the most effective measures (in this order) are the installation of acoustic ceilings with a high insulation value, the usage of soft materials for the floors (e.g. carpets instead of tiles) as well as curtains and wall hangings. The use of felt gliders on chair and table legs particularly in dining rooms can reduce background noise. When designing new living and working environments for people with intellectual disabilities and sensory impairments, the cooperation with experts with knowledge of room acoustics is advisable. Particularly, people with hearing impairment are easily distracted in their visual attention, therefore, it is crucial to avoid 'visual noise' (e.g. constantly switched on TV).

Adaptation of the Environment with Respect to People with Visual and/or Dual Sensory Impairment

Visual and dual sensory impairment is a high-risk factor for falls and accidents; therefore, it is important to design the environment in a way that supports the person to use touch and smell for orientation [13]. Contrasts can be of additional help for orientation (e.g. door frame, edge of a table and edge of a plate) and can, therefore, support people with visual impairment in their independence. A clear division of the rooms into contact and recreation zones can be helpful. It is especially important that nothing unexpected is put somewhere without informing the person about it. Easy-to-access wardrobes, possibly with haptic symbols on the doors, should be installed.

33.6.2 Interpersonal Communication

Even more important than creating an optimised environment is a constant focus on the quality of interpersonal communication.

Interaction Style That Fosters the Development of Communicative Abilities

Communicative deprivation during childhood is an additional difficulty, especially when parents did not communicate enough using an adequate communication mode. This childhood experience has a strong negative effect on people with an intellectual disability and sensory impairment. In order to improve communicative abilities in this population, it is important to develop a high sensitivity towards the communication partner with intellectual disability and sensory impairment by giving her/him enough opportunity to actively participate in the communication. It

is very important to respond to the signals the communication partner with intellectual disability and sensory impairment is sending. Being the dominant part of the conversation can be avoided by giving the person with sensory impairment enough time to process the information and respond.

Interaction with Deaf Individuals

The development of communicative abilities especially in deaf people with intellectua disability has to be a constant priority. The following bullet points (taken from Fellinger et al. [51]) highlight some practical aspects for successful communication with deaf individuals.

- Engage the person warmly and directly with eye contact as often and for as long as possible. Make it clear when focus needs to shift away.
- Ask the person about his or her preferred communicative approach. If it is sign language, collaborate with a signing professional or with a qualified interpreter.
- Be aware of the restricted effectiveness and fatigue of lip reading. Add clear visual elements to discourse – for example, gestures; writing notes and use of simple, key words and grammar, drawings and many visual aids.
- When speaking, ensure that the person has the best possible view of your face. Do not stand in front of a light source (e.g. window or lamp).
- When speaking, use simple language and short sentences. Speak at a natural speed and volume. Give clear, concrete examples, and avoid vague, general terms and jargon.
- Avoid simultaneous comments. Communicate first and then act.
- Accept that good communication with deaf people takes more time.
- Check for comprehension. Ask the person to summarise essential points. Do not ask whether he or she understood because nodding might not mean comprehension [51].

Use of Sign Language

Sign language is the preferred communication mode of many deaf people and signs are particularly important for deaf people with multiple disabilities even if access to this communication mode was not available in early childhood. Models of residential and work facilities, which provide constant visual communication in sign language for deaf people with intellectual disability, offer new opportunities for social learning and relationships. A recent study by the author of the present chapter shows the changes in adaptive skills profiles of eight deaf individuals with intellectual disability who are living in a fully inclusive therapeutic living community. Over a period of 12 years, particularly social awareness and community living improved in the participants [60]. Deaf professional staff members are of high value as role models and guarantee the constant use of sign language within the team [61].

Interaction with Deafblind Individuals

To identify the preferred sense for communication through an interactive assessment, as introduced by Jan van Dijk, is highly recommended for people with dual sensory impairment [62].

Fellinger et al. suggest a classification for dual sensory impairments that ranges from profound impairments in both senses, to those with profound in one but only moderate in the other and to those with only moderate impairment in both senses. Building on this, the provision of educational and care needs can be unique to each group. People in the dual profound group rely on touch and tend to withdraw into their own world of stereotypes and self-stimulation. Individuals with profound visual impairment and moderate hearing impairment rely mainly on touch. They can be alerted by clear auditory stimuli. Help can be provided with tactile cues and orientation. People with profound hearing impairment and moderate visual impairment can participate in social activities, but they are often having severe difficulties in communication. Some may benefit from simplified sign language and hearing aids. Provided that the hearing and/or visual conditions are optimal, people with dual moderate impairments can participate in social activities and are able to communicate.

Use of Tactile Communication

For not only people with dual sensory impairment but also for people with highly limited speech comprehension and a severe intellectual disability, the usage of tactile communication support is recommended. In this group of people, it is more important to identify the preferred mode of communication. This includes tactile cues, for example, the touching of the bottom lip with a spoon before feeding somebody. It is essential to give the person enough time to react after the tactile signal in order to respond with agreement or defence. Additionally, reference objects, known from everyday life, can be useful to announce imminent activities or changes, such as a sponge indicating bathing time. Reference objects can also be used as a tactile calendar to structure longer time periods and to encourage active participation in the daily life. People with prior knowledge of sign language (before deterioration of sight) benefit from tactile signs of a national sign language which means to perform signs hand over hands (Fig. 33.1). It is important to communicate the signs through leading the hands of the other person from underneath. In this way, the person with impairment has enough space to give an independent answer.

Easy-to-understand signs such as swimming movement of the arms and moving the hand to the mouth for eating are usually also understood by people without prior knowledge of sign language.

Fig. 33.1 Hands over hand communication. (Drawing by the author)

- Announcement of imminent activities and an accessible time schedule avoid unnecessary distress.
- A well-structured physical environment supports independence, especially in people with visual impairments.
- The use of sign language or tactile communication based on a responsive interaction style fosters the development of communicative and social skills.

Tip

An intellectual disability can have an overshadowing effect, especially on milder degrees of sensory impairments, which are not detected without appropriate assessment.

Key Points

- Proper assessments are necessary to detect impairments of sensory functions in people with intellectual disability.
- Awareness of the high prevalence rates of the combinations of intellectual disability and sensory impairments can improve the management of challenging behaviour and the creation of adequate environments.
- Everyone in the social environment of people with intellectual disabilities and sensory impairments should develop an attitude that encourages these individuals to actively participate in communication.
- Competences to use appropriate communication systems according to the needs of the respective individual have to be acquired and constantly implemented.
- Continuous development of communication competences of people with intellectual disabilities and sensory impairments helps to improve their autonomy and quality of life.

Acknowledgement The author thanks especially Magdalena Dall for her great engagement in undertaking searches, providing references and supporting him in drafting the manuscript.

Learning Objectives

- Formal and informal training available for medical and other staff who look after the mental health of people with intellectual disabilities in Europe and other countries.
- How advances in the understanding of mental health issues affecting people with intellectual disabilities in the last few decades changed the demand for training?
- How various national and international organisations developed specific projects for training?
- The need for a European or an international consortium to develop a worldwide training programme to standardise training in this area.

Health provision systems are typically governed and regulated by public authorities and governments and include measures for primary and tertiary health prevention as well as defining and promulgating a consistent health promotion policy. Further, governments frame and regulate the quality of the provision of services in the health system by defining, among others, standards in the basic education, training and continuous education for health professionals and paramedical professions, often in close collaboration with the respective professional guilds (e.g. national medical, psychological or psychiatric associations). With the massive rise in health-based knowledge as well as technical advances in this area, the number of specialists in the health field is steadily growing, acknowledging the scientific advances in the respective fields. The establishment of health specialists and health consultants, regulated generally by standardised and quality-controlled training curricula, contributes to quality assurance of services in the health sector. In the area of mental health, the early professionalism depicted best by the general psychiatrist, formerly taking care of people of all ages and all kind of disorders, often trained on a dual track in neurology and psychiatry, as so-called neuropsychiatrists. Many countries have established mental health professionals as specialists for children and adolescence and for adults and some for older people or for people with intellectual disabilities (ID) (i.e. learning disabilities).

Tip

In most countries in the world, there is a lack of formal structure for training doctors and other professionals who look after the mental health of people with intellectual disabilities.

34.1 Introduction

Awareness of the relevance of education and training professionals in mental health issues in people with intellectual disabilities (ID) has only be growing in the final decades of the twentieth century. Since 1980s the evidence base on mental health issues in ID is growing with a better understanding of its bio-psycho-social aetiology. Until recently mental illnesses and problem behaviours (PBs) were perceived as part of the ID phenotype caused by the underlying brain impairment [1]. Subsequently, as the underlying brain impairment of ID was seen as incurable, so was the co-morbid mental illness and PB. Similarly, psychosocial interventions and various forms of psychotherapies, including cognitive behaviour therapy (CBT), were seen as inapplicable to people with ID. Diagnostic nihilism was followed by therapeutic nihilism, as manifested in the failure to provide a systematic assessment of mental health problems in people with ID and led to the neglect in training for mental health professionals working in the field of ID.

An early textbook on mental health in ID edited in the USA by Menolascino & Stark [2] addressed this issue in a chapter on training mental health professionals. The authors reported that the upcoming de-institutionalisation of people with ID from large-scale psychiatric institutions, as early as the late 1960s, to community-based housing

facilities, had spurred the interest in providing both general and specialised training experiences in ID for mental health professionals [3]. Mental health of many of these people improved once resettled in small community-based accommodations, with more personalised support and more options for self-determination. In the USA, the new disability rights law leading to deinstitutionalisation of people with ID contributed to a better understanding of the bio-psycho-social model of mental illness and PB in this population.

The shift from institutionalised ID services to mainstream community-based provisions for people with ID called for a change in training structure for support staff. The professional skills and competencies of staff should support the concepts of social inclusion and empowerment of people with ID. Rose and colleagues' [4] systematic review of staff training in mental health in people with ID showed that effective training can improve skills, knowledge and attitudes of support staff. The authors discussed the importance of incorporating this specialised training within the generic training framework of support staff training within community services for people with ID.

With the emerging model of self-determination and inclusion, new training options in ID mental health arose. Most of the new training frameworks were implemented in Anglo-Saxon countries initially, followed a decade later by western European countries. The drivers in these training advances were the need for mental health support, as now experienced in community-based settings for people with ID [5]. The need to develop specialised mental health services exposed the need for a fundamental re-evaluation of support staff knowledge and awareness of current models and concepts in supporting people with ID. The idea was to introduce these new training frameworks founded on principles of social inclusion and person-centred care for people with ID both for staff working within the ID as well as mental health services. Educational programmes should always be based on strong evidence for their effectiveness. New training programmes should value the advances in the knowledge of assessment of mental health issues and PBs in people with ID using biological as well as psychological, cognitive behavioural and psychotherapeutic approaches [6].

Finally, two main reasons underpin the relevance of high-quality education and training need in ID mental health:

(a) High rate of mental ill health in people with ID, including PB and co-morbid additional neurodevelopmental disorders (NDDs), such as autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) [6–9].
(b) High risk of social exclusion, community placement breakdown and use of restrictive practice including inappropriate use of medication when mental illness and PB in people with ID do not receive appropriate intervention and support [6, 7, 10, 11].

In the following sections, we described how education and training is structured and organised in the field of mental health and ID, with particular reference to European countries, where the main authors of this chapter carried out most of their training activities. Examples include formal professional educational programmes providing continuing education, leading to postgraduate qualifications and online training. We have described the different organisations that are providing good-quality training for staff working with people with ID who have mental illness and PB and differences in the structure of training.

34.2 Challenges for Education and Training in ID Mental Health

Education and training frameworks in mental health and ID show a wide variation among the European countries. The *Declaration of Rome, 2003,* developed and promoted by the European Association for Mental Health and Intellectual Disability (EAMHID) [12], addresses many areas of inequality and discrimination with respect to the mental health of people with ID, with education and train-

ing of health professionals in the area of mental health and ID being one of these. The declaration calls among others for:

- *Policy makers and public administration officers to review and analyse the requirements for adequate mental health-care provision and to stimulate the development of special supports for those with ID and additional mental health problems*
- *Professionals in the care provision system to intensify their professional engagement, with special efforts in interdisciplinary collaboration, and mental health education and training*
- *Researchers to increase the scientific efforts to promote healthy mental development*
- *Finally, recognises that relatives and friends of people with ID claim intensified public awareness of this topic*

Systematic reviews on training of staff in ID and mental health are rare [13, 14]. This highlights the lack of recognition of the relevance and the need for formal training in mental health and ID nationally and internationally. Costello and colleagues [15] identified the factors promoting and hampering delivery of appropriate training for psychiatrists, psychologists and primary care physicians working in the ID field in five countries (the UK, the USA, Canada, Australia and Austria). Of these countries, only the UK has a formal nationally accredited training structure for psychiatrists working with people with ID.

A cross-sectional study, conducted by Dias and colleagues [16] in 2015, on 42 European countries, investigated the availability of ID training and found that only 23 (56%) countries provide postgraduate psychiatric training on ID. Training shows a wide variety in terms of duration and format (lessons, clinical rotations and case discussions) and a frequent exclusive reference to child and adolescent psychiatry (see Table 34.1). Only in Ireland and the UK, ID is recognised as a subspecialty of regular psychiatry training.

There seems to be a substantial correlation between a good-quality service provision and a high-quality training and education for the professionals working in the field of mental health and ID. Any service staff should be adequately trained and regularly updated, with further resources given to those with particular needs [17]. Rose and Gallivan [13] proposed a framework for staff training which identifies areas related to support and prevention. It includes training topics and processes that can be introduced proactively such as supervision and risk assessment but also reactive strategies (i.e. strategies contingent upon maladaptive behaviour, such as appropriate physical skills training, and responsive elements, such as incident analysis and behavioural skills training). A modified version of this framework is provided in Table 34.2.

Supervision (biweekly or monthly) is a methodology for maintaining or reinforcing the training intervention.

Formal standardisation of training and establishment of higher academic posts in psychiatry or psychology at professorial level are missing in most European countries apart from two exceptions, namely, Republic of Ireland and the UK. Similarly, apart from a few exceptions, most countries do not have specialist posts in ID psychiatry or psychology.

Recent advances in training in the ID field are often due to the effort of committed institutions, service providers, private and professional organisations [18]. Furthermore, major players are very often key individuals, collaborating in networks, and pulling together consortiums establishing European Union funded grants with projects producing further education material in this field. In many parts of Europe, mental health professionals working with people with ID and mental health problems have been self-taught, soon realising that they missed out during their formal professional training on gathering substantial knowledge and competencies necessary to provide appropriate support to people with ID who have mental health needs.

In the next sections, we described some good examples of formal nationally accredited mandatory training in the field of ID and mental health.

Table 34.1 Training on intellectual disability within psychiatry training across European countries

Country	Intellectual disability psychiatry as part of psychiatric training	Teaching format
Albania	No	–
Austria	No	–
Azerbaijan	Yes	Lectures
Belarus	Yes	Lectures, clinical rotation and case review
Belgium	Yes	Mandatory lectures and optional clinical rotation
Bosnia Herzegovina	NR	NR
Bulgaria	Yes	Part of CAP clinical rotation
Croatia	No	–
Cyprus	No	–
Czech Republic	Yes	–
Denmark	Yes	Very few lectures
Estonia	Yes	Lecture and CAP training
Finland	Yes	In CAP, it is possible to have clinical rotation in child neurology
France	No	–
Georgia	No	–
Germany	Yes	Lectures and optional rotation
Greece	Yes	Lectures
Hungary	No	–
Ireland	Yes	Learning outcomes for psychiatry of ID must be attained. Three years clinical training in HST is required for certification in ID (or 2 years in dual certification)
Italy	No	–
Israel	Yes	Lectures and case reviews
Latvia	Yes	NR
Lithuania	No	–
Luxembourg	Na	–
North Macedonia	Yes	Lectures

(continued)

Table 34.1 (continued)

Country	Intellectual disability psychiatry as part of psychiatric training	Teaching format
Malta	Yes	Lectures and clinical rotation
Montenegro	Yes	Lectures
Norway	No	–
Poland	No	–
Portugal	No	–
Romania	No	–
Russia	Yes	Lectures, examinations and rotations
Serbia	Yes	Lectures and clinical practice
Slovakia	No	–
Slovenia	No	–
Spain	Yes	–
Sweden	Yes	Lectures and clinical rotation
Switzerland	No	–
The Netherlands	No	–
Turkey	Yes	Lectures, outpatient practice and forensic psychiatry
Ukraine	Yes	Lecture
The UK	Yes	This is taught as part of the compulsory MRCPsych exam preparation course and is tested in the exam Some trainees may complete an ID placement during core training There is also the possibility of completing the 3-year higher specialty training programme in ID

Time of data collection is 2014–2015

34.3 Mandatory Formal Education and Training in Psychiatry and Clinical Psychology

From a European perspective, the cases of Austria and the UK might be examples of ways how an appropriate framework in the field maybe achieved for training psychiatrists and clinical psychologists.

34.3.1 Psychiatrists

In the UK, after leaving the Medical School, doctors spend 2 years in foundation training in different medical specialities, which may include placement in a psychiatric or ID service for 4 months. After that they can choose a medical speciality for further training including psychiatry. The core train-

Table 34.2 Staff training framework

Universal training	Specific training	Responsive training
Person-centred values and attitudes Increasing knowledge Training on the communicative aspects of challenging behaviour Training on attributions of challenging behaviour Training on emotional intelligence Training on risk assessment/risk management culture	Appropriate physical skills training	Nidotherapy Behavioural skills training Incident analysis Formulation

Adapted from Rose and Gallivan [13]

ing in psychiatry is for 3 years which may include a 6-month placement in psychiatry of ID. Within the core training, they will have to complete a Member of the Royal College of Psychiatrists (MRCPsych) UK examination. After that they enter a higher training phase for 3–4 years. For higher training, they can choose from six psychiatry subspecialties, one of which is in psychiatry of ID. During the whole training period, the doctors are in a salaried job seeing patients in various settings including inpatient admission units, outpatients, community homes, etc. For psychiatric training, the doctors work within a multidisciplinary team comprising nurses, clinical psychologists, speech and language therapist, social workers, etc.

During the psychiatric subspecialty, higher training doctors can spend time doing special interest session in neurology, genetics, forensic psychiatry, child psychiatry, neuropsychiatry, etc. Some dual training opportunities exist not only involving psychiatry of ID and forensic psychiatry but also psychiatry of ID and child and adolescent psychiatry. At the end of the subspecialty, higher training psychiatrists receive a certificate of completion of training (CCT), which allows them to apply for a consultant psychiatrist in ID job in the UK National Health Service (NHS) or private sector. In some cases, they can apply for a child ID psychiatrist job or a forensic ID psychiatry job. All trainings are based on a structured curriculum developed by the Royal College of Psychiatrists and accredited by the UK General Medical Council (GMC) that oversees all medical training including training in psychiatry in the UK. The UK universities also have professorial posts available in ID both for psychiatrists and psychologists.

In Austria, training of psychiatrists is regulated by the legal framework of 'Physicians Training System' [19]. Training lasts for 6 years, of which 4 years are spent in psychiatry. They spend one year each in neurology and internal medicine. After completing a final examination, they can apply for a professional title 'consultant in psychiatry and medical psychotherapy'. On-the-job training is provided within the hospital settings, which is a major obstacle in the way of gaining competency to provide community-based psychiatric-psychosocial services. The curriculum for this postgraduate training in psychiatry sometimes involves disability and, specifically, ID. However, subspecialty training in ID or disability is not mandatory. Training in psychiatry has no structure with regard to specific target groups, with the exception of the 'consultant in psychiatry of childhood and youth and medical psychotherapy' defined as a speciality of its own. Austrian universities do not provide professorships in psychiatry and ID. However, medical universities have established professorships in psychiatry of childhood and youth, covering in addition ASD and ID.

34.3.2 Psychologists

In the UK, the Doctorate in Clinical Psychology (ClinPsychD) is a 3-year-long postgraduate course accredited by the British

Psychological Society (BPS) and Health and Care Professions Council (HCPC). Those who hold this qualification can apply for a Consultant Clinical Psychologist post either within the UK NHS or in the private sector. All across the UK, 34 such courses are on offer. King's College in London hosts the UK's oldest programme which is underpinned by a bio-psycho-social model with an emphasis on integration of theory, research and practice in all aspects of training. The programme follows an evidence-based approach and has cognitive-behavioural therapy as its main therapeutic modality [20].

In each year, trainees spend 3 days per week on supervised clinical work and 2 days are dedicated to teaching and research. Trainees undertake six, 4-to-6-month clinical placements. The first year covers four core areas including adult and child mental health. Second year covers modules on older adults and ID, and the third year comprises two electives or specialist placements, with ID being one of the options. The academic curriculum includes clinical psychology as applied to ID as part of 1 of the 12 thematic areas. Other mandatory modules consist of adult mental health, forensic psychology, research methods, race-equality-diversity and leadership.

The curriculum is delivered through a combination of lectures, seminars, workshops, reflective practice meetings and small group tutorials, offering the trainees opportunities to reflect critically on theoretical issues and their application to clinical practice and research. Trainees are allocated clinical supervisors while on clinical placements and a clinical tutor who supervises overall training. Trainees also choose their own supervisors for the literature review and research projects. The available doctoral training posts are full-time positions paid by the UK NHS.

In Austria, post-graduate training is on two tracks, namely clinical psychology and health psychology, which is regulated since 2013 by new Psychologists' law [21], replacing the one of 1991, which consisted of theoretical and practical components. The theoretical part has a common basic trunk for both tracks followed by separate advanced training in either clinical or health psychology. The common trunk has a duration of a minimum of 340 units (one unit = 45 min), with 220 units minimum for the basic and 120 units minimum for the advanced branches. The basic trunk covers taught courses in groups of 15 (maximum) on professional legal and ethical topics, communication, counselling methods and supervision, assessment and diagnostic strategies, service provision system, psychological concepts of health prevention and health promotion as well as crisis intervention. The advanced branches, with a minimum of 120 units, are designed to train transfer of taught knowledge to practical clinical use in order to strengthen professional skills. In this section, trainees have to produce a number of individual case studies. The internship has a total of 1638 h for the health track and 2188 h for the clinical track. The trainee has to take at least 500 h of his or her internship timely in parallel to the theoretical component of the training programme, thus assuring the reflective supervision units (100 units health track and 120 units clinical track) to be offered by the programme certified for postgraduate training.

The internships for both professional psychology degrees follow separate pathways with practical training programmes linked to the health promotion sector or to the clinical prevention sector. The duration is spent in full-time employment for 1.5 years for the health track and for 2 years for the clinical track. The legal framework does not specify any elements mandatory in the theoretical and practical components from the ID field. The theoretical training programmes on offer have to be approved by the National Ministry of Health, and are set up either by professional psychology organisations, such as the Austrian Association of Psychologists, or by postgraduate programmes of public universities. A number of service providers from the ID field are accredited to provide internship placements for the two tracks. Upon successful completion of theoretical and practical components of the programme, the trainees take a final committee-based oral examination, and if successful are awarded the professional title of either Health Psychologist or Psychologist. The next step is the registration in the national

list of clinical psychologists and health psychologists at the National Ministry of Health. The trainee has to cover for the costs of the theoretical part of the training and is supposed to have a salary-based contract for the period of the internship.

34.4 Non-Mandatory Formal Training Options in ID Mental Health

Non-mandatory formal training programmes are currently the main options in a number of European countries to improve the competency and skills of professionals and front-line staff working in the ID field. A comprehensive training in mental health and ID is not only lacking for the psychiatrists and clinical psychologists but also for other professionals such as psychotherapists, social workers, educators and even disability caregivers or personal assistants. Therefore, some academics, researchers and managers in care provider organisations tend to provide training in ID and mental health. Such activities can be grouped under three major categories: (a) University-based postgraduate programmes; (b) Organisations or Associations provided training and (c) Training programmes developed within some European consortium projects.

34.4.1 University Based Programmes in ID Mental Health

Universities would typically offer specific bachelor and master's programmes on the overall topic on disabilities and/or ID in the department of education, special education, psychology and psychiatry. In worldwide, the UK, the USA, Ireland and Australia are examples of countries providing such University-based programme for higher degrees.

Postgraduate studies on a Master of Science level (MSc) in intellectual and developmental disabilities (IDD) offer advanced knowledge of psychological aspects of development in people with IDD, and aim to provide a grounding for students who are interested in studying later for a professional qualification in clinical or educational psychology, or a career in research. Such programs, designed for 1 or 2 years, provide practical knowledge in social psychology of IDD, skills in behaviour analysis, mental health assessment and intervention as well as knowledge and understanding of service issues in IDD. The programmes, frequently subject to charges, are on offer either as traditional in-person programmes or as online and distance-learning formats [22–24].

The University of New South Wales' Department of Developmental Disability neuropsychiatry is providing free online training in ID mental health [25], set up in partnership with other organisations in New South Wales. This ID mental health, e-learning platform provides training tracks tailored for three target groups: (a) carers and family, (b) health professionals, and (c) disability professionals [25]. In the UK, Imperial College London has developed an online training programme aimed at both paid and family carers of people with ID with a special emphasis on medicine review with the view to withdrawing unnecessary psychotropic prescriptions for the management of PB in adults with ID [26, 27].

34.4.2 Associations Promoting Advances in ID Mental Health

In many areas of the social field, non-governmental organisations (NGOs) are the key providers of services for vulnerable and socially marginalised groups, such as people with disabilities. The next section provides some examples of these organisations promoting ID mental health in Europe.

34.4.2.1 EASPD

In Europe, the *European Association of Service providers for Persons with Disabilities* (EASPD) has been promoting, for more than two decades, the views of currently 15,000 social services and their umbrella organisations. Apart from offering day-to-day support

for people with disabilities, the vast majority of these organisation promote equal opportunities for people with disabilities through effective and high-quality service systems [28] (for further information go to ► http://www.easpd.eu/en). However, in the health sector, and especially the mental health sector, equal opportunities are not assured for people with ID, with widespread inequalities for mental health and ID [29]. EASPD's activities regularly include awareness-rising campaigns on the need of appropriate staff qualification as well as European workshops on issues of health and mental health for people with ID.

34.4.2.2 ARFIE

Association de Recherche et de Formation sur l'Insertion en Europe, Association for Research and Training on Integration in Europe (ARFIE) assumes its responsibility by arranging consortiums developing appropriate training and continuous education programmes in the field of ID, in general, and ID mental health, in particular. Two of ARFIE's recent innovative training products relating to mental health and ID are as follows: (a) TRIADD and TRINNODD and (b) AGID project (see below). ARFIE's mixed membership includes from innovative service providers to leading researchers, which offers excellent conditions for setting up training projects to allow transfer of research into practice [30].

34.4.2.3 EAMHID

The *European Association for Mental Health and Intellectual Disability* (EAMHID), founded by leaders from academia, research and the clinical mental health field, contributes significantly with its biannual European conferences and pre-conference training workshops to the advances in research and practice in the field of ID. The purpose of the Association is to facilitate international cooperation and exchange of knowledge and experience in the field of mental health in people with an ID. Special emphasis is placed on the coordination and promotion of scientific activities and improving standards of care and support throughout Europe. EAMHID conferences offer a variety of formats attractive to the various professionals in the field of ID and mental health. Besides traditional formats like keynote presentations, solicited symposia, posters and individual presentations, a conference would typically encompass formats such as round-table discussions, coproductive symposia, a format of gathering up to five stakeholders to debate around an overall theme and half-day pre-congress courses offering training to improve skills based on recent evidence-based advances, for example, mental health assessment. Thus, EAMHID delegates benefit from accreditation, training credit points as required by most professions engaged in the field of mental health. For further information, see [31] ► https://eamhid.eu/. Finally, EAMHID keeps formal collaboration with other similar organisations like *The National Association for the Dually Diagnosed* (NADD) in the USA [32] (► http://thenadd.org/) or the *International Association for the Scientific Study on Intellectual and Developmental Disabilities* (IASSIDD) [33] (► https://www.iassidd.org/), and specifically, IASSIDD's Special Interest Group on Challenging Behaviour & Mental Health (SIRG/CBMH) [34] (► https://www.iassidd.org/content/challenging-behaviour-a-mental-health).

34.4.3 ID Mental Health: European Consortium-Driven Training Programmes

34.4.3.1 TRINNODD

The European training modules for staff supporting individuals with dual diagnosis TRINNODD (TRansfer of INNOvation for Dual Diagnosis) was a 2-year project (2008–2010) funded through the EU Leonardo da Vinci Lifelong Learning Programme [35]. TRINNODD aimed at updating the previous TRIADD (Teletraining Research and Information around Dual Diagnosis) project deliverables [36] and to transfer advanced knowledge on topics related to dual diagnoses (DD) to target groups, with little exposure to these issues in countries with little opportunities for continuous training options in that field. The contents of the training package to

develop were based on a survey of frontline staff and mental health professionals reporting their needs with respect to knowledge and skills to understand and handle mental health issues in people with ID. Findings not only revealed differences and commonalities in the needs between countries but also identified four key areas for training activities and training considerations: emotionality, quality of life, vulnerability and training methodology. Furthermore, modules developed with high priority were derived from the areas of stress prevention, assessment of quality of life of the person with ID as well as family members, complexity of the individual's vulnerability as well as psychosocial and contextual-environmental consideration (individual and community).

The development as well as the implementation of the training modules mainly followed the steps as defined in the knowledge transfer and exchange model (KTE) suggested by Saini and Brown [37]. This model considers, for the development of the training material, questions like: What is the knowledge and skill to transfer? What is the quality and evidence of the knowledge and skill? What are the limitations of the knowledge and skill? Further, considering the training session itself: Who is the audience? How can the message be tailored? How should the message be delivered?

Next, the use of the knowledge and/or skill as transmitted is reflected: Do the trainees use the product as expected? Is the product relevant for the trainees? And finally, the model considers the impact: Does using the product impact change on outcomes relevant to the goals, objectives and purposes of the KTE product? Training modules, with sessions totalling to 30 h, were delivered in Italy, Portugal, Romania and Spain. The training modules took in account a broad primary training background of the audience. Thus, trainees included physicians, psychologists, nurses, paramedical therapists, social workers and educators. The impact of the training was evaluated at two different points in time: First, directly upon delivery of the training, and second, 6 months after the delivery of the course in order to assess the impact on the trainees' daily practice. The training sessions themselves were positively evaluated by the trainees and the trainees reported 6 months later positive effects with regard to their professional life, such as improved competence to handle and/or to prevent stressful daily situations. TRINODD's materials as well as its achievements are located on [36] ► http://www.triadd.lu/index.htm. TRINODD's training material is disseminated through the Association de Recherche et de Formation sur l'Insertion en Europe (ARFIE) [30] (► www.arfie.eu).

34.4.3.2 AGID

Whereas TRINODD had its focus on mental health in general for adults with ID, AGID (Developing Training Modules for staff on Ageing and Disability Issues) focused on a bio-psycho-social perspective on the challenges of older people with ID [38]. The AGID project is funded by the EU Leonardo da Vinci Lifelong Learning Programme and co-funded by the Austrian 'Fonds Gesundes Österreich'. It was set up by mixed consortium of university-based academics and leaders form the service provision system, and aimed at the development of a free-to-use online training platform offered in five languages: English, French, German, Italian and Flemish [39] (► www.agid-project.eu).

The detection of topics with high relevance for continuous training in the area of ageing and ID was based on the appreciative inquiry methodology [40] using an inclusive strategy with regard to main stakeholders (e.g. health professionals, self-advocates, family members and frontline staff). This process leads to the definition and evidence-based development of six training modules:

1. Ageing process: Ageing process in general with a specific focus on people with ID.
2. Person-centred planning: Introducing to the basic conception and methodology of person-centred support aimed at improving participation and self-determination of an ageing person with ID.
3. Social network and communication of elderly people with ID: Strengthening the awareness of trainees for social networks of older people with ID, for example, the preventive function of social networks and

develop skills and techniques for maintaining, improving and initiating social contacts for older people with ID.
4. Emotional regulation for frontline staff: Provide staff with the necessary skills to reflect and systematically explore factors in their professional environment and to develop competencies in the application of strategies reducing stress, thus, contributing to prevent mental health problems in older people with ID as well as to prevent burnout of staff members.
5. Pathological ageing in people with ID: Transfer knowledge of common age-related diseases and disorders, competency in handling emergency, competency in effective communication with older people with ID and competency in creating a supportive environment for people with ID and dementia or depression.
6. Taking care: The main objectives of this module are to develop a professional attitude among staff and health professionals so they can be prepared and equipped to deal with the specific challenges when supporting older people with ID. The modules will train professionals on whom to implement 'good-care' in their everyday work while considering the self-determination approach.

An initial evaluation of AGID's e-learning platform based on 171 users revealed that overall users rated the platform attractive largely due to the multimedia content of the modules (images, interactive exercises and videos). Users reporting experience with e-learning platforms (n = 111), mainly the younger cohort, reported less need of support and training with the platform. In addition to the many positive comments received, there were some criticisms, with readability being one of the most cited. Nonetheless, the attractiveness of the platform had substantial acknowledgement by a large majority of the users, which is of particular importance as usability is considered as a significant factor. AGID's external evaluation focused on a general assessment of the project objectives, progress and outcomes, while pointing to issues like the importance of providing main theoretical reference for understanding the concept and measurement of quality of life or the need for an overview of the recent literature on policies and services, particularly in Europe.

34.5 World Perspectives

In low- and middle-income (LAMI) countries, there is generally a lack of well-trained therapists who could provide specialist interventions to support persons with ID/IDD and their families, especially with reference to the adult age. To have utility for LAMI countries, these programmes would need to be able to be delivered by non-specialist community workers or by family members of the persons with ID. In reference to the developmental age, reviews of parent training (both individual and group) carried out in LAMI countries indicate that the involvement of parents is both effective and cost-effective [41], although scientific rigour of available literature is scarce, especially for methods and outcome measures.

Since parents have frequent and consistent contact with their child across a range of settings, effective intervention, generalisation, maintenance and prevention are all more likely. Cost-effectiveness can be further improved if specialist professionals train paraprofessionals or lay volunteers to inform and support parents in turn [41]. Parent training outcomes, such as enrolment, dropout, consistent attendance and child improvement, have been associated with parental education, socio-economic status, expectations, values, marital relationships and being a single parent [42].

A training system that has already been effectively rolled out in the USA [43] and in Australia [44] and for which cross-cultural adaptations have been developed is represented by the Stepping Stones Triple P Parenting Program [45]. The World Health Organization (WHO) has implemented a caregiver skills training programme in Africa and in other LAMI countries across the world to train parents and key caregivers to improve outcome in children with IDD [46].

Training of professionals in the area of IDD in Nigeria is often incorporated into postgraduate paediatric and psychiatry training and accredited and supervised by National Postgraduate Medical College of Nigeria and West African College of Physicians in the West African sub-region [47]. Many sub-regions in Africa also have postgraduate training in Paediatric and Psychiatry, which contribute to training of professionals to attend to health needs of children with IDD. There is a pocket of mid-level professional occupational and speech therapists training schools across sub-Saharan Africa [48, 49].

In most Asian countries, the medical support for people with IDD focuses on basic physical care rather than meeting their psychiatric needs. It is well recognised that psychiatric disorders are common in both children and adults with ID [50, 51], but this area rarely receives adequate, if any, attention from the health administrators in Asian countries. The lack of specialist staff, particularly psychiatrists, is often offered as the major reason for not starting such services in this part of the world. Due to historical reasons, Hong Kong has adopted a British model for its medical education and specialist training. There are close ties between the Hong Kong College of Psychiatrists and the Royal College of Psychiatrists in the UK. To be an approved training scheme that is accredited by the Royal College of Psychiatrists of UK (so that trainees can sit for their examinations like MRCPsych), Hong Kong established its first formal psychiatric unit for adults (age 16 and above) with ID in 1995.

In Hong Kong, after registration as a psychiatric trainee, he or she has to go through a rotation where different types of clinical experiences are provided. The psychiatry of ID is among one of those specialties, but it is not mandatory. The training curriculum in this specialty consists of management of mental and behavioural problems in people with ID in inpatient, outpatient and community settings. Trainees are engage in multidisciplinary team work to tackle the different problems of this population under supervision. As the trainee goes through his training, he may sit for the Part I, II and III of the Fellowship Examination. He will be qualified as a specialist after completing at least 6 years of professional training and passing all three parts of the examination.

Among Asian countries, financial resources, manpower and expertise are always the most important challenges facing the development of medical and health-care services. Training and service development should go hand in hand and neither one should become a barrier for not providing appropriate mental health services for people with ID. Singapore should be appreciated for following the service development pathway of Hong Kong to set up a specialist psychiatric service for adults with ID and/or ASD. It is named the Adult Neurodevelopmental Service (ANDS) at the Institute of Mental Health (IMH) in Singapore. Singapore had invited a psychiatrist from Hong Kong to provide training and experience sharing before commissioning this specialist service. This is another example of how training and service development will eventually bring significant benefits to improve the total health care and quality of life of people with ID.

The Academy of the International Association for the Scientific Study of Intellectual and Developmental Disabilities (IASSIDD) has an International Visits Program, whereby individual members from any country may arrange to visit an accredited community agency, university or hospital for a period of approximately 2 weeks for the purposes of learning and training. The visitors will be provided with opportunities for attending classes, accompanying a support worker on his/her daily work, taking part in consultations and multidisciplinary meetings, assisting with research or a combination of these activities. An example is the study visit of the Rainbow Centre personnel of Singapore to three adult support services in the UK and the Netherlands in 2019 [52] (► www.iassidd.org/international-visits-program). Such programmes are considered to be valuable to many workers and trainees in Asian countries without specialist ID services.

In Australia and New Zealand, the number of psychiatrists who are specialising in IDD is promised to increase in the last decades. Of

course, the underlining need has been to provide adequate training for doctors in both the areas of physical and mental health. In both Australasian countries, this development has been slow. At the University of Sydney, the need for funding of special health clinics in the area of developmental disabilities was identified at the end of the 1990s but it took at least a decade before it was recognised. The inaugural Chair in Intellectual Disability Mental Health at the University of New South Wales was established in 2013. Of course, one of the factors which has inhibited both the training and delivery of mental health services for this population has been the slow recognition that people with ID do experience mental health conditions.

The body responsible for training and education of psychiatrists is the Royal Australia and New Zealand College of Psychiatrists (RANZCP). The highest standards in training pertaining to the psychiatry of IDD are promoted by the RANZCP Section of Psychiatry of Intellectual and Developmental Disabilities (SPIDD). This Section, through its Bi-national Section Committee, is also responsible for promoting and encouraging the study of psychiatry of IDD in all its aspects and the development of knowledge and practice, of the highest standard, for psychiatrists, trainee psychiatrists, medical students, related health professionals, students of related health professions, other medical practitioners and involved legal practitioners.

34.6 Further Considerations

In this chapter, we primarily concentrated on training for psychiatrists and psychologists. Because of lack of space we could not go into the detail of any training for other professionals such as nurses, social workers and speech and language therapists. Although we could not go into the detail of training for support (care) staff, a systematic review by Deb & Roberts [53] found 24 papers on staff training in ID. The authors divided the studies under (a) training in management, policy and intervention implementation; (b) training in behavioural issues and (c) training in the techniques of control and physical restraint. The authors found that most training increased staff knowledge on the subject and confidence to deal with mental health issues and PB in people with ID. However, the impact of training on the actual mental health and PB of people with ID they support is not known. In a more recent systematic review, Rose and colleagues [4] divided the type of staff training under three headings, namely (a) proactive, (b) reactive and (c) responsive training and support (see ◘ Table 34.1). Like Deb & Roberts, Rose and colleagues also found that the training by and large improved the knowledge and confidence among staff.

Further, future reviews on professional education and training should include the profession of *psychotherapist*. Psychotherapy as a profession is currently regulated by law in many European countries, however, there is no heterogenous curriculum in mental health in ID for these professionals. In a growing number of countries, psychotherapy for people with ID is included in the provisions financially supported by the national health insurance systems as there is good evidence on the effectiveness of talk-based therapies for this population [54]. Most recently, Germany has adopted a formal guideline for ID psychotherapy [55]. However, it is not known to what extent these trainings are mandatory in different countries.

Finally, *self-study options* are briefly addressed as these probably continue to constitute most relevant resources for those entering the field of ID mental health or ID in general when not having had the opportunity in their professional training to acquire appropriate knowledge and competencies in the area of ID mental health. In the UK, a family carer organisation, Challenging Behaviour Foundation (CBF), provides online material for family and paid carers on mental health issues in people with ID [56] (► www.challengingbehaviour.org.uk). Also, in the UK, Royal College of Psychiatrists' MindEd programme provides free online material on mental health issues in ID [57] (► www.minded.org.uk). Similarly, in the UK, both the British Psychological Society [58] (► www.

bps.org.uk) and British Institute of Learning Disabilities (► www.bild.org.uk) provide online material for professionals, carers on various aspects of mental health and PB in people with ID including Positive Behaviour Support (PBS). In Toronto Canada, Surrey Place Center provides online material on mental health issues in ID [59] (► www.surreyplace.ca). Autism Europe IPA+ project provides online learning modules on autism [60] (► http://ipa-project.eu/training/).

There are also a number of textbooks and journals that are a great source of knowledge and information in the field. Selective examples of textbooks include (a) *Psychiatric and Behavioural Disorders in Intellectual and Developmental Disabilities* [61], (b) *Diagnostic manual-Intellectual disability: A textbook of diagnosis of mental disorders in persons with intellectual disability, second edition* [62], (c) *The Oxford Textbook of Psychiatry of Intellectual Disabilities* [63], (d) *Advances of clinical psychology in the field of ID mental health* [64], (e) *Understanding and responding to behaviour that challenges in intellectual disabilities: A Handbook for those who provide support* [65], (f) *Handbook of Evidence-Based Practices in Intellectual and Developmental Disabilities, Evidence-Based Practices in Behavioral Health* [66], (g) ► www.intellectualdisability.info [67], (h) *Clinical Topics in the Psychiatry of Disorders of Intellectual Development* [68], (i) *Handbook of Psychopathology in Intellectual Disability: Research, Practice, and Policy, Autism and Child Psychopathology Series* [69], (j) *Intellectual disability and ill health-A review of evidence* [70], (k) *Intellectual Disability Psychiatry: a Practical Handbook* [71], (l) *Practice guidelines for the assessment and diagnosis of mental health problems in adults with intellectual disability (European Association for Mental Health in Intellectual Disability)* [72]; ► www.iassid.org [33], etc.

Some of the journals in the field include (a) *Journal of Intellectual Disability Research* (ed. Richard Hastings), (b) *Journal of Applied Research in Intellectual Disabilities* (eds. Peter Langdon & Jonathan Weiss), (c) *Research in Developmental Disabilities* (ed. Dagmara Dimitriou), (d) *American Journal of Intellectual and Developmental Disabilities* (ed. Frank Symons), (e) *Journal of Mental Health Research in Intellectual Disabilities* (ed. Angela Hassiotis), (f) *Advances in Mental Health and Intellectual Disabilities* (eds. Sarah Blainey & Debbie Spain), (g) *Journal of Policy and Practice in Intellectual Disabilities* (eds. Rhonda Faragher & Laurence Taggart), etc.

34.7 Conclusion and Outlook

Generally, it is considered that higher education training as well as postgraduate education or advanced professional training with respect to mental health are key resources and crucial factors when assessing the quality of a country's mental health provision system [73]. This chapter revealed major disparities in and lack of formal training curricula for mental health professionals in ID mental health, which highlights the need for immediate action in this area. At the European level, there have been suggestions for establishing a European training programme on mental health in ID [35, 74]. However, we have to consider the fact that, within the European Union, health policy is defined at the national level, so a consistent approach to developing a Europe-wide curriculum may have its challenges. However, this also highlights the need for relevant organisations and key players to come together to develop a pan-European curriculum for training in mental health in ID, which could be adapted by individual countries for their own use. This may have a positive impact on the consumers' right for equity in ID mental health services within and between member countries. Good mental health is a significant factor in the successful integration and inclusion of people with ID in the wider society [75].

Key Points

- Most countries in the world do not provide adequate training for professionals who look after the mental health of people with intellectual disabilities.
- Some national and international organisations and associations have set good

examples of providing specific inter-country training in this area.
- There is a need for action to develop a mental health education and training strategy for people with intellectual disabilities that can be adapted to the context of each country.

■ **Overview**

Specialist mental health (MH) services for people with intellectual disability (ID) have been a feature for over 30 years. Early pioneers such as Bouras and colleagues were not only instrumental in developing MH in ID services to complement mental health pathways but also developing Mental Health in Learning Disabilities (MHiLD) as a specialist field of psychiatry. Since the early model, put forward by Bouras, several service models have come into existence; however, robust research into the effectiveness of different models is lacking. This is for a number of reasons such as the methodology used, focussing on different outcomes, changing political picture and subtle changes in function and who is eligible for specialist services. More recently, to achieve equity of provision for people with an intellectual disability, there have been several quality initiatives aimed at improving access to services; however, this has seen varied results across different locations. This chapter will provide the historical context in the development of specialist mental health services for people with ID including a discussion of service models with specific examples including how we measure quality in services. An international perspective will be presented as well as how individual countries may take a national approach to the planning of services.

35

Learning Objectives

This chapter will provide a number of learning objectives including the following:

- An awareness of the developments of mental health services for people with intellectual disability and autism over the past decades from an international perspective.
- Increased knowledge on how to improve quality in services and how to measure the utilisations of services.
- An understanding on developing a community-based approach as illustrated by a specialist mental health model developed by Bouras and colleagues in the UK.

35.1 Introduction

The ongoing debate for the past 30 years has been on the model of mental health services for people with intellectual disability (ID), specifically around how these services should be delivered. This debate is focused in the UK on the development of services following the closure of the institutions leading to the development of community-based mental health services [1, 2]. Although our knowledge of mental disorder and how it affects people with ID has increased over the past three decades, this has not resulted in adequate or equity of service provision. As a result, mental and physical health care is more difficult for people with ID to access than for those in the general population [3–6]. This has led to a dialogue on how best to deliver community-based mental health care, whether through specialist teams or by improving access to mainstream mental health services.

