Abstract

Disorders of the thyroid are one of the most common endocrinopathies in childhood and adolescence. The thyroid hormone is not only essential for metabolism and organ function but also plays a key role in the regulation of myelination of the nervous system. It is therefore crucial for normal growth and development in children. Thyroid hormone release is regulated by the hypothalamus and the pituitary gland. Therefore problems in thyroid hormones can occur as a result of disruption in the hypothalamo-pituitary-thyroid axis at any level.

Problems with the thyroid axis usually manifest as an underactive (hypothyroidism) or an overactive (hyperthyroidism) gland. The

most common cause of an underactive thyroid in children is congenital hypothyroidism (CHT) followed by autoimmune hypothyroidism or Hashimoto's thyroiditis (HT), the incidence of which peaks in adolescence. Introduction of the newborn screening test for CHT has facilitated early diagnosis and treatment of CHT improving outcome related to intellectual disability. Other rare causes of hypothyroidism include TSH deficiency in cases of secondary hypothyroidism which can be part of multiple pituitary hormone deficiency or rarely isolated. Hypothyroidism can also occur following surgical removal of the gland for Graves' disease or damage following radiotherapy for cancer treatment.

The most common cause of hyperthyroidism is Graves' disease which is treated with anti-thyroid drugs (ATDs) in a block and replace or dose titration regimen. The right approach is heavily debated in the medical field. ATD treatment is followed by definitive treatment with surgery or radioactive iodine if the patient relapses after stopping ATD. Another rare but serious cause of hyperthyroidism which carries a significant mortality rate if undiagnosed is neonatal thyrotoxicosis (NT). NT occurs in babies born to mothers with Graves' disease or HT. This is a transient condition which may require treatment with ATDs. Hyperthyroidism can result from thyroid nodules such as toxic adenoma or multinodular goitre or rarely following radiotherapy and in McCune Albright syndrome.

Thyroid nodules can present as underactive or overactive thyroid but most frequently are not associated with thyroid dysfunction. Careful evaluation of nodules is critical due to the higher risk of these being cancerous in children compared with adults. Thyroid cancers can occur independently or as part of multiple endocrine neoplasias or familial neoplasias. Papillary thyroid carcinoma is the most common form of paediatric thyroid cancer. Other rare forms include follicular thyroid carcinoma and medullary thyroid carcinoma. It is important to consider the occurrence of thyroid cancers as part of multiple endocrine neoplasias.

Thyroid disorders are a common endocrinopathy in children and adolescents. Good clinical history and family history are vital in diagnosis, surveillance and planning follow-up in these patients.

Keywords
Thyroid · Hypothyroidism · Thyrotoxicosis · Thyroid nodule · Thyroid cancer

Abbreviations

ATDs	Anti-thyroid drugs
BR	Block and replace
CBZ	Carbimazole
CH	Central hypothyroidism
CHT	Congenital hypothyroidism
DBS	Dried blood spot
DT	Dose titration
ESPE	European Society for Paediatric Endocrinology
FTC	Follicular thyroid carcinoma
GD	Graves' disease
HT	Hashimoto's thyroiditis
L-T4	Levothyroxine
MTC	Medullary thyroid carcinoma
NT	Neonatal thyrotoxicosis
PTC	Papillary thyroid carcinoma
PTU	Propylthiouracil
SOD	Septo-optic dysplasia
T3	Tri-iodothyronine
T4	Tetra-iodothyronine or thyroxine
TFTs	Thyroid function tests
TPO	Thyroid peroxidase
TRAb	Thyroid receptor antibody
TRH	Thyrotrophin releasing hormone or TSH releasing hormone
TSH	Thyroid stimulating hormone
USS	Ultrasound scan

Key Terms

- **Congenital hypothyroidism:** low or inadequate thyroid at birth secondary to an genetic abnormality or error of thyroid metabolism or iodine deficiency
- **Hashimoto's thyroiditis:** an autoimmune form of hypothyroidism

- **Neonatal thyrotoxicosis:** is a rare condition in newborns of mothers with a history of Hashimoto's thyroiditis or Grave's disease
- **Thyroid nodules:** mostly benign masses in the thyroid
- **Multinodular goiter:** multiple benign masses in the thyroid
- **Thyroidectomy:** surgical removal of the thyroid gland
- **Thyroid ablation:** destruction of the thyroid tissue using radioactive iodine or radiofrequency treatment

Key Points

- Thyroid hormone is essential for regulation of growth, myelination of the nervous system, metabolism, and organ function.
- Congenital hypothyroidism is the most common condition of the thyroid affecting 1 in 3000 newborn children. It is diagnosed on a newborn blood spot screening test.
- Hashimoto's thyroiditis is the most common cause of autoimmune hypothyroidism in childhood, most common age at presentation is adolescence.
- The most common cause of thyrotoxicosis in children, adolescents, and adults is Graves' disease. Initial treatment is with anti-thyroid drugs with up to 60% requiring definitive treatment with surgery or radioactive iodine due to relapse after stopping anti-thyroid drugs.
- Neonatal thyrotoxicosis is a condition affecting babies born to mothers with Graves' disease or Hashimoto's thyroiditis. It is a rare but serious condition requiring close monitoring of the neonate due to a high mortality rate associated with it.
- Thyroid nodules in children and adolescents are more likely to be malignant and therefore careful evaluation is required.

32.1 Introduction

The thyroid is a butterfly-shaped gland located in the neck in front of the trachea just below the larynx. It comprises two lobes, which are attached by a band of thyroid tissue called the isthmus. Embryologically, the thyroid gland develops from the primitive pharynx and neural crest. Initially, the gland is located at the back of the tongue and during foetal development, migrates to the front of the neck before birth.

The thyroid gland produces two key hormones: tetra-iodothyronine or thyroxine (T4) and tri-iodothyronine (T3) which play a crucial role in the regulation of growth, myelination of the nervous system, metabolism, and organ function.

The thyroid gland uses iodine as its main source to synthesise thyroid hormones. Iodine deficiency can lead to thyroid problems such as underactive gland and enlarged gland (goitre) and is a common problem worldwide. Both T4 and T3 are produced by combining the iodine with the amino acid tyrosine. T4 is the predominant hormone (80%) which is then converted into T3, the more active hormone, in peripheral tissues. Thyroid hormone levels in the blood are regulated by the pituitary gland which is in turn regulated by the hypothalamus; both of which are situated centrally in the nervous system (see Fig. 32.1). Most hormonal axes are based on the negative feedback loop system. Low levels of circulating thyroid hormones stimulate the hypothalamus to release thyrotrophin releasing hormone (TRH) which in turn stimulates the pituitary gland to produce the thyroid stimulating hormone (TSH) which results in increased production of T4 and T3. Similarly high levels of circulating hormones feedback to the hypothalamus to suppress TRH and in turn TSH production.

Thyroid hormone levels vary widely during childhood (see Fig. 32.2). TSH and free T4 values decreased continuously with age, particularly during the first year of life with variance being greatest in the first month of life (Kapelari et al. 2008).

Hyperthyrotropinemia, i.e. raised TSH levels in the context of normal free T4 levels, has been noted in obese individuals. However, it has been heavily debated whether the raised TSH is the cause or effect of obesity.

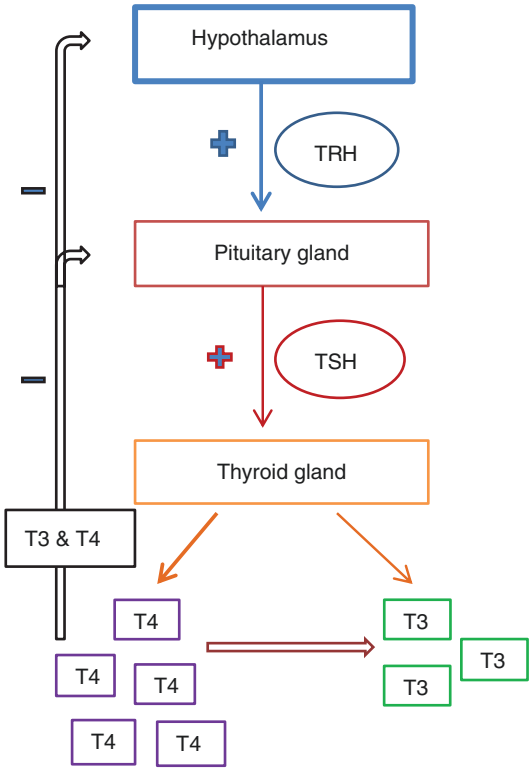

Fig. 32.1 Illustrates the hypothalamo-pituitary-thyroid axis. In response to low circulating levels of thyroid hormone tri-iodothyronine (T3) and tetra-iodothyronine (T4), the hypothalamus releases thyrotrophin-releasing hormone (TRH). The TRH stimulates the pituitary to produce thyroid-stimulating hormone (TSH) which in turn stimulates the thyroid to produce thyroid hormones. In the presence of high circulating levels of thyroid hormones, the T3 and T4 exert negative feedback control over the hypothalamus as well as anterior pituitary, thus controlling the release of both TRH and TSH

Disorders affecting the thyroid gland are common in childhood and adolescence. Early diagnosis and treatment are essential to prevent irreversible and permanent nervous system damage and developmental delay, especially in infants. Problems affecting the thyroid gland often manifest as an underactive gland (hypothyroidism) or an overactive gland (hyperthyroidism) with or without a swelling of the gland (goitre). Conditions affecting the thyroid gland are listed in the table below (Table 32.1).

We now discuss in detail some of the selected common endocrinopathies relating to thyroid dysfunction in children and adolescents using case studies.

32.2 Hypothyroidism

32.2.1 Congenital Hypothyroidism (CHT)

32.2.1.1 Introduction

CHT is a partial or complete loss of function of the thyroid gland (hypothyroidism) that affects infants from birth (congenital). The prevalence of CHT is 1 in 3000 live births.

32.2.1.2 Aetiology

The causes include:

1. Dygenesis (thyroid gland is absent, underdeveloped, or abnormally located)—80%
2. Dyshormonogenesis (abnormal biosynthesis of thyroid hormone)—20%

Commonest cause worldwide is maternal iodine deficiency, which is an essential element in the production of thyroid hormones.

A genetic cause may be present in 15–20% of the cases. Although the cause of thyroid dysgenesis remains unidentified in majority of the cases, 2–5% are said to be due to PAX8 and TSHR gene mutations. Thyroid dyshormonogenesis can occur due to mutation in one of the following genes: DUOX2, SLC5A5, TG, TSHB, and TPO (http://ghr.nlm.nih.gov/condition/congenital-hypothyroidism). Majority of the mutations are sporadic (new); however, a few children inherit it from their parents.

A very small percentage of patients have secondary hypothyroidism where the problem is in the hypothalamus or the pituitary (discussed later).

32.2.1.3 Diagnosis

CHT is diagnosed on dried blood spot (DBS) testing in the newborn. This is employed in all developed countries where blood is collected from a heel prick on all babies around day 5 of life. The diagnosis is mostly made on a raised TSH. The screening is aimed at identifying the more severe forms of primary CHT as early initiation of treatment (<3 months of age) minimises intellectual disability in children with CHT. In the UK, the aim is to start treatment within 21 days of birth. The flowchart (see Fig. 32.3) illustrates the screening and referral criteria and pathway.

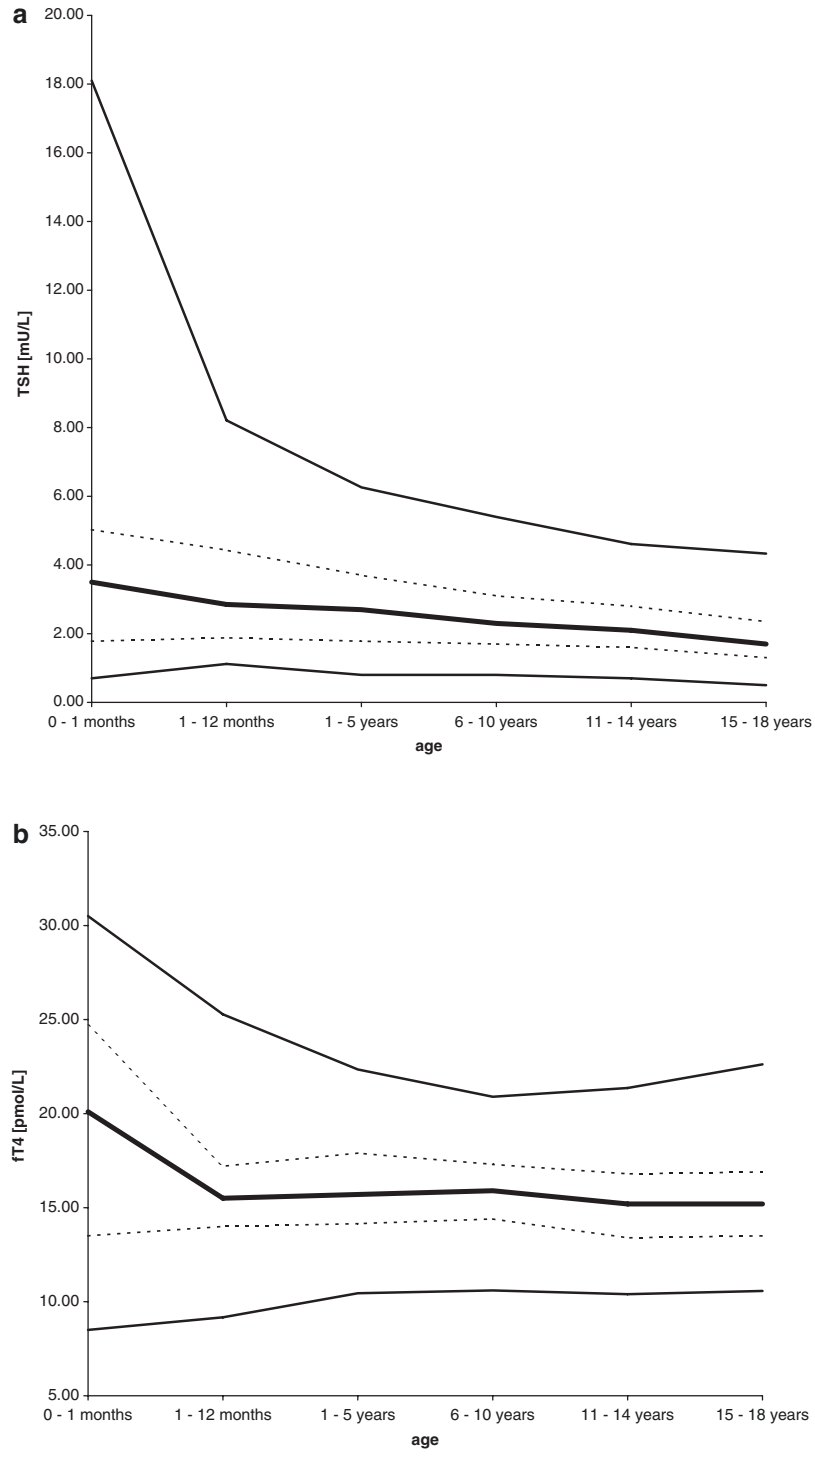

Fig. 32.2 Adopted from Kapelari et al. (2008): Age-related reference intervals for TSH (**a**) and free T4 (**b**). The central 95% range (2.5th, 25th, 50th, 75th, and 97.5th percentiles) are shown

Table 32.1 Conditions affecting the thyroid gland and hormones in the neonatal period, childhood and adolescence are listed below

	Hypothyroidism	Hyperthyroidism
Neonatal period	Congenital hypothyroidism	Neonatal thyrotoxicosis secondary to • Maternal Graves' disease • Maternal Hashimoto's thyroiditis
Childhood and adolescence	• Hashimoto's thyroiditis • Subacute thyroiditis • Following surgical removal of thyroid gland for Graves' disease or for thyroid nodule • Radiation damage to the thyroid gland following cancer treatment	• Graves' disease • Subacute thyroiditis • Hyperfunctioning thyroid nodule (toxic adenoma, toxic multinodular goitre) • McCune Albright syndrome
Rare	• TSH receptor defect causing congenital hypothyroidism • Congenital secondary hypothyroidism due to genetic mutations causing abnormal pituitary gland development	• Thyroid hormone ingestion (factitious or induced) • TSH hypersecretion secondary to pituitary tumours • Pituitary resistance to thyroid hormone • Activating mutation of the TSH receptor • Iodine induced hyperthyroidism

A second test should be considered in pre-term neonates, babies with very low birth weight and in babies who were ill at the time of first sample collection as TSH is known to be elevated.

Neonates may exhibit any of the symptoms and signs of CHT illustrated in the table below (Table 32.2) or may be asymptomatic and detected purely by a raised TSH on screening. A raised TSH on DBS should be confirmed on venous thyroid function tests at referral, prior to initiation of treatment.

The European Society for Paediatric Endocrinology (ESPE) consensus guidelines for CHT (Léger et al. 2014) suggest the following biochemical diagnostic criteria for initiation of treatment:

(a) If DBS reveals TSH of 40 mU/L, await serum results for 1–2 days before initiating treatment.
(b) Start treatment immediately if serum free thyroxine (FT4) concentration is below the normal range for age, regardless of TSH concentration.
(c) Start treatment if venous TSH concentration is persistently greater than 20 mU/L, even if serum FT4 concentration is normal.
(d) If TSH concentration is between 6 and 20 mU/L in a well-baby with normal FT4, consider diagnostic imaging to establish a definitive diagnosis.
(e) If TSH concentration remains high for more than 3–4 weeks, consider starting levothyroxine (L-T4) supplementation immediately (in discussion with the family) and retesting, off treatment, at a later stage; or retesting 2 weeks later without treatment.

32.2.1.4 Investigations

Thyroid ultrasound scan (USS) and scintigraphy are the recommended investigations for CHT. Often clinicians choose one of the two investigations; however, both should be considered in those with raised TSH to improve diagnostic accuracy.

An x-ray of the knee may be carried out to assess the severity of intrauterine hypothyroidism by the presence or absence of femoral and tibial epiphyses.

Treatment should not be delayed and can be initiated pending investigations.

Thyroid USS does not detect ectopic thyroid tissue and is user dependent. Thyroid scintigraphy can identify athyreosis (absence of uptake), hypoplasia of a gland, a normal or large gland in situ with or without abnormally high levels of uptake, and an ectopic thyroid at any point along the pathway of the normal embryological descent. It is ideal when performed within 7 days of starting L-T4 treatment.

32.2.1.5 Treatment

Treatment is with L-T4. It should be started before 2 weeks of age or as soon as a diagnosis is

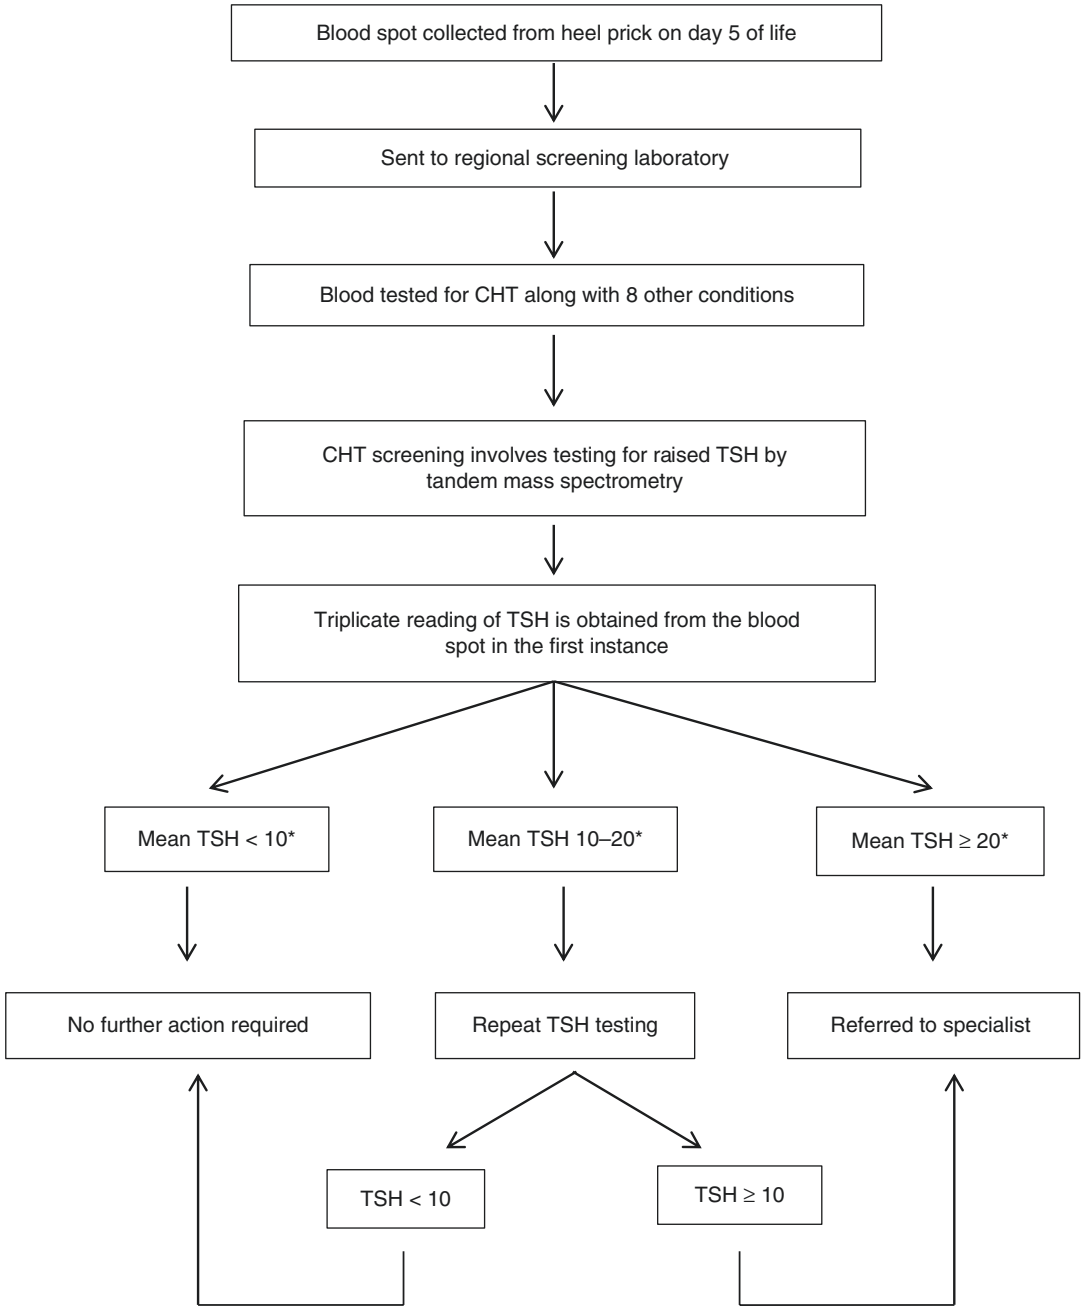

Fig. 32.3 Flowchart representing the screening and referral pathway in the UK. *Please note that different laboratories may have slightly different cut-off values for TSH for further screening and referral

made. The starting dose is 10–15 μg/kg/day. Treatment is monitored by thyroid function tests (TFTs) and tailored to maintain free T4 in the high end of normal range and TSH in the normal range.

32.2.1.6 Nursing Considerations

Levothyroxine is available in different strength solutions or tablets. The absorption is better with tablets. Nurses can be valuable in advising the parents on administering the medication. The

Table 32.2 Symptoms and signs of hypothyroidism in neonates

Symptoms	Signs
• Sleepiness • Constipation • Not waking for feeds • Poor feeding	• Prolonged neonatal jaundice • Cold extremities • Hypotonia • Macroglossia • Umbilical hernia • Dry skin • Coarse and puffy face • Large anterior fontanelle • Wide sagittal suture

majority of units suggest crushing and dissolving the tablets in milk and giving it via a teaspoon or a syringe. Crushed tablets are not to be added to a whole bottle of milk in case the baby does not complete the full feed. Other centres advise placing the tablet in the side of the baby's cheek at the beginning of a feed, which is then absorbed. Consideration must be given to the strength of tablet available when using the second method.

Parents should be provided with information leaflets. Where unit specific information leaflets are not available, in the UK, one can use generic leaflets available from British Thyroid Association or the UK National Screening Committee. Parents should also be directed towards support groups.

As with any other condition requiring lifelong treatment, it is crucial to emphasise on and ensure compliance at each visit.

32.2.1.7 Follow-Up

Regular 1–2 weekly follow-up is required initially to optimise treatment and achieve a normal TSH. Once TSH normalises, 3 monthly follow-up is recommended to monitor growth and development in the first year of life. More frequent visits may be required if there are clinical concerns.

Re-evaluation of the thyroid axis may be considered at the age of 3 years in those children where the aetiology remains unknown or in those where the presence of CHT is questioned either because treatment was commenced when the infant was unwell or in the presence of only slightly raised TSH at diagnosis.

32.2.1.8 Outcome

Since the introduction of newborn screening and early initiation of treatment, the neurocognitive outcome for children with CHT has improved (Grosse and Van Vliet 2011). Special measures must be put in place for those children in whom severe CHT affects motor development or school performance.

Case 1

The Paediatric team were notified that a baby girl had had a positive new born screening test result for congenital hypothyroidism with a blood spot TSH of 26.5 mU/L (mean of duplicate results). The family were contacted and the baby was reviewed in the Children's Assessment Unit on the same day.

Parents commented that she was a 'good' baby, and had to be woken up for the majority of her feeds. She was born at 40 weeks gestation by normal vaginal delivery with a birth weight of 2.8 kg. There was no family history of thyroid disease.

On clinical examination there were no dysmorphic features. She had no evidence of a goitre or lesion at the back of her tongue and was not jaundiced. She appeared clinically euthyroid and had no signs of cardiac abnormalities.

Abnormal TFTs with elevated TSH and low normal free T4 were confirmed on venous bloods (table below). Maternal thyroid functions were normal.

The baby was commenced on levothyroxine supplements at a dose of 25 mcgs daily. Thyroid ultrasound and thyroid uptake scan confirmed that the thyroid gland was in situ suggesting dyshormonogenesis as the cause of hypothyroidism.

The patient was seen for follow-up in the paediatric endocrine clinic in 2 weeks. The parents had noted that she was more awake and responsive and feeding well. Thyroid functions had improved.

Treatment	Pre	Post
Day	D9	D23
TSH mU/L (0.35–4.4)	55.2	7.99
Free T4 pmol/L (9–19.1)	13.4	24.2

Discussion: Careful examination of the infant with congenital hypothyroidism (CHT) should be carried out for presence of dysmorphic features and cardiac defects and vice versa. The prevalence of cardiac defects in children with CHT is higher than in the general population. Children with certain conditions such as Down's and Pendred syndrome and pseudohypoparathyroidism may have a slightly raised TSH in the neonatal period, which may not be picked up on new born screening test.

Points to Remember

- *Congenital hypothyroidism is diagnosed by a raised TSH or low T4 on a heel prick test done as part of the new born screening test.*
- *Early treatment, within 3 weeks of life, with levothyroxine minimises damage to the central nervous system and improves outcome.*
- *Close monitoring of growth and development in infants with CHT is essential.*

32.2.2 Autoimmune Hypothyroidism

32.2.2.1 Introduction

Autoimmune hypothyroidism also known as Hashimoto's thyroiditis (HT) or autoimmune thyroiditis is the commonest cause of acquired hypothyroidism in children and can present at any age but most frequently in adolescence. There are several forms of HT; however, the one in children is referred to as the juvenile form. Females are more affected than males and whites and Asians are more affected than other races. HT can occur in association with other autoimmune diseases such as type 1 diabetes mellitus, Sjögren syndrome, or other thyroid diseases such as papillary thyroid cancer, and is also more common in conditions associated with autoimmune conditions such as Turner Syndrome.

32.2.2.2 Clinical Features

The most common presenting feature of HT is that of a painless goitre and biochemical euthyroidism (normal thyroid functions). The next most common feature is subclinical hypothyroidism or overt hypothyroidism with clinical features of hypothyroidism (Table 32.3). A small proportion of patients present with features of thyrotoxicosis (Table 32.4) which is transient, known as hashitoxicosis (Htx), before developing permanent hypothyroidism. Htx is believed to result from unregulated release of stored

Table 32.3 Symptoms and signs of hypothyroidism in children and adolescents

Symptoms	Signs
• Muscular weakness • Fatigue • Sensitivity to cold • Constipation • Slowed mental processes • Poor memory • Reduced school performance • Sleep disturbance • Weight gain • Menstrual disturbance	• Low pulse rate and heart rate • Thick puffy skin • Coarse hair • Dry skin • Goitre (enlarged thyroid) • Delayed relaxation phase of deep tendon reflexes • Decreased growth velocity • Precocious (early) puberty • Delayed puberty • Raised prolactin levels

Table 32.4 Symptoms and signs of neonatal thyrotoxicosis

Symptoms	Signs
• Irritability • Jitteriness • Restlessness • Voracious appetite • Diarrhoea • Weight loss	• Goitre • Tachycardia and arrhythmias • Cardiac failure • Sweating and flushing • Acrocyanosis • Eye signs: periorbital oedema, lid retraction, and exophthalmos • Hepatosplenomegaly • Lymphadenopathy • Bruising and petechiae secondary to thrombocytopenia • Hyperviscosity • Craniosynostosis and microcephaly

thyroid hormones during inflammatory-mediated destruction of the thyroid gland. Children with long-standing hypothyroidism can occasionally present with iso-sexual precocious puberty (same sex early puberty) with delayed bone age and ovarian cysts, a triad referred to as Van Wyk Grumbach syndrome.

32.2.2.3 Diagnosis

The diagnosis of HT is currently established by a combination of clinical features, presence of serum antibodies against thyroid antigens (mainly to thyroperoxidase and thyroglobulin), and reduced echogenicity of the thyroid gland on USS. Antithyroid peroxidase (TPO) and antithyroglobulin (Tg) antibody titres are elevated in 90–95% of children with Hashimoto's thyroiditis (Grosse and Van Vliet 2011). A small proportion of children who are initially negative can become positive later. Around 20% of individuals who have antibody-positive test results do not develop hypothyroidism or hyperthyroidism (Catureglia et al. 2014).

32.2.2.4 Management

Treatment is by supplementation with L-T4 with a starting dose of 5 mcg/kg/day as a single dose. Children and adolescents with long-standing hypothyroidism should be started on a low dose of levothyroxine to prevent rapid overcorrection. Treatment is monitored by regular measurements of thyroid hormones and treatment is tailored to maintain a free T4 at the high end of normal and TSH in the normal range. Surgery is rarely required but must be considered if there are goitre-related pressure effects. It is essential to bear in mind that an increased prevalence of papillary thyroid carcinoma has been reported in patients with HT (Okayasu et al. 1995), although this remains debatable.

Around 20% of patients may return to a euthyroid state after completing puberty, therefore thyroid status should be re-evaluated at this stage by stopping treatment and monitoring using free T4 and TSH levels (De Luca et al. 2013).

Case 2

A 12½-year-old girl was reviewed in the endocrine clinic after recently being diagnosed with autoimmune hypothyroidism. She had first presented 2 months ago to her General Practitioner with a history of tiredness, dry skin, and weight gain. Parents had also reported that her teachers had noticed a decline in her energy levels. There was a family history of hypothyroidism in the maternal aunt.

On examination, the patient looked well and had a pulse of 86 beats per minute. Her height was on the 9th centile and her weight was just above the 50th centile. Previous measurements taken 2 years earlier from a community clinic had placed her height and weight on the 25th centile. There was a small, smooth goitre, not tender and not nodular. She was pre-pubertal.

Her initial TSH was raised with a low free T4 (table below) and TPO antibodies were positive at >1000 U/mL (normal <6.0). The GP had commenced her on levothyroxine 25 mcg daily. Her parents reported that there was a positive noticeable difference in their daughter since starting the medication.

Repeat thyroid function tests showed a reducing TSH and rising free T4. The dose of levothyroxine was increased to achieve a high normal free T4 and normal TSH. She was seen regularly in the endocrine clinic to review her progress and monitor her thyroid function tests.

Treatment	Pre	2 months post
TSH (0.35–4.4) mU/L	53.4	8.6
Free T4 (9–19.1) pmol/L	7.2	12.5

Discussion: Patients with autoimmune hypothyroidism may present with or without goitre. Increasing weight centile and decreasing height centile should always raise the suspicion of hypothyroidism. Treatment is aimed at maintaining a high normal free T4 and a normal TSH. The normal range for free T4 and TSH varies between laboratories and for different ages.

Points to Remember

- *Hashimoto's thyroiditis is the commonest cause of acquired hypothyroidism in children and commonly presents in adolescence.*
- *Majority of the children may be asymptomatic and biochemically euthyroid except for goitre at presentation.*
- *Tg and TPO antibodies may be absent at diagnosis and become positive later.*
- *Lifelong treatment with levothyroxine is required in the majority; a few children may be able to come off treatment once puberty is completed.*

32.2.3 Secondary or Central Hypothyroidism

Central hypothyroidism (CH) is defined as hypothyroidism due to insufficient stimulation by thyroid stimulating hormone (TSH) of an otherwise normal thyroid gland. CH can be congenital (present at birth) or acquired. Congenital CH (CCH) can occur in isolation but most often occurs in association with other pituitary hormone deficiencies. CCH is not identified on newborn screening test as the TSH levels in these neonates are low. The prevalence of CCH is said to be higher than previously known. Countries which use free T4 in the newborn screening report its incidence to be 1 in 16,000 (Schoenmakers et al. 2015). Mutations in transcription factors responsible for normal pituitary development (HESX1, LHX3, LHX4, SOX3, OTX2, PROP1, POU1F1) may cause central hypothyroidism with or without associated extra pituitary abnormalities (Schoenmakers et al. 2015). The other causes of CH in later childhood and adolescence include malignancies such as craniopharyngiomas, previous radiotherapy, previous pituitary surgery, traumatic brain injury, vascular defects, and infiltrative conditions such as histiocytosis.

Case 3

A baby girl born at 37 weeks by normal vaginal delivery was admitted to the neonatal unit due to poor tone (hypotonia) and suspected sepsis. Mum had had a normal pregnancy with normal antenatal scans.

The baby was treated with antibiotics for suspected sepsis. She was screened for prolonged jaundice at 2 weeks of age. Thyroid function tests done as part of screening revealed low TSH (2.9 mU/L) and low FT4 (8 pmol/L) raising suspicion of central hypothyroidism.

She was transferred to a tertiary centre for endocrinology review. Here she was screened for other pituitary hormone deficiencies. A short synacthen test demonstrated suboptimal cortisol response to ACTH revealing cortisol deficiency.

She was commenced on hydrocortisone replacement therapy followed by levothyroxine. Septo-optic dysplasia (SOD) as the cause of multiple pituitary hormone deficiency was suspected and further evaluated. Ophthalmology examination revealed right optic nerve hypoplasia and an MRI of the head showed an absent septum pellucidum, small anterior pituitary, and ectopic posterior pituitary, confirming the diagnosis of SOD.

Discussion: Central hypothyroidism is not diagnosed on new born screening test in countries where the screening programme uses high TSH levels to diagnose CHT. Countries measuring thyroxine levels in screening are more likely to detect babies with secondary hypothyroidism. However, measuring thyroxine is said to be less specific with high frequency of false positives and is therefore not universally practised. Presence of central hypothyroidism necessitates a thorough evaluation for the presence of other pituitary hormone deficiencies. Thyroxine replacement prior to hydrocortisone replacement in children with cortisol deficiency may precipitate an adrenal crisis.

32.3 Hyperthyroidism

32.3.1 Neonatal Thyrotoxicosis

32.3.1.1 Introduction

Neonatal thyrotoxicosis (NT) is the presence of an overactive thyroid (or hyperthyroidism) in the newborn. The prevalence of Graves' disease in pregnancy is 0.2% (Batra 2013). Of those pregnant patients with Graves' disease only 1–12.5% result in neonatal thyrotoxicosis (Batra 2013).

32.3.1.2 Aetiology

NT occurs due to transplacental passage of thyroid stimulating immunoglobulins (TSIs) from mothers with Graves' disease or Hashimoto's thyroiditis. The antibodies can persist despite previous treatment for Graves' disease in the mother. These antibodies which are IgG immunoglobulins cross the placenta and stimulate the foetal thyroid. Although this starts early in pregnancy the effect increases in the last trimester as the placental permeability increases, causing the foetal and maternal antibody levels to be equal.

Another rare cause of NT is an activating mutation of the TSH receptor. NT due to receptor mutation should be suspected if more than two generations in the family are affected by thyrotoxicosis and if there are difficulties in weaning ATDs. Rarely de novo (new) mutations have also been reported to occur. These individuals will need definitive treatment in the long term such as thyroidectomy.

32.3.1.3 Clinical Manifestations

Depending on the antibody levels and maternal control of the disease, the features of thyrotoxicosis may start as early as in the second trimester of pregnancy or not manifest in the neonate at all. Foetal growth can be restricted in utero due to hyperthyroidism and rarely a foetal goitre can be seen on antenatal scans in severe cases. There is an increased incidence of intrauterine death and premature delivery in pregnancies with maternal thyrotoxicosis.

Symptoms and signs (Table 32.3) of thyrotoxicosis may be apparent at birth or may be delayed due to the effect of maternal anti-thyroid drugs or coexistent blocking antibodies. In most cases, features are apparent by day 10 of life. Biochemically the neonate will have a raised free T4 and a suppressed TSH. TSH receptor antibodies (TRAbs) may be in high concentrations.

32.3.1.4 Management

Careful monitoring in pregnancy as detailed in the Endocrine Society Clinical Practice Guideline is essential (De Groot et al. 2012). Foetal thyrotoxicosis is treated by administering anti-thyroid drugs (ATDs), carbimazole or propylthiouracil (PTU) to the mother. These drugs act by preventing the synthesis of thyroid hormone and cross the placenta. Carbimazole is avoided, if possible, in the first trimester due to its association with congenital anomalies. Close monitoring of liver function on PTU is recommended due to its association with liver toxicity.

Neonatal thyrotoxicosis is treated with 0.5–1.5 mg/kg/day of carbimazole in the neonate. A beta blocker such as propranolol is used in a dose of 0.27–0.75 mg/kg 8 hourly in neonates who are symptomatic due to adrenergic stimulation (Ogilvy-Stuart 2002). Thyroid function must be monitored weekly in those on ATD.

In those neonates who are asymptomatic, thyroid function must be checked at birth, day 5–7 and then day 10–14. Parents should be warned of symptoms, as NT has been reported to occur as late as 45 days in certain cases.

32.3.1.5 Prognosis

Most neonates require treatment for no longer than 8–10 weeks. In those who require continued treatment, other causes must be considered. Craniosynostosis, intellectual disability, impaired growth and development have been reported in a small percentage of children with NT, although most of these are neonates with persistent thyrotoxicosis due to a genetic mutation rather than transient due to maternal antibodies.

Case 4

A baby boy was born at term by normal vaginal delivery. Mum had a history of hypothyroidism diagnosed 5 years prior to conception. She developed thyrotoxicosis in pregnancy and was treated with carbimazole. She had high levels of TPO

(2921 Ku/L; normal range 0–51) and thyroid receptor antibodies, TRAb (4.7 U/L; normal range 0–1).

The baby was observed in hospital for 48 h and was discharged home as he was feeding well and did not show any features of thyrotoxicosis such as weight loss, sweating, diarrhoea, tachycardia, or goitre. In an endocrine review on day 5 of life, the baby was tachycardic with a heart rate of 200 beats per minute. His weight was static and there was no goitre. NT was suspected and confirmed by biochemical tests (table below). Carbimazole (75 mcg/kg/day) treatment commenced. Propranolol (400 mcg/kg/day) was added in view of the tachycardia.

The TRAb (22 U/L; range 0–15) and TPO (675 Ku/L; range 0.0–5.6) antibodies were raised. TFTs were monitored and treatment weaned as below (table).

Treatment	Pre	1 week post	1 month post	3 months post	1 month off treatment	2 months off treatment
TSH (0.4–3.5) mU/L	<0.01	<0.01	0.3	0.3	0.35	0.5
FreeT4 (10.7–21.8) pmol/L	>77.2	18.4	9.8	15	14.5	14.2
Action	CBZ and propranolol	Propranolol stopped and CBZ halved	CBZ halved	CBZ stopped		

Discussion: Women with previous hypothyroidism can develop hyperthyroidism in pregnancy. Close monitoring of neonates with maternal Graves' disease or Hashimoto's thyroiditis is crucial. Treatment with anti-thyroid drugs (ATDs) can eventually be weaned.

Points to Remember

- *Neonatal thyrotoxicosis is caused by transplacental transfer of thyroid stimulating immunoglobulins in maternal Graves' or Hashimoto's thyroiditis.*
- *It is a rare and transient condition in the absence of genetic mutations.*
- *Close monitoring of neonates at risk of developing thyrotoxicosis is essential.*
- *Treatment with anti-thyroid drugs for a brief period may be required.*

32.3.2 Graves' Hyperthyroidism

32.3.2.1 Introduction

Hyperthyroidism is rare in children and adolescents. Majority of the cases are due to Graves' disease (GD). GD is an autoimmune disorder caused by an abnormal thyroid hormone production stimulated by thyroid stimulating immunoglobulins, the action of which mimics TSH. Inheritance is polygenic. GD is more common in some families. The production of immunoglobulins is thought to be triggered by certain infections involving the Yersinia series and also viruses. GD is associated with other autoimmune diseases such as diabetes mellitus, Addison disease, vitiligo, immune thrombocytopenic purpura (ITP), and pernicious anaemia. The incidence of GD is around 1 per 100,000 under the age of 15 years (Williamson and Greene 2010).

32.3.2.2 Clinical Features

The triad of GD includes goitre, thyrotoxicosis (Table 32.5), and ophthalmopathy (Table 32.5). However, not all patients present with ophthalmopathy. Fifty percent of patients with eye disease have a mild form and only 2–3% present with severe eye signs (Menconi et al. 2014).

32.3.2.3 Diagnosis

Diagnosis of GD includes elevated levels of serum thyroxine (T4) and tri-iodothyronine (T3), associated with undetectable serum TSH. Antibodies against the TSH receptor (TRAbs) are pathognomonic. They are detectable in the serum of about 98% of untreated GD patients (Menconi et al. 2014). TRAb measure-

Table 32.5 Symptoms and signs of hyperthyroidism and ophthalmopathy in children and adolescents

Symptoms	Signs
Hyperthyroidism	
• Weight loss • Increased appetite • Palpitations • Sweating • Heat intolerance • Tiredness and weak muscles • Nervousness, irritability, and shakiness • Mood swings or aggressive behaviour • Loose stools • Increased thirst and urination • Oligomenorrhoea	• Rapid pulse • Warm • Moist hands • Enlarged thyroid gland with or without a bruit • Tremor
Ophthalmopathy	
• Excess tearing • Irritation • Grittiness • Photophobia • Pain • Redness of the conjunctiva • Diplopia • Blurred vision • Reduced visual acuity	• Soft tissue involvement manifests as Swelling and redness of the eyelids Swelling of the caruncle Chemosis • Proptosis • Extraocular muscle involvement causing limitation of eye movement • Corneal involvement manifests as Stippling and ulceration • Optic nerve involvement • Lid lag

ment is not essential for diagnosing GD; however, it can be used when there is diagnostic uncertainty. Thyroid ultrasound demonstrates a hypoechoic picture with reduced colloid and increased vascularity. USS is also not essential for diagnosis but gives useful information about the size of the gland and detects any thyroid nodules not palpated clinically.

32.3.2.4 Management of GD

The initial management of GD includes anti-thyroid drugs (ATDs). The most appropriate regimen is highly debated. The goal of therapy is to render the patient euthyroid. This is not a cure and definitive treatment such as thyroidectomy or radioactive iodine is required in the long term in majority of the patients. Only half of the patients go into clinical remission following treatment with ATDs (Cheetham and Bliss 2016).

Anti-thyroid Drugs and Treatment Regimes

The most commonly used ATD in children and adults is carbimazole except in the first trimester of pregnancy or if carbimazole is not tolerated, when propylthiouracil (PTU) is used. Carbimazole is preferred to PTU, because of the evidence of a lower prevalence of severe side effects, especially idiosyncratic hepatitis and liver failure although this is rare. The other side effects of ATDs include skin rash and, very rarely, hepatitis, agranulocytosis, and vasculitis. It is important that all children and adolescents and their families are counselled about these potential side effects.

A beta blocker such as propranolol may be necessary in the initial stages to control the adrenergic symptoms of thyrotoxicosis. However, beta blockers are contraindicated in children with asthma and are therefore not used.

There are two main approaches to treatment with ATDs:

(a) *Block and replace* where high dose ATD is used to render the patient hypothyroid and levothyroxine is then added to treat hypothyroidism. Some clinicians believe that the side effects of ATDs are more with this regimen; however, others prefer this method as thyroid function is said to be more stable with this regimen and patients need fewer blood tests

and clinic follow-up visits initially (Cheetham and Bliss 2016).

(b) *Dose titration* where a titrating dose of ATD is used. This method is preferred by some due to reportedly fewer side effects and a simpler regimen; however, others report the need for frequent blood tests and dose adjustments due to unstable thyroid functions (Cheetham and Bliss 2016).

The relapse rate is reported to be similar with the two regimens, 51% in the block-replace group and 54% in the dose titration group (Abraham et al. 2010). The best approach remains debatable.

Surgery

For those that need definitive treatment, one option is thyroidectomy. Previously subtotal thyroidectomies were performed; however, now total thyroidectomy is increasingly recommended to prevent the recurrence of hyperthyroidism (<3%). The rate of complications with total thyroidectomy when performed by a skilled (high-volume) surgeon is said to be minimal. The most frequent complications include: pain and transient hypocalcaemia secondary to disruption of the parathyroid glands. Less frequent complications include haemorrhage, permanent hypoparathyroidism, and vocal cord paralysis.

Hypothyroidism, requiring levothyroxine replacement, is universal following total thyroidectomy.

Radioactive Iodine

The other option is radioactive iodine (I-131) which is increasingly being used in the treatment of GD and is gaining popularity. Radioiodine is preferably administered after achievement of euthyroidism with ATDs and ATDs are stopped 5–7 days prior to treatment.

The goal of the treatment is to induce hypothyroidism in order to achieve a stable remission. Oral I-131 targets and destroys the follicular cells in the thyroid gland; hence an initial rise in thyroid hormones may be noted. Beta blockers may be used to control symptoms of hyperthyroidism during this time. There is a risk of thyroid storm following I-131 treatment.

The dose of I-131 is calculated based on the gland size and radioiodine uptake by the gland. The reported doses in children and adolescents have ranged from 100–250 mCi/g thyroid tissue (Rivkees 2014). Treatment is less successful in patients with large goitre and high levels of circulating TRAb levels.

Very few short-term side effects are reported and are usually tolerable. Radiation thyroiditis can rarely cause pain and swelling of the neck and may require treatment with simple analgesia. The long-term persistence of hyperthyroidism and occurrence of hypothyroidism post treatment are variably reported and depend on the I-131 dose used. Both hypo- and hyperparathyroidism have been reported in the long term in a small percentage of patients. There is no evidence of an increased risk of thyroid cancer, other solid tumours, and leukaemia following I-131 therapy in adults with GD. Although the same has been shown in children, the numbers are small (1000 children) and the duration of follow-up (5–15 years) is short to make any definitive conclusions and long-term large studies are still required (Rivkees 2014). No long-term effects on the adult reproductive system in males and females have been described. Recent studies have focused on the association of I-131 therapy with the development or progression of ophthalmopathy, hence its use in patients with active Graves' ophthalmopathy is limited.

Case 5

A 7-year-old girl presented to her General Practitioner with symptoms of anxiety, poor sleep, and weight loss. On examination she was found to have an enlarged thyroid gland (goitre). She was not tachycardic and there were no eye signs.

Hyperthyroidism was suspected based on the history and clinical findings and confirmed on laboratory thyroid function tests. She had a raised FT4 (29 pmol/L) and a suppressed TSH (0.01 mU/L). She was positive for TPO (295 Ku/L; normal range 0–5.6) and TRAb (33 U/L; normal

range 0–15) confirming a diagnosis of Graves' hyperthyroidism. Thyroid USS showed multiple hypoechoic nodules and increased vascularity of the thyroid gland in keeping with the diagnosis.

She was treated with carbimazole (1 mg/kg/day in two divided doses). Treatment with propranolol was not indicated. Her free T4 normalised within 8 weeks although the TSH remained suppressed for longer. Following treatment she regained her weight and her sleep pattern was reported to have improved.

Treatment	Pre	2 weeks post	10 weeks post
TSH (0.4–3.5) mU/L	<0.01	0.01	0.03
FreeT4 (10.8–28) pmol/L	69.5	29	15.3

Discussion: Graves' hyperthyroidism is the most common cause of hyperthyroidism in children. Symptoms usually resolve following treatment with anti-thyroid drugs. In patients with increased adrenergic activity, namely increased heart rate and tremor, treatment with a beta blocker such as propranolol is indicated.