In most parts of the developed world, the focus has been also on closing the institutions and at the same time looking at whether disability services will provide for the mental health care of people with ID or whether this will be the remit of mainstream mental health services. One of the perceived benefits to community integration was that there would be a reduction in behavioural problems. However, for many, the transition resulted in an increase in problem behaviours and mental health problems in what was known as 'relocation syndrome' [7]. In countries, such as Australia, the provision of community-based services has led to either disability services looking to provide for the mental health care of people with ID or by improving provision within mainstream health services [8]. This is an illustration of how service delivery and models can differ by country. For example, in Ireland 'parents and friends' groups set up community-based residential services promoting normalisation [9]. In Spain, a specialist service model as a part of the Catalan Mental Health Plan (2006–2010) was developed, inspired by the Mental Health in Learning Disabilities (MHiLD) model in South East London, UK [10]. While in the

Netherlands, the development of a community model comprised of regional centres and the use of outreach models as an alternative to large asylums. This followed a randomised controlled trial in the 1990s that found no differences in outcomes in those with mild or borderline ID receiving hospital or community-based care [11].

Recent national policy in England has more and more emphasised the need to improve awareness and support in access to mainstream services for people with ID and those with/or autism [12]. At the same time, there has been a debate on how we develop specialist teams and how we improve outcomes for people with ID as well as those with/or autism spectrum disorder who have mental health needs. For example, the Royal College of Psychiatrists recently developed the role of a champion for autism within the College, although those with autism have received less attention from the national policy in transforming care [13].

In other countries, such as Canada, there has been an increasing understanding that some people with ID and mental health needs either have access to emergency services or inpatient service, with little in between. The research is mainly focused on the utilisation of these emergency and inpatient services and the benefits to the individuals and families [14].

In England, due to recent national policy on reducing the number of people with ID who are in hospital, there has been a development particularly around services for those with challenging behaviour or forensic history. This national policy has led to the model as described in Building the Right Support [12]. The central principles of this new model of service is that every person with ID should have person-centred care and live in the community and this care should come from mainstream mental health services.

35.2 Quality of Services

Measuring service outcomes has always been difficult given changing functions over time including fundamental changes to the client group served and their level of risk. One attempt was 'the matrix model' [15], which developed an international framework to compare services across five European countries, entitled the BIOMED-MEROPE project [16]. Another initiative aimed at achieving equity of mental health care for people with ID was the Green Light Tool Kit (GLTK), which was introduced in 2003 in England [17]. The GLTK provides a framework and self-audit toolkit aimed at improving mental health services for people with ID, providing a benchmark of what individuals should expect from services by including quality outcomes for services to meet. In 2013, the National Development Team for Inclusion (NDTi) produced a revised GLTK, also aimed at those with autism spectrum disorder (ASD) as well as ID [18]. This followed 'Reasonably Adjusted', a report outlining progress in terms of reasonable adjustments that mental health services were already putting in place for people with ID and/or ASD [19]. The latest GLTK has 27 items to self-report with items 1–9 forming the 'basic' audit, which examines physical health, eligibility and access, secure services, safeguarding, assessment, equalities, personalisation, staff attitudes and values and accessible information; items 10–18, titled the 'better' audit examine research, health and care records and care plans, local plans, how specialist services relate to local provision, skilled workforce, people needing personal care, user involvement in the governance of the service, psychological therapies and working together. The final section, items 19–27, titled the 'best' audit, examines advocacy, commissioning, buildings and environments, leadership, family and friends, employment support, checking services, monitoring and challenging behaviour. In terms of the impact of the Green Light Work, reflections on examples from five NHS Trusts [20] illustrate that the implementation is still a work in progress and in spite of 'positive steps' more time is needed to focus on the challenges and solutions faced. However, the commissioning of ID services in the UK has not always been seen as a priority in spite of a plethora of guidance to the contrary, which has often

seen best practice guidance such as closer to home, least restrictive environments and community placements ignored either due to lack of infrastructure or inability to see past current practices. For change, limitations in current service provision need to be addressed. One method is by quality improvement initiatives. Quality improvement is a systematic approach to improving health services based on iterative changes, continuous testing and measurement and empowerment of front-line teams [21]. Quality improvement is dependent on good leadership with sustained focus over time and a strong emphasis on service user involvement. The definition of quality in the National Health Service in the UK is based on three key areas of:

1. 'Patient safety', which is doing no harm to service users.
2. Experience of care, which is compassionate and delivered with dignity and respect.
3. Effectiveness of care, preventing people from becoming ill, improving quality of life and helping service users to recover.

These principles are applicable to mental health services for people with ID. However, the issue for people with ID and/or ASD is ensuring the effectiveness of care with such a low evidence base. All services can provide care that is safe for this group of service users in terms of their vulnerabilities, such as increased risk of physical health problems, for example, epilepsy, and the risk from others due to exploitation or abuse as happened at Winterbourne Hospital [22]. The issue of service user experience for people with ID and/or ASD also needs to take into account their social, emotional and sensory needs in order to deliver the positive experience for people when in contact with services [23].

A person with ID should have access to specialist health and social care, including access to high-quality inpatient care, when they need it. The debate needs to move on from just looking at models of care to instead asking what high-quality mental health care for people is with ID. The evidence base to date has mainly been on the characteristics of people with ID and mental health needs accessing services, however, in the future, there should be more emphasis on looking more on how to improve long-term outcomes. In countries with highly established mental health services for the wider population, which has an emphasis on prevention such as early intervention and health promotion, these approaches should also include those with ID and/or ASD into these quality initiatives [24].

The question comes what a high-quality service is. Around the world the mental health care for people with ID has very much been dependent on the availability of resources and as well as the availability of experts and specialists. A group in New South Wales in Australia [25] have looked at core models of health service delivery for people with ID. The review identified nine models of health service delivery from the UK including two from Australia. All these models emphasised the need for inter-agency working and highlighted the need for improving integration between mainstream and specialist mental health services. A number of barriers to accessing adequate mental health care for people with ID have been identified previously in Australia but are relevant to other countries [8]. These include the following:

- Clarity concerning roles and responsibilities and service coordination between disability services and mental health service providers.
- Training of mental health providers.
- Coherent service models and funding for ID mental health services.
- Specific inclusion of people with an ID in mental health policy.

The conclusion of this literature review was the need for high-quality research as none of the reviewed studies were meeting the requirements for a systematic review. To deliver services that are effective, safe and give service users a good experience, there is a need to collect further evidence to demonstrate how we can consistently improve the long-term outcomes of people with ID and/or ASD who are accessing mental health care.

The evidence so far for the improvement of mental health care in those with ID does

indicate the importance of inter-agency working [26]. In addition, specialists with expertise in assessment and management to make an informed formulation in the context of the individual's lives and their carers are required. A number of countries are responding to developing close inter-agency relationships and proving specialised psychiatric care in response to the evidence [27]. Difficulties with communication and emotional understanding are important in the assessment of people with ID. Those from a non-specialist background may not have the necessary skills to understand the needs of this population running the risk of over or underdiagnosing of the individuals' mental health needs [28]. Surveys within countries continually highlight the need to ensure adequate training for psychiatrists in the mental health needs of people with ID [29].

The evidence on service user experience is limited but interviews with people with ID accessing health-care services report that half of the participants have been treated unfairly or been discriminated against [30]. These accounts confirmed negative staff attitudes and failure of services to make reasonable adjustments. Some reported evidence on the experience of those with ID from different ethnic backgrounds in accessing mental health services [31]. Although the needs of people with ID from different ethnic communities are being increasingly recognised, they remain unrecognised in most mental health services research. In a comparison of two ethnic communities in South London, the black ethnic minority group were less positive about their overall experience, including the use of medication. There is little evidence as to the experience of individuals with autism of accessing mental health services. However, high-quality services do exist for those with ASD and there is increasing evidence to support the importance of accessible services which include a comprehensive assessment of their mental health needs [32]. The problems and burden of mental illness in people with ASD have been recognised for many years [33] but the delivery of good-quality mental health care in this group is not keeping pace with needs.

There is little research into the effectiveness of specialist models of mental health care for people with intellectual disabilities. However, what is agreed is that high-quality specialist services are characterised by inter-agency working and include professionals with appropriate expertise.

35.3 Service Utilisation

Utilisation of mental and behavioural services is the most commonly used type of health service for those with ASD, with up to 35–55% accessing such services annually in the USA [34]. There is still little evidence around the world on the utilisation of services by people with autism and mental health needs. This study from the USA indicates that those with ASD in contact with mental health services, which is evidence from mainly children and adolescents, found that those receiving individual or family therapy have a lower economic cost than those receiving mixed therapy, which included both family and individual therapy. Those having a co-morbid mental disorder were not associated with any substantial difference in service cost to those without a mental health problem. The average number of sessions per participant was lower than recommended through clinical guidelines. This reduced use of services may be due to the fact that the individuals found other services, such as specialist schools or community-based services, more helpful rather than attending mental health services, which may have presented too greater a burden for the families. Further evidence is needed to consider how to deliver effective therapy in appropriate doses for this group of service users. Social workers provided the lowest cost service, and this may be related to their training. They received training as case managers, and this may lead to reduced costs and benefits. Also, the younger the person, regarding children with autism, higher the dropout rates. The impact of this high

dropout rate may lead to decreased chances of improvement later on, so it is important to address any barriers to ongoing services for young people with autism and mental health needs [35].

Others have attempted to evaluate the mental health needs of people with ID accessing services as a way to understanding utilisation of services which has led to the development of a cluster-based approach. In the UK, this has been based on the Health of the Nation Outcome tool [36], which led to the development of 21 established mental health clusters that are divided into three groupings of psychosis, non-psychosis and organic conditions. This has resulted in a description of a further eight clusters specific to those with ID. The use of specific clusters is seen as an extension of these mental health clusters to ensure the better description of service users using specialist ID health services. These eight clusters including one of a low-level need, such as 'engagement minor support needs associated with mild ID (no autism)' to a cluster with a higher need of 'severe behaviour that challenge associated with autism and mild to moderate ID'. Within these eight clusters, there are three physical health clusters with their own degrees of severity. The challenging behaviour clusters and three physical health clusters together with the mental health clusters may allow greater comparison of services utilisation and better planning and resources within defined geographical areas.

The evidence to date on hospital admissions for people with ID shows those at increased risk for hospitalisation include: younger age, diagnosis of a psychiatric disorder, high levels of irritability, less severe ID, from a black ethnic minority group and not having a stable home [37]. However, the implementation of a community-based crisis and intervention programme can impact on these risk factors and so reduce the need for hospitalisation. The Mansell report [38, 39], first published in 1992, before a second edition in 2007, stated the need for robust supported housing in the community for those with challenging behaviour. Mansell emphasised it is not just the resources, but the quality of the services delivered that makes the difference. However, further evidence is still required on which aspects of community-based models and interventions reduce hospital admissions most effectively in the long term.

35.4 Service Models and Development of Services

In many areas, a lack of local community services has seen an artificial demand for unnecessary inpatient services that have warehoused and restricted people often in out-of-area placements [40–44]. It is only the scandal from Winterbourne view that has seen some attempts to address this problem. This section describes currently recognised models that have been established over time for illustrating an international perspective along with the recent national model for England.

Barriers to service improvement are often underpinned by historical and current philosophies of how society treats people with ID. Although there is outrage to scandals involving abuse, for example, [22, 45, 46], there is also disagreement on basic concepts such as normalisation and how these are interpreted day to day and misunderstanding of mental illness and the abilities of people with ID. This is reflected in the wide variation of approaches and attitudes of providers to certain treatments, for example, access to psychological interventions through Improving Access to Psychological Therapies (IAPT) services. The programme began in 2008 and targeted the treatment of adults with anxiety disorders and depression in England. Although over 900,000 people access IAPT services each year, there are still those who do not offer a service to people with ID. In the UK, there are variations in how and who delivers mental health services for people with ID. The official policy states that people with ID should access mainstream general mental health services [47, 48] with the addition of specialist mental health services for those with complex mental health needs. This group will often present with poor treatment outcomes, multiple admissions and, in some cases, are disadvantaged outside of

specialist services. In the UK, since the advent of community care, the mental health care for people with ID was the remit of Community Intellectual Disabilities Team that are primary care based and a type of one stop shop for looking after the healthcare of people with ID [49]. Arguably, the most celebrated mental health in ID service design is the Bouras and colleagues Mental Health in Learning Disability (MHiLD) model [10, 50, 51]. The MHiLD model predates the original Mansell Report, which put forward (as did the revised version) what is still considered the gold standard of how services should operate; and provided an impetus for the development of person-centred services. The MHiLD service is a dedicated service that enhances and complements existing adult mental health services for people with ID. The approach to early intervention means that those presenting with mental health issues have a chance to avoid potential negative consequences if left untreated or unidentified. This model as well as delivering specialist services has highlighted the need for specialist mental health services and right to mental health care for people with ID [26, 52–54]. Using a tripartite approach, Bouras and colleagues understood the need for service delivery, research and training as essential components of service delivery and set up the Estia Centre to support evidence-based service delivery. It is some years later that Academic Health Science Centres (AHSC) (a similar model) was adopted in the form of partnerships between Universities and large health Trusts in the UK. One of the strengths of the MHiLD model is its range of clinical and educational interventions [10] aimed at mental well-being and recovery, which include the following:

- Specialist assessment (e.g. mental health, neurodevelopmental or risk), all involving a detailed and holistic bio-psycho-social approach.
- Specialist interventions (including the development of an individualised care plan, management strategies, psychoeducation and training).
- Follow-up and review of care plans and mental health needs.
- Follow-up and review of psychotropic medication.
- Therapeutic sessions, support and reassurance.
- Crisis resolution.
- Care programme approach (CPA) coordination for people with ID who have severe mental illness or severe behavioural problems and where there is a high degree of risk.
- Mental health promotion for people with ID.
- Skills training for local ID service providers.
- Carer and family education and support.
- Court and other specialist reports.
- Consultancy and participating in delivering academic courses.
- Use of evidence-based approaches including specialist outcome measures of clinical effectiveness.
- Regular-quality audits and service evaluation.

The concept of models used with service user groups with long-term conditions, such as the chronic care model, which improves outcomes of chronic health conditions in primary care settings, had been looked at to adapt for service models for people with ID. The chronic care model is a framework based on a service user-centred approach with a positive alliance among the family, the carers, the service users and the practitioners. This approach, as described in the USA, ensures that community resources are carefully co-ordinated, follow evidence-based practice, multidisciplinary approach and take a lifelong developmental focussed framework. All members of a multidisciplinary team would receive extensive and ongoing training and supervision to a high level of expertise. In addition, integration into wider, general medical services leads to improved service user satisfaction and better health outcomes. This is exampled in the Centre for Autism and Development Disabilities (CADD) in Pennsylvania, which is an integrated health-care approach for individuals with ASD, or ID, based on the health-care home model, with the emphasis on service user-centred care [55].

However, there are challenges in delivering such specialist teams in terms of training, supervision and availability of specialist to meet the needs of a specific local population.

Others have advocated services to be delivered through a specific therapeutic approach, such as positive behavioural support [56], and that the best way to deliver this type of approach is through practice training in the real environment and reinforcements of staff practice through the local manage, practice leader level [57]. Models that provide easy access to community services and skilled professionals result in better outcomes [58]. Just arguing for more community service does not assure the importance of the quality of the service and does not necessarily address the need of the individual service user. Therefore, future research needs to focus on how the delivery of specialist support and services leads to lifelong improved outcomes for people with ID and/or autism who have mental health needs. Rather than the diluted approach of providing mainstream services to all [59], the evidence is always in the direction of specialist models being most effective [60]. The best example is developing the specialist MHiLD Teams, as already mentioned, in South London [10, 50, 51], where the specialist team support the critical mass of expertise and the development of the speciality, whereas a total generic approach undermines the importance of the need for expertise. This issue is not about mental hospital care or inappropriate care but what makes a difference in terms of outcomes and quality of life.

The introduction of specialist services requires the support of local commissioners along with a strategic vision at a national or state level. A dedicated service model that enhances and complements existing adult mental health services for people with ID seems to be the most effective model.

35.4.1 Service Planning

In the planning of services for people with ID and/or ASD, there is a need to see the wider context of their lives. For example, the level of mental health utilisation may differ according to ethnicity. In a systematic review [68], six studies reported an association between cultural and ethnic factors and mental health utilisation. These included higher proportion of African Caribbean and lower proportions of South Asian referred to MHID services in the UK, while in an Indiana study, African Americans have more doctors' visits. Some of the explanations put forward to try and understand this are utilisation of existing support networks. People with ID and/or autism will commonly be dependent on others for their care and require support from a variety of local agencies. Therefore, it is important that there are clearly defined working relationships between mainstream mental health services and specialist services, such as autism community teams and community ID teams. Whatever the service that is being provided for people with ID, it must have adequate psychiatric input, particularly in the diagnosis of complex presentations with a co-morbid mental disorder [51, 53]. The challenge comes when a person with ID and/or autism requires inpatient hospital care. Few mental health units have the environment to protect an individual with autism from bullying and harassment from other service users. The staff need expertise in the sensory difficulties, communication overload and the need for rituals. In addition, therapeutic approaches are needed to be adapted, including recognised psychoeducational programmes [61]. The physical environment needs to be suitable in terms of layout, noise level, being of low stimulus and suitable social clues. One major issue is a lack of meaningful user involvement in the development and planning of services. There is a need for mutual governance when developing services through service user involvement [17, 20, 47, 48]. Although this is an aspiration of many organisations, often this agenda is left to individuals or teams to ensure involvement [31, 62, 63].

The shifting service module from institutionalised hospital-based care to community-based services with a person-centred approach has been implemented in several countries. In the UK, as already mentioned, there has been an increasing shift to improve access to mainstream mental health services with the specialist services being more for those who have more complex needs. This debate between

specialists versus mainstream service continues but with an increasing acknowledgement that access to both types of services should be available [64]. The response is to some extent dependent on the available resources and expertise in each country; however, in most parts of the world, there has been the development of more specialist health teams. For example, in the Netherlands, the developments of services have been led by physicians. Specialist psychiatric unit for people with ID has been delivering care in Hong Kong since 1995 [65, 66]. In Australia, there are no specialist inpatient facilities for people with ID but there are specialist tertiary services which will meet the mental health needs of people with ID, for example, in Victoria [67].

35.4.2 International Perspective

In line with national and international policies and legislation, services for children and adults with ID are widely provided by both the governmental and non-governmental organisations. World Health Organization reported that only 39% of countries have policies or programmes related to ID [69]. There is a significant variation among the countries regarding the availability of mental health services for this population [70]. Some countries have highly specialised services [71], whereas other countries have limited or no services. This variation can be explained by the lack of clear health policy, lack of comprehensive and up-to-date mental health legislation, limited health-care funds and resources, a paucity of trained psychiatrists and mental health professionals and problems in deinstitutionalisation [72, 73].

There are very few studies that evaluated the effectiveness of mental health services at an international level in addressing this population by randomised controlled trials. In a study conducted across nine Southeast Asian countries, reported that all of those had some mental health services for this population [73]. However, these services varied by their type and range. In three places, Hong Kong, Taiwan and South Korea, there were provision of various types of psychiatric services such as inpatient, outpatient, day hospital and outreach service, for both children and adults with ID, whereas Vietnam provided only psychiatric services to children with ID.

Some reviews have discussed the current status of services in Latin America, South Africa, China, Greece, Asia, India, Taiwan, Serbia and Bulgaria [70, 74–81]. Firstly, these studies reported that knowledge about the effectiveness of these services is limited. Secondly, all countries are alerted about the existence of mental health problems in people with ID and have developed mental health services to tackle that. However, these services fail to cultivate the urgent need for creating a strong network of specialised mental health services for this population. These services are largely concentrated in secondary and tertiary centres of towns and cities, and the rural areas are marginalised [74]. Additionally, these services are provided by inpatient psychiatric units at district general hospitals and specialised psychiatric hospitals, which are mainly located in big University centres only. There is a lack of inpatient specialised mental health services for this population. In addition, in many other places, there are underdeveloped outpatient mental health services that are not enough to provide proper mental health care [81]. Kwok and Cheung [82] commented that decentralisation has added to the burden of general practitioners to manage physical and mental co-morbidities among people with ID. There are major gaps in treatment for people with ID in the community due to a number of factors related to their restricted mobility, behavioural and communication problems, sensory impairments along with the overall lower level of health professional skills and awareness to manage such complex cases.

Further, there are studies that focus primarily on the ethnic variation in utilisation of mental health service among children and young people with ID in high- and low-income countries [83–87]. Findings revealed that, in the UK, South Asian children and adults with ID have lower use of these services than Europeans of Caucasian or African origin [&, 83, 86, 87]. In 2011, Durà-Vilà & Hodes [87] reviewed four studies from three low-income countries – South Africa, Kosovo and

Pakistan –, to see the uptake of mental health services in children and young people with ID and concluded that there may be delays in seeking mental health service that often are related to culturally shaped ideas about ID.

35.4.3 Example of a National Service Model from England

The term learning disability used below is the term still commonly used in the UK to mean ID. In the UK, the principles underlying future service provision is set out in 'Building the right support', which is the national plan for the service model in England for people with ID and/or autism who display challenging behaviour, including those with a mental health need [12]. The principles can be applied in a strategic approach to developing services and these principles are listed below.

1. People should be supported to have a good and meaningful everyday life – through access to activities and services such as early-years services, education, employment, social and sports/leisure; and support to develop and maintain good relationships.
2. Care and support should be person-centred, planned, proactive and coordinated – with early intervention and preventative support based on sophisticated risk stratification of the local population, person-centred care and support plans, and local care and support navigators/keyworkers to coordinate services set out in the care and support plan.
3. People should have choice and control over how their health and care needs are met – with information about care and support in formats people can understand, the expansion of personal budgets, personal health budgets and integrated personal budgets, and strong independent advocacy.
4. People with ID and/or autism should be supported to live in the community with support from and for their families/carers as well as paid support and care staff – with training made available for families/carers, support and respite for families/carers, alternative short-term accommodation for people to use briefly in a time of crisis, and paid care and support staff trained and experienced in supporting people who display behaviour that challenges.
5. People should have a choice about where and with whom they live – with a choice of housing including small-scale supported living, and the offer of settled accommodation.
6. People should get good care and support from mainstream NHS services, using NICE guidelines and quality standards – with annual health checks for all those over the age of 14, Health Action Plans, Hospital Passports where appropriate, liaison workers in universal services to help them meet the needs of service users with ID and/or ASD, and schemes to ensure universal services are meeting the needs of people with a learning disability and/or autism (such as quality checker schemes and use of the Green Light Toolkit).
7. People with ID and/or autism should be able to access specialist health and social care support in the community – via integrated specialist multidisciplinary health and social care teams, with that support available on an intensive 24/7 basis when necessary.
8. When necessary, people should be able to get support to stay out of trouble with reasonable adjustments made to universal services aimed at reducing or preventing antisocial or 'offending' behaviour, liaison and diversion schemes in the criminal justice system, and a community forensic health and care function to support people who may pose a risk to others in the community.
9. When necessary, when their health needs cannot be met in the community, they should be able to access high-quality assessment and treatment in a hospital setting, staying no longer than they need to, with pre-admission checks to ensure hospital care is the right solution and discharge planning starting from the point of admission or before.

This approach allows services to develop to meet the increasing complexity of need with a foundation of services at community level,

through primary care and non-specialist services, which are available to people with ID and/or ASD as they are for the wider population [88]. These services need to have a preventative approach in promoting good mental health and well-being by encouraging healthy lifestyles and by reducing the risk for social isolation that many people with ID and/or ASD experience [24]. There is a need for more specialist well-developed community and inpatient service for those with complex presentations, including those with high-risk behaviours and those resistant to community-based treatment interventions. The literature continues to support that the most effective care for people with ID in the community is provided by services that are person-centred, multi-agency and with evidence-based therapeutic approaches [26]. There is an ongoing need to ensure that we have sufficient numbers of specialist mental health professions including nurses, psychologists and psychiatrists who can provide the expertise to improve outcomes and quality of life [89]. Professionals should act in accordance with legislation covering consent, capacity and decision-making. The service should be able to respond to crisis and there should be provision for out-of-hours care [90].

NICE guidelines on adults with autism (Clinical Guidelines 142) from England [91] describe the concept of local care pathways as the way forward in developing services for this group. These pathways ensure integrated delivery service across all care settings with a range of evidence-based interventions at each stage of the pathway and supporting adults with autism in their choice of interventions. These care pathways are designed to improve the overall quality of health care by promoting organised, efficient service based on the best evidence to optimise service user outcomes.

Tip

- The importance of recognising the need for strategic developments of services with a person-centred approach.
- Services cannot be delivered by one agency but require a multi-agency approach.
- Services must be planned in partnership with service users, their families and carers, respecting the diversity of people with ID requiring mental health care.

In conclusion, despite the existing concern about mental health services for individuals with ID, these services are limited by poor availability, accessibility and evidence of effectiveness [92]. There is a need to know and understand the true prevalence of ID and association of mental health problem [93]. Thus, there are more actions that remain to be done in this area; one is greater investment in mental health services and second is accessible for both urban and rural areas. Given the evidence that people with ID suffer mental health problems at greater rates and often atypically when compared to the general population, there will be always a need for specialist provision for those with most complex needs. The international evolution of comparable models is dependent on the sharing of knowledge, training and technology. In spite of progress and scandals that have made providers and commissioners reflect on what makes up suitable services, the main challenges are long standing [94] and include access to both mainstream and specialist MH services, clear interfaces with other agencies to provide joined up working, proactive commissioning strategies, development of academic centres and further research into service models that deliver improved outcomes.

The need to improve mental health care for people with ID and/or autism spectrum disorder must be based on a strategic approach informed by local and national policy using

the best available evidence. The emphasis needs to shift from what is the best model to which service produces the best outcomes in terms of service user safety, the experience of the person with ID and/or autism and the families that in the long term produce sustainable improved outcomes. This improvement in outcome is not only in the reduction of symptoms and challenging behaviour but also in the well-being and the quality of life of the person. For this to happen, services must be person centred, have staff with sufficient expertise and continue to respect the rights of the person with ID and/or autism spectrum disorder. Each locality within a country is different in terms of the needs of the population and their strengths and weaknesses. Service users come from a diversity of backgrounds but what is important is that the strengths of the local area and services are mobilised through a process of co-production of services developed with the person with ID and/or autism and their families acting as champions.

35

Key Points

- There should be care pathways that cover all health, social care, support and education services with each defining their own responsibility clearly for each service.
- A consistency of treatment and designated staff coordinating the care across the different care pathways with a focus on outcome and clear links to other pathways, such as for those with physical health problems.
- Specialist ID and mental health services should have clear aims to ensure that people's needs are met, including those of the families, carers and care workers who should be actively involved in any assessment and treatment of the individual.

Through the leadership of practitioners who have the courage and wisdom to build on the local capacity to overcome weaknesses such as lack of good policy or funding, there will be a constant drive to improve the quality of mental health care for people with ID and/or autism [95–97]. This chapter was written prior to the Covid-19 pandemic and as yet we do not know the full impact of the pandemic on the mental health of people with ID but restrictions on their lives and the increasing use of visual consultations may have long-term consequences that will need to be accounted for in the future planning of mental health services for people with ID and/or autism ([98]; see ► Chap. 43).

Learning Objectives

Costing is a useful approach in its own right but is also a key component in an economic evaluation. This chapter focuses on the estimation of costs incurred by providers as a result of treatment programmes or health service options. Before costs can be estimated, there are three interrelated stages: identification, measurement and valuation. These stages provide a general framework as many of the considerations related to the costing estimation exercise are dependent on the analytical viewpoint or perspective. A distinction is made between intervention and non-intervention to provide a framework for estimating costs in intellectual disabilities. The aim of this chapter is to provide readers with a practical guide to cost estimation in intellectual disability research. We focus on particular categories that have particular relevance to various decision-makers and are important for analysts, such as training, accommodation, health and social care professional input, and caregivers' time inputs.

After working through this chapter, you will be able to:

- Understand why health economics is relevant in intellectual disabilities
- Explain the main steps in cost estimation
- Understand what methods can be used to identify, measure and value resources and support in intellectual disabilities

36.1 Introduction

A comprehensive estimate of the costs of intellectual disability (ID) was reported in a 2016 review by Salvador-Carulla and colleagues [1]. Costs were derived from a model that combined epidemiological and economic data in 30 European countries [2]. The cost (in Euros PPP 2010 prices) of ID (referred to as mental retardation in the article) across all 30 European countries was Euros 43.3 billion, higher than child and adolescent disorders (Euros 21.3 billion), traumatic brain injury (Euros 33.0 billion), personality disorders (Euros 27.3 billion) and multiple sclerosis (Euros 14.6 billion) [3]. These high costs in ID were based on the use of healthcare resources but ID has far-reaching impacts on other sectors, more specifically the social care sector, largely driven by the residential services that respond to the needs of service users [4–9]. In addition, there are also hidden impacts on the families and friends of the person with an ID and the rest of society which are often overlooked [10]. In a study conducted in Australia, Doran et al. [10] found that cost for people with ID was AUS$14, 720 billion (2005–2006) annually of which caregiver time lost contributed 85% of the total costs.

An awareness of the monetary sacrifices involved in providing treatments, services and support to individuals with intellectual disabilities is necessary and important for stakeholders at all levels be they strategic decision-makers such as commissioners of services, charitable organisations or families, as it is often the consequences of these decisions that can be used to influence policy. Consider, for example, government agencies would need information on the types and amount of out-of-pocket expenditure incurred by families to care for people with ID if they are to provide benefit payments that can be used to recompense families and facilitate purchases of non-statutory services and support. But influencing policy responses is not the only reason cost estimates are important. They are also necessary because those who design and implement services recognise that resources will always be scarce relative to demands placed on them, and a central aim is to maximise well-being and quality of life for people with ID, which may require investment in additional resources. A good understanding of value of the sacrifices foregone to various sectors and how these costs are derived can also be useful for researchers and analysts alike as they illustrate the economic impacts of ID.

This chapter aims to provide an understanding of each of the main stages in the calculation of costs of services and support in ID research. Although a distinction can be made between the costs incurred to meet the needs of people with ID and what is provided, the principles used to derive costs in

both contexts are in the main similar. In the following sections, we first give an overview of the importance of economics in the provision of services for people with ID and the principles appropriate for use in economic studies. We then focus on how particular categories of costs are derived, generated from information on the services and support typically used by people with ID.

36.2 Economics of Intellectual Disability Service Provision

Economics is the study of scarcity and explores how choices are structured and prioritised to maximise welfare within budgetary constraints [11]. Economics plays an important role in the provision of care and support in intellectual disabilities given that scarcity has two sides; the high and growing levels of wants for most services and treatments; and a limited budget that can go towards staffing, therapeutic services, treatments and support to meet needs. The simple reason people demand these services and treatments is not only because they want to be healthy but because they want to live the lives that many people without a developmental disability take for granted. It is that desire to fully participate in their communities unconstrained by poor health that has led to an increase in the demand for care. There are a few more specific reasons for the increase in the demand for treatment and services such as population changes, changing expectations and government legislation we will cover in the sections that follow.

36.2.1 Population Changes

Changes in the number of people with an ID [12] have increased the demand for services. The increases are explained in part by an increase in life expectancy, especially among people with Down's syndrome. Other explanations for the increase have been related to natural increases in the population. As the population increases so too will the number of economically dependent individuals with an ID, largely due to the decreased mortality and increased life expectancy. Also, as migrant populations increase, the proportion of young adults from minority ethnic communities with an ID is likely to increase, as greater numbers of young people with severe and complex intellectual disabilities are surviving into adulthood [13]. These changes are also contributing to increases in the number of people with an ID in contact with services.

36.2.2 Changing Expectations

Families of people with intellectual disabilities have expectations of what services their loved ones should receive. More and more the expectation is that children will leave home when they reach adulthood and will live as independently as possible in the community instead of at home with their family.

36.2.3 Legislation

In some countries, government legislation has fuelled the increase in the demand for certain types of services for people with intellectual disabilities. Residential services have been on the rise due to legislation in the United States (dating from the 1960s, CMHA; P.L. 88–164 and 1980s, OBRA; P.L. 100–203) and in England and Wales, the Percy Commission, 1954–1957 recommended that more provision be made for people with intellectual disabilities in residential homes in the community, in part in an attempt to alleviate the strain on hospital provision. A series of inquiries (Committee of Inquiry at Farleigh Hospital 1971; Committee of Inquiry into Whittingham Hospital 1972; Committee of Inquiry into South Ockendon Hospital 1974; Committee of Inquiry on Normansfield Hospital, 1978) [14] were conducted following revelations of ill-treatment and neglect and squalid conditions which led to the Government White Paper [15]. This document reinforced the ambition of providing services in the community for people with mild or moderate intellectual disabilities.

In the United States, the number of people with an intellectual disability receiving residential services increased from 267,682 to 460,597 over 1988 to 2011, while over the same period the number of individuals with ID living in nursing homes and state-provided institutions steadily declined [16]. In England, the number of people living in institutions declined from 51,000 in 1976 to over 3500 in 2002 [17]. Concurrently, there was an increase in the number of people supported in smaller community-based residential provision based on the use of domestic accommodation. The movement to community-based settings, mainly hostels, semi-supported group homes, family placement schemes, bed and breakfast and independent living, primarily focused on people with least severe disabilities. Attention has since moved to the development of community-based housing for people with more severe and profound intellectual disabilities and the provision of health and social care treatment and support for carers.

36.2.4 Resources

The other side of scarcity relates to the finite nature of resources. The term 'resources' covers all inputs used to produce treatment and services. When we consider the provision of ID care at any one time, there is only so much funding available for health- and social-related care for those with typical and complex needs. There are also limited amounts of funding for individuals through benefits to provide mobility and disability allowances. Budgetary constraints impose limits on the provision of care irrespective of the sources of funding (see Table 36.1).

Table 36.1 Funding sources in selected European countries

Country	Funding source
Netherlands and Greece	Central government funded in the main
Spain and Belgium	Social administration on a regional level with some funding from charities, private sources and lottery sources
Sweden	Funded through taxation on a local, regional and national level. Social administration on the local level
Germany	Mixed system. Regional level funding for residential services. Social administration at local level and by care insurance or other social provisions, supported living funded
United Kingdom	Mixed system. Central (regional) level funding from the National Health Service (NHS) for health-related care and for those with more complex needs. There is also funding for individuals through benefit payments such as mobility and disability allowances. Local level, funding is provided through social services with some provision from housing services

Source: European Intellectual Disability Research Network [18]

Fixed budgets, demand and supply pressures impose constraints which limit the provision of care. Costing information is often used to assist decision-makers with evidence on the scale of the problem to better determine how to allocate scarce resources. Although limited because it does not consider outcomes, costing information is used to make a strong case to increase investment in intellectual disability service provision. Given the relevance for decision-making, it is important that researchers and practitioners are familiar with the need for determining the range of costs and components to include in any costing exercise.

36.3 Efficiency Versus Equity

The problem of scarcity presents challenging decisions about how best to combine the limited resources in such a way that can achieve

good outcomes. Health economics provides a theoretical and analytical approach to dealing with this concern within health systems while considering the economic principles of efficiency and equity. There are other principles used in health economic evaluations and we will consider these as we go through this chapter. Moreover, there are differing views on what is equitable and it seems reasonable that an equitable allocation of resources would mean that those who have the greatest needs should receive the most support. Equity therefore relates to the extent to which access to services and the outcomes from these services are distributed in a fair way across socioeconomic groups, elderly and the young and by regions. Economic efficiency, on the other hand, implies that society makes choices based on whether the benefits of service can be maximised for the available resources. The aim of the efficiency criterion is to ensure that the health of all those in society cannot be increased if resources are reallocated but makes no judgement about which members of society benefit from this increase. We include them here as they are important considerations in economics and particularly relevant in value for money discussions, though we do not discuss the implications for costing.

36.4 Financial and Economic Costs

Financial costs are the monetary payments associated with the price of a good or service traded in the marketplace. More specifically, it covers the expenses that a company incurs through operations, from factory costs to surcharges. Examples of financial costs include the cost of raw materials, semi-finished and completely finished products, administrative expenses, such as rent, salaries, insurance and utilities. For an economist, the notion of costs is not restricted to money but reflects the value of the gains given up by alternative options when one particular option is chosen. It is the value of the gains foregone or the losses that are incurred when a service or treatment is introduced that is key to understanding costs from an economic point of view.

36.5 Opportunity Costs

Another useful concept is that of opportunity costs. In economics, the gains foregone or the losses that are incurred when a service or treatment is introduced are referred to as 'opportunity costs'. For example, if Liz decides to stop working and go to school to train as a speech and language therapist, the opportunity cost of this decision is the lost wages Liz would have earned had she continued working. In intellectual disabilities economic research, the opportunity costs principle is often used to attach a monetary value to resources. One type of resource that features prominently in ID research is caregiver inputs. Family members or friends may be full-time carers depending on the severity of the ID. In other cases, caregivers may take the individual to daytime activities. The time a friend or family member spends giving support is often provided without any payment as a consequence and arguably so, unpaid caregivers often therefore forego the alternative use of their time such as taking up employment, education or career opportunities, as a result of spending time in caregiving activities. It is not always an easy task to identify what types of opportunities have been foregone to provide care. We revisit the application of this concept in more detail later in the chapter (see ► Sect. 36.8.4).

36.6 Perspective

The perspective is the point of view you use to examine the range of costs to include in the economic analysis. It is an important consideration as intellectual disabilities and comorbid mental disorders have wide-ranging impacts on the person with an ID, their caregivers, services and society. It is therefore important to be explicit about the perspective as this forms the basis for the types of costs to

be included in the costing. There are a number of possible perspectives to choose from including the following:

- People with intellectual disability
- Caregivers (family or friends)
- Health and social care providers
- Public sector providers (could include one or a combination of providers within health and social care, criminal justice or education sector)
- Third-party payers
- Societal perspective

If a given perspective is adopted, only the costs that are incurred by that perspective are considered. In England, the National Institute for Health and Care Excellence (NICE) guidelines currently advise that only National Health Services/Personal Social Service (NHS/PSS) costs be included for approval of new health technologies [19]. If a public sector perspective is adopted, only costs borne by the public sector agencies such as a health, social care, criminal justice would be included in the analysis. From a third-party payer perspective, only the resources paid for by insurance companies, managed care organisations are included. For example, any reimbursements to patients for income loss are an actual cost to the third-party payer. A societal perspective can include, but is not limited to, costs to public sector agencies, caregiver time costs and out-of-pocket expenses, service user out-of-pocket expenses and caregiver productivity losses.

Losses in the production of goods and services—productivity losses—feature in economic studies, and occur when individuals take time off work (paid and unpaid), become unemployed or take early retirement due to disability, or have reduced productivity at work [20]. Productivity losses have not been explored intensively in ID research, perhaps because a small number of people with ID will be in paid or unpaid employment. It is important to note that losses in productivity can also arise from caregivers taking time off for work to provide care. At the extreme, caregivers may be required to give up work all together to provide support or not take up employment in cases where intensive support for a young person or an adult with an ID may be required.

Reference is often made to a narrow or a broad perspective. A narrow perspective focuses on any one of the possible perspectives mentioned previously, for example, the perspective of health and social care providers or third-party payers. In countries with insurance-based systems, the majority of published economic studies involving people with intellectual disability use health claims/expenditure data, which do not capture the far-reaching impacts of intellectual disabilities which fall on non-healthcare sectors. These studies can be considered to have used a narrow perspective. A societal perspective is the broadest of all perspectives. Choosing any one perspective does not preclude using another. The results can be presented from each perspective and are particularly useful to satisfy the needs of different stakeholders.

Underpinning the costing of care and support in intellectual disabilities research are important concepts such as efficiency, equity, perspective and opportunity cost. Each of these concepts requires consideration, though they are not the only concepts which can be considered. We focus on these as they are the most widely used and applied in costing of care and support in intellectual disability research.

36.7 Steps in Cost Estimation

There are three necessary steps when estimating costs in ID research: identification, measurement and valuation. These steps can be done sequentially and will interact before costs are estimated by taking the quantity of each resource item and multiplying it by monetary *units* such as euros and dollars. The first step is to identify cost categories but these are driven by the perspective of the analysis. It is also useful to be aware of the range of resources and support costs that may be relevant to users of intellectual and developmental disability services (see ► Box 36.1).

Box 36.1 Services and support costs relevant to people with intellectual disabilities

- Accommodation costs (e.g. group homes)
- Training costs (e.g. trainers, advocates, managers)
- Medication costs (e.g. neuroleptics)
- Health and social care service costs (e.g. primary care, inpatient stays, community psychiatrist, social worker services, specialist intellectual disability services, community nurse, support worker)
- Education and training costs (e.g. adult education)
- Education facility costs (e.g. schools for children and young people with intellectual disabilities)
- Respite service costs (e.g. respite care)
- Private-sector services (e.g. home-care worker, alternative therapies)
- Person with ID costs (e.g. out-of-pocket expenses for travel to services)
- Unpaid caregiver expenses and costs (e.g. out-of-pocket expenses for child minding, travel; time spent providing support)
- Unpaid caregiver productivity costs (e.g. time off work)

Considering the range of resources and support, inconsistencies in the interpretation, scope and definition of direct and indirect costs, and how costs have been categorised and applied across a number of economic studies in intellectual disabilities; we categorise costs into intervention and non-intervention costs to describe the cost estimation process.

Intervention costs are associated with treatments, programmes or strategies designed to change behaviour or improve health and well-being and in ID research can be usefully sub-divided into facility-specific and non-facility specific for costing purposes. Facility-specific interventions can include residential services or settings where people with an ID access specialist care and support related to their ID or comorbid conditions, for example, an intensive support service, supported housing. Non-facility-based interventions may include medication or treatment not tied to a facility or place of delivery for the person with an ID. Any out-of-pocket expenses or costs to society can also be included here.

The categorisation of interventions, in this way, can also be used to cover interventions aimed at caregivers of people with an ID. Examples of facility-specific interventions aimed at caregivers might include respite care services for caregivers and non-facility-specific interventions could cover caregiver training interventions.

36.7.1 Identification

The identification process considers resources as cost-generating events in physical units and defines appropriate units for measuring resources and support. The units of measurement can be defined as an activity (e.g. blood test, inpatient days, outpatient appointments), physical resources, such as drugs (e.g. tablets), professional time-based inputs (e.g. social worker visits, psychiatrist contact hour, caregiving hours) and societal impacts, such as time off work (e.g. days per week).

The type of resource and issues surrounding practicalities of measurement are useful guiding principles when deciding on a unit of measure. If the unit of measure requires a complex and resource-intensive recording system, it may not be practical or efficient to measure the resource in those units. It is also necessary to take into account whether unit costs can be readily defined or estimated; otherwise, another unit of measure would need to be identified as informed by available unit cost data.

36.7.2 Measurement

There are two main ways to measure resources used by people with intellectual disabilities and the support they receive from caregiv-

ers; these are through the use of questionnaires and diaries. The Client Service Receipt Inventory (CSRI) [21, 22] is one of the most widely used questionnaires to collect information on service use and support in this population. This questionnaire was developed as part of the community demonstration programme 1984/1988 funded to develop community alternatives to hospital care for people with mental health problems, physical and intellectual disabilities, and was first piloted in people with intellectual disabilities. Since these pilots, the CSRI continues to be modified for use in economic studies. It has gone through a number of iterations having been used in well over 200 economic studies to date across a wide range of diagnostic areas including intellectual disabilities and autism, see, for example, [8, 9, 23–26]. The CSRI's seven main sections can be adapted depending on the scope of the economic study. Sections record client demographic information related to gender, marital status, ethnicity; accommodation—a major component in the provision and costs of care in the community; employment and income; daytime activities; service receipt—a core part of the CSRI which identifies health and social care services and specialist mental health services that are not funded by the accommodation budget; aids and adaptations; and unpaid caregiver support. Other questionnaires have been designed for use in children and young people with autism: Child and Adolescent Service Use Schedule (CASUS) [27] and the Service Assessment for Children and Adolescents (SACA) [28]. Diaries can also be used to collect data on the activity of staff working directly with the care recipient, but there is a balance to be stuck between precision and cost to implement. Professionals are asked to fill out how they use their time over a defined period, for example, a week, and then state for each period what they were doing, anything else they were doing at the same time, where they were or how they were travelling. Although not used in intellectual disabilities research, this approach can be adapted and used in recording unpaid caregiver inputs, where the time spent in different activities can be variable (see ▶ Sect. 36.8.4.1).

36.7.3 Sources of Resource Use Data

Questionnaires and diaries are used to collect data on resource use and support when economic analyses are conducted alongside intervention studies (e.g. randomised trials, non-randomised trials, matched *controlled trials)*, but there are a number of other sources from which data can be obtained. Sources such as administrative databases, clinical databases, medical records, focus groups and the literature can be particularly useful when populating economic parameters in economic decision analytical models (e.g. decision analysis and Markov chain analysis). However, there is a misleading distinction between the methods of data collection and the study design in which economic modelling can generally use data from trials (obtained from the literature) and economic analyses within a trial can involve economic modelling, particularly where there is the need to explore the impact of the intervention beyond the trial period. In many disorders, it is not possible to fund a study enrolling enough patients for a long enough period to collect the necessary data to establish sustainability of the intervention, which means that the efficacy of the results is limited to the duration of the trial.

Decision analytical modelling is used to estimate costs, outcomes and cost-effectiveness of alternative interventions and programmes. Data from several data sources are synthesised, and statistical techniques are applied with the aim of providing decision-makers with information on which of the alternatives should be adopted. Decision analytical modelling is growing in popularity in mental health and is already widely used in physical health research. Despite the flexibility it provides analysts and decision-makers, we have only been able to identify one published economic study to date that has employed this approach in the field of intellectual disabilities [29].

36.7.4 Valuation

In the valuation step, the aim is to determine the value for each resource which reflects the opportunity cost of an appropriate unit. For example, during the valuation stage, the analyst seeks to value a hospital inpatient stay, time GP spends during a visit or home care hours. The unit cost for a hospital stay, GP visit or time spent in home care by a home care assistant, for example, would be needed.

There are two main costing methods that can be used to derive unit costs: bottom-up or top-down costing methods. Bottom-up costing methods typically sum information on capital and overheads, salary, and salary on costs divided by the total number of units for the year. When this approach is used to derive, a cost per hour for a professional, salaries and the cost of shared resources such as overheads, buildings, utilities and equipment for the year are added together and the total number of hours is adjusted for travel to provide care or where pay affects by absences allowances would need to be made for annual and statutory leave days (see ► Sect. 36.8.3.1).