Points to Remember

- *GD is the most common cause of thyrotoxicosis in children and adolescents as well as adults.*
- *GD is a triad of thyrotoxicosis, goitre, and ophthalmopathy, although only a small proportion of patients present with all three features.*
- *Although the mainstay of initial treatment is with anti-thyroid drugs, the right regimen is highly debated (block and replace vs dose titration).*
- *In patients who relapse after stopping ATDs, the choice of long-term definitive treatment (surgery or radioactive iodine) depends on several factors such as disease severity, age of the patient, presence of ophthalmopathy, and the size of the goitre.*

32.4 Thyroid Nodules and Cancers

32.4.1 Thyroid Nodules

Thyroid nodules (TNs) are mostly benign and not cancerous, although a higher proportion of them are cancerous in children compared to adults (22–26% vs 5–10%, respectively) (Francis Gary et al. 2015). TN rarely present with clinical features, majority of them are incidentally picked up by physical examination, occasionally patients can present with a painless lump in the neck.

32.4.1.1 Evaluation of the Thyroid Nodule

Careful and thorough evaluation of TNs is essential due to the high risk of malignancy associated with it in childhood. This should include:

History: A detailed history focused on

1. Symptoms of hypothyroidism or hyperthyroidism (Tables 32.3 and 32.5)
2. Disturbance in voice
3. Swallowing difficulty
4. History of malignancy
5. Exposure to radiation
6. Family history of thyroid problems or other malignancies

Examination: A systematic physical examination should assess the thyroid gland, the lateral neck for surrounding lymph nodes, and if indicated, a laryngeal examination and systemic examination for signs of metastatic disease.

Investigations: should include thyroid function tests and ultrasound guided fine needle aspiration (FNA) biopsy.

The American Thyroid Association Guidelines (Rivkees 2014) provide detailed step by step guide on investigation and management of thyroid nodules, discussion of which is beyond the scope of this book.

Case 6

A 14-year-old girl was referred to the endocrine clinic with a 6 month history of feeling hot and shaky. She also had increased appetite and had felt her heart was racing for the past 2–3 months. She had lost weight and experienced irregular menstruation.

There was a family history of Graves' disease in the mother which was diagnosed 5 years ago and was treated with radioactive iodine. Paternal grandmother also had hypothyroidism.

On examination her heart rate was 104 beats per minute and she had mild tremor. She had a smooth, asymmetric, enlarged goitre which was bigger on the right compared to the left. She had no eye signs or lymphadenopathy.

Hyperthyroidism was suspected and confirmed on laboratory investigations. She had a raised FT4 (36 pmol/L) and suppressed TSH (<0.01 mU/L). She was commenced on carbimazole and propranolol to control adrenergic symptoms. Her TPO and TRAb were negative.

A thyroid USS identified a large well-defined solid and cystic lesion with increased vascularity. A fine needle aspiration biopsy was performed which showed normal thyroid tissue. The size of the goitre improved on carbimazole treatment. Technetium scintigraphy showed evidence of increased uptake within the single nodule suggesting a hot nodule amenable to surgery.

Discussion: Thyroid nodules must be evaluated thoroughly in children and adolescents due to the increased risk of cancer. In this case, further evaluation of the nodule with a technetium 99 scan to determine functionality indicated surgery would be the ideal definitive treatment.

32.4.2 Thyroid Cancers

Thyroid cancers are rare in children compared to adolescents. The annual incidence is 1 per million per year in children under 10 years compared to 15.4 cases per million per year in 15–19-year-olds (http://www.thyca.org/pediatric/about/). The two main types of paediatric thyroid cancers include differentiated thyroid cancer and medullary thyroid cancer.

1. **Differentiated Thyroid Cancer**: This includes papillary and follicular thyroid cancer and their variants.
   (a) *Papillary thyroid cancer* (PTC) is the most common type of thyroid cancer in both children, adolescents, and adults. The majority of children with PTC have local spread to the lymph nodes of the neck at the time of diagnosis and up to 20% have distant metastases (http://www.thyca.org/pediatric/about/). Recurrence of PTC is common. However, despite this the prognosis is excellent with appropriate treatment.
   (b) *Follicular thyroid cancer* (FTC) is rare in children, has aggressive characteristics and poorer prognosis.

The mainstay of treatment for both types of cancers is surgery aiming for a total thyroidectomy including resection of the surrounding affected lymph nodes. Radioactive iodine has also been employed followed by doses of L-T4 which suppress TSH levels for a period of time. Long-term follow-up and surveillance to detect recurrence is recommended.

2. **Medullary Thyroid Cancer (MTC)**: MTC is rare in childhood and accounts for 5–10% of all thyroid cancers (http://www.thyca.org/pediatric/about/). MTC comes from the parafollicular C-cells in the thyroid gland that produces a protein called calcitonin. Twenty-five percent of MTC cases are hereditary, the remainder are sporadic. MTC can occur as part of a multiple endocrine neoplasia. A family history of MTC, pheochromocytoma, or hyperparathyroidism may indicate multiple endocrine neoplasia 2A (MEN2A) or multiple endocrine neoplasia 2B (MEN2B), both of which are inherited in an autosomal dominant fashion. All family members should be genetically screened for this mutation. It can also occur by itself in familial medullary thyroid carcinoma (FMTC). MTC is treated with total thyroidectomy if diagnosed before metastatic

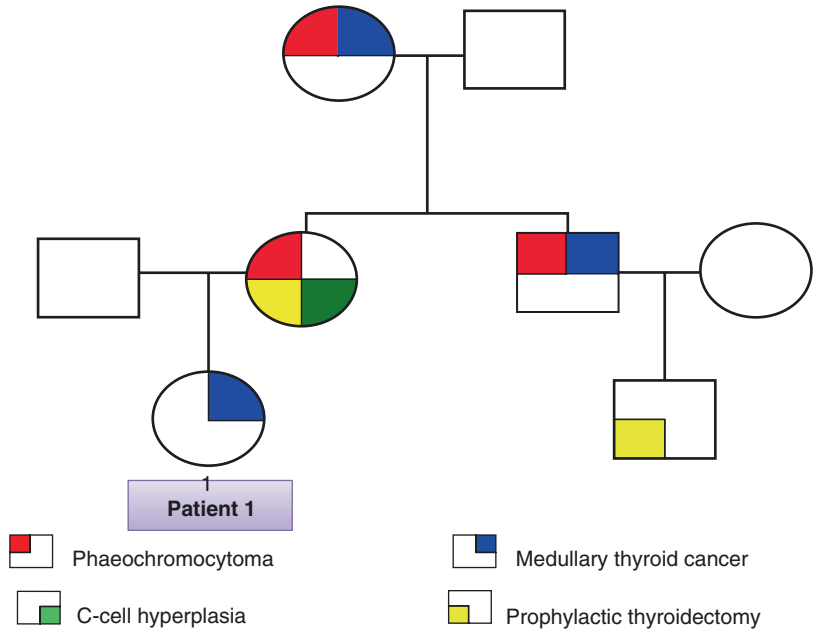
spread. Patients are monitored by serum measurement of calcitonin at follow up due to the risk of recurrence in the remnant thyroid tissue.

Case 7

A 14-year-old girl (patient 1) presents with a solitary neck lump. Thyroid function was normal. Ultrasound showed a left sided nodule. Fine needle aspiration (FNA) was inconclusive so she underwent left lobectomy of the thyroid which on histology was medullary thyroid cancer.

Calcitonin levels were checked postoperatively and were raised at 13.1 ng/L (<5 ng/L). Genetic screening was performed and she had a mutation in the RET gene. This mutation is associated with MEN2. The diagnosis of MEN 2A was made as she had no features like mucosal neuromas suggestive of MEN 2B. Plasma metanephrines were normal. She underwent a total thyroidectomy.

Four other family members were screened and were identified as having the same genetic mutation. One member of the family had been previously diagnosed with a phaeochromocytoma but this had not been followed up. Another two of the family members had biochemical and radiological evidence of medullary thyroid carcinoma and phaeochromocytoma.



Discussion: Children or adolescents found to have medullary thyroid cancer require genetic screening and if positive family screening. If a mutation is identified in the RET gene early prophylactic thyroidectomy (as medullary thyroid cancer occurs in 95%) is recommended along with ongoing screening for phaeochromocytoma (occurs in 40%) and hyperparathyroidism (occurs in 20%).

Points to Remember

- *Thyroid nodules are mostly benign; however, thorough evaluation is essential as 21–26% of these can be cancerous in children and adolescents.*

- *Papillary thyroid cancer is the most common type of thyroid cancer and has a good prognosis.*
- *Medullary thyroid carcinomas account for 5–10% of childhood cancers and can be inherited as part of multiple endocrine neoplasia or familial medullary thyroid carcinoma.*

32.5 Conclusions

Thyroid disorders of childhood are important endocrinopathies which need prompt investigation and treatment in order to allow for normal growth and development. Although rare, conditions such as foetal and neonatal thyrotoxicosis can be fatal necessitating careful maternal history and close monitoring of the foetus and the neonate. Thorough evaluation of thyroid nodules to exclude neoplasia is crucial. Knowledge of association of thyroid cancers with other endocrine neoplasias and a detailed family history are the key to diagnosing inherited thyroid cancers.

Abstract

Thyroid dysfunction affects approximately 3% of pregnant women. Adequate thyroid hormone levels are important for fetal development. Normal physiological changes of pregnancy can contribute to subclinical hypothyroidism which may require treatment with thyroxine during pregnancy. Pre-existing hypothyroidism requires an increase in thyroxine dosage. Pre-existing hyperthyroidism may or may not require continued treatment with anti-thyroid medication, though these medications can rarely cause adverse fetal effects. Gestational

hyperthyroidism must be distinguished from a new diagnosis of Graves' disease in pregnancy. Gestational hyperthyroidism does not require treatment with anti-thyroid medication. Graves' disease requires additional monitoring of mother and fetus and consideration of anti-thyroid medication. Post-partum thyroiditis is an underdiagnosed condition which can cause transient hyperthyroidism before recovery or hypothyroidism, or hypothyroidism without a hyperthyroid phase. Serial monitoring of thyroid function test is required. The vast majority of women with thyroid conditions can be managed to a successful pregnancy outcome.

Keywords
Pregnancy · Thyroid disease · Prenatal care · Postnatal care · Perinatal care

Abbreviations

bHCG	Beta human chorionic gonadotropin
IQ	Intelligence Quotient is an attempt to measure intelligence
T3	Free triiodothyronine
T4	Free thyroxine
TRAb	Thyroid receptor antibody levels
TSH	Thyroid stimulating hormone

Key Terms

- **Thyroid stimulating hormone (TSH):** a hormone made by the pituitary gland which stimulates the thyroid gland to make thyroxine (T4) and a small amount of tri-iodothyronine (T3).
- **Thyroxine (T4):** a hormone created by thyroid gland which travels in the circulation to the body's tissues.
- **Tri-iodothyronine (T3):** a more biologically active hormone mostly created by conversion of T4 to T3 in the body's tissues. A small amount is created by the thyroid gland itself.
- **Thyroxine-binding globulin:** a globulin protein, mostly created in the liver, that binds to T4 and T3 and carries it in the circulation.

Key Points

- The most common thyroid disorders in pregnancy include pre-existing disorders such as Hashimoto's hypothyroidism and Graves' disease as well as pregnancy-specific conditions such as gestational hyperthyroidism.
- The normal physiological changes of pregnancy play a key role in significant changes in thyroid hormone levels during gestation, including the development of subclinical hypothyroidism.
- Appropriate monitoring and management of thyroid conditions in pregnancy are important for health of both mother and fetus.
- Anti-thyroid medication improves the control of hyperthyroid conditions but may cause fetal adverse effects.
- The vast majority of women with thyroid conditions can be managed to a successful pregnancy outcome.

33.1 Physiology of Changes in Pregnancy Affecting Thyroid Function and Testing

The demands of pregnancy induce a number of significant physiological changes including profound cardiovascular adaptations, a 15% increase in basal metabolic rate, and a symphony of hormonal changes. Human chorionic gonadotropin levels increase greatly during the first trimester; oestrogen, progesterone, cortisol, and prolactin levels also increase, whilst lutenising and follicular stimulating hormone levels decrease. From an immunological perspective, a shift away from cell-mediated immunity (Th1 response) to humoral immunity (Th2 response) can result in some conditions such as Graves' disease improving during pregnancy.

Three key changes drive important changes in thyroid function (Glinoer 1998b)

1. **Increase in thyroid binding globulin levels**
   Thyroid binding globulin levels increase two- to threefold as a result of elevating oes-

trogen levels. As a greater proportion of thyroxine (T4) is bound to thyroid binding globulin, free thyroxine levels tend to decrease. Free triiodothyronine (T3) also tends to decrease. As is the case outside pregnancy, reduced thyroxine levels provide negative feedback to the hypothalamic-pituitary axis (Chap. 1) in order to try to maintain euthyroid equilibrium and steady state via a stimulus to increase in thyroid stimulating hormone (TSH). The increase in thyroid stimulating hormone is evident across trimesters. In women who have sufficient iodine intake, free thyroxine and triiodothyronine levels fall up to 15% during pregnancy.

2. **Action of human chorionic gonadotropin on the thyroid, particularly during the first trimester**
   Human chorionic gonadotropin is an essential hormone for a successful pregnancy. It is produced by the syncytiotrophoblast in the placenta and helps sustain the corpus luteum in the early stages of pregnancy. The corpus luteum produces progesterone which promotes the uterine thickening which allows the successful development of the implanted zygote/embryo.

   Absolute human chorionic gonadotropin levels vary between individuals, but increase exponentially after conception and Week 6 of pregnancy (beta human chorionic gonadotropin (bHCG) levels 1000–55,000 mIU/L), with further large increases to Week 12 (25,000–290,000 mIU/L), before decreasing to less than half the latter concentration by the time of delivery. There is evidence that human chorionic gonadotropin can directly stimulate the thyroid gland in a similar manner to thyroid stimulation hormone due to having a similar chemical structure known as molecular mimicry.

   In some women with bHCG levels greater than 50,000 mIU/L for more than 3 days, the stimulatory effect of human chorionic gonadotropin on the thyroid gland is sufficient to drive thyroxine and triiodothyronine levels high enough to cause symptomatic hyperthyroidism (e.g. with palpitations and tremor). There is a concomitant suppression of thyroid stimulating hormone production. Whilst most women do not suffer from hyperthyroidism in this manner, the effects of human chorionic gonadotropin do still exert a downward or blunting effect on thyroid stimulating hormone levels, particularly during the first trimester. Some research suggests that every 10,000 mIU/L increase in bHCG levels correlates with a 0.6 pmol/L increase in thyroxine levels and a decrease of 0.1 mIU/L in thyroid stimulating hormone level (Glinoer 1999).

3. **The placenta as an active endocrine organ**
   The placenta contains Type II deiodinase and Type III deiodinase. Type II deiodinase converts thyroxine (T4) to triiodothyronine (T3). It is also present in the thyroid gland. Type III deiodinase converts thyroxine and triiodothyronine to biologically inactive reverse triiodothyronine (reverse T3) and diiodothyronine (T2).

   The manner in which placental enzymatic activity regulates the hormonal environment for the developing fetus is not completely understood. It is generally agreed that the placenta plays a role in the need for increased maternal creation and turnover of thyroxine. This increased demand can result in women without sufficient iodine intake becoming hypothyroid.

33.2 An Approach to Abnormal Thyroid Function in Pregnancy

Iodine sufficiency should be ensured in all women, which usually requires supplementation of dietary sources (Box 33.1). Universal thyroid function testing is not currently recommended. Women with a personal history of thyroid disease should be tested when seeking to conceive and in the first trimester with management tailored to the particular condition. Women with a history of autoimmune disease should be considered for testing. Antibody testing is generally a useful adjunct to testing of thyroid function when patients have a history of autoimmune thyroid or other disease. Women who have a diagnosis of any thyroid disorder will require

Box 33.1 Practice Tips: Iodine Requirements in Pregnancy

Iodine is the key component for the biosynthesis of thyroid hormone. Inadequate intake predisposes a woman to hypothyroidism (Glinoer 1997). For both pregnancy and during breastfeeding, 250 μg/day is recommended by the World Health Organization and a number of key bodies, though not yet the United Kingdom Scientific Advisory Committee on Nutrition. This intake recommendation is higher than the 140–150 μg/day suggested for non-pregnant adults. Research has shown that iodine insufficiency does exist in developed countries including the United Kingdom.

Iodine is most often consumed in milk products, seafood, and shellfish. Organic milk contains less iodine. Grains may contain some iodine depending on the soil characteristics of cultivation, though levels vary. In some countries, salt is iodised.

All pregnant and breastfeeding women should be advised to take a supplement to ensure their intake of iodine is at least 250 μg/day. Different formulations of pregnancy vitamins can have different amounts of iodine and this should be scrutinised for adequacy prior to purchase and on clinical review. Consumption of more than 500 μg/day is not recommended.

monitoring throughout pregnancy though most conditions have a tendency to stabilise in the second and third trimesters.

33.3 Thyroid Disorders During Pregnancy

The two most common causes of hyperthyroidism in pregnancy are gestational hyperthyroidism and Graves' disease. Most women with Graves' disease are diagnosed before rather than during pregnancy. Rarer causes of hyperthyroidism can include the hyperthyroid phase of Hashimoto's disease, gestational trophoblastic disease (e.g. molar pregnancy), and exogenous taking of thyroxine tablets inappropriately or at the incorrect dose.

Hypothyroidism and subclinical hypothyroidism is most commonly caused by the physiological changes of pregnancy and is termed gestational (subclinical) hypothyroidism. Women with insufficient iodine intake are at greater risk of becoming hypothyroid. A second important cause is Hashimoto's disease which is an immune condition (See Chap. 30) can be diagnosed prior to or during pregnancy.

33.3.1 Gestational Hyperthyroidism

Gestational hyperthyroidism is due to the direct stimulatory effect of human chorionic gonadotropin on the maternal thyroid gland. It usually occurs during the first trimester and usually resolves by the end of the first half of pregnancy. This is because human chorionic gonadotropin levels are at their highest levels toward the end of the first trimester, and in some women are sustained at high enough levels to drive excess thyroxine (T4) production by the thyroid. Gestational hyperthyroidism is associated in some women with hyperemesis gravidarum which is characterised by severe nausea and vomiting. Both conditions are more common in twin pregnancy (Glinoer 1998a, b, c).

33.3.1.1 Diagnosis

Diagnosis of gestational hyperthyroidism is based on a combination of clinical features and laboratory investigations.

- Women often suffer from classical symptoms and signs of hyperthyroidism including palpitations, tremor, weight loss or lack of weight gain, anxiety and heat intolerance. On examination, they can be tachycardic. They do not have prominent eyes or an eye disease which is associated with Graves' disease. The thyroid gland is usually normal in size.

- On thyroid function testing, thyroxine and triiodothyronine levels are elevated beyond the reference range, and thyroid stimulating hormone production are usually less than 0.5 mIU/L and can be undetectably low.
- Thyroid receptor antibody levels (TRAb) are important to perform and are negative.

33.3.1.2 Maternal Concerns

Gestational hyperthyroidism can significantly diminish a women's quality of life (Glinoer 1998b).

Once a diagnosis is made, it is important to ask about symptoms of hyperemesis gravidarum, and seek specialist medical care for that condition if required. Even in the absence of hyperemesis gravidarum, weight loss and lack of weight gain caused by hyperthyroidism can be concerning for the patient, and increased caloric intake to compensate should be encouraged.

33.3.1.3 Fetal Concerns

Women who have gestational hyperthyroidism and hyperemesis gravidarum may not be able to meet nutritional requirements with consequent fetal risk of intrauterine growth retardation. The fetus of a woman with gestational hyperthyroidism only is not at significantly increased risk of adverse outcomes because of the transient nature of the condition.

33.3.1.4 Management

Steps in management include:

- Education and reassurance of the patient that the condition is usually self-limiting and very unlikely to cause any harm to the fetus
- Activate social supports including in cases of anxiety
- Encourage sufficient caloric intake
- Urgent referral to a specialist doctor if hyperemesis gravidarum is suspected
- Consideration of beta-blocker medication in severe cases, e.g. propranolol or labetalol. Side effects and safety in pregnancy should be discussed. Anti-thyroid medication is not required.
- Clinical review of the patient at 3–4 week intervals with repeat thyroid function tests until symptoms and thyroid function tests normalise

33.3.2 Pre-existing Hyperthyroid Conditions

Graves' disease is the most common cause of pre-existing hyperthyroidism. The condition is described fully in Chap. 28. Women of childbearing age with the condition should be counselled to use contraception until the disease is appropriately managed and disease activity levels are well controlled. Successful pregnancy is certainly possible for women with a history of the condition. Appropriate counselling should occur of the risks the condition poses for pregnancy, including the potential fetal effects of anti-thyroid drugs. Such pregnancies should not be considered "low risk". Women who have had a thyroidectomy to treat Graves' disease can still have circulating thyroid receptor antibodies which can affect a pregnancy. Antibody levels three times the upper limit of the normal reference range denote pregnancies of highest risk. Toxic (hyperfunctioning) nodules (see Chap. 28) can also cause hyperthyroidism in pregnancy.

33.3.2.1 Diagnosis

Diagnosis both in and outside of pregnancy is based on clinical symptoms and supporting investigation results. Women often present with symptoms of hyperthyroidism including weight loss, palpitations, hair loss, difficulty sleeping, and diarrhoea. Graves' disease can cause eye problems including exophthalmos (prominent or bulging eyes), slowed eye movements, and chemosis (swelling of the conjunctivae). Occasionally, women can present reporting that other people have told the patient that their eyes have changed.

- Thyroid receptor antibody (TRAb) levels can be measured in blood. The widely available test is accurate (both sensitive and specific)

Box 33.2 Case Example 1. Palpitations in Pregnancy

M.R is a 30-year-old lady who is 12 weeks into her first pregnancy. She reports suffering from palpitations and difficulty sleeping for a fortnight. She is anxious and concerned that she has not put any weight on for that period. M.R has no significant past medical history.

On examination she appears tired. Her heart rate is 118 beats per minute. The rest of the examination is unremarkable. Her thyroid function test results are TSH 0.1 mIU/L (Normal range-NR 0.5-4.0), T4 27 pmol/L (NR 10-20), and T3 5 pmol/L (NR 4-7).

What further test is it important to order? How would you counsel and manage M.R?

Please refer to the end of this chapter for answers related to this case

and is useful for diagnosis and as a marker of current disease activity.

- Thyroid uptake scans are a nuclear medicine scan which can also be used to diagnosis and assess the activity levels of Graves' disease. However, as the scan requires the use of a radionucleotide tracer which emits radiation, scans are not performed on pregnant women, and are generally avoided in the breastfeeding mother.

33.3.2.2 Maternal Concerns

Even when the condition is adequately treated, Graves' disease is associated with higher rates of miscarriage, pre-eclampsia, placental abruption, preterm delivery, and thyroid storm. Pregnancy carries with it a risk of worsening Graves' eye disease.

The medications used most commonly for Graves' disease in the United Kingdom are carbimazole and propylthiouracil. Methimazole is commonly prescribed in the United States. Both of these anti-thyroid drugs can cause disturbances in the production of red and white blood cells, with consequent anaemia and poor immune function. The medications can also cause disturbances in liver function, with rare cases of liver failure also reported particularly with propylthiouracil.

33.3.2.3 Fetal Concerns

Graves' disease is associated with intrauterine growth retardation, miscarriage, and pre-term delivery. The fetal thyroid develops from 6 weeks and produces thyroxine during the second half of pregnancy. The thyroid receptor antibodies associated with the Graves' disease can cross the placenta and stimulate the fetal thyroid causing hyperthyroidism. There is some evidence that hyperthyroidism may be associated with an increased risk of later seizure and neurobehavioural disorders.

Anti-thyroid medication reduces thyroxine and triiodothyronine levels in the maternal circulation with transmission to the fetus via the placenta which plays an active role in regulation of these hormones in the intrauterine environment. If such hormone levels are greatly reduced, the fetus can become hypothyroid. In rare cases, the fetus can develop a goitre as a consequence, which can put pressure on its trachea.

Anti-thyroid medication can also directly affect the fetus. Aplasia cutis (absence of a portion of skin, e.g. on scalp) and congenital abnormalities such as oesophageal atresia and dysmorphic facies have been reported with use of carbimazole (Yoshihara 2012). Face or neck cysts and urinary tract abnormalities in male offspring have been reported with propylthiouracil. As these abnormalities are not considered as severe as those with carbimazole, propylthiouracil is usually used during the first trimester, the key period of fetal organogenesis. Specialist medical advice should be sought on medication choice, as guidelines are being revised in a number of countries.

33.3.2.4 Management

Principles of management include:

- Pre-pregnancy counselling and disease control by a specialist physician.
- Regular clinical review with thyroid function tests during pregnancy—e.g. every 4–6 weeks if stable, every 2 weeks if medication changes are being made or the condition is not stable.

- In patients who require medication, use of the lowest dose of anti-thyroid medication required. Propylthiouracil Ideally 250 mg or less (total daily dose) is often used in the first trimester with consideration of patients being changed to Carbimazole Ideally 20 mg or less (total daily dose) in the second and third trimester. Remaining on a single type of medication throughout pregnancy is also appropriate in some cases. Although the potential fetal effects such as intrauterine growth retardation must be considered, beta-blocker medication such as Propranolol can be used to assist with hyperthyroid symptoms.
- Treatment is aimed to keep maternal thyroxine level at the upper limit of the normal range to minimise the risk of fetal hypothyroidism.
- Medication doses can often be reduced or ceased during the second and third trimester due to maternal immune system changes.
- Thyroidectomy can be considered in severe, resistant cases or in cases of allergies to medication.
- Thyroid receptor antibody levels should be performed regularly including at initial review, at 18–22, and at 30–34 weeks gestation to aid in estimating effects on the fetus.
- Post-partum review is essential as women are at risk of disease relapse particularly in the first 2 months after delivery.
- The neonate requires thyroid function tests at day 5 and day 10 and whilst mild abnormalities are often found, they are transient and rarely require treatment. However undiagnosed thyrotoxicosis in the neonate carries a high mortality rate, hence the need to perform these blood tests.
- Use of up to 20 mg of Carbimazole if needed is considered safe for breastfeeding.

Toxic Nodules

Toxic (hyperfunctioning) nodules are a rare cause of hyperthyroidism during pregnancy. Some women will have the nodules ablated using radioactive iodine prior to pregnancy and be euthyroid. Toxic nodules do not produce antibodies. Some women may need anti-thyroid medication through the pregnancy, usually at low doses. The risks of these medications are described in the previous section. There is no evidence that toxic nodules change their level of activity during pregnancy. Subclinical hyperthyroidism (suppressed thyroid stimulating hormone with thyroxine levels in the normal range) may not need treatment, but overt hyperthyroidism should prompt strong consideration of medication to avoid increased risks of miscarriage and other problems.

33.3.3 Pre-existing Hypothyroidism

Pre-existing hypothyroidism in pregnant women may be due to known Hashimoto's hypothyroidism, or an induced hypothyroid state consequent to the treatment of a hyperthyroid state (e.g. Graves' disease, toxic nodules) with radioactive iodine or thyroidectomy. Thyroidectomy may also have been performed as management for thyroid malignancy or multinodular goitre. Rarer causes of pre-existing hypothyroidism include pituitary dysfunction, previous pituitary surgery, and congenital hypothyroidism. Women with pre-existing hypothyroidism will likely already be on thyroxine replacement. Some will be seeing a specialist physician, though many will be managed at primary care level. The key issue in women with pre-existing hypothyroidism is the need for an increased thyroxine dose due to the physiological changes of pregnancy outlined above.

33.3.3.1 Diagnosis

The original cause of a women's hypothyroidism will usually have been diagnosed prior to pregnancy.

- If thyroxine doses are not increased, some women with pre-existing hypothyroidism will have an increase in their thyroid stimulating hormone levels in the first trimester.
- Women with pituitary dysfunction or previous pituitary surgery will not have such a rise as the pituitary is not able to respond to as

according to usual negative feedback principles (See Chap. 26).
- All women may have free thyroxine levels that reduce to the lower part of below the laboratory reference range. Even in the absence of conclusive evidence that thyroid stimulating hormone levels have risen or thyroxine levels have fallen, it is often the case that a greater dose of thyroxine is required.

33.3.3.2 Maternal Concerns

Women with pre-existing hypothyroidism who become pregnant can be asymptomatic or suffer the symptoms of over hypothyroidism such as tiredness and weight gain. However, symptoms of hypothyroidism may be confused with symptoms of normal pregnancy. Thyroid function testing is therefore essential. Profound untreated hypothyroidism is associated with an increased risk of maternal anaemia, heart failure, muscle weakness, pre-eclampsia, placental abruption, and post-partum haemorrhage.

33.3.3.3 Fetal Concerns

Severe maternal hypothyroidism, usually due to iodine deficiency in developing countries, can cause fetal cognitive, neurological, and developmental abnormalities including a constellation of these effects previously termed "cretinism". Many women with pre-existing hypothyroidism are at risk of milder hypothyroidism in pregnancy, therefore requiring early testing and an increase in the thyroxine dose as indicated. A large cohort study found a 7-point lower IQ in the offspring of undertreated hypothyroid mothers, with delays in motor skill development, language development, and attention at 7–9 years of age (Haddow et al. 1999). Maternal hypothyroidism is associated with an increased risk of a low birthweight baby and prematurity.

33.3.3.4 Management

- Women with pre-existing hypothyroidism should either have thyroid function tested as soon as possible after becoming pregnant with dose titration, or be instructed to increase their dose of Thyroxine by approximately 25% on becoming pregnant. As fetal brain development occurs predominantly in the first trimester, the dose increase should not be delayed whilst awaiting specialist review, or if thyroid function testing will cause undue delay.
- Thyroid function tests should ideally be done early in pregnancy and then 4–6 weekly during the first trimester, and then at least once in each of the second and third trimesters. Titration of Thyroxine dose to keep the thyroid stimulating hormone level at the appropriate trimester-specific range. Some women will need a 50% increase in dose. Rarely, after a significant dose increase, thyroid stimulating hormone levels may depress below the reference range. When this happens, the Thyroxine dose may need to be decreased slightly.
- Women should be re-educated in an ideal manner to take Thyroxine medication, on an empty stomach (usually morning), with a sip of water if required. Milk, including tea or coffee should not be consumed for an hour after taking Thyroxine, and other medication including pregnancy multivitamins should be taken at least an hour later.
- On delivery of the baby, the mother should be instructed to return to her pre-pregnancy dose of Thyroxine. No wean or gradual reduction is required.
- The mother should be asked to have repeat thyroid function testing 6–8 weeks post-partum, ideally with her primary care practitioner who will be managing her ongoing care.

33.3.4 Subclinical Hypothyroidism

Subclinical hypothyroidism is common in pregnancy due to the physiological changes of pregnancy outlined above. Treatment thresholds can vary and are in a state of change. Consequently, it is worthwhile consulting local guidelines and clinical leadership for any established management practices. Gestational subclinical hypothyrodism is a transient condition in which the requirement for treatment with thyroxine ceases on delivery. The condition may reoccur in future pregnancies.

Subclinical hypothyroidism is defined as an elevated thyroid stimulating hormone level with thyroxine and triiodothyronine levels in the normal range. Pregnancy and trimester-specific reference ranges should be used when available. Thyroid peroxidase antibodies should be tested to help determine whether the woman has hitherto undiagnosed hypothyroidism or is likely to develop long-term hypothyroidism due to Hashimoto's disease.

33.3.4.1 Diagnosis

In all cases of subclinical hypothyroidism, thyroxine and triiodothyronine levels should be in the normal range. If these levels are lower than the reference range, the patient has overt hypothyroidism and will also require treatment with Thyroxine.

- Total or free hormone level reference ranges can be used and ideally should be pregnancy specific. Usually, the normal range is defined as being between the 2.5th and 97.5th centiles of the relevant normal population (Table 33.1).

33.3.4.2 Maternal Concerns

Subclinical hypothyroidism has been associated with impaired fertility; with the use of thyroxine in women undergoing treatment with assisted reproductive technology becoming common. An association with miscarriage has also been a concern though more recent data has not supported this finding.

There have been studies and meta-analyses of the relationship between subclinical hypothyroidism and the risks of gestational diabetes, placenta previa, placental abruption, and/or pre-eclampsia. Results have differed considerably, partly because of variability in inclusion of overtly hypothyroid women.

Table 33.1 Thyroid stimulating hormone levels that prompt a diagnosis can vary depending on the guidelines being used

	Trimester			
	1	2	3	
TSH (mIU/L)	Pregnancy/ trimester-specific ranges			
TSH (mIU/L)	>2.5	>3.0	>3.5	European Thyroid Association 2014 (Lazarus et al. 2014)
TSH (mIU/L)	>4.0	>4.0	>4.0	American Thyroid Association 2017 (Alexander et al. 2017)

33.3.4.3 Fetal Concerns

As overt hypothyroidism has been associated with lower IQ in children, there has been concern that the offspring of women with subclinical hypothyroidism may also suffer adverse cognitive effects. Studies have reported conflicting results (Williams 2012). Treating pregnant women to a thyroid stimulating hormone level of <1.0 mIU/L did not improve IQ tested at 3 years of age (Lazarus et al. 2012).

One meta-analysis found an increased risk pre-term delivery and perinatal mortality with subclinical hypothyroidism (Van De Bougard et al. 2011) though many individual studies have not concluded this.

33.3.4.4 Management

- Women should be re-educated in an ideal manner to take Thyroxine medication, on an empty stomach (usually morning), with a sip of water if required. Milk, including tea or coffee should not be consumed for an hour after taking Thyroxine, and other medication including pregnancy multivitamins should be taken at least an hour later.
- On a diagnosis of subclinical hypothyroidism, Thyroxine should be commenced at a dose of 50 mcg. If the thyroid stimulating hormone level is grossly elevated (e.g. >10 mIU/L), and/or the patient is obese or has a high weight, a higher commencement dose can be considered.
- Further thyroid function testing should occur 4–6 weeks after dose commencement or change, at least once a trimester. Dosages can be titrated to achieve the required target thyroid stimulating hormone. In general, the dosage of Thyroxine will be more stable in the second and third trimester.
- Thyroid peroxidase antibody levels should be tested. If they are positive, strong consideration should be given to continuing Thyroxine after delivery with instructions for testing and titration 6 weeks post-partum by the primary care practitioner.
- If thyroid peroxidase antibodies are negative, and the woman thus has uncomplicated sub-

clinical hypothyroidism, the woman should be instructed to return to cease Thyroxine after delivery. No wean or gradual reduction is required (Negro et al. 2011).

Box 33.3 Case Example 2. Anxiety and Explanations

K.P is a 26-year-old lady who is 8 weeks into her second pregnancy. Her first child has Autism Spectrum Disorder. K.P is well and without symptoms. After missing her period, she visited her primary care practice. The GP registrar ordered a number of blood tests including thyroid function tests before referring her to your clinic. K.P is a little anxious about her results. She has no significant past medical history.

Examination is unremarkable. Thyroid function test results are TSH 5.5 mIU/L (NR 0.5-4.0), T4 13 pmol/L (NR 10-20), and T3 5 pmol/L (NR 4-7).

What further test is it important to order? How would you counsel and manage K.P?

Please refer to the end of this chapter for answers related to this case

33.3.5 Positive Thyroid Peroxidase Antibodies with Otherwise Normal Thyroid Function

Some women who are seeking to conceive or are pregnant will have positive thyroid peroxidase antibodies but will have thyroid stimulating hormone and thyroxine levels in the normal range. Whilst some research has suggested that commencing such women on Thyroxine will assist with fertility success, a greater number of studies have not supported such a finding. Whilst it is not necessary to cease Thyroxine if it has been commenced by another clinician, it is not desirable to commence Thyroxine in such women. There is a reported association between positive thyroid peroxidase antibodies and spontaneous miscarriage and premature delivery though guidelines do not recommend commencing thyroxine as there is insufficient evidence that this changes outcomes (De Leo and Pearce 2017).

33.3.5.1 Management

- When necessary, counsel women that the majority of the evidence indicates that commencing Thyroxine in their situation is unnecessary and does not change outcomes.
- Inform that the positive antibodies suggest a higher background risk of becoming or developing hypothyroidism in the future
- Monitor the woman's thyroid function tests 4–6 weekly until mid-gestation and then if stable at 30 weeks
- Inform the woman and communicate with her primary care doctor that she should have her thyroid function tested at 6 weeks post-partum, and thereafter 4–6 monthly for at least a year and then as her doctor guides. A woman with positive thyroid peroxidase antibodies is at a higher risk of post-partum thyroiditis and a long-term risk of hypothyroidism

33.4 Thyroid Disorders in the Puerperium (Post-partum) Period

33.4.1 Introduction

The most common thyroid disorder during the post-partum period is post-partum thyroiditis which affects approximately 5% of the population (Stagnaro-Green 2015). Unfortunately, this autoimmune condition is underdiagnosed, with symptoms often being attributed to the challenges of caring for a newborn child.

Approximately a quarter of women with post-partum thyroiditis will experience the "classical" course of hyperthyroidism followed by hypothyroidism. Half will develop hypothyroidism without a hyperthyroid phase. The remainder will have isolated hyperthyroidism only. Some women who become hypothyroid will remain so for the long term.

33.4.1.1 Diagnosis

Women can suffer from hyper- or hypothyroid symptoms (Chaps. 3 and 5) depending on the subtype of hypothyroidism.

- Common hyperthyroid symptoms in the condition are palpitations, heat intolerance, irritability, and fatigue.
- Tiredness, cold intolerance, dry skin, and impaired memory are common in those women who become hypothyroid.
- Post-partum thyroiditis is strongly associated with positive thyroid peroxidase antibodies, which is a useful adjunct test together with thyroid function tests. Women who test positive for thyroid peroxidase antibodies have greater than a 30% chance of developing post-partum thyroiditis.
- Thyroid receptor antibodies should also be tested to exclude Graves' disease—there is also an increased risk of the new development of Graves' disease in the post-partum period. The presence of thyroid receptor antibodies is very likely to indicate Graves' disease.
- Thyroglobulin antibodies may also be positive but provide limited further diagnostic value in the modern context.
- A nuclear medicine thyroid uptake scan (I-131, Tc-99m) can be used to help distinguish different types of thyroid disease. Such imaging is possible in the post-partum period provided breast milk is discarded for the required interval (4 days I-131, 1 day Tc-99m), but in practice other diagnostic methods are strongly preferred.
- Given the common nature of post-partum thyroiditis, there should be a low threshold for thyroid function testing during this time. Women are particularly at risk of developing the disorder 6–10 weeks after delivery but it can occur up to 12 months post-partum. Serial thyroid function testing every 2–3 months is often helpful in determining the subtype of disorder.
- Women with autoimmune diseases such as Type 1 diabetes and systemic lupus erythematosus have a two- to threefold increased over-background risk of developing post-partum thyroiditis. Women with Graves' disease are also at higher risk of developing post-partum thyroiditis. Such women should ideally be reviewed clinically approximately 6 weeks post-partum, with some clinicians reasonably opting to test thyroid function tests in this group regardless of symptomatology.

33.4.1.2 Maternal Concerns

Both the symptoms of hyperthyroidism and hypothyroidism can obviously make caring for a newborn or infant child even more challenging. Given hypothyroidism can cause low mood, particular interest has been focused on the relationship between post-partum thyroiditis and depression. The evidence is conflicting with some studies indicating increased risk whilst other studies have not demonstrated this link. It is prudent to screen women for common depressive symptoms (Table 33.2) and refer appropriately. Research has specifically not shown increased risk of the rarer condition of depression with psychotic features.

33.4.1.3 Neonatal Concerns

There is some evidence that selenium can reduce the risk and severity of post-partum thyroiditis in women who have positive thyroid peroxidase antibodies in pregnancy. However, commencing selenium in this context has yet to become clinical practice, pending further studies to replicate findings.

Table 33.2 Common depressive symptoms in post-partum period

Anhedonia—markedly diminished interest or pleasure in almost all activities
Low mood
Fatigue
Feeling restless or slowed down
Feelings of worthlessness or guilt
Poor sleep—sleeping excessively, difficulty sleeping, and/or early morning wakening
Poor appetite
Thoughts or preoccupation with death or dying including suicide
Irritability
Significant weight loss or weight gain
Difficulty with concentration/memory

Women with autoimmune conditions (e.g. Type 1 diabetes) should receive a clinical review and strong consideration of testing of thyroid function tests and thyroid peroxidase antibodies approximately 6 weeks post-partum.

33.4.1.4 Management

- Management of hyperthyroid phase in affected individuals who are significantly symptomatic is with beta-blocker medication, usually propranolol 10–20 mg three to four times a day.
- Women with post-partum thyroiditis require long-term follow-up to monitor for the emergence of hypothyroidism.

Box 33.4 Case Example 3. Post-partum Struggles

H.O is 5 weeks post-partum, having delivered her first child who was born healthy at term. Her thyroid function tests (thyroid stimulating hormone and thyroxine/T4) during pregnancy were normal though her thyroid peroxidase antibodies were on the upper limit of the normal range. H.O was not started on thyroxine. Her sister and mother have had Hashimoto's hypothyroidism for a number of years.

H.O phones you as you reviewed her during her pregnancy. She says she is struggling to sleep and noticed she is losing hair. H.O says she is often worried about her baby's feeding and sleeping and feels overwhelmed. Her husband works long hours, and her own family are overseas.

How would you manage H.O in this situation?
What tests would you organise and what would you expect to find?

Please refer to the end of this chapter for answers related to this case

33.5 Conclusions

Thyroid disease can have a diverse range of causes and presentations during pregnancy. The most common conditions of subclinical hypothyroidism and pre-existing hypothyroidism can be well managed with thyroxine commencement and adjustment, with regular thyroid function test monitoring. Gestational hyperthyroidism is a self-limiting condition which should be distinguished from Graves' disease. Graves' disease requires specialist input throughout pregnancy and surveillance in the post-partum period. Post-partum thyroiditis can cause hypothyroidism or hyperthyroidism. The condition is common and underdiagnosed. Thyroid function tests should be organised if there is clinical suspicion, and patients will require long-term follow-up.

Case Study 2–4. Answers

Case study 2: M.R symptoms of palpitations, difficulty sleeping, and not putting on weight are consistent with hyperthyroidism. Her thyroid function tests support this with an elevated thyroxine/T4 and supressed thyroid stimulating hormone levels. As she is in the first trimester, gestational hyperthyroidism caused by BHCG stimulation of the thyroid is the probable diagnosis. Although the condition is considered "benign" in that it does not cause fetal problems or long-term maternal problems, women can be significantly symptomatic. It is important to test for thyroid receptor antibodies to distinguish from the serious condition of Graves' disease. A positive result for such antibodies should prompt immediate contact with a specialist. M.R should be counselled that the condition is self-limiting and likely to improve in the next 2–6 weeks as BHCGs levels fall in the second trimester. She should be encouraged to eat more and to activate social supports. Beta-blocker medication can be considered in severe cases for short-term use with the involvement of a medical practitioner.

Case study 3: K.P has subclinical hypothyroidism as defined by her thyroid stimulating hormone being marginally elevated and her thyroid stimulat-

ing hormone being in the normal range. Most women with this condition are asymptomatic. In the context of having a child with Autism Spectrum Disorder, K.P may be particularly concerned about anything she has read or heard regarding a link between "low thyroid levels" and "intellectual problems". It is important to reassure K.P that this generally occurs in cases much more severe than her situation. K.P should be tested for thyroid peroxidase antibodies, the presence of these may indicate that she would benefit from post-partum monitoring for the development of post-partum thyroiditis or hypothyroidism. During pregnancy, a small dose of thyroxine (e.g. 50mcg daily) should be started with titration to the pregnancy-specific thyroid stimulating hormone targets outlined in this chapter, or as per local guidelines.

Case example 4: H's symptom of losing hair is consistent with hyperthyroidism. Her difficulty in sleeping and concern about her child's welfare may be expected with a newborn child, but may also be due or worsened by hyperthyroidism. It can be difficult to distinguish such a situation clinically, and therefore thyroid function and thyroid antibody tests, especially thyroid peroxidase antibodies, should be requested. Together these results (supressed thyroid stimulating hormone, elevated thyroxine/T4, positive thyroid peroxidase, and thyroglobulin antibodies) may indicate a diagnosis of post-partum thyroiditis. Serial clinical and biochemical monitoring of women with post-partum thyroiditis is required. In the long-term, hypothyroidism may develop and require treatment with thyroxine.

Abstract

The adrenal glands are important endocrine organ that produces corticosteroids including glucocorticoids, mineralocorticoids and androgens. These are important hormones that regulate sodium retention, blood pressure, fluid volume, the immune system, metabolism and behaviour. The adrenals also exert negative feedback mechanism in the hypothalamus and pituitary through the hormone cortisol. High levels of cortisol suppress the pituitary hormone ACTH whereas low cortisol stimulates ACTH secretion by increasing the release of hypothalamic hormones CRH and AVP. The adrenal medulla, which is located in the central part of the adrenal, forms part of the sympathetic nervous system and is referred as the sympatho-adrenomedullary system. It secrets epinephrine (adrenaline), norepinephrine (noradrenaline) and dopamine in response to stimulation by the sympathetic nervous system.

Abbreviations

ACTH	Adrenocorticotropic hormone
AGP	Adrenogonadal primordium
AngII	Angiotensin II
AR	Androgen receptor
AVP	Arginine vasopressin
CAH	Congenital adrenal hyperplasia
CBG	Corticosteroid-binding globulin
CRH	Corticotropin releasing hormone
DHEA	Dehydroepiandrosterone
DHEAS	Dehydroepiandrosterone sulphate
DHT	Dihydrotestosterone
GC	Glucocorticoid
GR	Glucocorticoid cell receptor
HPA	Hypothalamic pituitary axis
PAPS	3′-phosphoadenosine-5′-phophosulfate
PCOS	Polycystic ovarian syndrome
SCN	Hypothalamic suprachiasmatic nucleus
zF	Zona fasciculata
zG	Zona glomerulosa
zR	Zona reticularis

Key Terms

- **Outer layers of adrenal cortex:** This is made up of the zona glomerulosa (zG), zona fasciculata (zF) and zona reticularis (zR), comprising of 90% of the gland.
- **Inner layer of adrenal cortex:** The adrenal medulla is located in the middle of the adrenal gland beyond the zona reticularis (zR).

Key Points

- The adrenal consist of three outer zones: zona glomerulosa, zona fasciculata and zona reticularis. The inner layer is the adrenal medulla.
- The adrenal is a major endocrine gland in the human body.

34.1 Adrenal Development in Fetal and Postnatal Stage

The embryonic adrenal development derives from neural crest cells and intermediate mesoderm. The early stage of adrenal development appears as an adrenogonadal primordium (AGP) at 28–30 days post-conception in humans. Neural crest cells develop into the adrenal medulla while intermediate mesoderm regresses into the definitive adrenal cortex. During the embryonic stage, the neural crest cells differentiate into neuroblasts (sympathoblasts) and become sympathetic and autonomic ganglion cells as well as phaeochromoblasts, which later become phaeochromocytes or mature chromaffin cells. Phaeochromocytes which form the adrenal medulla are enveloped by mesenchymal primitive adrenal cortex.

During the fetal stage, the zone of adrenal cortex of is called the fetal zone; 80% of it consists of fetal zone cells. These cells produce large quantities of DHEA and DHEAS, which are converted to oestrogen by the placenta for the maintenance of normal pregnancy. Adrenocortical cells emerge by the 8th week of gestation to form the definitive zone that later develops into the adrenal cortex. During the last 6 weeks of gestation, the majority of the prenatal growth is due to the enlargement of the fetal cortex which is the largest zone at birth.

After birth, the fetal zone undergoes changes under the influence of the hormones angiotensin II (AngII) and ACTH, whereby the zona glomerulosa (zG) and zona fasciculata (zF) mature. Unlike the zona glomerulosa and fasciculata, the zona reticularis does not function actively between 6–8 years old in females and 7–9 years old in males. It begins to emerge between the zona fasciculata and the medulla in a process known as ‘adrenarche’, which involves the proliferation and production of adrenal androgens. Adrenarche is independent of ACTH or gonadotropins. Secondary sexual characteristics also begin to occur at adrenarche. The mechanisms

involved in postnatal adrenal formation and the maintenance of these distinct zones remain poorly understood.

34.2 Anatomy of Adrenal Glands

The adrenal glands weigh 4–5 g each in a normal healthy adult and sit on the upper end of the right and left kidneys (Fig. 34.1). The centre of the adrenal gland, the medulla, weighs around 1 g. The outer layer, the zona glomerulosa (zG), is composed of ovoid-shaped cells. The zona fasciculata forms the majority of the adrenal cortex and is organised in fascicles or bundles. There is no anatomical demarcation between medulla and cortex. The medulla is composed of chromaffin cells and contains small vesicles 100–300 nm in diameter in which catecholamines (adrenaline and noradrenaline) are stored and released. In the human, adrenaline accounts for 80% of adrenal catecholamine release into the circulation system and has effects on multiple organs.

The adrenal cortex synthesises corticosteroids, including over 50 distinct steroid hormones. Under normal condition in the absence of stress, the adult adrenal cortex produces approximately 10–15 mg of cortisol per day.

The adrenal glands are highly vascular, with three critical arteries supplying each adrenal gland. The superior suprarenal artery, the superior suprarenal artery and the middle suprarenal artery. Blood flows into the adrenal cortex and drains into the adrenal medulla before entering the inferior vena cava via the central vein on the right adrenal. On the left, the adrenal vein blood drains into the left renal vein. The drainage system of the adrenal gland plays a complex role in steroid synthesis and regulation. The adrenal gland is also well innervated. The nerve supply originates from the coeliac plexus and thoracic splanchnic region of the sympathetic autonomic nervous system, as well as some parasympathetic contributions from the phrenic and vagal nerves. The nerve supply also reaches the chromaffin cells in the medulla, and the innervation has been

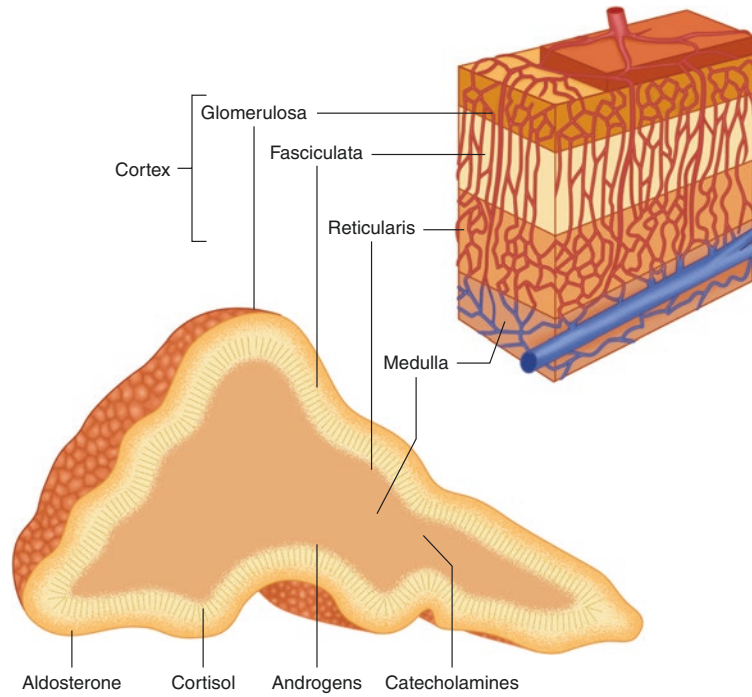

Fig. 34.1 Anatomy and hormones secretion of adrenal gland

suggested to reach the cortisol arteriolar and capillary bed to regulate cortisol blood flow. Chromaffin cells are also found in the vagus nerve, carotid arteries, bladder, prostate and liver. Besides secreting catecholamine and dopamine, the adrenal medulla also secretes other stress hormones such as enkephalins and neuropeptide Y. One of the most important actions of catecholamine is the fight-or-flight response which leads to an increase in respiration, heart rate, blood pressure and blood vessel constriction (in the skin and gut).

34.3 Functions of the Adrenal Glands

The adrenal cortex is responsible for the production of three major classes of steroid hormones: glucocorticoids, mineralocorticoids and androgens (Fig. 34.2). The zona glomerulosa synthesises the mineralocorticoids aldosterone, the zona fasciculata produces cortisol, while the inner layer zona reticularis secretes androgen steroids such as dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulphate (DHEAS), androstenedione and 1β-hydroxyandrostenedione. Glucocorticoids, such as cortisol, are secreted in high amounts around 10–50 mg/day whereas mineralocorticoids, such as aldosterone, are much less at around 100–200 μg/day. Surprisingly, DHEAS is also secreted in large quantities.

34.3.1 Aldosterone

First isolated in 1953, aldosterone has a plasma half-life of under 20 min and is weakly bound to plasma proteins. The adrenal secretes an average of 100–200 μm of aldosterone in 24 h. Its secretion is mainly stimulated by angiotensin II and an increase of extracellular potassium concentration, compared to other minor modulators such ACTH, stretch receptors in the heart, serum sodium and serotonin. Angiotensin II is converted in the lung from angiotensin I, which is stimulated by the release of the enzyme renin in the kidney (Fig. 34.3). Aldosterone promotes sodium and water retention and lowers plasma potassium levels by binding to mineralocorticoid receptors in the renal tubules. After binding to the receptor, the complex translocates to genomic DNA which causes gene transcription expression and in turn leads to reabsorption and retention of sodium and excretion of potassium and hydrogen. The sequence also affects blood pressure and extracellular fluid volume. This system is called the renin-angiotensin-aldosterone system and also has a small diurnal rhythm mediated by ACTH.

Aldosterone and corticosterone share the first part of their biosynthesis pathways. They are synthesised from cholesterol catalysed by enzyme of cytochrome P450 family located in the mitochondria (Fig. 34.3). The last part of the aldosterone pathway is mediated by aldosterone synthase, found only in the zona glomerulosa in the adrenal where pregnenolone is transformed to progesterone and then to aldosterone. Aldosterone is catabolised in the liver and kidney and a small amount is excreted in the urine. Aldosterone level in plasma is also affected by the time of the day and posture.

34.3.1.1 Aldosterone Dynamic

Aldosterone excess has a profound impact on blood pressure due to the increase in sodium and fluid retention, including extracellular fluid expansion as well as suppression of plasma renin activity. This chronic hypervolaemic state leads to hypertension. Aldosterone excess is found in primary hyperaldosteronism where excess secretion of aldosterone leads to suppression of renin, hypokalaemia and hypertension. In congenital adrenal hyperplasia (CAH), C21-hydroxylase deficiency caused by 21-hydroxylase gene mutation leads to increased ACTH levels and androgens but loss of major mineralocorticoids. Classic form of CAH presented with salt-losing and virilisation.

Conversely, patients with primary and secondary adrenal failure may present with low blood pressure, low sodium and hyperkalaemia, but only in primary adrenal failure there is loss of mineralocorticoids. Replacement with mineralocorticoid will rectify the electrolyte imbalance in such patients.

34.3.2 Cortisol

The 'stress hormone' cortisol plays a major role in the hypothalamic-pituitary-adrenal HPA axis (Fig. 34.4) (please read the Chap. 12 in Part III for more details). Cortisol exerts numerous effects including blood sugar control through gluconeogenesis, affects blood pressure through salt and water regulation and regulates the immune system through its anti-inflammatory effects. It also affects memory, emotion and cognition.

Cortisol production is stimulated by the pituitary hormone ACTH, which itself is regulated by corticotropin releasing hormone (CRH) and arginine vasopressin (AVP) from the hypothalamus. ACTH is a 39 amino-acid peptide secreted by the anterior pituitary gland. Its secretion also occurs in response to low circulating cortisol, anxiety and stress, as well as the underlying circadian rhythm. It is inhibited by high endogenous and exogenous circulating cortisol or other glucocorticoids, and thus forms a homeostatic loop.

Cortisol is produced in circadian manner (Fig. 34.5), peaking around 8–9 am and at several points throughout the day including following meals. At a cellular level, cortisol binds to the glucocorticoid cell receptor (GR). Once bound to the receptor, it is translocated to the nucleus and leads to changes in metabolism particularly on carbohydrate, fat and protein metabolism. The GR complex also up-regulates the expression of

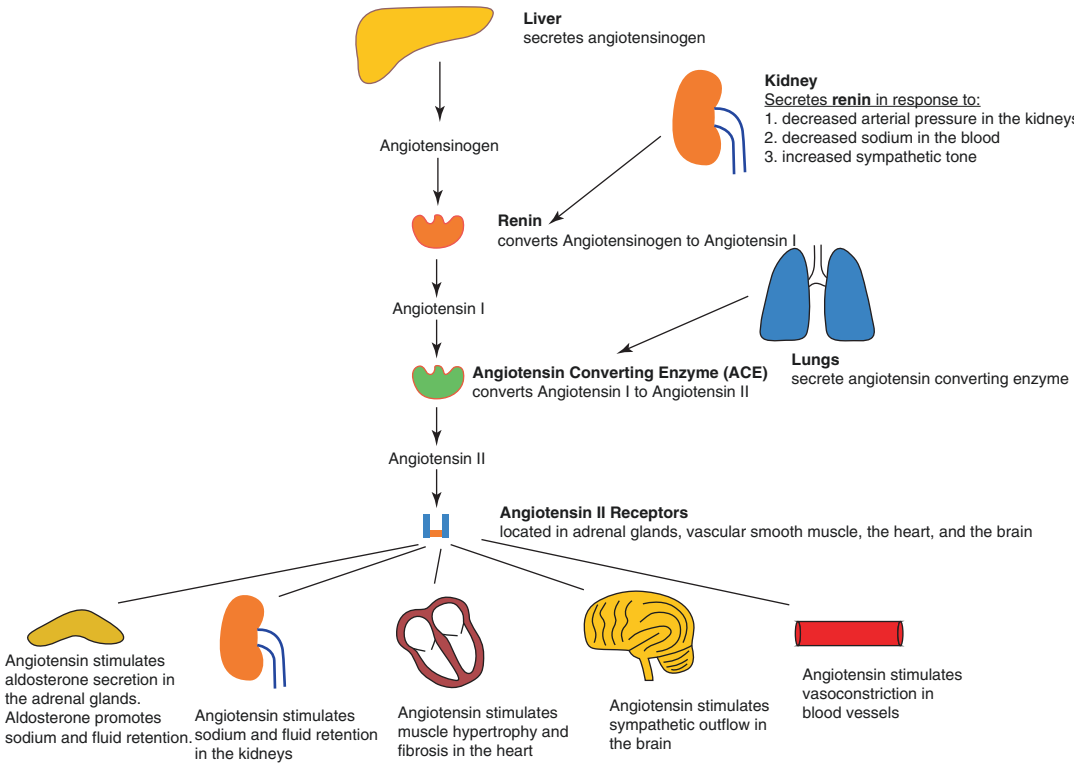

Fig. 34.3 The renin-angiotensin-aldosterone system

anti-inflammatory proteins in which represses the expression of pro-inflammatory proteins.

34.3.2.1 Body Circadian Rhythm of Cortisol Production

The circadian rhythm of cortisol secretion is shown in Fig. 34.5. ACTH is secreted in a pulsatile manner. Peak levels usually occur in the morning coinciding with peak cortisol production with a 30–60 min delay. It has a short life and the response is closely related to physical demands and environmental influences.

This circadian system is controlled by central clock in the hypothalamic—the suprachiasmatic nucleus (SCN)—which synchronises subsidiary cellular peripheral clocks. The SCN is located in the anterior part of the hypothalamus immediately dorsal, or superior (hence supra), to the optic chiasm. The intracellular mechanisms interlock negative and positive transcriptional-translational feedback loops that oscillate over a 24-h period.

34.3.2.2 Pharmacodynamics of Cortisol

Cortisol is circulated in three forms: protein bound, free cortisol and cortisol metabolites. The largest group is protein-bound cortisol which constitutes approximately 92% of the total cortisol in the circulation. It has a better affinity to corticosteroid-binding globulin (CBG) than to albumin. The free cortisol or unbound fraction is the active hormone that dictates physiological activity. When the cortisol secretion reaches a saturation point with normal CBG secretion, this leads to increased free or unbound cortisol in circulation. Most synthetic glucocorticoids have less affinity to CBG. Prolonged elevation of free or unbound cortisol in circulation adversely produces Cushingoid symptoms.

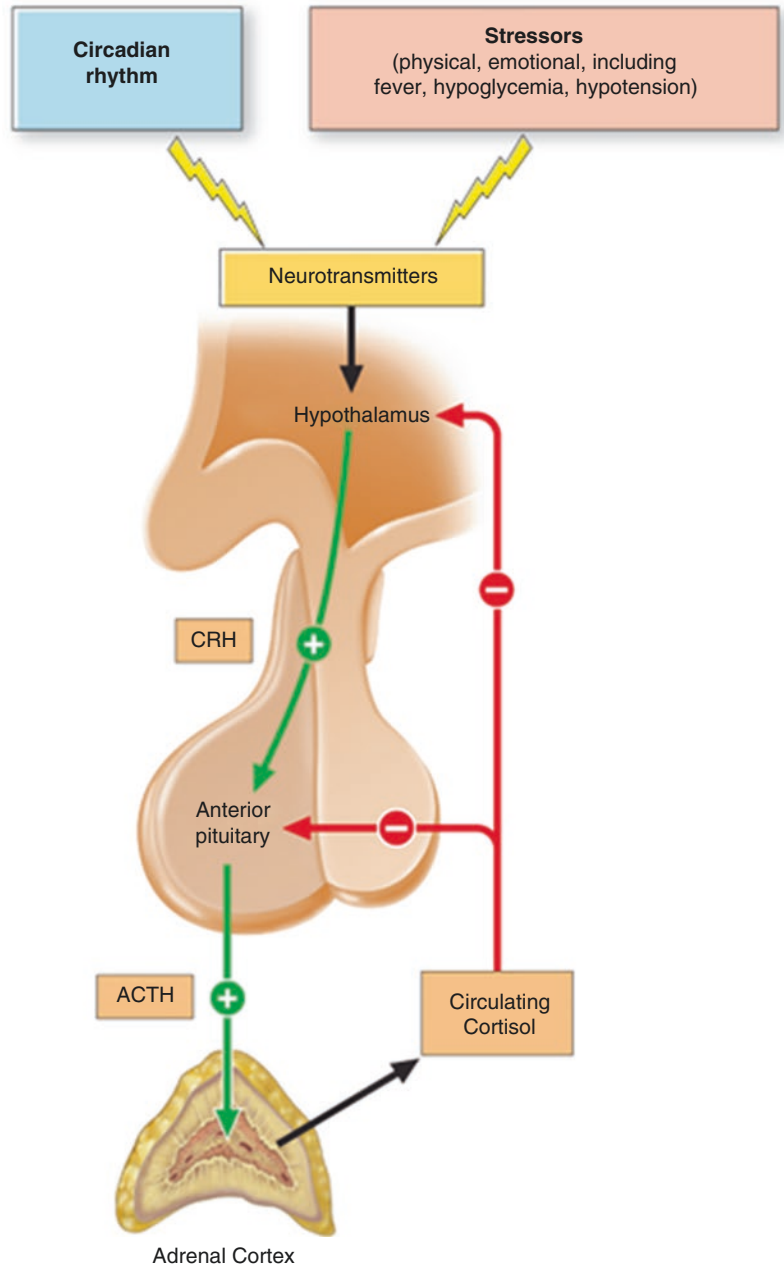

Fig. 34.4 The hypothalamic-pituitary-adrenal (HPA) axis and regulation of adrenal glucocorticoid secretion. (Used with permission from Arlt W (2017) Disorders of the adrenal cortex, chapter 8. In: Jameson JL (Eds) Harrison's Endocrinology, 4th Edition, McGraw Hill Education, New York, pages 107–135)

Cortisol is metabolised in the liver and metabolites are excreted via the kidneys.

Standard laboratory assays for serum cortisol levels include protein-bound and the free or unbound fractions in order to determine the total concentration. Cortisol can also be measured in the saliva and urine. Salivary cortisol reflects the amount of free unbound cortisol that escapes binding proteins and enters the tissues throughout the body. Salivary cortisol measures cortisol collected at that particular time: 24 h urinary free cortisol (UFC) captures total amount of free and

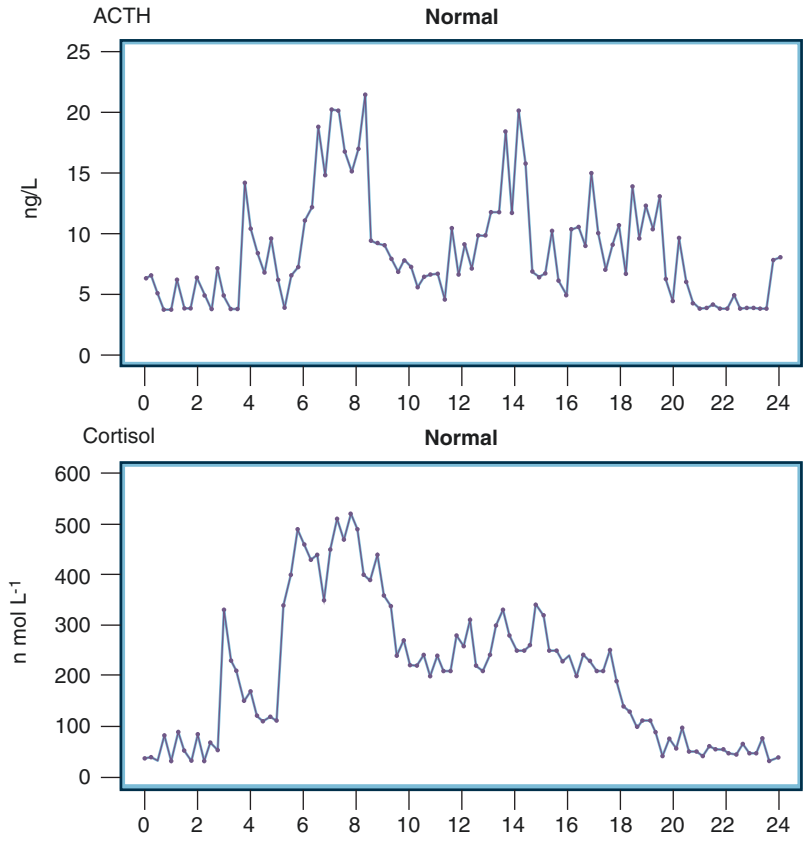

Fig. 34.5 The circadian rhythm of the cortisol production. (Used with permission from Stewart P.M. (2008) The adrenal cortex, chapter 14. In: Kronemberg H.M., Melmed S., Polonsky K.S. and Larsen P.R. (Eds) Williams Textbook of Endocrinology, 11th Edition. Saunders Elsevier, Philadelphia, pages: 445–503)

unbound cortisol excreted in urine over 24 h period. It should be emphasised that many cortisol assays will also measure, to some extent, other corticosteroids or their metabolites.

34.3.3 Androgens

Adrenal androgens are synthesised from cholesterol through a series of intracellular and extracellular actions involving oxidases and dehydrogenases. Unlike glucocorticoids, adrenal androgens have little activity at androgen receptors. Instead, they function as precursor molecules ready to be metabolised peripherally to potent androgens such as DHT or aromatised to oestradiol. The C_{19} steroids include DHEA, DHEAS, androstenedione and 11β-hydroxyandrostenedione. They are produced in adrenal gland and gonads in both men and women. Circulating levels of dehydroepiandrosterone (DHEA), DHEA-sulphate (DHEAS), androst-5-ene-3 beta, 17 beta-diol (5-diol), 5-diol-sulphate, 5-diol-fatty acid esters and androstenedione in both men and women were found to decline from the age of 20–80 years old (Labrie et al. 1997). The majority of DHEA and DHEAS comes from the adrenals, including 50% of secreted androstenedione. The conversion to potent androgens such as testosterone or dihydrotestosterone occurs in tissues that express HSD3-B1 and HSD17-B1/5 such as adipose tissue and the skin.

The adrenal gland secretes a small amount of testosterone. In men, testosterone is predominantly produced by Leydig cells in the testes. In women, DHEA can be taken up by ovarian theca cells to synthesise testosterone and may be converted to dihydrotestosterone in peripheral tissues once converted to androstenedione, without requiring transformation to testosterone (Nakamura et al. 2009). In healthy men, circulating testosterone levels are approximately ten times higher than women (Taieb et al. 2003).

DHEA is converted to DHEA-sulphate (DHEAS), an inactive steroid, through the enzyme DHEA sulfotransferase SULTA2-A1. When required, DHEAS is reactivated back to DHEA with the presence of the sulphate donor 3′-phosphoadenosine-5′-phophosulfate (PAPS). PAPS is synthesised by the two isoform of PAPS synthase, PAPSS1 and PAPSS2. The sulphation process is important to prevent excess androgen formation, which could in turn lead to increased androstenedione or testosterone.

However, the regulation of adrenal androgens remain poorly understood. It is thought that ACTH may play a role. This is from data collected from patients with ACTH stimulation during adrenal venous sampling (Rege et al. 2013) where ACTH administration increases DHEAS by fivefold, DHEA by 21-fold, androstenedione by sevenfold and 11β-hydroxyandrostenedione by fivefold. Whether this is physiologically relevant remains unclear.

Androgens play a critical role for the development and maintenance of the male reproductive system. They also influence insulin sensitivity as well as bone and muscle metabolism. It exerts its effects by a genomic mechanism by involving the hormones binding to androgen receptor (AR) resulting in the modulation of gene expression. The androgen receptor is a nuclear receptor that is activated by androgenic hormones such as testosterone or dihydrotestosterone in the cytoplasm, and then translocate into the nucleus. During male sexual development, testosterone is responsible for primary sexual characteristic development, while dihydrotestosterone is responsible for secondary male characteristics, particularly male genital development to form the penis scrotal pouches as well as hair follicle development.

Androgen increases the rate of bone remodelling by prolonging the lifespan of osteoclasts and shortening the lifespan of osteoblasts. This leads to slow the maturation of bone, but the more potent epiphyseal effect comes from oestrogen which is aromatised from androgens.

Androgens also impair adipose tissue to proliferate and differentiate. This in turn induces adipose tissue dysfunction and affects glucose uptake and leads to insulin resistance, intracellular stress and inflammation (Klöting and Blüher 2014). Treatment of androgen excess has been shown to reduce fasting insulin and improve the insulin sensitivity (Banaszewska et al. 2016).

34.3.3.1 Testosterone

Testosterone has a direct impact in body composition of men by increasing lean body mass and this leads to increase insulin sensitivity. Low testosterone independently affects insulin resistance. Androgen replacement therapy improves insulin sensitivity, diabetes and the metabolic syndrome in hypogonadal men (Haider et al. 2014; Traish et al. 2014).

High levels of testosterone correlate with high androstenedione levels in women with polycystic ovary syndrome (O'Reilly et al. 2014) who were found to have an adverse metabolic phenotype. However, Lerchbaum et al. (2014) argued contrarily that high androstenedione and the free testosterone index have a beneficial metabolic effect.

On the other hand, patients with adrenocortical carcinoma often present with Cushing's syndrome and androgen excess including DHEA/DHEAS, androstenedione and testosterone. High testosterone in women may cause hirsutism, acne, deepening of the voice, hair loss and amenorrhoe. However, testosterone excess in men raised haematocrit, seborrhoea, acne and some mood changes.

34.3.3.2 DHEA/DHEAS

Sulphation is an important pathway of DHEA metabolism. Any disruption in this pathway, including patients with PAPSS2 mutations, can lead to high active DHEA and a low DHEAS levels (Oostdijk et al. 2015). A similar pattern was found in two thirds of polycystic ovarian syndrome patients showing an increase in the DHEA/DHEAS ratio with significantly increased excretion of both major androgen metabolites, androsterone and aetiocholanolone (Kempegowda et al. 2016); 20–30% of PCOS women were found to have excess DHEAS levels (Goodarzi et al. 2015). In Asian women with PCOS, high serum

DHEAS is associated with the presence of acne and a significantly reduced risk of abdominal obesity, independent of serum testosterone concentration and insulin resistance (Chen et al. 2011). The study showed that DHEAS and total testosterone have different relationships with body weight, abdominal obesity and dyslipidaemia. A lower prevalence of acne was found in obese PCOS women with lower DHEAS concentrations (Afifi et al. 2017). Asian patients with PCOS have a lower prevalence and severity of hirsutism and obesity which might be attributed to genetic and environmental differences.

34.3.3.3 Conclusions

The adrenals play an important role in the dynamics of the endocrine system. Its complex interactions with hormone pathways, genetic factors, environmental influences and the body's circadian rhythm all play a vital role in its secretion, excretion and homeostasis. Excess and insufficient adrenal secretions underpin the balance between health and disease. Feedback mechanisms are often involved in the synthesis and pathway of the adrenal system.

Abstract

The adrenal cortex produces the steroid hormones, glucocorticoids, mineralocorticoids, and androgens, required for normal metabolic function. They are specifically involved in supporting the stress response, salt and water balance, and sex development. Congenital adrenal hyperplasia (CAH) is a group of genetic disorders caused by enzyme deficiencies in adrenal steroid production. More than 90% of CAH cases are caused by a deficiency of the adrenal steroid enzyme 21-hydroxylase (CYP21A2). Depending on the severity of deficiency, patients can have a variable spectrum of clinical presentation. Classic CAH is the most serious form and is life-threatening, due to severe glucocorticoid and mineralocorticoid deficiency (the so-called salt-wasting classic CAH), or isolated glucocorticoid deficiency but largely preserved mineralocorticoid deficiency (the so-called simple virilising classic CAH). Androgen excess leads to ambiguous genitalia in girls (also termed 46,XX disorder of sex development, 46,XX DSD) and precocious sexual maturation in childhood. Nonclassic CAH is associated with androgen excess and either normal glucocorticoid capacity or borderline glucocorticoid deficiency; it can present as precocious sexual maturation in childhood and hirsutism and irregular menses in adolescents and adult women. Classic CAH requires treatment to correct hormone deficiencies (glucocorticoids and mineralocorticoids) and mitigate androgen excess. In childhood, treatment focuses on issues of gender assignment, genital surgery, and optimisation of growth and pubertal development. Priorities change with increasing age, typically focusing on fertility in early adult life and prevention of metabolic syndrome and bone loss in middle and older age. Prevention of life-threatening adrenal crisis remains paramount throughout the life of these patients. Management of CAH is complex and involves multidisciplinary expertise throughout the life of these patients. This chapter provides endocrine nurses with a synopsis of the approach, evaluation, and management of patients with CAH. Particular emphasis is placed on providing comprehensive coordinated care that includes patient and family education and the understanding of the physical and psychological consequences of the condition.

Keywords

21-hydroxylase deficiency · Adrenal insufficiency · Adrenal crisis · Androgen excess Ambiguous genitalia

Abbreviations

17OHP	17-hydroxyprogesterone
46,XX DSD	46,XX disorder of sex development
ACTH	Adrenocorticotropic hormone
CAH	Congenital adrenal hyperplasia
FSH	Follicle-stimulating hormone
IM	Intramuscular
IV	Intravenous
LH	Luteinising hormone
SHBG	Sex hormone-binding globulin
TARTs	Testicular adrenal rest tumours

Key Terms

- **ACTH stimulation test:** diagnostic test to assess the adrenal steroid production after the administration of the synthetic ACTH analogue Tetracosactide (Synacthen®, Cortrosyn®, Cosyntropin).
- **Adrenal crisis:** life-threatening emergency caused by inadequate production of the adrenal hormone cortisol in situations of stress.
- **Adrenal insufficiency:** condition in which the adrenal glands do not produce adequate amounts of steroid hormones, primarily the stress hormone cortisol.
- **Ambiguous genitalia:** condition in which an infant's external genitals don't appear to be clearly either male or female.
- **Hirsutism:** excessive terminal hair that appears in a male pattern in women.
- **Virilisation:** abnormal development of male sexual characteristics in females or in prepubertal age boys.

Key Points

- Steroid 21-hydroxylase deficiency is the most common cause of congenital adrenal hyperplasia. It accounts for most of the cases of primary adrenal insufficiency in children.
- Severe congenital adrenal hyperplasia causes insufficient production of the adrenal hormones cortisol and aldosterone. Cortisol and aldosterone are necessary for life and patients need lifelong replacement.
- Congenital adrenal hyperplasia causes androgen excess, which can lead to problems in newborns (ambiguous genitalia), children (virilisation and short stature), and adults (hirsutism, infertility, and menstrual irregularities).
- Cortisol deficiency predisposes patients with congenital adrenal hyperplasia to life-threatening adrenal crisis. This is a medical emergency that requires immediate treatment with injectable hydrocortisone (equivalent to the endogenous hormone cortisol).

35.1 Introduction

Congenital adrenal hyperplasia (CAH) is an inherited condition with many physical and psychosocial dimensions. The enzyme deficiency responsible for this condition affects hormone production of the adrenal gland, resulting in a combination of cortisol and aldosterone deficiency and androgen excess, which have detrimental effects both pre- and postnatally (El-Maouche et al. 2017; White and Bachega 2012). In this chapter, we will focus on CAH due to steroid 21-hydroxylase deficiency, which is the most common cause of the condition. We will review pathophysiology, diagnosis, and management, focusing on age-specific challenges associated with this chronic condition.

35.2 Pathophysiology of Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive genetic disorders and is the most common cause of primary adrenal

insufficiency in children (1:10,000 to 1:20,000 live births) (White and Speiser 2000; Speiser et al. 2010). The most frequent genetic abnormality is a mutation in the *CYP21A2* gene, which encodes the enzyme 21-hydroxylase; this accounts for more than 90% of cases (White and Speiser 2000). CYP21A2 is a key enzyme of adrenal steroidogenesis (Fig. 35.1a).

Adrenal steroidogenesis takes place in the adrenal cortex and leads to the production of **glucocorticoids** (i.e. cortisol, required for normal metabolic function and involved in the response to stress), **mineralocorticoids** (i.e. aldosterone, regulating the level of electrolytes and water in the body), and **adrenal androgens** (serving as sex steroid precursors). Adrenocorticotropic hormone (ACTH) is released by the anterior lobe of the pituitary gland, regulated via negative feedback from circulating glucocorticoids, and is an important stimulus of glucocorticoid and adrenal androgen production, promoting uptake and utilisation of cholesterol from the adrenal cortex. Cholesterol is the substrate of all steroid hormones (Fig. 35.1a).

CYP21A2 is crucial for the production of glucocorticoids and mineralocorticoids. As a consequence, the synthesis of cortisol and aldosterone is impaired when this enzyme is defective. A lack of cortisol drives increased ACTH secretion from the pituitary; ACTH then stimulates the adrenal gland to produce excessive amounts of androgens, the only pathway not affected by the lack of CYP21A2 (Fig. 35.1b). Several mutations of *CYP21A2* have been described in CAH. The severity of the condition relates to the degree to which the mutations compromise 21-hydroxylase activity (El-Maouche et al. 2017), reflected by different levels of impairment in cortisol and aldosterone production. The common feature of all

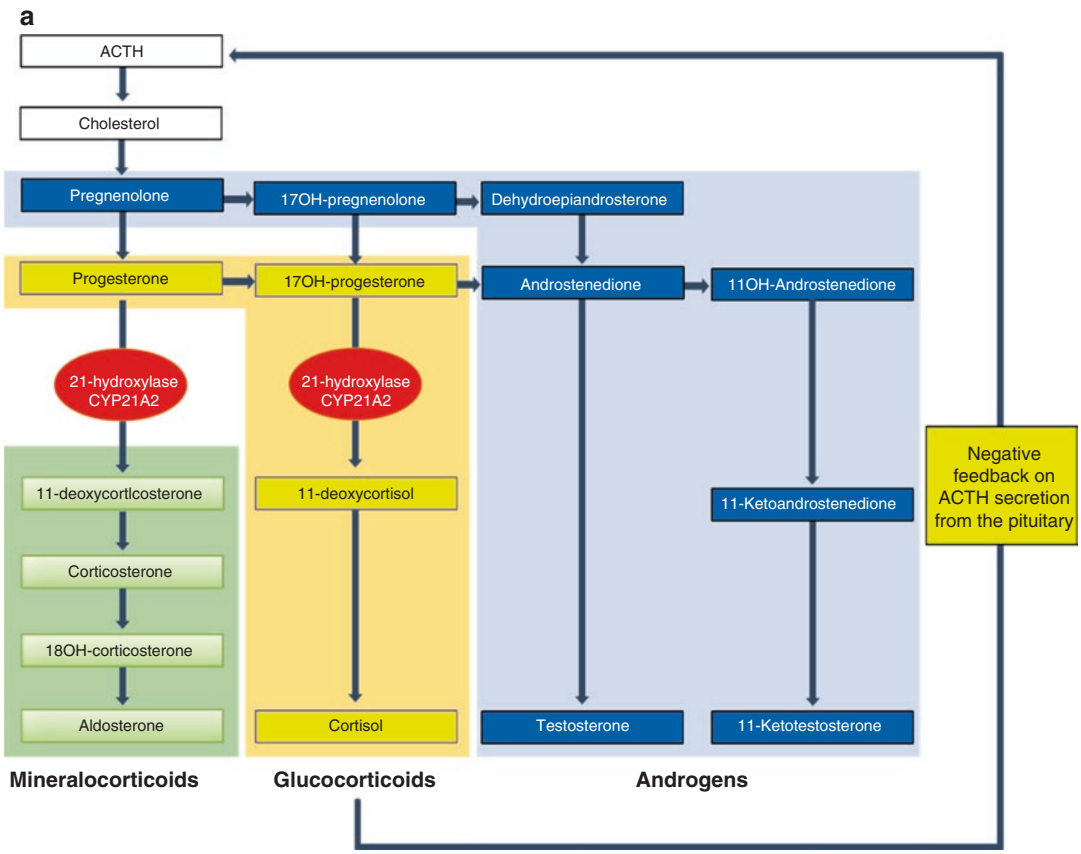

Fig. 35.1 Pathways of adrenal steroid synthesis. (**a**) Normal adrenal steroid synthesis. (**b**) Abnormal adrenal steroid synthesis in classic CAH (see next page); dotted arrows show the pathways affected by the lack of the enzyme 21-hydroxylase

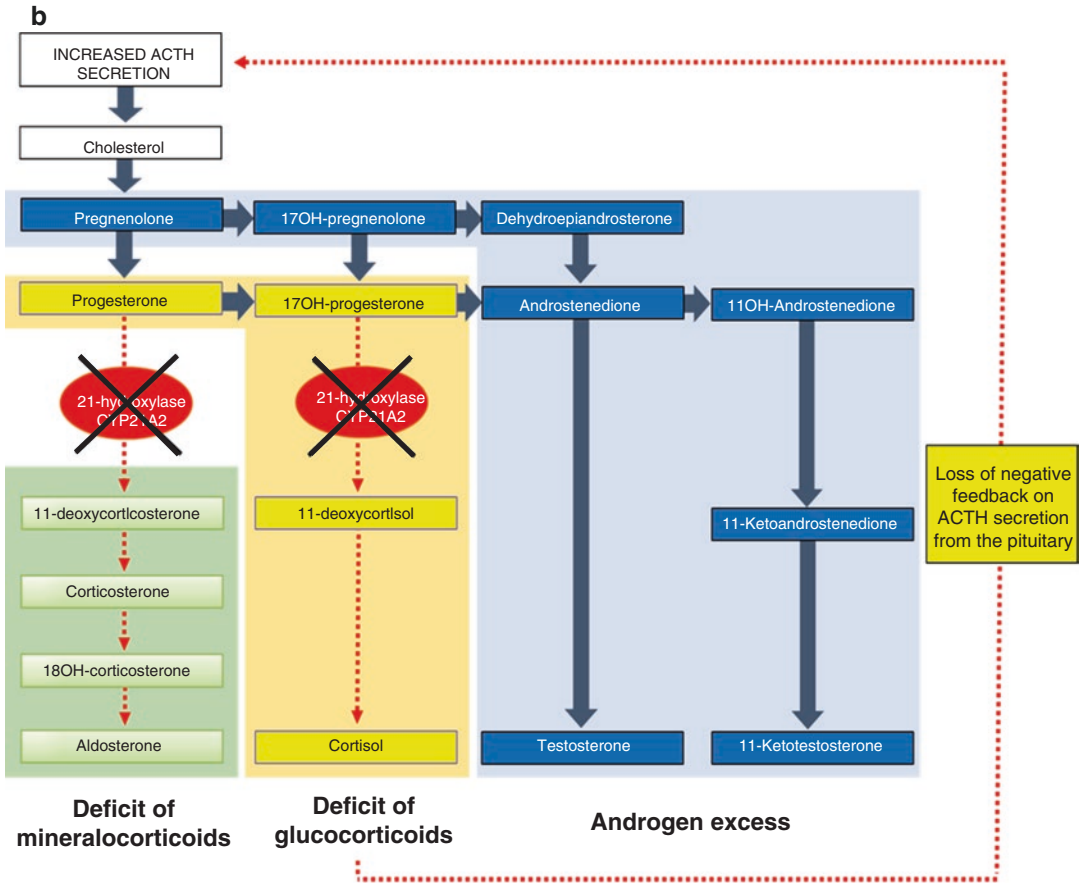

Fig. 35.1 (continued)

forms of CAH due to 21-hydroxylase deficiency is androgen excess.

35.3 Classification and Manifestations of Congenital Adrenal Hyperplasia

Depending upon the degree of cortisol and aldosterone deficiency and androgen excess, CAH can be classified as follows (White and Bachega 2012):

- **Classic CAH**: Severe deficiency of cortisol and androgen excess. Newborn females present with genital ambiguity (=46,XX disorder of sex development, 46,XX DSD). ~75% of newborns who are not identified at birth but harbour the most severe CYP21A2 mutations develop a salt-wasting crisis 7–14 days after birth (="salt-wasting" CAH—both cortisol and aldosterone deficiency). This is particularly relevant for newborn males, who do not present with genital ambiguity. Children with slightly less severe mutations and therefore largely preserved mineralocorticoid production also present with 46,XX DSD in affected girls at birth. However, affected boys are often only diagnosed in early childhood with signs of increased bone age and virilisation (="simple virilising" CAH—cortisol deficiency only). Children with classic CAH require glucocorticoid replacement (as well as mineralocorticoid replacement in "salt-wasting" genotypes), and this prevents further virilisation through excess androgen production via downregulation of the negative feedback and consequently diminished ACTH stimulation of the adrenal glands.
- **Nonclassic CAH**: It is the most common form of CAH and affects 0.1% of the general

population, with higher rates among Hispanics and Yugoslavs (1–2%) and Ashkenazi Jews (3–4%) (White and Speiser 2000). Patients with nonclassic CAH produce relatively normal amounts of cortisol and aldosterone at the expense of mild-to-moderate androgen excess. However, some patients may have borderline glucocorticoid deficiency and require glucocorticoid replacement during major stress; hence, all nonclassic patients warrant initial assessment of their glucocorticoid capacity through an ACTH stimulation test. They have no signs at birth and present later in childhood, adolescence, or adult life due to symptoms of androgen excess.

Table 35.1 describes the clinical manifestations of classic and nonclassic CAH.

35.4 Assessment, Care, and Management of Patients with Congenital Adrenal Hyperplasia

35.4.1 Diagnosis

In 2010, the Endocrine Society recommended universal newborn screening for CAH, and many countries have implemented this recommendation (Speiser et al. 2010), though there is no screening implemented in the UK at present. In many other countries, screening is done by measuring 17-hydroxyprogesterone (17OHP) in dried blood spots. Abnormal results should be confirmed by a second measurement (White 2009); specificity is increased by additional measurement of 21-deoxycortisol, a steroid only generated in large amounts in 21-hydroxylase

Table 35.1 Manifestations of congenital adrenal hyperplasia

Classic CAH	Nonclassic CAH (late-onset CAH)
Neonates: • Females: ambiguous genitalia (=46,XX DSD) • Males may have subtle findings such as scrotal hyperpigmentation or penile enlargement *~75% of patients present in a salt-wasting adrenal crisis 7–14 days after birth*: • History: failure to thrive; persistent poor feeding; excessive sleepiness; significant weight loss (>10%); vomiting; persistent jaundice • Observations: jaundice; hypothermia; tachypnoea; dyspnoea; dehydration (sunken fontanelle, poor skin turgor) • Hypovolaemic shock, cardiovascular collapse • Laboratory abnormalities: hypoglycaemia; hyponatraemia; hyperkalaemia; metabolic acidosis *Childhood*: • History of rapid growth (crossing centiles) • Advanced bone with reduced height prediction • Early pubic hair development or sexual precocity (typically at 2–4 years of age) • Clitoromegaly • Increased body odour • Oily skin and hair *Adolescence and adulthood*: • Hirsutism • Hair loss and receding hair line (male-patterned baldness in women) • Oily skin and hair • Excessive acne • Menstrual irregularities • Infertility in both men and women	Nonclassic CAH is usually associated with milder signs and symptoms of androgen excess. Patients can be diagnosed anywhere from early childhood to adulthood. Adolescent girls and adult women can have a clinical picture that is indistinguishable from the polycystic ovarian syndrome. Men are often asymptomatic. Affected females do not have ambiguous genitalia. *Late childhood*: • Early pubic hair development or sexual precocity (before the age of 8 years in girls or 9 years in boys) • Clitoromegaly (rare, mild) • Accelerated growth • Advanced bone age • Increased body odour *Adolescence and adulthood*: • Menstrual irregularities • Hirsutism • Hair loss and receding hair line (male-patterned baldness in women) • Excessive acne *Fertility*: Subfertility is milder in comparison to classic CAH. Men usually have a normal testicular function.

deficiency. If 17OHP is elevated, blood sodium, potassium, and glucose must be checked. The measurement of 17OHP after an ACTH stimulation test can be used to confirm the diagnosis (White 2009). Abnormal results should then be complemented with DNA analysis for *CYP21A2* mutations.

In females, the diagnosis of **classic CAH** is most commonly made at birth because of the ambiguity (atypical development) of their genitalia (=46,XX DSD). In males who don't undergo newborn screening and do not develop a salt-wasting crisis in the neonatal period, the diagnosis may be delayed and only present when they develop signs of androgen excess.

Most cases of **nonclassic CAH** are not picked up at neonatal screening (White 2009). The diagnosis of nonclassic CAH can be made at any time from childhood to adulthood, including asymptomatic individuals identified during genetic screening because of affected relatives. The initial assessment is done by measuring early morning 17OHP. Abnormal results should be followed up by an ACTH stimulation test for 17OHP and cortisol (Witchel and Azziz 2010).

35.4.2 Classic Congenital Adrenal Hyperplasia: Medical Treatment

Treatment includes glucocorticoid replacement which aims to normalise hormone balance and reduce excess androgen production from the adrenal glands. Treatment is required lifelong, and adherence to treatment is essential for normal growth and development throughout the lifespan (El-Maouche et al. 2017). It is crucial that families, children, and adult patients with CAH are able to learn the necessary skills to manage the condition and understand why treatment is needed and how it is managed (please refer to Chap. 37 for more information on how to support patients and improve their adherence to treatment in adrenal insufficiency).

The mainstay of treatment of classic CAH are glucocorticoids (**hydrocortisone [=cortisol] or, if difficult to control in adulthood, long-acting synthetic glucocorticoids such as prednisolone**) and mineralocorticoids (**fludrocortisone**). Glucocorticoids must be given in sufficient doses to replace cortisol deficiency and downregulate excessive production of ACTH from the pituitary and over-secretion of adrenal androgens. Fludrocortisone is given to keep electrolytes and intravascular fluid volume normal. Table 35.2 reports treatment goals and typical regimens in patients with classic CAH (El-Maouche et al. 2017; Speiser et al. 2010; Han et al. 2013a; Joint Lecahwg 2002). These should be seen only as a guide; treatment must be individualised after clinical and laboratory assessment.

Daily treatment in children includes hydrocortisone three to four times daily and fludrocortisone one to two times daily, with additional salt replacement in the newborns:

- For children with CAH, hydrocortisone is the drug of choice. The daily dose per m^2 body surface is higher compared to those children who have other causes of adrenal insufficiency because of the need to downregulate excess ACTH production and mitigate the androgen excess. Daily doses must be prepared from tablets when each dose is due, crushed, and administered in a small quantity of water prior to a feed—the use of oral hydrocortisone suspensions is discouraged, as they are not bioequivalent to the tablets (Speiser et al. 2010). The European Medical Agency has recently granted a paediatric use marketing authorisation for Alkindi® (Diurnal Ltd), a formulation of hydrocortisone granules that allows for more accurate and age-appropriate dosing in children and masks the bitter taste of conventional tablets.
- Fludrocortisone can be administered together with hydrocortisone. Neonates often require higher doses in the first months of life. Blood pressure should be monitored and doses minimised to prevent hypertension.
- Any need to increase treatment to maintain normal sodium and potassium levels can be addressed by the addition of salt (sodium chloride). Solutions of 20% (made by

Table 35.2 Medical treatment of classic congenital adrenal hyperplasia

Treatment goals	**All patients:** • Correct cortisol deficiency and prevent adrenal crisis • In patients with "salt-wasting" CAH: correct aldosterone deficiency to promote normal electrolyte balance • Mitigate androgen excess while avoiding iatrogenic glucocorticoid excess **Children:** • Promote normal growth, development, and final height outcome • Obtain normal sexual maturation **Adolescents and adults:** • Ameliorate hirsutism, acne, and menstrual irregularities in adolescents and women • Preserve fertility • Achieve positive sexual outcomes for females requiring genital reconstructive surgery
Neonates and infants	Medical treatment needs to be adjusted on an individual basis with frequent clinical and biochemical monitoring over the first months of life. Typical doses are initially: • Hydrocortisone: starting dose 20–30 mg/m^2/day in three divided daily doses. Higher doses may be used for initial reduction of markedly elevated androgens, but it is important to very rapidly reduce the dose when target hormone levels are achieved • Fludrocortisone: starting dose 50–100 mcg twice daily • Salt: starting dose 1–2 g/day of sodium chloride divided into several feedings. Salt supplementation can be discontinued as the child begins to eat table food and the taste for salty food increases • Fludrocortisone and salt supplements are balanced carefully with monitoring of blood pressure and electrolytes
Children	Medical treatment needs to be adjusted on an individual basis with frequent clinical and biochemical monitoring over time. Typical maintenance doses are: • Hydrocortisone: maintenance dose 10–15 mg/m^2/day in three divided daily doses • Fludrocortisone: maintenance dose 50–200 mcg/day • Encourage salt intake with exposure to hot weather or with intense exercise
Older adolescents and adults	• Glucocorticoids: hydrocortisone is the treatment of choice. However, long-acting glucocorticoids are often used in adults. Typical glucocorticoid regimens include one of the following: – Hydrocortisone: 15–25 mg/day in two to three daily doses – Prednisolone: 3–7 mg/day in one or two doses – Dexamethasone: 0.25–0.5 mg at bedtime • Fludrocortisone: usual maintenance dose 50–200 mcg/day. It is important to reassess mineralocorticoid requirements when the patient transitions from paediatric to adult care because they can differ significantly between these phases • Encourage salt intake with exposure to hot weather or with intense exercise • Oral contraceptive pills can be considered as an adjunct treatment in women to regularise menses and ameliorate the cosmetic effects of androgen excess (hirsutism and acne). Direct hair removal methods are also an option (e.g. photoepilation, electrolysis, eflornithine cream)

compounding pharmacies for accuracy) can be used to minimise the volume given, with the dose given neat just before a feed or mixed in a small amount of breast milk or formula. Babies adapt fairly quickly to the taste, and simple administration strategies need to be developed to enhance adherence to treatment. Children with classic CAH are salt–losers and therefore have a preference for salty foods. As toddlers, salt should be added to their cooked foods to balance their intake, with older children having the ability to balance their own by "adding salt".

Long-acting glucocorticoids (prednisolone or dexamethasone) are often used in adults instead of hydrocortisone due to convenience of less frequent dosing (Table 35.2). When possible, hydrocortisone should be favoured because of the lower risk of over-replacement; both prednisolone and in particular dexamethasone are long-acting, and activate the glucocorticoid receptor

for much longer including evening and nighttime when circulating cortisol concentrations in healthy individuals are physiologically low. A novel modified-release formulation of hydrocortisone (Chronocort®, Diurnal Ltd) has been designed to mimic physiological cortisol secretion and improve control of the androgen excess (Mallappa et al. 2015). A phase-III clinical trial is currently evaluating its efficacy in adult patients with classic CAH.

35.4.3 Classic Congenital Adrenal Hyperplasia: Treatment and Prevention of Adrenal Crisis

Patients with classic CAH have primary adrenal insufficiency and do not have the capacity to secrete extra cortisol in situations of stress. If the dose of glucocorticoids is not increased in these situations, a patient with classic CAH can develop a life-threatening adrenal crisis. If not promptly recognised and treated, an adrenal crisis rapidly leads to systemic collapse, hypovolaemic shock, and death (Table 35.3) (Bornstein et al. 2016).

Adrenal crisis is a common occurrence in patients with classic CAH (Hahner et al. 2015; Reisch et al. 2012). Precipitating factors include intercurrent illness, infections (particularly gastroenteritis and respiratory infections), persistent vomiting or diarrhoea, fever, significant pain, trauma (e.g. fractures), emotional distress, and strenuous physical activity (Hahner et al. 2015). Surgery requiring general anaesthesia, preparation for invasive diagnostic procedures (e.g. colonoscopy), and oral surgery (e.g. dental extractions) are further risk factors. Patients with CAH can also become acutely unwell if they do not have good adherence to medical treatment or do not follow the simple sick day rules outlined below (refer to Chap. 62 for more information on prevention and management of adrenal crisis).