Unit costs also may be obtained from publications and national unit cost databases. In the United Kingdom, each year since 2001, the Personal Social Services Research Unit (PSSRU) has published annual estimates of the unit costs of health and personal social services in the community or other settings for people with an intellectual disability, autism and mental illnesses. This widely used national compendium derives costs using the principles outlined in this chapter and is recognised internationally as an authoritative source for unit costs in economic studies.

The values of services based on the prices offered in markets free of government involvement are good measures of the unit cost of a service as they represent the true opportunity cost of resources. Moreover, in countries where the government provides health care such as the United Kingdom or Sweden, the use of market prices will not represent opportunity costs. The same is true for tariffs. Tariffs are prices set by the government or an insurer for payment to healthcare providers. These prices may be set to include incentives for a level of provision. Prices may be set high to encourage provision or low tariffs to discourage it [30]. In some countries such as the United States, the charges from providers to insurers are used to value service use and, in many cases, these charges are set higher than the opportunity costs to subsidise the cost of other activities within the hospital.

A top-down approach takes the total budget and divides it by the unit of measure. For example, to estimate the cost per hour of therapy using a top-down method, the total therapy budget would be divided by the number of hours of therapy delivered. This approach is particularly useful when for some services it is difficult to determine a cost per unit of measure due to complexities around payment arrangements [21].

There are three basic steps conducted in any costing exercise in ID research: identification, measurement and valuation. The Client Service Receipt Inventory (CSRI) was one of the first service use questionnaires to be used to measure services and support in service users with an intellectual disability. The CSRI was developed as part of the community demonstration programme 1984/1988 funded to develop community alternatives to hospital care.

36.8 Costing Intellectual Disability Services and Support

We can apply the stages seen in (► Sect. 36.7) when resources are used to provide training programmes, accommodation, professional services to meet the needs of people with intellectual disabilities and when costing caregiver time inputs.

36.8.1 Training

Training programmes have been used as a way to build capacity in staff but also in families, friends, paid support and front-line staff to put individuals with an intellectual disability

at the centre of matters related to their personal, social and economic well-being. The approach to costing training programmes applies the three stages but includes a preliminary stage—description of the programme. The training programme would need to be described with a view to identifying the resources consumed regardless of whether they can be measured or not; then quantified into physical units such as per person, per hour or per session; and valued by applying a cost to each different type of resource identified. The resource costs across the training sessions would then be derived by summing the costs across all sites (in a multisite study) and weighting it by the number of trainees to derive a cost per trainee.

Usually, when training costs are calculated, they are allocated according to either the number of people assigned to the group or the number of people attending a group. The former approach is more commonly taken because group sessions will usually proceed unless no one attends. It has also been argued [31] that this is the most appropriate approach for estimating participant-level costs, with the exception of programmes with limited places where dropouts are likely to be replaced from a waiting list.

When conducting training programmes not only for the benefit of the participants but also for the benefit of a third party, there are additional concerns that may arise. In this case, using data on the number of participants trained to allocate the cost of the training programme would not provide a link between the cost of training and the individuals the programme is directed towards—people with intellectual disabilities. To explore this relationship, the training costs could be allocated to the number of participants in the training programme or the number of participants who achieved the outcome for which the training was conducted instead of the actual number of people trained. If the number of participants in the training programme is greater than the number of participants who achieved the desired outcome from the training, then the cost per person is likely to be on the conservative side.

► Study example 1—Training

Robertson et al. [32] and Romeo et al. [33] illustrate how a cost per participant can be estimated in a training programme used to support people with intellectual disabilities. Training across the sites was undertaken in a variety of settings; in some cases, a nominal rent was paid for the facility and in other areas use of the facility was provided 'free' of charge. To ensure that capital was consistently employed across all sites, standard capital cost estimates were used. Capital costs were estimated using new build and land requirements for a local authority training room, annuitised at a rate of 3.5 percent over 60 years. To calculate the cost per trainee of attending training, the average costs of each of the elements were summed to give an average cost for the training programme.

36.8.2 Accommodation

Care for people with ID includes some combination of housing provision and services and support that are coordinated by providers external to the residential setting. The type of residential provision is very important for a person with ID as they may need varying levels of support given challenges remembering information, grasping the concept of time, managing self-care and related activities, and carrying out daily life skills. Many individuals live in a house or flat with relatives, or in supported housing or residential care homes. People who can live more independently and do not require any support may choose to live in their own home, rent from private landlords, council or housing associations. When attaching a cost to rented accommodation convention indicates that the rent (fee charged to the service user) can be used as a proxy, this fee is set at an amount that covers both capital and revenue covering the cost of the original capital investment [21]. Similarly, when costing private sector residential or nursing home provision, the fee or charge for boarding and care can be a practical option.

There are various forms of supported housing arrangements: adult placement, sheltered housing, group homes and hostels. There are

instances where people with an ID in supported settings may be charged rent and required to cover additional costs, for example, service charge for communal area maintenance and a charge for any support. Perhaps, the most flexible housing arrangement provided by individuals unrelated to the service user is adult placement schemes. Adult placement schemes involve the individual with an ID living in the home of their landlord or landlady, who also provides them with care and support. There are examples of placement services in the United Kingdom that charge a placement fee that covers rent paid directly to the carer, usually out of the benefits the client receives. There can be an additional fixed payment for food and utilities, agreed upon by the individual with ID and the carer [34].

Residential care can be provided in a registered care home managed and run by a service provider who is responsible for all aspects of the client's daily needs and well-being. The main groups of service elements that make up residential care and the information required to derive costs are detailed in Beecham [21] (adapted in ◘ Table 36.2). The cost can be categorised into establishment costs and costs of services provided by external services. Establishment costs are built up from capital costs, revenue costs and other personal living expenses for items such as food, utilities, personal care and leisure.

When calculating the capital cost of public sector services, the annuity generated by the valuation of the facility over the useful life of the building represents the annual opportunity cost of the capital investment in that facility. In order to derive the annual cost of the capital information on the rate of return or rate of interest on public sector investments, the building valuation and the useful life of the facility commonly estimated at 60 years is required. Revenue costs can be obtained from income and expenditure account held by the finance department and produced annually. There are challenges when using this approach to calculate establishment costs for private sector services as buildings' valuations in the private sector may not be readily available. In this case, the fee or charge to the resident can be used as a proxy for capital and revenue elements.

◘ **Table 36.2** Costing residential care

Elements	Sources
Capital:	
Building, location and size	Capital costs for building and land can be calculated using market valuations of property. Capital costs would be annuitised over 60 years
Revenue:	
Staffing (direct and non-direct staffing)	Staff-related costs and expenditure accounts
On-site administration	Expenditure accounts
Agency overheads	
Other costs:	
Personal living expenses for items such as food, utilities, personal care and leisure	Expenditure accounts if provided by the service. Personal allowances/benefits can be used as proxies for personal consumption if these expenses are not covered by the service

▶ Study example 2—Accommodation costs

Felce et al. [35] estimated and compared both the costs and quality of life outcomes of adults with intellectual disabilities living in semi-independent accommodation to similar individuals living in fully staffed group homes. Costs of accommodation were estimated from agency financial accounts that managed and provided room, board and support for each individual participant. Accommodation costs included the costs of direct and non-direct staffing, administration (on-site) and central agency overheads. Costs of non-accommodation included the costs of daytime services, hospital and community-based services and were estimated from a service use questionnaire. To calculate the total weekly cost of the accommodation

service packages, the average costs of accommodation and non-accommodation costs were summed to provide an estimate for the average total weekly costs of semi-independent living and fully staffed group homes.

36.8.3 Non-accommodation Service Costs

Services and support provided external to the setting where people with intellectual disabilities live can be delivered in a healthcare system with many agencies providing a variety of services. Often there is no basic package of care offered to people with intellectual disabilities and services such as health, social care and specialist mental health services which may not be funded within the budget of the housing setting. Typical services provided external to the living setting may include but are not limited to hospital-based inpatient and outpatient services or speech and language therapy and GP services. Support services provided by a home care assistant to help with personal care, washing up, dressing, housekeeping and other domestic work or services, such as meals-on-wheels, may also be available. In some countries such as Denmark, the government provides home help which may also include some physical exercise and mental stimulation of the individual to help maintain physical and mental capabilities. Currently, in England, local authorities have the powers to make direct cash payments to individuals with intellectual disabilities, who can then arrange and pay for their own care. Families and friends can be paid out of these payments for the care they provide, once they are not living at the same address.

36.8.3.1 Costing Non-accommodation Services

There are different methods that can be used when costing the time spent by professionals who visit individuals where they live or are visited by people with an ID in a clinical setting. The bottom-up costing methods can be used to calculate a cost per hour of contact with a professional. The professional's annual costs are aggregated using elements related to the profession, grade, working hours; capital based on location size of the office or clinic; overhead costs to the provider for administration and management as well as office, training and utilities and general management and support services such as finance and human resources. For each of these elements, information on salary-related costs, salary scales, national insurance, superannuation rates; capital, overhead costs to the provider for administration and management, office, training and utilities; overheads such as general management; and support services such as finance and human resource departments are summed and then divided by the total number of hours worked for the year based on the professional's conditions of service. If the total number of hours includes annual and statutory leave, it is assumed that pay is not affected by absences. When pay is affected by absences, the total number of hours would need to be adjusted accordingly. For professionals who make home visits, the denominator—the total number of hours—will be substituted by the average number of domiciliary visits per week. ◘ Table 36.3 illustrates the valuation of an hour of time for a community occupation therapist.

36.8.4 Caregiver Inputs

Often tasks provided by family members for which no payment is received (referred to as unpaid caregivers) can also be performed by paid caregivers. For simplicity, most economic analyses, make no statements about the equivalence of the quality and efficiency of the care provided by paid and unpaid carers. In these analyses, the implicit assumption is that the care provided by both paid and unpaid caregivers are equivalent in both respects, although there may be marked differences [36].

Despite the importance of unpaid caregiver support to the individual and impacts on the care recipient's outcome, there remains a paucity of studies that have included caregiving support in economic analyses in intellectual disabilities. Our own review of published articles covering or including economic analy-

Table 36.3 Illustration of community occupational therapist

Element	
A. Salary/wages	£32,419
B. Salary on costs	£8873
C. Overheads	£18, 582
Working time	40.9 weeks per year; 37 hours per week
Travel time	£2.80 per visit
Ratio of direct to indirect time:	
Face to face	1:0.67
Clinic contacts	1:0.33
Home visits	1:0.73
Length of contact	60 minutes per home visit
Unit cost:	
£40[a]	Per hour
£53[b]	Per hour in clinic
£71[c]	Per home visit

[a](32,419 + 8,873 + 18,582)/(40.9 × 37)
[b][(32,419 + 8,873 + 18,582)/(40.9 × 37)] × 1.33
[c][[(32,419 + 8,873 + 18,582)/(40.9 × 37)] × 1.73] + 2.80

sis of caregiver inputs in intellectual disability up to February 2018 identified no studies that focused solely on the costs of informal care; however, five studies incorporated the cost of care provided by paid or unpaid caregivers into their economic analyses [25, 26, 37–39].

Although public decision-making bodies in some countries may not explicitly recommend the inclusion of unpaid care costs in cost-effective analysis of health and public health interventions, it is important to note that a failure to include unpaid caregiver impacts from costs-effective analyses of health and social care interventions, which could lead to different conclusions about value for money as seen in a study of people with dementia [40]. Careful consideration of the likely impacts of a failure to include unpaid caregiving impacts is required [41]. Tranmer and colleagues [41] take the view that as a greater proportion of care is being provided and received within the home and community settings, the exclusion of these costs could provide a misleading estimate of the true costs of healthcare programmes. It is therefore advisable that any decision to exclude unpaid caregiver costs is justified.

36.8.4.1 Measurement of Caregiver Time

Measurement in this context involves quantifying how much time is used to provide care to the person with an ID by the family member, friends and other individuals such as volunteers. There are three main methods that can be used to collect time use data: interviews, diaries and direct observation. Interviews involve asking respondents to recall retrospectively the time devoted to caregiving activities over a defined time period, for example, average time spent preparing meals in a typical week. Care should be taken when looking at the period of recall. Shorter periods of time are more easily remembered than longer periods. It may be possible to collect more accurate data for the past week than the past year. Interview questions would need to be carefully worded as caregivers may perform more than one activity at the same time (also referred to as joint production) such as preparing meals and socialising with the care recipient. Shearer et al. [42] suggest that concerns with allocating time to each activity can be overcome by wording one of the two activities as the main activity and the others as secondary or combining both activities into one. Another method that is a more accurate way to record time inputs than an interview but can be time-consuming is the use of dairies. Diaries involve the caregiver recording the time spent supporting the care recipient with caring activities. Information can either be recorded over the course of the day or retrospectively. It is less time-consuming than diaries but potentially a greater imposition is the use of direct observation. During direct observation, the observer records as accurately as possible the amount of time the caregiver is spending on various activities. One of the

advantages of this approach is the richness of the data. An observer who has no personal involvement with a caregiver may also be able to gain valuable insights, which a person more familiar with a situation may miss. It also requires less active involvement and cooperation by the caregiver. Despite these advantages, this method is resource intensive requiring a trained observer to perform that can be susceptible to observer bias.

36.8.4.2 Valuation of Caregiving Inputs

Different methods have been used when valuing caregiver time inputs; many have been described as controversial [40]. Three methods considered by Brouwer et al. [20] include market price, replacement costs and opportunity cost.

Caregivers often provide support free of charge, but although there is no money received for the support they provide, caregiving inputs are not free in an economic sense. The time the unpaid caregiver is involved in caring activities is time which could be spent in any of a number of different activities, for example, paid work, unpaid work or leisure. Consequently, then, there is a cost in terms of the opportunities they have foregone. Using this approach, the alternative activities given up as a result of the time devoted to caring can be identified and valued. If the time spent caring is at the expense of paid work, then time inputs would be valued by wages. Similarly, for unpaid work, time could be valued by estimating the wage paid to someone in the paid care sector who would be employed to provide the same activities. For example, wage rates for home care assistants can be used to value time spent providing support with managing money, dressing, mealtimes and shopping. Leisure time valuation is particularly tricky as there are no widely used methods or conventions when valuing leisure time inputs for unpaid caregivers. Hourly wages as shadow prices have been suggested for valuing leisure time by caregivers [43].

The replacement valuation method is based on the cost of buying the same number of hours of unpaid care from the formal care sector. In the replacement cost method, the wages for paid caregiving support would be used to value time spent providing unpaid support. However, replacement cost valuation methods may not be different from the opportunity cost approach, in which the unpaid caregivers could theoretically take on paid caring roles if they were not caring for their family member or friend. The value of the unpaid caregiver's time could be reckoned in terms of the wages of a paid carer [42]. In research conducted by Barron and colleagues in an inner London Borough with adolescents with intellectual disabilities and challenging behaviour between the ages of 16 and 18 years, the authors found that there was a potential saving to local authorities in England of £1554 per week where unpaid caregivers were providing unpaid care and support [37]. In a study of a health check intervention designed specifically for adults over the age of 16 years implemented in the Greater Glasgow Health Board area, Scotland, Romeo and colleagues (2009) applied an hourly rate of a home care work to full time unpaid caregiver inputs to provide a monetary measure of the cost of these time inputs [26]. In the same study, opportunity cost principles were applied where the average gross hourly earning of caregivers in full time or part time paid employment was used to value the unpaid care giving inputs by those caregivers to service users. In research where unpaid care was provided by students, caregiving and support was valued at the minimum hourly wage and an average hourly pre-retirement wage for retired caregivers [25, 38, 39].

Other methods of valuing caregiver time can be used which reflect the preferences or the loss in well-being experienced. Preference-based methods such as contingent valuation and conjoint measurement can also be applied to value unpaid care. Both of these valuation methods measure from the caregivers themselves how much they feel they should be paid. In the case of contingent valuation techniques, the caregiver is asked how much they are willing to accept (WTA) to provide care for an additional hour [44] and in the case of conjoint analysis, trade-offs are made between

the caregivers current caregiving situation and hypothetical caregiving situations [45]. The well-being method considers the psychological impact on the caregiver and is based on the loss in well-being suffered as a result of caregiving activities. Using this method, the value of unpaid time inputs is estimated as the amount of income required by the unpaid caregiver to maintain the same level of well-being after an additional hour of care is provided [46, 47].

Tip

The three main steps in costing estimation exercises have tended to be used when estimating costs for training programmes, accommodation and professional services offered to people with intellectual disabilities. It can also be used to cost caregiver support provided to service users.

Key Points

- Estimating costs is necessary and important as it is often the economic consequences that influence policy responses even though the health and quality of life impacts of intellectual disabilities are usually the focus of public concerns.
- The main steps in the estimation of costs are identification, measurement and valuation of resources and support to people with intellectual disabilities. The estimation process mainly applies to studies where data can be collected as part of a trial or observational study.
- The majority of studies in intellectual disabilities to date are trials or observational research which do not explore the economic impacts beyond the study period. These limitations can be overcome through the use of decision analytical modelling where data can be obtained from the literature, large administrative datasets and focus groups.

Learning Objectives

The aim of this chapter is to give the reader:

- An awareness of how residential and community-based services for people with intellectual disability have changed over time.
- An awareness of the current living situation of people with intellectual disability.
- An understanding of the importance of outcomes in thinking about the quality of services.
- An understanding that although an ordinary home dispersed in the community is a necessary condition for better quality of life outcomes, it is not sufficient on its own.
- An understanding of the importance of paying attention to structures and processes, in particular, the nature and quality of the direct support provided.

37.1 Introduction

Over the past decade and a half, there has been a growing recognition internationally that being an active participant in society is about fundamental rights and that governments should provide the necessary support to enable all people to enjoy these rights, including persons with disabilities [1, 2]. The move from institutional to community-based support for all persons with disabilities is an important part of this process [2, 3].

In 2006, the United Nations adopted the Convention on the Rights of Persons with Disabilities [4] that since then has been ratified by the majority of governments across the world. The Convention marks a global paradigm shift in the recognition of disability as a predominantly medical/clinical to a human rights and social issue [5, 6]. The treaty calls on all states to take "effective and appropriate measures" to facilitate the full inclusion and participation of people with disabilities in the society, including respect for a person's autonomy and independence (Article 3). It also requires that States ensure "the equal right of all persons with disabilities to live in the community, with choices equal to others" and "have access to a range of in home, residential and other community support services, including personal assistance to support living and inclusion in the community" (Article 19).

This chapter will provide and discuss the definitions of community living and residential care as concepts as well as different models of each. It will then explore some of the historical contexts: "deinstitutionalisation", the drivers and lessons from the process so far in the United Kingdom and internationally. Third, it will focus on the evidence base for community living and residential care in terms of outcomes for people with intellectual disabilities and what is needed for good quality of life outcomes. This chapter will primarily draw on the already published literature, but it will also draw on experience as a practitioner and consultant, working with colleagues and organisations to bring about improved outcomes for people they support (see Acknowledgements).

37.2 What Is "Residential Care"?

Residential care is an arrangement where the person is provided with both accommodation and support by the same provider, where the two are linked, whereas community living is associated with the idea of "independent living", which does not mean unsupported functional ability but choice and control over daily living arrangements and support. People can live independently in the community with formal (paid) support, with informal or no support, or a combination of the two. In the past residential care was synonymous with large size and institutions but as a result of deinstitutionalisation, models of residential care have become more diverse. Meanwhile, the term institution/institutional is increasingly used to describe the structural characteristics of services, marked by four key features: "depersonalisation" (the removal of personal

possessions, signs and symbols of individuality and humanity), "rigidity of routine" (fixed timetables irrespective of personal preferences or needs), "block treatment" (processing people in groups without privacy or individuality) and "social distance" (symbolising the different statuses of staff and residents) [7, 8]. Nonetheless, there was, and still remains, a clear relationship between such institutional care practices and the size of settings, which Mansell and Beadle-Brown [9] argue is not coincidental.

There has been no research that has provided evidence that institutions can achieve the same outcomes for people as good community-based services [10–12]. It has also been recognised that the same institutional practices and ways of thinking can be—commonly—found in services in the community, even in very small settings [13, 14].

This has led to definitions of institutions such as that used by People First of Canada: "An institution is any place in which people who have been labelled as having an intellectual disability are isolated, segregated and/or congregated. An institution is any place where people do not have or are not allowed to exercise, control over their lives and their day-to-day decisions. An institution is not defined merely by its size."

1. People with intellectual disability have a right to live in the community, with choice over their living situation, on an equal basis with others and with support to be active participants in society.
2. Residential care is an arrangement whereby people receive accommodation and support together.

Tip

We need a nuanced view of accommodation and support options—it is not as simple as residential care equals bad and supported living equals good.

37.3 Deinstitutionalisation

37.3.1 What Is It?

Deinstitutionalisation is the replacement of institutional services with community-based support, and it has been described as one of the most important changes social care in the last decades [15]. It is important to note that deinstitutionalisation is not just about the closure of hospitals or large residential care services but about the development of services in the community that both prevent people from being admitted to institutional services in the first place and provide a place for people to move to from institutions. For a successful transition, the services that need to be developed are not just accommodation and support services, but transport, health care, social care, education and other public facilities all need to be made accessible and skilled enough to provide services for people with disabilities, if people are to be truly integrated into the community.

37.3.2 What Drives the Process?

Mansell and Ericsson [16] noted four key drivers of deinstitutionalisation in countries which started the process early. Although the exact process has differed in different countries, these four factors have consistently remained important. These drivers included (1) changes in *ideology* (e.g. the rise of normalisation, social role valorisation and an Ordinary Life [17–19]; (2) the availability of *alternative models* often led by professionals, especially for those with more complex needs [20–22]; (3) revelations in the media of *scandals* in institutions and public opinion (this has continued to be important in many countries, with recent scandals such as the Winterbourne View in the United Kingdom); and (4) the balance of *costs*, that is, whether community care was seen as less expensive, as in the United States, better value for money, as in the United Kingdom, or the right thing to do and therefore cost was not seen an issue, as in Sweden [16, 23, 24].

37.3.3 Deinstitutionalisation of Services for People with Intellectual Disability: The Example of the United Kingdom

Trajectories of institutionalisation and deinstitutionalisation differed across the four nations of the United Kingdom with many similarities and some notable differences. Devolution has further promoted diversity in the provision of social services, including for adults with intellectual disabilities. We attempt to highlight some of these below.

By the Second World War, large residential institutions, often built in the nineteenth century, were the typical form of provision for people with intellectual disabilities, people with mental health problems, orphans and the homeless in the United Kingdom [3].

Institutions for people with intellectual disabilities and those with mental health conditions were transferred as hospitals to the newly created National Health Service after 1948. However, it was in the late 1960s when a series of scandals involving ill-treatment, overcrowding, understaffing, poor environments and various indications of management failure in hospitals came to media attention that things began to change.

In 1971, the white paper "Better services for people with mental handicap" [25] proposed a reduction in institutional places through the provision of more places in "small" residential homes provided outside long-stay hospitals.

During the 1980s and 1990s, substantial progress was made towards the development of community-based supports and the closure of the long-stay hospitals for people with disabilities in England and Wales [20]. This happened without the government clearly articulating the goal of closing institutions and a "firm legal or constitutional basis for non-institutional services", which led to "trans-institutionalisation" (the move from one type of institution to another) for many people [3]. In more recent years, this same lack of clear guidance, policy and legal basis has resulted in new institutions being built, in particular, for people with specific needs such as challenging behaviour or autism. The size of community-based services has never been specified in terms of policy or legislation in the United Kingdom (unlike in some other countries such as Ireland or Norway), although NICE guidance on the treatment and management of adults with autism has recommended no more than six people on one site [26]. Some local authorities are beginning to stipulate the size of services they will commission but in general there remains no legal or financial barrier to setting up large, congregate and clustered services.

In Scotland and Northern Ireland, progress with deinstitutionalisation was initially slower, however, gathered pace in more recent years [27, 28].

Alongside the largely professionally led replacement of institutions with community-based services, the disability movement began to develop the idea of independent living. This was an alternative model of support based not on buildings and services but on the provision of personal assistance, through the provision of direct payments [29], and later personal social care, health and education budgets can be made in lieu of services, so that people could make and control their own arrangements. The emphasis on individualised funding mechanisms has not been without criticism, in particular, in terms of implementation and how much choice people really had with a personal budget [30–32], but the government has continued to promote individualised funding and services for everyone with disabilities [33–35].

1. Deinstitutionalisation is the closure of institutions and the development of housing and community-based support.
2. Key drivers of change have included ideology, cost incentives and disincentives, scandals, and the available of alternatives.
3. The power of each driver has varied by country.

37.4 The Paradigm of Community Living

One of the first definitions of "community living" came from the Ordinary Life Initiative in the United Kingdom [17] which referred to community living as

- Local housing with support for people of all levels of disability.
- Work and work experience as an alternative to day care.
- Widening participation of people with all levels of disability in community life.
- Supporting people with challenging behaviour in the community.

More recently, Mansell [36] and Mansell and Beadle-Brown [9] pulled together these and other pre-existing definitions from a range of sources to offer the following definition of community living:

> The aim of community living is to enable people with disabilities to use the same range of accommodation, living arrangements and patterns of living that are available to the rest of the population, and to have a good quality of life, participating as full citizens in social, cultural and economic activities to the extent and in the ways the individual chooses. ([9], page p. 106).

This requires that those providing services and support are

- Using accommodation located among the rest of the population, which is adequate, appropriate and accessible to the individual.
- Using the range of accommodation options ordinarily available to the wider population.
- Enabling people, to the greatest extent possible, to choose where, with whom and how they live.
- Providing whatever help is required to enable people to participate successfully in the community.

This latter point means that in order for community living to be successfully implemented there has to be attention paid not just to housing and support for daily living but to the willingness and capacity of communities (including generic services) to welcome and support people with intellectual disabilities. Attention must be given to accessibility of leisure facilities, work environments, health and social care environments in the community, opportunities for social connectedness, etc.

37.5 Types of Living Arrangements Used by People with Intellectual Disabilities

In many countries, the majority of adults with intellectual disability still live with their families, although in some countries such as Norway, more people live in their own home with support or in group homes than with their family [37]. In England, in 2014/15, the most common living situation for adults with intellectual disabilities getting long-term social care support was with family/friends [38].

There are also very little data available about the nature of accommodation options for people with intellectual disabilities across Europe [2, 3, 39]. In particular, there is little information about the size and quality of these services. The information that does exist from different sources uses different definitions and often conflates accommodation and support. Ireland is the only country that has a register of people with intellectual disability recording the numbers who access different types of services [3, 27], although Norway has also been developing such a register [40]. Although limited by the lack and completeness of data, Šiška and Beadle-Brown [39] reported that there were at least 1,438,696 children and adults with disabilities and mental health still living in institutions. The number of people in institutions was almost the same as the figure reported by Mansell et al. [3]. At least some residential care was still provided for all groups, even for children without disabilities. Only in Sweden was all residential provision for adults with disabilities, small scale and community-based. In most countries, such small residential services

were a minority form of services. This study also identified that those who had seen the least change were those with intellectual disability and those with mental health problems. Looking in more detail at England, the most recent source of data on accommodation status for people with intellectual disability is from 2015 to 2016 (Community Care Statistics, Social Services Activity—England, LTS004.b).[1] According to this, in 2015–2016, 129,055 people with an intellectual disability aged 18–64 were receiving social services support from local authorities in England. More than 75% (96,285) were reported to be in "settled accommodation" in the community: with tenancy rights either as an individual or as part of a household. The remainder were classed as being in "unsettled accommodation" without tenancy rights, such as registered care homes (22,435), nursing homes (1090) or acute/long-term healthcare residential facility or hospital (470). In addition, the most recent figures, at the time of writing, from the Assuring Transformation data set[2] indicate that at the end of January 2019, there were 2325 people with learning disabilities, autism (or both) placed in inpatient settings by NHS England and Clinical Commissioning Groups. Just over half of people (52%) in hospital were in general (non-secure) settings, 28% were in low-secure settings, and 20% were in medium- or high-secure settings. More than half of people (57%) had been in hospital for more than 2 years and 15% more than 5 years. Although the majority of the population in these units are adults, there are also some children aged under 18 years (11%).

Outside of Europe, there is also generally a lack of data available on living situation of people with intellectual disability in Asia, where most of the research has focused on children and the impact of the transition from institutional care. In Australia, as in Europe, the majority of people with disabilities live in their own home or with their family [41], while those with intellectual disabilities, in particular, those with more severe disabilities, primarily live in residential care settings. Most of these tend to be relatively small (6 or fewer people) although some are larger in size, with 11,000 people (under 65 years of age) living in "cared accommodation" (e.g. hospitals, nursing homes, hostels and other homes with six or more people) and with almost 8000 people with disabilities under 65 identified as living in aged care services [42][3].

In the United States, the situation varies from State to State—with some states only providing community-based settings (e.g. Vermont) but with others still providing residential institutions for a substantial number of people with intellectual disabilities (e.g. Texas). Lulinski, Tanis & Nelis [43] reported that in 2015 more than 21,000 people with intellectual disabilities (18% of all people living outside the family home) across 37 states still lived in congregate accommodation including state institutions. The remaining 82% lived with six or fewer people and in 2015, 13 States had no state-run institutions [43].

In the remainder of this section, I will outline in more detail the different models of residential and community living accommodation and support options in use in the United Kingdom. The boundaries between some of these models have become increasingly blurred over the past 10–15 years, while others have remained relatively unchanged. As such, this section will attempt to describe both the "pure" model where one exists and outline where some of the newer models sit. Where available some indication of the size and numbers of people accessing each different type of service will also be included. Most of these models—sometimes under different names—can be found in other countries in Europe, Australia and North America.

37

1 From 2016 to 2017, only expenditure is reported in the Adult Social Care Activity and Finance Report with limited breakdown available.

2 ► http://digital.nhs.uk/catalogue/PUB30227

3 ► https://www.aph.gov.au/Parliamentary_Business/Committees/Senate/Community_Affairs/Young_people_in_aged_care/Report

1. The majority of adults with intellectual disability live with their families.
2. When not living with their family, people with intellectual disabilities are much more likely to be living in large congregate settings (institutions) than people with other types of disabilities.

37.5.1 Congregate Settings

Congregate settings are usually settings where people are accommodated together in larger groups under one site and under one roof. In the United Kingdom, the old learning disability (mental handicap) hospitals fell within this category. These types of provisions have different names in different countries (e.g. institutions, residential hospitals, social care homes). These tend to range from around 30 places (e.g. in France and Ireland) to around 1000 people in some parts of Eastern Europe. The main types of congregate settings still used in the United Kingdom are hospitals, secure/forensic units, and assessment and treatment centres.

■ Hospitals, Secure/Locked Units and Assessment and Treatment Services

Although all the old long-stay hospitals for people with intellectual disability were closed by the mid-2000s in England and Wales, newer hospitals and secure residential settings have grown up over time, primarily to serve the population of people with learning disability who have complex health needs, show challenging behaviour or have forensic support needs. These tend to be run by independent (usually for-profit) organisations or the National Health Service.

Some of these services were designed as long-term secure accommodation options but most were set up as short-term "assessment and treatment" services, many with a focus on challenging behaviour. However, as noted above, almost 60% of people were in these settings for more than 2 years. Although originally people could be detained in such units without a legal basis, recent figures indicate that 90% of people admitted to these inpatient services were subject to the Mental Health Act (MHA), with 51% subject to MHA Part II. Of the 10% who were admitted informally, 92% were in general (non-secure) settings.

■ Transitional Services/Step-Up–Step-Down/Rehabilitation Services

In the early stages of deinstitutionalisation, the concept of transitional services for people to learn the skills needed to live in the community emerged. These were sometimes referred to as "half-way houses" and were often on the site or just outside the gates of the initial institution. For some people, these became permanent homes but for the most part people moved on to smaller group homes or more independent living arrangements.

This option reflected what was known as the "readiness model"—the idea that people had to be "ready" to move into the community. As time went on, this was replaced by what became known as the "support model", in which it was considered possible for anyone and everyone to live in the community with the right support [44].

Recently, we have seen a resurgence in transitional or step-down services (sometimes referred to as rehabilitation units) in the context of people moving from inpatient units as part of the Transforming Care programme in England. The idea that people will need to get to the point where they are "ready" to live in the community has re-emerged. While there may be a small number of people who have to get re-accustomed to certain aspects of living in the community, it is more likely that it is professionals and service providers who need the "safe space" in which to find out how best to support the person in the community. Whatever the situation, such an arrangement should always be short-term, with a clearly defined purpose and services should still conform to best practice. Very little is known about how many such services exist or how many people they provide services for in the United Kingdom. Of the 2465 people recorded in the Assuring Transformation data in January 2018, 18% were living in what was known as forensic rehabilitation or complex care/rehabilitation.

37.5.2 Clustered Settings

Clustered settings are usually settings where people live in smaller self-contained houses or flats but with more than one home grouped on the same site. There are three main types of clustered settings: village communities, campuses and cluster housing.

Intentional and Village Communities

These communities are typically founded on spiritual principles and distinguished by having support workers, who are often unsalaried, and sometimes their families living communally with people with intellectual disability to facilitate close personal relationships, and provide them with a social and cultural framework for work, community service, worship, and education. In some communities, there is a core set of paid staff which is supplemented by volunteers often from overseas. The size of these village communities varies but some have over a hundred residents.

Examples of village/intentional communities include Camphill, Ravenswood or L'Arche. Some of these communities have changed over time and now also providing dispersed, community-based support. Usually, village communities for adults provide accommodation, support and meaningful occupation for between 11 and 30 people.

In the United Kingdom, village communities are registered as residential care and there is no breakdown as to the numbers of people specifically in this type of setting. However, Mansell and Beadle-Brown [12] note that village communities are typically a relatively small part of the total amount of service provision, partly because they rely heavily on volunteers wishing to share their lives with people with disabilities. There are little data available on village or intentional communities in other countries but we know that at the time of writing L'Arche had "more than 154 communities and 19 projects in 38 countries"[4]; there are more than 100 Camphill Communities in 23 countries.[5]

Campuses

Residential campuses were often developed as part of the programme of closure of institutions and were modelled partly on village communities and partly on residential services in the Netherlands and Belgium. Like village communities, they are often self-contained with day provision and other services on-site and in some cases also had schools and colleges on-site. These were often set up by the National Health Service (NHS) for people with severe and profound disabilities, for whom dispersed housing was not considered a viable option at the time. In 2007 the Department of Health responded to evidence of poor quality care and announced the complete closure of all NHS residential campuses [45]. At that time, there were just over 1600 people in NHS campuses in England, living in units of 8–10 people [46]. Just over 10 years later, most of these campuses have now closed.

However, some campuses run by independent organisations still exist in England, registered as residential services, usually alongside more community-based options run by the same organisations. Some of these settings were originally set up by families, usually around a particular activity such as farming, and some developed into campuses from one larger home as the land around the larger home was available for building on.

Recently, a range of services have emerged in the United Kingdom, which call themselves "villages" but they do not have the social, spiritual or cultural framework of the village communities outlined above, and they can be considered campuses.

Cluster Housing

Cluster housing typically consists of a relatively small number of houses on the same site; for example, forming a cul-de-sac in housing for the wider community, or several houses in the same road all accommodating people with disabilities. Cluster housing can

4 ► https://www.larche.org/en/what-we-do

5 ► https://camphillfoundation.org/about-camphill/

operate as a registered residential care service where housing and support are provided as part of a package or can offer supported living arrangements for people (see below). The most recent developments in this area are clustered flats where six or more people have individual or shared flats within a larger development of flats all for people with intellectual disabilities or autism. Some of these developments can be quite big—we know of some as big as 30 people living in flats, sometimes all receiving support from the same provider.

■ Residential Schools and Colleges

As already noted above, some residential schools and colleges are part of a village community or campus-type arrangement. There are others that are standalone schools and colleges run by private or voluntary organisations.

Children who attend residential schools tend to be those with complex health or behavioural issues. A recent study by Tomlinson et al. [47] identified 342 residential educational settings in England with a total of at least 8740 placements available for young people aged 16+ with intellectual disabilities or who are autistic, with the majority of these being full-time and often out of area.

37.5.3 Community-Based Residential Care Homes, Group Homes and Individualised Services

In the first wave of deinstitutionalisation, services conceptualised as community-based were smaller than the old hospitals but still quite large—for example, it was not uncommon for early services to be residential care homes/hostels for between 12 and 20 people. Even now there still remains a substantial number of places in the United Kingdom that support more than 10 people. Later, a more common form of provision was group homes that were initially for around eight people living together and overtime these have reduced in size.

The number of people with learning disabilities in England supported in residential care in 2017–2018 was just over 25,000.[6] The most common type of residential care setting in the United Kingdom has for some time been what is usually called a "group home". In the United Kingdom, most group homes accommodate between three and eight people. The Care Quality Commission (2016) found that services that were smaller than 10 places performed better in terms of inspection standards. Staffing arrangements in group homes vary from a few hours per week of outreach support for specific tasks to 24-hour support. Currently, in the United Kingdom, it is unusual to find people in group homes only receiving drop-in or outreach support—for the most part these people would now be in supported living settings where they rent (or occasionally, own) their own home and support comes to them.

Internationally, there are differences in what is defined as a group home [3, 37]. For example, in Germany, group homes more commonly provide accommodation and support for around 24 people with a mild to moderate intellectual disability. In Sweden, a group home usually consists of six or eight individual flats clustered together with staff facilities and a communal area. In Ireland and Norway, a group home can be no more than four places. In Australia, this type of service might be referenced to as shared living (but this term would also be used if people were renting the property). In Australia, people with much less severe disabilities have lived in group homes until much more recently than in the United Kingdom [11], and people of similar levels of ability (at the upper end) can be found in both group homes and in supported living arrangements [48].

■ Adult Placement/Shared Lives Schemes

Adult placement, or Shared Lives schemes as commonly referred to in the United Kingdom, is used as an alternative to residential care for

6 ► https://digital.nhs.uk/data-and-information/publications/statistical/adult-social-care-activity-and-finance-report/2017-18

adults with a variety of support needs. The disabled person is matched with an approved carer who provides them with accommodation and support in their home, sharing their family and community with the individual.

Shared Lives is a relatively small form of provision in England with around 2–3% of people supported by local authorities using such service (Community Care Statistics, Social Services Activity, 2015–16).

Supported Living

The main tenet of supported living is that housing and support are separate. People live in an ordinary house that they own or rent (the same type of house in which people without disabilities live in that country), giving them security and the rights that come with a tenancy or ownership. Support then comes into their home and depending on their needs it can vary from a few hours a week to 24-hour support.

The main principle behind supported living is the one of choice: people have choice and control over where they live, with whom they live, who supports them and how, and what lifestyle they live [49]. The National Disability Team conceptualised supported living as follows:

- Separating housing and support.
- Focusing on one person at a time.
- Full user choice and control.
- Rejecting no one.
- Focusing on relationships; making use of informal supports and community resources.

In the United Kingdom, there are a series of standards called the REACH Standards for Supported Living (Paradigm, 2002; revised 2013) which identify the following as essential for any arrangement to be supported living[7]:

- I choose who I live with.
- I choose where I live.
- I have my own home.
- I choose how I am supported.
- I choose who supports me.
- I get good support.
- I choose my friends and relationships.
- I choose how to be healthy and safe.
- I choose how I am part of the community.
- I have the same rights and responsibilities as other citizens.
- I get help to make changes in my life.

The litmus test for whether an arrangement is truly supported living is to ask whether the person could decide to move house but keep their current support provider or whether they could stay in that house but choose to be supported by a different support provider. If both of those situations do not apply, then the arrangement is not truly supported living.

Of the 18,845[8] people with learning disabilities in England reported in 2015 by local authorities as having tenancies or ownership, there is no information about how many of those are meeting the REACH standards. While there are many good providers of supported living arrangements, it is generally accepted that there are many arrangements in the United Kingdom that are called "supported living" but which really are not supported living. There are a number of reasons for this.

At the point Supporting People funding[9] became available, many providers and local commissioners saw the possibilities for this

7 Accessed 21/03/18 ► http://qualitycheckers.org.uk/about-aqc/quality-checking-tools/the-reach-standards

8 ► https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/613183/PWLDIE_2015_data_tables_NB090517.pdf, page 14.

9 Supporting People was a government initiative launched in 2003 with the initial aim of supporting people to live independently and help them to remain in their home by providing them funding to maintain their social housing tenancies. However, over time it was broadened to provide housing related support for anyone regardless of housing status. This included private and social tenants, home owners, homeless people and those in temporary accommodation as well as people in sheltered accommodation or other specialist housing. Eventually though the funding stream was stopped as it had cost the government substantially more than ever anticipated.

pot of money to be used for funding people with intellectual disabilities. As a result many providers de-registered existing care homes and, in one way or another, created a tenancy for people and then referred to the service as supported living in order to access the funding. In general, nothing changed for the people who lived there in terms of their support, their staff or their level of choice. Staff also did not see any change—on a project trying to implement person-centred support into services recently de-registered and turned into supported living, staff where asked what is "supported living", "what does it mean to you?", the response was invariably "it is just the new name for residential care".

The second factor that influenced the expansion of supported living arrangements in the United Kingdom was the introduction of the Ordinary Residence principle (published in 1993). Although, a complex principle, in essence, the implication was that when people who had been placed out-of-area moved into supported living arrangements, responsibility for funding that individual shifted from the placing to the receiving authority. This created some perverse incentives for placing authorities to "move people on" to supported living arrangements in the area in which they had lived [36], sometimes without even moving house.

Although not documented particularly well, there has been a recent surge in the development of what I will call *quasi*-supported living. Examples include where people are paying rent to a housing agency that is a branch of the same organisation providing the support; where ownership or management of the property has been transferred to the local authority but with the agreement that the original organisation would provide support to the people who lived there; where the setting is a clustered flat arrangement where people rent from a letting agency, property developer or from the local authority but where the local authority has made an arrangement with one provider to support everyone in the flats. The latter is a relatively common response to the Transforming Care agenda—local authorities and private providers are building blocks of flats as provision for people moving out of inpatient services but this is the only option available immediately limiting the choice people are experiencing.

One of the major contributing factors to this situation is a lack of social or affordable housing in almost every area of the country, compounded by a lack of creativity and collaborative working between different social service departments (e.g. adult services, housing and town planning) and the lack of a long-term view for service provision and creating inclusive communities. Austerity has made this situation worse as there is now greater need for social housing as poverty affects more and more people, including those with disabilities (Robson[10]). Lack of any housing, never mind adequate and appropriate housing, was a key theme across Europe in Šiška and Beadle-Brown's [39] recent review.

1. In most countries with an existing service system, there remains a mixture of service and support types, from larger hospital style settings to supported and independent living.
2. Only in a very small number of countries there are only community-based options, although these still include residential care for those with more severe disabilities.

37.6 Quality and Outcomes of Residential Care and Community Living

37.6.1 What Do We Know from Official Statistics?

As reported in Mansell et al. [3] and Šiška et al. [2] official statistics rarely report on the quality of services and measures of quality of life outcomes rarely feature in official reporting by inspection and registration bodies. In some countries such as the United Kingdom,

10 ► https://www.jrf.org.uk/report/using-social-housing-green-paper-boost-supply-low-cost-rented-homes, accessed 21/03/18

reports from inspection bodies do look at the experience of people in terms of whether they have their basic needs met, have choice, are treated with respect and dignity and can complain if things are not going well for them. In most countries, official statistics, where they exist, are more likely to monitor where people live (although even here they are limited, often to just the numbers in institutions with little information on where people live in the community) and how they are funded. There are few countries that collect data that allow us to monitor whether people with disabilities are really experiencing community living in the sense of being a full and active member of their community [2, 3]. Although there are a number of state and federal level outcome monitoring schemes in the United States, these all come with some challenges in terms of giving a clear picture of how well community living is being achieved in the United States [50].

37.6.2 What Do We Know from Research?

Over the years, there have been many different models for looking at the quality of services, but it is generally agreed that ultimately the quality of any service should be defined by the outcomes it achieves for the people supported [51, 52]. However, in order to achieve good outcomes for people, certain "inputs" or "structures" and "processes" are also important to recognise and understand, especially if outcomes are not as good as they could be [53, 54].

Defining Outcomes

The most common way that outcomes have been defined in this field has been through use of the concept of "quality of life". There are many other publications summarising the concept of quality of life and how it can be measured (e.g. [55–59]). The following brief summary is provided to contextualise the relationships between quality and the type and design of services.

Schalock et al. [57] suggested that quality of life is experienced when a person's needs are met and when they have the opportunity to access life enrichers. The international collaboration outlined eight domains and indicators of quality of life, with both objective and subjective indicators being seen as important (see ▶ Chap. 15 of the present textbook). Often we hear people in services saying that certain quality of life domains might not be "appropriate" or "achievable" for those with severe and profound intellectual disabilities and those with multiple disabilities or we experience people having lower expectations of what each domain might look like for those with the most severe disabilities. Bigby et al. [59] describe potential indicators for each Quality of life domain for people with profound and multiple disabilities, illustrating that the domains apply even to those with the most severe disabilities.

Engagement in meaningful activity and relationships has been considered a particularly important outcome, in which it is the vehicle by which almost every aspect of quality of life are realised [60–66]. In addition, Mansell and Beadle-Brown [64] argue that engagement is also an indicator of good quality of life—if people choose to be engaged then it is a sign of emotional well-being and a sign that the support for that person is working well.

Quality of Service and Quality of Life Outcomes in Residential Care and Community-Based Settings

Research has consistently shown that community-based services and support produce better quality of life outcomes than large congregate settings [67–70] and that dispersed settings produce better outcomes than clustered settings [12]. Supported living is considered to be particularly important for allowing people the security of tenancy rights or ownership and potentially more choice and control over where and with whom they live and who should support them in what activities. Research into the outcomes of supported living is limited but what there is suggests that choice and, in some studies, participation in recreational or community-based activities were better in supported living. However, outcomes in terms of safety (vulnerability to

exploitation), the frequency of scheduled activities, health and managing money were found to be poorer (See Bigby et al. [48] for a review).