A patient with a suspected adrenal crisis must be promptly treated with lifesaving injectable hydrocortisone (IM as priority pending IV access). Diagnostic measures should never delay treatment. If an adrenal crisis is suspected, act immediately and refer to hospital emergency management guidelines, if available. As a guide (Joint Lecahwg 2002; Bornstein et al. 2016):

- STEP 1: Give hydrocortisone immediately (injection of hydrocortisone IM or IV): 25 mg in those <3 years of age; 50 mg in those

Table 35.3 Adrenal crisis and signs and symptoms of over- and under-replacement

Adrenal crisis	Adrenal crisis is a life-threatening emergency. Patients present with at least two of the following: hypotension (systolic blood pressure <100 mmHg), nausea or vomiting, severe fatigue, fever, somnolence, confusion, and coma. Laboratory evaluation can show hyponatraemia, hyperkalaemia, hypoglycaemia, increased serum creatinine, and metabolic acidosis. Hypoglycaemia is common in children
Glucocorticoid treatment	*Over-replacement*: insomnia, increased appetite, proximal muscle weakness, skin thinning, easy bruising, red stretch marks, weight gain and central obesity, disproportionate supraclavicular and dorsocervical fat pads, facial and upper neck plethora, facial rounding. Reduced growth rates and weight gain in children can be an indication of glucocorticoid over-replacement *Under-replacement*: fatigue, weakness, nausea, lack of appetite, dizziness, hypotension, weight loss, skin hyperpigmentation (due to ACTH excess)
Mineralocorticoid treatment	*Over-replacement*: hypertension, peripheral oedema *Under-replacement*: orthostatic hypotension (e.g. dizziness, lightheadedness, and fainting when standing up); postural blood pressure drop on examination (lying to standing); fatigue, leg cramps, salt craving
Inadequate androgen suppression	*Children*: increased growth rate (before epiphyseal closure); early pubic hair development; early sexual development; clitoromegaly; increased sebaceous secretions; increased body odour *Adolescent and adult women*: hirsutism; excessive acne; oily skin; menstrual irregularities; male-patterned baldness in females

3–12 years of age; 100 mg in those >12 years of age.
- STEP 2: Start rapid rehydration with isotonic saline infusion according to protocols for age and weight.
- STEP 3: Correct hypoglycaemia, if present (IV dextrose). Hypoglycaemia can be common in children with adrenal crisis.
- STEP 4: Start continuous IV infusion of hydrocortisone after the bolus injection: 25–30 mg per 24 h in those ≤3 years of age; 50–60 mg per 24 h in those 3–12 years of age; 100 mg per 24 h in children >12 years of age; 200 mg per 24 h in adults. Alternatively, the total daily dose can be split and administered IM or IV every 6 h.
- STEP 5: Treat the precipitating factor of the crisis, if possible (e.g. infection, trauma).
- STEP 6: Contact an endocrinologist for urgent review of the patient and advice on further tapering of hydrocortisone.

In order to prevent an adrenal crisis, several measures need to be in place (Bornstein et al. 2016). These are simple and are lifesaving:

- Educate parents, patients, and partners regarding correct adjustment of glucocorticoid replacement in case of stress ("sick day rules"):
  - **Sick day rule 1**: double or triple daily oral glucocorticoid dose during illness that requires bed rest and/or antibiotics or is associated with high fever (>38 °C) until recovery. Children should get hydrocortisone in three to four doses and given sweet drinks and salt supplements if off their food. Double or triple the dose on the day of any minor procedure/surgery that do not require fasting (e.g. procedures requiring local anaesthesia and tooth extraction).
  - **Sick day rule 2**: administer hydrocortisone per IM or IV injection during severe illness, prolonged vomiting or diarrhoea, acute trauma and if the patient is confused, drowsy, or unconscious. Hydrocortisone per IM or IV injection must be given in preparation for surgery/procedures requiring general anaesthesia and during prolonged fasting (e.g. preparation for colonoscopy). In adults, the recommended dose is 100 mg via bolus injection, followed by 200 mg/24 h.
- Educate patients, parents, and partners regarding symptom awareness and possible precipitating factors of adrenal crisis. They should be advised that "if in doubt" they should give a hydrocortisone emergency injection and seek medical advice.
- Ensure patients have an additional supply of tablets so that they can double/triple their dose for at least 7 days, for example, when travelling abroad. If a patient is unable to tolerate tablets, hydrocortisone should be given IM and medical advice promptly sought.
- Provide patients and caregivers with a hydrocortisone emergency injection kit. Check regularly that their kit is up to date.
- Educate patients, parents, and partners on how to self-administer and inject hydrocortisone IM (for example: www.pituitary.org.uk/information/treating-a-pituitary-condition/hydrocortisone/how-to-give-an-emergency-injection-of-hydrocortisone; www.CAHPepTalk.com).
- Provide the patient with a steroid emergency card (for example: www.endocrinology.org/adrenal-crisis) and encourage them to wear medical alert bracelets or necklaces. Patients must keep the steroid emergency card with them at all times and show it to any health professional they are dealing with.
- Instruct parents of school-aged children affected by CAH to inform school staff about the condition. An emergency letter and response plan can be of use (as an example: www.cah.org.au/products-resources; www.CAHPepTalk.com).
- Provide patients and caregivers with emergency phone numbers for on-call services and the ambulance service (register with their consent onto the red flagged ambulance emergency service, if available locally).
- Instruct patients and caregivers to inform the endocrinologist before surgical procedures so that proper advice can be given to the hospital staff.
- Encourage salt intake with exposure to hot weather or with intense exercise. Before major

physical activity (e.g. long distance running, major sports, or competitive dancing), patients might benefit from taking a small dose of extra hydrocortisone.
- Regular review of the patient by health professionals to reinforce the sick day rules and adherence to treatment.

35.4.4 Classic Congenital Adrenal Hyperplasia: Monitoring

Patients with classic CAH require lifelong care. While the correction of cortisol and aldosterone deficiency and the control of androgen excess are common aims in children and adults, treatment goals do change over time (Table 35.2). In children with CAH prevention of early puberty and achievement of an acceptable final height are paramount. Upon completion of pubertal development and attainment of adult height, continued monitoring of symptoms of androgen excess (menstrual irregularities, hirsutism), quality of life, sexual health, and fertility become increasingly more important. The avoidance of the long-term side effects of excess glucocorticoid treatment is also crucial (e.g. stunted linear growth in children and, in particular in adults, metabolic syndrome, increased cardiovascular risk and osteoporosis) (Reisch et al. 2011; Arlt and Krone 2007).

Medical treatment of CAH can be challenging and is a fine balance between over- and under-treatment (Table 35.3). The goal is achieving the best clinical results with the lowest possible daily glucocorticoid dose. Regular clinical assessment and blood tests are required to monitor the effectiveness of treatment (Table 35.4 and Fig. 35.2) (Escobar-Morreale et al. 2012). The frequency and modalities of monitoring need to be tailored to the individual patient. Management can be complex and should involve multiple heath care professionals including endocrinologist, endocrine nurse specialist, genetic counsellors, gynaecologists, urologists and surgeons, fertility specialists, mental health providers, and social services. The endocrinologist and the specialist endocrine nurse play a pivotal role in coordinating management to guide the patients and their carers to achieve satisfactory health outcomes.

35.4.5 Classic Congenital Adrenal Hyperplasia: Management in the Neonatal Period

A female newborn with 46,XX DSD requires urgent consultation with the paediatric endocrine team and specific management strategies to provide the family with appropriate information and support to manage the shock and grief process until gender is determined. Placating comments and judgements regarding the gender of the baby should not be made. The focus should be on "your baby" who is "well and beautiful" with positivity expressed about the labour and delivery. Parents are advised that specialist endocrine team will be consulted immediately to explain the situation and assist in ascertaining the gender of their baby.

The paediatric endocrinologist will direct the plan to determine the diagnosis and gender and develop a treatment strategy to manage the glucocorticoid and mineralocorticoid deficiencies. The initial assessment is made on the physical findings, electrolyte and hormone analysis, radiological investigations, and genetic testing. The severity of genital malformation is assessed according to the Prader scale (Fig. 35.3) (White and Speiser 2000).

The surgical management of children born with 46,XX DSD is complex. Patients should be referred to centres with substantial experience and a team of paediatric surgeons, paediatric endocrinologists, mental health professionals, and social work services (Speiser et al. 2010).

Boys with classic CAH who did not undergo neonatal screening can present aged 1–3 weeks of life with a salt-wasting adrenal crisis—a state of systemic collapse which can lead to death if not managed quickly (Table 35.1). Because of the serious state of circulatory collapse, intravenous access may be difficult an intraosseous access may be required. A blood gas will give an immediate indication of the blood glucose, electrolytes, and assess for acidosis. At any stage of concern,

Table 35.4 Monitoring of patients with classic congenital adrenal hyperplasia

Frequency of monitoring	• At least monthly during the first 3 months of life • Every 3 months in the neonate and infant • Every 3–6 months in children and adolescents • Every 6–12 months in adults on stable medical treatment
Clinical assessment	• History taking, including current medications and comorbidities • Assess the adherence to medical treatment • Monitor growth velocity in children • General physical examination • Vital signs and body measurements: height; weight; waist circumference; blood pressure sitting and standing (to look for hypertension and orthostatic hypotension) • Look for signs and symptoms of over- or under-replacement (Table 35.3) • Examination of the genitalia to look for any signs of virilisation in children (e.g. clitoromegaly and precocious pubic hair development) and assess the outcome of reconstructive surgery in girls. It is imperative that such examinations are discussed with the parents and child and are undertaken discretely, particularly as children become older. Testicular examination should be performed periodically in adolescents and adults, looking for palpable masses or testicular atrophy • Assess the menstrual function in adolescents and premenopausal women • Assess women for hirsutism, using the modified Ferriman–Gallwey score (Fig. 35.2) • Assess health-related quality of life. Questionnaires can be used in older children and adults (e.g. PedsQL™ Generic Core Scale, PedsQL™ Fatigue Scale, WHOQoL-BREF scale, MAF scale, SF-36®; EQ-5D™). Investigate psychological, social, and sexual health issues, as well as current health concerns • Ask if the patient had any sick days since the previous visit and needed to increase the dose of glucocorticoids or required hospitalisation • Reinforce the sick day rules and confirm that measures are in place to prevent and treat promptly adrenal crisis (e.g. hydrocortisone emergency injection kit, steroid emergency card, medical alert bracelet) • Investigate family plans in patients of reproductive age
Laboratory assessment	*Hormonal evaluation*: • CHILDREN: morning serum 17-hydroxyprogesterone and androstenedione. Testosterone measurement is sometimes useful in patients whose disease is not well controlled. Adrenal androgen secretion should not be completely suppressed; normal levels of 17-hydroxyprogesterone generally indicate overtreatment • MEN AND WOMEN: morning serum 17-hydroxyprogesterone and androstenedione. The goal is individualised to achieve patient goals, but androstenedione should not be suppressed • MEN: morning serum testosterone, sex hormone-binding globulin (SHBG), and gonadotropins (FSH and LH) • WOMEN: morning follicular-phase progesterone should be checked in those seeking fertility. Testosterone measurement is sometimes useful in patients whose disease is not well controlled *Plasma renin activity or direct renin concentration*: it is used to monitor fludrocortisone replacement. Reference intervals are based on postural state and age, and data should be evaluated accordingly. A suppressed result reflects overtreatment and increases the risk of hypertension *Other tests*: • Blood sodium, potassium, and kidney function • Fasting plasma glucose: in neonates and young children glucose must be monitored because of the risk of hypoglycaemia, particularly if the child is unwell or requiring salt replacement. Conversely, adults are at risk of developing diabetes mellitus • In adults: lipid panel; glycated haemoglobin (HbA1c); vitamin D
Radiological assessment	• Regular bone age assessment in children (X-ray of the hand) • Regular testicular ultrasound in males from adolescence onwards • Monitor adults periodically for low bone density (DEXA scan)

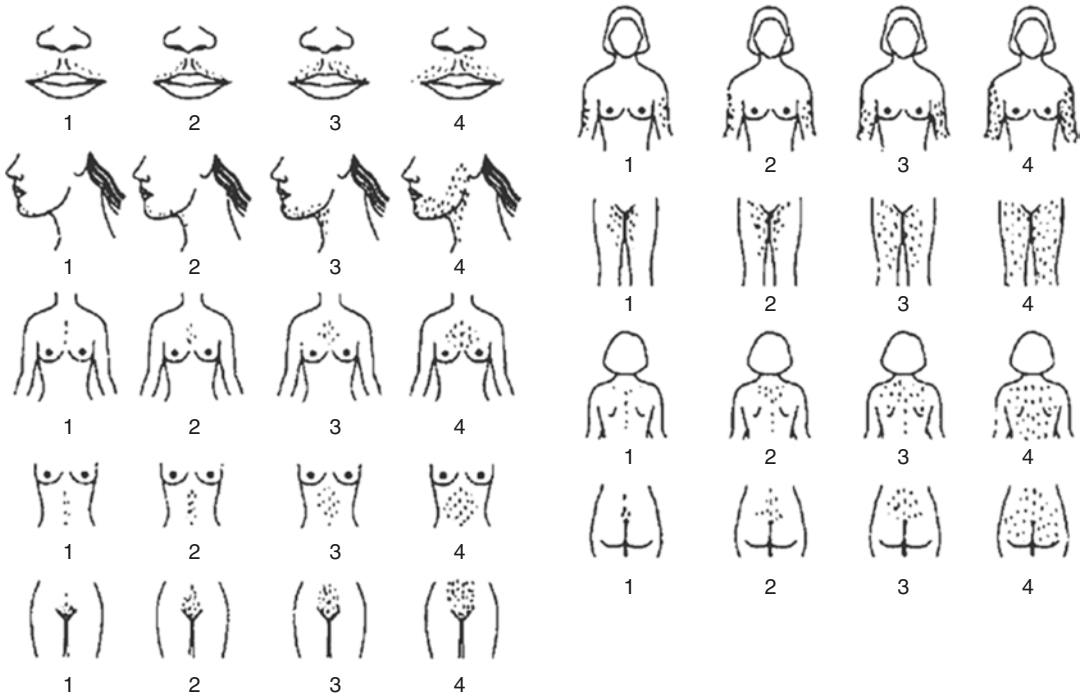

Fig. 35.2 Modified Ferriman–Gallwey score is the gold standard for the evaluation of hirsutism, scoring nine body areas (upper lip, chin, chest, upper and lower abdomen, arm, thigh, upper and lower back). Ferriman–Gallwey total scores that define hirsutism in women of reproductive age are: US and UK black or white women, ≥8; Mediterranean, Hispanic, and Middle Eastern women, ≥9 to 10; South American women, ≥6; Asian women, a range of ≥2 for Han Chinese women to ≥7 for Southern Chinese women. Reproduced with permission from Escobar-Morreale et al. (2012). Copyright Oxford University Press, 2011

or if there is a delay in obtaining intravenous access, hydrocortisone followed by glucagon should be administered IM for suspected adrenal insufficiency and hypoglycaemia. Once intravenous access is established, IV hydrocortisone, dextrose, and normal saline should be administered to correct hypovolaemia, hypoglycaemia, and the electrolyte abnormalities.

35.4.6 Classic Congenital Adrenal Hyperplasia: Management During Infancy and Childhood

The psychosocial adjustment of the parents to the diagnosis of CAH initially, and later for the child, is critical to achieving a positive outcome for the child and the family in the long term. Having a child with a complex chronic condition is a life-altering experience, with the impact on parents and family members depending greatly on individual coping abilities, and also influenced by social background, cultural and family beliefs (Patterson et al. 1990). A family's adjustment to a new diagnosis can be greatly enhanced by a health professionals' approach to the situation through counselling, education, and support (Hatton et al. 1995). By facilitating a process of understanding and adjustment health professionals can increase the likelihood of families having the knowledge, understanding, and confidence to manage difficult situations when they occur, such as a possible adrenal crisis. This education process should be reviewed regularly at clinical follow-up.

Psychological support is important for the parents but also for the children as they grow and adapt to living with a complex condition and its physical and emotional consequences. Managing intercurrent illness in order to prevent serious

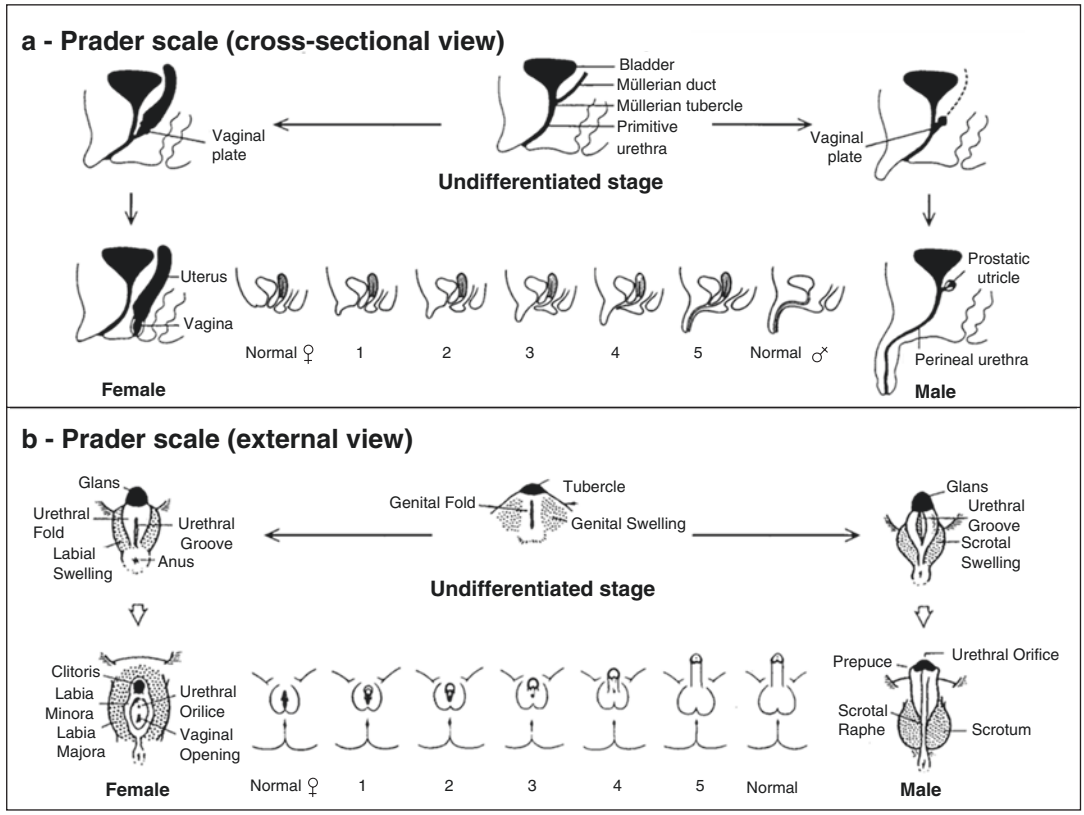

Fig. 35.3 Prader scale. The severity of virilisation is often quantitated using the five-point Prader scale. (**a**) Normal and abnormal differentiation of the urogenital sinus and external genitalia (cross-sectional view). (**b**) Normal and abnormal differentiation of the external genitalia (external view). Reproduced and edited with permission from White et al. (2000). Copyright The Endocrine Society, 2000

deterioration to a possible life-threatening adrenal crisis is a serious concern for parents and always at the forefront of their minds. They have to adapt their daily routine around their child's medication plan, attendance for regular medical reviews, and routine investigations. Health professional should aim to help families adapt the care required for these children into their daily lives in order to ensure positive health outcomes in the long term.

CAH has an element of androgen exposure in utero, which can affect brain development and function (Webb et al. 2018). Girls can have male-typical childhood play and more interest in male-typical activities during childhood and adolescence (Dittmann et al. 1990). Health professionals need to be aware of parental concerns regarding this variation to the norm and guide parents appropriately. Counselling with a psychologist will assist in this process for both the parents and the child. Autism, which is more often found in males than females, has been found to be more prevalent in patients with CAH of both sexes (Knickmeyer et al. 2006).

Support groups are important for parents and extended families, enabling them to share with others their experiences and difficulties in having a child with a diagnosis of CAH. Not all parents are ready to meet other families and will do so in their own time. Support groups can be invaluable in providing families with a sense of normality, and being able to meet other children who have grown up having the diagnosis of CAH. It is important that patients themselves are able to share their experiences in confidence with others with the same diagnosis.

35.4.7 Classic Congenital Adrenal Hyperplasia: Management During Adolescence

Adolescence is the phase of transition from childhood to adulthood. Managing CAH at this stage of development can be challenging, with a rapidly changing body and the impact of the hormonal changes of puberty (Merke and Poppas 2013). Adolescence is also a time of significant emotional change and often adherence to medical treatment is an issue.

Adolescent females can struggle with hormonal control at puberty, which often requires an increase in routine hydrocortisone doses. They may also need the addition of an oral contraceptive pill to regulate their monthly cycle and reduce acne and excess body hair. The outcome of reconstructive genital surgery carried out in infancy should be reviewed in adolescence and discussed with an appropriately skilled surgeon. If (additional) surgery is desired, particular expertise is imperative to ensure comprehensive understanding, appropriate consent by the adolescent and parents for adequate surgical outcomes.

In adolescent males with classic CAH, ACTH hypersecretion can cause hyperplasia of ACTH-sensitive cells present in the testes. This leads to the development of testicular nodules known as "testicular adrenal rest tumours" (TARTs), which can cause infertility (see section on fertility below) (El-Maouche et al. 2017). Poor adherence to hydrocortisone treatment and severe loss-of-function CAH genotypes have been identified as risk factors for the development of TARTs, which should be actively monitored for by ultrasound starting in adolescence, at the latest at the point of transition to adult care.

35.4.8 Classic Congenital Adrenal Hyperplasia: Management in the Adult Care Setting

With adolescence, the patient with CAH must gradually assume primary responsibility for his/her care and eventually transition to adult care. The adolescent's needs and concerns shift to a more adult focus on quality of life, long-term health and eventually relationships, fertility, and family planning (Reisch et al. 2011; Han et al. 2013b; Auchus and Arlt 2013). As patients with classic CAH often require higher doses of glucocorticoids to control the androgen excess, they are at increased risk of obesity, diabetes mellitus, dyslipidaemia, cardiovascular disease, and bone loss during adult life (Auchus and Arlt 2013; Arlt et al. 2010; Han et al. 2014). Consequently, a key priority when managing adults with CAH is to minimise long-term consequences of both the condition itself and its treatment.

The transition of care from a paediatric to an adult care setting remains a major challenge and many patients are lost to follow up (Gleeson et al. 2013). Ideally, patients should be jointly reviewed by the paediatric endocrinologist, the newly introduced adult endocrinologist, a clinical nurse specialist, and a geneticist on their first appointment. Apart from clinical and laboratory assessment, the initial evaluation should also focus on the following:

- Get to know the patient and understand their childhood journey.
- Assess the patient's understanding of the condition, goals of, and adherence to treatment.
- If available medical records are incomplete, these few questions are helpful: "At what age were you diagnosed?" "When did you stop growing?" and "Did you have any genital surgeries?" (Auchus and Arlt 2013).
- If indicated, an external genital examination may be necessary. Discuss sexual health with the patient and consider referral to a gynaecologist or urologist, if appropriate.
- Discuss family plans. Refer the patient to a fertility clinic, if appropriate.
- Consider the need for psychological counselling.

Ongoing follow-up will depend on this baseline assessment. Patients can have both or alternating appointments with their endocrinologist and the clinical nurse specialist, usually on yearly basis if they are on stable medical treatment (Table 35.4). Establishing a good nurse–patient relationship can enhance continued engagement for ongoing care.

35.4.9 Classic Congenital Adrenal Hyperplasia: Fertility

High rates of infertility can occur in patients with classic CAH (Reichman et al. 2014). Fertility correlates with the severity of the condition and can be reduced in both sexes.

Women have low fertility rates mainly due to androgen excess and menstrual irregularities with anovulatory cycles. 46,XX DSD and related surgical outcomes can also impact on sexual relationships and the chance of a positive pregnancy experience. Women seeking a pregnancy often need to intensify glucocorticoid treatment to obtain a more stringent control of the androgen excess and, consequently, promote their ability to ovulate and conceive. They should also be referred for review of the outcomes of previous genital reconstruction surgery; women with complex genital surgery should deliver by Caesarean section.

About 30–50% of men with classic CAH develop TARTs (Auchus and Arlt 2013), hyperplastic adrenal-like tissue, which can compress the surrounding testicular structures and cause oligospermia. Moreover, the adrenal-derived androgens can suppress gonadotropins and cause testicular atrophy. Men should be taught to self-examine their testes and have regular testicular ultrasound examinations to assess atrophy and the presence of TARTs. The term "tumour" should not be interpreted as a neoplasm because these masses actually represent hyperplastic tissue and do not show increased proliferation. It is therefore important not to confuse TARTs with primary testicular tumours when discussing a case with the patient and colleagues from other disciplines (Auchus and Arlt 2013). Poor adherence to glucocorticoid treatment is an important risk factor for the development of TARTs and intensified treatment is sometimes required, but not always effective for decreasing the size of the masses and restore fertility. Adult males with TARTS should be offered semen analysis and counselled on sperm banking.

35.4.10 Classic Congenital Adrenal Hyperplasia: Management of a Genetic Diagnosis

Once a child has been diagnosed with CAH, genetic testing will identify the specific mutation present. This should be arranged following referral for genetic counselling, firstly to determine the mutation in the neonate, and then the carrier status of the family members. This will have an impact on their pregnancy planning in the future.

CAH is autosomal recessive. Parents of a baby with CAH both have one of their two 21-hydroxylase DNA alleles affected and thus have a one-in-four chance of having another baby with CAH and one-in-eight chance of having a female baby with CAH and 46,XX DSD. Treating the mother with dexamethasone before the major period of fetal sexual differentiation (6–8 weeks post-conception) can help to prevent the 46,XX DSD in the female fetus. However, dexamethasone can have adverse effects on the mother receiving treatment during pregnancy and also possible long-term effects on the baby, which require discussion before starting treatment (Speiser et al. 2010). Previously, there was also concern of treating unaffected pregnancies as treatment had to be initiated before the sex of the child was known and before there was clarity about whether or not the child was affected, which previously could only be found out after invasive measures. However, nowadays both the chromosomal sex of the fetus and whether it is affected by 21-hdyroxylase deficiency can be readily detected through analysis of fetal cells circulating in maternal blood, offered by specialist genetic units. A pregnancy undergoing dexamethasone treatment requires frequent monitoring by endocrine and obstetric specialists.

35.4.11 Management of Nonclassic Congenital Adrenal Hyperplasia

Patients with nonclassic CAH do not need continuous glucocorticoid replacement; however, some patients may require glucocorticoid replacement in major stress, such as surgery, trauma, or ICU treatment. If glucocorticoids are needed to control the detrimental effects of androgen excess, they should be given up to the achievement of the treatment goal and then stopped (Auchus and Arlt 2013). Treatment can be considered in:

- Children with progressive signs of virilisation and accelerated growth.
- Women with anovulatory infertility.

If fertility is not desired, glucocorticoids should be avoided in women with bothersome hirsutism and/or menstrual irregularities. In such cases, treatment with oral contraceptives including an anti-androgenic progestin component (e.g. drospirenone or cyproterone) is preferred (Speiser et al. 2010).

35.4.12 Additional Aspects of Optimal Care

Health care professionals have a vital role in assessing and guiding individual and family adjustment to the diagnosis of CAH (Auchus et al. 2010). It is essential that health care professionals understand the need to provide a clear and simple explanation about the diagnosis in a positive way. Information needs to be given in limited amounts at a time, remembering that it may need to be repeated a number of times for it to be retained. Evaluating the information given is understood is an important step in this process. Using a timely approach will ensure that patients and families will acquire the appropriate information they need to manage the condition and assist in allaying any anxieties which may persist (Hatton et al. 1995). Continuous reinforcement of health information is also key.

The nurse–patient relationship is an extremely important factor in achieving effective health education for patients and families (Auchus et al. 2010). The nurse needs to be sensitive to the emotional needs of patients and caregivers, and assess their readiness for learning. For families with a child with a chronic condition such as CAH, the education process takes place over a continuous period of time as the child progresses through the developmental stages of childhood, adolescence, and into adulthood.

Finally, consistency and continuity of care by staff are considered one of the most important factors for patients with CAH, with transition from paediatric to adult care carefully planned (Merke and Poppas 2013; Auchus et al. 2010; Kruse et al. 2004). Adolescence and early adulthood are crucial times in the life of these patients and associated with significant physical and psychological adjustment. It is important to support the young person in making decisions which build confidence to direct their own care over time. Patient education and assumption of responsibility are critical for adherence to treatment, continuity of care, and successful outcomes.

35.5 Role of Patient Advocacy Groups in Improving Patient Care and Education in CAH

Patient advocacy groups are a highly valuable resource for patients and their families, not just as a clinical and supportive tool, but by also enabling empowerment and enriching the relationship between patients, families, and their health care providers. The advent of social media, with websites and online support groups can add to this, and patients have a reliable and trusted resource for peer support. Most PAGs work very closely with clinical teams to develop evidence-based information and support clinical research; they can form a useful resource and can reach patients and health care teams across the globe especially for rare conditions such as CAH.

35.5.1 The CAH Support Group (Reprinted Permission from CAH Support Group (UK) Patient Advocacy Group)

Robin Brett had CAH and was just 18 years old when he sadly died in 2014. He was taken to hospital with vomiting and unable to keep his medication down; this preceded by constipation which was treated by a large dose of enema. Although an IM injection of hydrocortisone was administered on admittance to hospital, no further medication was given on the ward and few checks were made. Just over 16 h after admittance, he went into an adrenal crisis and subsequently a cardiac arrest from which he could not be revived.

Robin's parents had been members of the CAH Support Group since shortly after he was

born and regularly attended conferences so were knowledgeable about his condition but, despite raising concerns about his treatment, were not listened to.

We were very saddened to hear of his death, the cause of which was not originally recorded accurately, which the family found particularly upsetting. However, his brave mother was determined to discover the truth and the support group put her in touch with one of our medical advisors who agreed to view the Coroner's report. After he read this, he issued his own report categorically stating that death was obviously caused by "*acute adrenal insufficiency consequent on a lack of adequate steroid replacement*". His conclusion was then confirmed by another specialist who was instructed by the Coroner's Office and the death certificate was altered accordingly.

Although nothing could bring Robin back, his mother was determined that her son's death would not be in vain and was keen to work with the support group to try and ensure the mistakes that occurred at the hospital where Robin was admitted would not happen again and cause another family to suffer as they had. We put her in touch with another eminent endocrinologist (who agreed to help) and she tirelessly wrote to the medical director of every hospital trust in the UK, explaining what had happened to her son and asking them to put measures in place to prevent another tragedy. In particular, she asked that a note be added to a patient's medication, requesting to utilise a note function on the current electronic prescribing system, highlighting the importance of administering steroids and also requesting measures are put in place to ensure patients with adrenal insufficiency receive appropriate care, to prevent any more unnecessary deaths.

Mrs. Brett received a fantastic response from these letters, with medical directors promising to make changes as suggested and to better educate staff about adrenal insufficiency/crisis. Robin even featured in a very poignant and moving training video as a result, which we believe helped highlight how fragile life can be for those with CAH and other steroid-dependent conditions.

The primary aims of the CAH group are to support all families affected by CAH and to increase awareness of the condition to the public and the medical profession. We believe the above tragic account of just one of our members is evidence on how we work together with families and the medical profession in order to do this. We provide a variety of information booklets and leaflets, organise conferences, social meetings as well as a regular newsletter to keep our members up to date. We also encourage and contribute to research projects.

35.5.2 The CARES Foundation (Reprinted Permission from CARES Foundation (USA) Patient Advocacy Group)

The Leight family founded CARES Foundation in 2001 after their daughter was diagnosed with Congenital Adrenal Hyperplasia (CAH), a rare disorder of the adrenal gland. When attempting to learn more about the disorder, they found that there was no support for families and affected individuals and few resources for information. Today, CARES Foundation serves as a global resource for patients and families affected by CAH.

In 2001, only 27 states in the USA were screening newborns for CAH. CARES initiated a grass-roots campaign to advocate for the inclusion of CAH in the newborn screening panel in all 50 states. As of 2008, every state in the USA tests for CAH, saving numerous lives. In 2009, CARES Foundation embarked on another national campaign to establish EMS (emergency medical service) protocols for adrenal crisis which are currently available in nearly 30 states.

CARES Foundation has an extensive support network for patients and families that includes one-on-one support; regional and specialised support groups; regularly scheduled teleconference calls with participation from expert providers, and private support groups on social media. CARES provides referrals to expert physicians

and access to online expert via the "Ask the Expert" service.

Education is a key component of our mission. Our educational efforts include:

- Annual education conferences for patients, families, and health care professionals
- A newsletter containing information on new treatments, research studies, and other valuable information
- Guides for educating school and camp personnel
- A guide for travelling with CAH
- Emergency instructions
- Educational packet for school nurses
- Website containing valuable information

Providing patients with access to quality health care is another cornerstone of CARES Foundation. To this end, CARES designated four centres of excellence across the USA where expert care is provided by a multidisciplinary team addressing patient needs throughout their lifecycle. These centres are also conducting research to advance patient care. CARES is also where patients and researchers turn for participation, recruitment, and information on clinical trials.

Since 2001, CARES has established itself as a global resource for not only patients with CAH and their families but also for health care professionals. We encourage all health care professionals to offer CARES as a resource for their patients. Professionals are also encouraged to take advantage of our services.

For more information about CARES Foundation, contact Dina Matos, Executive Director of CARES Foundation, at dina@caresfoundation.org or Tel: 866-227-3737 (USA). You can also visit our website www.caresfoundation.org

35.6 A Patient Perspective (Published with Patient Consent)

I am a 30-year-old woman who is lucky enough to be in a loving relationship but who does have long-term medical conditions to cope with every day. I recently tried to deal with fertility treatment and had two unsuccessful rounds of intrauterine insemination (IUI). Dealing with infertility is emotionally and physically draining. It makes you feel inadequate and alienated from life. I can't express how much I yearn to be called mummy and dream of a future with my own family. I'm having a break from it now and want to share my story with you as this is the most recent in a long series of medical battles in my life.

I was diagnosed with CAH at birth and salt-wasting CAH a few weeks later when I had a salt crisis which nearly put me in a coma. I will always be under the care of an endocrinologist and managed with steroid replacement therapy.

I had surgery at the age of one and then again at four, I remember the later vividly. The surgery for girls with CAH is very painful and sensitive as it involves cosmetic changes to the vagina and clitoris to normalise the genitals. Although cosmetic the extent of these surgeries was enormous and resulted in psychological problems for many years to come, in my case without any professional support. Put simply this isn't something you can speak about freely or easily.

My teens were particularly difficult, not only was I dealing with regular hospital appointments and medication but I also had the underlying problem of knowing I wasn't "normal" and believing there was absolutely no way I could *ever* have sex, which in my young mind equated to *never* being loved (my vaginal entrance was the size of my little finger; need I say more?). I began asking myself if I was asexual and taught myself to avoid all situations which may compromise me and bat away any attention. That way I could ignore the problem and live in denial. I continued with this approach into my early 20s.

My periods started a bit late at age 14 (and have gone on to cause me many problems over the years) and I went into hospital again for vaginal stretching under anaesthetic. The aim: to enable me to use a tampon. The timing: it could not have been worse. Can you imagine experiencing this during puberty in addition to all the usual ups and downs? Constantly being asked by kids at school if you're a lesbian because you're not interested in boys? If only it were that simple. I have never felt as isolated as I did at secondary school. All I can say is I'm pleased I had a happy

childhood and loving parents to look back on; it wasn't all bad but it was very challenging!

And the fun didn't stop there. When I was 16 I was diagnosed with Crohn's disease and had surgery a few months later; a right hemicolectomy removing my ascending colon and some of my small intestine all of which had become ulcerated and was causing me incredible pain, nausea, and diarrhoea. Again I was managed with yet more steroids which this time brought along the added frustration of unwanted weight gain and associated difficulties as a teenager. I ended up missing most of year 11 but am pleased to say I did really well in my exams, which I took at home and went on to sixth form college, and later to university. I eventually let my hair down, had a LOT of fun forgetting all that I had been through and enjoying being with people who didn't know me or my past. That said I know now that I was avoiding dealing with my issues by partying all the time rather than seeking help.

In 2005, I moved to another city and finally got up the courage to see a gynaecologist. I desperately wanted to have sex and enjoy my sexuality which I had oppressed for so many years. After an initial period of overdoing "it" I met my partner and we are planning to get married next year…as they say, the rest is history!

Learning points:

- The struggles to live and lead a normal healthy life continue in patients with CAH hence, lifelong monitoring, support, and individualised approach is required.
- Education in the prevention and management of adrenal crisis is paramount for everyone involved in the multispecialty care of patients with CAH.
- The positive patient-health care engagement, empowerment of patients and their families/carers in voicing their concerns, and active involvement of patient support groups will improve all aspects of care being received.

35.7 Conclusions

Classic CAH is a rare and life-threatening chronic condition that needs lifelong adrenal replacement therapy. Patients and families are required to have a good knowledge and understanding of the condition and its management needs in both the short and long term. Their involvement with the health system will be lifelong and requires regular review and ongoing treatment and medial management. Health professionals have a crucial role in coordinating the care of patients with CAH. Treatment goals must be agreed with family and, as soon as possible, with the patient. The management plan is individualised and needs to be modulated throughout the patient's lifetime. For a patient with CAH, a sense of feeling connected and understood within the health system is one of the most important aspects in achieving positive health outcomes and satisfaction with their life's journey.

Aknowledgments With special thanks to Sue Elford, Chair, and Sallyann Blackett, Treasurer, from *The CAH Support Group*, website: www.livingwithcah.com and Dina Matos, Executive Director, from the CARES Foundation, website www.caresfoundation.org for their contributions with patient case studies and details on information and resources available through their Patient Advocacy Group.

Abstract

This chapter will discuss in detail the background, evaluation, and management of adrenal tumours, with an additional focus on the role of endocrine nursing in the care of these patients. It is divided into three parts, each providing a comprehensive outline of: A) Adrenocortical functioning adenomas and adrenal hyperplasia, B) Pheochromocytomas and Paragangliomas, and C) Adrenal incidentaloma and adrenocortical cancer (ACC).

Evaluation of adrenal tumours and adenomas requires a thorough history and physical examination. Family history is particularly important as adrenocortical disease can be caused by germline mutations passed down from generation to generation. More commonly, however, sporadic somatic mutations are the cause of spontaneous tumour formation and autonomous hormone secretion.

Adrenocortical adenomas, hyperplasia, and incidentalomas are non-cancerous "growths" or proliferation of cells in the adrenal cortex. Adenomas are rare in childhood but become more frequent as humans age. Approximately 20% of adenomas are functional; that is, they produce hormones to some degree in an autonomous or dysregulated manner. Functional adenomas most commonly produce cortisol or aldosterone, whereas androgen-producing tumours are quite rare and may portend a cancerous aetiology. Co-secretion of more than one hormone from adenomas/hyperplasia is also possible.

The biochemical work-up, with screening as well as confirmatory testing, and relevant imaging will be discussed in detail. The treatment, management, and long-term monitoring are also discussed for each of the adrenal tumours, respectively. Discussion in this chapter is illustrated with a rich content of figures, box inserts, and case studies.

Keywords

Adrenal adenoma · Adrenal hyperplasia · Cushing syndrome · Primary aldosteronism · Cortisol · Aldosterone · Adrenocortical cancer · Pheochromocytomas and paraganglioma

Abbreviations

ACC	Adrenocortical cancer
ACE	Angiotensin-converting enzyme
ACTH	Adrenocorticotropic hormone
APA	Aldosterone-producing adenoma
ARR	Aldosterone-to-renin ratio
AVS	Adrenal venous sampling
BMI	Body Mass Index
CAH	Congenital adrenal hyperplasia
CPA	Cortisol-producing adenoma
CRH	Corticotropin releasing hormone
DHEA	Dehydroepiandrosterone
GRA	Glucocorticoid-remediable aldosteronism
HNPGL	Head and neck paraganglioma
IV	Intravenous
L-DOPA	L-dihydroxyphenylalanine
MRA	Mineralocorticoid receptor antagonist
PA	Primary aldosteronism
PAC	Plasma aldosterone concentration
PCC	Pheochromocytomas
PCOS	Polycystic ovarian syndrome
PGL	Paraganglioma
PMNT	Phenylethanolamine *N*-methyltransferase
RAAS	Renin-angiotensin-aldosterone system
SDHx	Succinate dehydrogenase complex

Key Terms

- **Adrenocortical functioning adenomas:** hypersecreting tumors of the adrenal cortex
- **Adrenal hyperplasia:** enlargement of the adrenal glands
- **Adrenal incidentalomas:** incidentally found benign adenomas on evaluation of unrelated symptoms
- **Co-secretion:** more than one hormone secreted from adrenal adenomas/hyperplasia
- **Cushing Syndrome:** hypersecretion of cortisol from an adrenal adenoma
- **Catecholamines:** are produced in the adrenal medulla and are essential for the stress response
- **Pheochromocytomas:** are tumors arising from the adrenal medulla that produce excess catecholamines

- **Paraganglioma:** are also tumors that produce catecholamines, but they originate in paraganglia along the parasympathetic and sympathetic chains

Key Points

- List the most common hormones produced by adrenal functioning tumours/hyperplasia
- Describe common presenting signs and symptoms of primary aldosteronism, Cushing syndrome, adrenocortical cancer, pheochromocytoma, paraganglioma
- Explain the evaluation for suspected adrenal tumours/hyperplasia
- Discuss the possible treatment and management options for adrenal tumours
- Emphasize and describe the role of the endocrine nurse in the care of these patients

36.1 Part A: Adrenocortical Functioning Adenomas and Adrenal Hyperplasia

36.1.1 Introduction

As described in the anatomy and physiology chapter of this section, the adrenal gland is comprised of two main layers: the cortex and the medulla. The medulla derives from neuroectodermal tissue in early fetal life and is mainly composed of chromaffin cells. The cortex develops from the mesoderm and is organized into three layers: the zona glomerulosa, zona fasciculata, and zona reticularis, responsible for producing the hormones aldosterone, cortisol, and androgens, respectively (Avisse et al. 2000). Part A of this chapter focuses on functional benign adrenal tumours and hyperplasia of the cortex; Part B covers pheochromocytomas and paragangliomas; and Part C covers adrenal incidentalomas and adrenocortical cancer (ACC). Congenital adrenal hyperplasia is covered in a separate chapter in this section.

Tumours and hyperplasia can be thought of as two ends of the same spectrum. A tumour is a proliferation of cells derived from a single progenitor cell. Hyperplasia, in contrast, is a "tissue-wide" proliferation of cells. Patients can develop a single discreet nodule, multiple nodules (in one or both adrenals), or hyperplasia. Additionally, nodules can grow in the background of a hyperplastic gland (Fig. 36.1). Adrenal adenomas and hyperplasia can occur secondary to chronic hormonal stimulation (e.g. ACTH stimulation in CAH or Cushing disease), or due to a somatic or germline mutation (Hsiao et al. 2009).

The imaging characteristics of adrenal tumours and masses are discussed in greater detail in Part B. Briefly, most (~60–90%) benign adrenocortical adenomas are comprised mainly of lipids and are therefore commonly described as "lipid-rich". On CT imaging, they have a lower density than surrounding organs, such as the liver, kidneys, or spleen, and therefore appear darker. The Hounsfield Units (HU; a measure of density) of the adenoma on non-contrast CT is typically less than 10 HU. Additionally, these tumours have a relatively high "washout" of IV contrast, when examined 10–15 min after contrast injection (Zeiger et al. 2009a).

"Lipid poor" adrenal masses, on the other hand, have higher density on non-contrast CT and commonly have low washout. Benign adrenocortical tumours (either functional or non-functional) can be lipid poor; however, other types of diseases, such as pheochromocytomas, ACC, adrenal haemorrhage, or metastatic lesions from other organs, can also present as "lipid poor" masses on CT (Zeiger et al. 2009a).

Benign adrenal tumours are extremely rare in childhood, increase to a prevalence of about 3% by age 50, and 10% in elderly adults (Minnaar et al. 2013; Fassnacht et al. 2016). Although 80% of adenomas are non-functional (Zeiger et al. 2009b), the signs and symptoms of a functional adrenal adenoma can be subtle and easily missed for many years, so most adenomas should undergo evaluation for functional status upon initial discovery (Fassnacht et al. 2016; Zeiger et al. 2009b).

The region in which the functional tumour or hyperplasia is located typically determines the hormone produced. In other words, a functional tumour in the zona glomerulosa will typically cause primary aldosteronism, whereas a functional tumour in the zona fasciculata will lead to

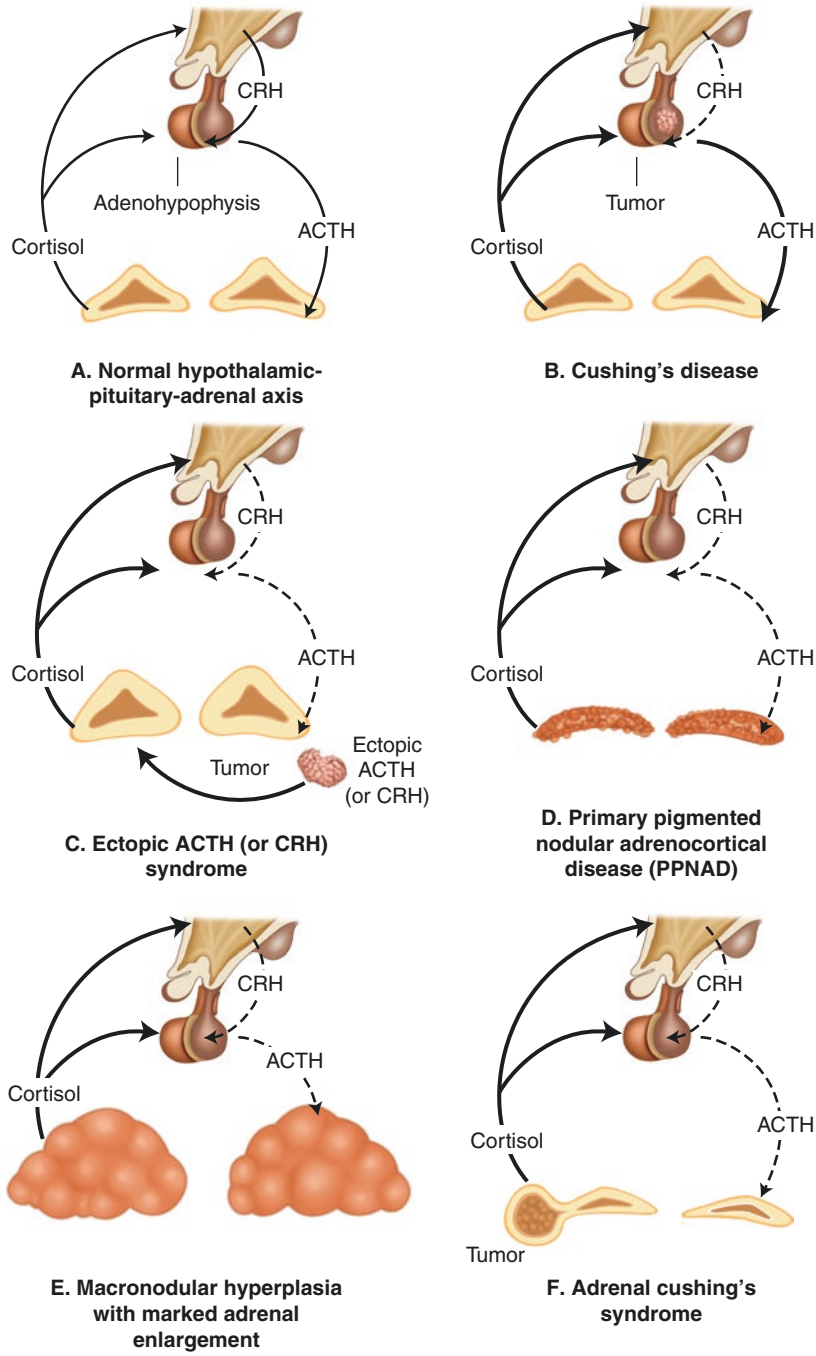

Fig. 36.1 Adrenal adenomas and hyperplasia

cortisol excess and Cushing syndrome. Functional tumours solely producing androgens are rare and often suggest a malignant, rather than benign, pathology. However, co-secretion of multiple hormones (e.g. cortisol and aldosterone) from benign tumours or hyperplasia can occur (Willenberg et al. 2010; Sakai et al. 1993).

36.1.2 Primary Aldosteronism

Aldosterone, a mineralocorticoid produced by the zona glomerulosa, is a major regulator of blood pressure and intravascular volume status. It exerts its effects primarily by acting on the distal convoluted tubule and collecting

duct in the kidney. By binding to its intracellular receptor, aldosterone stimulates production of the ENaC sodium channel, which enables increased sodium and water reabsorption from the urine. To counteract this cationic influx, potassium (and to a lesser degree hydrogen) ions are simultaneously excreted into urine.

Aldosterone synthesis is regulated by several mechanisms. The primary regulator is intravascular volume status via the renin-angiotensin-aldosterone system (RAAS), with hyperkalaemia also being a potent stimulus of aldosterone secretion (please see anatomy and physiology chapter in this section). Adrenocorticotropic hormone (ACTH) can also provoke aldosterone release but plays a minor role overall.

Primary aldosteronism (PA, a.k.a. Conn's syndrome) is the dysregulated hyperproduction of aldosterone from either one or both adrenal glands. Unilateral disease is seen in approximately two-thirds of cases (Mathur et al. 2010) and typically stems from an aldosterone-producing adenoma (APA, a.k.a. Conn's adenoma), frequently caused by a somatic mutation (e.g. *KCNJ5*, *ATP1A1*, *ATP2B3, CACNA1D,* or *CACNA1H*). In contrast, bilateral disease most commonly occurs as a result of bilateral adrenal hyperplasia. Heritable forms of PA make up less than 10% of cases; germline mutations include *KCNJ5, CLCN2, ARMC5,* or a chimeric *CYP11B1/CYP11B2* gene translocation (a.k.a. glucocorticoid-remediable aldosteronism or GRA) (Zilbermint et al. 2015; Dutta et al. 2016).

The most common presenting sign of PA is uncontrolled hypertension. In fact, PA is the leading secondary cause of hypertension, responsible for 5–10% of cases of "presumed" essential hypertension (Funder et al. 2016). Patients may commonly present with symptoms of recurring headache, chest pain, or oedema. More severe cardiovascular sequelae, such as myocardial infarctions, strokes, or congestive heart failure, may manifest at an early age (<40 years). Hypokalaemia is seen only in a minority (~30%) of patients with PA, but can be unmasked when loop diuretics are initiated (Funder et al. 2016).

36.1.2.1 Diagnosis and Treatment of Primary Aldosteronism

In recent years, it has become apparent that other comorbid conditions, including hyperparathyroidism, osteoporosis, nephrolithiasis, renal cysts (Petramala et al. 2014), obstructive sleep apnoea (Di Murro et al. 2010), and insulin resistance, are strongly associated with PA. Moreover, it is important to take a detailed family history, asking specifically about early-onset cardiovascular or cerebrovascular disease in first-degree relatives, as PA can be familial.

Patients should be screened for PA if they have (see Box 36.1 for more details):

1. Blood pressure greater than 150/100 mmHg on more than three occasions
2. Greater than 140/90 mmHg despite using three antihypertensive medications
3. Controlled blood pressure requiring four or more antihypertensive medications
4. Hypertension with adrenal incidentaloma on imaging
5. Hypertension with obstructive sleep apnoea
6. Hypertension with hypokalaemia (even if diuretic-induced)
7. Hypertension with first-degree relative with PA
8. Hypertension with first-degree relative with early-onset hypertension or stroke (age <40) (Funder et al. 2016)

Box 36.1 Principles of Good Clinical Practice for Screening for PA

It is important to follow below instructions when screening for PA, and this is a crucial aspect of the endocrine nurse role. The patient should be appropriately informed and educated about the procedure; supporting patient leaflets to reinforce this information are vital and should be written in an easy to understand language.

Screening consists of measuring a plasma aldosterone concentration (PAC) and plasma renin activity to calculate the

aldosterone-to-renin ratio (ARR). Ideally testing should be performed in the morning, after the subject has been out of bed for at least 2 h. Patients should be instructed to be on a liberal salt diet and be volume replete prior to testing. This will suppress the renin level, meaning that most of the circulating aldosterone is probably autonomously produced (i.e. dysregulated), rather than stimulated by the RAAS system. Patients **must** have stopped mineralocorticoid receptor antagonists (e.g. spironolactone, eplerenone) and potassium-wasting diuretics (e.g. furosemide, torsemide) for at least 4 weeks prior to ensure an accurate result. As hypokalaemia can impair aldosterone secretion, patients should also ideally be potassium replete ($[K^+]$ >4.0) prior to testing. Blood should be drawn with the patient in a seated position, rather than recumbent. It should be drawn slowly, ideally into a syringe rather than a vacutainer to avoid haemolysis, transported at room temperature (**not** on ice), and processed within 30 min of collection. An ARR ≥750 (SI units) or ≥30 (conventional units) with PAC ≥280 pmol/L (10 ng/dL) is strongly suggestive of PA (Funder et al. 2016).

Confirmatory testing should be performed, as no diagnosis should depend on a single lab result. Testing options include an oral salt loading test with 24-h urine collection of aldosterone (cut off >33 nmol/day, 12 μg/24 h), saline infusion test (cut off PAC ≥280 pmol/L, 10 ng/dL), captopril challenge test, and fludrocortisone suppression test (Funder et al. 2016).

Once confirmed, the patient should undergo CT imaging with IV contrast to better define the adrenal and associated venous anatomy. Because clinicians may be fooled by a non-functional adenoma on imaging, and the disease in fact may be on the contralateral gland or bilateral disease, it is often recommended that patients who are surgical candidates should subsequently undergo adrenal venous sampling (AVS), the current gold standard to confirm the laterality of disease. The rate of success of this technically demanding diagnostic procedure depends on the expertise of the interventional radiologist, so referral to high-volume centre is recommended. Patients younger than 35, with profound aldosterone concentrations (>830 pmol/L or 30 ng/dL), spontaneous hypokalaemia, and an obvious solitary lipid-rich nodule on imaging can forgo AVS and proceed directly to unilateral adrenalectomy (Funder et al. 2016).

Similarly, if AVS lateralizes to one side, it is recommended that the patient proceed to unilateral adrenalectomy (typically performed laparoscopically). Surgery will, in most cases, cure the patient of hypokalaemia and improve hypertension. Hypertension may not improve immediately but may continue to improve even up to 1 year post-operatively (see Box 36.2). Factors that portend a lower rate of hypertension cure include male sex, longer duration of PA (>6 years), multiple antihypertensive medications preoperatively, and overweight or obesity (BMI >25 kg/m^2) (Aronova et al. 2014).

Box 36.2 Important Message for Patients for Post-operative Care for PA

Advise your patient that hypertension may not improve immediately and can continue to improve even up to 1 year post-operatively. Lifestyle factors can influence this so encourage weight loss for your overweight patients.

If the disease is determined to be bilateral by AVS, however, surgery is typically not offered, and medical management with a mineralocorticoid receptor antagonist (MRA) is instituted. Spironolactone is typically cheap (as it is generic), may be the most potent MRA, and is commonly the first-line medication. However, it

can have mild off-target anti-androgenic effects leading to gynaecomastia or sexual dysfunction in males. Eplerenone, a newer and more specific MRA, does not cause these side effects and may be a better choice for male patients (Parthasarathy et al. 2011). However, it can also be significantly more costly if not covered by health insurance. If a single medication is unable to control the hypertension, additional agents, such as a calcium channel blocker, ACE inhibitor, or triamterene (ENaC channel blocker) may be added.

36.1.3 Cushing Syndrome

Cortisol, a glucocorticoid produced by the zona fasciculata, has many wide-ranging effects on the body, including regulation of blood pressure, glucose, immune function, metabolism, and bone turnover. Its synthesis and secretion are primarily regulated by ACTH, which is produced in the pituitary.

Among adrenal adenomas, between 5 and 25% have some degree of autonomous cortisol production (Rossi et al. 2000; Mantero et al. 2000). The vast majority of these cortisol-producing adenomas (CPA) do so in small quantities and rarely progress (<1%) to produce overt signs and symptoms typically associated with Cushing syndrome (prevalence 1 per million), such as moon-like face, plethora, dorsal buffalo hump, violaceous abdominal striae, thin skin, easy bruising, frequent infections, fragility fractures, or proximal muscle weakness (Fassnacht et al. 2016; Newell-Price et al. 2006) (Fig. 36.2). Thus, these CPAs have classically been denoted in the literature as causing "Subclinical" Cushing syndrome. In recent years, however, it has been realized that even subclinical Cushing syndrome may have subtle clinical signs such as obesity, acne, or hirsutism and is associated with an increased risk of hypertension, type 2 diabetes, hyperlipidaemia, and osteoporosis (Fassnacht et al. 2016; Rossi et al. 2000). Moreover, as this represents a degree of cortisol excess along a spectrum, the term "autonomous cortisol secretion" is preferred to subclinical Cushing syndrome.

36.1.3.1 Diagnosis of Cushing Syndrome

A thorough history needs to be taken, as effects of hypercortisolaemia may be subtle. Patients may have menstrual irregularities or low testosterone (in men), acanthosis nigricans or skin tags from insulin resistance, acid reflux or peptic ulcer disease from enhanced gastric acid production, and/or silent vertebral compression fractures. Mental disease may be a prominent feature and be very distressing to the patient, manifesting as anxiety, depression, insomnia, mood instability, anger outbursts, fatigue, forgetfulness, or even hallucinations (Rasmussen et al. 2015). Like primary aldosteronism, Cushing syndrome can result from germline (inherited) or somatic (sporadic) mutations (Lodish and Stratakis 2016); therefore, obtaining a good family history is also paramount.

Screening for hypercortisolaemia begins with a 1 mg overnight dexamethasone suppression test (Box. 36.3). Patients are instructed take 1 mg of dexamethasone, a synthetic glucocorticoid that is not recognized by the cortisol laboratory assay, between 11 pm and midnight, and a cortisol level is drawn at 8 am the following morning. Dexamethasone inhibits the hypothalamic production of corticotropin releasing hormone (CRH) and pituitary secretion of ACTH, thereby suppressing normal adrenal cortisol production. A morning cortisol >138 nmol/L (>5 μg/dL) is consistent with autonomous cortisol secretion, whereas a cortisol of ≤50 nmol/L (≤1.8 μg/dL) effectively rules out the disease. A cortisol between these two values is a grey zone and represents "possible" autonomous cortisol secretion (Fassnacht et al. 2016). It is important to note that women on oestrogen (e.g. oral contraceptives) may have a false-positive as oestrogen raises the circulating cortisol binding globulin. Also, some advocate to measure a dexamethasone level simultaneously with the morning cortisol to assess if a) the patient is a "hypermetabolizer" or b) if the patient did not actually take the medication, as both could lead to a false-positive result (Meikle 1982; Nieman et al. 2008).

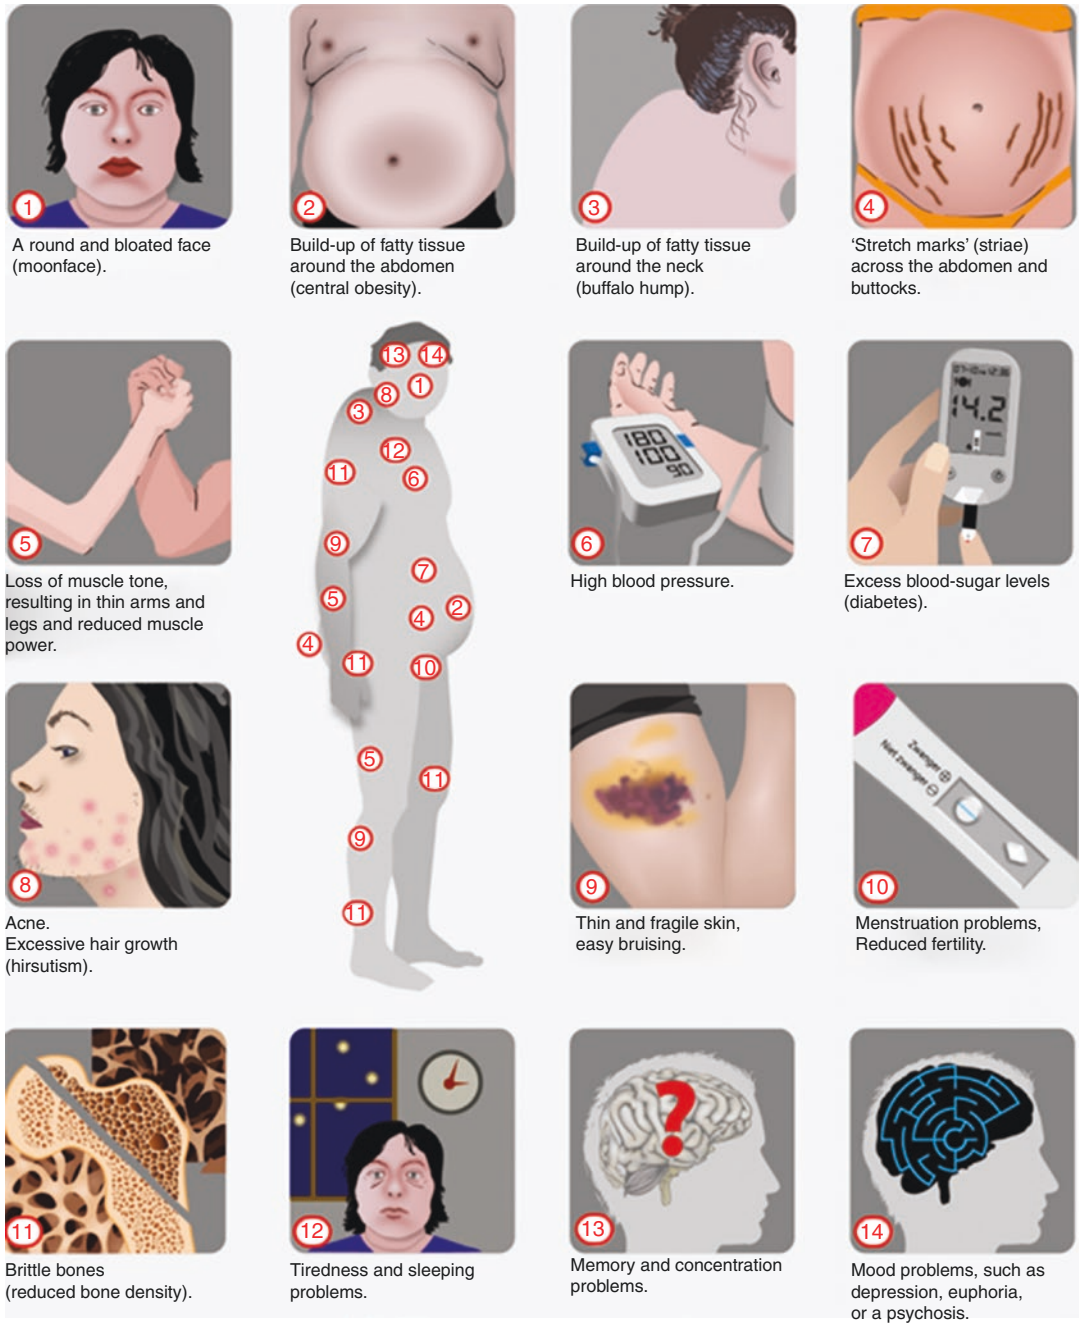

Fig. 36.2 Possible manifestations of cortisol excess (Cushing Syndrome). Used with permission from AdrenalNET and accessed via https://adrenals.eu/infographics/cushings-syndrome-infographic/

Patients with signs consistent with overt Cushing syndrome should undergo other screening tests, such as a 24-h urine collection for free cortisol (repeated at least twice), a late-night salivary cortisol (repeated at least twice), or a 48-h low-dose dexamethasone suppression test. Two positive screening tests in the setting of overt signs is consistent with the diagnosis of Cushing syndrome.

Box 36.3 Principles of Good Clinical Practice for Overnight Dexamethasone Text

Provide the patient with detailed information on why and how to take dexamethasone. Confirm that the patient has taken the tablet at the required time in order to interpret results accurately. Confirm the patient is not taking oestrogen or oral contraceptive pill (OCP) by asking "are you on the contraceptive pill?" rather than just "do you take other medication?". Patients often don't view the OCP as medication.

It is important to remember that ACTH excess (e.g. functional pituitary adenoma) can cause adrenal hyperplasia ± nodules. A suppressed ACTH level (<1.1 pmol/L, <5 pg/mL) is consistent with an adrenal, rather than an ACTH-dependent (e.g. pituitary or ectopic) source; however, unsuppressed ACTH levels (<3.3 pmol/L, 15 pg/mL) can be seen with adrenal disease as well (Newell-Price et al. 2006). In this case, an 8 mg overnight dexamethasone suppression test or CRH stimulation test may be helpful to distinguish between the two aetiologies.

36.1.3.2 Treatment of CPA Causing Cushing Syndrome

CPA causing Cushing syndrome should be surgically removed, if possible, via laparoscopic resection. If bilateral disease is seen on imaging, the surgical strategy should be thoroughly discussed with the patient. In the past, frequently both adrenal glands were excised leaving the patient cured, but with permanent adrenal insufficiency, requiring lifelong glucocorticoid (e.g. hydrocortisone) and mineralocorticoid (e.g. fludrocortisone) replacement. Recent studies have suggested that simply removing the larger gland on CT/MRI, or the more hypermetabolic gland on FDG PET, may lead to successful remission (Patel et al. 2016; Debillon et al. 2015).

The evidence regarding surgical intervention for autonomous cortisol secretion is less clear. Limited studies suggest that adrenalectomy for individuals who are surgical candidates and who also have related comorbid conditions, such as obesity, hypertension, type 2 diabetes, hypertension, or osteoporosis, may derive benefit (Fassnacht et al. 2016). For non-surgical candidates, medical therapy such as ketoconazole, metyrapone, mitotane, pasireotide, and/or mifepristone can be considered (Sharma and Committee 2017).

36.1.4 Adrenal Androgens

Androgens produced from the zona reticularis include dihydroepiandrostenone (DHEA), DHEA-sulphate (DHEAS), and androstenedione. Regulation of adrenal androgens is a complex system, partially under the control of ACTH. However, numerous other hormones may play a part in regulating the zona reticularis as well, including growth hormone, gonadotropins, oestrogens, and insulin (Parker 1991).

Females suspected of androgen overproduction may present with mild symptoms, such as hirsutism, acne, and menstrual irregularities. These patients should be assessed for non-classical congenital adrenal hyperplasia (see Chap. 35) and PCOS (see Chap. 39). Unlike in NCCAH, PCOS classically has been thought to result from dysregulated ovarian androgen synthesis. However, it has been recently suggested that a subgroup of PCOS patients suffer from mildly hyperactive adrenocortical function and adrenal hyperplasia (Gourgari et al. 2016). Benign androgen-producing adrenal adenomas have been previously described but are exceedingly rare (Ghayee et al. 2011; Goodarzi et al. 2003).

More rapid presentation and severe signs/symptoms of virilization, including deepening of the voice and male-pattern baldness, may signify an androgen-secreting adrenocortical cancer. For this reason, paediatric or female patients with confirmed hyperandrogenism, and particularly those with aggressive disease, should undergo imaging of the adrenals to help establish the aetiology. In instances of ACC or a benign functional adrenal adenoma, surgery is warranted.

Individuals with PCOS may benefit from spironolactone due to its anti-androgenic properties.

36.2 Part B: Pheochromocytomas and Paragangliomas

36.2.1 Anatomy and Physiology

The adrenal medulla is responsible for producing catecholamines (the hormones dopamine, norepinephrine, and epinephrine), which are essential for the stress response, otherwise known as the "fight or flight" response. The catecholamine pathway begins with the conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase, the rate limiting step. L-DOPA is then converted to dopamine by DOPA decarboxylase, and subsequently to norepinephrine (a.k.a. noradrenaline) by dopamine hydroxylase. The final step is catalysed by phenylethanolamine *N*-methyltransferase (PMNT) to form epinephrine (a.k.a. adrenaline) (Flatmark 2000).

Norepinephrine and epinephrine have potent cardiovascular effects. They can both bind to α1, α2, β1, and β3 adrenergic receptors. α1 binding mediates smooth muscle contraction and increases vascular tone; α2 binding leads to a negative feedback reduction of catecholamine production, decreased gastrointestinal motility, among numerous other actions; β1 binding causes increased heart rate and cardiac contractility; and β3 binding stimulates increased brown adipose tissue thermogenesis. Epinephrine has much greater affinity for the β2 adrenergic receptor than does norepinephrine, leading to increased smooth muscle relaxation in pulmonary bronchi and decreased gastrointestinal motility (Insel 1996, 1989; Sagrada et al. 1987).

For the most part, these hormones are stored in vesicles rather than directly released into circulation. Only upon stimulation do the vesicles fuse with the plasma membrane, thereby releasing the catecholamines in appreciable quantities. In contrast, metabolites of catecholamines (e.g. normetanephrine and metanephrine) are continuously excreted into circulation and are useful for diagnostic purposes (Lenders et al. 2014).

36.2.2 Pheochromocytomas and Paragangliomas

Tumours arising from the adrenal medulla are termed pheochromocytomas (PCC). Paraganglioma (PGL) are similar to PCC in that they can also produce catecholamines, but they originate in paraganglia along the parasympathetic and sympathetic chains. Sympathetic paraganglia are derived from chromaffin cells, are commonly located in the para-axial region from the neck to the pelvis, and secrete catecholamines in response to sympathetic stimulation. Parasympathetic ganglia, on the other hand, are not derived from chromaffin cells and are often found in the head and neck or close to their target organ, such as the carotid body, jugulotympanic ganglion, or along the vagus nerve (Fig. 36.3) (McNichol 2001). Thus, the location of a PGL can clue a clinician to its hormone secretory status; namely, paravertebral PGL often are biochemically active, whereas head and neck PGL (HNPGL) are commonly either non-functional (silent) or only dopamine producing.

PCC/PGL are rare, with an estimated incidence of 1 in 2000–5000 individuals. PCC make up about 80–85% of these cases, with PGL being less common. Sporadic PCC typically presents between ages 40 and 50 although 2–10% of cases are diagnosed in paediatric patients. Both sexes are affected equally (Wyszynska et al. 1992; Lenders et al. 2005; McNeil et al. 2000; Martucci and Pacak 2014).

PCC/PGL classically present with paroxysms of sympathetic excess, including episodic headache/migraines, sweating, and tachycardia. Both blood pressure spikes or sustained hypertension can be seen with PCC/PGL. Hypertensive crises caused by catecholamine surges can present with or lead to heart attacks, strokes, or death (Mazza et al. 2014; Whitelaw et al. 2014). Conversely, patients with predominantly epinephrine-producing PCC can present with orthostatic hypotension or even shock (Bergland 1989; Streeten and Anderson Jr. 1996). Other symptoms can include flushing or facial pallor, palpitations, diz-

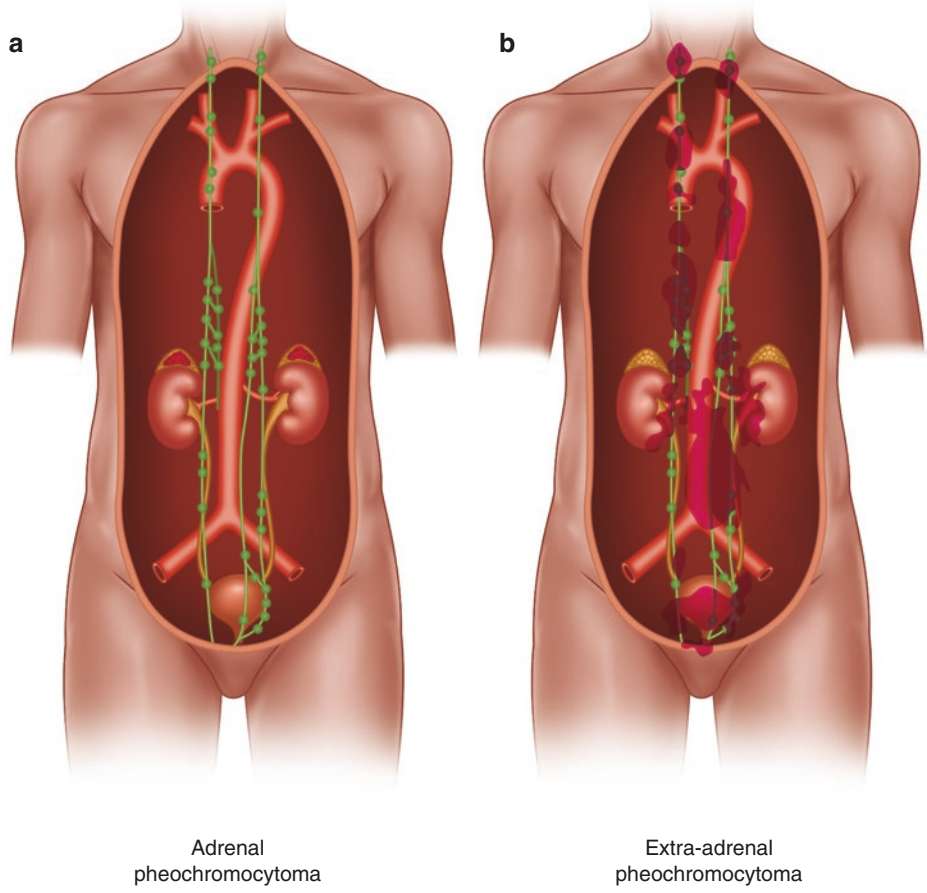

Fig. 36.3 The paraganglial system and sites of shown in red on the adrenals and extra-adrenal

ziness, visual disturbances, and feelings of anxiety or impending doom. Nausea and vomiting can present, particularly after exercise (Martucci and Pacak 2014). Constipation, commonly overlooked, can be severe and significantly impact patient quality of life (Thosani et al. 2015). Lastly, fasting hyperglycaemia or frank diabetes is a rare manifestation of PCC/PGL, particularly in younger patients without other diabetes risk factors (La Batide-Alanore et al. 2003).

The symptoms may occur spontaneously or may be brought on by stimuli, including the ingestion of certain tyramine-containing foods, micturition (in the cases of urinary bladder PCC), or certain medications or illicit drugs (Hodin et al. 2014). Anaesthesia or manipulation of a PCC/PGL during surgery can also lead to a catecholamine surge. PCC/PGL can also be discovered incidentally on imaging. Indeed, up to 5% of adrenal incidentalomas are found to be PCC (Mantero et al. 2000).

36.2.2.1 Diagnostic Testing

The initial diagnostic test of choice for PCC/PGL is either plasma-free metanephrines or 24-h urine fractionated metanephrines, which have greater than 90% sensitivity and specificity. The plasma or urine metanephrines are typically elevated more than threefold above the upper limit of normal for the reference range. Urine collections should also be measured for creatinine to ensure proper collection (Box. 36.4). These tests have demonstrated superior sensitivity and specificity over plasma or urine catecholamines or vanillylmandelic acid (VMA) (Lenders et al. 2002, 2014). HNPGL tend to be biochemically silent, or only secrete methoxytyramine, a dopamine metabolite,

for which commercial biochemical testing is not yet widely available (Rao et al. 2017).

Box 36.4 Principles of Good Clinical Practice for Testing for Pheochromocytomas

It is important to consider the conditions under which the samples are obtained, as they may affect the reliability of the results. Patients should have an indwelling intravenous catheter and be supine for at least 30 min prior to sampling. Phlebotomy performed with a butterfly needle or in the seated position can increase the likelihood for false-positive results (Lenders et al. 2014). Ideally, caffeine, nicotine, and alcohol should be avoided for at least 12 h prior to the test. Medications can also falsely elevate metanephrines, including acetaminophen, labetalol, phenoxybenzamine, tricyclic antidepressants (TCAs), decongestants, and buspirone (Lenders et al. 2014). Patients with chronic kidney disease will have decreased clearance of metanephrines, and therefore may have false-elevations (Martucci and Pacak 2014). Lastly, evaluation of PCC/PGL should not occur in the setting of an acute physical stress (e.g. acute myocardial infarction, infection) as increases in catecholamine production is a normal physiological response in such states.

Because up to 20% of metanephrine measurements may be false-positives (Yu and Wei 2010), equivocal results (e.g. metanephrine or normetanephrine elevation 1–3× the upper limit of normal) should be repeated, removing any possible offending medications. Patients with persistently equivocal tests or unclear diagnosis can also undergo a clonidine suppression test. The alpha receptor blocker clonidine specifically blocks norepinephrine released from neurons but does not block its release from the adrenal medulla or from PCC tumours. In individuals with PCC, plasma metanephrine levels do not suppress (<40% decrease) at 3 h after clonidine administration. This test has a specificity of 100% with sensitivity of 97%, but has not been validated prospectively. Importantly, the clonidine may cause significant hypotension, so patients should be monitored during this test (Lenders et al. 2014).

Once a diagnosis is established, patients should undergo imaging to locate the PCC/PGL. Typically, a CT of the abdomen and pelvis is pursued since most PCC/PGL are located in the abdomen. Because PCC are typically dense, a lesion with >10 Hounsfield units (HU) on non-contrast CT increases the likelihood, whereas a lesion with <5 HU almost definitively rules out the culprit lesion. To obtain washout values, contrast is injected, and the patient undergoes scanning one and 15 min later. The absolute washout $((HU_{1\,min} - HU_{15\,min})/(HU_{1\,min} - HU_{baseline}))$ is often less than 60% in PCC/PGL, reflecting their vascular and hypermetabolic nature, and therefore retaining (not "washing out") the IV contrast (Blake et al. 2010; McCarthy et al. 2016).

MRI imaging can be pursued instead, particularly in the paediatric population or in pregnant individuals, as it also has excellent sensitivity. On T1-weighted imaging, PCC/PGL have a signal intensity similar to liver, kidney, and muscle, which distinguishes them from the more common and benign cortical adenomas, which appear bright. Additionally, PCC/PGL do not have "signal drop out" between the in- and out-of-phase images. On T2-weighted images, PCC/PGL have a hyperintense appearance, sometimes nicknamed the "lightbulb" sign (Fig. 36.4) (Blake et al. 2010; McCarthy et al. 2016; Elsayes et al. 2005).

Ultrasound has much poorer sensitivity than CT or MRI, and therefore is not often used in the diagnosis of PCC/PGL, except when bladder PGL or liver metastases are suspected.

If a tumour is not localized on CT/MRI or metastatic disease is suspected, functional imag-

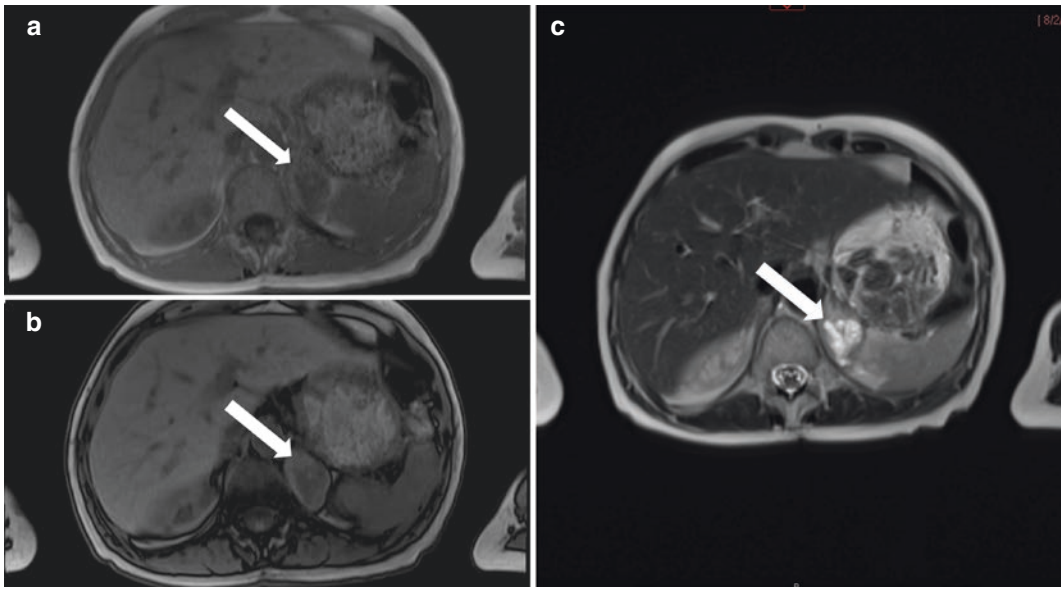

Fig. 36.4 MRI images of a pheochromocytoma (white arrows). Key: (**a**) T1 weighted MRI of the Abdomen In-phase with arrow pointing to pheochromocytoma at the left adrenal gland; (**b**) T1 weighted MRI of the Abdomen Out-phase with arrow pointing to pheochromocytoma at the left adrenal gland; (**c**) T2 weighted MRI of the Abdomen with arrow pointing to a bright pheochromocytoma lesion at the left adrenal gland. **Image provided by and used with permission from Dr Mayank Patel, MD, Special Volunteer, Section on Medical Neuroendocrinology, NICHD/NIH**

ing should be pursued. MIBG is available at many institutions and has classically been the first-line functional imaging test, as MIBG has high affinity for norepinephrine transporters. ^{131}I-MIBG is less sensitive and emits greater γ radiation than ^{123}I-MIBG and is no longer recommended. However, up to 50% of normal adrenal glands can demonstrate uptake, and false-positivity of MIBG is a significant problem. Conversely, MIBG has poor sensitivity for the detection of malignant, bilateral, or extra-adrenal PCC/PGL, or those related to certain germline PCC/PGL-driver mutations (e.g. *RET*, *VHL*, or *SDHx*) (Lenders et al. 2014; Timmers et al. 2012).

PET imaging is superior to MIBG with respect to PGLs or metastatic disease and is more commonly being used over MIBG in the evaluation of PCC/PGL. ^{18}F-dihydroxyphenylalanine (FDOPA) has been shown to have excellent sensitivity (>90%) and specificity in metastatic disease but is not commonly available. ^{18}F-fluorodeoxyglucose (FDG) PET is most frequently used and has excellent sensitivity due to the increased metabolic demand PCC/PGL. However, inflammation, infection, benign adrenal adenomas, and other tumours/cancers may also demonstrate positive FDG-PET uptake. Also, if the patient has hyperglycaemia or uncontrolled diabetes mellitus, the elevated circulating glucose may compete with the FDG tracer for uptake, thereby resulting in a false-negative scan (Timmers et al. 2012; Taieb and Pacak 2018).

Lastly, ^{68}Ga-DOTATATE has been shown great promise as a functional imaging modality, particularly in *SDHB* metastatic disease and HNPGL, and has exceptional sensitivity and specificity in abdominal and thoracic PGLs as well (Taieb and Pacak 2018; Janssen et al. 2015, 2016).

As 30–40% of PCC/PGL may arise as part of an inherited syndrome, genetic testing should be offered to all patients diagnosed with PCC/PGL. With improvements and cost reduction in genetic sequencing a plethora of new genes have been linked with PCC/PGL formation, including over 10 major driver genes and 20 minor or rare driver genes (Dahia 2014; Curras-Freixes et al. 2017). Mutations in the succinate dehydrogenase complex (SDHx), a multimer of different protein subunits involved in the electron transport chain, are the most commonly inherited PCC/PGL-driver gene mutations, with *SDHB* and *SDHD* representing 10% and 9% of cases, respectively. Genetic testing is important as it can give prognostic information (e.g. *SDHB* frequently cause metastatic disease), may help with preconception planning or screening of family members, and may guide biochemical and radiologic testing.

36.2.2.2 Treatment for Pheochromocytoma and Paraganglioma

For biochemically active tumours, patients should be started on alpha-blockade immediately (Box. 36.5). For tumours which are very symptomatic (e.g. frequent hypertensive crises, uncontrolled blood pressure) or have very elevated metanephrines, phenoxybenzamine, a powerful non-selective irreversible alpha-blocker, is recommended. Less active tumours may do well with a selective α1-antagonist (e.g. terazosin, doxazosin, prazosin) (Hodin et al. 2014).

Box 36.5 Nursing Considerations for Patients on Alpha-Blockers

The role of the endocrine nurse is crucial in monitoring blood pressure and pulse and titrating alpha-blockers medications. It is important to educate patient about the side effects of these medications and that these can cause postural hypotension. The patient is advised to avoid sudden change of position, i.e. abrupt standing whilst sitting or lying. The patient is advised to increase fluid intake as blood volume is diminished because of excess adrenaline.

Beta-blockers, such as atenolol or metoprolol, can be started at least 3 days after alpha-blockade initiation to help control tachycardia. Beta-blockade prior to alpha-blockade can cause unopposed alpha stimulation and precipitate a pheochromocytoma crisis. Additionally, beta-blockers with both alpha- and beta-adrenergic blocking ability (e.g. labetalol) should be avoided as single or first-line therapy, as the beta-blockade is much more potent than the alpha-blockade and may precipitate a crisis (Lenders et al. 2014). Calcium channel blockers may be used in addition to or instead of alpha-blockers, particularly in those with mild disease or who are intolerant of alpha-blockade (Hodin et al. 2014).

Metyrosine, a tyrosine hydroxylase inhibitor, prevents catecholamine synthesis and can be used in refractory patients. However, it is expensive, difficult to obtain, and poorly tolerated with significant side effects, including depression, fatigue, nausea, and somnolence. Therefore, it should be used as an adjunctive treatment to the above mentioned medications in selected patients (Hodin et al. 2014).

Once medically controlled, most patients should be referred to surgery. Because patients with inherited forms of PCC/PGL may have recurrences and/or bilateral disease, partial cortical-sparing adrenalectomies are preferred when possible to avoid lifelong glucocorticoid and mineralocorticoid replacement. Most surgeries can be performed laparoscopically; however, for large (e.g. >5 cm), invasive, or metastatic tumours, open laparotomies may be required (Lenders et al. 2014). Patients should have intravenous fluids initiated in the immediate preoperative period to ensure adequate intravascular fluid repletion and to help prevent cardiogenic shock from the rapid decline of catecholamine levels post-operatively (Parenti et al. 2012). Patients should be followed up for at least 10 years post-operatively for surveillance (Box. 36.6). Of note, recurrences occur more frequently for patients with familial forms of PCC/PGL or extra-adrenal disease (Lenders et al. 2005).

Tumours greater than 5 cm, *SDHB* carriers, extra-adrenal location, and high Ki-67 on pathology are prognostic markers placing individuals at increased risk for developing metastatic disease. Select patients with malignant PCC/PGL still can be referred to surgery. Although not generally

Box 36.6 Important Message for Patients for Post-operative Care for PCC/PGL

Advise your patient that follow-up for at least 10 years post-operatively for surveillance is necessary even if they feel well due to the risk of recurrence for pheochromocytoma and paraganglioma. Recurrences occur more frequently for patients with familial forms of PCC/PGL or extra-adrenal disease.

curative, debulking or rending a patient with no evidence of disease may reduce time to recurrence, improve symptoms and quality of life, and may possibly improve response to chemotherapy (Parenti et al. 2012). Radiofrequency ablation may provide benefit for liver or bone metastases. For MIBG-positive tumours, ^{131}I-MIBG therapy may be attempted, although this is rarely curative (Martucci and Pacak 2014). A combination of cyclophosphamide, vincristine, and dacarbazine (CVD) is often used for unresectable metastatic disease (Parenti et al. 2012). Somatostatin analogues (e.g. octreotide, a.k.a "cold" somatostatin) have shown the ability to slow tumour progression in several case reports or small case series although this has not been well studied (van Hulsteijn et al. 2013; Duet et al. 2005). Several new targeted therapies, including radiolabelled DOTA peptides (e.g. ^{177}Lu-DOTATATE) and tyrosine kinase inhibitors, are currently under study (Martucci and Pacak 2014). Patient advocacy groups such as Pheo Para Alliance (USA) (Box. 36.7) provide great support and valuable resources for patients and clinicians and the reader is encouraged to refer to their website.

Box 36.7 Case Study and Resources Provided by the Pheo Para Alliance (USA) (Published with Consent)

Often called the "Great Mimic", pheochromocytoma and paraganglioma mimic stress-related disorders with symptoms ranging from high blood pressure, flushing, and headaches, to anxiety and panic attacks. Often written off as being overly anxious, it takes the average patient six frustrating years to receive an accurate diagnosis. In some cases, such as mine, a family member makes the diagnosis based on "family history" due to the strong genetic disposition of the disease. My father-in-law had the disease, as do my husband, his siblings, our three adult children, and now two of my young grandchildren have tested positive for the genetic mutation.

Pheochromocytoma and paraganglioma are extremely rare neuroendocrine tumours. Patients with these tumours suffer from the initial challenge of a complicated diagnosis and the difficulty of finding healthcare providers that understand proper diagnosis and treatment. The ***Pheo Para Alliance*** provides educational support and resources from the time of initial diagnosis through treatment and a lifetime of monitoring. Patients may never meet another patient with their same diagnosis, which is one of the many reasons that the Alliance is so vital to the pheo/para community. We provide an opportunity for members of our community to meet, if not in person, virtually with others who understand what they're going through. Additionally, with a greater understanding of the strong genetic component of the disease, we're helping educate patients and their healthcare providers about the importance of genetic testing for patients and their family members. With the increase in genetic testing, patients are being diagnosed at a younger age, with a lifetime of looking for tumours ahead of them.

36.3 Part C: Adrenal Incidentaloma and Adrenocortical Cancer (ACC)

36.3.1 Adrenal Incidentaloma

Adrenal incidentaloma refers to a mass of the adrenal area discovered fortuitously on a medi-

Founded in 2007, the Pheo Para Alliance is the longest standing internationally recognized leader in advocacy for and awareness of pheochromocytoma and paraganglioma. Since our inception, the Pheo Para Alliance has dedicated more than $2 million towards research, diagnosis, education, advocacy, and finding a cure for this disease. In August 2017, we consolidated our power and influence by merging with our partner group, the ***Pheo Para Troopers***, a true alliance of forces working with a common mission: investing in research to accelerate treatments and cures whilst empowering patients, their families and medical professional through advocacy, education, and a global community of support.

Community support is provided through the following services:

- Website with educational articles and videos for patients and healthcare providers
- Monthly Pheo Para Alliance newsletter with articles on the latest research, educational opportunities, and patients' stories
- Patient forum: An online opportunity for patients and caregivers to reach out for information and support
- Educational brochures provided to medical centres for newly diagnosed patients
- Facebook page
- Annual Pheochromocytoma and Paraganglioma Patient Conference
- Support for patients and families to attend regional patient education forums
- Funding grants for research
- Doctor tracker: The Alliance assists patients from all over the world in finding healthcare providers and facilities equipped to handle their unique requirements
- Pheo Para Alliance medical advisors are on three continents, helping us keep patients advised of medical treatments that are available in their part of the world.

Once referred to the Pheo Para Alliance, patients are able to connect with a global community that understands the unique healthcare challenges they face. Advocacy, education, research, and a community of support form the core of the Alliance's work on behalf of those with these rare neuroendocrine cancers.

cal imaging indicated initially to explore a "non-adrenal" disease or symptom (Fassnacht et al. 2016; Grumbach et al. 2003; NIH 2002; Terzolo et al. 2011; Tabarin et al. 2008). The frequency of these masses of more than one centimetre varies from 1 to 8.7% on autopsy series. In the radiological series, the prevalence is between 0.3 and 4.4% and increases with age to reach 7% from 60 years. Five to ten percent of adrenal incidentaloma are bilateral. The etiologies are multiple and summarized in Table 36.1. Among these lesions some must be operated (primary malignant tumours of the adrenal or secreting tumours), others treated medically

Table 36.1 Adrenal incidentalomas—frequency of the different causes [adapted from Fassnacht et al. (2016)]

Type of adrenal mass	Median % (range %)
Benign adenomas	80
Non-functioning	75 (71–84)
Autonomously cortisol-secreting	12 (1.0–29)
Aldosterone-secreting	2.5 (1.6–3.3)
Pheochromocytoma	7.0 (1.5–14)
Adrenocortical cancer	8.0 (1.2–11)
Metastasis	5.0 (0–18)

(lymphoma) and most simply monitored (non-secreting benign adenoma).

36.3.1.1 Diagnostic Testing

In fact, most incidentalomas are benign non-secreting adenomas, but it is important to rule out first other diagnosis. This highlights the importance of a rigorous diagnostic approach to define the management of an incidentaloma (Box. 36.8). This approach is based on the analysis of imagery and biological investigations. Several consensus conferences or guidelines, the most recent being released by the European Society of Endocrinology, have defined this diagnostic procedure and patients management (Fassnacht et al. 2016).

Box 36.8 Important Message for Patients Diagnosed with Adrenal Incidentaloma

Advise your patient that most adrenal masses cause no health problems and usually are asymptomatic (there are no symptoms or signs of the disease). The majority are non-functioning, benign tumours but a small number can cause serious disease. Consult and prepare the patient that they may have to undergo several investigations to set the diagnosis and to define the management of an incidentaloma.

Radiological investigations are by definition the initial step. It gives essential data and must focus on providing a certain amount of information to clarify the nature of the lesion and its risk of malignancy. This sometimes requires to repeat the initial imaging to have a specific and rigorous analysis of the adrenal mass. CT-scan or MRI are the methods of choice for this initial investigation. Some lesions (pure cysts, myelolipomas, haematoma) have specific imaging characteristics that allow an accurate diagnosis. In addition to these particular situations, the first step is to define whether the lesion can be formally classified as a benign adenoma (the most common case) or not (leaving the possibility of a malignant tumour). CT-scan with spontaneous density measurement can provide very reliable parameters (Figs. 36.5 and 36.6). A spontaneous density of less than 10 HU is specific of a benign adenoma (Hamrahian et al. 2005). The washout after injection of the contrast medium with a signal drop of more than 50% is also a very specific element for a benign adenoma. The MRI study with chemical shift analysis can be used as an alternative or in addition to CT-scan for the diagnosis of benign adenoma. In practice, a well-conducted CT-scan may be sufficient for imaging of an incidentaloma if it classifies it as a benign adenoma. When the mass cannot be classified with this imaging, MRI and eventually FDG-PET scan can be done.

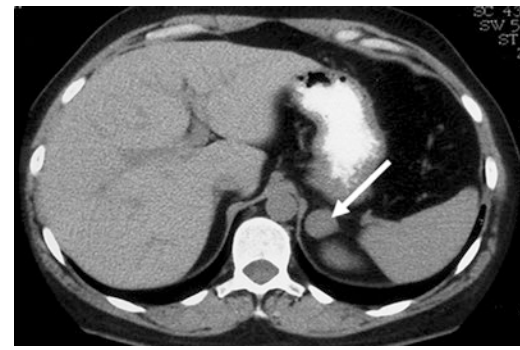

Fig. 36.5 CT-scan of a left adrenal adenoma (white arrow) incidentally discovered

Fig. 36.6 CT-scan of a right adrenocortical cancer (white arrow) incidentally discovered

Adrenal tumours found in the investigation of an adrenal incidentaloma can cause excess secretion of steroid or catecholamine. It is important to identify the lesions responsible for hypersecretion that may warrant therapeutic intervention. The detection of a hormonal alteration is also an important step in the initial investigation for the diagnosis of an incidentaloma. Secreting tumours can be diagnosed after hormonal investigations in patients whose clinical signs are absent, modest, or non-specific, justifying a minimal systematic biological search whatever the clinical presentation. Bilateral lesions caused by infiltrative process or metastatic tumours can cause adrenal insufficiency, which should also be investigated by systematic biological investigations (Tabarin et al. 2008). Hormonal investigations will therefore be more complete in the context of bilateral lesions to explore this possibility. The initial reading stage of the imagery and the clinical data can obviously guide the hormonal work-up; however, a systematic minimal hormonal investigation is recommended by most consensus or guidelines (Fassnacht et al. 2016; Grumbach et al. 2003; NIH 2002; Terzolo et al. 2011; Tabarin et al. 2008).

It is recommended to systematically search hypersecretion of catecholamine and cortisol to look for hypokalaemia and hyperglycaemia. The systematic search for a pheochromocytoma is justified by the frequency of this tumour in the operated incidentalomas (about 10%), and the potential risk represented by hypersecretion of catecholamine, mostly cardiovascular complications. Screening for pheochromocytoma can be done on 24-h urine metanephrine derivatives with simultaneous measurement of urinary creatinine or on plasma assay when available. Urinary assays have a very good sensitivity and acceptable specificity and have been most often used in published series. The chromogranin A assay, by its lack of sensitivity and specificity, is not recommended systematically in the incidentaloma. The investigation of a potential hypersecretion of cortisol should detect tumours of the adrenal cortex responsible for Cushing syndrome.

A significant part of the incidentalomas is represented by the benign adenomas responsible for a more modest hypersecretion of cortisol, called "subclinical" or "autonomous cortisol secretion". Although the consequences of this cortisol excess are still a matter of debate, it is admitted that it should be screened systematically as 10–20% of patients with adrenal incidentaloma might have benign adenoma responsible for autonomous cortisol secretion. The biological investigations used for the diagnosis of clinical Cushing syndrome (cortisoluria, midnight cortisol) have a good specificity but are not sensitive enough in this situation. The 1 mg dexamethasone suppression test is more sensitive (Box. 36.9), using a stringent cut-off (Fassnacht et al. 2016).

Box 36.9 The 1 mg Dexamethasone Suppression Test

It is recommended to detect cortisol autonomous secretion by an overnight 1 mg dexamethasone suppression test with a threshold of cortisolaemia at 18 ng/mL (50 nmol/L) (Fassnacht et al. 2016). It is important to remember that this is a very sensitive threshold (>98%), but not very specific (<80%). For this reason, a patient with a cortisol level above this threshold should be further investigated and the test might have to be repeated few months later. In this situation, cortisoluria, blood or salivary midnight cortisol, and ACTH can be added to the diagnostic work-up.

Screening for aldosterone excess will be done in patients with hypertension and/or hypokalaemia. It is then suggested to carry out as a first screening blood assay of aldosterone and renin (or renin activity) (Fassnacht et al. 2016; Tabarin et al. 2008). The assay of androgens (testosterone, DHA or SDHA) or precursors (17 hydroxyprogesterone, compound S, DOC) will not be systematic but may be performed according to the radiological or clinical data, or preoperatively in a suspected adrenocortical cancer.

In the bilateral incidentalomas, an ACTH-stimulation test (250 μg) with 9 am cortisol and 17-hydroxyprogestrone assays, as well as an ACTH measurement will be added to this hormonal workout. This aim at the screening of

adrenal insufficiency requiring substitutive steroid treatment and it is also interesting for the etiological diagnosis. The purpose of the 17-hydroxyprogesterone assay is to search for 21-hydroxylase deficiency (congenital adrenal hyperplasia). The aim of the ACTH assay is to demonstrate the primary origin of the adrenal failure when present. Conversely, in situations of bilateral adrenocortical lesions such as macronodular hyperplasia, which is nowadays more often diagnosed in patients with incidentaloma causing cortisol autonomous secretion, the dosage of ACTH can help to refine the assessment of adrenal autonomy; ACTH being suppressed in this cause of Cushing syndrome.