One very consistent finding across the research looking at outcomes in community-based services is the variability in outcomes within different types of services. For example, Emerson and Hatton [67] found substantial variation between engagement levels in small group homes in the community across different studies. Although levels of engagement were on average higher in community-based housing than in small or large institutions, there were people in small group homes in the community, which were experiencing similar or poorer outcomes to those in institutions. However, no study has ever shown that congregate or clustered settings can achieve as good outcomes as have been achieved in community-based settings. And some research has shown that size is particularly important in terms of choice and control [71]. These findings led to the conclusion that small, ordinary and dispersed housing in the community is a *necessary* but *not sufficient* condition for a better quality of life [9, 72].

What has emerged very clearly from the research over the past 50 years is that, apart from the severity of disability, only one factor has been found to consistently and directly relate to quality of life outcomes and that is the way that people are supported minute-by-minute [11, 72]. Outcomes have been found to be significantly better when staff used an enabling and empowering style of interaction that focused on doing things *with,* not *for* or *to*, people. This style of support is usually referred to as "Active Support" (See Mansell and Beadle-Brown [64] for a review). Mansell and Beadle-Brown [64] describe active support as an enabling relationship by which staff and other carers provide graded assistance to ensure success—assistance that is tailored to the needs, pace and preferences of the individual delivered in a person-centred, warm and respectful way and making the most of all the opportunities available at home, in school, in the community, at work.

Of course, active support is not the only form of person-centred support but has been argued to be an important foundation for other approaches such as positive behaviour support, alternative and augmentative communication, autism-friendly practices such as the SPELL (Structure, Positive approaches and expectations, Empathy, Low arousal, Links) framework [54, 64, 73–78]. It is also argued to be a good indicator of support that produces better outcomes for people with Intellectual and Developmental Disabilities [73]. Active support is founded on evidence-based practice—combining elements of applied behaviour analysis, learning theory, occupational therapy and physiotherapy but in a holistic person-centred package, which can be practiced every moment of the day in any environment [64]. Research has found that, in addition to increasing levels of engagement in meaningful activity and interactions in the home, implementing active support results in more involvement in a bigger range of activities at home and in the community, more opportunities for community inclusion and for self-determination, increases in skills, reductions in challenging behaviour, and improvement in mental health [53, 73, 79–86]. It has also been found to improve job satisfaction and retention of staff [79].

In terms of what determines whether staff work in this way, the evidence base is still developing. To date research has indicated that practice leadership by front-line leaders plays a key role, and that training (including both classroom-based and hands-on elements) is also a contributing factor of higher levels of active support [73, 87–89] . In addition to the impact of practice leadership and training in active support, recent research from Australia [90, 91] also indicated that inputs and structures such as size of setting are important in determining how well staff provide active support and how well it is maintained over time—a setting for more than six people was associated with lower levels of active support and poorer maintenance of quality of support over time.

Experience of supporting organisations to implementing change has shown that management awareness of and commitment to new practices to be introduced is key [64], and this has been supported in recent research by

Bigby et al. [92]. Bigby et al. found that better implementation of active support was associated with a number of organisational and senior manager factors:

- Fewer settings provided by the organisation.
- Greater time implementing active support.
- Senior leaders shared prioritisation of practice and active support.
- Senior leaders strongly supporting practice leadership.
- Practice leadership located close to front-line service delivery.
- Concentration of practice leadership tasks with front-line management.

Although research to explore this would require a multi-national study, having a supportive wider motivational context is likely to be important in helping organisations to work in ways that make a difference in terms of outcomes for people in any type of setting. Policy, funding systems, inspection and registration systems, auditing systems and the focus of staff education and workforce development will all influence to what managers and staff pay attention [64, 80].

1. Living in an ordinary house dispersed in the community is a necessary but not sufficient condition for a better quality of life.
2. The factor that makes the most difference is whether people are supported in a way the enables and empowers them.
3. For staff to work in this way, they need the right skills through training and leadership and they need to be motivated.

37.7 Benefits, Risks and Solutions

This final section summarises how well some of the current models of community-based housing and support can promote a good quality of life and how well they reflect Article 19 of the UN Convention on the Rights of Persons with a Disability (UNCRPD).

Owning or renting your own home, a home that is part of the ordinary community and does not set you apart from others in the community is unequivocally the best option for people's quality of life. This is what is intended by Article 19 of the UNCRPD. This model can provide a higher level of emotional well-being (security), material well-being (owning or renting own's home), social inclusion (physically part of a local community) and rights (e.g. tenancy agreement) than any other form of accommodation or support arrangement.

Of course, as mentioned above, just owning or renting your own home does not guarantee a good quality of life in any other domain. Without the right support to make choices about where and with whom you live, to take advantage of all the opportunities available in the home and community, and to experience full and active citizenship, people can perceive as much disengagement, disempowerment and isolation as in a large institution [73].

Even when coupled with a personal budget to pay for personal assistance, many people with intellectual disability still need support to make choices about who they want to support them or how to spend their time. They will only have real choice if there is more than one good service to choose from, or a bank of staff with the right knowledge and skills to employ. Employers (whether an agency or an individual themselves) have to be able to provide training, support and leadership to staff if they are going to be able to work in a way that improves outcomes for the people they support. While people with physical disabilities and those with less severe communication difficulties can often guide and even train staff themselves, this is not so true for those with more severe disabilities. Families can often be a source of useful knowledge but they themselves may not be aware or have had little training in how to support higher levels of quality of life. Of course, it is perfectly possible to create a system whereby anyone who wants to work with people with disabilities in any setting can gain the right skills (which then would be adapted to the individual(s) they are supporting) and where those

managing staff can learn about and receive support to manage a staff team. However, currently this does not yet exist in any country.

While supported living, personal budgets and personal assistance offer the greatest possibilities for choice and control and potentially for being a full part of society, these are not yet options in many countries where the money available for people to live in the community is very limited. People do not have benefits such as housing benefits that can help them pay rent. Rightly or wrongly, mental capacity and guardianship laws while under revision in many countries, often mean that people cannot sign contracts. Housing in the main community can be so poor that it can be unsafe for those with disabilities and people do not have the money to fix or maintain such environments.

Even in countries where supported living and personal budgets are available, issues such as lack of adequate and appropriate housing to rent can create barriers, as discussed above. For example, this is one of the reasons often given for why those in assessment and treatment units and private hospitals in England face delays in being discharged and why there has been an increase in the development of clustered flats for those with intellectual disability and/or those on the autism spectrum.

As such, in order to ensure that people are not living in institutions or other larger congregate settings, we may need to compromise slightly in order to make change in the right direction happen. If we wait to make until personal assistance and/or supported living is available everywhere, then there are several risks and it can be counter-productive in the progressive realisation of Article 19 of the UN Convention. First, it will mean that those in institutions will stay there for longer, potentially forever in some countries. Second, it will mean that organisations will develop services that are called "supported living" but which are not in the true spirit of supported living, that is, where people really do not have choice over their living and support arrangements (or in many cases over their day-to-day lives) and will live in larger groups that sets them apart from the rest of their community.

Jim Mansell once wrote about compromise for a workshop focused on developing community-based services for people with disabilities in Eastern Europe:

» I would not agree that group homes were *needed* for people with more severe disabilities, since we know that everyone can have a good life in their own home. I am more comfortable with the justification that we are providing some group homes because that is all we can pay for at the moment (i.e. the justification is nothing to do with the individuals we serve and all to do with the context in which we are working at the moment)… I would not agree that grouping more than a handful of people together was sensible. So for me, it would be no to institutions, villages, campuses, hostels, units or clusters. But what about a group home for three or four people? Well the research on group homes shows that run well they can achieve many good things for the people living in them, and that the difference between a well-supported group home and supporting people in their own homes is not necessarily very great. I would still prefer to support people in their own homes (because I would value the greater housing rights this would give people as well as the symbolism) but if a small group home was all that could be achieved [right now] I would be inclined to agree, while all the time pushing for the features that would make it more like supported living (so e.g. choice of co-residents, choice of staff, legal tenancy)…

» My picture of the service development landscape is that way ahead in the distance are the *present boundaries of the possible*. These are the things that we know are possible and desirable but they are the leading edge. This boundary is a horizon, so that as we approach it the definition of what is now possible moves ahead (because of changes in technology but also changes in attitudes and expectations). Behind this boundary there is an area in which we are working with models that, though we know they are not ideal, seem to us to be steps on the road to the horizon, not least because they are *capable of transformation*. At the back of

> this zone is another boundary, beyond which models of service seem now to be unacceptable. We look at them and think "how could we ever have thought that was acceptable"? Our task in supporting principled service development is to move this *frame of consensus* forward, connecting people to the vision on the horizon and helping them see that they are on a journey. Not everyone is going to be able to be a pioneer out there near the horizon but those who come behind need to know they are heading in the same direction.

In conclusion, the model most in line with the UNCRPD is that of supported living/personal assistance—where people receive the support they need and choose, in their home that they rent or own (individually or with others, according to their choice). This home needs to be dispersed in the community, chosen by the person from the same range of homes in which other people in the community live and which is adapted to the needs of the individual. Where this is not possible right now for resource reasons, then the model that offers the next best outcomes for people is that of small group homes (residential services where the organisation provides both the accommodation and the support). Ideally, these should be for 3–4 people and certainly for not more than six people. Where people want or need to live on their own but appropriate housing is not currently available for them to rent or own in their own right, then living in an individualised residential service, where an organisation already owns or rents the property, should be considered over and above a clustered setting where everyone has an intellectual disability. In such small individualised or group home settings, it is possible for people to have a key to their front door and be supported to use it, for staff to work on the basis that they are supporting people to live their lives in their own home and own community, for people to be supported to make choices about where and with whom to live, whom they wish to support them, how they wish to spend their money. The main quality of life domain limited in this model is that of rights—in particular, tenancy rights and security of living situation. Owning or renting your own home is also an indicator of material well-being and an indicator of status in most societies. Even if people have to live in small good quality residential care settings initially, looking for possibilities to expand the range of future possibilities for living in their own home with support should be the next stage of progressive realisation of article 19 of the UNCRPD.

1. Supported living ideally through the use of personal budgets and personal assistance is the model of housing and support that is most in line with the UNCRPD Article 19.
2. However, this option is not yet available in all countries for all people with intellectual disabilities.
3. If we wait until the system is fully developed before we move people from institutional settings, then we risk people never moving and attitudes of society will never change.
4. If compromise is needed in the form of small residential care settings, then we have to pay attention to ensuring that these promote the inclusion, self-determination and rights of the people who live there.

Key Points

- People with intellectual disability have a right to live and participate in the community with choice over where and with whom they live and support to achieve this right. Many people with intellectual disabilities still live in congregate settings and experience poor quality of life outcomes.
- People with intellectual disabilities are more likely than other people with disabilities to live in large congregate settings, with little choice and with limited participation in the community as active citizens.
- At home people with intellectual disabilities spend most of their time disengaged and with little contact from

others, including those they live with. This is likely to result in challenging behaviour.

- Quality of life outcomes is determined not only by where people live but by the support they receive—how people provide support is critical. Outcomes are better when support is enabling and empowering, doing "with" the person not "for" or "to" the person. This type of support has become known as person-centred active support. When staff have the skills and motivation to work in this way, outcomes for people are substantially better.

Acknowledgements The ideas expressed in the present chapter are rarely solely mine but reflect discussions I have had with many other people across the globe. I particularly acknowledge Agnes Turnpenny, Bev Murphy, Jan Šiška, Jill Bradshaw, Helen Toker-Lester, Peter McGill, Chris Bigby, Camilla Parker, Jan Tøssebro, Theresa Joyce, Christine Linehan and of course the late Jim Mansell, one of the pioneers of community-based services for people with intellectual disabilities in the United Kingdom and founder of the Tizard Centre. I thank Agnes Turnpenny for helping with proofreading and referencing.

Learning Objective

- The main purpose of our contribution is to expand some aspects of the research and practice about employment and employment services for people with intellectual and developmental disabilities (IDD) for which authoritative summaries and presentations are already available [1–5]. We will explore the role played by the co-occurrence of intellectual and psychiatric disorders on employment outcomes, and we will extend, whenever possible, the analysis to different national contexts, emphasizing the role of contextual factors in getting and maintaining a job.
- The reader will learn that with the approval of the United Nations Convention on the Rights of Persons with Disabilities (UNCRPD), a complete and binding declaration of rights of persons with disabilities has been established [6–8]. Despite these international commitments, the majority of persons with IDD continue to work in segregated settings and with substantial pay gaps compared to non-disabled population.
- One of the fundamental learning objectives of this chapter is to offer an international overview of the employment rate and presence in the labor force of people with IDD. The chapter then focuses on the main empirical evidence on factors explaining access to work of people with IDD [9].
- The complexities of employment projects for people with IDD are elucidated as well as the need for an employability conceptual framework to guide employment projects.
- The panorama of the strategies, services, and techniques of Vocational Rehabilitation (VR) is presented, and the reader can have an updated reference framework on sheltered workshops, supported employment, and social firms' programs.
- The scientific evidence supporting the importance of work on personal identity development, social inclusion, and quality of life of persons with IDD is discussed.

38.1 Introduction

The issue of access to work for people with disabilities has long been central in debates on national and international welfare policies and programs of care and rehabilitation.

In the last decades of the last century, the scientific community agreed on considering employment as one of the fundamental aspects for social inclusion, independence, and quality of life of persons with disabilities and therefore one of the ultimate goals of rehabilitation processes.

However, to date this position has not been sufficiently implemented in many systems of policies and services across the world, and people with disabilities, especially those with intellectual disabilities (ID) and/or autism spectrum disorder (ASD), continue to have much lower opportunities and employment rate than the rest of the population.

In recent years, scientific research in the field gained momentum, and several studies have addressed barriers to employment participation and effectiveness of the interventions adopted.

Policies and support programs are very heterogeneous across different countries, both in terms of nomenclature and methodology, and thus difficult to compare. Nevertheless, available studies are providing important indications on the most effective actions that should be put in place by health and social services to increase occupational opportunities.

The present chapter provides a comprehensive overview of the current knowledge on work and occupation of people with ID and/or ASD, with a main focus on factors that can hinder or facilitate work access, the role played by the co-occurrence of psychiatric disorders, and employment options and support programs that can improve outcomes, especially person-centered outcomes.

38.2 Employment Rate and Labor Force Participation in the Population with Intellectual and Developmental Disabilities

Studies on employment rate and labor force participation of persons with IDD do not share common definitions and metrics [11–13]. The identification criteria of population are quite different, and often the characterization of participants is poor or absent with regard to comorbidities and ability levels. Very often disability is self-reported and not clinically confirmed. It is worth noting that similar problems affect the majority of the scientific literature on this topic [14]. Common definitions include terms such as "mental retardation," "learning disability," "cognitive performance restrictions," "cognitive disability," "developmental disability," "developmental delay," "intellectual and developmental disabilities," and "autism." Sometimes, it is not clear whether the definition refers to clinical diagnostic criteria or functioning profiles. Also, the way occupational outcomes are conceptualized makes international comparisons difficult. Furthermore, in many countries, current legal framework allows persons with disabilities to work in segregated firms, commonly indicated as sheltered workshop or paid facility-based work, and with subminimal wages [15–17]. In many cases, statistics on employment rates do not distinguish between jobs in open labor market and in segregated settings.

To give an updated picture of the employment rate and work conditions of persons with IDD, we chose population-based studies and tried to select data and information useful to enhance between-country comparisons. Cameron [18] has reported data from the 2006 Canadian Participant and Activity Limitation Survey (PALS). Persons with "intellectual disabilities" were identified by asking the participants if a doctor, psychologist, or other professionals ever said them that they had a developmental disability or disorder. Twenty-five percent of the identified persons with ID were working compared with about 50% of people with other disabilities and about 75% of people without disabilities. Persons with ID were about six times more likely than others to have never worked. The Canadian survey did not report data about the proportion of people working in sheltered workshops. For working-age people with ID and any employment income in year 2005, their average earnings were $18,172 compared with $29,669 among people with other disabilities and $37,944 among people without disabilities. The proportion of people with ID below poverty threshold was 19.7% and among persons without disabilities, 10.2%. A secondary analysis of the 2012 Canadian Disability Survey confirmed that 24.1% of people with "developmental disabilities," self-identified as in PALS survey, were employed, while the estimate of the specific employment rate of people with autism was 14.3% [19]. The proportion of labor force participation was 34.1%, approximately half of the proportion of the pooled group of persons with disabilities.

Yamaki and Fujiura [20], analyzing data derived from the Survey of Income and Program Participation, a national representative longitudinal household survey of noninstitutionalized adults in the United States, have found that only 27.8% of adults with IDD had a job in any given month compared with 75.1% of the general population. Monthly earned income for workers with IDD was approximately half of that of population without disabilities. Average earned income was estimated $1298 for persons with IDD versus $2206 for general population. In this case, adults with IDD were identified using the following criteria: they were between the ages of 22 and 65 years, had a childhood originated condition that resulted in work limitation, and had either any of the categorical labels associated with the old definition of IDD or functional limitations in two or more of the six life activity domains, as described in the Developmental Disabilities Assistance and Bill of Rights Act (2000). The 2010 survey edition [21] has confirmed an estimate of 26.1% of employed persons with ID and 30.8% of persons with other developmental disabilities. Siperstein et al. [22] estimated that 34% of adults with IDD aged 21–64 years

were in the labor force compared with 83% of adults without disabilities. The study sample was selected from approximately 341,000 households. Respondents were parents/guardians of adult children aged 21 or older who declared that their adult children had been diagnosed with an ID. Of the adults in the sample with mental retardation or intellectual disability, 18% were in competitive employment and 13% were employed in a sheltered setting. The remaining 3% were either self-employed, or their employment setting was not categorized. The unemployment rate in the sample was 9% versus 21% in adults with and without disabilities, respectively.

National Core Indicators project, based on the 2012–2013 Adult Consumer Survey collected a wide range of information on recipients of state developmental disability service in the United States. The employment rates of non-institutionalized working-age persons (ages 21–64 years) with IDD based on the 2012–13 survey were 14.7%. Slightly less than half of the service recipients participated in an unpaid facility-based activity during the day. Over one-quarter (27%) were in paid facility-based jobs, and 22.6% took part in unpaid community-based activities during the day [23]. Since 2008, the American Community Survey (ACS) allowed people to self-report "cognitive difficulty" on six questions regarding physical, mental, emotional problem, having difficulty remembering, concentrating, or making decisions. Data for 2014 show that persons with any disability or a "cognitive difficulty" were employed at much lower rates (33.7% and 23.5%, respectively) than those without disabilities (72.9%) [24].

The National Longitudinal Transition Study-2 (NLTS2) focuses on the experiences of the US secondary school students with disabilities, as they go through their early adult years. A subset of young adults with disabilities, who were out of secondary school, and in the ages of 21–25 years were selected, telephone interviews were conducted with their parents and, whenever possible, with the young adults themselves; 38.8% of persons with "mental retardation" and 37.2% with "autism" were involved in any type of paid employment outside the home at the time of the interview [25]. Average hourly wage was $7.90 for "mental retardation" and $9.20 for "autism." The hourly wage for all categories of disabled persons ranged from $7.90 to $11.10.

A recent study on wages of persons with disabilities in the United States has provided important insights into the theme. Based on a comparison of several national databases and an accurate evaluation of the work position and qualification of workers, the study has confirmed the wage gap between disabled and non-disabled population but the estimated gap was smaller than that showed by a crude comparison. Persons with "cognitive disability" appear among the most disadvantaged groups, but the main source of inequality is related to the hiring process and the kind of job acquired [26].

International data show lower rates of employment in Europe than in Canada and the United States. This trend has been clearly depicted by Parmenter [1]. Although the issue should be better investigated, we will try only to highlight some partial evidence. Through the Intellectual Disability Supplement of the Irish Longitudinal Study on Aging (IDS-TILDA) [27], a representative sample of 753 individuals with ID (45% male and 55% female) from across Ireland were drawn from the National Intellectual Disability Database [28]. The nature of service provision in the intellectual disability area in Ireland ensures an almost complete capture of data on all individuals with a moderate, severe, or profound ID. Overall, 6.6% of the study participants were in real paid employment (supported or competitive) and a further 12% working in a sheltered workshop. A total of 73.5% of respondents were not in labor force.

In 2013–14, the proportion of adults with a "learning disability" in paid employment in England had decreased to 6.7% from 7.0% in 2012–2013 and 7.1% in 2011–2012 [29]. Similar estimates were published in the "People with learning disabilities in England 2015: Main report" [30]. Overall paid/self-employment rate for working-age adults with

learning disabilities reached a peak at 7.1% in 2011–2012 and was at 6.7% in 2013–2014. In 2014–2015, the employment rate was 6.0%. Employment rates are broken down by gender, with men with learning disabilities consistently reporting employment rates 1.1–1.8% higher than women with learning disabilities.

In Norway in 2010, 22% of adults with ID participated in state-organized job creation or the regular workforce. Sixty percent had their day activities in municipal day centers, and 17% of these were mainly involved in production activities. Three percent participated in adult education, while 16% had no day activities of any kind, a rise from 3% in 1989 [31]. Similar results were found in Sweden where a significant and increasing majority of people participated in day activity centers [31].

Official estimates of the population with disabilities in Italy are based on a National Health Interview Survey (NHIS) [32], conducted every 5 years. The survey is carried out on a sample of about 60,000 households and 162,000 respondents distributed in 1456 municipalities. 8.7% of individuals between 15 and 64 years of age, self-reporting mental retardation in NHIS 2013, were employed, and the labor force participation estimate was 17.7%. There are no national estimates of the proportion of people with IDD involved in segregated work settings. A Finnish study [33] based on a cohort of people with ID born in 1966 showed an employment rate in the period 1993–2000 of 24% with a mean duration of the working periods of 6.8 months. The same group experienced an unemployment rate of 56% with a median duration of unemployment of 138 days per year.

Studies on employment rate and labor force participation of persons with IDD do not share common definitions and metrics; therefore, only conditional indications can be drawn. Population-based studies confirmed the presence of a gap between disabled and non-disabled population in employment rate and in average earned income. International data show lower rates of employment in Europe than in Canada and the United States.

38.3 Employment Outcomes in Selected Groups of People with Co-occurring Intellectual and Developmental Disabilities and Mental Health Problems

The clinical and epidemiological literature have described the importance of co-occurrence of IDD and mental illness. Despite the difficulty of the prevalence estimates and the limitations in the available studies, it seems established that co-occurring mental disorders in children, adolescents, and adults with IDD are more predictive of major restrictions in educational and vocational participation and social inclusion than the severity of the IDD [34–36].

Unfortunately, the specific effects on employment of co-occurring ID and mental illness or autism and mental illness have not been investigated at population level. In order to assess the effect of these co-occurrences, we have to consider clinical studies on selected populations. To the best of our knowledge, the original studies are very limited in number and with many methodological pitfalls.

Considering that the international literature has developed a considerable evidence about the low rates of labor force participation, below-average earnings, and poor working quality for people with mental illness, it seems reasonable to hypothesize that individuals with co-occurring IDD and mental illness encounter additional barriers and problems in getting and maintaining a job, and that cognitive impairment worsens work problems [37]. Cook et al. [38] designed a randomized implementation effectiveness trial by comparing different models of supported employment with a variety of different control conditions in a population of 1273 persons with severe mental illness.

Co-occurring ID was specifically considered an independent variable both in experimental and control groups. Diagnosis was coded using a uniform protocol from personal case file by a panel of three disability experts. Employment outcomes evaluated during the 24-month follow-up period included total

earnings, total hours worked, and access to competitive employment. The study supported the evidence of an influence of comorbidities on some but not all work outcomes and has also shown an effect of intellectual disability on competitive employment: individuals with ID were less than two-thirds as likely to work competitively. The supported employment group has shown better results than the control group for the main employment outcomes.

The already cited cross-sectional study based on Intellectual Disability Supplement of the Irish Longitudinal Study on Aging (IDS-TILDA) [27] has shown that the proportion of people in real paid employment is strongly associated with the severity of ID. People with a diagnosis of depression in real paid employment were half the number of those in sheltered workshops, and most elderly people with ID are unemployed, as McCausland and colleagues said [39].

Martorell et al. [40] studied the personal factors that determined work outcome in a group of 179 adults with ID, in Spain. The predicted outcome was the achievement of remunerated employment that means, with reference to the Spanish context, assignment to "sheltered workshop" versus "sheltered employment program." Presence of psychiatric disorders was evaluated using the Spanish version of Psychiatric Assessment Schedule for Adults with Developmental Disability (PAS-ADD) [41]. The presence of psychiatric disorders is significantly related to a lower likelihood of paid jobs.

Holwerda et al. [42] analyzed data from a Dutch cohort study, "Young Disabled at Work" whose aim was to find predictors of work participation in young adults aged 15–27 years. The study enrolled only persons with mild ID certified by a physician of the Dutch Social Security Institute. Interestingly, people with moderate and severe ID were excluded because very often certified, a priori, as unable to work. Occurrence of psychiatric and other comorbidities was coded from the same certification process records. The authors selected a long list of personal and social influencing factors or work-related participation ranging from sociodemographic variables to psychological characteristics (self-esteem, motivation, expectations, etc.), to social and family support.

The two final Cox regression models estimated for explaining job finding and job maintaining failed to show any direct effect or comorbidities and specifically of psychiatric comorbidities on occupational outcomes, while individuals living with parents or family or living independently appeared to be three times more likely to find work than individuals living in residential placements or sheltered accommodation. Highly motivated individuals were three times more likely to find work than less motivated individuals. The authors suggested that living situation and motivation may be interpreted as a proxy for disability severity that was not directly included in the study. In particular, individuals who were in residential placements probably had more severe disabilities and in general showed very low levels of participation in any kind of work.

Siperstein et al. [43] evaluated the effect of a large set of predictors on the pathways to employment of people with ID. The study group was composed of 1055 parents or guardians of adult children aged 21 years or older contacted by telephone. The final estimated multinomial logistic regression models showed that the presence of a diagnosis of an "emotional/behavioral disorder" halved the likelihood of employment in both competitive and sheltered settings.

Sung and colleagues [44] studied the predictors of competitive employment in a sample of people with Autism Spectrum Disorders (ASD) receiving Vocational Rehabilitation (VR) services in the United States. Data were extracted from the Rehabilitation Service Administration Case Service Report. The final sample comprised 857 males and 839 females aged 16–25 years. Co-occurring anxiety and depression caused a 43% reduction in the odds of finding employment in males but not in females.

Bush and Tassè [45] provided a comparative cross-sectional analysis of employment outcomes of three groups of persons with dis-

abilities: ID, ASD, and Down Syndrome (DS). Data were based on National Core Indicators' Consumer Survey that randomly selected approximately 20,000 individuals receiving public services from their state developmental disabilities system. The authors found that 16% of individuals with DS, 14% of individuals with idiopathic ID, and 10% of individuals with ASD were employed in the community. For all three disability groups, lower severity levels of ID were associated with increased probability of paid community employment. Reporting fewer reasons for "taking psychotropic medications" was related to an increased probability of paid community employment in all the three groups considered.

Despite scarcity and methodological shortcomings of available studies, it seems that in children, adolescents, and adults with IDD, co-occurrence of mental disorders increases the risk of restrictions in educational and vocational participation and social inclusion more than severity of IDD.

38.4 Framing Services and Practices for Employment of People with Intellectual and Developmental Disabilities and Related Research

38.4.1 Target Population

The access to employment or VR services is regulated by country-specific eligibility processes and criteria. In many countries, these processes include a medical evaluation of the work capacity. In a series of interconnected studies, the Organization for Economic Co-operation and Development (OECD) [46–49] has documented the progressive growth, in all OECD countries, of the percentage of people recognized as unable to work. The low participation in the labor force of persons with disabilities and in particular of people with IDD and mental health problems may be due, at least partially, to evaluative practices, dominant in legal medicine, which emphasize the limitations in activities due to impairments. The role of contextual factors is ignored as well as the impact of physical and relational barriers or the enabling potential of environmental facilitators [50].

Bickenbach [51], in discussing the opportunity to overcome the concept of work capacity and arguing on the opportunity to introduce an evaluation model based on the International Classification of Functioning Disability and Health (ICF) [52], recalls the endorsement of ICF conceptual framework made by the US Institute of Medicine. In particular, the Institute of Medicine studies of the Social Security Administration's (SSA) disability evaluation [53, 54] has concluded that the ICF interactive model of work disability was both conceptually and empirically more realistic than the impairment-based model implicit in the SSA disability evaluation of the claimant's ability "to engage in any substantial gainful activity." Nonetheless, "SSA does not have the resources to perform such an extensive assessment for each of the approximately 2.6 million disability applicants who come through its doors each year" [54].

Bickenbach argues that evaluative practice based on a strict consideration of impairment evaluations not only increases social spending, but it would be a violation of basic principles of human rights, and the underlying values of equal dignity and respect. Similar risks have been noted also when the access procedure is directly managed by employment and vocational rehabilitation services [55]. The use of the ICF in the evaluation of workability of people with disabilities has been the subject of intense research work in the countries of northern Europe in the last 10 years but, still, with limited practical implementation [56].

Although country-specific differences, evaluation of work capacity is generally limited by an excessive consideration of impairment-derived limitations in activities and an underestimation of the impact of physical and relational barriers, environmental facilitators, and contextual factors.

38.4.2 Labor Market

It has been argued in several studies and literature reviews that the employment of persons with disabilities has traditionally been studied from the point of view of the "supply side," examining the medical, educational, psychological, and vocational inputs that affect a person's functioning and job skills. This approach, however, ignores the fact that the employment requires an alignment between the supply of individuals and the demand for labor on the part of the employer [9]. Labor market can be defined as the market in which the employees look and compete for employment and the employers look and compete for workers. The labor market affects the decisions of the participants who in turn, by their own decisions, affect the labor market itself. The major idea of labor market economics is the analysis of the determinants of various dimensions of labor supply and demand. Moreover, the dimensions of labor supply and demands interact to determine wages, employment, and unemployment.

Labor market is influenced by global competition, free trade, change, and technological innovations. Especially in recent years, the rapidity of technological, communicative, social, and political changes is making the labor market and the supply and demand dynamics that rule it ever more unpredictable than before [57]. Services for the employment of people with IDD are confronted with the dynamics of the labor market. Far from being a mechanical process of "matching" between the person and a specific job, as it was sometimes conceived in the past, the main goal of services is to increase the chances of their recipients getting to work. We can generally describe their effort as means to increase the "employability" of persons with disabilities.

Traditional principles of labor market economics, based on the analysis of the determinants of various dimensions of labor supply and demand, ignore the fact that employment requires an alignment between the supply of individuals and the demand for labor on the part of the employer and need to be adapted to specific characteristics of persons with ID/ASD.

38.4.3 Employability

Promoting employability of disadvantaged people is one of the main goals of labor market policies promoted at national, regional, and local levels [58, 59]. Employability has been defined as a "cornerstone of the new labor approach to economic and social policy" [60]. The United Nations (UN) has considered employment as one of its four policy priorities. In 2001, the UN Youth Employment Network has suggested that "…all countries need to review and re-orient their educational and vocational training and labor market policies to facilitate the school to work transition and to give young people a head start in working life" [61]. However, employability is often used with reference to a wide range of meanings. Over the years, different definitions of the concept have been used. Some of these mainly emphasize the role of individual skills and competencies [62, 63].

McQuaid and Lindsday [64] have conducted a current and historical analysis of the different applications of the concept in labor market and suggested a broad conceptual framework with three main interrelated components such as (1) factors related to individuals (including employability skills and attributes, demographic characteristics, health and well-being, job seeking, adaptability, and mobility), (2) personal circumstances (including household circumstances, work culture, access to resources), and (3) external factors (including demand factors, enabling support factors). They have provided a detailed list of domains and variables describing these three main components.

This employability framework is consistent with the theory of evolutionary systems and the bio-psycho-social and contextual models of functioning and disability [64–66], which consider the individual evolution as the result of the interaction between the person

and the context [67–69]. Research literature on the employment of people with disabilities can be easily classified within this conceptual framework, considering domains and variables included in the analysis and the causal links investigated. Rarely, all the domains of the depicted framework are included in a single study and, in general, an excessive simplification of the employability framework is the main methodological limitation of many studies. Some areas, for example, personal circumstances and the relationship between individual and external factors, remain underrepresented in international literature.

Employability research must be guided by the consideration of a broad list of personal and contextual factors organized in an appropriate conceptual framework. Many empirical studies traceable in literature are based on poor representation of the factors influencing employability.

38.4.4 Employment Services and Practices for People with ID and ASD

The World Health Organization has defined rehabilitation as "a set of measures that assist individuals, who experience or are likely to experience disability, to achieve and maintain optimum functioning in interaction with their environments." It is a process aimed at enabling disabled persons to reach and maintain their highest level of adaptation, to remain in or return to their home or community, live independently, and participate in education, employment, and civic life [70]. It is common in international literature to identify VR as an umbrella term to identify a large area of practices and services that consider employment and full inclusion of adults with disabilities in society the main goal [44, 71]. However, there is no consensus on a common definition of VR at international level, and also the implementation of VR service at national level is extremely different. An adequate understanding of the VR organizations would require a country-specific description that is outside the scope of this text. We will highlight some common traits, and we will suggest some useful literature references.

For the Vocational Rehabilitation Association VR is "… a process, which enables persons with functional, psychological, developmental, cognitive and emotional impairments or health conditions to overcome barriers to accessing, maintaining or returning to employment or other useful occupations" [72]. Marnetoft enriches the definition, including all actors involved in VR, and emphasizes the search for evidence-based practices. In its perspective, VR is "a multiprofessional, evidence-based approach that is provided in different settings, services, and activities to working-age individuals with health-related impairments, limitations or restrictions with work functioning, and whose primary aim is to optimize work participation" [73].

The absence of a general consensus on the definitions but, above all, the great diversity in the practices at the national level have not helped the construction of solid scientific outcomes. Several authors have claimed that evidence on employment outcomes for people with IDD and mental disorders remains fragmented and insufficient to develop guidelines for best practice [74]. However, the literature reviews and systematic reviews [75–78] converge in identifying main macro-approaches to VR in respect to which a vast amount of research has been carried out over the past 50 years. We briefly describe these main approaches distinguishing them into three groups: *Sheltered Employment programs*, *Supported Employment programs*, and *Social firms*.

The term *Sheltered employment programs* is used to address a wide range of segregated vocational and non-vocational programs for individuals with disabilities [79]. These programs present wide heterogeneity in terms of mission, services offered, and sources of funding. They are designed for individuals considered temporarily or permanently unemployable in competitive settings. The majority of employees are individuals with disabilities, who perform typically easy, repetitive tasks such as prod-

uct assembly or packaging, often below minimum wage. Support and skill training are provided on-site [80]. Employees may receive a training allowance in addition to other social benefits [1].

The large majority of literature on sheltered employment programs comes from the US research and debate. Sheltered employment programs are usually classified into two groups [81]:

- Extended employment programs: They refer to a long-term or permanent placement.
- Transitional employment programs: They provide specific training required for a successful employment in the open market.

Sheltered employment programs and services remain the most common destination of adults with IDD in the United States despite a large political and legal effort to their re-sizing [82]. In the last 20 years, approximately 80% of public resources have been directed to facility-based work or non-work settings programs versus 20% directed to supported employment programs [83]. This unchanging situation generated a wide and lively debate and a rich research work aimed at highlighting "pros and cons" of this type of program. There is a substantial evidence showing that sheltered employment programs have a low rate of successful transition of individuals to competitive employment [80, 84]. So the long-term impact of sheltered employment on community integration of individuals with disabilities is very limited [85].

The sheltered employment wages are low or insufficient to allow economic independence of employed people [83]. A well-known study by Cimera [86] has compared employment outcomes for two cohorts of people with ID: one in supported employment programs and the other that participated in sheltered workshops. The study has revealed no statistically significant difference in the percentage of people employed in the two groups; the weekly earning was significantly higher for supported employees than for people in sheltered workshop and the employed sheltered workshop cohort was more expensive to serve than the supported employment group. Similar results were found in studies comparing selected cohorts of people with ASD and ID [87, 88].

In a research aiming to investigate "Why do adults with intellectual disabilities work in sheltered workshops?" [16], it was found that employment outside sheltered workshop was often considered too complex or frustrating for many persons with IDD [89]. In other cases, the decision to stay in a sheltered workshop was related to lack of transportations accessing community employment settings, and fear of losing disability benefits. However, Migliore [16] discovered that 40% of the families, 46% of the adults with ID, and 60% of staff members of sheltered workshops reported that nobody had encouraged the adults with ID to seek employment outside of sheltered workshops.

The supporters of sheltered employment emphasize the avoidance of physical and psychological risks of competitive work and the greater opportunities that protected work offer to establish and maintain friendly relationships [90]. Despite these uncertainties, most authors, research work, and the political commitment support the idea of re-sizing sheltered workshops in favor of supported employment strategies. In this regard, the National "Employment First" initiative in the United States promotes employment in integrated community-based business as the first preferred option of youth and adults with significant disabilities [82].

There is no common definition of sheltered workshops at the European level; however, like in the United States, an important research identified, also in European countries, two main types of sheltered workshops. Traditional sheltered workshops are long-term permanent places of employment for people whose disabilities preclude them from entering the open labor market, while transitional sheltered workshops aim to provide people with disabilities with the support and the skills needed to access non-sheltered employment. For some European countries, it has been documented that people with IDD

are the prevailing group in sheltered workshops (i.e., 77% in Germany) [91].

The employment status and remuneration of sheltered employees vary across the European Union (EU). Some member states grant employee status to disabled people in sheltered workshops, which entitle them to a minimum wage. However, the majority of sheltered workers do not have employee status and receive varying forms of remuneration but not a salary. It is not possible to collect comparable data on the nature and scale of sheltered workshops for the EU. This is primarily due to the existing differences in the names, structures, and legal frameworks, which implement sheltered workshops in the member states. The research documented a shift toward the transitional model of sheltered workshops in Europe. However, the estimate of people in transitional sheltered workshops that move on to the open labor market is no more than 3% [91].

Supported employment (SE) is a VR alternative approach to sheltered employment clearly oriented to place people with disabilities in competitive job positions without any extended preparation and training [1, 77, 92]. Since its introduction in the early 1970s, it has become a worldwide practice to help individuals with disabilities who are unable to successfully gain or retain employment by themselves and to enter the open labor market with the same dignity as people without disabilities.

People with disabilities are supported in finding as quickly as possible an employment in competitive settings. Furthermore, they receive intensive on-job support and training through job coaches. All supported employment projects, especially those for people with IDD, share the belief that long training programs drive away from the job placement, risk to promote dependency, discourage people from seeking a competitive employment, and are not effective in helping people with disabilities to acquire the skills required by the future job [93, 94]. The SE programs have gradually spread to become the internationally preferred VR practice, in particular, because they respect the core principles of the UNCRPD and support the right to inclusive work for all persons with disabilities.

According to a widely shared vision in literature [95–97] and public documents [98], SE can be defined as "a competitive paid work in an integrated setting with ongoing support services for individuals with severe disabilities for whom competitive employment has not traditionally occurred or for whom competitive employment has been interrupted as a result of a severe disability" [96]. The European Union of Supported Employment defines supported employment as a practice that provides "support to people with disabilities or to other disadvantaged groups to secure and maintain paid employment in the open labor market" [99].

Both definitions incorporate the main values and criteria that have guided the development of SE programs in the past decades. They are as follows: (a) every individual, regardless of the severity or the type of disability, may aspire to a job in the community; (b) services have to respect self-determination and choices of person with disabilities; (c) wages and benefits have to be equal to that of co-workers performing the same or similar jobs; (d) job coaches have to focus their intervention on capacity and capabilities of the person with disability; (e) within the workplace mutual respect and acceptance have to be established between disabled and non-disabled workers; and (f) supports have to be provided before, during, and after the job placement [4, 94, 96].

The effective opening of the SE programs to all persons with disabilities has often been challenged. McInnes et al. [100] explored panel data of all clients served by South Carolina Department of Disabilities and Special Needs from 1999 to 2005 with a sophisticated statistical modeling in order to investigate the hypothesis that IQ and presence of emotional–behavioral problems may negatively affect the likelihood of entering SE programs. In other words, the authors supposed that the better outcomes of SE programs observed in many studies may be due to a selection bias. The authors concluded that even after correcting for these biases better statistical treatment effects of SE remain.

Depending on the mix of the support intensity, duration, timing, and characteris-

tics, scientific and professional literature has defined several SE practices. Therefore, for example, in customized employment programs the support is specifically finalized to the personalization of the relationship between employees and employers in ways that meet the needs of both. Customized employment assumes the provision of reasonable accommodations necessary for an individual to perform the functions of a job. In the United States, the Office of Disability Employment Policy provided a formal definition of customized employment, its characteristics, and a practical manual [101].

Individual Placement and Support (IPS) is an evidence-based variant of SE originally developed to help job search for people with severe mental illness. In IPS, the client's preferences are central. The client decides whether or not employers and potential employers know about her/his mental illness and whether or not the employment specialist will talk to employer/s on his or her behalf. The client also decides which jobs to apply for and how much he or she wants to work. Recently, IPS has been extended to people with autism [102].

SE programs have also assumed the form of targeted projects. The Treatment and Education of Autistic and Related Communication Handicapped Children (TEACCH) system, since the '90s, developed a specific version of SE for people with autism [103]. "Project SEARCH," also involving people with autism, is a recent and complex version of SE aiming to realize a seamless transition from school to work [78]. "Project SEARCH" can be described as a business-led transition model where schools create collaborative partnerships with local large businesses such as hospitals, banks, or government centers. Such businesses afford students in transition to adult life the opportunity to work in internships across their senior year of high school. The importance of the program consists of an integrated real-life work experience, training in employability, and independent living skills [104].

While in the United States, Australia, and Canada, SE programs have a clear legal foundation and an established organization, a recent study on SE promoted by the European Commission has revealed that in many of the investigated countries, funding of SE appears to be unstable and unpredictable. In particular, the risk is that the service model is not institutionalized and that it continues to have a pilot project character with a more limited impact [105, 106].

The cited European report has underlined that, for the majority of European states, unemployed people in general receive support through the public employment services while disabled jobseekers tend to be referred to external agencies [105]. Paradoxically, one of the most studied service models and one of the better documented in terms of outcomes is not yet completely and coherently recognized in European countries, as a first choice in accompanying people with IDD to employment. Also in most of the studied countries, reliable statistical data on SE programs and clients are not readily available [105].

Social Firm/Enterprise (SF): Like other textbooks and authors, we included SF within the framework of VR practice even if their main aim is the creation of new employment opportunities for disabled people. The Confederation of European Social Firms, Employment Initiatives and Social Cooperatives (CEFEC) underlines these issues defining the profile of a Social Firm [107]:

- It is a business which uses its market-oriented production of goods and services to pursue its social mission (more than 50% of its income should be derived from trade);
- A significant number of its employees will be people with a disability or other disadvantage in the labor market;
- Every worker is paid a market-rate wage or salary appropriate to the work, whatever their productive capacity;
- Work opportunities should be equal between disadvantaged and non-disadvantaged employees. All employees have the same employment rights and obligations.

Worldwide SF includes different business models under different labels. In Western Europe, most social enterprises operate under

the legal form of either a nonprofit association or a cooperative.

The general idea that guided the development of SF was to create completely new ways of meaningful production and working to find an answer to the problem of unemployment and discrimination in the labor market by increasing the available work opportunities for the most disadvantaged groups. The first social cooperatives were established in the late 1970s by mental health professionals and former psychiatric patients and they gave a decisive impulse to the psychiatric service reform promoted in Italy by Franco Basaglia [108]. The involvement of persons with disabilities in the foundation and management of the cooperative was a "provocative" choice and remains a model of participation with unchanged values in terms of empowerment and respect of disabled people's capacity and role.

The idea of creating employment as an alternative to traditional sheltered workshops contrasting the low employment opportunities in the private sector proved to be successful. As a result, the number of SF in Italy and, later, across other countries in Europe increased constantly. Currently, there is a wide variety of SF models across Europe with a different business focus, models, and approaches to support disabled and disadvantaged people. Many SF started as standalone business start-ups, mainly from the social sector, as vocational training projects, established by larger nonprofit organizations that manage a variety of supporting programs for disadvantaged and disabled people [109]. SF represent an important chance for employment, even if the scientific research on individual outcomes is quite limited [108].

Vocational Rehabilitation is an umbrella term to identify a large area of practices and services which enables persons to overcome barriers to employment or other useful occupations. In this frame, Supported, Sheltered Employment, and Social Firm are the main Vocational Rehabilitation modalities reported in the literature.

Tip

There is substantial (however, not definitive) evidence that sheltered employment programs have a low rate of successful transition to competitive employment and limited long-term impact on community integration.

38.4.5 Development of Work Skills

A broad research work has tried to give scientific evidence to practices and interventions whose aim was to teach relevant instrumental and relational work skills.

Dutta et al. [110] describe a rich and varied list of interventions commonly proposed by the US VR services, ranging from assessment practices to vocational rehabilitation counseling and guidance, from occupational/vocational training and basic academic remedial literacy training to disability-related, augmentative skills training, job placement, job search assistance, and on-the-job support. The authors show that job placement, on-the-job support, counseling and guidance, and miscellaneous training practice were significant predictors of employment for people with mental disability in a large population of people with disabilities coming from the US VR services [110].

Several studies investigated the role of in-school service variables in predicting employment of individuals with IDD [111–116]. Carter et al. [112] investigated factors associated with the early work experiences of adolescents with severe disability using data from the National Longitudinal Transition Study-2. Severity of disability had a stronger influence in reducing access to paid work. A strong role was also played by family expectations. Further, youths who were given more household

responsibilities had more than twice the odds of holding a paid job. Three prevocational experiences seemed to have had a positive impact on acquiring a paid work: career skill assessment, job skill training, and internship.

Mazzotti et al.'s systematic review [115], based on the study of Rowe et al. [116] in which 16 in-school service predictors of employment are identified, shows positive evidence for the majority of interventions investigated in the literature. Fifty-five significant positive effects across the 11 studies reviewed were detected ranging from $r = 0.19$ to $r = 0.934$ with a median effect of $r = 0.335$. Twenty-one relationship results in large effect sizes such as those for self-care/independent living skills, social skills, goal setting, and parent expectations.