36.3.1.2 Monitoring and Treatment of Adrenal Incidentalomas

The majority of adrenal incidentalomas are benign adenomas. If the hormonal investigations exclude cortisol autonomy, a simple monitoring will be offered. In the case of hypersecretion of steroids or catecholamine surgery is the rule. In patients with a "subclinical" Cushing due to a benign adenoma surgery will be discussed on an individual basis depending on potential complications of cortisol excess (diabetes, hypertension, obesity, osteoporosis). When imaging investigations suggest malignancy or if there is a remaining doubt about a malignant lesion, surgical removal is indicated (Fig. 36.7).

36.3.1.3 Nursing Role in the Diagnosis of Adrenal Incidentalomas

During the diagnostic phase, the endocrine nurse meets the patient for review to get a complete history, organize, and coordinate baseline adrenal biochemistry work-up to be completed and to ensure the patient understand the rationale of the tests. More specifically, the nurse will consult the patient in the following diagnostic aspects of the work-up:

1. *Metanephrine levels*
   Plasma normetanephrine and metanephrine test can have false-positive results, and it is important to consult the patient appropriately. Antidepressants, caffeine, and nicotine could potentially induce an elevation in the results. The endocrine nurse may organize for a fasting supine plasma metanephrines to ensure that there's no interference with the results.
2. *Overnight dexamethasone suppression test with 24 h urinary-free cortisol collection*
   Overnight dexamethasone involves taking a 1 mg of dexamethasone tablet between 11 pm

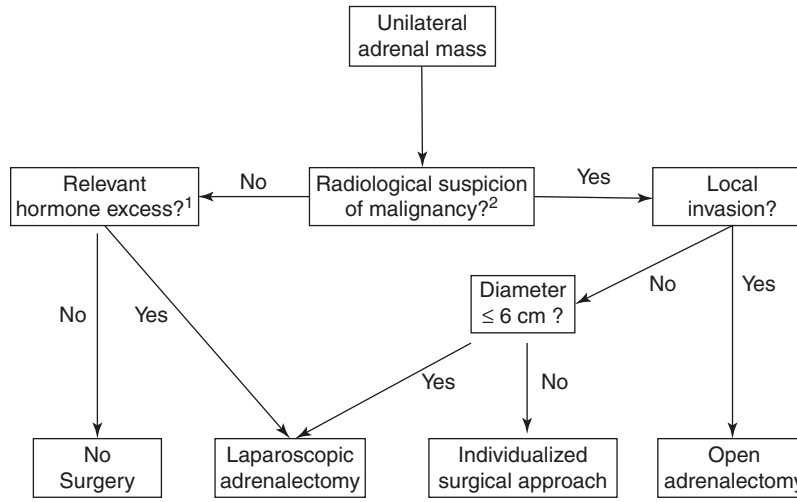

Fig. 36.7 Management of adrenal masses considered for surgery [reproduced from Fassnacht et al. (2016)]

[1] Autonomous cortisol secretion is not automatically judged as clinically relevant

[2] In tumors with benign radiological features and a tumor size >4 cm, surgery might also be individually considered

and 12 mn, the cortisol level the following morning by 9 am should be suppressed in patients who do NOT secrete excess steroids.

The 24 h urinary-free cortisol collection involves a collection of urine in a plain bottle for 24 h, usually starts in the morning with the first void discarded to ensure that the bladder is empty thereby ensuring an accurate collection, then collects all urine for the next 24 h including the first void the next morning. This test will determine the total cortisol excretion within a 24 h period which is usually <130 nmL/24 h.

It is important to advise the patient the importance of proper timing of the test and the rationale behind the test, i.e. to complete the urine collection first before the dexamethasone test. The patient does not need to fast and can take their usual medications as prescribed. However, there are factors that need to be considered which can cause false-positive and false-negative results.

False-positive can occur in female patients taking oestrogen which increases the cortisol binding globulin leading to increase in total cortisol. The patient should be advised to discontinue oestrogen for 6 weeks before testing. Patients on medications that induce the enzyme CYP3A4 (e.g. antiepileptic, rifampicin, alcohol) can increase hepatic clearance of dexamethasone.

False-negative can occur on patients with renal failure because of the drop in albumin and cortisol binding globulin, patients with liver failure and patients on medication that inhibits the enzyme CYP3A4 (e.g. fluoxetine, cimetidine) decreasing hepatic clearance.

If required, salivary cortisol can be completed. This involves the patient to chew a salivette (swab) for at least 2–3 min, ensuring that the swab is saturated with saliva. The salivette comes in a plastic container to put the sample back after. The patient is advised not to eat, drink, or brush teeth for at least 30 min before collection. The patient can rinse mouth with water at least 15 min before collection. The sample needs to be put in the fridge if not delivered within 2–3 days.

3. *Plasma aldosterone and renin levels*
   It is very important to identify any medications that can interfere with the renin-angiotensin system (e.g. angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs)) before performing the tests. The endocrine nurse will review the medication history of the patient and identify and replace medications that can interfere. Once initial blood test suggests hyperaldosteronism, a saline suppression test is performed. The patient should be advised that test will require a day admission for minimum of 5 h. The patient will receive saline infusion of 500 mL/h for 4 h whilst the patient is lying in bed. Aldosterone and renin will be checked before and after the procedure. The patient needs to be potassium replete. Normal response shows a suppressed aldosterone as a response to the high plasma sodium. Failure to suppress suggests hormone aldosterone excess secretion.

36.3.2 Adrenocortical Cancer (ACC)

Cancer of the adrenal cortex (adrenocortical cancer, ACC) is a rare tumour, the annual incidence being estimated between 1 and 2 per million. In the USA, the Surveillance, Epidemiology and End-Results Study (SEER) studying deaths from 1975 to 1992 estimates the incidence of ACC at 1.8 cases/million/year. The Norwegian cancer registry from 1970 to 1980 reports a rather similar incidence of 1.5 cases/million/year. In children, ACC is considered ten times rarer than in adults. In southern Brazil, however, the incidence of ACC is very high in children, close to that of adults. Children's ACC in Brazil are due in almost all cases to the existence of a specific germline mutation of the *TP53* tumour suppressor gene (R337H) (Else et al. 2014; Libe et al. 2007; Fassnacht et al. 2009).

36.3.2.1 Diagnosing ACC

ACC can cause adrenal steroid excess in about three quarter of the cases. Signs of hypersecretion are mainly related to androgens in women and cortisol in both sexes (Libe et al. 2007). Androgen excess causes hirsutism, acne, and menstrual disorders (spaniomenorrhoea or amenorrhoea). In man, a tumour-secreting oestrogen can lead to the development of gynaecomastia. Excess glucocorticoid causes all the clinical signs of Cushing syndrome. When the tumour secretes aldosterone or steroid precursors with mineralocorticoid activity, arterial hypertension with hypokalaemia and oedema can be observed. When referred to an endocrine clinic, most patients are diagnosed by the presence of these endocrine signs and clinical symptoms. In some patients, ACC is diagnosed in the presence of clinical symptoms due to tumour mass or growth. It is primarily pain, more rarely venous thrombosis. In recent years, it is becoming more evident that some ACCs, previously considered as non-secreting, in fact secrete some urine steroid metabolites and recently urine steroid metabolomic analysis have been introduced in routine use (Arlt et al. 2011).

Adrenal incidentaloma has become an increasingly common mode of discovery. This mode of discovery often reveals a localized tumour whose prognosis after surgery is much better. Although the frequency of the adrenal cortex among the incidentalomas is low (3–10% of the operated tumours), this diagnosis must obviously be systematically considered. Recent advances in the survival of patients with adrenocortical carcinomas are certainly largely related to this earlier mode of diagnosis, allowing resection at a stage where the probability of complete remission is better (Libe et al. 2007; Fassnacht et al. 2009).

36.3.2.2 Management of ACC

The management of ACC requires a multidisciplinary expertise, which can be difficult to assemble in the case of a rare tumour. Complete surgical excision is without any discussion currently the best treatment of ACC (Gaujoux and Brennan 2012). If it is possible in stages 1 and 2 that are localized to the adrenal, it remains difficult in stages 3 (loco-regional extension), sometimes justifying sacrifice of adjacent organs. Half a century after its first use, mitotane (O, p'-DDD) remains to date the first-line medical treatment (De Francia et al. 2012). Although the place of mitotane is recognized by most teams in non-operable ACC (stage 4 mainly as seen in Fig. 36.8), there is currently no consensus on its place in adjuvant treatment after complete surgical resection. The side effects of mitotane are mostly digestive (nausea, vomiting) but also neurologic (confusion, somnolence, ataxia). By its adrenolytic action, mitotane also induces adrenal insufficiency requiring a steroid coverage, whose dosage adjustment is not always simple.

The assay of mitotane blood level is a valuable indicator to adjust the treatment. In fact, the severe adverse effects, in particular neurologic signs, are most often observed for mitotane blood levels higher than 20 mg/L. Different studies have showed that mitotane is more effective on tumour progression when its blood levels are higher than 14 mg/L. The therapeutic range (14–20 mg/L) is therefore narrow, which requires regular monitoring and frequent dose adjustment. In patients whose tumour disease progresses after surgery and under mitotane, various cytotoxic chemotherapies have been used (Berruti et al. 2012). Cisplatin is the most consistently successful drug. The first international randomized trial (FIRM-ACT) has established the association of Cisplatin, Etoposide, and Doxorubicin (Fassnacht et al. 2012) as the first-line cytotoxic chemotherapy in progressive ACC.

36.3.2.3 Nursing Role Considerations for Mitotane Treatment of ACC

Mitotane treatment should be performed only after the patient has received detailed information on the expected toxicity and its treatment. The main role of the endocrine nurse once patient is on adjuvant mitotane therapy is to counsel the patient about the medication, its mode of action, side effects and how to lessen its side effects, follow-up, and monitoring of the mitotane level. Patients are at risk of adrenal insufficiency and should be initiated on hydrocortisone replace-

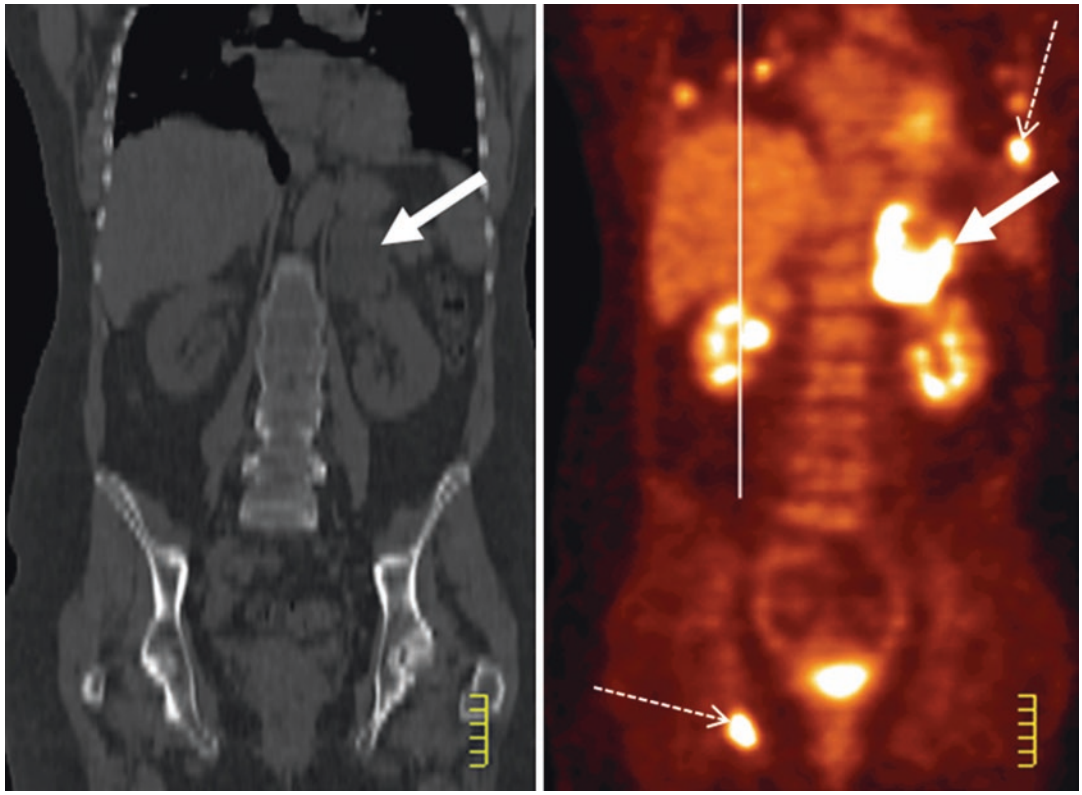

Fig. 36.8 FDG-PET scan of a left stage 4 adrenocortical cancer (white arrow) with distant metastasis (dotted thin arrows) (right image: CT-scan; left: FDG-scintigraphy)

ment concurrently with mitotane treatment to avoid potential adrenal crisis. High doses of hydrocortisone are needed (e.g. 20-10-10 mg or 20 mg three times daily) due to a substantial, mitotane-induced increase in cortisol binding globulin.

Patients should be consulted and be provided with comprehensive advice and education on management of adrenal insufficiency, sick day rules and prevention of adrenal crisis (please refer to Chaps. 37 and 62 for details). The endocrine nurse plays a vital role in this aspect.

Mitotane is lipophilic, accumulates in adipose tissue, from where it is slowly released back in to the blood stream. This means that plasma mitotane levels may substantially increase during ongoing treatment with the same dose. Thus, doses easily tolerated at the beginning may later cause significant side effects. The endocrine nurse should make patients aware of this potential adverse event and emphasize the need for regular follow-ups and monitoring of plasma mitotane levels.

Patient Case Study and Key Learning Points

A 46-year-old male patient, with no previous medical history or health issues, was diagnosed with hypertension in 2011. In the second half of 2012, he complained of being increasingly unwell, abdominal bloating, discomfort, and dyspepsia and was diagnosed with type 2 diabetes. A CT abdomen was done in December 2012 and showed a large adrenal mass. The patient was referred to his local hospital and was reviewed by the surgeons who subsequently referred him to the GI surgeons at the local tertiary specialist hospital. He was reviewed at the sarcoma MDT and as protocol; all patients with retroperitoneal masses, undergo biopsy. The patient was scheduled for CT-guided adrenal biopsy after a 24-h urine collection for catechol-

amines was sent for analysis. Prior to receiving the results, the patient was admitted for a CT-guided adrenal biopsy and had a large venous bleed as a result.

Key Learning Points:

- Biopsy should not be done for adrenal masses without prior confirmation of ALL these distinct criteria: history of malignancy, CT pre-contrast tumour density >20 HU, exclusion of pheochromocytoma with plasma metanephrines. Outcome of these test will dictate the therapeutic strategy.
- The cells obtained by a needle biopsy of an adrenal tumour cannot confirm whether the tumour is a benign adrenal mass or a rare adrenal carcinoma. It will only help in determining a primary adrenal tumour versus metastatic tumour. Most commonly, a biopsy is done if there is evidence of cancer outside the adrenal gland, or a patient with a known cancer has a suspicious adrenal mass. It is important to exclude a pheochromocytoma with biochemical testing prior to a biopsy.

36.4 Conclusions

The role of the endocrine nurse in the patient's journey following the incidental finding of an adrenal adenoma starts from diagnosis to follow-up. It involves coordinating the tests accurately and in timely manner, support in the diagnosis and management in close collaboration with the core members of the adrenal multidisciplinary team, education and training, follow-up of patients, and counselling. During this time, it is also important to take into consideration the possible psychological impact of the diagnosis to the patient and their families.

Acknowledgments With special thanks to Diane Silverman, Interim Executive Director, and Emily Collins, President, of the Pheo Para Alliance (Pheochromocytoma and Paraganglioma) www.pheopara.org for their contribution to this chapter with a case study and information on the Patient Advocacy Group. Also special thanks to Dr. Mayank Patel, MD, Special Volunteer, Section on Medical Neuroendocrinology, NICHD/NIH for providing the MRI image on pheochromocytoma.

Abstract

Adrenal insufficiency (AI) is a common life-threatening endocrine condition. It is caused by the inability of the adrenal glands to produce cortisol, a hormone essential for life, either due to failure of the adrenals (primary AI), or due to diseases affecting the hypothalamus or the pituitary which control the adrenals (secondary AI). Patients with AI require lifelong glucocorticoid (GC) replacement therapy and increased GC doses during periods of intercurrent illness or other major psychological and physical stress to mimic the normal increase in physiological cortisol response to such situations. Inadequate GC replacement for daily maintenance and increased doses during illness, can precipitate an adrenal crisis (AC) an adrenal crisis which can be fatal if the immediate administration of parenteral hydrocortisone is delayed.

The prevalence of primary AI is 93–140 patients/million population and of secondary AI is 150–280/per million. Standard mortality rate for patients with AI is more than twofold compared to the general population according to retrospective hospital data. AI has significant impact on patients' quality of life, and suboptimal GC replacement (over- or under-replacement) can lead to acute and long term complications such as osteoporosis and type 2 diabetes.

AI encompasses a wide variety of medical diagnoses and can be an unrecognised underlying condition masked by another diagnosis in both paediatrics and adults. There should be a heightened sense of suspicion in the presentation of any seriously unwell neonate, child or adult where an unexplained presentation, deterioration of an intercurrent illness or other stress (e.g. surgery or significant trauma) may have precipitate an AC.

The diagnosis of AI brings many challenges for children, parents, adult patients and their families with the impact of a multiple daily medication routine, and the need for sick day surveillance and management, and for vigilance to detect potential illness and possible events which may be life threatening. Health professionals need to provide adequate ongoing psychological support and education for patients and families long term as they adapt to their health needs of their condition and incorporate treatment plans into their daily lives. Understanding of the education process is crucial and one of the most one important aspects of the role of the endocrine nurse.

Keywords
Adrenal insufficiency · Adrenal crisis · Hydrocortisone · Glucocorticoids · Fludrocortisone · Patient education · Primary adrenal insufficiency · Secondary adrenal insufficiency · Quality of life

Abbreviations

AC	Adrenal crisis
ACTH	Adrenocorticotropic hormone
AD	Addison's disease
AI	Adrenal insufficiency
CA	Cortisone acetate
CAH	Congenital adrenal hyperplasia
CRH	Corticotropin-releasing hormone
CSHI	Continuous subcutaneous hydrocortisone infusion
DHEA	Dehydroepiandrosterone
GC	Glucocorticoids
HPA	Hypothalamic-pituitary-adrenal axis
ITT	Insulin tolerance test
PAI	Primary adrenal insufficiency
QoL	Quality of life
SAI	Secondary adrenal insufficiency
SST	Short synacthen test

Key Terms

- Adrenocorticotropic hormone (ACTH) is the hormone responsible for stimulating cortisol production from the adrenal glands, which is essential for life.
- Adrenal insufficiency (AI) refers to the failure or impairment of the adrenal glands which can be primary adrenal insufficiency (PAI) most commonly autoimmune or Addison's disease, or secondary adrenal insufficiency (SAI) due to hypothalamic-pituitary diseases, resulting in cortisol deficiency.
- ACTH stimulation test is a diagnostic test to assess the adrenal steroid production after the administration of the synthetic ACTH analogue Tetracosactide.
- Adrenal crisis is life-threatening emergency caused by inadequate production of the adrenal hormone cortisol in situations of stress.

Key Points

- Patients with adrenal insufficiency need to have adequate steroid replacement in order to have a better outcome in quality of life, reduce their risk of adrenal crisis, and preventable hospital admissions and fatalities.
- GC replacement needs to take in account a patient's needs, the daily dosage variation and timing, and consideration of the most effective delivery options for effective absorption in order to maximise the benefit of therapy.
- Endocrine nurses play a key role in the care of patients with adrenal insufficiency. They provide education and support in order to engage with these patients life-long to ensure they achieve positive health outcomes for life.

37.1 Introduction

Adrenal insufficiency (AI) is a common life-threatening endocrine condition. It refers to the failure or impairment of the adrenal glands which can be primary adrenal insufficiency (PAI) most commonly autoimmune or Addison's disease, or secondary adrenal insufficiency (SAI) due to hypothalamic-pituitary diseases. In children, the most common cause is Congenital Adrenal Hyperplasia (see Chap. 35). Long-term corticosteroid treatment which can lead to adrenal gland atrophy can also result in AI, and is often referred to as tertiary adrenal insufficiency. The adrenal glands produce glucocorticoids (GC) (cortisol in humans, but e.g. corticosterone in rats), mineralocorticoids (aldosterone), and androgens. Cortisol secretion exhibits a distinct circadian rhythm reaching peak levels in the early morning prior to awakening and low levels in the evening with lowest levels at midnight (Arlt 2017). In the case of neonates, their circadian rhythm is not established until later in their first year of life (Miller et al. 2008; Mendoza-Cruz et al. 2013); hence cortisol levels are difficult to interpret and can be confusing. Please read Chap. 34 for more details on anatomy and physiology of adrenal glands. It is important to have a clear understanding of the circadian rhythm as it plays a crucial role in the planning of GC replacement therapy.

The prevalence of primary AI is 93–140 patients/million population and of secondary AI is 150–280/per million (Arlt and Allolio 2003). AI arising from prolonged administration of corticosteroid treatment leading to suppression of the hypothalamic-pituitary-adrenal axis (HPA) is much more common, occurring in 0.5–2% of the population in developed countries (Arlt 2017); in the UK for example an average of 0.75% of the population was prescribed long-term oral corticosteroid therapy (e.g. prednisolone, dexamethasone) at any time point (Fardet et al. 2011).

37.2 Causes and Clinical Presentation of Adrenal Insufficiency in Children and Adults

Primary adrenal insufficiency (PAI) refers to glucocorticoid deficiency in the context of adrenal failure or disease in the gland itself, whereas secondary adrenal insufficiency (SAI) arises because of ACTH deficiency due to causes affecting the hypothalamic or pituitary function (Fig. 37.1). A major distinction between PAI and SAI is that PAI is invariably accompanied by deficiency of mineralocorticoids which are regulated by the renin-angiotensin-aldosterone (RAA) system (please see chap. 34 for anatomy and physiology of the adrenal gland); this does not occur in SAI because only ACTH is deficient, and the RAA system is intact (Arlt and Allolio 2003; Stewart 2008). A summary of the most common causes and associated features of AI is presented in Table 37.1 (Arlt 2017; Arlt and Allolio 2003; Stewart 2008; Barthel et al. 2016; Bancos et al. 2015).

37.2.1 Primary Adrenal Insufficiency

Thomas Addison was the first physician to describe the clinical phenotype of PAI in 1855 hence the name Addison's disease. PAI is most commonly caused by autoimmune-mediated adrenalitis accounting for 68–94% of cases in adults. It can occur in isolation (30–40% of cases) or in combination with other autoimmune diseases as part of the autoimmune polyglandular syndrome type 1 (APS1) in 10–15% of cases, and type 2 (APS2) in 50–60% of cases (Table 37.1). In children, most frequent monogenic cause of AI is congenital adrenal hyperplasia (CAH) which is caused by mutations in enzymes involved in steroid hormone synthesis, most commonly mutations in CYP21A2 encoding 21-hydroxylase, with an incidence of 1 in 12,000–15,000 people (Arlt and Allolio 2003; Bancos et al. 2015) (please see Chap. 35). Worldwide, infectious diseases such as tuberculosis fungal infections, HIV and cytomegalovirus, are common causes of AI (Stewart 2008).

37.2.2 Secondary Adrenal Insufficiency

SAI is the consequence of the dysfunction of the HPA axis. The most frequent causes of SAI are tumours involving the hypothalamic-pituitary region associated with ACTH deficiency caused by tumour growth leading to suppression of the pituitary function, or treatment with surgery or radiotherapy resulting in hypopituitarism (Table 37.1) (please see chapters in Section 3, the Pituitary Gland). In children, SAI is due to mal-development of the hypothalamus and pituitary gland: aplasia, hypoplasia or ectopic placement of the pituitary are most common and lead to multiple pituitary hormone deficiency (MPHD). In neonates and infants, birth trauma, and in childhood head injury and brain tumours are other causes of SAI (Migeon and Lanes 2009; Miller et al. 2008).

37.2.3 Iatrogenic Adrenal Insufficiency

An underestimated and significant cause of AI is the suppression of the HPA axis by exogenous long-term GC treatment leading to atrophy of adrenal cortex. This becomes apparent when patients cease treatment and HPA axis is not restored for endogenous production of ACTH and hence cortisol. Two recent systematic reviews demonstrated that the risk of AI after cessation of GC therapy varied significantly and there is no administration form, dosing, treatment duration, or underlying disease for which AI can be excluded with certainty (Joseph et al. 2016; Broersen et al. 2015). This risk increases with a

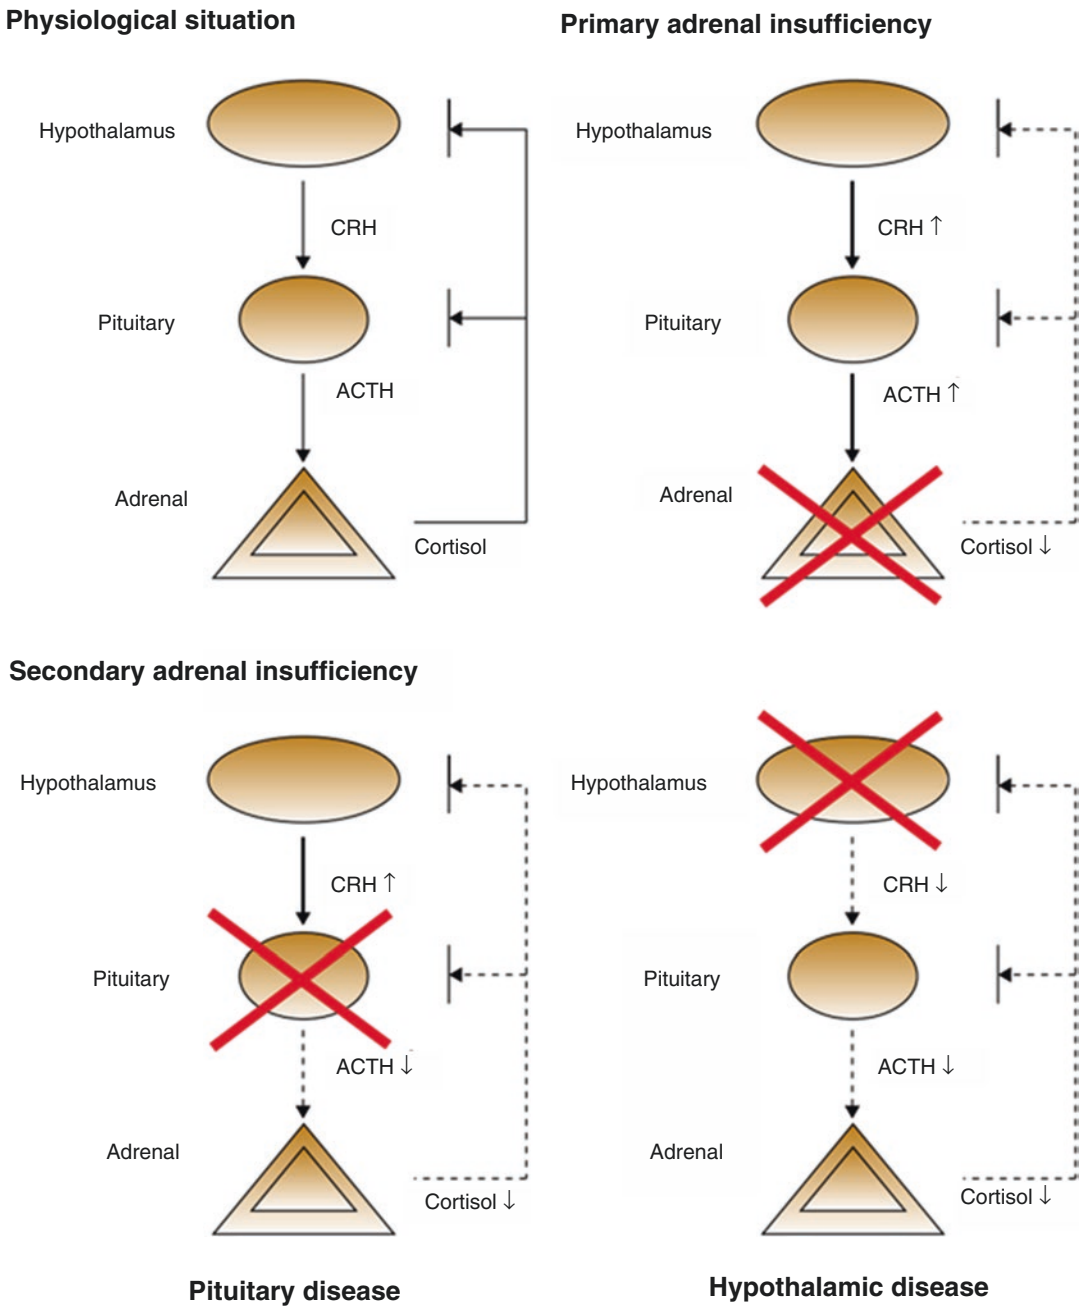

Fig. 37.1 Differentiation between primary and secondary adrenal insufficiency. Key: *ACTH* adrenocorticotropic hormone, *CRH* corticotropin-releasing hormone. Used with permission from Arlt, W. & Allolio, B. 2003. Adrenal insufficiency. *Lancet,* 361, 1881–93

dose equivalent of 5 mg of prednisolone or higher for longer than 4 weeks, irrespective of route of administration, i.e. topical, inhaled, oral, or injected (Bancos et al. 2015; Joseph et al. 2016). The risk of AI is difficult to predict hence all patients must be generally considered at risk of developing AI and consulted regarding prevention and management of adrenal crisis (Joseph et al. 2016; Broersen et al. 2015; Quinkler et al. 2013) (see Chap. 62). Administration of exogenous opioids, e.g. in pain therapy, may also cause suppression of plasma ACTH and serum cortisol, leading to AI, particularly in susceptible individuals (Policola et al. 2014; Lee and Twigg 2015).

Table 37.1 Common causes and associated features of adrenal insufficiency [adapted from Arlt (2017), Arlt and Allolio (2003), Stewart (2008), Barthel et al. (2016), and Bancos et al. (2015)]

Primary Adrenal Insufficiency (PAI)
Autoimmune adrenalitis (Addison's disease)
Isolated autoimmune adrenalitis
Adrenalitis as part of autoimmune polyglandular syndrome
Type 1 (APS1 or APECED): hypoparathyroidism, chronic mucocutaneous, candidiasis, other autoimmune disorders
Type 2 (APS2): thyroid disease, type 1 diabetes mellitus, other autoimmune diseases
Type 4 (APS4): Other autoimmune diseases, excluding thyroid disease or diabetes
Adrenalitis caused by infections
Tuberculosis, HIV, systemic fungal infections occurring mostly in immunosuppressed patients (histoplasmosis, blastomycosis, cryptococcosis, coccidioidomycosis), cytomegalovirus
Genetic disorders leading to adrenal insufficiency
Adrenoleukodystrophy, adrenomyeloneuropathy
Demyelination of CNS (cerebral adrenoleukodystrophy), spinal cord, or peripheral nerves (adrenomyeloneuropathy)
Congenital adrenal hyperplasia (see Chap. 35)
Ambiguous genitalia, salt wasting
ACTH insensitivity syndromes (familial glucocorticoid deficiency)
Glucocorticoid deficiency, but no impairment of mineralocorticoid synthesis
Triple A syndrome (Allgrove's syndrome)
Alacrima achalasia, neurological impairment, deafness, mental retardation, hyperkeratosis
Bilateral adrenal haemorrhage
Meningococcal sepsis, primary antiphospholipid syndrome
Adrenal infiltration
Amyloidosis, hemochromatosis, adrenal metastasis, lymphomas, sarcoidosis
Bilateral adrenalectomy
For management of Cushing's or other adrenal disease, after bilateral nephrectomy
Drug-induced adrenal insufficiency
Treatment with mitotane, aminoglutethimide, etomidate, abiraterone, trilostane, ketoconazole, suramin, mifepristone
Secondary Adrenal Insufficiency (SAI)
Pituitary adenomas (see Part III)
Adrenal insufficiency caused by ACTH deficiency from tumour growth or post-surgery or radiotherapy.
Idiopathic hypopituitarism (see Chap. 25) or isolated idiopathic ACTH deficiency
Other tumours of the hypothalamic-pituitary region
Craniopharyngioma, meningioma, ependymoma, and intrasellar or suprasellar metastases
Pituitary irradiation for tumours outside the hypothalamic-pituitary axis, e.g. leukaemia
Lymphocytic hypophysitis
Autoimmune hypophysitis
Often associated with pregnancy; may present with isolated ACTH deficiency or panhypopituitarism; can also be associated with autoimmune thyroid disease, vitiligo, premature ovarian failure, type 1 diabetes, pernicious anaemia
Pituitary apoplexy or Sheehan's syndrome (see Chap. 64)
Pituitary infiltration or granulomatous disease
Tuberculosis, actinomycosis, sarcoidosis, histiocytosis X, Wegener's granulomatosis
Head trauma
Iatrogenic Adrenal Insufficiency
Prolonged treatment with exogenous glucocorticoids
Treatment with opioids leading to ACTH suppression

37.3 Clinical Presentation of Adrenal Insufficiency in Adults

Table 37.2 presents a summary of the clinical manifestations of AI (Arlt 2017; Arlt and Allolio 2003; Stewart 2008; Bornstein et al. 2016). Presenting symptoms of AI are often non-specific such as fatigue, loss of energy, loss of appetite, nausea, or weight loss which often result in a delayed or missed diagnosis, for example, depression or anorexia (Arlt 2017; Bancos et al. 2015). In a study by Bleicken et al., less than 30% of women and 50% of men with AI were diagnosed within the first 6 months after onset of symptoms

Table 37.2 Clinical manifestations of adrenal insufficiency [adapted from Arlt (2017), Arlt and Allolio (2003), Stewart (2008), and Bornstein et al. (2016)]

Common sign and symptoms in PAI and SAI (caused by glucocorticoid and androgen deficiency)
Fatigue, lack of energy or stamina, reduced strength
Anorexia, weight loss (in children failure to thrive)
Gastric pain, nausea, vomiting (more frequent in PAI)
Myalgia, joint pain
Dizziness
Fever
Low blood pressure, postural hypotension, and dizziness (pronounced in PAI)
Hyponatraemia (more common in PAI)
Hypoglycaemia
Symptoms specific to adrenal androgen deficiency
In women: dry and itchy skin, impaired libido loss of axillary or pubic hair
In girls: absence of adrenarche or pubarche
Sign and symptoms specific in PAI (caused by mineralocorticoid deficiency)
Salt craving
Skin hyperpigmentation
Raised serum creatinine
Hypercalcaemia
Hyperkalaemia
Increased thyroid stimulating hormone
Additional sign and symptoms in SAI
Related to pituitary adenomas, such as acromegaly, Cushing's, prolactinoma (see relevant chapters in Part III), hormone deficiencies in hypopituitarism (see Chap. 25), and visual-field impairment from compression of the optic chiasm.

and 20% suffered for longer than 5 years before being diagnosed. Almost 70% of patients were given a false diagnosis and had consulted at least three physicians in the process (Bleicken et al. 2010a). This is more common in PAI as a history of pituitary conditions affecting the HPA axis with an increased risk of SAI prompts for further investigations to confirm ACTH deficiency. Hypothalamic-pituitary conditions can also manifest with other symptoms such as visual impairment caused by chiasmal compression suggesting a possible pituitary or brain tumour. It is important to remember that AI resulting from cessation of exogenous GC therapy can present with all the symptoms associated with GC deficiency even though these patients appear clinically Cushingoid from previous long-term exposure to GC therapy (Arlt 2017).

The most obvious clinical feature that distinguishes PAI from SAI, which is often present in PAI, is skin pigmentation caused by excess POMC stimulation, the precursor peptide of ACTH and melanocortin-1, the latter stimulating melanocytes. This is mostly seen in sun-exposed areas, pressure points, axillae, nipples, genitalia, and mucous membranes. Vitiligo and other autoimmune endocrinopathies (hypothyroidism) can often present in patients with autoimmune Addison's disease (Stewart 2008) (Fig. 37.2). A high biochemical measure of ACTH will also distinguish between PAI (being excessively raised) from SAI where the level will be low.

The clinical features of PAI in adults (Addison's disease) result from the loss of both glucocorticoid and mineralocorticoid and tend to be more acute in the onset. Hyponatraemia and hyperkalaemia are found in 80% and 40%, respectively, of patients with PAI at diagnosis. Acute AI presents with postural hypotension which can progress to hypovolaemic shock; it can also present with acute gastrointestinal symptoms of abdominal tenderness, nausea vomiting, and fever. Symptoms can often be mistaken as episodes of isolated gastroenteritis or appendicitis and if misdiagnosed can lead to a potentially life threatening AC. Autoimmune causes are rare in childhood, but the occurrence increases in the second decade of life into adolescence and onto adulthood (Arlt 2017; Kwok et al. 2005; Rushworth et al. 2017).

37.3.1 Clinical Presentation of Adrenal Insufficiency in Children

Similar to adults, undiagnosed AI in children can often be overlooked when another more significant diagnosis arises with symptoms often masking the underlying cortisol deficiency and which can mislead or confuse the diagnostic process. A new diagnosis of AI can reveal itself with either an acute presentation or have a prolonged insidious onset with a history of evolving features and concerns by parents with failure to thrive, poor weight gain and growth failure, and prolonged recovery from illnesses. An acute presentation occurs with the presentation of a infant or child in a state of systemic collapse, often precipitated by a significant intercurrent illness, when their adrenal function is no longer adequate to support their

(**b**) Pigmentation and vitiligo in a patient before and (**c**) after treatment with hydrocortisone and fludrocortisone. (**d**) Change in skin pigmentation of the hands of a 60-year-old man with tuberculous PAI before and after GC replacement, and (**e**) buccal pigmentation in the same man before treatment. Used with permission from Stewart P.M. (2008) The adrenal cortex, Chapter 14. In: Kronemberg H.M., Melmed S., Polonsky K.S. and Larsen P.R. (Eds) Williams Textbook of Endocrinology, 11th Edition. Saunders Elsevier, Philadelphia, pages: 445–503

metabolic needs in response to stressful situation (Migeon and Lanes 2009; Miller et al. 2008).

37.3.1.1 Acute Clinical Presentation of AI in Children and Neonates

In acute presentation of AI, examination will reveal a pale and lethargic child, with progressive signs of deterioration of a listless and floppy demeanour and a reduced level of consciousness due to hypoglycaemia. The child will be cool to touch and has hypothermia due to, hypovolaemia and peripheral shutdown (evident with poor skin turgor, delayed capillary return), dry mucous membranes and a history of minimal urine output indicating significant dehydration. Background history may reveal a period of intercurrent illness, poor oral intake, maybe a period of persistent diarrhoea and/or vomiting. Observations reveal tachycardia, dyspnoea, hypotension, and hypoglycaemia. A blood gas and peripheral blood is needed to confirm or rule out any biochemical cause, and a septic workup to determine a bacterial or viral cause for the presentation (Migeon and Lanes 2009; Miller et al. 2008).

An acute presentation in a neonate or infant is life threatening. It may occur following a history of persistently poor feeding, excessive sleepiness, persistent jaundice, and failure to regain birth weight, with significant weight loss of >10% of their total body weight. Acute episodes of AI require to be managed immediately, guided by standard emergency protocol guidelines, to prevent otherwise a fatal outcome due to AC (see Chap. 62 for more details).

37.4 Diagnosis of Adrenal Insufficiency in Adults

The diagnosis of AI is based on the patient's medical history, clinical sign and symptoms suggestive of AI, adrenal and/or pituitary imaging, and diagnostic biochemistry provocative tests. Figure 37.3 presents the diagnostic algorithm for adults with clinical sign and symptoms suggestive of AI and diagnostic test which can set the differential diagnosis (Bancos et al. 2015).

The diagnosis of AI is established by the ACTH stimulation test, also known as the short

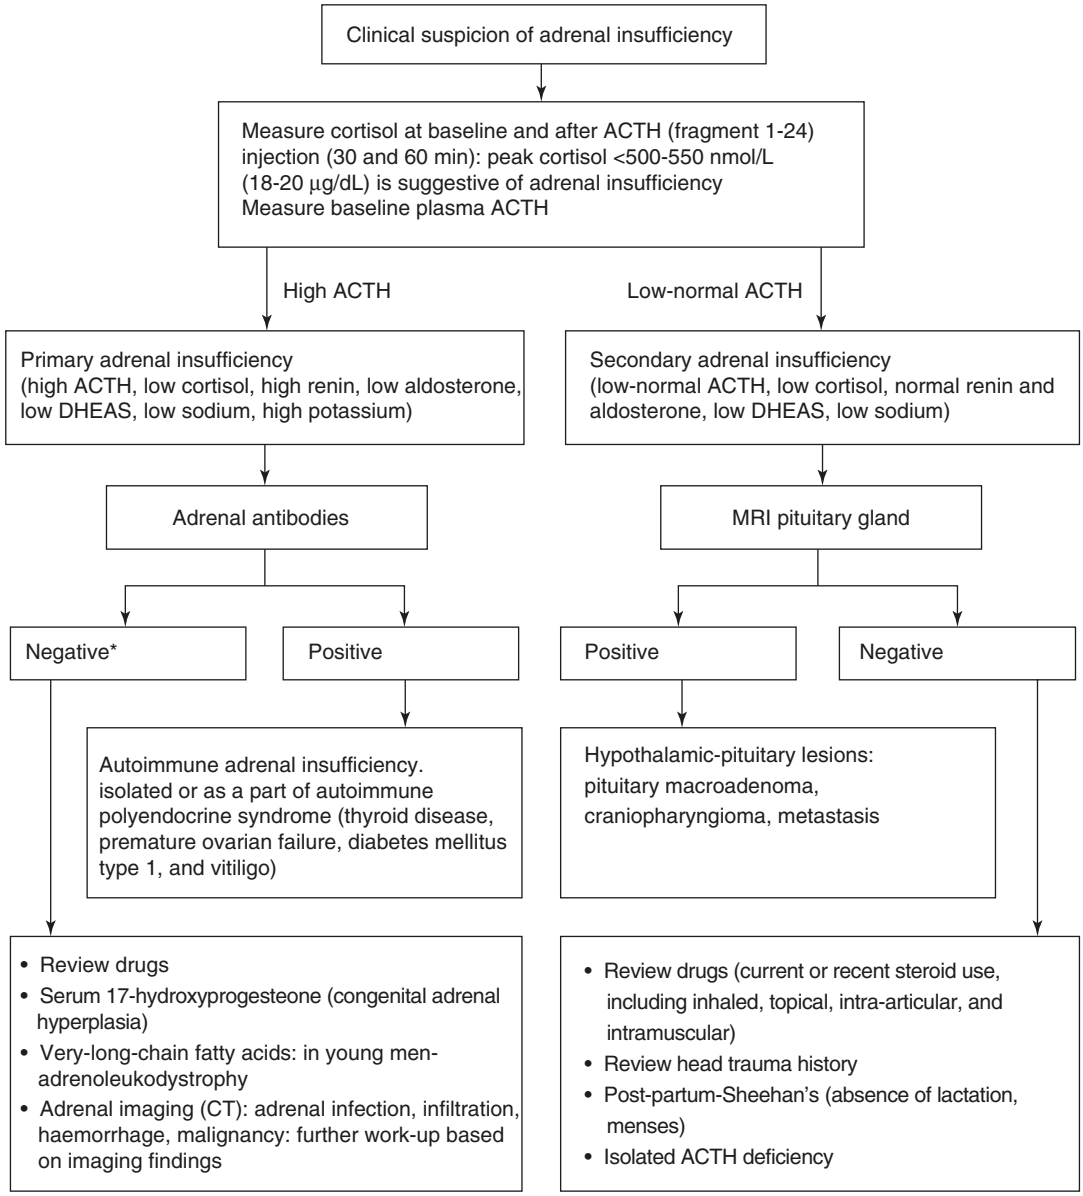

Fig. 37.3 Diagnostic algorithm for adults with clinical signs and symptoms suggestive of adrenal insufficiency. Key: *ACTH* adrenocorticotropic hormone, *DHEAS* dehydroepiandrosterone. Important to remember: Diagnostic measures must never delay the start of hydrocortisone treatment in suspected adrenal crisis and should be done when the patient is better. Cut-off values to exclude AI vary depending on the assay uses; always check local reference ranges. Used with permission from Bancos, I., Hahner, S., Tomlinson, J. & Arlt, W. 2015. Diagnosis and management of adrenal insufficiency. *Lancet Diabetes Endocrinol,* 3, 216–26

cosyntropin or short synacthen test (SST), through assessment of cortisol at baseline, 30 min and 60 min post administration of synthetic ACTH hormone of 250 μg for adults and children ≥2 years of age, 125 μg for children <2 years of age, and 15 μg/kg for infants (Bornstein et al. 2016). Cortisol response tends to be slightly higher at 60 min but there are no documented advantages in specificity and sensitivity for either time point (Bancos et al. 2015).

The cut-off values for cortisol for exclusion of AI are recommended at 500 nmol/L (18 μg/dL) (Bornstein et al. 2016), but this may vary according to the assay used. For example, a study reported that the low reference limit for cortisol 30 min after ACTH stimulation ranged from 420 to 574 nmol/L (15.2–20.8 μg) depending on the assay used (El-Farhan et al. 2013); cut-off values for cortisol may differ significantly between measurements using immunoassays or mass spectrometry assays and therefore specific local reference ranges must always be confirmed before setting the diagnosis.

The ACTH stimulation test is a test of adrenal function and therefore should not be used to diagnose SAI before adrenal gland atrophy has occurred, which takes approx. 3–4 months. Therefore, testing with the SST for SAI, for example, within a month after a pituitary insult and suspected ACTH deficiency, may not detect SAI. It has also been suggested that ACTH stimulation testing could lack sensitivity in chronic SAI due to the 250 μg supraphysiological dose and the 1 μg was advocated as an alternative (Dorin et al. 2003). However, later evidence found that significant proportion of patients fail the 1 μg test using the agreed cut-off cortisol limit, and this could lead to unnecessary lifelong GC replacement (Neary and Nieman 2010); therefore, it is not recommended to use as a diagnostic test. In addition, diluting a 250 mg ampoule in 1 mg portions is not recommended. The insulin tolerance test (ITT) is an alternative, but it is more invasive and contraindicated in patients with a history of seizures, cardiovascular disease, untreated hypothyroidism, and elderly patients, and in particular it is contraindicated in children owing to the dangers of significant hypoglycaemia and risk of an AC (Miller et al. 2008). (please refer to Chap. 15, in Part III for more details on provocative diagnostic testing). In addition, ITT should be avoided in SAI when random morning cortisol concentrations are lower than 80 nmol/L (3 mg/dL) which are strongly predictive of AI (Bancos et al. 2015). Suspected AI presenting with acute AC must be treated promptly with parenteral hydrocortisone (Bancos et al. 2015; Bornstein et al. 2016; Wass and Arlt 2012) (Box 37.1). In the paediatric population the IV synacthen test has been useful in determining suspected cortisol deficiency and utilised in determining recovery of the adrenal gland function following adrenal suppression following iatrogenic use of steroids (Mendoza-Cruz et al. 2013).

Box 37.1 *Treat first, diagnose later*! Management of Acute AI

For patients admitted with adrenal crisis where AI is suspected, hydrocortisone must be given without delay along with intravenous fluid resuscitation. Blood samples for paired cortisol and ACTH should be taken if there is an opportunity but it is crucially important to promptly treat the AC and undertake diagnostic investigations later when the patient is better (please see Chap. 62 for more details on management of AC).

It is also important to remember that oral oestrogen preparations increase total cortisol concentration (which is measured in current assays) by increasing circulating cortisol-binding globulin (CBG) and therefore should be discontinued for at least 6 weeks prior to evaluating cortisol levels although one study showed that these effects were not seen in patients using transdermal oestrogen replacement (Qureshi et al. 2007).

37.4.1 Diagnosis of Adrenal Insufficiency in Children

Specific considerations need to be given making the diagnosis of AI in children and neonates in addition to those discussed earlier in the diagnosis of adults with AI. In addition to clinical manifestations of AI described earlier, observations confirm **hypothermia** (temperature less than 36 °C), **hypoglycaemia** (<2.6 mmol/L) via peripheral blood glucose analysis or blood gas, and **hypotension** with unmeasurable blood pressure. Table 37.3 presents a summary of the relevant biochemistry and microcytic investigations

Table 37.3 Investigations in the differential diagnosis of AI in children

Investigation	Biochemical features and results
Venous blood gas	Immediate assessment of BGL, EUC metabolic status/acidosis
EUC	Hyponatraemia and high serum potasium indicating aldosterone deficiency
Urea and creatinine	Assess for dehydration Elevated levels confirm dehydration
Blood glucose	Confirms hypoglycaemia Lack of glucocorticoid and gluconeogenesis (fasting and vomiting)
Insulin	Normal insulin level in presence of hypoglycaemia rules out hyperinsulinism as cause of low BGL
Cortisol, growth hormone	Low levels in view of hypoglycaemia, confirms—multiple pituitary hormone deficiency (MPHD) and cortisol deficiency
Thyroid function tests	Low TSH/T4 confirms MPHD
17 OHP, androgen profile	Raised levels indicate possible CAH
ACTH	Raised level ++ Indicates—primary adrenal insufficiency
Lactate/pyruvate, free fatty acid, ammonia, carnitine	Assess metabolic acidosis as cause of hypoglycaemia—rule out metabolic diagnosis Rule out deficiency—causes hypoketotic hypoglycaemia
Aldosterone and renin	Low levels of aldosterone with high levels of renin indicate PAI, e.g. salt losing CAH—deficiency
Urinary keto-steroids	Positive levels determine CAH Minimise multiple blood tests requiring large amounts of blood (not done if acutely unwell)
Blood culture	Rule out sepsis
Urine culture	Rule out urinary tract infection

undertaken in the differential diagnosis of AI in children.