The study of Holwerda et al. [114] confirm the strong influence of expectations on employment for people with IDD and give evidence that school teacher's expectation plays the main role. Park and Bouck [117] using a sample of people with ID from the National Longitudinal Transition Study-2 show that those who received vocational instruction, job readiness vocational services, instruction in looking for jobs, and placement support had a better chance of employment after high school. However, different effects were observed for the group with mild ID versus the group with moderate/severe ID. It is worth noting that when individual transition plans included competitive employment, the students were three times more likely to be in paid employment than other students, while the students who had sheltered employment plans were 0.17 times less likely to be in paid employment than other students.

Moving from macro-categories of interventions to specific interventions, the research landscape appears fragmented and the evaluation of effectiveness appears difficult to summarize. We present here only some interesting references. A large number of studies have focused on social skills training for people with ASD, and they have reported positive results on employment outcomes [118]. The TEACCH-supported employment program was developed using a structured ASD-specific visual supporting approach. A report about 96 clients who received TEACCH-supported employment services show good hourly wages and job retention rate (89%) which was not related to clients' status at referral [103, 119]. Training oriented to enhance conversational skills [120], emotion understanding [121], perspective-taking [122], utilization of sight words in self-instruction [123], and acquisition of self-help skills [124] seem to have some effect in increasing the likelihood of obtaining an occupation.

During the last 10 years, we have witnessed the development and application in the VR field of technologies and techniques used for different training purposes, such as tactile prompting, picture guiding, audio cuing, video modeling, computer-aided instruction, virtual reality, and robotics, implemented mainly among individuals with ASD [125]. The use of personal digital assistant reduced the number of hours of job coaching and increased the number of hours worked in a supported environment [126]. A multimedia program was found to improve interviewing skills and rates of attaining competitive employment [127, 128]; touch screen tablet computers increased independence, confidence, time management, and organizational skills at work [129]. These studies have provided support for the use of behavioral techniques to teach workplace skills and modify behavior in individuals with ID and ASD [130]. Other studies have described interventions conducted by video modeling or audio coaching [131–134] and behavior training on different skills and tasks using smartphone applications [131].

Lattimore et al. [135] evaluated a multiple-stimulus assessment for identifying work preferences among adults with autism prior to beginning supported jobs. Opportunities to work on preferred tasks can enhance job performance as well as overall quality of work life and is a specific requirement of the US-supported employment legislation.

Lattimore et al. [136] showed a substantial increase in independent job performance with newly assigned tasks when simulation training was provided prior to on-the-job training. Wehman et al. [137] investigated the effect of an enhanced version of Project

SEARCH in which the structure and intensity of the learning experiences were increased by the use of applied behavioral analysis (ABA) techniques. A treatment (n = 38) and control group (n = 18) of youth aged 18–21 years with ASD were compared on employment outcomes with 49 non-ASD youths (18–21 years). The results of the study demonstrated the effectiveness of the supported employment practice in producing positive employment outcomes and which reduced significantly the support intensity needs (as measured through the Supports Intensity Scale; SIS) [138] in employment activities. At 3 months post-graduation, 90% of the treatment group acquired competitive part-time employment earning, compared with 6% of not-in treatment conditions; 87% of those individuals maintained employment at 12 months post-graduation compared with 12% of the control group. The study provided also a detailed description of project activities connected with Project SEARCH guidelines, method used, and team leader identification.

In a recent systematic review of interventions on adults with ASD, Headley et al. [118] postulated that despite the availability of many studies there are serious problems in generalizing results due to the large range of skills and interventions investigated and the small number of individuals involved in these studies.

The literature on Vocational Rehabilitation describes a rich and varied list of interventions commonly proposed by services. It also underlines the importance of prevocational experiences such as evaluation of professional skills, professional training, internships, and in particular competitive work experiences. Research findings also describe the important role that self-care and independent living skills, social skills, self-determination, and parents' "and teachers'" expectations have on the likelihood of getting a job.

Tip

Future researches should ascertain the promising impact of TEACCH and ABA-based techniques on supported employment programs as well as the usefulness of new technologies for training purpose in the Vocational Rehabilitation field.

38.5 Employment-Related Outcomes

As we stated previously in this chapter, the majority of authors consider employment as a fundamental social goal with great value for every human being. Competitive employment promotes the sense of belonging to society and positively affects the quality of life of people with IDD [139]. For this reason, placement rates, the duration of employment, earnings, and job tenure are often considered main outcomes in themselves [140].

However, researchers consistently believe that the effect of employment on quality of life (QoL) and other non-working outcomes have the same importance and require to be carefully, empirically investigated. It is worth remembering that QoL's objective indicators correspond to condition of individual's life as it appears to an external observer, considering that there are aspects of life that have a qualitative value for everyone. The subjective dimension corresponds instead to the individual perception of satisfaction for existence or for a specific life domain and can be assessed only through the opinion of the person himself. Both dimensions can be considered fundamental components of any QoL concept (see ▶ Chap. 15).

Relatively few studies have explored the impact of employment on QoL and subjective well-being of people with ID and ASD [141, 142]. In the study of Kober and Eggleton [143], 117 people with ID were interviewed using the QoL questionnaire [144]. The results of this study indicated that people with ID in open employment report a better QoL than those in sheltered employment. In particular, open employment correlated with a greater sense of social belonging and empowerment.

Community-integrated employees also reported a greater level of QoL in the domains of health, productivity, and emotional well-being than those involved in less inclusive activities [92]. Jahoda and colleagues [145] reported a systematic review of 15 years of studies on QoL, social life, and autonomy of people with ID related to the employment experience. Fifteen studies were selected. Assessment instruments documented in the review appeared heterogeneous as well as research designs (in many cases no control groups were selected) and sample sizes. Entering employment seems to produce positive outcomes for all the main dimensions investigated. However, the authors observed that the opportunity that work experience offers to increment social relationship and interactions with peers and co-workers did not seem to translate into a sense of belonging or reciprocal relationship.

A recent systematic review supports the idea that the positive effect of paid employment on physical or mental health is similar for adults with and without IDD [146].

Lack of social acceptance remains a prevailing concern for people with ID. Service providers should place more focus on assisting their clients and find placements that would provide them with adequate social and emotional support. In a recent study by Blink et al. [147], the QoL of 447 adults with ID was evaluated with Essential Data Elements, an 85-item comprehensive, structured interview and compared among three groups involved in three different settings: open employment, sheltered workshops, and adult day care centers. Participants in community-integrated employment indicated a higher sense of community inclusion and reported more opportunities of choice and control on several dimensions of their life and financial autonomy, compared with participants of sheltered workshops and adult day care centers [148].

A dimension closely linked to the concept of subjective well-being is "job satisfaction." It can be defined as "a pleasure or positive emotional state resulting from the appraisal of one's job" [149]. It is basically defined by the same constructs as subjective well-being (see ▶ Chap. 14), whereas the affective part addresses either negative or positive affect and the cognitive part refers to an individual's global evaluation of their satisfaction with their job. It is the result of both situational work environments and personal characteristics and of the interaction between them [150, 151]. We do not have a satisfactory review of the studies in this area of research. However, the existing literature indicates crucial aspects of job satisfaction of people with ID such as the nature of their work, working conditions, financial benefits, growth opportunities, and self-determination [92, 152–155]. Examining the subjective experiences of a group of people with ID, who were starting employment, Jahoda et al. [156] found that employment helped people with ID to "get out of their house" and to lead a more active life. At the same time, work may cause anxiety, especially at the beginning of the job experience.

A recent study analyzed, adopting "Photovoice" method [157], the job satisfaction of nine employees with ID in integrated and sheltered employment [158]. The authors considered nine domains of job satisfaction: (a) the nature of work itself, (b) working conditions, (c) experienced job demands, (d) social relations at work, (e) received support, (f) perceived autonomy, (g) opportunities for using competencies, (h) opportunities for growth, and (i) development and meaningfulness. The results indicated that people with ID appeared to consider most of the same topics relevant to job satisfaction as do people without ID. However, some domains may be more distinctive for workers with ID such as received support, opportunities for using competencies, perceived autonomy, and opportunities for growth and development. These data showed that people with ID seemed to be aware of their abilities and limits as a natural aspect of their own working life. On the other hand, the sense of autonomy and growth showed a desire of these individuals to become more capable and independent.

A systematic review of employment programs and intervention outcomes targeting

adults with ASD dedicated a section to non-employment-related outcomes [14]. Only eight studies corresponded to the selection criteria. The examined outcomes were heterogeneous, ranging from examining the effect of supported versus sheltered employment on core ASD symptoms, QoL, and cognitive skills to evaluating the impact of specific interventions in improving social behavior and social communication, literacy, or reduction of challenging behavior in the workplace. The number of subjects involved was quite small, and the heterogeneity of the evaluated outcomes made generalization difficult. Furthermore, the authors concluded that the few studies investigating outcomes unrelated to employment were generally of poor quality so that, to date, evidence is lacking, in terms of outcomes beyond obtaining employment, such as cognitive, mental health and well-being, symptom severity, adaptive functioning, and quality-of-life factors.

Social inclusion as an outcome of work experience has been relatively poorly investigated in the literature. As mentioned in the introduction, the employment itself is considered an adequate indicator of social inclusion. In their scoping review on inclusion as a focus of employment-related outcomes, Lysaght and colleagues [159] found that no more than five articles focused on central aspects of inclusion, such as sense of belonging, reciprocity, and fulfillment needs. This area of research should receive more attention.

A useful descriptive framework oriented to a joint analysis of the effects of employment on QoL [160], social and economic engagement [161], and social inclusion [162] has been proposed in a recent comparative study on the perceptions of a sample of 51 people with ID involved in three different types of employment, namely, open employment, SE (the Australian term corresponding to sheltered workshops in the United States and Europe), and social enterprises. The authors found that across all employment types, relationships and getting paid or achieving material well-being were the most important employment outcomes to people with ID. Skill development and participation were the next most important outcomes. People working in open employment appeared to have the most knowledge about rights, respect, and equity.

Emerson and colleagues [163] investigated the influence of employment on health status of persons with ID analyzing a population-based cohort from which a proxy measure of childhood IQ was derived. Despite people with ID and borderline intellectual functioning had lower employment rates and poorer health than other participants at all waves of data collection, those in full-time employment showed a better health status than those in part-time employment or inactive, and those in any kind of employment showed a better health status than those unemployed.

- Most common employment-related outcomes are represented by placement rates, length of employment, earning, and job tenure, while little consideration has been given to person-centered outcomes.

- Available literature reports that persons working in the open labor market show higher quality of life, job satisfaction, and community inclusion than those in sheltered employment.

Tip

Employment has been commonly regarded as an indicator of social inclusion; hence, research on the impact of employment on community inclusion is limited, especially in reference to persons with ID/ASD. It is to be hoped that this gap can be filled in future studies.

38.6 Employability: Workplace Characteristics and Employers' Attitude

As already noted employability is modulated by a complex set of "external" factors, that is, not directly related to the person, among which McQuaid and Lindsday [63] consider

labor market factors, macroeconomic factors, recruitment factors (including employer and colleagues' attitude, required skills, and workplace characteristics), employment policy factors (including availability of vocational services, employment agencies, and policies), and other enabling policies such as accessibility and affordability of public transport, child care, and other support services. We will briefly address some of these issues.

38.6.1 Access to Work for Persons with Disabilities: Legal Protection and Reasonable Accommodation

A long tradition of research and practice, with its roots in the 1970s, has underlined the crucial role of accessibility and workplace adaptation in facilitating employment of disabled people. The general goal was to overcome, as much as possible, the disability effects and to enable the disabled person to participate in the labor market. Some of these interventions regarding a barrier-free design and adaptation of workplace, barrier-free access to communication, the provision of facilities, and means of transportation (bus, train, aircraft) may be crucial for people with ID.

Hendricks [164], reviewing a rich literature on the topic, has provided a list of workplace modifications commonly needed by persons with ASD, such as noise reduction, avoiding crowding, adjusting lighting, and facilitating space navigation. "The workers with autism benefit from clearly defined work tasks and, also by providing a consistent schedule for completion of work tasks, job predictability can be increased. Idle time in the workplace may prove to be problematic and also requires restructuring" [165].

However, to facilitate employment of people with IDD, a wider set of other opportunities ranging from education and professional training to hiring practices, customizations, or restructuring of job tasks are required [165]. Special employment protection rights like disability quotas [166, 167] or additional allowances and benefits, such as tax relief [168], are common in many countries. Over the years, cumulative practices and research are offered to professionals and people with disabilities' guidelines to access services and benefits and/or tools for the analysis and evaluation of the needed workplace adaptations [169, 170].

Article 27 of the UNCRPD summarizes 4 macro-principles, widely recognized and shared in international literature, in national legal frameworks and embedded in service practice:

(a) Non-discrimination, as the right to work on an equal basis with others;
(b) Accessibility, as the right of living in a work environment that is accessible, identifying, and removing barriers that hinder persons with disabilities from carrying out their work on an equal basis with others;
(c) Reasonable accommodation, as a necessary and appropriate modification and adjustments not imposing a disproportionate or undue burden were needed in a particular case, to ensure to persons with disabilities the enjoyment or exercise on an equal basis with others of all human rights and fundamental freedoms;
(d) Adoption of positive measures to promote employment besides a duty to impose obligations on private- and public-sector employers [8].

In the last 50 years, laws and regulations at national level have granted rights and benefits to disabled people. One of the first and most cited is the American with Disability Act (ADA) [171].

A recent report analyzing legal developments at UN and EU level (the 28 EU Member States, Iceland, Liechtenstein, and Norway) has shown that "all the countries, with the exception of Liechtenstein and Iceland, have implemented non-discrimination and reasonable accommodation duties, although a range of different approaches are taken to the types of legislation in which this duty is located. Barriers to enforcement are often associated with the costs of the proceedings, access to legal assistance, and advice and procedural issues such as time limits for bringing actions. In addition, disabled claimants sometimes

encounter barriers in the form of inaccessible court (or other) buildings and inaccessible communication or information" [172]. The report has also revealed a lack of data about the number and nature of cases on reasonable accommodation, in most countries.

In this regard, an interesting source of information is the US-Integrated Mission System of the Equal Employment Opportunity Commission for allegations of discrimination involving Title I of the ADA. Van Wiren et al. [171] analyzed all US-resolved allegations from 1992 and 2008 and found that only 1626 involved people with ID (1459) and ASD. By comparison, the same database contained 45,560 allegations for back impairments, 14,515 for diabetes, and 11,421 for hearing impairment. The small number of allegations involving people with ID and ASD may be related to obstacles to both recognizing and reporting instances as well as to the low presence of ID and ASD in the labor market. As far as we know, there are no comparable data available for other countries.

The UNCRPD includes four principles that have been widely recognized in the international literature as external factors that can considerably facilitate employment of people with ID/ASD: non-discrimination, accessibility, reasonable accommodation, and adoption of positive measures to promote employment.

38.6.2 Employer Attitude and Practice

The definition of a legal framework has to be supported by an effective capacity to promote the rights of persons with disabilities by all the involved subjects and first of all by employers, managers, and work colleagues. It seems strategic that workers with ID and ASD were recognized as a valuable addition to the workforce and not included on the basis of solidarity principles or corporate social responsibility only [173, 174]. A recent scoping review of the research literature around employer responses to disability in the workplace found that the number of studies on the topic has increased significantly since 1991 [175]. However, Ellenkamp et al. [10] in their systematic review on work-related factors of employment found no more than 26 articles in the last 20 years specifically related to ID. Most of the selected studies in this review were conducted in the United States. While employers' surveys have generally found that employers express positive attitude toward the idea of hiring people with disabilities, these findings do not seem to translate to real-world behaviors, perhaps because respondents to such surveys tend to give socially desirable answers [176].

There is strong evidence that in the workplace employees with ID were confronted with misconceptions about their capacities. Underestimation and negative attitude of colleagues seemed a relevant issue [177]. A study of workers with ID in competitive employment has revealed that "awareness" of stigma themes was found in almost half of the interviewees [10]. Comparing people with different types of disabilities, several studies have shown that employers' attitude is the least favorable for people with ID and mental disorders [178, 179].

However, employers who had experience with people with IDD had a more positive attitude and lesser stereotyping and disengagement attitude toward these employees compared with employers without such experience [10]. The importance of engaging employers throughout the process of creation of inclusive practices and policies with work environments is critical to the successful employment, career navigation and economic parity, workplace accommodation, job restructuring, and job customization [180].

Expanding and improving relationship between employers and VR services may create a great focus on work participation of employees with ID, but as noted by Luecking [181], employment service providers do not speak the same language as employers, and also disability employment service providers and employers use different success metrics. The author strongly supported the idea of a dual customer approach, that is, the employer is simultaneously targeted as an end user of

employment service program while the program supports the job-seeking individual.

A well-known initiative trying to develop a sharing language and vision between vocational service and employers is the already cited Project SEARCH [104, 182]. However, Luecking [181] supported the idea that a close relationship between employers and employment services could be established in an ordinary way without the "proliferation of special programs."

It is worth noting that in the majority of the 26 studies reviewed by Ellenkamp and colleagues [10], the employees' perspective was not included. The authors suggested that "self-advocacy of employees with ID supported by job coaches or families in promoting dedication to their work in combination with disability educations for employers and colleagues could be helpful in generating ID awareness by employers and reducing underestimation of capacities of workers with ID" [10].

There is strong evidence that employees with ID/ASD, especially those with co-occurrence of mental disorders, are exposed to prejudice about their capacities, negative attitude, and discrimination by colleagues and employers.

Key Points

- We have tried to synthesize a huge and complex literature, and this complexity does derive from the intrinsic nature of the matter. Accompanying people with IDD to employment is an interdisciplinary work, which requires specialized skills on the medical, rehabilitation, educational, social, and legal levels. Job placement takes a long time and involves a number of institutions: schools, health and social services, vocational services, and companies. Generating employment opportunity for people with IDD would require overcoming stereotypes and stigmatization, compliance with anti-discrimination rules, and a strong alliance with employers. Kirsh et al. [176] in an interesting summary article "of the lessons learned" in decades of research and fieldwork have identified the key prerequisites for advancing research and social changes in the field of work integration: cultural, legal, technical aspects, professional, and organizations should find full synergy and an operational synthesis. However, this scenario is far from being accomplished even in countries with a more consolidated and rich welfare system.
- Despite the different research approaches and the difficulties in interpreting and comparing data from different social and cultural contexts, there are some convergent empirical evidence in employment trends of people with IDD. Labor force participation and employment rates remain at the lowest levels among the different groups of people with disabilities in all countries for which data are available. There is some evidence that among the group of developmental disabilities people with autism show lowest levels of labor force participation and employment rates. Hourly wage and total earnings of people with developmental disabilities are approximately half of those of persons without disabilities and lower than other people with disabilities.
- Despite the different definitions (diagnosis, medications, emotional problems, depression, etc.), the large and mixed set of psychological variables considered, the difference in statistical measurement of adaptive behavior and behavioral problems, mental health problems seem to reduce employment rates and increase probability of unemployment and participation into sheltered workshops. However, the effect of comorbidities and severity of disability on employment rates and labor force participation at population level is only partially documented. In particular, the representation of the psy-

chopathological conditions appears inadequate; often, diagnostic categories come from administrative documentation and are not clinically confirmed; in other cases, we can observe only proxy variables. To our knowledge, no study demonstrated to respond to stringent quality criteria for diagnosis [34].

- The number and variety of available studies testify to a notable interest and commitment of the international scientific community on the issues related to the employment of people with IDD. Nevertheless, the heterogeneity in the assessment of clinical conditions and severity of disability, associated with small samples investigated and methodological limitations in research design, make it difficult to generalize and compare outcomes of different employment programs. To our knowledge, the literature reports only one experimental study and no meta-analysis.
- However available evidence suggests that supported employment is the most effective practice in improving employment rate and significant employment-related outcomes relevant for people with IDD. The positive impact of employment on quality of life and subjective well-being of persons with IDD is relatively well documented in literature and particularly in the case of supported employment programs. Many specific aspects of employment-related outcome need to be better investigated, for example, the impact on functioning profiles. The heterogeneity of the evaluation tools used and limited data comparability remain two of the main problems in this crucial field of research.
- There is worldwide evidence of no significant improvement in the IDD employment rates at population level, at least in the last 10 years. Labor force participation and employment rates of people with developmental disabilities seem higher in North America and Australia than in Europe, but this may be partly due to the lack of reliable data on sheltered work in European countries and differences in definition of target population. Access to supported employment services is not guaranteed to all persons with IDD, and the level of funding has been substantially stagnant in the last 10 years, both in Europe and in the United States. However, the absence of significant increases in access to work for people with IDD should not be interpreted only as a failure.
- The labor markets are undergoing extraordinary changes that seem to move toward reducing occupations suitable for people with IDD but also for non-disabled workers. Even without following the catastrophic prophecies of Rifkin about the "end of work" [183], it is impossible not to be worried about the future. The "aseptic" OECD employment outlooks underline the role that technological progress and globalization are playing in polarization and de-industrialization "both associated with disruption in workers' lives and rising inequality" [184]. Reflecting the changes in organizational structure of companies, Chan [173] has observed that: "the organizational chart is now flatter and team-based and the emphasis is on flexibility, productivity, and workplace socialization skills." It seems clear that people with ID are facing tremendous and growing challenges for access to work. These challenges extend to employment services. Chan argues that "… therefore rehabilitation professionals must have a thorough understanding of the real concerns of employers about the hiring and retention of persons with disabilities and needs. Helping people with disabilities develop flexible, versatile, and adaptable work skills to meet employer expectations and requirements for jobs in the

new economy will improve their odds of obtaining employment" [173].

- The effort focused on enabling personal skills and abilities is not enough. It has to be accompanied by a parallel effort in creating new employment opportunities and perhaps the culturally dominant idea of work has to be reinvented as well [185]. International data and research suggest some possible tracks. Public campaigns, legal frameworks, employment benefits, and services seem to be targeted to big companies. The potential of small firms for the inclusion of people with IDD has to be largely explored [186]. Additional effort should be dedicated to initiative for promoting self-employment and microenterprises led by disabled people [187–189]. A policy of support of SF may also open new employment perspective [1, 190].
- Dealing with work for people with IDD has also a political value. If people with IDD can find work in the future, opportunities and hopes will also open for many non-disabled people. The complex sector of institutions and interventions, we have described so far, can also be seen as a great cultural, social, and political "laboratory" at the service not only of people with disabilities but of great utility for the whole society.

Learning Objectives

- Cultural issues related to the lives of people with intellectual disability (ID) and Autism Spectrum Disorder (ASD), at the policy, service, and clinical levels.
- Impact of these cultural issues on services and programs as well as implications for care and interaction with individuals and families.
- Organizational culture and its impact on programs and services.
- Current evidence-based screening and diagnostic procedures and tools in different countries.
- Availability of services that facilitate independent living and community integration for people with ID and ASD in many cultural contexts.
- Variations between how informal caregiving are provided.
- Indications for better policies, practices, and future research.

39.1 Introduction

Culture permeates the context in which people live and many contextual factors are closely related to culture (in fact, culture itself is a contextual factor). Both constructs—culture and context—are important frameworks for understanding personal and environmental factors that influence human functioning and quality of life, for supports planning and for public policy development and improvement. Therefore, in this chapter we will discuss both cultural and contextual issues that have a major impact on lives of persons with intellectual disability (ID) and Autism Spectrum Disorder (ASD) and explore how these elements constitute frameworks for providing high-quality services and supports as well as developing public policies. In addition, we will review how certain cultural practices and issues can lead to stigma and abuse, or low-quality services.

Although the concept of culture has been frequently mentioned as an important issue in terms of research about services for people with ID and ASD—in terms of measurement of prevalence, detection and diagnosis to some extent, and support services including especially residential or day programs—a variety of definitions of culture have been used and in many instances culture has been mentioned but not actually taken into account in analysis, evaluation, or planning. Bigby et al. [1] developed a definition of culture that is useful for evaluating and improving support services (including residential and day programs) for people with ID and ASD. In addition to a formal culture as endorsed by an overarching institution that provides administrative indications and proposes the model of care to be implemented, there is also an informal culture that is expressed through what care professionals and teams do in their day-to-day activities in order to implement this model of care (or often, not implement or at least not implement entirely) [1]. These authors adapt a definition proposed by Schein (1992) which states that culture is "A pattern of shared basic assumptions that the group learned as it solved its problems of external adaption and internal integration, that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems" (Schein 1992, p. 12, cited in Bigby et al. [1]). Adapting Schein's ideas, Bigby et al. [1] posit three levels of culture: artifacts (visible organizational structures and processes); espoused values (strategies, goals, philosophies or espoused justifications); and basic underlying beliefs, perceptions, and feelings, which are unconscious or taken-for-granted, for example, "local" common sense among the staff.

As with the construct of culture, the term context is often referred to in relation to ID and ASD but a consensus on the definition is lacking. According to Shogren et al. [2], "Context is a concept that integrates the totality of circumstances that comprise the milieu of human life and human functioning" and incorporates "factors that affect both positively and negatively human functioning." Contextual factors include culture and related aspects such as ethnicity and place of residence (including institutional or family, rural or urban, or specific country), among others.

In order to understand why within Shogren, et al.'s [2] definition of context, human functioning is so central, one needs to consider how definition and measures of disability, and the organized social response to them have changed in recent decades [3, 4]. An important engine behind this transition has been the political organization of people with disabilities themselves [5, 6]. While previously disability was defined as an individual characteristic or condition that was usually perceived to be a deficit, this construct has been developed into "an interactive human phenomenon with its genesis in organic and/or social factors" [2]. It is both the organic and the social factors that lead to functional limitations, always depending on the context (physical and social). Thus, functioning limitations of persons with ID or ASD cannot be attributed only to an individual impairment but to the complex relationship between this impairment, the impaired person, and the whole context (especially supports provided) in which the person lives. This makes it easier to visualize the context as "an intervening variable that can influence human functioning through organization and systems-level policies and practices, and public policies" [2].

Just as the definition of disability has changed at the theoretical level, in terms of policy this has been intertwined with the tendency in some countries to move away from institutionalization of people with disabilities and toward greater inclusion, in schools, living accommodations and communities, and employment [5, 6]. Thus, policies in some places have transitioned from an individual, medically focused perspective to a social approach that recognizes the contextual factors that can disable people (for example, make them unable to use transportation, move through the community, or receive information) [5, 6].

In summary, these definitions of disability, culture, and context are useful as frameworks for thinking about and understanding ID and ASD in order to take into account the impact of culture [1] and contextual factors [2] on human functioning. They can also act as tools to evaluate and improve the outcomes achieved by support systems and other services and care for people with ID and ASD.

Culture and contextual factors are interrelated fundamental frameworks for a correct conceptualization of ID and ASD as well as for adequate provision and planning of mental health services. Implications on grading of individual functioning impairment, support needs, and quality of life are also relevant.

39.2 Diagnosis and Services for People with Intellectual Disability and Autism Spectrum Disorder in Different Cultures and Contexts

In many middle- and lower-income countries, effective models of primary care with broad coverage are often lacking for health issues in general and especially for mental health [7]. Professional competencies in mental health are rarely strengthened. These issues, as well as cultural and other variables, lead to a lack of screening and early identification of neurodevelopmental disorders [7]. A clinical perspective focusing on the individual tends to predominate, while a focus on the family as well as cultural and social dimensions and the need for broad screening is lacking. In general, a public health approach to mental health for ID/ASD and an appropriate consideration of cultural and social issues (at the conceptual or practical levels) are absent. This includes educational, economic, and employment issues. This public health and sociocultural focus, and specifically providing broad screening, is necessary in order to maximize equity and social justice.

Implementation of population-level or large-scale mental health interventions is highly complex. In addition to this, there is an extremely low level of spending on mental health in almost all middle- and lower-income countries. This reflects both the existence of many other priorities in health care and a lack of recognition of the importance of mental health issues. The low level of spending on mental health is often compounded by the tendency to invest all funds in the operation

of psychiatric hospitals and treatment for addictions. This reflects a generalized model of care that focuses on curative medicine instead of prevention and what in the field of ID and ASD has often been called rehabilitation as well as support systems. Also, the number of psychiatrists in relation to the population is often extremely low in middle- and lower-income countries. For example, while Switzerland has close to 44 psychiatrists per 100,000 inhabitants, Mexico has only 3.68, and the proportion of child psychiatrists is often lower, such as in Mexico where there are only 0.69 per 100,000 inhabitants under the age of 15 years. Similarly in Pakistan, there are less than ten child psychiatrists for about 100 million children and adolescents.

Likewise, in many lower-income countries, overwhelmingly in public health care and to some extent in private care, current, evidence-based tests for diagnosing ID or ASD are not available. This is in great part because many entail a high cost. At the clinical level, many diagnostic tests for ID and ASD have been adapted to different languages and cultures. This has often occurred through formal procedures, although other times (perhaps especially initially, before formal adaptation has taken place) there has been informal adaptation and use in clinical practice. However, as mentioned, in a variety of contexts the cost of using current, high-quality diagnostic tests or scales are prohibitive and so older versions or in many cases non-evidence-based diagnostic tools are used.

In many middle- and lower-income countries, a public health approach to mental health for ID/ASD is often lacking, especially in reference to preventive interventions. The number of psychiatrists in relation to the population is often insufficient.

These and other sociocultural and contextual factors lead to difficulties and delays in the identification of persons with ID and ASD and in the implementation of adequate management. Up-to-date tests for diagnosing ID or ASD are not available, because their cost is prohibitive. Even guidelines for diagnosis and treatment are often inappropriate and partial.

Studies in Africa suggest that ASD is rarely diagnosed except in the presence of ID, indicating the likelihood that only the most severe spectrum of ASD presents to orthodox practice in Africa [8]. It has also been suggested that high comorbidity of ASD and ID among sub-Saharan African children may be due to the fact that onset of ASD coincides with a period of vulnerability of children in African contexts to neurological infections and complications like cerebral malaria, meningitis, and kernicterus, among others [9]. So, comorbidity of ASD and ID is very common among sub-Saharan African children [9], and ID co-occurs with other neurodevelopmental disorders [10], likely due mostly to sociocultural and contextual reasons.

Assessment of ID in Africa, as regards to Intelligence Quotient (IQ) score, presents a peculiar problem because of the influence of wide sociocultural variations across cultural and ethnic groups in the region, with a tremendous impact on child-rearing practices in different African communities, which may affect early child development. Given this, standard Western intelligence scales or assessment instruments such as the Wechsler Intelligence Scale for Children (WISC) have shown limitations for use in most African settings. This is because of variations in expectations for and levels of early childhood development in many African communities, which are influenced by a variety of sociocultural practices. Therefore, often an adaptive or modified method of IQ score assessment is employed in sub-Saharan Africa [11].

A substantial proportion of the population residing in African countries (close to 50% and with even higher levels in rural communities) attribute the etiology or origin of ASD and ID to spiritual causes, such as witchcraft, possession by evil spirits, a sinful act, and ancestral curses, among others [12, 13]. These aetiological explanations, which may also be held by caregivers or parents of children with ASD and ID, tend to influence perceived or lived stigma as well as help-seeking behavior [13]. A majority of caregivers or parents of children with ASD and ID in African societies experience frequent stigma, ranging from derogatory comments from

neighbors to outright social exclusion. Many of these parents are ashamed to let members of their communities know that they have children with ASD or ID [9, 13]. Consequently, many of these children are repeatedly locked into their homes and thus deprived of necessary early interventions or eventually any services or care (as well as, obviously, social inclusion, and deprivation of basic rights), given the generalized and severe stigma associated with their condition and the lack of policies to combat it [9, 13, 14].

Because aetiological explanations and other cultural issues greatly influence help-seeking behavior, many children with ASD and ID in Africa have local traditional and religious healers as their first points of contact in the help-seeking process. Local traditional healing settings may offer some form of psychological support to parents and their children with these conditions. However, practices in these settings often lead to late presentation at formal healthcare support, depriving such children of necessary early interventions. Religious healers consist mostly of Alfas and Pastors in Pentecostal Churches, who promise spiritual healing and very often employ exorcism. Religious healers may provide some psychological support, but at the same time they give false hopes of a cure, which often leads to delay in presentation at formal healthcare settings where evidence-based care might be provided [8, 9]. Collaborative work between clinical healthcare providers, public health institutions, government entities, and traditional and religious healers is needed to diminish stigma and promote help seeking by families both from traditional or religious healers and formal (clinical) health care. Healthcare providers need to receive training on acceptance of cultural beliefs held by parents and other caregivers, in order to provide empathic care, which is more acceptable to the parents. Also, these traditional beliefs do not necessarily conflict with clinical etiology [13].

In addition to cultural practices which can have a negative impact on help seeking, a number of other factors, mentioned below, have been identified as being responsible for the late presentation and diagnosis of African and Asian children with ASD and ID in formal healthcare settings [12]:

- Inadequate healthcare facilities and trained personnel for interventions.
- Social, cultural, and economic obstacles in pathways to care/help-seeking behavior.
- Poor knowledge and awareness about ASD and ID.
- Stigma manifested in negative cultural attitudes, beliefs, and practices toward ASD and ID.

There is also a lack of implementable social policy in many African countries. Laws and social policies that are enabling and needed to enhance service provision for persons with ASD and ID are often lacking in African countries. The absence of such laws and social policies makes person with disabilities even more vulnerable to human rights abuse and leads to deprivation of services like medical care and education [15]. The possible areas of human rights abuse common among individuals with ID and ASD in Africa include physical, psychological, and sexual abuse, the last of which tends to be more common in individuals of female gender [15]. Many parents in Africa are often subjected to exorbitant, out-of-pocket payments for social and rehabilitation services (both medical and educational) for children with ASD and ID. Thus, access to education, especially in independent living and other opportunities to learn skills for children, adolescents, and adults with ID and/or ASD is limited in most African societies.

In Africa, the absence of protective laws and social policies makes persons with ID/ASD highly vulnerable to human rights abuse and leads to deprivation of services like medical care and education. A substantial proportion of the population residing in African countries attribute the etiology or origin of ASD and ID to spiritual causes, and this tends to influence perceived or lived stigma as well as help-seeking behavior. Other factors, as inadequate healthcare facilities and trained personnel for interventions, economic

obstacles, and stigma, are responsible for the late presentation and diagnosis of African and Asian children with ID/ASD.

As with Africa in general, in Latin America there is a lack of early detection and referral of children with ASD and ID. A Latin American Guide for Psychiatric Diagnosis exists which is approved by the Latin American Psychiatric Association. However, this guide tends to lead to diagnosis of severe cases only and, therefore, to under-registration and misclassification of people with mild to moderate ID. Nor does the guide offer general norms for diagnosis or criteria appropriate for different age groups. In general, diagnostic guides produced in Latin America are lacking in criteria for diagnosing different levels of ID severity or ASD support needs. Some lack clear references to ASD, while others include tools or standards that are very out of date. A Latin American guide that is up-to-date based on local and international expertise and clinical research is needed for the region [16].

Although in general Latin American countries do not have policies that specifically seek to segregate and institutionalize people with ID or ASD, the lack of a culture (and accompanying policies) of respect for human rights, inclusion, and non-discrimination often leads to social exclusion. The social exclusion that people with ID or ASD experience in Latin America has three components: economic deprivation, sociocultural aspects, and political issues. In terms of economic deprivation, in Latin America, people with ID or ASD often have no employment or irregular, very low paid employment with no job security, and so have insufficient or no income. Social deprivation can imply isolation, segregation, and weakened or ruptured family and social ties due to institutionalization or because their families hide them due to discrimination, stigma, and the complete lack of opportunities for cultural, social, and community participation. Most people with ID or ASD in Latin America have little or no control over their daily lives nor do they have political representation, even through proxies (such as their families or guardians). Their social exclusion and lack of opportunities for employment lead to greater poverty for them and their families. This exclusion and segregation is the result of the interaction between their condition, local cultures of discrimination, and the incapacity of social institutions to provide access to education, employment, health care, and public services in general. Cultural, social, and political processes must be instigated and supported in Latin America that will lead to universal access to health care and other services. Also needed is professionalization of healthcare personnel who work with people with ID or ASD in Latin America, including clear definitions of the competencies they must achieve and the diverse training curricula as well as promotion of psychiatry and associated specializations as careers [16].

High-quality measurement of the prevalence of ID in children, adolescents, and adults in Mexico is lacking, and only very recently have improved tools been applied for a better population-level measurement in children and adolescents. Therefore, the magnitude of this public health problem is unknown. At the clinical level, the presence of ID and ASD at all ages is underestimated, due to the use of inadequate diagnostic tools and lack of clinical competencies. Specialized (tertiary) public hospitals provide diagnostic services to a limited proportion of the population with treatment, therapies, and rehabilitation focused almost exclusively on children. In terms of health policies related to ID and/or ASD in Mexico, there is a scarcity of adequately trained human resources. Guidelines for prevention, early diagnosis, and management are lacking as well. Once people with ID or ASD become adults, if they are living in a public residential institution they are expelled when they reach age 18 and there is a complete lack of governmental health infrastructure or social services available to them. In summary, the Mexican State is basically absent in terms of public policies for people with ID or ASD. The most important element of this context is perhaps the lack of an institutional model focusing on independent living, social inclusion, and employment. In private care, there are a few exceptions, but in public services this type of approach is absent.

Nongovernmental organizations fill in some of the gaps, but most of these organiza-

tions only serve those under 18 years of age and their work is often not based on scientific evidence. Also, given lack of resources, the interventions offered by nongovernmental organizations are local and have very limited coverage. Most programs developed by such organizations in Mexico are the result of anecdotal, nonscientific evidence and fail to achieve the desired outcomes in the disabled population. They have also been unsuccessful in altering public policies and opinions, which would allow for greater reach of programs and services (this would only be appropriate when services are evidence-based and undergo rigorous evaluation). Above all, the topic of autonomy or independent living and promotion of social inclusion and employment for people with ID or ASD tends to be absent in these programs.

Education policies for children with ID implemented in Mexico have focused on the creation of schools for special education as well as on the integration of children and adolescents with ID in general primary education. Although these strategies are useful for promoting diversity in the classroom, the skills taught are academic and not useful for facilitating independent living. In addition, specialized teacher training is either nonexistent or inefficient in providing teachers with skills for meeting the needs of students with ID or ASD, particularly when attempting to use them in a classroom integration model.

The situation in Argentina is somewhat different from other countries in Latin America since in 1966, legislation was passed to provide resources to support people with ID. This legislation stipulates that disabled people must receive basic care and services from the health system. In addition, the judicial system has supported this legislation by guaranteeing funding when services have not been provided. The obligatory services are broad and include early interventions, support for school integration in regular or special schools, therapeutic centers, centers for promoting preparation for employment as well as day and residential centers. Nevertheless, as in other countries in the region, service providers are insufficient and not always adequately trained, since training opportunities are often limited and very expensive [16].

In Chile, there is a national policy for inclusion of people with ID, although the education sector is the only area which has achieved high levels of integration. A systematic program for integration of children with any type of disability, including ID, was implemented. Also, more recently, financial resources for the purchase of educational materials and for teacher training have increased. However, as in other countries, once children with ID or ASD complete secondary education, there are limited opportunities for obtaining paid employment and they are exposed to discrimination and social exclusion since, as with the rest of Latin America, services focusing on rehabilitation, training, or social inclusion for adolescents or adults with ID or ASD are extremely limited and are provided exclusively by nongovernmental organizations, many of which lack appropriate funding [16].

- In Latin American countries, causal factors of social exclusion of persons with ID or ASD can be classified into the following three groups: economic deprivation, sociocultural aspects, and political issues.

- In Mexico, public policies are lacking as well as an institutional model focusing on independent living, social inclusion, and employment. In Argentina, most health service providers are still insufficient and not adequately trained, although the right of persons with ID to specific health care has been adopted into domestic law for over 50 years. In Chile, there is a national policy for inclusion of people with ID, but the education sector is the only area which has achieved high levels of integration.

In Asia, the prevalence of ID and ASD appears to be similar to that in other countries. As in other cultural, social, and economic contexts, discrimination and stigma can cause social exclusion of people with ID or ASD as well their families and especially their caregivers. In Asian countries where research has been done, such as Vietnam, cultural issues which lead to stigma and discrimination have been confirmed. One such issue is the perception that community harmony is

upset when members with ID or ASD are unemployed and unmarried (and with no evident prospects or opportunities for becoming employed or having social relationships). This is seen as a threat to the person's and the family's status. These cultural perceptions lead to lived stigma and discrimination that in turn can determine social exclusion of both caregivers and their family members with ID or ASD [17].

Many Asian countries have not had a history of institutionalization of people with ID and ASD; instead, they have resided with their families, although this has often not implied social inclusion. As in other regions of the world, in Asia, access to and use of the limited services that do exist for people with ID and ASD can be impeded by stigmatization. The limited access to such services can be caused by, as well as lead to, social exclusion. In Taiwan, a greater amount of research and publications about people with ID and ASD exists as compared to many Asian countries. Disability-rights advocacy has also existed in Taiwan, which has not been the case for some other Asian countries. Public policies contribute to reduced costs for some healthcare services for people with ID and ASD in Taiwan, although inequalities in health care are still present (for people in rural areas, for example) and the quality of care needs to be improved. Most caregiving is informal and is provided by female family members. In Taiwan, people with ID and ASD may live longer than in other contexts, which leads to needs for greater care and their caregivers tend to be elderly as well; however, there are limited or no public services to help families resolve this difficult situation [18].

Pakistan is the fifth most populous country in the world with a population of about 220 million. Half of this population is below age 18. There are very few child and adolescent psychiatrists and limited services for children and adolescents including a complete lack of structure and services for individuals with ID and ASD and their families [19]. High rates of depression and anxiety have been reported among caregivers who take care of these individuals in Pakistan [20]. In addition, there is lack of knowledge among professionals regarding ASD and ID leading to delay in diagnosis and timely interventions [21].

Self-determination within a context of living and working in the community is the primary indicator of quality of life. Community centers can be an effective alternative in achieving this goal, as has been widely documented for people with ID or ASD living independently in residential placement, where they can acquire much needed skills and adaptive behaviors. However, such centers must implement programs based on scientific evidence and undergo external evaluations to guarantee high-quality care and achieve the proposed outcomes for people with ID or ASD. This type of program is generally absent in lower- and even middle-income countries.

In order to achieve successful community inclusion (successful in that it improves their quality of life) of people with ID or ASD, there is a need for broad coverage of programs that incorporate certain primary components. These include the following:

- Self-determination developed through previous training.
- Providing sufficient skills for community and home living.
- Guaranteeing good access to services for physical and mental health and related behavioral problems.
- Periodic planning for recreational activities.
- Good distribution of free time.
- Ongoing support for maintaining contact with families as well as personal relationships.

The State must provide an organized social response to the needs of people with ID or ASD and their families, not only with respect to health needs but also in terms of social and labor inclusion. More than a medical issue, this situation reflects the enormous social and economic disadvantages faced by people with ID or ASD and their families in many parts of the world.

Future research, activism, and policy-making as well as service provision in general should focus on the following:

- Defining the magnitude of the problem of ASD and ID and needs assessment for individuals with disabilities in lower- and middle-income countries through well-implemented epidemiological studies and the use of other methodologies (qualitative research especially) when useful.
- Genetic and environmental studies as related to ASD and ID in lower- and middle-income countries, which are of importance in order to continue furthering our understanding of risk factors.
- Capacity building in terms of training for healthcare personnel and promoting human resource development in the area of interventions for ASD and ID in lower- and middle-income countries.
- Full implementation of existing legislation when useful and passage of pending or new legislation when needed that promote education (including independent living skills specifically) and opportunities for employment and community inclusion for people with ID and ASD in lower- and middle-income countries.
- Social policy formulation that addresses the financial or economic aspects of healthcare and special education provision for individuals with ASD and ID since this is not presently covered by any social policy in the majority of lower- and middle-income countries.
- Lastly, research and social policy development should focus on massive public health education to positively influence help-seeking behavior for children, adolescents, and adults with ASD or ID, in order to avoid late diagnosis and provide interventions and services aligned with the UN (United Nation) convention on the rights of persons with disabilities (CRPD) [22].

In Asia, discrimination and stigma can cause social exclusion of people with ID or ASD as well their families and caregivers [14]. Although in general Asian countries do not have policies that specifically seek to segregate and institutionalize people with ID or ASD, the lack of a culture (and accompanying policies) of respect for human rights, inclusion, and non-discrimination often leads to social exclusion. In Taiwan, disability-rights advocacy, academic research interest, and public policies are higher than in other Asian countries as well as life expectancy of persons with ID/ASD, although inequalities in health care are still present, especially in rural areas.

Tip

- In lower- and middle-income countries, there is a general lack of a public health approach and population-level screening for developmental delays and other indications of the possibility of an ID or ASD.
- An important pitfall in diagnosis is not using evidence-based tools; lower- and middle-income countries need greater dissemination of current, evidence-based tools, and most importantly training in their application.
- Psychiatrists and other healthcare providers need to take into account the cultural beliefs of parents of children (or adolescents or adults) with ASD or ID when providing diagnosis, treatment, or services; working with traditional or faith healers can also be important in some cultural contexts.
- Governmental and nongovernmental organizations must provide an organized social response to the needs of people with ID or ASD and their families, not only with respect to health needs but also in terms of social and labor inclusion. The services provided should receive input from both healthcare professionals and family members of people with ID or ASD and where possible, people with ID or ASD themselves.

39.3 Informal Caregiving

The type and level of informal caregiving provided to people with ID and/or ASD, especially adults, varies from culture to culture, from context to context. The burden of informal caregiving is also highly dependent on sociocultural issues as well as on existing policies and services. In many low- and middle-income countries, most adults with ID and/or ASD are cared for at home by family members. In higher-income countries, there is a greater variety of services that provide support both to people with disabilities and their families and caregivers [24]. In England, for example, about 35% of adults with ID live in an informal setting (with family or friends). The economic value of caregivers' work is enormous but infrequently estimated or considered; in the United Kingdom, it is reported to exceed the annual budget of the whole health system [23].

In low- and middle-income countries, the proportion of adults with ID and/or ASD seems to be relatively high, although data on prevalence are lacking. In fact, prevention of developmental disabilities is generally much lower (sometimes nonexistent) than in high-income countries, and survival into adulthood is increasing worldwide in this disabled population. Thus, the need for services and support both for the persons with disabilities themselves (such as educational, employment, and community participation, as well as care when informal caregivers are no longer present) and the caregivers is likely to be high as well, but the services that exist are extremely limited or may be absolutely nonexistent. Also, disadvantages are greater in families with members with a disability (especially multiple disabilities or adjunctive health conditions), including poverty, health problems, and social isolation [30].

Internationally, independent of culture, mothers tend to be the caregivers of family members with disabilities, including children and adults with ID or ASD. In many lower- and middle-income countries, various members of the family, including the extended family, are often involved. Nevertheless, as for higher-income countries, when younger members of the family leave the home, the parents are almost invariably those who continue in the informal caregiver role, even when they get older. Some research indicates that in the absence of programs and services to support adults with ID and/or ASD, which also end up supporting the caregiver and the rest of the family, personal resources become increasingly important, including religion or spirituality and a positive outlook. These personal resources can be even more important in those cultural contexts where discrimination and stigma are greater [30].

In all cultures and contexts, informal caregivers report that their role involves burdens and stress but also satisfaction and gratification. Nevertheless, cultural differences do exist in terms of levels of depression and positive attitudes among caregivers, as research shows. One example is a study on Latina and Anglo mothers of children with ID, cerebral palsy, Down syndrome, or ASD, with pervasive support needs. In this study, the Latinas reported high levels of depressive symptoms (a good population-level indicator of depression), independently of the type of syndrome their child had (i.e., it would appear that the cultural difference was more important than the type of syndrome). Also, while negative impact of caregiving for children with ID did not differ by culture, Latina mothers reported more positive feelings and positive implications for their own life than Anglo mothers [31].

Although caregivers in lower-income contexts have low material and cultural support, research results indicate that mothers and others who provide care are still able to carry out their role for many hours a day and across years. These findings have prompted specific research interest on what psychosocial, spiritual, and other personal factors can make caregiving a positive experience and increase caregivers' resilience. Studies in this area have not yet produced significant results but may be available in the near future [21]. Particular attention must be paid

to ensuring that the identification of personal protective factors in caregivers does not unduly induce socio-health policy-makers to ignore the strong need for public services and support of these caregivers and persons with ID/ASD.

Research has tended to focus on the negative impacts of caregiving or portrayed it through a negative lens. While measuring the negative impact is important, for example, to estimate need for services, an exclusive focus on negative issues does not allow the development of services aimed at enhancing caregiver strengths [25]. In addition, there are methodological limitations of studies with an exclusively negative focus on caregiving that prevent establishing if those negative outcomes that are measured actually stem from caregiving [25].

Informal caregivers of persons with ID do not seem to have lower quality of life than other caregivers (i.e., people with mental health issues or dementia) but show a considerable risk increase of reporting poorer health status, even though poorer health is not necessarily to be attributed to caregiving [25, 26]. Actually, poor health status may have existed before caregiving began; for example, a person with poor health status may choose caregiving because (previous to beginning caregiving) they can not be employed outside the home.

On the other hand, caregivers of persons with ID, mental health problems, or dementia seem to experience more negative impact on their lives as compared to caregivers of persons with other conditions and carers of people with ID are more likely to have financial difficulties and a high caring load [20, 25].

Certain aspects of caregiving may vary by type of disability, while others may vary by culture, although main caregivers' needs seem to be rather stable across different cultures and contexts. For example, caregivers and families in both higher- and lower-income countries (with very different levels of services) seem to agree that family-centered approaches or home-based community support are of value both to themselves and to their family members with disabilities [21]. Also, the lack of employment opportunities or residential care later in life for people with ID or ASD adds greatly to the burdens of caregivers in lower-income countries, while those in higher-income countries also value these opportunities and may see the need for even greater options.

Policy specifically designed for informal carers is lacking in many cultural contexts, especially in low- and middle-income countries. At the policy (macro) level and at the provision (meso) level, caregivers' needs are often conflated with those of the person they are supporting and policy-makers often neglect the complex and sometimes conflicting dynamics of actual (micro-level) caregiving relationships [27–29]. For example, leisure or occupational opportunities provided to persons with ID/ASD may not always be in line with caregivers' needs and wishes. Furthermore, informal caregivers often face health and social problems themselves and therefore become providers and recipients of care at the same time, leading to adjunctive difficulties in constructing policies for their needs [29].

- In most low- and middle-income countries, most adults with ID and/or ASD are cared for by family members. Poverty and long caregiving hours seem to have the highest impact on caregivers' susceptibility to negative well-being. In the absence of programs and services to support caregivers and persons with disabilities they care for, personal resources become increasingly important, including religion or spirituality and a positive outlook.

- Some caregivers support strategies seem to be valued across different cultures and contexts such as family-centered approaches or home-based community support.

Tip

- When treating people with ID/ASD, it is important to take into account their informal caregivers (appreciation/recognition of the caregiving burden is essential);
- Caregiver or family supports/services are important for the quality of care/life of the person with ID/ASD, even though they are not provided directly to them (a family-centered approach);
- Needs of informal caregivers do not always coincide with those of persons with ID/ASD they care for; thus policies for the support of informal carers have to be assessed for such potential conflicts.

39.4 Organizational Culture and Context in Programs and Services

Both organizational culture and context affect the quality of care and outcomes achieved by services and programs for people with ID and/or ASD. For example, in order to develop an analysis focusing on culture in group homes for people with severe ID, Bigby and collaborators [1] used literature about staff performance that puts forward a differentiation between the formal culture of the overarching organization and the informal culture of the staff. The former refers to the culture on which different models of care are based and articulated in terms of processes, strategies, and goals; the latter describes what staff members think about these strategies and goals and how they, therefore, actually implement them in practice. In relation to evaluating and improving services or programs, the authors of these definitions [1, 25, 30, 32] concluded that when the informal culture of the staff is aligned with the formal culture expressed in the model of care, outcomes will be better. When the staff recognizes and takes on the utility of strategies and goals included in the model of care (understood to be part of the formal culture of the overarching organization), and, therefore, actually try to implement them, assuming that the model of care is evidence-based and effective, this alignment of the two cultures will improve outcomes. These two cultures have been termed formal and informal, the latter of which refers to organizational or staff culture as performed at the level of direct interaction with people [1]. Research has shown that it is more common for these two cultures to lack alignment than to achieve it, within support programs for people with ID [1, 31, 32].

Using culture as a construct to analyze the quality of care in services for people with ID and ASD (residential facilities, day centers, or other services, at staff level and/or general organization level) makes it possible to identify problems that do not derive from the model of care espoused by the organization providing the services. That is, when culture is examined and alignment of culture in different parts of an organization is studied (by applying this theoretical construct), issues in implementation of the model of care can be visualized, described, and analyzed in order to propose solutions. The model of care itself may be completely adequate, but obviously if it is not implemented as designed, it will not have the desired positive outcomes for services users (in this case, people with ID and ASD). Thus, analyzing the situation through the lens of culture can offer clarity about whether the problem is in the model of care itself, or (more likely) in how it is being implemented (with fidelity to the original model) [1].

Considering cultural aspects in evaluating the performance of services and programs for persons with ID/ASD can also favor the identification of a series of relevant issues, such as the following:

- How power and leadership are exercised at different levels within services and programs.
- Whether leadership or direction as well as practices in general are aligned with the values that underlie the model of care.
- Whether there is resistance to change, new models of care, new practices, or new ideas

among providers/staff or openness and receptivity instead.
- How service users (people with ID and/or ASD) are regarded; for example, as individuals or only as a group; as fundamentally different/"other" or as fellow humans.
- How the goals of care or services are perceived by providers or staff; for example, whether staff practices are oriented toward "doing things for" people with severe disabilities or "doing things with them;" whether staff practices lead to community presence or actual community participation; whether everyday practices address staff priorities or actual service users' needs [1].

Context is also an important construct with respect to services and supports for people with ID and/or ASD. Although there is no consensus on its definition, context is generally described as the set of personal and environmental factors that interact with health conditions such as ethnicity, socio-demographic characteristics (e.g., gender, age, place of residence), economic factors, cultural factors, education, family wealth, and nutrition [33]. Within the International Classification of Functioning, Disability, and Health [34], environmental or contextual factors represent major determinants for all life activities and participation (involvement in life situations).

When applied to the analysis of support needs for a person with ID and/or ASD, context can be considered as both an independent and intervening variable. As an independent variable it comprises personal (values, goals, and desires) and environmental characteristics, while as an intervening variable, it refers to the organizations, systems, and policies as well as sociocultural practices that take place in the person's environment. Thus, context can be used at three different levels: (1) to describe personal and environmental factors that need to be taken into account when planning for or evaluating supports; (2) to plan the actual support to be provided; and (3) more broadly, to develop policies related to support systems [2].

Contextual factors with the highest impact on the quality of support systems or other services provided to people with disabilities are represented by the level of consideration of person-centered planning and care in general, and the breadth of options provided by the caregiving organization as well as associated managerial strategies and practices.

In terms of policy development, contextual factors need to be taken into account at all levels that influence human functioning outcomes, that is, at the individual (microsystem), family (mesosystem), and societal (macrosystem) levels [2, 35]. A framework to guide policy development that focuses on an operational definition of context has been proposed by Shogren et al. [2]. It includes administrative principles such as collaboration, accountability, individualization, cultural responsiveness, and prevention or amelioration. This framework also proposes outcomes such as personal independence, productivity, social inclusion, and self-determination, as well as positive outcomes at the family and social levels. All these outcomes are also permeated by culture.

- Organizational culture can affect implementation of the model of care and quality of services.
- When the staff recognizes and takes on the utility of strategies and goals of a model of care (understood to be part of the formal culture of the overarching organization), and try to implement them, assuming that the model of care is evidence-based and effective, quality of care and outcomes achieved by services and programs improve.
- Analyzing the situation through the lens of culture can permit evaluation of the efficacy of the model of care itself and how it is being implemented within the support systems for people with ID and ASD.
- In terms of policy development, contextual factors need to be taken into account at all levels that influence human functioning outcomes, that is, at the individual (microsystem), family (mesosystem), and societal (macrosystem) levels.

Tip

- A common pitfall is assuming organizational culture has no effect on care or that it will be the same at any institution (big or small, e.g., a large institutionalized residential setting or a small group home);
- The concept of organizational culture can be used as an heuristic tool for improving quality of care or services; for example, it can be incorporated into evaluations of programs and services in such a way as to produce not just a score on how good or bad the services are but ways problems could be dealt with or in which quality could be improved.

Key Points

- Good data about the prevalence of ID and ASD can allow stakeholders to advocate for better coverage and better quality of services, including expansion of existing programs and establishment of new programs.
- There is a lack of a public health approach and population-level screening for developmental delays and other indications of the possibility of an ID and/or ASD.
- In many contexts, there are few psychiatrists per inhabitant and diagnosis may be carried out using tools that are not current or that are not evidence-based.
- Type and level of informal caregiving vary from culture to culture; the burden it implies also varies depending on sociocultural issues and on existing policies and services.
- Research on caregiving through a positive lens (focusing on positive effects instead of exclusively on negative impacts) is needed to provide inputs for services and programs that can build on caregiver strengths.
- The context of and organizational culture in support systems, programs, and services for people with ID and ASD can impact how well the model of care is implemented and quality of care.

Spiritual Issues

Johannes Fellinger, Marco O. Bertelli, Stefano Lassi, and Bill Gaventa

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_40

Learning Objectives

- To become aware of the connection between spirituality and quality of life.
- To become aware of the importance of spirituality and religion for individuals with intellectual disabilities.
- To learn about spiritual concepts and expression of people with intellectual disabilities.
- To learn about models of spiritual care.
- To learn about characteristics of inclusive faith communities.
- To learn about ways to support people with intellectual disabilities and professionals in addressing spiritual needs.

40.1 Introduction and Overview

Spirituality as a fundamental human need is getting increasing attention in society and health care. Pierre Teilhard de Chardin addresses the indefinable complexity of the whole human nature: 'We are not human beings having a spiritual experience, we are spiritual beings having a human experience' [1].

The title of this chapter 'spiritual issues' indicates that the vast dimension of different facets of the human condition, which reaches beyond the here and now can be addressed only fragmentarily, not only due to the scarcity of empirical studies.

After a brief discussion of definitions of the terms 'spirituality' and 'religion', the relationship between spirituality and health with a special focus on mental health is addressed.

A brief introduction of cognitive and emotional aspects of spirituality leads into a section in which research findings of spiritual lives of people with intellectual disability (ID) are presented. This is followed by a part focusing on the relationship between quality of life and spiritual well-being.

The section on spiritual care for people with ID and/or autism spectrum disorder with high support need (ASD-HSN) also encompasses attitudes of different religions towards disability in general, aspects of inclusion in faith communities and policy statements, which call upon the 'spiritual rights' of people with ID and ASD-HSN.

40.2 Definition

The place of spirituality and religiosity in society is under constant change. The complexities and controversies in defining the concepts are shown in a perennial discourse. Although the terms spirituality and religion are frequently used interchangeably, in recent social science, the concepts are differentiated [2].

The broad concept of spirituality is understood for instance by Swinton as that aspect of life that gives it its 'humanness'. Generally, the term is linked to the personal quest for understanding answers to the ultimate questions about life, meaning and purpose. Further, it includes dimensions of the quest about relationship with the sacred or transcendent, as well as the 'holy amongst us'. Religion is seen as the more specific version of spiritual expression finding place in an organized belief system, practices, shared rituals as well as symbols which facilitate experiencing closeness to the sacred or transcendent [3–5].

Spirituality is often seen to be an individual quality whilst religion is linked to entities, with religious rites at the centre, but also usually characterized by membership and containing related social, cultural, service and economic activities and aims [6].

However, it is argued that the distinction between religion and spirituality should only be taken cautiously. It could implicitly denote the wrong assumption of spirituality being good and religion being bad. Further, the polarization tends to neglect that many spiritual experiences occur in, and are shaped by, organized religious contexts, where the difference between religion and spirituality is not perceived as such. Such a distinction additionally can lead to unnecessary duplications in concepts and measures [7].

In research, spirituality is often assessed either in terms of religion or by positive psychological, social or character states like questions asked about meaning and purpose in life, connections with others, peacefulness, existential well-being and comfort and joy. This approach can lead to a bias that spirituality – defined as good state of mind and positive psychological or social traits – is found to correlate with good mental health [8].

40.3 Spirituality and Health/Mental Health

Research findings display a considerable positive impact of spirituality and religiousness on physical and mental health, in general and in terms of mortality, morbidity, disability and better recovery from illness [9, 10].

As found by a systematic review examining the literature from the years 1990 to 2010, two-thirds of the studies showed a relationship between the level of spiritual/religious involvement and a lower prevalence of mental disorders, whilst only 5% have identified a negative relation. The positive effect was found in all studies on dementia, suicide and stress-related disorders and about two-thirds of the studies focusing on depression and substance abuse. Mixed results were found on the relationship between religion/spirituality and schizophrenia and no or negative association in studies on bipolar disorder [11]. A review on religion, spirituality and mental health in the West and Middle East shows the positive relationship with well-being, hope and optimism as well as meaning and purpose. Further, more internal personal control and a higher self-esteem were reported amongst the more religious/spiritual individuals [12].

40.4 Spirituality and Quality of Life

In various studies on healthcare practices for people with chronic illnesses, a fundamental and strong correlation between the concepts of quality of life (QoL) and spirituality could be shown [13].

Spirituality was detected as a predictor of high level of QoL and subjective well-being in the medium and long term, together with optimism, good mood, collaboration in care and social support even in studies on complex psychosocial factors.

Further, there seems to be a link between the importance given to spiritual life, the level of satisfaction and positive health and well-being, both physical and mental [14].

Considerable evidence exists that supports the association of spirituality with the improvement of cognitive performance, affectivity, impulse control, coping mechanism and functioning of the immune and endocrine systems, increase of the life expectancy and reduction of psychopathological vulnerability, suicide risk and cardiovascular diseases, which could also be relevant for people with ID and ASD-HSN [15, 16].

Spirituality is also presumed to manifest in various psychological domains, such as self-esteem, motivation and relatedness [14, 16].

The concept of spiritual well-being (SWB) is a recent attempt for an operationalization of the strong connection between spirituality and QoL. The focus lays on the way and the amount by which spirituality affects individual well-being and QoL [17]. Due to being a well-defined and objective concept, spiritual well-being is used in a number of studies in which a strong association with mental and physical health could be shown [18].

The spiritual well-being scale (SWBS) is the most popular tool used to measure spiritual well-being. Good psychometric characteristics have been proven for the instrument [19]. Furthermore, the validation in numerous countries makes it usable in many different cultural and religious backgrounds, both in healthcare and in general research [17, 18, 20, 21].

Through studies of the general population, which also included people with borderline intellectual functioning and milder forms of ID, a link between the level of SWB and personality traits could be seen, such as extroversion, easy adaptability and willingness to understand [22]. Furthermore, SWB seems to correlate positively with the ability to set goals, with motivation and with self-confidence as well as with participation in religious activities. SWB correlates negatively with individualism, loneliness and manifestations of unconditional personal freedom [23].

Further studies on the relationship between spirituality and QoL have been conducted by the World Health Organisation (WHO). This also led to the development of another widespread tool – the WHOQOL Spirituality, Religiousness, and Personal Beliefs (WHOQOL-SRPB [24]). Through the appli-

cation in 18 different countries (with a sample of more than 5000 people), it was found that the concepts of spirituality, religion and personal faith represented relevant areas of QoL in all of them. Spirituality correlates especially with the general QoL, psychological being and socialization. In a hierarchical and stepwise regression analysis of the data from a sample of people with health problems (N = 588), including a small percentage of individuals with ID and ASD-HSN, spirituality was found to be the third amongst four domains explaining most of the variance (52%), after the level of independence and the environment but before physical being [24].

To date, both SWBS and WHOQOL-SRPB have not been used very much with people with ID even though the dimension of spirituality and QoL could be interesting dimensions in the planning of interventions [25].

Spirituality may have a high impact on the QoL of PwID/ASD. It represents a core element in the system of values of many persons with ID, across the various cultures and the different geographical and ethnic contexts. Thus, spirituality should represent a main reference area in intervention planning and outcome assessment.

40.5 Cognitive and Spiritual Development

Theories on the connection between cognitive and spiritual development draw different parallels focusing, for example, on the ego development, autonomy and self-awareness as they affect and are affected by relationship to others and the divine. Other theories aim to illustrate the development of moral understanding and consequent behaviour towards others or suggest that individual faith development reflects a 'meaning-making' process in which individuals seek the understanding of their own lives in relation to possible guiding values and commitments [26, 27].

Contrary to approaches which link cognitive and spiritual development, recent neuroscientific findings suggest a potential sense and development of an interior transcendent dimension even amongst people with the most severe neurodevelopmental disabilities [28]. The emotional functions which might be considered as the precondition for spirituality can be distinguished from the current conceptions of intelligence, logical and deductive skills upon which the diagnosis of ID is based primarily. These emotional functions are mainly located in subcortical ancient brain areas whereas neocortical areas are responsible for logical deductive thinking [29]. The role of music as universal language with a direct pathway to the human emotional and spiritual dimension deserves further investigation especially in people with ID [30].

In fact, people with disabilities are sometimes viewed as experiencing a greater intensity of spirituality or even as being 'closer to God', whilst rationality is considered an obstacle [31]. One needs to be cautious about equating spirituality with the capacity to reason [32, 33].

Recent neuroscientific findings suggest a potential sense and development of an interior transcendent dimension even amongst persons with most severe neurodevelopmental disabilities.

40.6 Spiritual Life in People with ID

In 2017 a systematic review article was published by Sango and Forrester-Jones on intellectual and developmental disabilities, spirituality and religion. In their extensive literature search of studies conducted between 1990 and 2015, the authors identified 57 publications. Only five articles met the inclusion criteria of being empirical and focusing on the adult population with ID directly. One of those had some quantitative measures. Additionally, to the studies, which were part of the review, the results of a qualitative research by Liu and colleagues interviewing 20 young people with autism and ID are reflected.

In the following, we address main findings regarding the importance of spirituality and

religion, religious concepts, expressions as well as the impact of religion and spirituality reported by the individuals with ID themselves [4].

40.6.1 Importance of Spirituality/Religion

A stimulating qualitative research on religious interest or background has been conducted in northwest England at the beginning of the new millennium, as part of a larger research project on users of adult services for people with ID [6]. Authors report the ability of people with ID of diverse faiths to express positive and strong religious identities. Further distinctions of one's own religion and its connected practices from other religions were made. Some of the participants even made clear that their faith did not root in childhood or family life, but was their own choice. Even against indifference or hostility from support providers, participants showed persistence in religious expression.

Shogren and Rye report 83% of participants with intellectual disabilities indicating a self-view of being religious. A belief in God was stated by 95% of participants. An even higher percentage of 95 stated that they thought about God quite frequently. Religion was described as somewhat (34%) or very important (56%) to them. A significant correlation between the ratings of importance and self-reported ratings of frequency of religious participation could be found [34].

Swinton reports about results from individual and focus group interviews with people with learning disabilities, support workers and service providers in Scotland and England without giving methodical details. He found that in contrast with minor indication of importance of spirituality by carers and support workers, the majority of people with disabilities expressed a deep spirituality [33].

Understanding and defining individual conditions of disability from a spiritual perspective is paramount when considering the impact of cultural components on mental health needs and care of persons with neurodevelopmental disorders [35, 36].

> Understanding and defining individual conditions of neurodevelopmental disability from a spiritual perspective is paramount when considering the impact of cultural components on mental health needs and care.

40.6.2 Understanding of Spiritual or Religious Concepts

The importance of friendship as a significant spiritual relationship became clear during many of the interviews in Swinton's survey. He reported that people's understanding of God was most often expressed in the language of friendship and tended to refer to God in human with terms as 'a friend', 'me mate', 'a good man', 'the gaffer'. God was seen as a natural extension of everyday social relationships and a vital form of social support. It has to be mentioned though, that these perceptions were evolving from a Christian context and that there is a need to explore the ideas of people with intellectual disabilities from other religious backgrounds [33].

From Shogren's study, 29 participants (71%) drew an anthropomorphic picture on the Draw God task. Abstract drawings in 17% showed a heart with written 'God loves me' or a church with the letters ILG which meant 'I love God'. There was no difference between participants with mild and moderate ID with respect to the degree of an anthropomorphic image of God [34].

In the same study, a religious picture identifying task was performed with 24 pictures from the three categories 'concrete', 'abstract' and 'non-religious'. These pictures were presented to the participants one at a time in random order with the question: Does this make you think about God or religion? A Bible (98%) and a church (98%) were chosen with the greatest frequency from the concrete scale. From the abstract religious scale, 78% chose

a heart with LOVE underneath. Interestingly, also money (27%) and muffins (24%) were associated with God and religion as they reminded them of occasions when they gave money or ate cake at church [34]. In Turner's 29 semi-structured interviews, many participants used religious language and expressions and were aware of their own religious affiliation as Catholic, Protestant or Muslim [6].

40.6.3 Expression of Spiritual Life in People with ID

Prayer proved to be a primary avenue of spiritual expression. This became evident in Turner's, Liu's and Shogren's interviews with individuals with ID. About 90% reported to pray regularly [6, 34, 37].

In the study by Shogren and Rye, 76% of participants reported that they attended worship services, with 49% of these individuals quoting at least weekly attendance. There were only few other activities participants engaged in more frequently on a weekly basis.

Other less prominent ways in which the young peoples' spirituality found expression was through rites of passage, through social connections or through acts of service or ministry to others [37].

40.6.4 Impact of Spirituality or Religion in People with ID

Spirituality seems to have a strong beneficial impact on the life of persons with ID/ASD, in terms of aid, friendship, love, warmth and protection. It also helps in providing meaning for life and coping with negative life events [6, 37, 38]. Spirituality and religiosity may also represent a unique resource in the understanding of the life and death cycle, as well as in bereavement [39].

Having a religious faith has been found to support personal growth and to increase the perception of life as active and satisfying. Catholic persons with ID defined christening, communion and confirmation as some of the significant experiences of their life and as extraordinary facilitators for the acceptance of their disability, since they made them feel loved, valued and understood by God [37]. Additionally, the benefit related to a sense of religious connectedness and belonging could be seen [6].

In people with Down syndrome, spiritual well-being has been associated with a general satisfaction towards life and with many other aspects of existence that are linked to a good QoL, such as psychological balance and personal control, building positive relationships, acceptance of life's difficulties and changes, internalization of purposes and dimensions transcending the individuality [40, 41].

The positive role of beliefs in the lives of people with ID could further be seen in the interviews of support providers in Shogren and Rye's study [34]. The proxy's descriptions indicated that religious participation supported the development and enhancement of positive social and personal values.

The impact of spirituality on mental health has been studied more than that on physical health, with around three quarters of research findings reporting a strong relationship between the level of involvement in spiritual activities and the lower prevalence of mental disorders, especially for pathological anxiety, depression, substance abuse and suicide. This has been ascertained for different religions, specifically Catholic, Protestant, Jew, Muslim and Buddhist [11, 14]. Carrying out spiritual activities in daily life, such as doing things that allow to feel at peace with themselves, helping other persons, celebrating anniversaries and special occasions or being an active member of a religious organization, may favour feelings of trust, safety and security as well as positively influence life expectancy and perceptions of themselves and of others [42].

Interviews with adolescents and adults with ID, integrated with information from their caregivers, have confirmed that being satisfied with prayer, inner faith and participation in religious group activities have positive effects on mood [37, 43].

Interestingly, research on the potential negative impact of religion/spirituality on people with ID is lacking. The limited literature available indicates that sometimes

religious dogmas, precepts and icons can represent a liability to mental ill-health more than a protective factor. Hallucinations, obsessive thoughts and delusions with religion contents are frequent in clinical practice and can give rise to problem behaviours. In more vulnerable individuals, warped interpretations of religion and practices may strengthen neurotic tendencies, enhance feelings of fear or guilt, limit socialization and being used in primitive and defensive ways to avoid making necessary life changes [8, 13].

Spirituality seems to have a strong beneficial impact on many aspects of many PwID/ASD's lives, such as aid, friendship, love, warmth, protection, meaning for life, coping with negative life events, understanding of the life and death cycle and bereavement.

40.7 Family Spirituality

The experience of spirituality of family members in the particularities of marriage, sexual intimacy, procreation, parenting, building and sustaining relationships, providing, sheltering and feeding transcendental experiences represents a fundamental reference for the person with ID/ASD in the development and consolidation of his or her own spirituality, especially whilst living in the family [13]. Spirituality in the family is also relevant for the identification of spiritual needs of the person with ID/ASD and the provision of satisfactory support in their living environments [32, 44]. Persons with ID/ASD living outside their families seem to need more concrete personal relationships and to rely more on transcendent sources of help than those who live with their family. Nevertheless, the extent of the impact of family spirituality on spirituality of the person with ID/ASD and associated aspects of QoL is yet to be determined [13, 45]. To date, the few studies addressing this issue have focused primarily on the extent to which parents find spirituality and/or religion to be an important resource for their life [46–49]. Religious faith was described as important or very important by the vast majority of parents of children with ID, ASD and other developmental disabilities in different cultural contexts [50–52]. However, the level of actual involvement in the array of activities offered in or through a local congregation has not been examined in depth. Available literature shows that only six of ten religious parents attend religious services at least weekly, and three of ten attend yearly, or even less frequently or never [45, 53].

Persons with ID/ASD living outside their family seem to need more concrete personal relationships and to rely more on transcendent sources of help than those who live with family [40].

High levels of spirituality or religion in parents were found to have a positive impact on the QoL of the whole family as well as on problem behaviours and support needs of the person with ID/ASD-HSN, especially during transition to adulthood [54]. For mothers of children with ID/ASD, the maintenance of a spiritual or religious dimension has been associated with stress reduction, containment of mood drops, increase in self-esteem, general life satisfaction, optimism, and self-control [55–57]. Spiritual and religious beliefs have been found to also improve parents' response to disability, understanding of disability, coping and family adaptation and to provide a source of meaning, hope, and strength [48, 58].

However, attaching great value to spirituality across their life does not exempt parents and other family members from the risk of not providing their child or relative with ID/ASD with all the opportunities they need to appropriately develop their own sense of spirituality. In fact, the birth of a child with ID/ASD-HSN and/or the persistence of adaptive or behavioural difficulties across years can lead parents and other family members to a spiritual crisis as well as the great burden of daily practical needs and future planning can determine a neglect of the spiritual dimension [41].

Anecdotally, many families will share stories of experiences of rejection or neglect by faith communities, but there has been little research on the extent of those experiences. Hoping and trusting a religious community to

be welcoming is indeed a risk, with the potential for great benefits but also disappoint [59].

As individuals, families of PwID/ASD may experience different impacts of spirituality and religiousness on their QoL on the basis of the sociocultural context, which can also be determinant for acceptance of disability, quality of diagnosis and care and community inclusion [13]. For example, in sociocultural contexts where prevalent religions interpret children with disability as a divine gift, mothers seem to maintain a higher QoL than in those contexts whose religions consider disability as a divine punishment [60, 61].

The support that parents and other family members of PwID/ASD draw from their spirituality, religious involvement and congregational connections is another important point, which has been scarcely addressed by research [62–64]. The few available findings show social support to be rather easy to achieve and to be associated with family quality of life improvement and highlighted sense of strength [65]. Lower rate of religious/spiritual social support has been reported in case of urgent need of help, greater disability severity and higher frequency and intensity of challenging behaviours [45].

Spirituality/religion is a relevant aspect of the lives of parents and caregivers whose family members have ID. It is also very important for the identification of spiritual needs of the person with ID/ASD and support in satisfaction. Congregational involvement, spiritual beliefs and practices and religious/spiritual social support comprise most important areas of inquiry. Services and supports can be improved by better understanding individual needs and preferences.

40.8 Spiritual Care for People with ID

Understanding the importance and the place of spirituality in people with ID inevitably leads to implications for service providers. In fact, it should become an urgent service priority. This includes that religious interest is identified proactively. Staff training to ensure that religious issues become routinely addressed within service practices is recommended. Further, the development of individual plans addressing people's religious needs and preferences is suggested [6].

According to Swinton [33], who interviewed support workers and service providers, the importance of spirituality was not always seen and given attention to. Whilst some apparently have dealt with this issue, some stated never really having thought about the relevance of spirituality, or, if they did, that it was not very relevant for their daily practice. As the issue never occurred in any training, amongst many it was only brought up when they were particularly religious or spiritually orientated themselves.

Frequently, wariness is shared about the ability of people with ID to have a spiritual life due to their cognitive limitations and the perception that spirituality and faith in God require a higher level of abstract thinking as well as the presumption of a cognitive threshold for the membership in a faith community. Further, some are sceptical of religion and a possible enforcement of unhelpful values and morals on a group of people, which might be particularly vulnerable to psychological manipulation [33].

Also, Carter mentioned that the intersection of faith and disability is sometimes marked by hesitation and uncertainty for service providers. Concerns about state-supported proselytization can lead some staff to ignore the spiritual needs of those individuals they serve, whilst eagerness to encourage religious connections can lead other staff to trump people's preferences [66].

In a study by Sango and colleagues, the perceived and operationalized spiritual and religious aspects of care for people with intellectual disability in a stated 'faith-based' service (Adam's House) and another service stating 'no-faith' (Greenleaves) were examined [4].

They chose a mixed-methods approach interviewing 42 support workers, as well as gaining information through observations of service participants over a time span of 6 months in each service. Furthermore,

information about the self-assessment of 'spiritual competence' and attitudes towards providing spiritual care to individuals with ID was gathered using the 'spiritual care competence scale' (SCCS) and the 'spiritual care perspectives scale' (SCPS).

Eighty-one per cent of Adam's House staff stated that their belief and spiritual background played a role in their daily lives and their approach to work. Only 62% of staff working in Greenleaves who had a religious background expressed its influence on their lives and jobs, especially during difficult times. The effect of a 'code of practice and conduct at work' was mentioned by the others.

In terms of attitudes towards spiritual care, as for example being positive about the residents' spirituality, no differences between the care providers of the two sites could be found. There was also no difference between the two staff groups regarding the question if enough attention was devoted to residents' spiritual care, or participants' own spiritual care competence and experience.

Regarding training, significant differences became evident, as 62% of Adam's House staff reported of receiving training in spiritual care as part of their formation, whilst 90% of Greenleaves claimed of not having received any training with that perspective.

Though both groups reported support of the residents' attendance of church service, further aspects of spiritual care were approached differently.

The homely functional care approach of Greenleaves focuses on the individuals' physical needs, promotes empowerment and independence as well as it respects and supports personal choices. Even though individuals expressed interest in and requested spiritual and religious activities, activities of spiritual nature were missing in the daily schedules.

Adam's House shows a structure which allows the staff and service users to share their daily life experiences, as for example the tradition of eating together, which is also connected to the Christian value system. This serves as ground for spiritual intimacy between service providers and users, enabling individuals to reveal special spiritual needs as the request for prayers. Further, the less institutional setting seems to lead to apparently more familiar attachments and care relationships with a personified dimension of spiritual community. In Adam's House, alternative ways of communication like religious and spiritual pictorial images were used for simplifying prayer and praise sessions.

Over 50% of staff of both services agreed that barriers included themes and categories such as 'communication issues', 'shortage of staff' and 'staff perception of spiritual understanding'.

Similarly, Swinton [33] indicated that communicational barriers prevent caregivers from exploring the emotional and spiritual aspects of the lives of people with ID.

Assumptions of staff were found to be the main barrier in providing spiritual care. As for instance 50% of Greenleaves staff suggest that residents 'might not have a spiritual need' or did not comprehend spiritual matters due to their 'mental capacity'. A lack of knowledge or belief in 'spiritual things' and absent confidence on how to provide religious or spiritual care were stated as further obstacles. This reinforces Swinton's statements.

Although empirical research of different faith-based and secular care models is not available, the model of L'Arche as a Christian faith-centred shared community living for individuals with and without disabilities attracts worldwide attention [67, 68].

Inspiration of spiritual care provision can be drawn from the example of the therapeutic living communities for deaf people with multiple disabilities set up by the first author of the present chapter [69]. In the regular morning meetings in the three facilities with 16–30 residents each, members with disabilities and professional staff participate voluntarily and actively. During these morning meetings, stories from the Gospel of Jesus are shared through real-time painting, role plays and discussion in sign language. By this therapeutic and adaptive principles like conflict resolution and forgiveness, overcoming hardship and trauma and being an active and positive member of the community are conveyed.

Tip

In the current organization of health and social-educational services, the consideration of the spiritual needs of PwID/ASD is scarce. Specific staff training and individual intervention plans are recommended for future policies. High quality research evidence also has to be promoted.

40.9 Inclusion in Faith Communities

40.9.1 Religious Approaches to Disability in General

Even within different religions, the ways how disabilities are seen and addressed vary widely [70]. Some researchers have noted how 'disabling theology' links disability with impurity and sin and proposes suffering as a way to gain heavenly rewards [71, 72].

Most religions emphasize the responsibility of faith community members to recognize the plight of persons with disability and to improve their condition and state, which, to some extent, nurtures overprotective and paternalistic stances [73].

The wide diversity of perspectives even within a religion is reflected in a qualitative research amongst Roman Catholic leaders. Patka and McDonald identified five religiously anchored narratives of intellectual disabilities ranging from viewing individuals with ID as having a special relationship with God, being eternal children, needing to conform to existing settings, being defective to them, being a natural part of human diversity [31]. Surveys amongst parents indicate similar assignments to their children's disabilities as: gifts from God, abundant blessings, disabled by design, tests of their faith, punishment for sin etc. [74].

Interactions between personal experiences, several cultural practices and religious views may explain the variety of approaches in perceiving disability [75] which mainly influence the inclusion of people with intellectual disabilities in the respective faith communities.

40.9.2 Inclusion and Participation in Faith Communities

Inclusion in community activities has relevant implications for quality of life of most people with ID/ASD. Several position statements have been made by major organizations acknowledging the rights of people with disabilities to access supports, opportunities and relationships in this dimension of their lives [76]. According to TASH (The Association for persons with Severe Handicaps), an international organization advocating with and on behalf of people with significant disabilities:

> 'Supports shall enable children and adults with disabilities to participate in every aspect of socio-cultural life including, but not limited to, home, school, work, cultural and spiritual activities, leisure, travel and political life.' [77].

Participation in faith communities is one community activity that is often difficult for people with disabilities [78]. A survey of the US Kessler Foundation and the National Organization on Disability conducted in 2010 shows that there is a gap of approximately 14% between people without and with severe disability attending faith community services at least once a month ([65, 79, 80]).

A survey by Carter amongst 12,700 adults with ID in the US reported a similar high number of around 50% attending religious services in the past month, with variations related to individual and contextual factors with respect to involvement. The difference in the rate of participation, however, does not necessarily originate in the lower importance of faith in the individuals lives. A survey conducted by the US National Organization on Disability determined that faith was considered important by 84% of people with and 87% of people without disabilities. Consequently, the disparities in attendance cannot be due to the lack of interest [81].

Studies which interviewed individuals with intellectual disabilities themselves clearly indicate the high importance of attendance in faith community activities [34, 37].

The meaning of the term 'inclusion' and the way it should be increased in faith settings

has been and still is debated by many religious leaders and congregants through position statements, expert opinion papers and some studies [59, 65, 82–87], but a consensus definition of an 'inclusive faith community' has not yet been reached.

The topic of accessibility was addressed in a study by Larocque and Eigenbrood, who aimed to examine the current physical and attitudinal accessibility of religious congregations for people with disabilities. The results show that the majority of the 91 participating congregations were in the phase of planning for the inclusion, with only a small number of congregations (4.4%) reporting that they had 'not started'. Most of the congregations also indicated that they are on their way to enhance inclusion through specific actions. Apparently medium (501-1500) and larger (1501 and more) size congregations rated themselves significantly more accessible than smaller congregations [88].

In the United States of America, there has been significant debate about whether a congregation should have a 'special ministry' with people with disabilities versus including them in all aspects of a congregation's life, or a combination of the two [32].

In the last decade, the debate has progressively moved from accessibility to inclusion to belonging [32], with an increasing focus on how to make connections basing on shared identities, regardless of ability [32, 78]. Carter proposed 10 dimensions of belonging, ranging from being invited to being needed and loved and their salience to inclusion [59].

40.9.3 Characteristics of Inclusive Faith Communities

There is only a small number of empirical studies aiming to explore the characteristics and factors related to successful inclusion of people with ID in faith communities.

Griffin and colleagues conducted a survey on characteristics of faith communities related to greater inclusion in the United States. In total, 160 individuals responded to the web-based survey, including people with disabilities, their family members and leaders of faith communities and congregants [79].

The Survey on Inclusion in Faith community comprised 145 items. Besides questions related to the respondents' characteristics as demographics, quantity of attendance in services, demographic characteristics of faith communities as, for example, size, location, distance travelled to attend or number of congregants with disability, disability-related characteristics of faith communities were collected.

The survey questions concerning inclusive outcomes converged on three factors, which accounted for 65.78% of the variance.

Factor I related to how welcoming and inclusive the faith community was to people with disabilities. It accounted for 47% of the variance and included activities like the assistance provided for people with disabilities to become members, the provision of accommodations and adaptations for full inclusion, support for their families and the adoption of a welcoming attitude.

Factor II related to the roles of people with disabilities, which was quite specific and asked if people with ID for instance were included/encouraged to serve on committees, as church officers, greeters/ushers or to participate in outreach programs.

Factor III of the community's physical accessibility subsumed the approachability of for instance the restrooms, classrooms or fellowship areas.

Further, five independent predictors related to the three outcomes were identified: commitment of leadership, educational resources, positive portrayals in religious teachings, closer relations to disability organizations and commitment to social justice. The most significant of the variables was the community leaders` commitment to inclusion. The faith community's demographic characteristics, such as the community's size, location or number of congregants with disabilities did not play a significant role.

Ault and colleagues reported qualitative findings from a mixed-methods study exploring the perspectives of 416 parents on the welcome and support they have experienced within faith communities, both for themselves

and for their sons or daughters with developmental disabilities [50].

Most parents emphasized the important role of accommodations and specific support provided by a faith community to have impact on themselves and their children's participation. Examples given were about the support during religious education classes received by peer tutors, volunteers or hired assistants. It further was presented positively when faith communities gained information about adaptations appropriate for their children, including information about the child's behaviours and needs. However, the majority expressed their dissatisfaction about the lack of support. This includes the non-existence of accommodations for the child as for instance the access to sign language interpreters or available visually accessible materials as well as the lack of understanding of the behavioural supports needed for their children. Some parents also reported either explicit non-acceptance into programmes or inappropriate placements in religious education programmes. Parents and/or siblings often were the ones responsible for providing the support their children needed to participate in programmes.

Another major factor was the children's traits. For example, parents (93.7% of the comments) described their children as having behavioural characteristics such as 'being noisy in church', 'unable to sit still', 'touching others', 'overwhelmed by the noise', 'aggressive with others', 'unable to understand religious education lessons' and 'overstimulated'. These behaviours led to results ranging from embarrassment of the parents, to parents being told to not to bring their child back to services or activities. How important a particular person, as for instance a congregational leader or an individual acting as advocate, can be in including the family in the faith community, was another main finding [50].

In accordance with Griffin's predictors [79], the use of educational resources and links to disability organizations, the need for expertise and knowledge was emphasized by the parents. They described ways in which education and training were needed and how people who were educated about disabilities could be particularly helpful to the family.

Church leaders might be encouraged by a study by McNair and Sanchez who found in a survey for the National Organization on Disability's 'Accessible Congregations Campaign' amongst church leaders that people with disability were not regarded as being expensive to the church, driving potential members away, nor taking excessive time away from other potential areas of service [71].

In a recent systematic review, Miller and Skubik-Peplaski [89] identified the following specific supports to increase participation for individuals with disabilities in faith communities:

- Welcoming/positive attitude towards all members
- Accessible environment
- Education and training to members
- Parental support
- Spiritual counselling
- Special worship services for people with special needs
- Accessible materials
- Support groups
- Advocate support for individuals with special needs
- Peer tutors, volunteers or hire assistants.

Although people with ID want to be part of faith communities, the reality of inclusion is lagging behind. Religious attitudes towards disability influence the extent to which inclusion of people with disabilities is accomplished in faith communities. A welcoming atmosphere, active involvement of persons with ID and physical accessibility are characteristics of inclusive faith communities. Leaders of congregations have a major responsibility for the process of inclusion.

40.10 Conclusion and Policy Statements

Recent policy statements endorse tactful consideration of individuals' spirituality and religious practice.

The World Psychiatric Association (WPA) asks psychiatrists not only to understand spirituality and religion in their relationship

to aetiology and treatment of psychiatric disorders but also to get specific training in order to approach religion and spirituality in a person-centred way and to collaborate in a multidisciplinary way with faith communities [36].

The professional position should in no terms be used to proselytize for spiritual or secular worldviews. But in contrast, awareness, respect and sensitivity to spiritual/religious beliefs and practices are requested and should be demonstrated both in relation to the patients as well as staff.

Both the beneficial and the harmful potential of religious, spiritual and secular worldviews and practices should be addressed and information should be shared with the wider community for supporting the promotion of health and well-being.

In the joint position statement of the American Association on Intellectual and Developmental Disabilities (AAIDD) [76] and the Arc [67], it is emphasized that spirituality, spiritual growth and religious expression as well as the choice not to participate in religious or spiritual activities are rights and should be paid respect to by service systems and faith-based communities.

Key Points

- Spirituality is an important dimension of human beings exceeding cognitive capacities. In individuals with ID, openness to spiritual experiences and interest in religious issues are frequently not attended by professional care and support workers, which may be due to uncertainties and hesitation about ways of adequate provision.
- Different models of spiritual care range from faith-based communities to individual approaches of inclusion in faith communities. Inclusive faith communities are characterized by accessible environment, education and training for all members, parental support as well as special worship services for people with special needs. Spirituality comprises a dimension where professionals can learn from people with ID.

Forensic Issues in Intellectual Disability and Autism Spectrum Disorder

Eddie Chaplin, Jane McCarthy, and Nick Bouras

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_41

This chapter provides an overview of offending in adults with ID and/or ASD covering epidemiology including risk factors for offending behaviours, offence type along with clinical presentation, risk assessment, interventions and a brief description of UK-based forensic/secure services as it relates to this population when in contact with the criminal justice system.

Learning Objectives

1. Knowledge of prevalence rates for offenders with ID and/or ASD across the criminal justice system.
2. Understanding of main types of offences committed by adults with ID and/or ASD.
3. Awareness of approaches to risk assessment for use in forensic settings working with people with ID.

41.1 Introduction

Both ID and ASD are neurodevelopmental disorders listed in the Diagnostic and Statistical Manual DSM-5 [1]. The American Association of Intellectual and Developmental Disabilities defines ID as follows: 'Intellectual disability is characterized by significant limitations both in intellectual functioning and adaptive behavior as expressed in conceptual, social, and practical skills. This disability originates before age 18' [2]. Whereas ASD is characterized by a triad of impairments in social communication, interaction and imagination. The rates of ID in people with ASD are estimated between 41% and 51% [3, 4] with the prevalence of ASD increasing with the greater severity of ID [5]. People with ID and ASD are more likely to suffer comorbid conditions such as mental illness and other neurodevelopmental disorders such as attention deficit and hyperactivity disorder (ADHD) [6–8].

The relationship between the diagnosis of psychopathology and offending is poorly understood in people with ID and ASD, with recent studies taking a wider perspective to understand those with neurodevelopmental disorders and offending, for example, the link between ADHD, conduct disorder [9], or foetal alcohol spectrum disorder [10] to offending. Few studies have examined and compared offenders with ID and ASD to non-offender groups [11] so limiting our understanding of this at risk group in terms of outcomes and development of community-based services to meet their needs. The focus of this chapter is on those offenders with ID and to some extent ASD and their pathway through the criminal justice system (CJS).