The most common cause of AI in childhood is Congenital Adrenal Hyperplasia (PAI) with mineralocorticoid deficiency or associated with multiple pituitary hormone deficiency (SAI). The distinguishing feature between PAI and SAI is the presence or absence of a significantly raised ACTH, 17OHP level and significant electrolyte imbalance in PAI. The synacthen test and a urine steroid profile (Miller et al. 2008; Koyama et al. 2014) are useful in diagnosing PAI. In SAI, determining diurnal variations in serum cortisol (8 am and 4 pm) and understanding normal secretion rates in neonates, infants and childhood can be helpful in interpreting the results (Migeon and Lanes 2009; Miller et al. 2008; Koyama et al. 2014). Other investigations for SAI include a closely monitored brief fasting study in a neonate or infant to measure the response of counter-regulatory hormones (cortisol & growth hormone) along with insulin to rule out hyperinsulinism in response to hypoglycaemia. A glucagon stimulation test (GST) can be useful in place of an ITT (contraindicated in childhood) to determine a child's cortisol response to hypoglycaemia along with possible growth hormone deficiency in children (Miller et al. 2008).

37.4.1.1 Psychological Impact of Diagnosis of AI on Children and Parents

The diagnosis of AI in the child can have a significant psychological impact on the parents. The parental role to nurture and protect is challenged by a medical condition which has life-long implications. The distress and shock following the diagnosis impacts greatly on the parents' ability to rationalize the situation which is out of their control. As such the effectiveness of information which the medical and nursing staff impart can be diminished (Betman 2006). As health professionals, we have no control over this process, other than to provide emotional support and explanation in a timely manner in an initial and ongoing process. The significance of a potentially life-threatening condition, challenges parental strengths and weaknesses and puts many relationships under extreme pressure. They need to grieve for the loss of their expected healthy child and fear the limitations such a diagnosis will have on their child's future life. Eventually, rationalising their fears and worries about the future will see subsequent resolution with final acceptance to move forward and manage the care required for their child. The endocrine nurse needs to understand the grief process that parents experience following a significant diagnosis in

order to provide the support they need to move forward with their child's journey in life (Betman 2006).

37.5 Treatment of Adrenal Insufficiency

Treatment of AI is multifaceted and, although it is primarily focused on replacement therapy, it should not be considered in isolation from the self-management and psychological well-being of patients and their families. A holistic overview of the patient's psychosocial environment, quality of life (QoL), well-being, other health needs and comorbidities, as well as their priorities, beliefs on and expectations from their treatment, is necessary. In addition, patient/family empowerment and shared decision-making are crucial in achieving an individualised treatment regimen and improved patient adherence. The objectives for treatment in AI are summarised in Box 37.2 [summarised from Arlt and Allolio (2003), Barthel et al. (2016), Bancos et al. (2015), Bornstein et al. (2016), Fleseriu et al. (2016), Grossman (2010), and Chapman et al. (2016)].

37.5.1 Mineralocorticoid Replacement Therapy

Mineralocorticoids are vital for maintaining water and electrolyte homeostasis, and thereby blood pressure. Only patients with PAI have mineralocorticoid deficiency as this is controlled by the RAA system and not the HPA axis. Fludrocortisone is a synthetic mineralocorticoid used to replace aldosterone in patients with PAI. It is recommended that all patients with confirmed aldosterone deficiency should be on fludrocortisone replacement starting at 50–100 μg and taken on waking up together with GC. In childhood, fludocortisone doses may be required

Box 37.2 Objectives for Treatment Optimisation in Adrenal Insufficiency

The following objectives should be taken into consideration when planning and monitoring the treatment regimen for patients with AI:

- To provide optimal replacement for GC, androgens and, specifically for patients with PAI, mineralocorticoids
- To involve patients and families in planning a treatment regimen which is tailored to each patient's individual needs in order to minimise or avoid where possible complications and symptoms from over- or under-replacement
- To restore normal well-being, quality of life, sexual function, weight balance, normal growth for children, and social, family, and professional activity
- To ensure patients and families are well informed of their condition and can recognise the symptoms of over- or under-replacement
- To ensure patients and families receive support and education on their treatment so they can self-manage their daily replacement, adjust GC appropriately during intercurrent illness, and know how to prevent an adrenal crisis
- To ensure that the education provided translates to behavioural change for patients and families; any potential detrimental medication behaviours need to be identified and patients should be supported to address these factors
- To develop an infrastructure and health service that supports the needs of patients with AI and ensures prompt management of AC to minimise or avoid hospitalisations and to eradicate preventable deaths from AC

twice daily in the first few years of life, owing to mineralocorticoid pathway resistance. The addition of salt supplements is essential in neonates and infants as dietary sodium is inadequate in this age group (Migeon and Lanes 2009; Miller et al. 2008). Fludrocortisone is primarily monitored based on clinical assessment of salt cravings, postural hypotension, or presence of peripheral oedema alongside blood pressure, blood electrolytes (sodium and potassium) and renin (Quinkler et al. 2015); salt intake should not be restricted (Bornstein et al. 2016). For patients who develop hypertension, a reduction in the dose of fludrocortisone is recommended alongside monitoring of electrolytes but antihypertensive treatment can be initiated whilst continuing fludrocortisone if blood pressure remains uncontrolled (see also Box 37.3). During pregnancy fludrocortisone doses often need to be increased due to the antimineralocorticoid effect of progesterone (Quinkler et al. 2015). Also during episodes with hot weather fludrocortisone dose increases of 50 mg/day often lead to better physical performance. Hydrocortisone also exerts a mineralocorticoid activity and a 20 mg dose is equivalent of 50 μg of fludrocortisone (Arlt 2017; Bornstein et al. 2016) hence with increasing the dose of hydrocortisone during illness or managment of an AC, there is no need to increase the dose of fludrocortisone.

Box 37.3 Key Points in the Assessment of Mineralocorticoid Replacement

Does your patient crave salt, feel lightheaded, have low blood pressure, postural hypotension, low blood sodium, high potasium and reports a general feeling of being unwell? If the answer is YES, replacement is inadequate, and the dose of fludrocortisone should be increased. Advise your patient that temporary dose increments of fludrocortisone by 50–100% or increase in salt intake are also needed in a hot climate or situations that promote excessive sweating.

37.5.2 Adrenal Androgen Replacement Therapy in Women

Dehydroepiandrosterone (DHEA) is the main source of androgen production in women and plays important role in maintaining sexual function, energy, and libido. DHEA replacement in women with AI also leads to development or restoration of pubic hair and may therefore have a role in pubertal females (Neary and Nieman 2010). DHEA replacement at 25–50 mg as a single dose should be considered for women with PAI complaining of low libido, depressive symptoms, dry skin, and fatigue when GC and mineralocorticoids are optimised (Bornstein et al. 2016). This can be on a 6-month trial and can be discontinued if there is no benefit. Women should be monitored for possible androgenic side effects of hirsutism or hair thinning. Small studies found that patients with SAI also reported improvement in psychological well-being on DHEA replacement (Brooke et al. 2006). However, evidence in this patient group population is controversial regarding QoL outcomes and recent guidelines recommend against routine use of androgens for women with SAI (Fleseriu et al. 2016).

37.5.3 Glucocorticoid Replacement Therapy in Adult Patients with AI

As already discussed, cortisol secretion exhibits a circadian rhythm and the objective for GC replacement therapy is to mimic this rhythm in an as closest as possible manner although this has so far been a challenge. A crucial step to understand is the regulation of cortisol metabolism by interconversion of cortisol to cortisone, governed by the intracellular 11β-hydroxysteroid dehydrogenase (11β-HSD) enzymes; type 1 (11β-HSD1) modulates local tissue cortisol levels by converting cortisone (*inactive* GC) to cortisol (*active* GC) and type 2 (11β-HSD2) converts cortisol to cortisone which functions as a systemic glucocorticoid reservoir (Oksnes et al. 2015; Aulinas et al. 2013). Box 37.4 lists the three aspects which should be considered for optimal GC replacement.

Box 37.4 The Three Important Aspects of Optimal GC Replacement Therapy

Consult and educate the patient and their families on the following three aspects of GC replacement therapy:

1. **Circadian rhythm daily dosing for oral GC**

   Objective: to optimise well-being, improve adherence and minimise or avoid negative effects of over- or under-replacement

   Action plan:
   - work with patient and family to select an individualised treatment regime and the correct dose and type of GC
   - advise patient of special situations such as travelling, shift working, extreme physical or emotional stress
2. **GC replacement during intercurrent illness—"sick day rules"**

   Objective: to support the patient and aid recovery from illness by increasing GC dose as needed

   Action plan:
   - advise your patient and family on the different situations which require "sick day rules" and how to adjust the dose of their GC
   - patients are often on different GC regimens so a blanket rule of "double or triple" dose will not be applicable to everyone
   - provide supporting information, e.g. leaflets, emergency ID card, and an emergency GC injection kit, smartphone applications, as well as education on how to recognise and prevent AC
3. **Prevention and management of adrenal crisis**

Objective: recognise and manage AC in a timely manner to avoid hospitalisation

Action plan:
- ensure patients and their families are aware of the symptoms of AC and able to take immediate action
- check that patents wear emergency ID card and have access to GC injection which can be administered promptly
- advise patients on supporting services which they can call upon in case of AC, e.g. ambulance service, inform family and friends about risks of AC

There are several GC formulations used to treat AI (Table 37.4). The most commonly used GC is hydrocortisone (cortisol) given in two or three divided oral doses daily (total daily dose of 15–25 mg for patients with PAI (Bornstein et al. 2016) and 15–20 mg for patients with SAI (Fleseriu et al. 2016)). Cortisone acetate two to three times daily to a total of 20–35 mg is also used although not available in some countries such as the UK or Germany. Contrary to hydrocortisone, cortisone acetate (*inactive*) requires activation via hepatic 11β-HSD1 before it becomes biologically *active* cortisol. This may result in broader interindividual variability of cortisol which can make it difficult to obtain a precise profile. However, it has been suggested that the slower onset and offset of cortisol levels may be advantageous in smoothing fluctuations in levels (Grossman 2010), and this would be a good option for patients complaining of "energy dips" between doses.

The first and largest dose of hydrocortisone should be given on waking up on empty stomach, for faster absorption and as early in the morning as possible. The second dose is given at lunch time and the third dose, if required, given late afternoon but no more than 4–6 h before sleep (with a 5–6-h gap between doses). Generally, patients with PAI require higher and more frequent doses of hydrocortisone compared to patients with SAI who may have some residual cortisol reserve. Caution is required in patients

Table 37.4 Formulations, characteristics, and dose equivalent for GCs

GC name	Equivalent GC dose (mg)	Potency relative to hydrocortisone	Half-life plasma (min)	Duration of action (h)
Hydrocortisone	20	1	90	8–12
Cortisone acetate	25	0.8	30	8–12
Prednisone	4–5	4–5	60	12–36
Prednisolone	3–4	5–6	60	12–36
Dexamethasone	0.5	30–50	200	36–54

with SAI to avoid over-replacement (Grossman 2010). The general aim is to give the lowest possible dose of hydrocortisone without compromising the patient's well-being or put them at risk of AC. Two large studies including more than 1000 patients with AI, showed that most patients take hydrocortisone, i.e. 75% (Forss et al. 2012) and 87.4% (Murray et al. 2017), respectively, at either twice or thrice daily. The most common regimen of hydrocortisone was 10 mg on waking up, 5 mg at lunch time, and 5 mg late afternoon or evening (Murray et al. 2017), which is generally the most accepted regimens we use in clinical practice. Interestingly, both studies showed a large variation of daily regimens, regarding total daily dose and number of divided doses; Murray et al. reported that 25 different regimens were being used by patients to deliver a total daily hydrocortisone dose of 20 mg (Murray et al. 2017). This emphasises that requirements for GC replacement are individual to each patient's needs. Endocrine nurses have a pivotal role in identifying and addressing these needs to plan an optimal GC replacement regimen for patients. A small study concluded that hydrocortisone dosing and regimen should be adjusted according to the patient's weight (Mah et al. 2004), but there is no robust evidence to support this approach over current practice, and this would add to the already very complex regimen for patients with AI.

Prednisolone 3–5 mg once or twice daily, which is a long-acting GC, can be considered as an alternative treatment option for patients who continue to report impaired QoL or poor adherence to the twice or thrice daily regimen (Bornstein et al. 2016). It is however not a preferred choice, as it has been associated with an increased tendency to adverse metabolic complications including weight gain, dyslipidaemia, and type 2 diabetes (Filipsson et al. 2006; Quinkler et al. 2016), and osteoporosis (Frey et al. 2018). Dexamethasone should not be used as GC replacement in AI due to the Cushingoid side effects and difficulties in dose titration (Bornstein et al. 2016) although there is a rare indication for use in certain patients with CAH (please see Chap. 35).

The modified dual-release hydrocortisone (Plenadren®) is an alternative option for GC replacement. It comes in tablets of 20 mg and 5 mg taken once daily on waking up. It has an immediate release coating combined with an extended-release core and provides physiological levels and a smoother cortisol profile during the day when compared to immediate release thrice daily hydrocortisone (Aulinas et al. 2013; Johannsson et al. 2009) (Fig. 37.4). It is important to note that the bioavailability of Plenadren is 20% less than hydrocortisone which may require a dose adjustment. In addition, cortisol levels during the evening decrease by up to 58% (Johannsson et al. 2009) and some patients may experience fatigue in the last part of the day especially if they are active. Two randomised studies showed that after switching from conventional thrice daily to once daily modified-release hydrocortisone, patients have a more circadian-based cortisol profile during the day, improved QoL scores, and a reduction in body weight, blood pressure, and glucose metabolism over 12 and 24 weeks (Isidori et al. 2018; Johannsson et al. 2012).

Infacort® (licenced for use in children with AI and CAH) is an immediate-release, granule

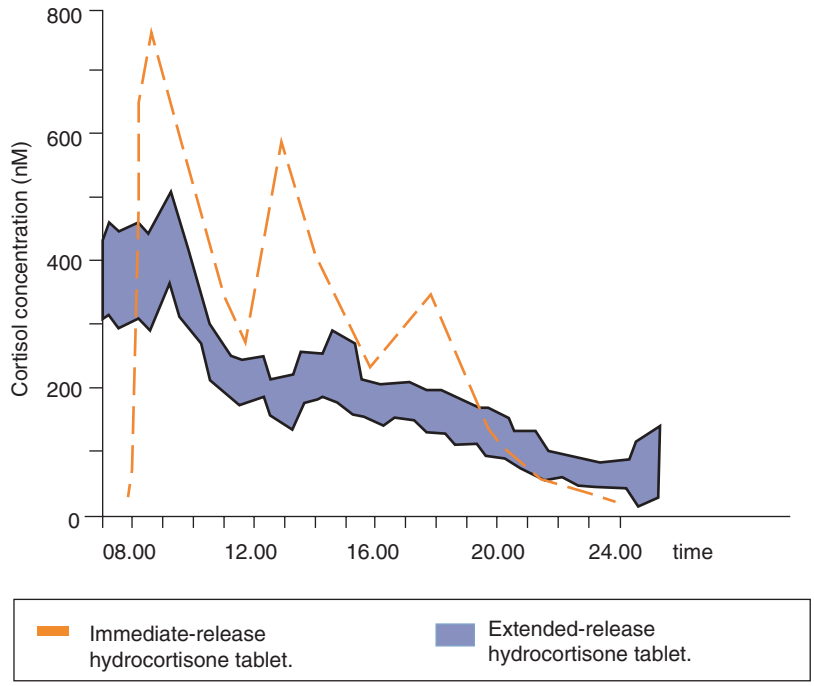

Fig. 37.4 Comparison of cortisol profiles between thrice daily immediate release and once daily modified-release hydrocortisone. Used with permission from: Aulinas, A., Casanueva, F., Goni, F., Monereo, S., Moreno, B., Pico, A., Puig-Domingo, M., Salvador, J., Tinahones, F. J. & Webb, S. M. 2013. Adrenal insufficiency and adrenal replacement therapy. Current status in Spain. *Endocrinol Nutr,* 60, 136–43

formulation of hydrocortisone with taste masking for a dose-appropriate formulation of hydrocortisone for children with adrenal insufficiency (Neumann et al. 2018; Uta et al. 2018). Chronocort® (developed for adults with CAH) is a modified-release hydrocortisone formulation based on a multi-layered multi-particulate technology where the sustained release and enteric coats are varied to provide differing release profiles (release of hydrocortisone 4–5 h after intake). Taken twice daily, 20 mg before sleep and 10 mg on waking up, it can mimic circadian rhythm of cortisol with a release of hydrocortisone in the early hours of the morning providing a pre-waking cortisol rise, which is not provided with other oral GCs (Whitaker et al. 2014).

Up to now, there has been no robust evidence to inform us whether one GC formulation is superior to the others regarding short term and long term goals (Grossman et al. 2013); therefore more research is needed in this area. It is important however to remember that every patient has different needs, and treatment should be individualised. The endocrine nurse has a crucial role in identifying and addressing these needs by adopting a holistic care approach.

37.5.3.1 Continuous Subcutaneous Hydrocortisone Infusion (CSHI)

Continuous subcutaneous hydrocortisone infusion (CSHI), using an insulin pump (Fig. 37.5), can mimic the physiological cortisol rhythm and is suggested as a potential alternative treatment option for patients with difficult to control AI and those in whom oral GC are not absorbed (Oksnes et al. 2015), as also demonstrated by our patient in the case study (Box 37.5). Preliminary evidence suggests that CSHI improves health-related QoL scores and improves fatigue in patients with AI (Oksnes et al. 2014) although it can be quite a cumbersome regimen for patients. Further studies are however needed to investigate long-term outcomes of CSHI treatment and to refine the infusion regimen.

37.5.3.2 GC Dose Adjustment During Intercurrent Illness in Adults

Patients with AI need to increase the dose of their GC replacement in order to mirror the physiological increase in serum cortisol levels during major stress and illness. This is normally referred to as “sick day rules”. There is no

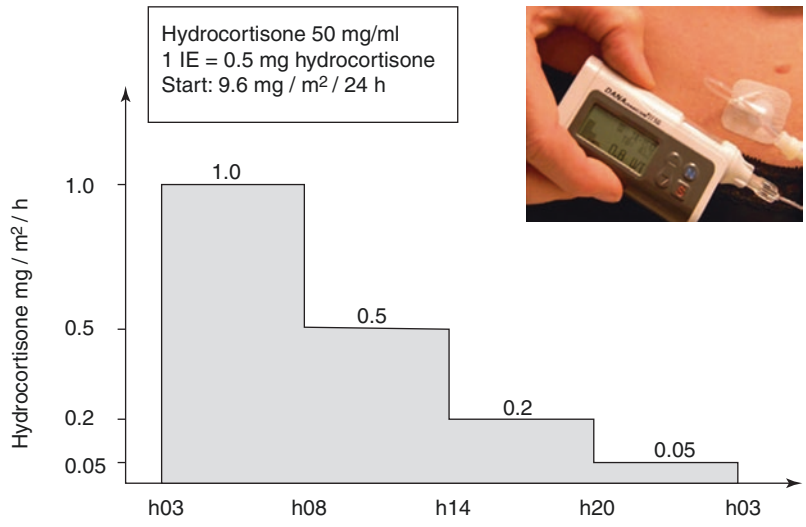

Fig. 37.5 Starting doses for continuous subcutaneous hydrocortisone infusion. The insulin pump reservoir is filled with hydrocortisone 50 mg/mL. Doses are adjusted to body surface area (BSA/m2). The daily dose is divided into four dosing intervals, with the highest dose during the last part of the night, half that dose during the first part of the day, and further decreasing doses in the afternoon and early part of the night. **Used with permission from:** Oksnes, M., Ross, R. & Lovas, K. 2015. Optimal glucocorticoid replacement in adrenal insufficiency. *Best Pract Res Clin Endocrinol Metab,* 29**,** 3–15. [Figure 4, page 11]

Box 37.5 Case Study of a Patient Using Continuous Subcutaneous Hydrocortisone Infusion (CSHI) for GC Replacement

What being on the CSHI Pump means to me

I was diagnosed with severe adrenal insufficiency in September 2016 even with oral hydrocortisone my blood cortisol levels were virtually non-existent.

I also have several pre-existing gastric issues—I have gastroparesis so reliably taking oral hydrocortisone was impossible as I was vomiting several times daily… Secondly, as I have Crohn's disease which is refractory and always active to some degree I was having diarrhoea several times daily so was burning through the hydrocortisone…

Between the end of March and beginning of May I had 6 back-to-back infections including a life-threatening sepsis and pneumonia. Since being on the pump I have been infection free…

I had heart palpitations due to tachycardia, constant terrible headaches which are so painful that I couldn't sleep, extreme fatigue—I had no energy and even sitting zapped me of my resources, every day I fainted up to five times daily as my blood pressure was persistently low… Since being on the pump I now have energy, my life is much more predictable and whilst I have a life-threatening condition I am much more in control of it rather than it controlling me. … my quality of life is exponentially better, and I no longer feel like death warmed up. The gastric and duodenal ulcers are now a thing of the past…

The other great thing is I am now on 21 mg of hydrocortisone daily… This means my chances of getting long-term side effects from excess steroid treatment, e.g. diabetes, heart disease, are drastically reduced … Some people may think being on a pump is restrictive but in all honesty most of the time I forget I am even wearing it…

(published with patient consent)

evidence on the optimal replacement during illness, but general consensus is to double or triple the dose of GC tablets for minor to moderate illness were oral intake is possible. For more severe illness and when the patient is unable to take oral tables in situations such as vomiting, diarrhoea or nil by mouth procedures, hydrocortisone needs to be administered immediately intramuscularly or intravenously at 50–100 mg starting dose followed by 50–100 mg every 6 h or 100–200 mg/24 h by continuous intravenous infusion (Arlt and Allolio 2003; Bornstein et al. 2016; Husebye et al. 2014). Patient education is crucial to ensure that patients and their families are familiar with the sick day rules. The endocrine nurse should take a detailed history of the patient's treatment, how and when they take their medication. A blanket rule of "double the dose" as reflected in the case study presented in Box 37.6, is not always applicable to every patient and patient education needs to take an individualised approach. Please read Chap. 62 for a comprehensive overview of the management of intercurrent illness and the diagnosis, prevention and timely management of AC. Chapter 62 also provides details on best approaches to patient education in AI.

Box 37.6 Case Study of GC Dose Adjustment During Intercurrent Illness

John is a 49-year-old man with SAI. He calls for an urgent consultation and is seen in the nurse-led clinic. He tells me he has not been feeling well and has had a lingering nasty cold for over 3 weeks, even though he doubled the dose of his hydrocortisone. His prescribed daily dose is 10 + 5 + 5 mg three times daily, but on further questioning, he tells me he has been taking 20 mg first thing in the morning. He also takes the double dose of 40 mg as single dose on waking up. Following an education session, John understands the rationale for thrice daily regimen based on his insulin tolerance test results. A blood test when we met, taken 9 h after 40 mg of hydrocortisone, also shows a very low level of cortisol 68 nmol/L. We discuss ways to help him remember his second and third doses. He calls me a month later to say he has recovered and energy levels have "picked up".

37.5.4 Treatment of AI and GC Adjustment for Intercurrent Illness in Children

The treatment objective in children is to find a balance between under- or over-replacement with GC, to minimise acute and long-term complications and to minimise the risk of AC with a dose that allows normal growth and pubertal development (Bornstein et al. 2016; Salprietro et al. 2014; Kwok et al. 2005). The Endocrine Society guidelines recommend treatment with hydrocortisone in three or four divided doses (starting daily dose of 6–8 mg/m^2 in children with SAI and 12–16 mg/m^2 in children with PAI. For its short acting properties, hydrocortisone is used in preference) over other GC replacement therapies in children (Migeon and Lanes 2009; Bornstein et al. 2016; Fleseriu et al. 2016). Children with PAI and confirmed aldosterone deficiency should be treated with fludrocortisone (starting dose of 100 μg daily); it does not require adjustment by body surface and generally remains the same throughout early life. However, in neonates and infants, mineralocorticoid pathway resistance requires higher fludrocortisone doses of 50–200 μg daily in order to maintain sodium levels in PAI (Migeon and Lanes 2009; Miller et al. 2008). Many of these patients also require sodium chloride supplementation of 1–2 g daily divided in several feedings (Bornstein et al. 2016).

Treatment of inter-current illness requires increasing the dose of oral hydrocortisone to at least 45–50 mgs/M2/day in divided doses 6 hourly until well again. In children with SAI, where there is a lower maintenance replacement

dose, doubling or tripling the daily dose maybe inadequate (Miller et al. 2008). Regular clinical review and monitoring of growth and development are essential long term. Blood tests and a yearly bone age X-ray are included in this process to ensure hormonal and biochemical parameters are stable. The endocrine nurse should support parents to manage their child's condition and treatment and ensure there is an understanding of the importance of adherence with medication administration and attendance for clinical reviews to monitor growth and development. Patient and parent education is a critical component in the care of these children as parents integrate managing their child's care into their daily lives and in the future empower their children to gain independence as adolescents and adults.

Understanding the importance of managing health issues with stress hydrocortisone is imperative. All patients need stress hydrocortisone along with consideration of a sweet drink to prevent hypoglycaemia. Children with PAI require the addition of a salt supplement when unwell because of the risk of possible hyponatraemia and failure or absorption of their oral medication. At home this may be administered using salt tablets/sachets in water, rock salt, or with high salt containing foods. Table 37.5 presents a summary of daily and stress treatment for children with AI. Please refer to Chap. 62 for more details on management of adrenal crisis.

Table 37.5 Maintenance and stress dosing for children with AI

Two different dosing plans for children with AI	
Primary Adrenal Insufficiency (PAI)	12–16 mgs/m^2/day hydrocortisone 0.05–0.2 mgs per day Fludrocortisone *(Note: in CAH patients doses need not only to replace but also to suppress excess androgen secretion to prevent virilisation)*
Secondary adrenal insufficiency (SAI)	6–8 mgs/m^2/day *(Exact replacement dosing)*
Stress doses for hydrocortisone doses are the same in PAI and SAI	
Stress dosing—oral *Moderate illness*	45–50 mgs/m^2/day divided into 4 doses 6-hourly
Stress dosing—Intramuscular injection or intravenous *Significant illness, vomiting, diarrhoea, reduced consciousness*	45–100 mgs/m^2 stat Followed by: 45–100 mg/m^2/day divided in 4 doses 6-hourly 6-hourly or Hydrocortisone infusion with 100–200 mg/24 h

37.6 The Importance of Patient Education in AI

Patient education is paramount in optimising replacement therapy and minimising complications of over- and under-replacement. Endocrine nurses play a crucial role in educating patients and their families on day-to-day self-management, intercurrent illness, or special situations and how to prevent AC. Their role is also vital in educating other healthcare professionals and raising awareness of the life-threatening nature of AI. This is especially important in the care of children as parents can be in a state of shock. Endocrine nurses begin their patient education by assessing parental grief, understanding and coping strategies in adapting to their child's diagnosis. It is important to instil confidence into parents' coping abilities and to reassure them that there is advice and support available to guide them through any difficulties they may encounter in managing the day-to-day care of their child. At each consultation, it is crucial to check the patient's knowledge on management of intercurrent illness and prevention of AC, and provide relevant education if gaps are identified. The process of patient education is described in more detail in Chap. 62.

37.7 Role of Adherence to Medication in Optimising GC Replacement

Current treatment options, although not yet perfected, can offer an individualised approach that can meet the needs of most patients with AI, especially with the new formulations developed recently. However, "*drugs don't work in patients*

who don't take them" (C.Everett Koop, MD, US Surgeon General, 1985). Nonadherence has been recognised as a significant challenge by the World Health Organisation suggesting that only 50% of patients with chronic conditions take their medications as recommended (Nunes et al. 2009). More specifically in AI, adherence to GC replacement encompasses the three aspects of appropriate dosing of daily GC to avoid over- or under-replacement, dose adjustment during intercurrent illness and prevention of adrenal crisis (AC).

Adherence to medication is defined as the extent to which a patient's behaviour matches agreed recommendations from their healthcare professional (Nunes et al. 2009). It is also important to understand that adherence to medication is not always in the patient's control. To understand this, Professor Robert Horne uses a simple analogy of "*patients don't want or cannot take their medications*" (quote from personal communication, November 2016). His *Perceptions and Practicalities Approach* provides a theoretical framework to understand the complex human behaviour nature of nonadherence (Horne et al. 2005; Horne 2006) which can be:

- Unintentional where the patient wants to adhere but is prevented from doing so by **practical barriers** or resources beyond their control (*ability*). These include barriers such as forgetfulness, complexity of regimen, difficulty with prescriptions, poor recall or lack of information about the medication, and side effects.
- Intentional where the patient decides not to follow the prescribed treatment regime whether this is conscious or subconscious. **Perceptual barriers** such as beliefs about medicines or fear of side effects can influence patient's *motivation* to start and continue treatment.

37.7.1 Evidence of Nonadherence to GC Replacement

Tailoring the GC dose to patients' needs and achieving optimal adherence are two of the main challenges reported by endocrine clinicians (Grossman et al. 2013). Forss et al. found that 23% of patients with AI (N = 1245) report dissatisfaction with treatment, 38% find multiple daily dosing problematic, over 50% perceive that GC interferes with life aspects such as work, travel, or sex life, and many missed tablets or took them before sleep which resulted in fatigue or insomnia (Forss et al. 2012). Chapman et al. found that 25% of patients took higher doses than advised (Chapman et al. 2016) which can lead to complications. Both studies found that over 50% of patients report concerns about side effects and long-term complications (Chapman et al. 2016; Forss et al. 2012); concerns were strongly associated with nonadherence (Chapman et al. 2016). About 1 in 25 patients reported prolonged treatment interruptions (Chapman et al. 2016); GC dose reduction or cessation was a significant factor to trigger AC for 3.9% (Smans et al. 2016) and 5.5% (Hahner et al. 2010) of patients with AI.

37.7.2 How to Identify and Address Nonadherence to GC Replacement

The endocrine nurse is the best placed person in the multidisciplinary team to identify nonadherence factors and to support patients, their families, and other healthcare professionals to improve adherence to GC replacement; Box 37.7 summarises the key steps in this process adapted from (Horne 2006).

Box 37.7 Key Steps in Improving Adherence to GC Replacement Therapy

1. **Provide a rationale for the need to take GC replacement and the various treatment adaptations**

   Provide patients and their families with a clear rationale for why they should take GC daily, emphasise the difference between a hormone replacement therapy and a steroid pharmacotherapy, and explain the need for dose adjustment in intercurrent illness and

prevention of adrenal crisis. Explain what diagnostic tests mean. Illustrations or other patient stories often help patients to understand and to recall the information received.

2. **Elicit and address concern about GC replacement and potential side effects**

   GC treatment in high doses is associated with a high prevalence of side effects, and these can affect patients' adherence as they increase their concerns and beliefs of harm from taking the medicine. Similarly, some patients may take more than the prescribed dose believing that more is better which can lead to adverse effects and treatment nonadherence. Advise patients of potential side effects from the start, how to recognise and deal with them. Emphasise that GC replacement is individualised and not a "one size fits all" treatment.

3. **Identify and address the practical barriers**

   Adopt a shared decision-making approach when planning GC replacement and develop an easy-to-follow managed care plan which can guide patients, their families, or parents of children with AI, on how to manage the daily GC regimen. Identify and address any barriers which may potentially prevent the patient from following this regimen, such as: Can they remember or are they able (external barriers) to take their tablets? What hours do they work? How do they get their prescriptions? Will the school teachers/nurses help? These are some of the factors that can inhibit adherence and are not always within the patient's control.

4. **Patient and family beliefs**

   Nonadherence may also be associated with concerns arising from more abstract beliefs about medications. They may come with preconceived misconceptions about steroid treatment. Some of my patients tell me they "*don't want to take hydrocortisone and get fat*". Adopt an empathetic and non-judgmental approach when eliciting and addressing these beliefs and emphasise that with appropriate monitoring and correct GC dose, complications can be minimised.

37.8 Glucocorticoid Replacement in Special Therapeutic Situations

37.8.1 Fertility and Pregnancy

Total cortisol concentrations start to rise in pregnancy and free cortisol also increases substantially in the third trimester from the 22nd week of gestation onwards. Hydrocortisone is recommended over cortisone acetate, prednisolone, or prednisone during pregnancy; dexamethasone should not be used because it is not inactivated in the placenta (Bornstein et al. 2016). Common AI symptoms (fatigue, nausea, hyponatraemia, vomiting) are difficult to differentiate in pregnancy, and it is recommended that hydrocortisone doses are increased based on individual patient assessment. It is also recommended that hydrocortisone dose should be increased by 50% in the third trimester (Arlt and Allolio 2003; Bancos et al. 2015; Bornstein et al. 2016).

In addition, the increased levels of serum progesterone in pregnancy exert an anti-mineralocorticoid action, but clinical assessment can be difficult due to overlapping unspecific symptoms of oedema and postural hypotension. Fludrocortisone should be adjusted if necessary according to blood pressure and serum sodium and potassium; while plasma renin is not accurate as it is physiologically increased during pregnancy. During delivery

(active phase of labour) parenteral hydrocortisone should be administered at doses similar to that used in major surgical stress (refer to Chap. 62 for more details) and after delivery hydrocortisone can be tapered back to pre-pregnancy doses within 2–4 days (Bancos et al. 2015; Bornstein et al. 2016).

37.8.2 Thyroid Dysfunction

Hyperthyroidism increases cortisol clearance and therefore in patients with AI and unresolved hyperthyroidism, GC doses should be doubled or tripled. In addition, thyroxine treatment should only be initiated once GC deficiency has been excluded or confirmed and GC replacement has been established (Arlt and Allolio 2003). Thyroxine can precipitate adrenal crisis in untreated hypocortisolism and the patient needs to be advised appropriately when reviewing their treatment regimen and adherence to medication.

37.8.3 Growth Hormone Deficiency in Adults

In growth hormone (GH) deficiency in adults, there is an increased 11β-HSD type 1 activity which results in increased cortisol tissue exposure (see Sect. 37.5.3). This is reduced after initiating GH treatment (high GH and IGF-1 levels enhance conversion of cortisol to cortisone, i.e. lower levels of active cortisol) which can unmask central hypoadrenalism and predispose the patient to AI and risk of AC. Therefore, the assessment of the HPA axis to confirm or exclude AI is mandatory prior to starting GH replacement (Filipsson and Johannsson 2009; Giavoli et al. 2004).

37.8.4 Increased Physical and Emotional Stress

In healthy subjects, in addition to the circadian profile, cortisol levels increase in response to stressful daily stimuli such extreme physical extortion or emotional distress. Patients with AI should take an extra dose of 5–10 mg prior to being exposed to the stressful situation (Grossman 2010; Quinkler and Hahner 2012). It is often difficult to define "stress" for individual patients and a detailed history would reveal fatigue, feeling unwell and light-headed, the same or the next day after exerting increased levels of stress. Examples include training and running a marathon, mountain biking, triathlon, moving to a new house, long flights, bereavement, or acute depression episodes. Short lasting stressor, such as exams, house work, or work-related meetings, do not normally require dose adaptation.

37.8.5 Prolonged Fasting or Shift Working

During the month of Ramadan, Muslims tend to fast, i.e. abstain from eating, drinking, and use of oral medication from predawn to sunset. This can put patients with AI at risk of dehydration, fainting, hypotension, or low glucose levels which can precipitate AC. A cross-sectional study of 180 patients with AI found that of the 91 patients who did fast, 67% developed complications such as asthenia, intense thirst, dehydration, and symptoms of hypoglycaemia; one patient was hospitalised with AC (Chihaoui et al. 2017). It is important that patients wanting to fast during Ramadan are well educated on the risks of fasting and given the option for alternative treatment. A longer acting formulations such as immediate-sustained release hydrocortisone (Plenadren® 20 mg) or prednisolone 4–5 mg at dawn before starting the fast is a preferred option during the fasting period.

Similarly, the cortisol circadian rhythm is misaligned in people who sleep outside a normal sleep cycle such as shift workers or during jet lag. Patients with AI who work shifts or travel between wide timezones should adapt their GC intake to their wake-sleep pattern (Quinkler and Hahner 2012), i.e. take first dose of hydrocortisone on waking up and the last dose no later than

5–6 h before sleep. Short acting hydrocortisone versus long-acting formulations is advisable to avoid exposure to cortisol during the sleep periods which can result in increased risk of glucose intolerance or impaired quality of sleep. The case study in Box 37.8 delineates the importance of adapting hydrocortisone intake during night working.

Box 37.8 Case Study of a Patient on Emergency Night Shifts

Richard is 54 and has SAI following pituitary surgery. He takes hydrocortisone 10 + 5 mg twice daily on waking up at 7 am and at 3 pm. He volunteers as coast guard and often is called on emergencies in the middle of the night. This can be quite stressful physically and emotionally. He described feeling exhausted the next day of such events and on one occasion he developed adrenal crisis for which he needed a hospital admission. We advised him to take 10 mg of hydrocortisone as soon as he is being called for duty and another 10 mg if he is out at sea for longer than 5 h. This helped him significantly to overcome fatigue post emergency duty he did not experience any further AC episodes.

37.8.6 Medications and Food Interactions with Glucocorticoids

Table 37.6 presents a list of drugs and food types that interact with GC and mineralocorticoids in AI (Arlt and Allolio 2003; Liu et al. 2013; Methlie et al. 2011). It is important to take a detailed history from patients on prescribed medication, including oral contraceptive pill, over the counter medications, supplements, herbal remedies, and foods that can decrease or increase concentrations of bioavailable cortisol.

37.9 Morbidity and Mortality Related to Glucocorticoid Replacement Therapy

AI was a fatal condition until cortisone was synthesised and used as life-saving treatment in 1949 by Kendall, Reichtein, and Sarrett (Arlt and Allolio 2003). Even though GC treatment has been available for over half a century, optimal replacement therapy in AI, negative acute and long-term health outcomes, including hospitalisations from AC, GC-induced morbidities, and impaired QoL, are still presenting major challenges.

37.9.1 Mortality and Risk of Adrenal Crisis

The standard mortality rate (SMR) for patients with AI is more than twofold compared to the general population (Tomlinson et al. 2001; Bergthorsdottir et al. 2006). AC is a factor that increases the mortality rate in patients with AI. SMR was significantly elevated in patients diagnosed before the age of 40 years; this was more pronounced in males with SMR 2.03 (CI 1.19–2.86) and younger patients were at higher risk of sudden death from AC (Erichsen et al. 2009). Approximately 1 in 100 patients with AI are expected to die from a potentially preventable AC (Hahner et al. 2015). One in 12 patients report at least one hospital admission per year related to AC (Forss et al. 2012; Hahner et al. 2015; White and Arlt 2010) and about 10% of patients with PAI who reported AC, had this on four or more occasions (Hahner et al. 2015) indicating that there is a subgroup of patients at high risk, and we need to identify and support them with relevant individualised treatment planning and education. AC is mainly precipitated by gastrointestinal infection and fever but also other stressful physical or emotional events (more details on AC mortality are discussed in Chap. 62).

Table 37.6 Common food and drug interactions with glucocorticoids

Interacting drug class (drug example) or food type	Interaction mechanisms (key: ↓-reduces; ↑-increases; GC-glucocorticoids)	Suggested management
Anticonvulsants (phenytoin, carbamazepine, phenobarbital)	Enhanced GC metabolism ↓ Efficacy of GC may persist for weeks following discontinuation of anticonvulsant	Monitor outcomes, may need GC dose adjustment (increase)
Anti-Tuberculosis (rifampicin, rifabutin)	Increases cortisol clearance ↓ Efficacy of GC which may persist for weeks following discontinuation of anti-tuberculosis drugs	Monitor outcomes, increase GC dose during rifampicin
Antifungal drugs (ketoconazole, itraconazole)	↑ GC bioavailability	May need antifungals or GC adjustment if show signs of GC overdose
Anticoagulants (warfarin)	May ↑ effects of anticoagulant and ↑ risk of GI bleeding	Monitor INR within 3–7 days, may need significant warfarin dose adjustment
Antibiotics (erythromycin, telithromycin, and clarithromycin)	May inhibit the metabolism of corticosteroids ↑ GC bioavailability	Monitor signs of GC over-replacement, may need to change antibacterial or adjust GC dose
Antidiabetic agents (insulins)	Antagonism of hypoglycaemic effect ↓ Efficacy of GC	↑ frequency of blood glucose monitoring adjust antidiabetic therapy
Antivirals (atazanavir, indinavir, ritonavir, saquinavir)	↑ GC bioavailability	Monitor signs of GC over-replacement
Oral oestrogen replacement and oral contraceptive pill	Increases circulating cortisol-binding globulin False high plasma cortisol levels	Oestrogen needs to be discontinued for diagnostic investigations
Mitotane	↓ concentration and increased metabolism and efficacy of bioavailable GC	Usual GC doses need to be at least doubled or tripled
Herbal remedies (St John's wort)	↑ GC bioavailability	Avoid or take at least 2–3 h later
Grapefruit, grapefruit juice, Liquorice	↑ GC bioavailability	Avoid or take at least 2–3 h later

37.9.2 Bone Metabolism

GCs affect the rate of bone remodelling; they impair the replication, differentiation, and function of osteoblasts, induce the apoptosis of mature osteoblasts and osteocytes, and increase osteoclastogenesis. Supraphysiological doses of GC are associated with a decrease in markers for bone formation and resorption, leading to osteoporosis (Canalis et al. 2007). Several studies found that patients with AI on GC replacement have lower bone mineral density (BMD) scores compared to the average population and that BMD decreases with increasing doses of hydrocortisone over 30 mg daily (Zelissen et al. 1994; Lovas et al. 2009; Schulz et al. 2016; Bjornsdottir et al. 2011). A population-based cohort study identified hip fractures in 6.9% of patients with PAI compared with 2.7% of controls although authors did not investigate association of fractures with GC dose (Bjornsdottir et al. 2011). Schulz et al. found that by reducing the total daily dose of hydrocortisone equivalent to 20–25 mg from 30 to 35 mg, values of BMD significantly improved 2 years later, and the risk of AC did not increase (Schulz et al. 2016). It is therefore important to remember that high doses of GCs have a detrimental effect on bone health (Johannsson et al. 2015) and replacement doses of hydrocortisone should be maintained generally to a total daily dose below 20–25 mg, where indicated. Patients should be reassured that the risk of AC will not increase if they adjust GC doses appropriately during increased stress and illness.

37.9.3 Blood Pressure, Glucose/Lipid Metabolism, and Body Composition

The physiologic circadian rhythm of cortisol affects fluctuations in glucose tolerance throughout the day. Abnormal glucose tolerance is therefore more common in patients with AI. This is especially important to keep in mind for patients with PAI and concomitant type 1 diabetes as insulin requirements, especially in the afternoon, are higher compared to patients with type 1 diabetes alone (Johannsson et al. 2015).

Patients with hypopituitarism and SAI are at higher risk of developing metabolic syndrome with a combination of hypertension, dyslipidaemia, central obesity, and insulin insensitivity (Johannsson et al. 2015). A large pharmacovigilance study of patients with hypopituitarism (N = 2424) treated with growth hormone, compared patients with and without ACTH deficiency. Patients with ACTH deficiency treated with a total daily dose of hydrocortisone-equivalent of 20 mg or more had an unfavourable metabolic profile with greater body mass index, waist circumference, serum levels of total cholesterol, triglycerides, and low-density lipoprotein; this was not observed in patients taking doses lower than 20 mg (Filipsson et al. 2006). Changes in body weight and blood pressure may also be a contributing risk factor to the increased prevalence of premature cardiovascular deaths in patients with AI (Tomlinson et al. 2001; Bergthorsdottir et al. 2006). Detrimental effects of over-replacement can be more significant in patients with SAI as there is often residual cortisol production and it is very important to plan for an individualised GC replacement regimen. The modified-release hydrocortisone also has a favourable profile with regard to body weight, glucose metabolism, and insulin insensitivity at equivalent total daily doses of hydrocortisone (Muller and Quinkler 2018; Johannsson et al. 2012).

37.9.4 Quality of Life (QoL) and Subjective Well-Being

AI has significant impact on patients' lives with 64% of them reporting impaired QoL, 40% absence from work/school every 3 months, and 38% at least one hospital admission annually (Forss et al. 2012). Almost a quarter of patients with AI receive disability pension compared to 4–10% of the general population (Lovas et al. 2002; Hahner et al. 2007). Delay in the diagnosis of AI has a negative impact on QoL; Bleicken found that patients who received a correct diagnosis within 3 months reported significantly better subjective health status compared to those for whom diagnosis was delayed (Bleicken et al. 2010b). Higher GC replacement doses are associated with a negative effect on the patient's QoL, although it is unclear if the increased dose itself diminishes QoL, or if the dose was increased by the clinician due to an impaired QoL. Two studies found that QoL decreased with increasing dose of GC and the worst QoL was reported by patients who took hydrocortisone-equivalent doses of more than 25 mg daily (Filipsson et al. 2006) and 30 mg daily (Bleicken et al. 2010a), respectively. This was more significant in patients with SAI. Additional hormone deficiencies in SAI may also impact on QoL and often patients increase the dose of GC to compensate for impaired QoL and fatigue caused by unoptimised concomitant deficiencies.

It is also important to remember that current conventional GC replacement therapy in patients with PAI does not restore the unphysiologically low cortisol levels in the night, particularly the last part of the night, which may reduce early morning glucose levels (Oksnes et al. 2015). Patients may complain of impaired quality of sleep and waking up with nausea, dizziness fatigue, and headaches, and it is important to discuss a GC therapy regimen that can combat these symptoms.

Validated questionnaires are useful in clinical practice to assess patient's QoL and agree on a

relevant care plan to respond to individualised needs. In addition, they can be used to track improvement or deterioration of QoL over time or post changes in the management of patient's care. The AddiQoL is a validated Likert scale questionnaire of 36 items with high internal validity and psychometric properties which make it a useful tool for use in clinical practice (Lovas et al. 2010).

37.10 Long-Term Monitoring of Patients with AI

The goal of treatment and follow-up for patients with AI is to restore normal well-being by optimising replacement therapy, to minimise or avoid complications from over- or under-replacement, and to minimise episodes of AC and avoid hospital admissions due to AC. Monitoring of replacement is mainly based on clinical symptoms but cortisol day curve may be useful and indicated when symptoms persist or when malabsorption of hydrocortisone is suspected (see case study in Box 37.5). Similarly, random cortisol levels are helpful to obtain evidence of adequate cortisol uptake (Bornstein et al. 2016) and to establish peak and trough levels, but they must only be interpreted with an accurate history of timing and dose of hydrocortisone and are not needed routinely.

Routine laboratory analyses and imaging are requested depending on diagnosis and cause of AI; these should include blood serum sodium and potassium levels for patients with PAI. In addition, surveillance for other autoimmune disorders, such as thyroid disease or type 1 diabetes, is necessary in patients with PAI given the increased prevalence of concomitant autoimmune disorders; genetic counselling should also be provided to patients with PAI due to monogenic disorders (Bornstein et al. 2016). Patients should be made aware and educated on possible symptoms related to other autoimmune disorders.

It is recommended that adults and children with PAI are seen by an endocrinologist or a healthcare provider, including nurses, with expertise in endocrinology at least annually. Infants should be seen at least every 3–4 months (Bornstein et al. 2016). There is no consensus regarding frequency of monitoring for patients with SAI as this depends on other concomitant comorbidities, but patients should be seen at a minimum 6–12 monthly (Fleseriu et al. 2016).

Patients should be examined and asked questions to evaluate physical and psychological (QoL, subjective health status) condition in relation to possible over-replacement or under-replacement and adverse effects from the GC therapy. A UK-wide study of patients with asthma showed a dissociation between patient-reported concerns and side effects about corticosteroid treatment and those perceived by physicians (Cooper et al. 2015). Medication side effects are strongly associated with nonadherence and treatment discontinuation. It is therefore important to take a detailed history of any possible side effects to the AI medication and address them accordingly; this should also include possible interactions with other concomitant medications, food and over-the-counter supplements and hormone deficiencies.

A holistic assessment will identify and support patients with medical but also psychosocial and educational needs. It is crucial to ensure that patients are familiar with and are provided with education on management of intercurrent illness and prevention of AC. Exploring and addressing all potential needs in a single consultation can however be time consuming for the nurse. It is also difficult to remember all relevant points relating to AI and GC treatment which need addressing, particularly if patients have other comorbidities or treatments. Consultation checklists are often useful toolkits which nurses can use to ensure a productive and effective consultation. On the other hand, there is a risk of "information overload" for patients or repeating what they already know to the detriment of missing out on information which patients really need.