41.2 Epidemiology

The worldwide prevalence of ID is estimated to be 1% in high-income countries and higher in middle and lower income countries [12], whilst severe and profound ID is uniformly distributed geographically, irrespective of socio-economic status, mild ID rates are open to variation and are influenced by socio-economic factors [13], parental lifestyle, for example, foetal alcohol syndrome. ASD affects 1% of adults [5]. Often disorders such as ID and ASD will go unrecognized in adults and in high-risk populations such as those in the prison system [14] as is the case with other neurodevelopmental disorders. Historically, mental deficiency (MD), an early term for ID, was put forward by the typological school of criminology. It was thought that hereditary biological inferiority or degeneracy and those with MD made up a significant proportion of the criminal population, particularly Moral Imbeciles [15]. Whilst early studies showed a correlation between intelligence and crime, there was no evidence of a causal relationship. As today, many of the studies were flawed in some way whether due to location bias, a lack of standardized instruments being used and the definition or level of MD. There was in early research the assumption that offenders were biologically different, to non-offenders [16]. ASD and offending have a more recent history, even so, it is often put forward that ASD is overrepresented in offender populations, Aspergers syndrome has been reported at a rates of 1.5% in high secure hospitals in the United Kingdom [17]. For all

substypes of ASD, a review of inpatient services reported a range between 2.4–9.9% [18] and 2.7–8.3% in the dangerous and severe personality disorder unit at Whitemoor Prison [19]. Despite this, there is limited research on the prevalence of ASD and offending and what there is, has often been in highly selective samples, with methodological issues such as uniformity in diagnostic procedures and limited evidence of the reliability and validity of measures in forensic settings [20].

The detection of offenders with ID and ASD has not been a priority across the CJS, which has concentrated on identifying offenders with severe mental illness. The evidence to date indicates that people with ID and ASD may be overrepresented in the CJS [21] and the presence of ASD and ID within the CJS is associated with poorer outcomes [22], increasing the likelihood of future recidivism, or custodial or more restrictive or punitive sentencing [23]. Often there are methodological flaws in studies of offenders with ID although authors acknowledge these limitations. There is a need to place results in context as these are often misquoted or taken out of context for the subpopulations they report. To provide an insight into the prevalence and risk of offending by people with ID whole population studies overtime is required.

Estimates of prevalence of offenders with ID vary across settings. In a study of 237 people in community ID services, 49 had prior contact with the CJS, while the other 188 had histories of anti-social behaviour but no CJS contact. Although most of the offender group were more able, mild ID was not a statistically significant predictor of contact with the CJS [24]. In a larger study of 1326 adults known to ID services in South West England, 7% had contact with the CJS, with 3% having a conviction and 0.8% serving a current sentence [25].

Responses to those committing a crime by the CJS can vary by country and within a country and the interpretation of national and local legislation and policy. A study based in Cambridge, United Kingdom, of 385 adults with ID found that 2% (n = 7) in residential homes or attending day services had been in contact with the police in the preceding year with further action being taken in only one case where the person was cautioned [26]. Whereas in a study in London, United Kingdom, of 180 people identified with an ID, 17 people had contact with the police in the last 12 months, with nine people having been arrested, received a caution, appeared in court or been convicted [27].

Most recent studies of prevalence have been identifying offenders with ID and ASD aided by screening tools aimed at people with ID and ASD and have included studies in court settings. These include the Rapid Assessment of Potential Intellectual Disability (RAPID) [28], Hayes Ability Screening Index (HASI) [29], Learning Disability Screening Questionnaire (LDSQ) [30] and the Kaufman Brief Intelligence Test (K-BIT) [31] for ID and the AQ-10 for ASD [32]. There is very little research into the prevalence of ID and ASD in the court setting and, therefore, varying estimates from 3 to 23% are reported for ID and ASD at this point in this pathway. In a sample of 60 defendants appearing at four Magistrate's Courts in Australia, 2 (3.5%) were estimated to have an ID, with this figure rising to 12% for those with IQ up to 75 [22]. Reporting on studies at six Magistrate's Courts, 208 individuals appearing at court were examined, 47 individuals (23.6%) were labelled ID using the KBIT [31], with another 28 (14.1%) in the borderline range. Those with ID were also more likely to present with mental health problems. Despite differences in IQ assessment, many of those with mild and borderline ID had similar characteristics [33], which were different to defendants/offenders without ID [34]. Given current evidence, it is difficult to estimate the prevalence and it is suggested that many defendants/offenders with ASD and ID are missed at the court stage, with reports of 58% of probation detainees not being identified by police [35].

An international review of 12,000 prisoners estimated prevalence rates for those with ID ranging from 0% to 2.9%. Results were highly dependent on the assessment and criteria used to define ID, for example, in two studies where basic screening techniques were used, rates of ID increased as high as 11.2% [36]. However, many who reach the screening cut-off for ID with borderline intellectual

functioning (BIF) will still suffer a degree of cognitive and social impairment and have unrecognized or unmet needs. This increases their vulnerability as those with BIF will not normally meet eligibility criteria for health or social care services, therefore receiving little support or intervention. The No One Knows reports [37, 38] estimated 7% of prisoners had an IQ of less than 70 with a further 25% had an IQ of below 80. In ASD, the evidence suggests that they have lower rates within the prison population and in some areas, are not overrepresented. A study of referrals to ID offender services reported 10% of referrals had ASD, and showed similar offending patterns of those without, with less contact sex offences, leading the authors to conclude that ASD was not a risk factor for offending [39]. A study of Scottish prisoners estimated the prevalence of ASD at 1% [40]. However, a screening study in a North American male maximum security prison reported rates of 4.4% [41]. In a study of Prisoners in South London, 7.5% [19] were screened for then diagnosed with ID with a further 15 having BIF. The prisoners with ID were more likely to be from a white ethnic background, be under 35 years of age and be single, homeless or unemployed before coming into prison. They were significantly more likely to have mental health problems with 25% have thought about suicide in the last month more likely to be housed in the vulnerable prisoners' wing [42]. In the same study, 10% screened positive for ASD, with 2% meeting diagnostic criteria [43] along with high rates of co-existing ADHD [8, 23].

Screening rarely equates to diagnosis and, as a result, screening studies can be over-inclusive. However, those screening positive and not meeting diagnostic threshold will have similar needs in many cases. In a study of 87 prisoners who screened positive for neurodevelopmental difficulties, compared to neurotypical prisoners, reported neurodevelopmental difficulties group had significantly higher rates of current mental disorder and more likely to have thought about self-harm and suicide in the last month [44].

Higher rates of psychiatric disorders, self-harm and suicide-related thoughts and behaviours in prisoners with ID, ASD and other neurodevelopmental disorders than in those without neurodevelopmental disorders have also been reported in previous studies [45–50]. Psychosis and substance misuse seem to be the common issues, but depression, mania or hypomania, generalized anxiety disorder, social phobia, obsessive compulsive disorder, post-traumatic stress disorder and anti-social personality disorder are quite frequent [44–46].

- Estimates of prevalence of persons with ID and ASD in prison vary across the pathway of forensic services. The estimated international prevalence rates for ID range from 0% to 2.9% and up to 7% in a UK study. For prisoners with autistic traits, the estimated prevalence range is from 1% to 4%.

- Prisoners with ID and/or ASD are more likely to have co-morbid mental disorder, self-harm or suicide-related thoughts and behaviours than those without neurodevelopmental conditions.

41.3 Risk Factors for Offending Behaviour

The Cambridge Delinquency Study, of 411 working class boys living in South London born in 1953, reported several predictor variables of future criminality by the age of 32 including poor socio-economic status characterized by increased poverty, poorer education and academic achievement, higher rates of unemployment and the presence of neurodevelopmental disability such as ADHD [51, 52]. Prediction of future offending was based on a measure of the vulnerability of children aged between 8 and 10, specific predictors within the measure included low family income, large family size (five or more children), a convicted parent, poor child rearing and low non-verbal IQ (90 or less), 46 of 63 (73%) assessed with three or more of these adverse factors in childhood had displayed criminal behaviour by age 32.

One hundred and ninety-two people with ID from the 1953 Swedish birth cohort study were studied retrospectively. The study reported increased rates of offending by women with ID who were four times more likely and men with ID were three times more likely to offend than the rest of the population and 25 more times more likely to commit a violent offence [53]. Similar results were repeated in a Danish population study of over 300,000 people born between 1944 and 1947, women and men with ID admitted to psychiatric facilities were 5.5 and 6.9 times, respectively, more likely to have committed an offence than those who had not been admitted. However, the definition of ID used were unreliable in that it covered those in special school who may or may not have had ID.

Offending rates in females with ID have been reported as compared to the general population [54]. Although referrals to services for offending and anti-social behaviour have been reported at 40% for women, compared to male referrals of just over 60% and at a greater rate than in the general offending literature relating to women [24]. Similar to forensic populations without ID, the severity and types of crimes associated with males and females are different. The Wheeler study found that women with ID were more likely to have committed offences or have convictions against children such as neglect and cruelty. The danger is that a group of women with ID are being criminalized for crimes that would have not been committed if adequate support had been put in place for mother and child. Although females have been included in a limited number of studies, there is a lack of specific research relating to women with autism [55].

One theory of offending often put forward is linked to the characteristics that may be considered to be more associated with ID and ASD and so may predispose a risk for contact with the CJS such as:

- Anxiety, anger and impulsivity.
- Mental health problems.
- Peer pressure and exploitation.
- Social naiveté or misunderstanding of social situations.
- Communication difficulties.
- Change in environment or disruption to routines.
- Lack of capacity to distinguish between right or wrong.
- Lack of empathy.

41.4 Offence Types

Findings from a systematic review [55] suggest that there are relatively few differences in types of offences between the ASD offenders and the non-ASD offenders, aside from lower rates of driving offences and drug offences although there are three types of offences have had a historical association with offenders with ID and ASD, namely, fire-setting behaviour, sex offending behaviour and crimes involving violence.

41.4.1 Fire-Setting

Historically, abnormal psychosexual development, poor impulse control, being of weak mind and being predisposed to crime by having low intelligence have been put forward to explain fire-setting behaviour in adults with ID [56]. An association that ID is predictive of repeat fire-setting along with disorders such as schizophrenia and antisocial personality disorder has also been put forward [57–60]. However, the assumption that individuals with ID are more likely to be firesetters is being challenged with insufficient evidence to support a clear association between ID and fire-setting [54, 61].

In a study across services for people with ID, fire-setting accounted for 2.9% (2/69) of index offences in community settings, 21.4% (15/70) in medium/low secure services and 6.8% (5/73) in high secure services, with those with a previous history of fire-setting accounting for 11.6% (8/69) in community services, 27.1% (19/70) in medium/low secure services and 11% (8/73) in high secure services [62].

Several studies have put forward specific characteristics associated with people with ID who are firesetters. For example, being male, have emotional and behavioural characteristics in childhood related to temperamental difficulties and conduct disorder, increased likelihood of relationship difficulties, introversion, previous psychiatric treatment and a history of self-injury [63].

The Functional analysis theory [64] is widely used and outlines five factors thought to underlie fire-setting:

1. Psychosocial disadvantage.
2. Life dissatisfaction and self-loathing.
3. Social ineffectiveness.
4. Fire experiences.
5. Triggers.

This model is designed to allow clinicians to establish emotional, cognitive and situational antecedents that may predispose, precipitate and perpetuate fire-setting behaviour through a detailed analysis of the behaviour itself [65]. Within treatment, there are several key targets for treatment including communication, anger, poor assertiveness, low self-esteem, social isolation and frustration. One example showing the practical application of cognitive behavioural therapy (CBT) using a single case study of a young man's assessment and treatment of fire-setting is reported [66]. Research has moved from the reporting of case information to intervention-based studies [67]. A case series of six female with a history of fire-setting behaviour, using a CBT approach reported improvement in clinical measures relating to motivations for fire-setting behaviour and no reports of fire-setting 2 years following completion of the programme [68]. In a comparison of firesetters (n = 38) with non-firesetters in a UK forensic ID service, from a sample of 138 patients over 6 years, found fire-setting was associated with psychosis and personality disorders. In terms of criminality, 14 (47%) had a conviction for arson and were more likely to convicted of violent offences [69]. In terms of treatment, this suggests that offence treatment aimed at arson in some cases may be a secondary consideration and whether treatment needs differ from firesetters without intellectual disability [70].

41.4.2 Sex Offending

Like fire-setting behaviour, there is growing evidence that offenders with ID are not over-represented among sex offenders and paraphilics in general [71]. In a New South Wales prison, 3.7% of those with ID had committed a sexual offence compared with 4% of offenders without ID [72]. Increasingly, there are more and more community studies of sex offenders. A 12-year follow-up community Scottish study compared three groups, male sex offenders (N = 121), other male offenders (N = 105) and female offenders (N = 21). In terms of characteristics and propensity to future recidivism, the sex offender group was more likely to be older and has problems with relationships and daily living skills, whilst those most at risk of higher reoffending were male offenders (59%) followed by male sex offenders (23%) and female offenders (19%) over 12-year period [54]. An essential part of treatment for sex offences is often adapted CBT programmes to address the impact of cognitive impairments for ID/ASD offenders to reduce the risk of sexual reoffending [73–75]. More recent studies have suggested that treatment success might be affected by the severity of the offence [76]. A diagnosis of ASD in the past has been associated with worse outcomes and more likely to engage in further sexually abusive behaviour. The SOTSEC-ID project (Sex Offender Treatment Services Collaborative – Intellectual Disabilities) [77] reported on a 1-year cognitive behavioural therapy group, evaluated 13 groups, consisting of 46 men with mild to borderline ID with 'sexually abusive behavior'. Both during the programme and 6 months post intervention, there were no non-sex offences committed reported. Three men (6.5%) were responsible for eight incidents of non-contact sexually abusive behaviour during the project, and at 6-month follow-up, four (8.7%) men were responsible for nine incidents of non-contact sexually abusive behaviours and two incidents of contact sexually abusive behaviour. The three (75%) who were involved in sexually abusive incidents had a diagnosis of ASD with poorer pre-post-

and follow-up scores on measures of cognitive distortions suggesting implications for future treatment and monitoring.

41.4.3 Violence

Crimes involving violence have also had a long association with ID, with widely different rates being reported between studies and settings. Rates of between 20% and 60% have been reported across community and inpatient settings [78, 79]. Gray and colleagues [79], compared a group with ID of 118 (81.4%) men and 27 (18.6%) women, and a non-ID group of 843 (85.6%) men and 153 (15.4%) women. The ID group was reconvicted at a significantly lower rate, with a reconviction rate for violent offences after 2 years of 4.8% compared to the non-ID group of 11.2%, while for general offences, the rate of reconviction was 9.7% for the ID group compared to a rate for the non-ID group of 18.7%. Estimating prevalence rates of offenders with ID committing violence is difficult and can be examined from several different perspectives. A lack of comparison studies involving ID and non-ID offenders makes this direct comparison difficult [80]. Violence has been put forward as the most common offence perpetrated by people with ASD [81]. The motivation and function of violence are varied, and it among the targets for intervention is anger, which can precede violence. A systematic review of two randomised controlled trials (RCTs) and four pre-post unmatched groups suggests that anger management is an effective intervention in this group, a lack of robust methodological controlled studies means more evidence is required to support such a conclusion [82].

There are few differences in types of offences committed by offenders with ID or ASD when compared with other offenders, aside from lower rates of driving and drug offences. The most common offence for those with ID or ASD requiring a therapeutic intervention is violent behaviour.

41.5 Risk Assessment

Risk assessment for offenders with ID and ASD is usually supplemented using standardized tools developed for the wider population. Concerns have been voiced as to whether conventional risk assessment tools can capture the reasons and motivation for offending in these groups. A study of ASD violent offenders ($n = 21$) motivation compared to ASD sex offenders ($n = 12$) reported that the violent offenders were more likely to have severe mental health problems but intellectually more able than the sex offenders. In terms of motivation, six (29%) were motivated by revenge and five (24%) thought to have been motivated by misunderstandings or idiosyncratic ideas, five (24%) were thought to be reactive. Revenge, misunderstanding, rigidity, special interest and idiosyncratic ideas were not identified in the sex offender group, whose offences were found to be instrumental [83]. An individual formulation is often recommended to supplement risk assessment tools [84], for example, with ASD, although conventional risk factors may be present the assessment may not highlight the specific difficulties associated with ASD that might increase the individual's vulnerability to offend [55, 85]. Offenders with ID will share similar risk predictors with non-ID offenders, for example, being young, male, substance abuse, antisocial behaviour, higher unemployment, poorer socio-economic status and histories of abuse [86–88]. Of the 477 people with ID referred to forensic services, 35% (165) had experienced abuse or neglect as a child and started offending at a young age [89].

The shared characteristics between ID and Non-ID offenders have seen increasing use of risk assessment tools validated in non-ID forensic samples. The majority used will support a structured professional judgement such as the HCR-20 (Historical, Clinical, Risk-20 factors) [90] which has been reported as an effective predictor of violence for individuals with ID discharged from medium secure services [79] and a significant predictor across different levels of security (high, medium and low), [62]. In another study of individuals

with ID in high security, 60 people were followed up with the HCR-20 performing better than the Hare Psychopathy Checklist-Revised (PCL-R) [91] in predicting institutional aggression over a year [92]. Although good predictor value has been reported, the usefulness [93] with differences in subscale scores between ID and comparison groups also reported [94]. Risk assessment tools are now incorporated into existing assessment protocols as a matter of course to screen for and offer a more reliable estimate of risk.

There are also many specialist risk tools to measure the likelihood of risk involving specific offences, such as the:

- STATIC-99 [95] which is predictive of sexual risk.
- The Rapid Risk Assessment for Sex Offence Recidivism (RRASOR) [96].
- Assessment of Risk and Manageability of Intellectually Disabled Individuals who Offend Sexually (ARMIDILO-S) [97].

There is less evidence of the effectiveness of specialist tools. In a study of 88 sex offenders divided into two groups (1) ID to borderline intellectual functioning (IQ 70–80) and (2) those with no ID found the ARMIDILO the best predictor for sexual reconviction for those with ID compared to the RRASOR, the Risk Matrix 2000-non sexual Violent (RM2000-V), the Sexual Violence Risk-20 (SVR-20), with the first two measures reported to be no better than chance for the special needs group [98].

There is little in the way of bespoke ASD risk assessment measures. Often cognitive or sensory difficulties in generic risk assessment are not considered. Therefore, the initial assessment should focus on specific difficulties of those with ASD that traditional risk assessment tools find difficult to capture, which may be why people with ASD are detained longer in secure hospitals than other offenders [88]. As a result, the evidence of risk assessment in ASD is less developed.

Consideration to the predisposing, precipitating and maintenance factors for violent and offending behaviour can often focus on what underlies the risk behaviour being assessed and targets for intervention:

- Inability to seek an appropriate course of action in response to perceived or actual difficulties caused by others and reacting to such difficulties by using violence which the individual thinks is appropriate justice. This is exaggerated by a difficulty to seek solutions by meaningful discussions.
- Inability to appreciate social boundaries, and engaging in inappropriate behaviour, sometimes combined with inappropriate sexual or other unusual interests/preoccupations. Misinterpreting events, rules and situations.
- Overriding obsessions, misjudged relationships, innate lack of empathy, lack of ability to recognize fear and difficulties in accepting justice and taking matters into their own hands due to limited social understanding.
- Passive aggression by refusing to cooperate, eat, speak, dress or attend self-care as a way of protest.
- Limited awareness of the consequences of their actions to themselves or others.
- The presence of co-morbidity such as depression, anxiety or other mental disorders [99, 100].

Risk assessment for offenders with ID and ASD who commit violent offences involves using structured professional judgement tools such as the HCR-20 as used in the wider population. The evidence to date indicates that the HCR-20 is an effective predictor of violence in people with ID.

41.6 Services in the United Kingdom

Forensic services for adults with ID or ASD in the UK are made up of both community and secure services. Secure hospital services for people with ID/ASD are divided into three levels of security in the United Kingdom. High secure care for people with ID is provided at the national centre at Rampton Hospital, whilst medium secure [101] and low secure care are provided by both the NHS and

independent sector with the majority of patients being in a low secure unit.

Aside from high security services for ID, the development of less secure services has a common beginning, starting with the Butler report [102] which introduced medium secure services. The Reed report [103] for the first time highlighted the needs of the ID group. The Bradley report put ID on an equal footing with mental health in terms of what providers of services need to consider and called for better cooperation between CJS and health providers to reduce delays between and within services encouraging joined up working and pathways between agencies. In terms of best practice to support people outside of health and CJS services, the Mansell Reports, outline best practice guidance for developing and managing services for people with ID and challenging behaviour in the community [104, 105]. Mansell advocates care within community settings wherever possible with the development and expansion of person-centred services. However, abusive practices and unacceptable standards have been highlighted by several recent inquiries despite a policy of least restrictive practice [106, 107].

The provision of specialized secure/forensic inpatient services for offenders with ASD is a recent development over the last 5 years as historically this group would have resided in services for those with mental illness or ID. A comparison of men with and without ASD in low secure services has found those with ASD being significantly less likely to have a personality disorder or history of drug abuse. One-third had the additional diagnosis of schizophrenia or related psychosis, an indication of their complex presentation within secures hospitals [108]. Differences in ASD and ID offending group have also been noted in other studies. In a study of 138 patients in a forensic ID service [109], the 42 with a diagnosis of ASD were more likely to be detained without restrictions and on a civil section and less likely to have been convicted in the past for violent offences, sex offences and arson. However, in a subset of 114 for whom data were available, the ASD group was more likely to display self-harm and institutional aggression and was significantly more likely to be subject to physical intervention.

An evaluation of completed admissions of offenders (n = 45) vs non-offenders (n = 41) within a London based, assessment and treatment service for adults with intellectual disability found the non-offender group lacked a history of custodial sentences or previous high secure admission but were more likely to be involved in assaults on staff and other patients and to use weapons, whilst the offender group had a higher rate of personality disorder and self-injurious behaviour (SIB) and less likely to be admitted from or be discharged into the community. Another study of 138 patients (77 discharged and 62 inpatients) examined short-term outcomes of a medium secure unit and reported around 90% of patients going to lower levels of security and a third going to community placements (Median length of stay 2.8 years) [101]. In terms of readmission to secure services, a specialist ID service, containing both low and medium secure provision, of 40 male patients, 27 patients (67.5%) were discharged into the community with 14 patients having sole support from the community ID services and 4 from the community forensic services. Of these, 20% were readmitted within the study period and 22.2% received further convictions via the CJS following discharge [110].

A lack of local or regional specialist services offering a high degree of structured community and secure services for people with ID has given rise to out of area placements particularly in the United Kingdom [111, 112] and added to the problem of difficult to discharge patients [101]. Chaplin and colleagues reported on and contrasted the characteristics of 44 people with ID placed out of area compared to those placed locally, near their community [111]. Violence against the person was the most likely event to precipitate and maintain out of area placements.

Women's secure services have developed at a much slower pace, given demand. Facilities are based upon the same model with the omission of women's' high secure services which

have been replaced by enhanced medium secure facilities, with women who offend, generally more likely to be managed at lower levels of security, than men [113].

The move towards treatment and care being delivered in the least restrictive environments has been somewhat thwarted by a lack of appropriate community provision for this group. The emphasis of future service research is likely to focus on recognizing people with ID and/or ASD earlier in the criminal justice pathway and diverting them to more appropriate treatment services if cost-effective. The responses to those committing crime from the criminal justice system vary by country and within countries. The provision of community forensic services is still underdeveloped for offenders with ID and ASD across the United Kingdom, but this is not the case in other countries [114]. Where there are services, deficits in ability, understanding and functioning associated with ID and/or ASD often means lifelong involvement from multiple agencies for those who have contact with the criminal justice system. For many, diversion from prison has meant long periods in hospital. However, there is a tendency that treatment and care are delivered in the least restrictive environments, although currently, the provision of community forensic services is still underdeveloped for offenders with ID and/or ASD, as it in prisons and the entire criminal justice system. Services within prisons and across the entire criminal justice system need to be developed to be effective in meeting both the vulnerabilities and risks of individuals with ID and ASD.

Tip

- Research into offenders with ID has suffered from wide methodological disparities, but there is increasing use of screening tools such as the Rapid Assessment of Potential Intellectual Disability (RAPID) [28], Hayes Ability Screening Index (HASI) [29], Learning Disability Screening Questionnaire (LDSQ) [30] to improve identification across the criminal justice system and so inform future research.
- Risk assessment for offenders with ID and ASD is usually supplemented with standardized tools used in the wider population such as the HCR-20 [90], but in more recent years, specific tools for people with ID have been developed such as Assessment of Risk and Manageability of Intellectually Disabled Individuals who Offend Sexually (ARMIDILO-S) [97].

This chapter has outlined the current evidence relating to the advances in understanding of a number of areas linked to people with ID or ASD who commit offences. These include how the characteristics of the individual are used to understand clinical presentation to inform treatment. There is a move towards least restrictive practice principles in managing this group of offenders. We have also shown that although research has increased, it is still an under researched area when compared to offender research into the wider population. There is a need for further research to include larger population studies which looks at the spectrum of neurodevelopmental disorders.

Key Points

- It is estimated that 7% of prisoners had an IQ of less than 70 with a further 25% had an IQ of below 80.
- There are three types of offences that are commonly reported for offenders with ID and/or ASD, namely, fire-setting behaviour, sex offending behaviour and crimes involving violence.
- Offenders with ID will share similar risk predictors with non-ID offenders, for example, being young, male, substance abuse, anti-social behaviour, higher

unemployment, poorer socio-economic status and histories of abuse.
- Specific risk tools have been developed for use with offenders with ID, but there is little in the way of bespoke ASD risk assessment measures.

Learning Objectives

- To understand disability as a human rights issue
- To recognize human rights standards related to disability, according to United Nations Convention on the Rights of Persons with Disabilities
- People with disabilities worldwide experience discrimination and inequalities particularly concerning self-determination, participation in society, quality of life, and healthcare provision.
- The United Nations Convention on the Rights of Persons with Disabilities represents a legal, political, and development instrument, with the aim to promote, protect, and ensure the full and equal enjoyment of all human rights and fundamental freedoms by all persons with disabilities.
- It adopts a social concept of disability and guarantees the universal recognition of the intrinsic dignity of every person.
- Human rights provide a robust framework for strengthening the voices of people with disorders of intellectual development.
- The United Nations Convention on the Rights of Persons with Disabilities does not allow exceptions or distinctions based on disability, promoting the adoption of a bio-psycho-social model founded on respect for human rights and more effective social inclusion.
- Persons with disabilities have a central role in monitoring activities, which includes reporting, corrective action, and follow-up.

42.1 Introduction

The United Nations (UN) define human rights as being inherent to all human beings, regardless of race, sex, nationality, ethnicity, language, religion, or any other status. They include the right to life and liberty, freedom from slavery and torture, freedom of opinion and expression, the right to work and education.

They apply from birth until death, irrespective of place of origin, personal beliefs, or how people choose to live their lives.

Human rights may also be regarded as defining the minimal conditions required to lead to worthwhile lives [1], particularly in terms of achieving personal goals. From this perspective, all individuals must have the opportunities to put their ideals and desires into actions and to give meaning to their lives, regardless of whether they have a disability or not.

Nevertheless, throughout history, there has been the tendency to downgrade the value and the dignity of persons with disorders of intellectual development (DID) and subject them to injustices and neglect.

Persons with disabilities and their associations have largely used the concept of human rights to argue for greater equality and for receiving dignified and respectful treatment.

Gewirth [2, 3] states that freedom and well-being are essential conditions for the achievement of goals. In fact, without freedom to act individuals would not be able to achieve their own objectives and in order to act people require a certain level of well-being, both physical and mental, and the access to various material, social, and psychological resources.

Actions by the UN on the issue of the human rights of persons with disabilities have included the UN Standard Rules on the Equalization of Opportunities for Persons with Disabilities [4] and the Convention on the Rights of Persons with Disabilities (CRPD) which was adopted in New York on December 13, 2006 [5]. While the first document essentially represents a set of guidelines, indicating the UN endorsement of persons with disabilities' human rights, the CRPD embodies a significant "turning point" in that it represents a legal, political, and development instrument, elaborated and monitored together with people with disabilities. It adopts a social concept of disability and guarantees the universal recognition of the intrinsic dignity of every person with this condition. The CRPD does not allow exceptions or distinctions based on disability, promoting the

adoption of a bio-psycho-social model founded on respect for human rights and more effective social inclusion.

Tip

The condition of people with specific characteristics depends on a complex combination of bio-psycho-social factors which can be modified on both the social and individual levels. Removing or reducing disability is a responsibility of States and society as a whole.

42.2 Rights of Persons with Disorders of Intellectual Development and the UN Convention on the Rights of Persons with Disabilities

The link between the condition of people with disabilities, including DID, and human rights arises in part from the criticism of the medical model of disability prevalent in the 1970s and 1980s and from the first reflections of the UN, begun in 1981 with the work of the Sub-Commission on the Human Rights of Persons with Disabilities. The CRPD stems from the observation that there were 650 million people with disabilities in the world, 80% living in poor countries that were not able to meet their needs and that worldwide people with disabilities faced barriers in their participation in society and lower standards of living.

It was noted that while the existence and universal nature of previous treaties may have been expected to include people with disabilities, without a specific focus this population was often "legally invisible" in their societies and internationally.

The approval of a convention on human rights represents a significant moment of political and social recognition of the will to recognize, uphold, and protect the rights of the interested parties. A convention sets a new theme within the global and national agenda, creating the conditions for changing policies and legislation. The primary impact concerns governments, parliaments, national and local institutions. Its cultural impact is equally important since it influences the whole society and offers new approaches to social vision that is often attributed to groups subject to human rights violations. This impact can be supported by initiatives, such as public awareness campaigns, involvement of communication media, and appropriate cultural and social mobilization.

In ratifying the Convention, States undertake to comply with its articles through national legislation and policies. The United Nations Conventions prevail over all other forms of legislation, and therefore, the principles and obligations therein must be known and interpreted, in order to guarantee the highest level of protection of human rights at national and local level. In addition to the implications for information and communication systems, the Convention must also have an impact on training in various areas of expertise, encouraging at all levels, the acquisition of knowledge and skills consistent with the aims of the Convention. The Convention, in many ways, represents a unique instrument. It has been developed and monitored together with people with disability. It is a legal and political instrument which considers disability as a matter of human rights, adopting a social concept of disability itself. The Convention ratifies the universal recognition of the inherent dignity of all individuals with disability and does not admit exceptions or distinctions based on their condition. This approach considers people with disability as subjects of rights, able to demand their rights, to make their own decisions about their life, and to actively contribute to society. The general obligations of the Convention include guaranteeing the fulfilment of all the rights for all people with disability, adjusting statutory legislations and policies, and taking the necessary steps to ensure appropriate supports and reasonable compromises (Article 4). Specific obligations include taking effective and appropriate measures to guarantee full legal capacity and necessary supports to exercise it (Article 12), to supply adequate residential and community services (Article 19) as well as educational and

professional opportunities (Article 24, 27), and to provide for physical, psychic, social, and occupational rehabilitation of people with disability (Article 26). Rights guaranteed to persons with disabilities are summarized in the table below (Table 42.1).

The main purpose of conventions is to promote and safeguard human rights all over the world—human rights are for all. They are not new and special rights specifically for people with DID or other particular disabilities.

Table 42.1 Rights guaranteed to persons with disabilities

Article 10: Right to life	Article 21: Freedom of expression and opinion, and access to information
Article 11: Situations of risk and humanitarian emergencies	Article 22: Respect for privacy
Article 12: Equal recognition before the law	Article 23: Respect for home and the family
Article 13: Access to justice	Article 24: Education
Article 14: Liberty and security of the person	Article 25: Health
Article 15: Freedom from torture or cruel, inhuman or degrading treatment or punishment	Article 26: Habilitation and rehabilitation
Article 16: Freedom from exploitation, violence, and abuse	Article 27: Work and employment
Article 17: Protecting the integrity of the person	Article 28: Adequate standard of living and social protection
Article 18: Liberty of movement and nationality	Article 29: Participation in political and public life
Article 19: Living independently and being included in the community	Article 30: Participation in cultural life, recreation, leisure, and sport
Article 20: Personal mobility	

The human and civil rights of all people with DID must be honored and protected but nowadays, as throughout history, have often been unjustifiably limited or denied. These rights include autonomy, dignity, family, justice, life, liberty, equality, self-determination, community participation, property, health, well-being, access to voting, and equality of opportunity and others recognized by law or international declarations, conventions, or standards. The presence of other characteristics such as age, gender, race/ethnicity, sexual orientation, cultural or linguistic diversity, economic status, or severity of disability exposes people with disabilities to increased risk of violations of their rights.

In reality, many individuals, state and local government agencies, and other organizations ignore the human and civil rights of this population. As a result, people with DID face unique challenges, including a history of discrimination, segregation, and exclusion from meaningful choice and participation in society, cultural attitudes of devaluation, and social failure to provide the supports needed for the improvement of participation, equal opportunity, or independent living.

The CRPD promotes the adoption of a bio-psycho-social model founded on respect for human rights and more effective social inclusion. A human rights-based approach to disability implies that persons with disabilities need to participate in all spheres of society on an equal basis with their non-disabled peers.

42.3 Fundamental Principles

The fundamental principles of the CRPD are expressed in article 3 and refer to "respect for inherent dignity, individual autonomy including the freedom to make one's own choices, and independence of persons, non-discrimination, full and effective participation and inclusion in society, respect for difference and acceptance of persons with disabilities as part of human diversity and humanity, equality of opportunity, accessibility, equality between

men and women, respect for the evolving capacities of children with disabilities and for their right to preserve their identities" [5].

42.3.1 Equality, Non-discrimination, and Dignity

The concept of equality alludes to the creation of conditions which ensure full participation and equal opportunities for all persons. This right derives in turn from the principle that diversity (including neurodiversity) represents a characteristic of humankind and a resource for its maintenance and improvement.

In some cases, achieving this goal requires additional adaptations and supports. For example, people with DID might need assistance in making choices and in exercising their legal capacity on equal terms with others [6].

Non-discrimination refers to the fact that rights are assured to everyone without distinction or limitations based on disability or on origin, sex, language, religion, or any other status. It should be noted that article 3 refers to discrimination considered in all its forms.

Inherent dignity refers to the worth of every individual, to his/her innate right to respect and ethical treatment. When the dignity of persons with disabilities is respected, it means that their experiences and opinions are valued [6].

The medical model of disability has led to the dissemination of different approaches and treatments compared to those addressed to other people, developing solutions and interventions that have often generated violations of human rights of persons with disabilities. According to the UN Standard Rules on the Equalization of Opportunities for Persons with Disabilities (v.s.) "persons with disabilities have the right [...] to receive the support they need within the ordinary structures of education, health, employment and social services. [4]" In support of this, States have produced anti-discrimination laws, which also protect people with disabilities, prohibiting any discrimination based on their condition through a legal basis that provides for the removal of discriminations by means of "reasonable accommodation" (Article 5) [5]. Discrimination affects people on the basis of characteristics that are subject to different treatments, prejudices, and barriers to full social participation. When characteristics of gender, race, culture, religion, political opinion, age, and disability condition combine with each other, the result is a multiple discrimination that leads to people who have these characteristics even more vulnerable. A typical example may be represented by women with disabilities, who are subject to severe limitations with respect to access to rights, services, and social participation in respect of relationships, sexuality, childbearing, etc. Disabled people are more likely to experience exclusion, isolation, and discrimination [7, 8] and face a range of other marginalizing factors and there is a universal need for reformulating a new concept of justice for people with disabilities, based on inclusion, empowerment, cultural and social change, respect for human rights, and promotion of human diversity. Exclusion is a process which expresses itself through the denial of opportunities; inclusion is a complex process which requires willingness to "change the rules" and to actively seek feasible solutions.

42.3.2 Autonomy and Self-Determination

Respect for the individual autonomy of persons with disabilities entails that they are enabled to exercise their own decisions about their lives, with support where needed. Applying this principle, for example, to a person with mental disabilities should result in them being offered a range of alternatives for maintenance of their mental health together with the liberty to make decisions on the basis of individual preference.

People with DID have the same right to self-determination as everyone else. They must have opportunities and supports to exercise control over their lives and to advocate on

their own behalf. Nevertheless, many individuals with DID have not been afforded these opportunities and often others make decisions not only about key elements of their lives but also with regard to the everyday activities of daily living. This may be compounded by a lack of experiences that would enable the learning of decision-making skills and making choices, the lack of opportunities impeding participation as valued members of their communities, as well as from making decisions about important aspects of their lives.

People with DID therefore should be given: the assurance that their desires, interests, and preferences will be respected; opportunities to acquire skills which better enable them to make general and specific choices; the lead in decision-making about all aspects of their lives; the opportunity to self-direct their own supports and services and allocate available resources [9].

42.3.3 Independent Life and Social Inclusion

All people with DID benefit from full inclusion and participation in society. Nevertheless, they are not treated equally and often they are separated from their community and labeled as having "a disability," experiencing several forms of exclusion. Negative views can often be encountered about the economic costs of inclusion particularly where public resources are severely constrained in low- and middle-income countries. Morgon et al. [10] in their review of studies describe "pathways" to economic impact of exclusion and inclusion in the areas of education, work and employment, and health concluding that exclusion can lead to a significant economic burden for individuals and their families and also to society as a whole. Such evidence may be helpful when advocating for inclusion in national or local policy or strategy; however, it must be understood that inclusion is a human right and, as with other rights, does not have to be justified.

Inclusion is a right based on the full participation of persons with disabilities in all the fields of life, without discriminations, respecting the dignity and giving value to human diversity through appropriate interventions.

Article 19 of the Convention [5] sets out the right of all disabled people to "live in the community, with choices equal to others," requiring States to enable disabled people to be fully included and participate in society. According to the text of the article:

(a) Persons with disabilities have the opportunity to choose their place of residence and where and with whom they live on an equal basis with others and are not obliged to live in a particular living arrangement.
(b) Persons with disabilities have access to a range of in-home, residential, and other community support services, including personal assistance necessary to support living and inclusion in the community, and to prevent isolation or segregation from the community.
(c) Community services and facilities for the general population are available on an equal basis to persons with disabilities and are responsive to their needs.

People with disabilities should be included in all aspects of our society and receive the supports they need to participate actively in community life. They should have the opportunity to have relationships with other individuals in the community, live in a home where and with whom they choose, have access to the supports that they need, engage in meaningful work in an inclusive setting, and enjoy the same leisure activities that are available to the general public [9].

For participation and inclusion to be achieved, public and private dimensions of society must be organized in order to enable all person to take part effectively and to be recognized as equal participants; full and effective inclusion is achievable only through accessible physical and social environments.

According to Article 26: *States Parties shall take effective and appropriate measures, including through peer support, to enable per-*

sons with disabilities to attain and maintain maximum independence, full physical, mental, social and vocational ability, and full inclusion and participation in all aspects of life.

This necessitates the provision of comprehensive services and programs for habilitation and rehabilitation particularly in the areas of health, employment, education, and social services, and ensuring that these:

(a) *Begin at the earliest possible stage, and are based on the multidisciplinary assessment of individual needs and strengths;*
(b) *Support participation and inclusion in the community and all aspects of society, are voluntary, and are available to persons with disabilities as close as possible to their own communities, including in rural areas*

Article 26 also emphasizes the promotion of training for professional staff in such services and also the availability knowledge and use of assistive technologies [5].

Article 3 identifies key principles of a human rights approach to disability, including respect for inherent dignity, individual autonomy, non-discrimination, inclusion in society. Fundamental principles are very important for interpreting the rights and other articles in the Convention, and to assist States in understanding and implementing its provisions effectively.

42.3.4 Quality of Life

People with DID are entitled to a life of quality but they often do not have the adequate supports and personal relationships they need or desire in order to achieve this[1]. A meaningful quality of life exists when they receive, at all stages of their lives, the support, opportunity, and resources to explore and define how they want to live, choose the services and supports they need, have a life enriched by friends and family and have opportunities for intimate relationships, experience life-long learning and develop decision-making skills, and enjoy the same rights and respect for their dignity and privacy, as do people without disabilities [9]. Hence, quality of life and the preservation of human rights are closely related.

In recent years, increased research attention has been devoted to person-centered outcomes and quality of life. The latter in particular has repeatedly been defined an essential reference in the intervention planning and evaluation toward DID, where the recovering of neuropsychic functions cannot be pursued as in other mental or physical conditions in the general population. Evaluation of quality of life aims to identify how the individual might achieve a satisfying life and experience participation, opportunities, and the possibility of making independent choices. It is a multidimensional concept, involving several definitions and applications [11–13]. There is general agreement on the fact that Quality of Life measurement should be based on both qualitative and quantitative variables [12, 14], from both subjective and objective positions [15]. The Quality of Life model is a useful conceptual parameter in maintaining the life aims of people with DID aligned with those of other non-disabled people. The model has been shown to have a number of positive implications for care and intervention for those with neurodevelopmental disorders, including caregiver burden, supports, health services, and health policies [16]. There remain still many challenges in reaching an optimal implementation of the concept of Quality of Life into daily practices, such as matching with the non-reductionistic approach of the phenomenological tradition and the very specific cognitive impairment.

There is a close relationship between the quality of life domains and the articles of the Convention. Focusing on enhancing quality of life and human rights encourages organizations to provide individualized supports and involve people with DID in the decision-making of their own lives.

1 For further reflections on Quality of Life in people with DID, see ▶ Chaps. 14 and 15 on this volume.

42.4 Access and Quality of Physical and Mental Health Care

People with DID have higher rates of morbidity and mortality than the general population. Cooper and colleagues [17] in looking at multiple morbidity in those with DID concluded not only is the greater burden, occurring at a much earlier age, with a different health profile but also that specific initiatives are required in order to reduce inequalities.

The National Learning Disability Mortality Review program (LeDeR) [18] in reviewing the deaths of 1081 people with a learning disability aged 4 years and over between 2016 and 2018 recorded a median age of death for males with a learning disability (intellectual disability) of 60 years compared with 83 for men in the general population and median age of death for females of 59 years compared with 86 for females in the general population.

Yet more disturbing was the finding that 15 people had their cause of death recorded as "learning disabilities," and the term "learning disabilities" or "Down's syndrome" had been recorded as the reason for a Do Not Attempt Cardiopulmonary Resuscitation order.

The LeDeR report concluded that 71 adults had been subject to failings in care that was far short of good practice and that had had a significant impact on their well-being or been a direct contributing factor to their cause of death.

It might be inferred that such discrimination and inequalities in health could be addressed by bringing a human rights-based approach in the pathways of access to healthcare provision.

A government led initiative, The Human Rights in Healthcare Programme was established in England in 2005 to embed human rights into public services. The Programme was a collaboration between the Department of Health, the British Institute of Human Rights, and, over time, by eight National Health Service (NHS) trusts.

The program defined five principles, known as the PANEL principles, as being fundamental to a human rights-based approach:

- People's right to participate in decisions that affect their lives;
- Accountability of duty-bearers to rights-holders;
- Non-discrimination and prioritization of vulnerable groups;
- Empowerment of rights-holders;
- Legality: the express application of the 1998 Human Rights Act (UK).

A review of the impact of this program by Dyer [19] concluded that the Human Rights Act in the United Kingdom, which attempted to enshrine the European Convention on Human Rights into UK law, had not resulted in the anticipated cultural change in health services. While there was evidence that the development of human rights-based resources could have a beneficial effect, the program had not addressed the "big human rights questions about health care" nor adequately engaged a multidisciplinary approach.

In respect to mental health, which is the object of the present textbook, the right for care (Article 25) of people with DID is still challenged by many issues in most countries across the world.

The World Health Organization recently carried out a project addressing mental health, human rights, and standards of care in institutions across the European Region [20]. Phase 1 was comprised of a survey of institutions that provide long-term care for adults with psychosocial and intellectual disabilities across 31 participating countries. In Phase 2, observance of human rights was assessed in a sample of institutions using World Health Organization Quality Rights toolkit. This toolkit has 25 standards within five interrelated themes referenced to related article of the CRPD:

- Theme 1. The right to an adequate standard of living (Article 28 of the CRPD);
- Theme 2. The right to enjoyment of the highest attainable standard of physical and mental health (Article 25 of the CRPD);

- Theme 3. The right to exercise legal capacity and the right to personal liberty and the security of person (Articles 12 and 14 of the CRPD);
- Theme 4. Freedom from torture or cruel, inhuman or degrading treatment or punishment and from exploitation, violence, and abuse (Articles 15 and 16 of the CRPD);
- Theme 5. The right to live independently and be included in the community (Article 19 of the CRPD).

Assessments were carried out by government nominated national assessment teams in 75 facilities across 24 World Health Organization Member States and also Kosovo.

The findings showed that long-term institutional care for people with psychosocial and intellectual disabilities is significantly below standard in many European countries and there were many examples of violations of people's fundamental rights including their legal capacity, autonomy, dignity, liberty and security of person, physical and mental integrity, and freedom from torture and ill treatment and from exploitation, violence, and abuse. Concerns were also raised about use of mechanical and pharmacological restraints to manage difficult behavior, a "culture of impunity with regard to reported cases of sexual abuse" and "numerous irregularities concerning informed consent, discrimination and barriers to access to high-quality care for general and reproductive health, lack of alternative or complementary mental health treatment options and a general lack of opportunities for meaningful daily activities within or outside the institutions."

The clinical approach to people with DID still largely neglects the therapeutic relationship, diagnostic evaluation, and outcome measures of the interventions, and many people often encounter difficulties in receiving adequate assistance. Literature shows a considerable amount of evidence on the lack of specific services for people with DID, particularly for those who suffer from additional mental health problems. In fact, various studies have pointed out that to date the health needs of people with DID remain largely unsatisfied, both in qualitative and quantitative terms. At the European level, the greatest difficulties have been identified in relation to access to treatment, diagnostic evaluations, psychopharmacological prescriptions, treatment of psychiatric disorders in comorbidity, and reception and support offered. Particularly important is the difficulty that clinicians may face in detecting and evaluating symptoms in people with DID, due to communication problems, poor quality of informant accounts, and the diagnostic overshadowing of disability. This and poor quality of care in the choice of interventions are mainly due to the lack of specific training and often linked, in turn, to the presence of prejudices and beliefs that further reduce the effectiveness of practices. The high psychiatric needs of people with DID are not adequately addressed by mental health services and delays in detection, assessment, and treatment often lead to a progressive deterioration of psychological and behavioral conditions. Furthermore, there is an excessive prescription of antipsychotics, neuroleptics, and psycholeptics [21]. Literature indicates that some pharmacological treatments have been shown to be effective on certain behaviors, but it is not possible to define specific therapeutic relationships [22].[2] Although their efficacy has not been proven, mood stabilizers, neuroleptics and benzodiazepines, as well as selective serotonin reuptake inhibitors, and new generation antipsychotics, are often prescribed. Polypharmacy is also common in people with disabilities even if it is not supported by evidence. Great attention must be paid to the ethical implications of drug treatments in people with DID. Research in this field has been severely limited by ethical concerns related to the inability of people with most severe DID to consent to participate in randomized and controlled trials for treatments. People with DID end up being deprived of the right to receive therapies based on strong evidence and being subject to unwanted effects of medications prescribed for unjustifi-

2 For further reflections on psychopharmacology in people with DID, see ▶ Chap. 11 on this volume.

able reasons constitutes infringements of article 25 (and on occasions article 15) of the CRPD.

To date, health needs of people with DID remain largely unsatisfied, both in qualitative and quantitative terms. Discrimination and inequalities could be addressed by bringing a human rights-based approach in the pathways of access to healthcare provision and improving specific trainings for healthcare professionals.

42.5 Monitoring the Rights of Persons with Disabilities: An Overview

When monitoring the rights of people with DID, it is essential to start communicating directly with the person, if necessary through the use of augmented communication, tools, or support persons. The frequent exhortation from the disability activism of the 1990s of "nothing about us without us" is a cry for not only inclusion but also empowerment and enablement in being active agents in the determination of the quality of their own lives.

Monitoring the rights of people with disabilities requires us to ask what society has or has not done which is impeding the full enjoyment of their rights. For example, when monitoring the right to education, recognizing that negative attitudes and prejudice or inaccessible schools may underlie the person being unable to enjoy the rights to education [6].

Monitoring processes should be in place in order to evaluate whether States are respecting their obligations in relation to the rights set out in the Convention; the use of the World Health Organization Quality Rights toolkit quoted above is one example. Monitors should ensure that they understand the Convention's relevant articles and apply the "respect/protect/fulfill" framework accordingly [6].

Comprehensive and effective monitoring includes reporting, corrective action, and follow-up. There should be a process of assurance that the monitoring report has provided a complete and adequate summary together with clarity of recommendations and responsibilities for subsequent corrective action.

It is fundamental to bear in mind the central role of persons with disabilities in monitoring activities. The Convention states that this role must be continuous, requiring States parties to "closely consult with" and "actively involve" persons with disabilities in decision-making processes related to them (Article 4). According to article 33 of the Convention, "civil society, in particular persons with disabilities and their representative organizations, shall be involved and participate fully in the monitoring process" [5]. Besides being included, opinions and experiences of persons with disabilities must be central in the monitoring process since they are the experts on their own situation. It is also important to ensure that the monitoring of the rights of persons with disabilities involves all persons regardless of their types of disabilities and from all socio-economic and ethnic backgrounds or age groups.

Tip

Monitoring process should not strengthen an approach that considers persons with disabilities as intrinsically different from others. The *voice* of *people with disabilities* produces important reflections in the field of human rights protection and significant examples of monitoring disability policies.

42.6 Conclusion

Due regard to human rights highlights the fact that people with disabilities too often experience segregation and social exclusion in society, they are subject to discrimination, and in mental healthcare are in receipt of differentiated, poor quality, and degrading treatment. There is a pervasive violation of their human rights.

The protection of human rights is linked not only to respect for individual freedoms but also to the cultural and social construction of inclusive societies, where prejudices

and barriers are eliminated and everyone can live without his personal characteristics being stigmatized. This opens up a new field of cultural and political action that involves society as a whole: a way of including human diversity within societies and within models of economic and social development. The specific theme of the reformulation of the cultural and social vision of disability becomes a paradigmatic example for the comparison with ideologies that have become "common sense," built on secular practices of segregation and exclusion [23]. The new social universe must be based on a pervasive approach to the construction of environments, goods, and services, on the basis of equal opportunities for all citizens and elimination of any form of discrimination.

Key Points

- The adoption of the UN Convention on the Rights of Persons with Disabilities reinforced a key paradigm shift with the move from the medical model to the social and rights-based model
- A human rights-based approach ensures that rights such as dignity, non-discrimination, participation and inclusion, respect for difference, equality of opportunity, and accessibility are upheld and secured for all.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_43

Learning Objectives

This chapter's primary objective is to provide information on the use of telehealth, specifically teleassistance and telerehabilitation, for PwID/ASD in a condition of epidemic emergency and in general. Most frequent TA and TR activities are reviewed, together with their prerequisites, ways of use, objectives, efficacy, and limits.

43.1 COVID-19 Outbreak and Associated Vulnerability and Support Needs for People with Intellectual Disability and Autism Spectrum Disorder with High and Very High Support Needs

Intellectual disability (ID) and autism spectrum disorder with high support needs (ASD-HSN) represent the two neurodevelopmental disorders with the greatest negative impact on communication skills, self-insight skills, and individual functioning. Furthermore, these conditions have a high co-occurrence of physical and psychiatric disorders [1], significantly higher and with earlier onset than the general population. They can often be found together in the same individuals [2, 3], thereby causing an even more complex vulnerability [1].

People with ID and/or ASD-HSN (PwID/ASD-HSN) belong to one of the populations most vulnerable to the COVID-19 epidemic and related stressors due to several factors: multimorbidity, low levels of health literacy, the difficulty in following complex hygiene rules, the high need to maintain daily routines, and the dependence on other subjects for their health care.

Physical multimorbidity includes endocrine diseases, hypertension, respiratory problems, cancer, and other conditions associated with a higher risk of severe acute respiratory distress syndrome and other COVID-19 (SARS-CoV-2) complications.

Research on previous respiratory viral epidemics, including influenza A virus (H1N1) and respiratory syncytial virus (RSV), indicates that people with genetic syndromes counting ID and ASD-HSN are more likely to develop complications and need hospitalization than the general population [4–6].

A preliminary study about COVID-19 sequelae risk rate was initiated in mid-March by the Italian Society for Neurodevelopmental Disorders (SIDiN) in reference to the whole Italian territory.

The data collected so far concern 660 cases of only six regions (Tuscany, Lombardy, Emilia-Romagna, Piedmont, Campania, and Sicily); data indicate the presence of severe-critical symptoms in a much higher percentage than the general population (19–51% vs. 15.6%). Variability mainly depends on the epidemic area and housing condition.

Another recent study conducted mainly on the USA territory through the TriNetX COVID-19 Research Network platform has contributed to validate the notion that COVID-19 can present a greater risk to people with intellectual and developmental disabilities [7]. The study has been conducted to explore the trends in comorbidities, number of cases and number of deaths, and case-fatality rates among patients with intellectual and developmental disabilities who received a diagnosis of COVID-19 through May 2020. The results have shown that this population had a higher prevalence of specific comorbidities associated with poorer COVID-19 sequelae. Moreover, distinct age-related differences in COVID-19 trends were reported, with a higher concentration of COVID-19 cases at younger ages [7].

For what concerns psychiatric vulnerability, PwID/ASD-HSN have a very high rate of psychiatric disorders, with a lifetime prevalence of up to 44% or even higher when the two conditions are associated. Anxiety and affective disorders are the most frequent disorders. The disorders' symptoms are often quite different from the general population, especially in people with low or absent verbal communication skills, who express themselves only by problem behavior [8]. Therefore, the comorbidity of unidentified psychiatric disorders is also very high in PwID/ASD-HSN, with prevalence rates estimated above 50%, even in specialized support settings.

Because of difficulties in understanding and communicating, the high need for routine and for predictability, low adaptability, and the probability that the environmental and social changes associated with the pandemic may cause psychological distress, or even psychopathological problems in PwID/ASD-HSN is very high. Previous epidemic studies indicate that the drastic changes in the daily routine (e.g., restriction or interruption of regular activities, places, and interpersonal contacts), forced coexistence, loss of support, and extended perception of loneliness can determine regression, loss of ability, psychological distress, and physical disturbances in these subjects [9–12]. Furthermore, the risks associated with the epidemic may also relate to the appearance or aggravation of problem behaviors, such as stereotypies, self-stimulation, self-injurious, aggressive behaviors toward objects or other people, and oppositional behaviors. The mere reduction of interpersonal contact can exacerbate problem behaviors [13]. The high prevalence of problem behaviors in PwID/ASD-HSN has been associated with a proportionate frequency of psychiatric disorders [14–19]. In fact, in PwID/ASD-HSN with severe cognitive and communication difficulties, psychiatric symptoms are expressed with significant behavioral changes [20–22], including the presence or the aggravation of problem behaviors. Obviously, problem behaviors can also be related to many other factors, such as physical pain or unspecific emotional reactions to stress.

The symptoms of mental suffering related to the COVID-19 epidemic during the lockdown phase were the subject of a survey of the Italian Society for Neurodevelopmental Disorders (SIDiN) conducted throughout the national territory since April 2020. Two adaptations of an online questionnaire (short and easy to complete) were anonymously submitted to caregivers and family members of persons with ID living with family or in small apartments in the community, and to operators of social-health residential services for PwID/ASD. In total, 56.9% of caregivers/family members who answered the questionnaire referred to persons with co-occurrence of ID and ASD, 27.7% to PwID, and 15.4% to PwASD. On the other hand, most healthcare professionals referred to PwID (66%), 30% to people with co-occurrence of ID and ASD-HSN, and only 4% to PwASD.

Preliminary results on persons living with family or in small apartments in the community indicate an increase in agitation (53.8% of the sample), irritability (52.3%), sleep disturbances (54%), increased appetite (43.1%), stereotypies (43.1%), soliloquy (30.8%), and social withdrawal (27.7%). Moreover, 29.2% needed the activation or modification of psychopharmacological treatment for the management of problem behaviors. This data support experts' opinions, which were already being expressed since the early days of the mass quarantine on a risk increase of behavioral and mental issues [23, 24].

Preliminary results on persons living in social-health residential services indicate an increase in irritability in 21.4% of the sample and agitation in 14.5%. Other behavioral changes were present in less than 14% of the sample. Many operators declared that significant changes were not observed in about 50% of cases during the mass quarantine in the free annotations section of the questionnaire. In total, 93.9% of the cases did not require the activation or modification of pharmacological interventions.

In general, the behavioral changes detected could reflect an increase in anxiety associated with psychopathological and non-psychopathological syndromes. In fact, irritability, psycho-motor agitation, and stereotypies increase have been listed among the typical behavioral equivalents of anxiety in PwID/ASD-HSN [8]. Many behavioral changes associated with affective disorders, such as increased closure to others, changes in appetite, and insomnia were also found in the sample of people living in families or small apartments in the community [8, 25]. These alterations could be related to the loss of important activities – before the mass quarantine, 52.3% of the sample attended day centers and 75.4% recreational associations.

PwID/ASD-HSN families have a greater vulnerability to distress compared with families of the general population [26, 27], especially if the PwID/ASD-HSN has entered adulthood since a long time [28].

These are often single-parent families and/or with elderly parents and/or with autistic traits [29]. These parents find it challenging to offer social support to their sons, have low coping strategies, and present a high risk of developing affective disorders [30, 31].

Problem behaviors, interpersonal conflicts or tensions, and lack of social networks are frequent even in ordinary life and negatively impact the quality of PwID/ASD-HSN's family relationships.

For all these reasons, remote assistance could usefully provide various support needs, especially through their integration, as far as possible, with traditional interventions. During the COVID-19 emergency, for the purpose of health protection, methodologically rigorous and easy-to-use interventions through the use of technology were requested.

People with ID and/or ASD-HSN belong to one of the populations most vulnerable to epidemics and related stressors. Risks may also relate to the appearance or aggravation of problem behaviors, such as stereotypies, self-stimulation, self-injurious, aggressive toward objects or other people, and oppositional behaviors. Problem behaviors can reflect an increase in anxiety or mood alteration associated with psychopathological syndromes.

43.2 Care Needs Manageable Through Telemedicine Services

Persons with developmental disabilities represent potential users of telemedicine services together with persons suffering from psychiatric disorders, chronic diseases, rare diseases requiring constant contact with healthcare structures and health practitioners, people who need special non-deferrable supports, including psychological supports, or people who require long-term treatments that are usually managed by territorial services or residential structures.

During the 2020 COVID-19 health emergency, service providers had to manage the activation and continuous implementation of interventions for many PwID/ASD-HSN in quarantine or fiduciary isolation. These interventions were necessary to guarantee continuity of care even during the emergency period due to the pathological conditions and the frailties described. All these needs have been addressed in sanitary emergency conditions, with a lack of material and human resources and the extreme obligation to respect the anti-contagion rules for the protection of staff, PwID/ASD-HSN, and their families. Therefore, remote interventions were indispensable [32]. Many leading technical-scientific bodies of different countries have indicated that these telehealth services must be provided primarily through updated digital and telecommunication technologies that can ensure more appropriate support opportunities than the previous technologies.

The realization of remote interventions requires first to consider the relational needs of people with disabilities with the social-educational-health system.

The isolation within one's home or the inability to access services in person makes it particularly desirable to be able to count on a service that can be easily used remotely, being able to quickly access the interview with health professionals and educators, as needed.

PwID/ASD-HSN and/or his family or caregivers may expect to receive the solution of their problem already through the first telematic contact or at least to perceive the concrete possibility of being assisted effectively and safely for any need. In case these expectations are not met, they will tend not to trust the proposed system and not to use it, especially when they are faced with urgent needs.

This kind of relationship dynamics between users' needs and resources offered are very frequent in all assistance and health services; in remote services, they are even more intense due to the interposition of technologies and related relational limits, including the possible difficulty in the use of technologies by PwID/ASD-HSN and their families.

It is essential to set up the remote service by analyzing the different possible situations of its use and the different types of needs of the persons to whom the service is addressed.

The literature indicates a higher possibility of direct fruition by people who have residual cognitive and communicative skills, while people with higher levels of impairment require a constant mediator/assistant's support [33, 34].

In order to counter the spread of the infection and to monitor any clinical aggravations related to COVID-19, the national health system of many countries has identified four types of people for whom it was necessary to provide isolation and home health checks:

1. Asymptomatic person who had contact with a positive COVID-19 case (quarantine up to 14 days from the last contact with the positive case)
2. Paucisymptomatic person who had contact with a positive COVID-19 case, with a negative COVID-19 test (isolation up to 14 days from the last contact with the case)
3. Paucisymptomatic person with positive COVID-19 test (isolation until tests become negative and symptoms disappear)
4. Person discharged from the hospital as clinically healed but still positive to SARS-CoV-2

These epidemic contrast actions can be performed by health services that operate in telemedicine with numerous advantages, such as (a) monitoring at home, the evolution of clinical and health conditions of suspected asymptomatic subjects or subjects presenting mild or moderate symptoms of illness; (b) considerably contain the risk of contagion even in situations where the quantity of positivity tests for COVID-19 is insufficient; and (c) reduce any difficulties of the health system.

Telemedicine interventions may be appropriate for PwID/ASD to manage some care needs related to their condition (impairment and disability), physical and psychological co-occurring problems, including symptoms of an epidemic disease and for the limitation of contacts and access to services determined by the epidemic emergency. However, it is important to clarify that telemedicine should not be used to perform home medical treatments for people with severe illnesses who instead require intensive hospital care.

During an epidemic emergency, telemedicine can be appropriate for PwID/ASD to manage several health, rehabilitation, and assistance needs, in respect to both the prevention and treatment of the epidemic illness and the continuity of care necessary for the condition of developmental disability and co-occurrent physical or mental disorders.

43.3 General Objectives of Teleassistance and Telerehabilitation Services

In telemedicine, although innovative, technology is used properly only when it allows progress in healthcare practice. During an epidemic emergency, the main objective of teleassistance (TA) and telerehabilitation (TR) services for PwID/ASD is to provide health, rehabilitation, and assistance interventions to persons in isolation in order to proactively monitor their health conditions concerning both the prevention and treatment of the epidemic illness and the continuity of care necessary for the condition of developmental disability and associated disorders.

This general objective is useful for directing organizational actions within the framework of evidence-based methods, which can also facilitate implementations and optimization of service delivery. However, further aims have to be taken into account to meet every service user's specific needs. Programming telemedicine services requires to identify diagnostic, therapeutic, educational, and care practices appropriately that can be carried out remotely, through technologies that are available and usable by persons with different levels of disability.

The Health and Socio-Educational Team (HSET) in charge of treatment must choose from time to time what setting and technology are the safest and effective for the person to care. It should not be thought that PwID/ASD-HSN can find in technology, however advanced, a unique solution to their problems. People can achieve concrete improvements through technology only if used appropriately within a clinical approach

aimed at the care of the individual and not at the use of technology [32].

TA and TR objective must be aligned with the more general objective of every individualized therapeutic and rehabilitation plan, which is to promote and favor the quality of life of the PwID/ASD-HSN.

The individualization of the objectives, tools, and methods of service delivering should be based on a generic (whole-person) Quality of Life model, both in reference to the person with ID/ASD and their family. Most comprehensive Quality of Life models and tools are those that envisage: (a) a broad articulation of the area of Being/Well-Being, which includes spirituality; (b) a multidimensional assessment of individuality, including at least the dimensions of importance and satisfaction; and (c) an integration of direct assessments on the PwID/ASD, when possible, with assessments carried out through external informants (at least two and at least one of which should be represented by a family member) [35].

Generic quality of life represents the best framework for defining and sharing therapeutic and rehabilitative goals by technicians, PwID/ASD, family members, and other significant figures, upon which to establish a good therapeutic alliance and through which to promote good compliance with interventions.

TA and TR objective must be aligned with the more general aim of every individualized therapeutic and rehabilitation plan, which is to promote and favor the quality of life of the PwID/ASD.

43.4 General Principles for Teleassistance and Telerehabilitation Services Implementation

Teleassistance (TA) is a support modality, operated remotely by professionals with direct or indirect interaction on the local system. Direct interaction occurs when the assistant can directly operate in full autonomy with the PwID/ASD, sending instructions, indications, or comments and analyzing their responses without any local intermediation. This type of remote assistance is possible only with PwID/ASD who have fair cognitive and communication skills and are able to use technological devices. Productivity is high in the direct interaction setting, as the duration is limited to the time strictly necessary to carry out required tasks.

TA with indirect interaction takes place with the intermediation of a subject on the local side, which can be represented by a family member, a habitual caregiver, or a technician, depending on the type of assistance requested. For indirect TA, the remote assistant needs good technical and relational skills to correctly provide and interpret instructions even in the presence of technical problems. It is worth underlining that this modality of interaction is often preferred by users, as the human presence is perceived as an added value. In the indirect interaction setting, productivity can be significantly lower than in the direct one, due to the non-determinability of the time to spend with the remote assistant.

Telerehabilitation (TR) is a form of telemedicine that allows providing remote rehabilitation services directly at the patient's home or in another place chosen by them. TR uses different types of telecommunication technologies, including telephone, video, websites, and computer programs, to support the patient in the type of rehabilitation required. In some cases, virtual reality and robotics are also used [36].

TR activities include psychological exercises, learning tasks, physical movements, and behavioral techniques, which are defined by the HSET based on individual needs and carried out through most suitable devices, software, and IT applications. These applications are often integrated with video cameras that allow the HSET to monitor patients' health conditions and progress. TR allows the continuity of some positive characteristics of the normal educational-therapeutic relationship. The patient can continue to receive feedbacks for their needs and to achieve positive treatment outcomes, and the HSET can continue to use a personalized approach to care, adapting structures and interventions to the needs and abilities of the user.

In case the HSET needs to choose between different care and rehabilitation options (i.e., getting on with home care or hospitalizing the patient after an episode of severe self-injury or aggression toward family members), the following relevant technological aspects should be considered:

- Preliminary conditions for making telemedicine service possible
- Health responsibility during telemedicine activities
- List of the elements and tools necessary to carry out home services
- Effectiveness of telemedicine services
- Initial steps to activate the service

Further information on the correct use and problem management of digital and telecommunication technologies is available on the documents produced by experts in the field [37, 38].

TA and TR are operated remotely by professionals with direct or indirect interaction with the PwID/ASD. Direct interaction is possible only with PwID/ASD who have fair cognitive and communication skills and are able to use technological devices. Indirect interaction takes place with the intermediation of a subject on the local side, which can be represented by a family member, a habitual caregiver, or a technician. TR uses different types of telecommunication technologies, including telephone, video, websites, computer programs, virtual reality, and robotics. TR activities include psychological exercises, learning tasks, physical movements, and behavioral techniques, which are defined by the HSET based on individual needs and carried out through most suitable devices, software, and IT applications.

43.5 Effectiveness and Limits of Teleassistance and Telerehabilitation

Studies on TA and TR's efficacy for PwID/ASD-HSN are limited in quantity and quality, especially concerning adulthood. Most of the studies are represented by case reports or case series, only a few relatively large-scale cohort studies have been produced. No randomized and/or controlled studies were found. Almost all the studies used pre-post evaluation, questionnaires, and interviews to determine interventions outcome. No comparisons were made with traditional "face-to-face" interventions.

More than 90% of the studies used the satisfaction of service users (people with disabilities, family members, other habitual caregivers, professional assistants, clinicians who assist the person with disabilities in the use of the service, etc.) as the only outcome measure. Other outcome measures were also used in some studies based on specific objectives, including physical functioning, mental state, communication skills, self-care skills, cost and time savings, duration of service, number of hospital admissions, and objectives achievement. The duration of the interventions varies across different studies from a few hours to 2 years.

Most of the available studies report a high level of satisfaction from professionals, family members, and other caregivers [39–42]. One of the main positive factors has been identified in the possibility of avoiding travels to reach face-to-face services, often requiring complex organization, personnel, and equipment, and identified as a cause of distress and/or problem behaviors in many PwID/ASD-HSN.

TR showed efficacy in improving cognitive and adaptive skills in children and adults with ID and/or multiple disabilities [41, 43]. In collaborative occupational therapy with parents of children with ASD, it was able to increase carryover of home programs by providing opportunities for parents to ask questions, review sensory techniques, and understand the therapist's clinical reasoning [44]. In aging persons with Down's syndrome, it has been usefully inserted in programs for the prevention of cognitive decay [45].

TA has been found to be quick to obtain and easy to perform, families often receive rapid reassurance with respect to doubts of symptoms or prompt advice for the management of problem behaviors [39, 40]. This helps

family members and caregivers to become more confident in their ability to independently determine the severity of various difficult situations and when professional intervention is needed. Many family members and caregivers have shown good skills in using the technology for TA and TR or good learning skills of how to use them [39].

When preceded by face-to-face interventions (as in the case of normal rehabilitation practice before a mass lockdown), TA and TR interventions showed the ability to maintain a good relationship with the HSET and to keep on working on simple rehabilitation targets, both directly with the PwID/ASD and through the mediation of their caregiver as well as to provide useful suggestions and advice for the management of ordinary and extraordinary activities or critical episodes [33, 46].

Especially with adult users, family members have often moved from a position of delegation and dependence with respect to professional figures to a proactive position, discovering new empowerment skills in the relationship with the PwID/ASD, expanding the range of educational strategies, and promoting positive and collaborative interactions. This active participation of the parent in the definition of the enabling objectives for the PwID/ASD and of the intervention projects to achieve them has often allowed him/her to understand their importance better, renewing and strengthening the alliance with the operators. However, it has also fostered a wider capacity for recognizing and enhancing the characteristics and potential of the PwID/ASD-HSN, mitigating concerns for the future. Regular video calls have been shown to have a reassuring effect for the user and the caregiver and give continuity to the relationship with the HSET and the previously done rehabilitation work. They also reduce the distance between the rehabilitation center and the home, allowing the center's professionals to witness some dynamics and activities of domestic life and to widen the knowledge of the PwID/ASD and his family [39–42].

Even the interventions based on applied behavioral analysis principles seem to be well achievable through the TA and TR systems. Some researchers and clinicians have defined specific techniques and processes in this regard [47, 48].

The main limit is represented by the lack of all aspects of the therapeutic relationship related to physical interaction, so TA and TR have to be considered integrative and not substitutive of traditional (face-to-face) care. Other important limitations are represented by PwID/ASD-HSN's and their caregivers' ability to use the technology for TA and TR and the availability of the technology itself (lack of devices, bad connection quality, etc.). Further possible problems include privacy, informed consent, the definition of costs, and the cultural attitude of an entire community context [39, 49].

The presence of family members or other stimuli associated to the home environment can be a distracting factor and reduce the effectiveness of TR interventions compared to those in presence and appropriate setting. In respect to assessment and clinical interventions for psychopathological aspects, some studies have revealed difficulties in carrying out remotely [50] and favoring pharmacological rather than holistic approaches [51]. Other studies did not find significant differences or even suggested aspects of superiority compared to traditional in-person visits [39, 52–54]. Telepsychiatry has satisfied almost all users and professionals included in specific trials, has been associated with a marked reduction in access to emergency services and hospitalizations, and has resulted in costs for services provision significantly lower than those of traditional psychiatry [51, 54, 55].

Studies on TA and TR's efficacy for PwID/ASD-HSN are limited in quantity and quality, especially concerning adulthood. Available literature shows effectiveness on (a) improvement or maintenance of PwID/ASD's cognitive, adaptive, and occupational skills; (b) management of PwID/ASD's ordinary and extraordinary activities or critical episodes by family members or other caregivers; (c) empowerment of caregivers' skills in the relationship with the PwID/ASD, expanding the range of educational strategies, and promoting positive and collaborative interactions.

Compared with traditional face-to-face services, main advantages have been identified in higher availability and accessibility and shorter physical and psychological distance between the rehabilitation center and the person's home. The main limits are represented by the lack of all aspects of the therapeutic relationship related to physical interaction, possible poor ability to use technology, availability of the technology itself, privacy issue, and distracting factors associated to the home environment.

43.6 Prerequisites for Teleassistance and Telerehabilitation Services

In the short time allowed by the health emergency, the preliminary conditions' assessment takes the place of the phases of analysis and study preparatory to a detailed plan of the telemedicine services. This assessment must be straightforward and capable of being done quickly; it clearly has significance for the fact that the services have been and must be implemented within a short timeframe.

The preliminary conditions' assessment needs to be carried out with reference to the service provider, the user, and the territory where they are located. It must also consider the technological, health, and regulatory aspects, reporting territorial information and user needs. The decision about the possibility of providing TA and TR services during an epidemic emergency should be made on the conditions described in the following paragraphs and summarized in Table 43.1.

43.6.1 Conditions Referring to the Telecommunications Infrastructure

The technologies for delivering TA and TR services can be assigned to three main groups:

1. Telephone calls, text messages, interactive voice response (IVR) systems, and e-mail
2. Video calls (VC) using technologies such as Skype or WhatsApp
3. Specific applications for telemedicine services

Telephone calls, text messages, IVR systems, and e-mail can help organize, encourage, and remember TA and TR activities, but not for carrying out the activities themselves. They are also much more challenging to use for most individuals with ID/ASD-HSN [40, 56].

In more than 80% of the available studies, the assistance and treatments were provided

Table 43.1 Prerequisites for teleassistance and telerehabilitation services

Prerequisite	Teleassistance specification level	Telerehabilitation specification level
Connectivity to the domicile	5	5
Connectivity of the work station from where the socio-educational/healthcare personnel will take action	5	5
Accessibility of the service	5	5
Time schedule for providing the service	5	2
Security of personal data	5	5
Autonomy in the use of digital systems (by the recipient)	2	2

The authors of this document's specification levels have been indicated based on a Likert scale from 1 (minimum) to 5 (maximum)

through VC, with different technologies based on the type of assistance/treatment and suitability for the user. In the remaining studies, a website-VC combination or a store-and-forward technique was used [40]. The latter approach provides that information, even in the form of video, which is sent to an intermediate station where it is stored and transmitted later to the final destination or another intermediate station.

It is important to emphasize that the recipient's ability to connect represents the actual technological limit for any service employing information and communication technologies (ICT). In recent years, ICT and VC systems, which are the basis of telemedicine services, have developed significantly in Italy, but problems of availability and operation are still frequent among individuals with ID/ASD-HSN [40]. Poor connectivity can be caused by various infrastructural factors or the type of service made available by the telecommunications operator. For example, in-home users often experience a marked difference between the download transmission speed compared to the upload speed, with the consequent possibility that an in-home user will receive much more data within a specific unit of time than what he can send. A common consequence of this problem is a low quality of images coming from a patient in his home – a quality insufficient for use. Simultaneously, the observation of mimicry, gestures, and behaviors is critical for the technicians providing remote services [32].

In emergencies, it is sufficient to check to determine:

- If the person has a WiFi or cable connection, compatible with good data exchange
- If the person is at a correct distance from the router during connections
- If the person has digital devices that can be connected to the network and the type(s) of devices (e.g., smartphone, tablet, laptop, and/or desktop)
- Whether the person's computer or other digital devices have a video camera, microphone, and headphones
- If the person also has digital medical devices and their level of connectivity (WiFi or Bluetooth) on the network or with other devices that can be connected on the network

Services providers should advise users to download apps compatible with all smartphones and with simple log-in procedures.

Within the social-healthcare facilities, the operational work stations usually enjoy optimal connectivity. However, tests are recommended to check connection speed and verify the local network's real possibilities to support data traffic for the average volume of simultaneous download and upload requests. Such tests will be useful for: (i) ensuring the proper functioning at the time the services are rendered and (ii) documenting the quality of the work done during the emergency period. It is also recommended that the social-healthcare facilities equip themselves with various communications systems (e.g., SMS, e-mails with encrypted texts, video communications, and so forth). Video calls should be made with systems that are easy for the patient to use, directly from the app, preferably with web-based systems that do not require any installation of software on the device used.

43.6.2 Conditions Referring to the Treatment Services Provider and the Territorial Healthcare Organization

A TA service inclusive of treatments upon request should entail the same hours of operation generally provided before the implementation of the COVID-19-related precautionary measures. In doing so, the service provider can help people in isolation or at a distance for as long as possible and encourage a better quality of use by the service recipients. Experience and research indicate that the certainty of having a service available for extended periods usually prompts people to make more rational and less emotional use of the service [32].

It follows that, if the remote service is well structured from the start, with different activities sensibly offered over an extended time interval, it is possible to calibrate and orga-

nize the workload in a sustainable manner without the need for a huge number of operators. If it is not possible to offer the remote service over the usual time interval, or if it is deemed inappropriate to adopt the usual time interval, then it would become significant to explain to the user, from the very first contact, not only the rules of access and use by electronic means, but also a clear and exhaustive description of the alternative procedure to be followed at times when the service is not available.

For TR, it is possible to predefine with the user the times when the services will be rendered. TA and TR services require the acquisition of new skills by the professionals rendering the services. Therefore, it is useful to conduct training as soon as possible to address the use of telecommunications tools and the understanding of the peculiarities of the remote communications/interaction dynamics for two parties and groups, with particular reference to the treatment relationship. Teamwork should also be redefined and tested for specific needs.

The acquisition of trust and confidence in TR on the part of the professionals who must deliver the service is critical to the treatment's success, especially during the phase of building a treatment relationship.

43.6.3 Conditions Referring to Personal-Data Security and Digital Devices at the User's Home

The management of cybersecurity and data processing issues cannot be entrusted to improvisation, or even worse, abandoned, without excessively increasing the risk of intrusions, criminal activities, and improper use of patients' health data.

The socio-educational/healthcare workers who engage in telemedicine are required to observe the rules concerning the correct processing of patients' data and to avoid any behavior that can facilitate cyber-attacks. In this regard, it is noted that the behavior required by professionals to protect patients' personal data is simple and do not presuppose specific technical knowledge.

Concerning cybersecurity, the treatment facilities' remote-control systems must ensure the best possible IT security. Using impromptu solutions with social media platforms should be reserved for situations where it is impossible to pursue any other method and should be limited to the shortest possible time.

On the other hand, high standards of cybersecurity cannot be expected from the patient. In making remote services possible, particularly during this emergency, the telemedicine system must necessarily leverage the use of the devices at the patient's home, addressing the related risks as best as possible.

Adequate disclosures are needed to inform patients at home, and without needless red-tape, of the procedures concerning the risks for data security and cyberbullying in relation to the system used.

The commercially available systems dedicated to healthcare are practically all compliant with the EU General Data Protection Regulation ("GDPR") No. 679/2016 to which they had to adapt before the health emergency. Should particular situations arise as a result of the health emergency status, whereby the application of the data-processing rules would prejudice the provision of services, it would then be advisable to agree on a specific solution with the regulatory authority responsible for the personal data processing. Given the market presence of GDPR-compliant systems, there is no justification for not applying the rules, even in an emergency.

The rules relating to the certification of the medical devices that ID/ASD patients can use at home as part of TA and TR services are complex, have relevance for the sector's technicians, and are not detailed in this document. According to the primary reference standard (EC Directive 93/42), software programs that provide healthcare professionals with useful elements for making decisions for the patient are considered to be medical devices and, therefore, they must have adequate certification to be used. The certification mentioned above provides for different classes that correspond to increasingly stringent quality and safety requirements consistent with the

intended use. When delivering medical care procedures remotely, health professionals remain liable for the use of any software that is not certified for the use or is of unknown and non-verifiable origin (as could happen for software downloaded indiscreetly).

43.6.4 Conditions Referring to the In-Home Patient's Capability to Cooperate

In addition to sophisticated technological systems, telemedicine services also require the capacity of individuals to interact with these systems. For a telemedicine service to function correctly, the patient must be trained in its use. Over the years, the practical importance of networking has been better understood. Nowadays, many individuals with ID/ASD have better learned how to use network services, with various forms of tutoring. The service provider's staff needs to verify the extent to which the patient can interact with the necessary technologies. However, many ID/ASD patients are unable to use internet connection devices, obviously not only because of training deficiencies but because of the primary impairment of their learning and relationship skills. In such cases, the person needs a mediator for interacting with the service provider. Sometimes even family members or other habitual caregivers can have difficulty managing connections, both with regard to external parties and devices in the home.

Because of these problems, it is advisable that graphic interfaces are as intuitive and straightforward as possible, that the instructions are simple to follow and available both verbally and in writing, and that the staff in charge make the first contact with the recipient of the service, or with his caregiver, by means of a phone call. This first contact makes it possible to explain the type of service offered and indicate the most appropriate way to connect via video call for further and more detailed explanations and instructions. Numerous technological solutions available for video calls are easy to use, even from smartphones and tablets. During the dialogue in the first video call, information may also be requested to assess the extent to which the person can work with the available system, particularly with respect to sending the data to the referring doctor. Although many telephones, ADSL and fiber operators currently offer contracts with Internet traffic that is unlimited or high-volume and thus more abundant than what a person needs typically in everyday use, it is advisable to notify any patient who will receive TA and, more importantly, TR, that data traffic will necessarily be higher than usual with the activation of these services.

In general, the contents and the methods for delivering TA and TR must be defined from time to time based on the characteristics of the users of the service (e.g., the age and the degree of cognitive skills) and the service providers (e.g., the level of understanding of individuals with ID/ASD).

It is advisable to optimize the comfort levels by paying attention to the "sensory dimension" and the "clarity/comprehensibility" of the experience [57].

The expression "sensory dimension" refers to the sense-perceptive elements, especially visual and auditory sense-perceptive elements, which could distract or disturb an individual with ID/ASD. Elements to be considered include shaky images; continuous changes in the background; excess brightness; flashing screens; and excessively loud or confusing noises. The use of monitors needs to be carefully assessed, with respect to the type and the duration for the many individuals with ID/ASD-HSN who also have photosensitive epilepsy.

With the "clarity/comprehensibility" of the experience, reference is made to the extent of the structuring and the organization of services. Precise sequences, clear steps, and routines can foster a sense of predictability and control. The words, the contents of the communication, and the interactive methods (e.g., in terms of length of the statement, the tone used, the speed of speech, etc.) must be aligned with those that have proven to be the most effective over time for each ID/ASD patient.

The sensory dimension can be controlled through the choice of devices in relation to

the skills of people who use them. For example, the images captured by a smartphone or tablet in the hands of a person who tends to move about will be much shakier or blurred than those of the same devices fixed to a support or a PC. The stimuli that can pollute the sensory field of remote interaction can also be controlled by choosing the place and time for making the connection.

43.7 Type of Teleassistance and Telerehabilitation Services

When planning TA and TR services, it is crucial to do a specific-needs assessment using ad hoc tools. The assessment is necessary to become familiar with the ID/ASD patient's clinical-functional conditions and those of his family unit and the family's social support network. The assessment becomes the basis for arranging calibrated activities, according to an order of priority dictated by the urgency and seriousness of each situation.

TA and TR services can fulfil the following functions:

- Psycho-diagnostic assessments during the emergency
- Management of urgent situations
- Psycho-education
- Individual and/or family support
- Direct and indirect treatment [40, 58–61].

TR can be done individually or in small groups.

Concerning the psycho-educational function, it is essential in the emergency phase to provide the ID/ASD-HSN patient and his family members/caregivers with information about: the virus and the epidemic; hygiene and health standards; restrictions concerning routine activities; new ways of relating to others; physical and/or psychological symptoms that could arise due to distress (e.g., neuro-vegetative symptoms, insomnia, appetite changes, panic, depression, etc.); and services available (e.g., grocery delivery, online medical prescriptions, and assistance in hygienic/sanitary practices) through local services, residential structures, and day-care centers.

The psychological support function can be addressed to the individual with ID/ASD-HSN and those who interact with the individual, thereby ensuring the continuity of the relationship with the key-contact professional and possibly with the treatment facility frequented by the individual. Through this approach, it will be possible to moderate the feeling of loneliness, to ensure the availability of the professional's involvement in the event of an emergency that is difficult to manage, to explain information from the mass media that is not always comprehensible, and to avert distress through a series of therapeutic strategies.

The treatment function can be remotely implemented directly not only by the professional but also through the training and telemediated support of the caregivers (family members and in-home occupational therapists who work together on the ID/ASD-HSN patient's treatment program).

Informational, educational, and treatment techniques that are specifically used are:

- Social histories
- Various types of documents translated into alternative augmentative communications (AAC) forms
- Video-modeling or video-coaching (direct or indirect, individual, or group)
- Video tutorials (direct or indirect, individual or group)

There is a diversified array of telerehabilitation activities, along with numerous objectives. The activities can involve the individual with ID/ASD, as well as his caregivers and family members. Below is a list of the most frequent, which is based on literature and the practices of the authors of this document:

- Communicate and converse to favor the reception and the appreciation of messages of affection, acknowledgment, consideration, encouragement, and counsel and to obtain answers to questions
- Perform tasks together (collaborate) through VCs

- Carry out activities to enhance coping skills and resilience to distressors and to reduce the risk of stress and other psychiatric disorders
- Parent-training initiatives
- Interviews aimed at assessing the quality of life
- Provide support for the self-compilation of tools for assessing the quality of life
- Conduct assessments and applied behavioral analysis, with particular reference to instructions and help to carry out an assessment of the ID/ASD-HSN patient's preferences and to define a hierarchy of rewards (e.g., tangible, social, symbolic, and dynamic)
- Practical indications for identifying the psychological/behavioral suffering of the ID/ASD-HSN patient in relation to changes linked to the epidemic, evaluating symptoms, and problem behaviors through diagnostic tools, functional analysis cards, or supervision of video documents
- Help in compiling the aforementioned psycho-diagnostic and functional analysis tools
- Help in identifying specific reinforcing stimuli to motivate the ID/ASD-HSN patient to carry out hygiene practices, personal and domestic care activities, possible educational activities, etc.
- Supply indications for managing states of psychological and behavioral distress
- Maintain interpersonal ("friendly") contacts with both the ID/ASD-HSN patient and his caregivers (family members or in-home occupational therapists involved in this phase) to reduce the possible feelings of solitude and the sense of abandonment
- Help to build daily and weekly visual agendas to organize the ID/ASD-HSN patient's time and to maintain a daily routine
- Indicate how to increase the skills of the family unit, for example, through video monitoring of relationship dynamics
- Provide support for the continuity of the previously defined treatment plan, with a definition of objectives to be pursued within the home environment and related strategies
- Engage in a shared structuring of educational, occupational or recreational materials for time management
- Supply indications for the acquisition of new skills
- Provide indications for reducing the sense of ineffectiveness and powerlessness
- Provide indications for mobilizing prosocial and spiritual resources that may have been subdued to rediscover pleasant family experiences

43.8 Other Indications for Organizing and Delivering Teleassistance and Telerehabilitation Services

In addition to the guidelines set out in the previous paragraphs, the authors of this document have formulated further indications to be followed for organizing and managing the TA and TR services provided to individuals with ID/ASD-HSN. They are shown below:

- Follow the planning criteria and outcome measures focused on the ID/ASD patient; the identification of the objectives, tools, and methods for delivering the services must be based on a generic quality of life (whole-person) model
- Consider schedules, expectations, lifestyles, and needs about the ID/ASD patient's entire family
- Check in with the ID/ASD patient, his family members, and other significant caregivers/professionals, at regular and predefined intervals to determine if the activities carried out are meeting the needs and expectations and, if necessary, renegotiate the objectives and tools to achieve them, based on the assessment of the individual quality of life
- Have frequent interdisciplinary discussions about the objectives and progress of TR, with the inclusion of the case manager and the psychologists coordinating the program

- In the case of individuals with ASD, it is essential that the operator knows of a possible tendency to avoid eye contact and how to manage it. It might be useful to avoid being too close to the camera (so that the operator's face does not appear too large on the patient's monitor) or to avoid a continuous search for eye contact, for example, by asking the person to turn his attention to something close to him or by sharing a screen of the operator's device to show the ASD patient an image that can be watched together

43.9 Indications for Delivering Psychological Support

The service is designed to allow the person in isolation to have contact with a psychologist or psychotherapist. The video call is activated at the request of the patient and/or family members, regular care providers, or legal representatives, using a procedure that allows for the service as soon as possible, based on the resources available, directly at the patient's home.

By definition, these types of activities cannot be standardized. Therefore, the professional care provider is urged to seek references to optimize delivery, ensure safe conditions, and apply scientifically correct methods.

The service does not entail medical assistance but solely consists of a conversation with a psychologist, which aims to support people in isolation suffering from discomfort, limitations on relationships, and fears caused by the specific situation. The board-certified psychologist interacts via video call with the people who request the service, and can agree on further video call sessions with the person once the first contact is established and where he deems it necessary. The conversations will nonetheless be subject to the Order of Psychologists' Ethics Code and will not be recorded.

Before starting a session, the psychologist should identify the person with whom he is conversing, using the most appropriate procedure.

Given the nature of the individual conversation (with the use of no equipment) and in consideration of the healthcare emergency, the video-call system for psychological counseling only requires functional connectivity to allow the psychologist to comprehend both verbal and non-verbal language during the session.

If amenable to the service users, sessions can be conducted with groups, with activities, for example, based on sharing facts, experiences, or moods.

Professional care providers must seek references to optimize delivery, ensure safe conditions, and apply scientifically correct methods. If amenable to the service users, sessions can include group activities, such as sharing facts, experiences, or moods.

43.10 Future Prospects

This work has been conceived in view of the COVID-19 health emergency. Consequently, the authors did not focus specifically on the implications of using telemedicine services beyond epidemic conditions.

Although TA and TR services for individuals with ID/ASD have been shown to be feasible and effective, it is unlikely that they will be able to replace traditional practices, at least in the near future. However, they could represent a supplement to an integration of or a temporary alternative to conventional practices. For this purpose, numerous insights would be necessary, especially regarding the indications of the various activities, the methodology for evaluating the different services, and the various methods of implementation in the integration of public services and publicly subsidized private services. The adaptability of the TA and TR services at the local level and the assurance of their operational stability over time are two other factors requiring further analysis.

Part of the future research will have to focus on the use of artificial intelligence, machine learning, and interactive avatars [62].

Tip

Future research should provide insights on indications, efficacy assessment, contextual implementation, and operational stability over time of specific TA and TR activities. Further investigations should address the use of artificial intelligence, machine learning, and interactive avatars.

Key Points

- People with ID and/or ASD-HSN belong to one of the populations most vulnerable to the COVID-19 epidemic and related stressors due to several individual and environmental factors.
- The risks associated with the epidemic may also relate to the appearance or aggravation of problem behaviors.
- Persons with developmental disabilities represent potential users of telemedicine services as other patients who need continuous support.
- During the 2020 COVID-19 health emergency, remote interventions were indispensable to guarantee continuity of care for many PwID/ASD-HSN in quarantine or fiduciary isolation.
- It is essential to set up a remote service by analyzing the different possible situations of its use and the different types of needs of the persons to whom the service is addressed.
- Programming telemedicine services requires to identify diagnostic, therapeutic, educational, and care practices appropriately that can be carried out remotely, through technologies that are available and usable by persons with different levels of disability.
- TA and TR objectives must be aligned with the more general aim of every individualized therapeutic and rehabilitation plan, which is to promote and favor the generic quality of life of the PwID/ASD and his family.
- TA and TR are operated remotely by professionals with direct or indirect interaction with the PwID/ASD. Direct interaction is possible only with PwID/ASD who have fair cognitive and communication skills and are able to use technological devices. Indirect interaction takes place with the intermediation of a subject on the local side, which can be represented by a family member, a habitual caregiver, or a technician.
- Studies on TA and TR's efficacy for PwID/ASD-HSN are limited in quantity and quality, especially concerning adulthood, even if the available literature shows some areas of effectiveness (e.g., improvement or maintenance of PwID/ASD's cognitive, adaptive and occupational skills; management of PwID/ASD's ordinary and extraordinary activities or critical episodes by family members or other caregivers) and some advantages (e.g., higher availability and accessibility and shorter physical and psychological distance between the rehabilitation center and the person's home).
- Compared with traditional face-to-face services, main limits are represented by the lack of all aspects of the therapeutic relationship related to physical interaction, possible poor ability to use technology, availability of the technology itself, privacy issue, and distracting factors associated to the home environment.
- The decision about the possibility of providing TA and TR services during an epidemic emergency should be made on evaluating the service provider, the user, and the territory where they are located as well as technological, health, and regulatory aspects.
- When planning TA and TR services, it is crucial to do a specific-needs assessment using ad hoc tools.

Acknowledgments We acknowledge the following experts for the contributions given to the identification of specific contents of the present chapter: Roberto Cutajar, Daniela Scuticchio, Michele Rossi, Michele Boschetto, Francesca Faggi, Francesca Poli, Daniele Mugnaini, Pier Franco Gangemi, Fabrizio Giorgeschi, Giampiero Lapini, Patrizia Panicucci, Giuseppe Mussi, Giulia Vannucchi, Anna Bevilacqua, Rita Di Sarro, Teodosio Maffongelli, and Maria Grazia De Lucia.

A special thank goes to Ms. Ann Pollak for her support in the English translation of some paragraphs of the chapter.