It is useful to advise patients to come with a list of questions and concerns which can be addressed during each consultation and are pertinent to each individual's needs. There is however evidence to suggest that patients often do not know what to ask, believe that concerns are

not relevant to their condition or treatment, feel there is too little time to address everything, or feel embarrassed to disclose information such as nonadherence to medication or sexual dysfunction (Henselmans et al. 2015). To facilitate the process of consultations and to provide support for self-management, our research team developed a one-page questionnaire based on behavioural medicine, which can help patients identify concerns about their AI and GC replacement therapy (Box 37.9), adopting this way an individualised approach to patient care and treatment planning. The questionnaire is accompanied by a comprehensive patient information booklet designed to address the concerns identified in the questionnaire which patients can read before attending clinic. This is also used as an aid to stimulate further questions or help the patient to identify more needs. An online survey involving 100 patients with AI, members of the Pituitary Foundation in the UK, showed good acceptability of this consultation aid and booklet as a resource to support self-management in AI (Llahana et al. 2016).

Box 37.9 A Questionnaire to Identify and Address Individualised Patient Needs in the Treatment and Management of AI

This questionnaire was developed specifically to help with the management of cortisol replacement therapy for patients with adrenal insufficiency (AI). The questionnaire aims to get you thinking about the things that matter most to you about your AI and your cortisol replacement therapy. You may also be taking additional medications for AI and other conditions. However, please ONLY take into account your cortisol replacement therapy when answering these questions.

There are no right or wrong answers—simply answer the questions by ticking the relevant box if it applies to you. Use the answers to guide you to the most relevant sections of the accompanying booklet, specific to you and your needs. You can also use this questionnaire during your consultation with your doctor or nurse to focus your discussion on areas which you identified as a concern.

Section A: Managing Adrenal Insufficiency			
A1	I know how to adjust my cortisol replacement dose during illness	**Yes**	**No**
A2	I need help in managing an adrenal crisis	**Yes**	**No**
A3	I often feel tired during the day	**Yes**	**No**
A4	The quality of my sleep is impaired (I don't sleep well)	**Yes**	**No**
Section B: Medication (managing cortisol replacement therapy)			
B1	I am not sure why I need to take cortisol replacement therapy every day	**Yes**	**No**
B2	I am concerned about the side effects of my cortisol replacement therapy	**Yes**	**No**
B3	Having to take cortisol replacement therapy affects aspects of my life:		
	Travel	**Yes**	**No**
	Physical activities	**Yes**	**No**
	Family	**Yes**	**No**
	Social	**Yes**	**No**
	Work	**Yes**	**No**
	Other—please specify	**Yes**	**No**
B4	Having to take more than one dose every day is an inconvenience for me	**Yes**	**No**
Section C: Your way of taking cortisol replacement therapy			
C1	I sometimes/often miss my doses for a day or more	**Yes**	**No**
C2	I sometimes/often miss my second or third dose	**Yes**	**No**
C3	I sometimes/often take an extra dose just to feel better	**Yes**	**No**
C4	I don't take extra doses when I'm ill or have "sick days"	**Yes**	**No**
C5	I don't always take my dose(s) at the recommended times	**Yes**	**No**
Please include any additional information here			

Original version of the questionnaire and the patient booklet are available by request from Spoonful of Sugar, a behaviour-change consultancy in London, http://sos-adherence.co.uk/

37.11 The Role of Patient Advocacy Groups in Improving Patient Care and Education

Patient advocacy groups (PAGs) are a highly valuable resource for patients and their families, not just as a clinical and supportive tool, but by also enabling empowerment and enriching the relationship between patients, families, and their healthcare providers. The advent of social media, with websites and online support groups can add to this, and patients have a reliable and trusted resource for peer support. Most PAGs work very closely with clinical teams to develop evidence-based information and support clinical research. As seen in the example below, PAGs can form a useful resource and can reach patients and healthcare teams across the globe especially for rare conditions such as AI.

37.11.1 The Australian Addison's Disease Association Inc (AADAI)

Through an amazing amount of volunteer work by people across the nation, the Association has grown from just a handful of members to over 300 spread across this vast country. The goal of the AADAI is to:

- Educate the medical profession and the general public to have a higher awareness of Addison's disease and AI
- Supply up-to-date information to people living with Addison's disease/AI
- Create a caring network to give support for people with Addison's disease/AI

To provide the best possible information and support to people living with adrenal insufficiency, the association works closely with healthcare professionals, especially endocrine nurses and endocrinologists. All our online and print educational and resource materials are thoroughly reviewed before publication by our medical advisor; seminars are presented each year for people living with AI and these are strongly supported by key healthcare professionals.

Our quarterly member newsletter focuses on a range of support and medical information issues. These are written by people with medical expertise including our medical advisor and our pharmacy advisor. The website provides detailed information about materials we produce. These include new member packs: online and print information material and the regular newsletter. A telephone support service to help members find specific information is also offered by the AADAI President and the Secretary. To find out more about the AADAI, please visit our website at http://addisons.org.au.

37.12 Conclusions

AI is a life-threatening condition if not managed appropriately but with correct and individualised replacement therapy and adequate support and education, patients can lead a normal life. This is a chronic condition and the initial diagnosis will have a significant impact on how the condition is perceived by the patient and their families and especially for parents and their young children. Patients and their families require sensible day-to-day management plans, careful dosing regimens, and an action plan for times of illness, injury, or procedures. The endocrine nurse is a key person in supporting patients and families in the process of acceptance, understanding, and confidence to manage situations as they arise.

AI is a condition where mortality rate is high and a team approach and interdisciplinary collaboration in key to offering the best treatment options to improve patients' health outcomes and QoL. Patients with AI and their families need to gain an understanding about their condition and treatment, which can be very complex especially when dose titration is required during stress, intercurrent illness, and prevention of AC. Having an endocrine service with sound and knowledgeable endocrine nursing team can offer best treatment options in chronic disease condition such as AI. Endocrine nurses with advanced practice skills can utilise their specialist knowledge and excellent communication skills to tailor treatment options to meet individual needs of their patients.

Acknowledgments With special thanks to our patients for their case studies and to Grahame Collier from the Australian Addison's Disease Association Inc (http://addisons.org.au; email: secretary@addisons.org.au) for the information on their Patient Advocacy Group.

Abstract

At birth, a female baby already has her lifetime supply of oocytes that will be released through ovulation when she is sexually matured, between menarche and menopause. Puberty initially starts with thelarche (breast budding) around the age of 11 and menarche usually starts at an average age of around 13. Initial cycles are anovulatory, but subsequently a single egg is released each cycle during a woman's fertile years. The menopause is the end of menstrual cycles. Puberty, menstrual cycles, and establishment of pregnancy are controlled by the hypothalamic, pituitary, and ovarian hormones. Following the menopause, the ovaries are no longer able to produce enough oestrogen and ovarian failure results in a rise in the gonadotropins.

Keywords
Female reproduction · Puberty · Menstrual cycle · Ovulation · Menopause · Pregnancy Menarche · Thelarche · Tanner Stages

Abbreviations

17-OHP	17-Hydroxyprogesterone
DHEA	Dehydroepiandrosterone
DHEAS	Dehydroepiandrosterone sulphate
FSH	Follicle-stimulating hormone
GABA	gamma-aminobutyric acid
GnRH	Gonadotropin-releasing hormone
hCG	Human chorionic gonadotropin
IGF-1	Insulin-like frowth factor-1
IHH	Idiopathic hypogonadotropic hypogonadism
IVF	In vitro fertilisation
KISS1	Kisspeptin
LDL	Low-density lipoprotein
LH	Luteinising hormone
LPD	Luteal phase deficiency
PCOS	Polycystic ovarian syndrome

Key Terms

- **Puberty:** the period of 2–3 years prior to menarche when secondary sexual characteristics begin to develop and the final and most substantial growth spurt occurs, with fusion of the epiphyseal plates.
- **Thelarche:** breast budding
- **Adrenarche:** the onset of androgen hormone release from the matured adrenals
- **Pubarche:** the development of pubic hair
- **Menarche:** first period
- **Climacteric:** the 6–7 years leading up to the menopause, when menstrual cycles tend to be irregular and anovulatory
- **Menopause:** last period

Key Points

- The female endocrine reproductive system relies on the relationship between the hypothalamus, pituitary, and ovaries.
- A female is born with a finite number of oocytes 300–400 of which will be released through ovulation during a woman's reproductive life.
- Puberty starts around the age of 11 with breast budding and it's complete around 2.5–3 years later with the onset of menarche (first period). Initial cycles are irregular and tend to be anovulatory.
- Pregnancy is maintained by hormones released by the corpus luteum and subsequently the placenta and have a wide range of functions, including immune suppression in the mother to prevent loss of the pregnancy through immune mediated response.
- Climacteric starts in the late 40s and lasts around 6–7 years. Menstrual cycles during this period are also irregular and tend to be anovulatory until the menopause (last period).

38.1 Introduction

The female reproductive system is controlled by hormones secreted by the hypothalamus, the anterior pituitary, and the ovaries, which interact with each other in a dynamic way. Gonadotropin-releasing hormone (GnRH) is secreted by the hypothalamus in response to neuronal activity in the limbic region of the brain, which is predominantly influenced by emotional and sexual factors.

GnRH is a small polypeptide which regulates the release of gonadotropins: luteinising hormone (LH) and follicle-stimulating hormone (FSH), by the gonadotrope cells of the anterior pituitary gland. The gonadotropins are then released in short bursts every 1–4 h, stimulating cells in the ovaries to synthesise and secrete oestradiol and progesterone, which in turn promote and regulate menstruation and ovulation.

High concentrations of oestrogen and progesterone in the serum provide negative feedback to the hypothalamus and therefore inhibit further secretion of GnRH (Fig. 38.1). Please refer Chap. 12 in Part III for more details on the menstrual cycle regulation by FSH and LH and the hypothalamic-pituitary and gonadal feedback.

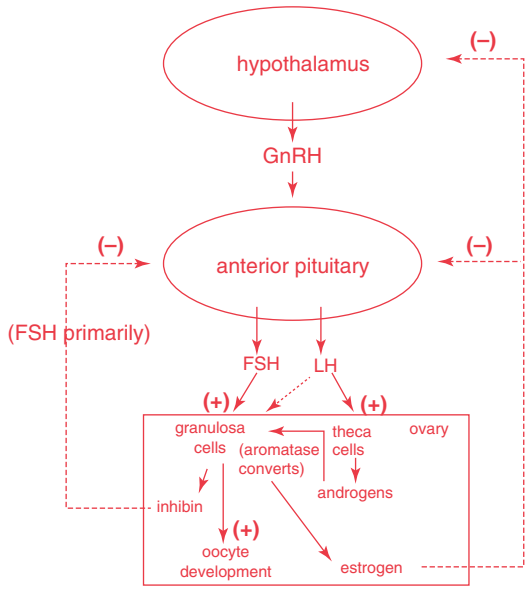

Fig. 38.1 The interplay between the hypothalamic, anterior pituitary, and ovarian hormones

GnRH released by the hypothalamus stimulates FSH and LH secretion by the anterior pituitary which in turn stimulates the secretion of oestrogen and progesterone by the ovaries.

FSH receptors only exist on the granulosa cell membranes of the ovaries and as the numbers of granulosa cells increase in late luteal phase, in parallel to increasing FSH levels, so does oestradiol secretion by granulosa cells, in response to FSH levels. The formation of LH receptors on the granulosa cells is stimulated by FSH, in the presence of oestradiol, facilitating these cells to also become responsive to LH and allowing secretion of small amounts of progesterone and 17-hydroxyprogesterone (17-OHP). These two hormones then have a positive feedback on the pituitary gland which has been primed by the high oestrogen levels to release LH.

FSH also stimulates the production of aromatase and 3β-hydroxysteroid dehydrogenase (3β-HSD). LH receptors are found on the theca cells of the ovaries, which produce androstenedione and small amounts of testosterone. Androstenedione is transported to the granulosa cells and converted into oestrone, by aromatase, and eventually converted to oestradiol by 17-β-hydroxysteroid dehydrogenase type I (17-β-HSD).

FSH also stimulates the secretion of inhibin from the granulosa cells, which suppresses FSH. There are two types of inhibin: *Inhibin B*, which reaches a peak in the early- to mid-follicular phase and has a second peak at ovulation and *Inhibin A*, which reaches its peak in the mid-luteal phase. Inhibin secretion is inhibited by GnRH and enhanced by insulin-like growth factor-1 (IGF-1).

Only unbound oestrogen and progesterone are biologically active, stimulating the target organs of the reproductive system (breasts, uterus, and vagina). However, most of the oestrogen and progesterone found in the bloodstream are bound to proteins. In general, oestrogen and progesterone inhibit the release of GnRH but around the time of ovulation stimulate gonadotropin secretion. Oestrogen and progesterone also have both direct and indirect effects on other major tissues including bone, skin, and muscle.

38.2 Ovarian Follicular Development

A female baby is born with a fixed number of germ cells (egg precursors). Germ cells begin as primordial oogonia that proliferate significantly by mitosis during the 3rd and 4th months of gestation of a female foetus. Around the same time, some oogonia begin to undergo meiosis, which halves the number of chromosomes to 23, resulting in the formation of haplotype primary oocytes. Beginning after the 4th month of gestation, oogonia and later oocytes are spontaneously lost by apoptosis, through a process called atresia. Eventually more than 99.9% of the original oogonia are lost by the time of birth.

The surviving germ cells (haplotype oocytes), become arrested in the meiotic prophase and are termed primary oocytes. By the 7th month of gestation, each viable primary oocyte develops a surrounding layer of granulosa cells, forming a primordial follicle. All primordial follicles, each containing its primary oocyte, potentially available for future reproduction during a woman's life are, therefore, present in the ovaries at birth. The so-called ovarian reserve is the number of oocytes or primordial follicles in a woman's ovaries at any given time, and this can be estimated by direct ultrasound visualisation or through measuring Mullerian hormone, with the latter being less reliable but often more widely used.

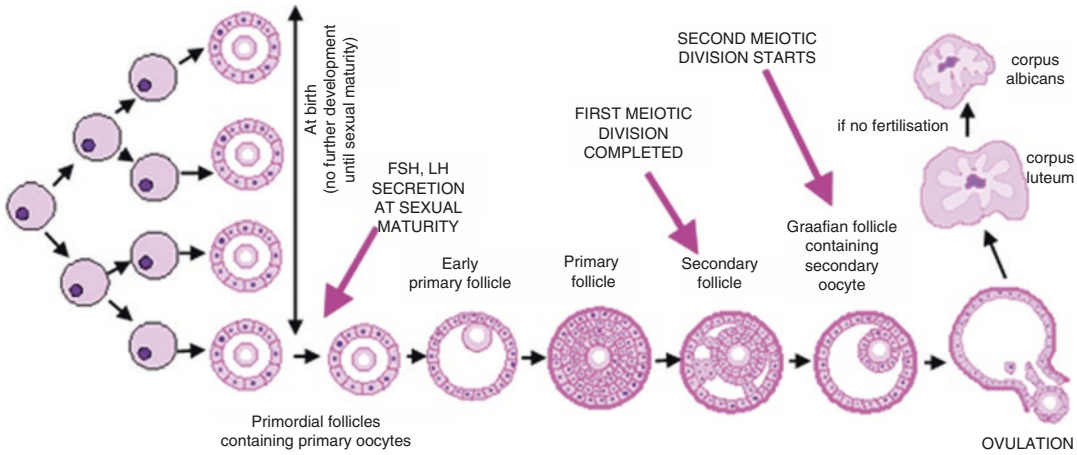

Fig. 38.2 Ovarian follicular development. Used with permission from Professor Michelle Peckham, Professor of Cell Biology, University of Leeds, School of Molecular and Cellular Biology, accessed via http://www.histology.leeds.ac.uk/female/FRS_ova.php

At birth, the ovary contains approximately 400,000 primordial follicles, with each one containing a primary oocyte. Primary oocytes do not undergo any further mitotic divisions and remain arrested in the **prophase** stage of **meiotic division I**, until after sexual maturity has been reached.

Following sexual maturity (completion of puberty), FSH and LH cause these primordial follicles to develop. In each ovarian cycle, FSH induces follicular growth in the ovaries and about 20 primordial follicles are activated to begin maturation and recruited for accelerated growth. Usually in each cycle, only one follicle fully matures and achieves ovulation (Fig. 38.2). This dominant follicle releases its oocyte at ovulation and promotes atresia of the other previously recruited follicles (please refer to ovulatory and luteal phases below for more details).

Over a woman's reproductive life, only ~300–400 eggs will be released, through ovulation.

38.3 Puberty

Puberty is the sequence of events that occur in order for a child to eventually sexually mature into an adolescent and eventually become an adult, acquiring adult physical characteristics and the capacity to reproduce. It is associated both with the development of secondary sexual characteristics, as well as rapid growth in height and weight.

Circulating LH and FSH levels are elevated at birth but fall to low levels within the first few months of life and remain low until puberty (see Fig. 38.7). The reproductive target organs undergo very few qualitative changes before the onset of puberty. While puberty primarily involves a series of physical transformations, the process can also have an effect on the psychosocial, behavioural and emotional development of the adolescent.

The mechanisms that initiate puberty are still not entirely clear. Central influences that regulate release of GnRH include neurotransmitters and peptides (e.g. gamma-aminobutyric acid [GABA] and kisspeptin [KISS1]). These and other factors may inhibit release of GnRH during childhood, but then initiate its release, to induce puberty in early adolescence (Watanabe et al. 2014; Zeydabadi Nejad et al. 2017).

Kisspeptin (KISS1), is a neuropeptide that acts upstream of GnRH-neurons and appears to be critical for maturation and function of the reproductive axis (Watanabe et al. 2014). Kisspeptins bind to and activate the G protein-coupled receptor, GPR54, located on the GnRH-neurons of the hypothalamus (Zeydabadi Nejad et al. 2017). Kisspeptin appears to be one of the

major activators of the GnRH-neurons and a prerequisite for the onset of puberty and maintenance of normal reproductive function. Abnormal KISS1/GPR54 system has been reported in both animal models and patients with certain forms of infertility, e.g. idiopathic hypogonadotropic hypogonadism (IHH) and polycystic ovarian syndrome (PCOS) (Zeydabadi Nejad et al. 2017; Seminara et al. 2003).

38.3.1 Age of Onset of Puberty

The timing of the onset of puberty is not completely understood and is most likely determined by a number of different factors. The age of onset of puberty varies amongst individuals and the rate of development through different stages is influenced by different factors. Over the last 150 years, the age at which puberty starts has been decreasing, primarily because of improved health and nutrition (Knudston and McLaughlin 2018; MedicineNET 2018). This trend has plateaued over the last few decades and occurs on average between the ages of 10 and 14 in girls (MedicineNET 2018).

Both environmental and genetic factors are involved in the onset of puberty. One theory is that reaching a critical weight or body-fat composition may be crucial, in the onset of puberty. It may be, that the overall earlier onset of puberty in the general population in recent years is related to the increase in childhood obesity (MedicineNET 2018).

Puberty appears to occur later than average in severely underweight and undernourished girls (Rosenfield et al. 2009). These observations suggest that there is a critical body weight or amount of fat necessary for the onset of puberty (Knudston and McLaughlin 2018; MedicineNET 2018; Soliman et al. 2014; Rosenfield et al. 2009), which may in turn vary between individuals or populations (Herman-Giddens et al. 1997).

Leptin, a hormone produced by the adipocytes, has been suggested as one possible mediator of the timing of puberty (MedicineNET 2018; Gueorguiev et al. 2001). In research studies, animals deficient in leptin, did not undergo puberty and administration of replacement leptin, resulted in restoration of puberty (Gueorguiev et al. 2001). Furthermore, girls with higher concentrations of leptin are known to have an increased percentage of body fat and an earlier onset of puberty than girls with lower levels of leptin. The concentration of leptin in the blood is known to increase just before puberty in both boys and girls.

Many other factors can influence the onset and progression of puberty. Genetic factors are also involved, as puberty occurs earlier in girls whose mothers underwent sexual maturity earlier. It has also been found that the onset of puberty also occurs earlier in girls who live in urban areas (Ameade and Garti 2016; Choudhary et al. 2016) and in blind girls (Flynn-Evans et al. 2009), but the underlying mechanisms for these observations are still unclear. The age of onset of puberty also varies amongst ethnic groups (Herman-Giddens et al. 1997) and it has been suggested that perhaps this is secondary to the mechanisms discussed above, i.e. genetic factors and body-fat composition.

38.3.1.1 Precocious Puberty

Precocious puberty is when a child enters puberty too early, often defined as before the age of 8 in girls and before the age of 9 in boys. It leads to the development of the secondary sexual characteristics because of increased sex steroid production, either because of aberrant gonadotropin stimulation or because of intrinsic disease of the ovaries or adrenals. The classic definition of sexual precocity is the appearance of secondary sexual characteristics before the age of 8 years in girls, but this cut-off may vary in ethnic minorities. The overall incidence of sexual precocity in America is estimated around 1:5000 to 1:10,000 with a female preponderance of around 10:1 (http://www.endotext.org). For more details, refer to the Chap. 4 in the Paediatric Part I of the textbook. Early activation of pulsatile gonadotropin-releasing hormone (GnRH) secretion is the most common mechanism and it is usually idiopathic but it can rarely be due to serious conditions such as hypothalamic tumours.

38.3.1.2 Pubertal Delay

The guidelines for initiating an evaluation of girls with pubertal delay are as follows (http://www.endotext.org):

- If there is no breast development by the age of 13 years
- If there is absence of menarche by the age of 14 years in the presence of hirsutism or if there is a history suggestive of an eating disorder or excessive exercise or an outflow abnormality
- If there is absence of menarche by the age of 15 years

These guidelines should be used in context of the patient circumstances and presentation.

In more than 90% of cases, delayed puberty is due to constitutional delay in growth and puberty. It, therefore, occurs in children who are otherwise healthy but have slower physical development than average. Typically, these children will be shorter than other children of the same age, they are often thin and there's a family history of delayed puberty. Sometimes delayed puberty and growth can be secondary to a chronic illness (e.g. Crohn's disease or cystic fibrosis), malnutrition (e.g. malabsorption), excessive exercise (e.g. competition athletes), or physical and psychological stress.

38.3.2 The Physical Changes of Puberty

Early in puberty, the hypothalamus becomes less sensitive to the inhibitory actions of oestrogen and progesterone on GnRH-release. This results in an increase in the release of GnRH, which in turn stimulates gonadotropin (LH and FSH) secretion. Gonadotropin secretion then stimulates production of the sex hormones, primarily oestrogen, which drives the development of secondary sexual characteristics.

Adrenarche occurs when a child's adrenal cortex starts to secrete adrenal androgen precursors and ultimately an increase in the production of the adrenal androgens dehydroepiandrosterone (DHEA) and DHEA sulphate (DHEAS). Adrenarche occurs several years before the onset of puberty and is thought to stimulate pubic and axillary hair growth (Novello and Speiser 2018). DHEA, a weak androgen agonist, is the most abundant product of the adrenal cortex and is thought to be responsible for the clinical signs of pubarche (first appearance of pubic hair) by conversion to more potent androgens, testosterone, and dihydrotestosterone. DHEA becomes sulphated outside the adrenals to DHEAS, which is a stable marker for adrenal androgenic activity. Pubarche is the physical manifestation of androgenic hormone production and includes the development of pubic and axillary hair, adult body odour, and acne.

In general, there is a typical pattern in the physical changes that an individual undergoes during puberty, and the sequence of events tends to be fairly predictable (please refer to Chap. 4 in Paediatric Part I in the textbook). In most girls, the first sign of puberty is thelarche (breast budding) which is the beginning of breast development, and occurs at an average age of approximately 11 years. Pubic hair growth typically begins next, followed by the growth of axillary hair. However, in a minority of girls, pubic hair growth begins before breast development. The growth spurt tends to peak after the appearance of pubic and axillary hair.

Menarche (the onset of menstruation) usually happens after all the other physical changes and occurs approximately 2.5–3 years after the first signs of the onset of puberty. An underlying growth spurt also occurs in parallel to puberty, which peaks immediately before or around the time of the menarche. Body habitus changes, body fat increases and the pelvis and hips widen, partly due to accumulation of fat in the hips and thighs (Fig. 38.3). The growth spurt is limited after menarche, as the epiphyses fuse. Menstrual cycles are usually irregular at menarche and can take up to 5 years (average 2–3 years) to become regular.

The sequence of changes in puberty is referred to as the sexual maturity rating or Tanner stages, named after Tanner, a physician who in 1969 published a description of the sequence of physical changes that occur during

puberty (Figs. 38.3 and 38.4). The Tanner stages are determined by the development of secondary sex characteristics and encompass changes in the size and appearance of the external genitalia, the development of pubic hair, and breast development in girls from thelarche (breast budding) to adult female breast development. Tanner stages allow doctors to classify the extent of development of sex characteristics into five distinct steps ranging from stage 1 (pre-pubertal) to stage 5 (mature adult type) (Marshall and Tanner 1969; Novello and Speiser 2018).

Immediately after the start of menarche, there is a temporary period with anovulatory cycles. Several studies have shown this period of anovulatory cycles tends to be longer as the age at menarche increases (Hosokawa et al. 2012; Lee et al. 2013; Apter 1996). Therefore, girls who experience menarche before the age of 12 have a more rapid onset of ovulatory menstrual cycles than girls whose menarche started later (Apter 1996). Furthermore, studies have shown that 50% of adolescent girls whose first menstruation was after the age of 13 will not ovulate regularly over the next 4.5 years (MedicineNET 2018).

38.4 The Menstrual Cycle

Menstruation is the periodic discharge of blood and disintegrated endometrium, from the uterus through the cervix and vagina. It is caused by the rapid drop in progesterone and oestrogen levels secondary to reduced production from the ovaries, which takes place during each cycle if egg fertilisation, implantation, and pregnancy don't occur.

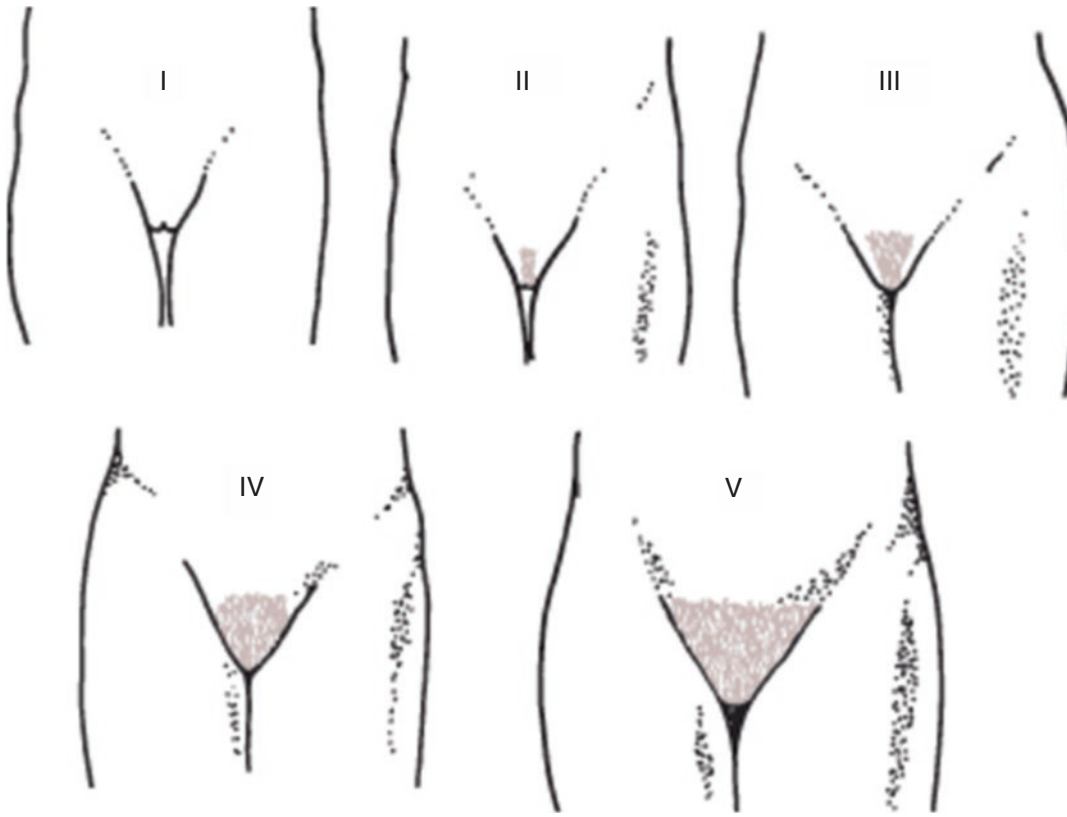

Fig. 38.3 The Tanner Stages I–V for pubic hair development in girls (Marshall and Tanner 1969)

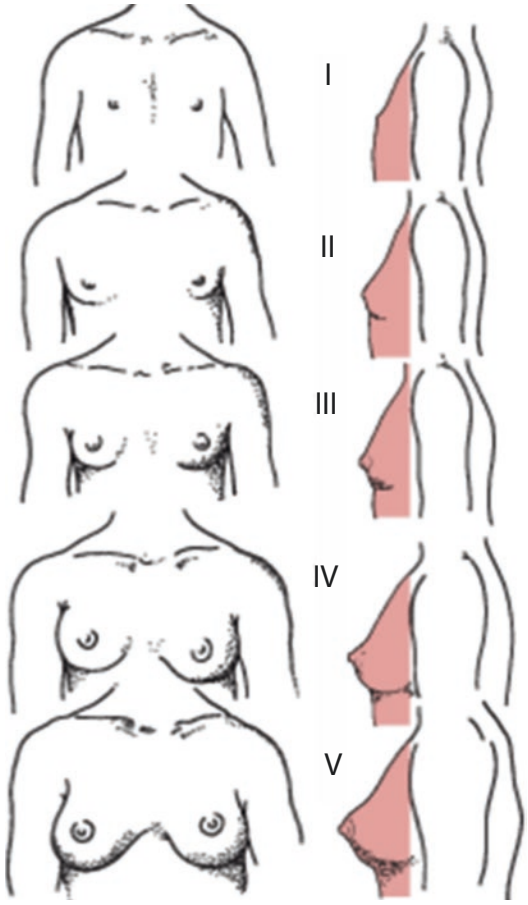

Fig. 38.4 The Tanner Stages I–V for breast development in girls. Used with permission from Marshall WA, Tanner JM: Variations in patterns of pubertal changes in girls. Arch Dis Child 1969;44:291–303

Menstruation occurs throughout a woman's reproductive life in the absence of pregnancy. Menopause is the permanent cessation of menstruation.

The average duration of bleeding is around 5 (normal range 3–7) days. The average blood loss per cycle is around 30 mL (normal range 15–80 mL) and is usually maximal on the second day. Menstrual blood does not usually clot (unless bleeding is very heavy), probably because of fibrinolysin and other factors that inhibit clotting (Dockeray et al. 1987). Menorrhagia is the term used to describe heavy blood loss which can be because of a number of different reasons, e.g. uterine fibroids, clotting disorders.

The median menstrual cycle length is 28 days (usual range 21–35 days in adult women; 21–45 in adolescents). In general, menstrual cycles are longer and most variable in the years immediately after menarche and immediately before menopause, when ovulation is less regular. Irregular periods are more likely to be anovulatory. Based on consensus the menstrual cycle begins and ends with the first day of menstruation (day 1).

As depicted in Fig. 38.5, oestrogen levels are low in childhood and start rising during prepuberty, reaching a critical level at puberty when the development of secondary sexual characteristics begins. The peak level induces the onset of menarche and remains at a similar level with

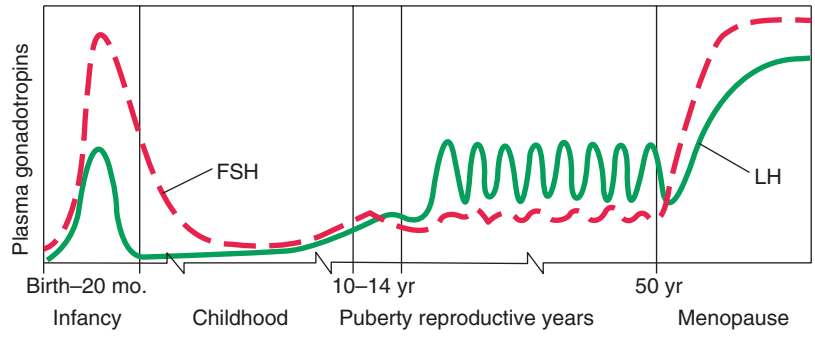

Fig. 38.5 LH and FSH levels throughout a female's life [Hall JE (2017) Disorders of the female reproductive system, chapter 13. In: Jameson JL (Eds) Harrison's Endocrinology, 4th Edition, McGraw Hill Education, New York, pages 192–201]

cyclical fluctuations during the woman's reproductive years, in synch with ovulation. Ovulation is irregular in the first few years following menarche and the few years prior to menopause (climacteric). After the menopause, the levels decline rapidly due to ovarian failure and lack of further production. The hormonal changes of the menstrual cycle cause ovulation and induce changes in the endometrium that prepare it for implantation.

38.4.1 Menstruation

The menstrual cycle is generally 28 days and includes the following phases: menstruation, proliferative phase, follicular phase and luteal phase.

Days 1–4 of the cycle is menstruation:

At the start of the menstrual cycle, the endometrium is lost and its hormonal support is withdrawn. Myometrial contraction, which can be painful, is accompanied by vasoconstriction to reduce blood loss.

38.4.2 The Proliferative Phase

Days 5–13 of the cycle are the proliferative phase:

The proliferative phase of the menstrual cycle can be sub-divided into two ovarian stages: follicular (pre-ovulatory) and luteal (post-ovulatory) phases.

The dominant follicle develops through a three-stage process: (1) Recruitment, (2) Selection, and (3) Dominance. Recruitment takes place during days 1–4 of the menstrual cycle, when FSH leads to recruitment of several follicles from the available cohort of non-proliferating follicles. Between days 5–7 of the cycle, a single follicle is selected amongst the recruited follicles, for ovulation and the remaining follicles undergo atresia. By the 8th day of the cycle, one follicle becomes dominant and promotes its own growth, suppressing the maturation of the other ovarian follicles thus becoming the dominant matured follicle, which subsequently releases its ovum in the process of ovulation (Fig. 38.6).

38.4.2.1 The Follicular Phase

This phase is the most variable in terms of length. During the early follicular phase (the first half), the recruited follicles become larger.

The gonadotrope cells in the anterior pituitary contain little LH and FSH at this stage. Oestrogen and progesterone levels are also low. However, pulses of GnRH from the hypothalamus stimulate LH and FSH release by the anterior pituitary. Overall, FSH secretion increases slightly, stimulating growth of the recruited follicles, with slower subsequent rise in circulating LH levels (1–2 days after the peak in FSH). The recruited ovarian follicles are eventually able to produce oestradiol which in turn stimulates the synthesis of LH and FSH but also inhibits their secretion, via a negative feedback mechanism. This usually results in only one follicle maturing and one ovum being released into the fallopian tube.

During the late follicular phase (second half), the follicle selected for ovulation matures and accumulates granulosa cells, which secrete hormones.

The antrum of the follicle enlarges with follicular fluid, reaching a size of approximately 18–20 mm immediately before ovulation. The levels of the gonadotropins decrease, with FSH being markedly more affected than LH. From this point on, the levels of FSH and LH begin to diverge because oestradiol inhibits FSH secretion more than LH secretion, but also because the developing follicles produce inhibin, a hormone which inhibits FSH secretion (Fig. 38.1), but not LH secretion (Berga and Naftolin 2012). Furthermore, the half-life of LH is around 20–30 min, whereas that of FSH is much longer at 2–3 h. Levels of oestrogen, particularly oestradiol, rise exponentially.

As the oestradiol levels continue to rise and reach their maximum, a positive feedback effect on the hypothalamus and pituitary, causes LH levels to rise sharply and ovulation follows.

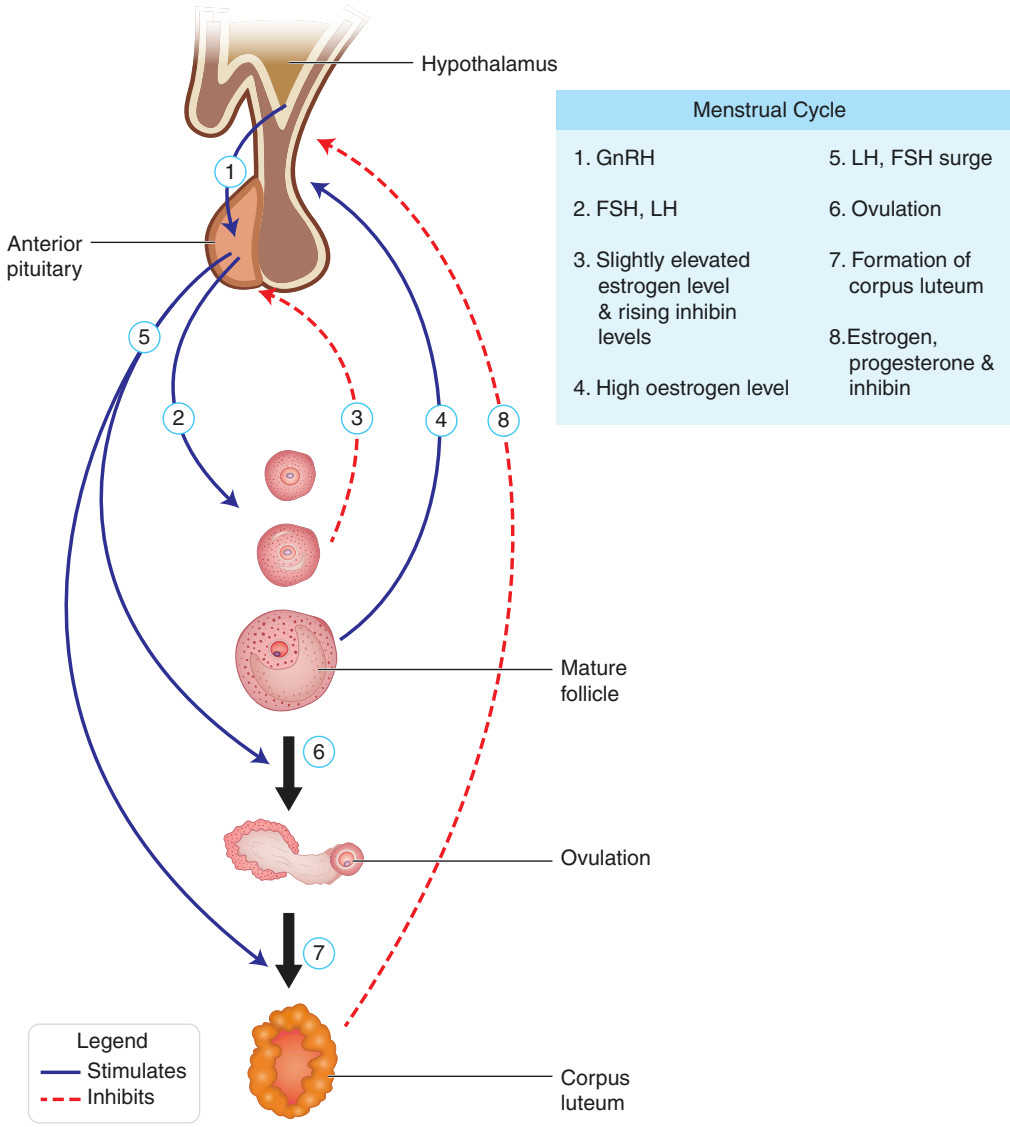

Fig. 38.6 Regulation of menstrual cycle and ovulation in the hypothalamic-pituitary-ovarian axis

Oestradiol levels usually peak as the ovulation begins. Progesterone levels also begin to increase. The LH stored in the pituitary is released in massive amounts in a process called the "LH surge", which occurs over 36–48 h. There is a smaller increase in FSH.

The LH surge occurs primarily because the high levels of oestradiol trigger LH secretion by the gonadotrope cells of the pituitary, via a positive feedback mechanism. The LH surge is also stimulated by GnRH and progesterone. The LH surge stimulates the release and activation of enzymes that initiate breakdown of the wall of the follicle and release of the now mature ovum within about 16–32 h. The LH surge also triggers completion of the first meiotic division of the oocyte within about 36 h. During the LH surge, the oestradiol levels decrease, but progesterone levels continue to rise (Fig. 38.6).

38.4.2.2 Luteal Phase

After releasing its ovum, the dominant follicle transforms into the corpus luteum. The length of this phase is the most consistent, averaging 14 days (range: 11–17 days). If pregnancy doesn't occur within these 14 days, the corpus luteum degenerates. A shortened luteal phase may indicate luteal phase deficiency (LPD) and a proposed diagnostic criterion for LPD is a shortened luteal phase of <9 days. However, a short luteal phase can occur in up to 5% of healthy fertile women which is often comparable to the luteal phase seen in the infertile population (Mesen and Young 2015).

The corpus luteum secretes primarily progesterone in increasing quantities, peaking at about 25 mg/day 6–8 days after ovulation. Progesterone stimulates development of the endometrium (the lining of the uterus), which is necessary for implantation of the zygote, should fertilisation occur and establishment of pregnancy. Progesterone is thermogenic, leading to an increase in the basal body temperature of about 0.5 °C.

During most of the luteal phase, the levels of circulating oestradiol, progesterone, and inhibin are high and negative feedback on the pituitary causes a reduction on the LH and FSH levels. Eggs can survive about 12–24 h after release (and sperm can live for 3–5 days). If pregnancy does not occur, the egg disintegrates and progesterone levels fall. About 12–16 days later, tissues from the lining of the uterus are expelled as menstrual bleeding and the cycle starts again. If pregnancy doesn't take place, oestradiol and progesterone levels fall late in the luteal phase and the corpus luteum degenerates, into the corpus albicans. If implantation does occur, the corpus luteum does not degenerate and remains functional in early pregnancy, with the support of human chorionic gonadotropin (hCG) that is produced by the developing embryo.

38.5 Pregnancy

During the luteal phase, progesterone stimulates the endometrium to change from proliferative to secretory form, which is very vascular and composed of spiral arteries. The glandular secretory endometrium secretes chemokines, growth factors, and cell adhesion molecules, all of which establish and maintain a favourable environment for implantation.

After ovulation and fertilization, the zygote (fertilised egg) remains in the ampulla of the fallopian tube for up to 3 days and undergoes a sequence of cell divisions, differentiation and eventually forms the morula (the group of cells from the dividing zygote). This process is independent of the hormones in the fallopian tube and uterus and can be performed in vitro during in vitro fertilisation (IVF). The morula then travels along the isthmus to the uterus, in a process that takes around 10 h and enters the uterus as an embryo. It continues to develop and 3–6 days after fertilisation, it becomes a blastocyst and floats in the endometrial cavity.

The blastocyst secretes several substances that improve the chances of implantation via enhanced maturation of the endometrium. These also render the endometrium more receptive to an imminent implantation. The success of implantation relies on the precise synchronisation between the developing blastocyst and the maturing endometrium. The blastocyst then becomes implanted into the thickened endometrium and implantation is complete (Fig. 38.7).

After implantation is initiated, the embryo actively secretes human chorionic gonadotropin (hCG), which stops the corpus luteum from disintegrating into the corpus albicans. This allows the corpus luteum to continue producing progesterone and therefore maintains the thickened endometrium for continued gestation. The main hormones produced by the corpus luteum are progesterone, 17 β-progesterone, oestradiol, and androstenedione. Low-density lipoprotein (LDL) cholesterol is the main precursor of these steroid hormones. The function of the corpus luteum naturally begins to decline between sixth and seventh week of gestation. The production of progesterone gradually shifts from the corpus luteum to the developing placenta, over a few days in a process called the "luteal-placental transition period", which occurs at approximately the seventh to ninth weeks of gestation.

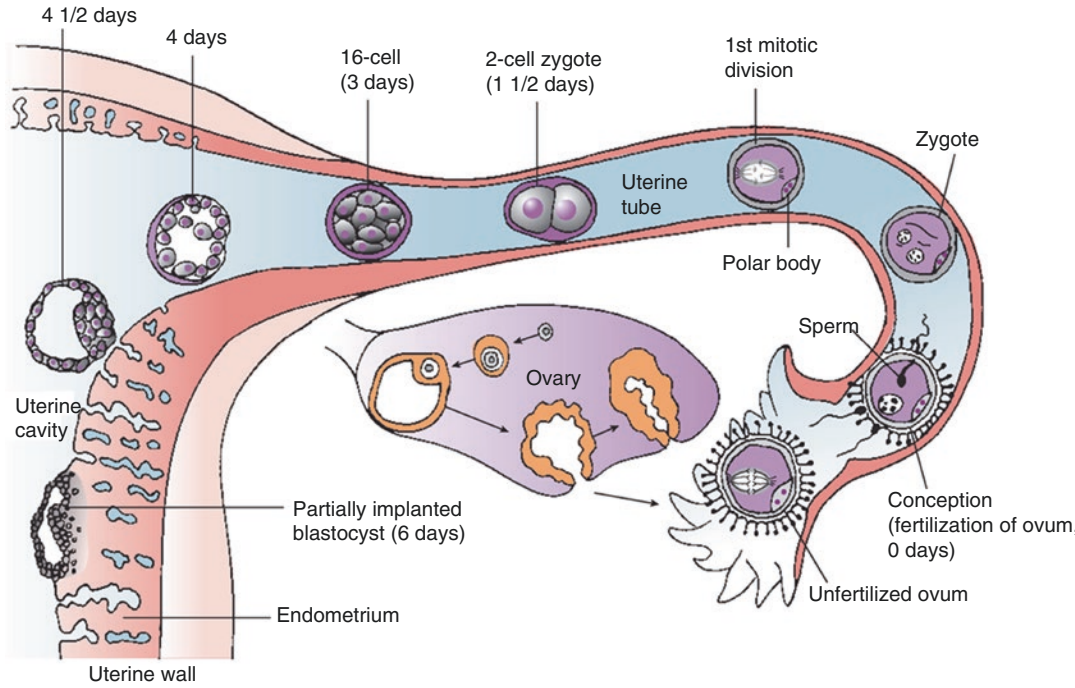

Fig. 38.7 The fertilisation and implantation stages

This process is vital for maintaining a viable pregnancy, as progesterone is the most important hormone as it can single-handedly maintain an early pregnancy that would be aborted if the corpus luteum was to be lost prematurely. Progesterone can be given as an injection to women pregnant through IVF from an egg donor to maintain the pregnancy, in the absence of a corpus luteum, during the first trimester until the secretion of progesterone is established by the placenta (Sauer et al. 1990). Similarly, in patients with corpus luteum dysfunction, exogenous progesterone is frequently administered until around the tenth week of gestation (Mesen and Young 2015; Sauer et al. 1990).

The outer blastomere cell layer of the blastocyst is known as the trophectoderm, and they can be identified at as little as 5 days following fertilisation. These cells eventually form the placenta. The main structural and functional units of the placenta are the chorionic villi, which increase in number during the first trimester of pregnancy. The villi provide a large surface area for absorption and nutrient and gaseous exchange between the mother and foetus. The maternal blood is delivered via the spiral arteries, circulates through the intervillous space, whilst the foetal blood moves in the core of the chorionic villi of the villous vessels. The foetal and maternal blood therefore never mix.

The trophoblasts are key cells within the chorionic villi, and they have the ability to multiply, invade, migrate, and differentiate through aggregation and fusion. By 10 days after fertilisation, the invading trophoblasts form two separate layers. The inner layer is called the cytotrophoblasts which are individual and rapidly dividing cells. The outer, thicker layer is known as the syncytiotrophoblasts which is a syncytial layer of multinucleate cells that line the placental villi of the foetal side of the intervillous space.

The syncytiotrophoblasts appear to be present in two distinct forms, each of which appears to produce either hypothalamic-like hormones: GnRH, CRH, and TRH or pituitary-like hormones: hCG, ACTH, and human chorionic thyrotropin (hCT). The Syncytiotrophoblasts are therefore the main site of hormone production in the placenta.

Due to their large surface area and the fact that they line the intervillous space, the hormones are directly released into the maternal blood stream, almost exclusively and at much higher concentrations compared to the foetal circulation.

The decidua (the endometrium during pregnancy) is a site of maternal hormone production, which maintains and protects the pregnancy from the mother's immune system. Cortisol secreted by the decidual endometrium in synergy with the foetal progesterone and hCG suppresses potential immunological rejection. The decidua also produces decidual prolactin which is a peptide hormone with identical chemical and biological properties to the pituitary prolactin and its production is induced by progesterone. It is released into the amniotic fluid and is not affected by administration of dopamine agonists (e.g. Bromocriptine and Dopamine) as its control is not dopamine dependent. It reduces the permeability of the amnion in the foetal to maternal direction and therefore regulates fluid and electrolyte movement through the foetal membranes. Pituitary prolactin is also secreted in the foetal circulation (by the foetal pituitary) and the maternal circulation (by the maternal pituitary) and these are both suppressed by maternal ingestion of Dopamine agonists.

Relaxin is a peptide hormone produced by the corpus luteum (in pregnant women only), the placenta, decidua, and chorion. Its main function in the mother appears to be with ripening (softening) the cervix, inhibiting uterine contractions and relaxing the pubic symphysis in preparation for labour. In the foetus, it binds to the foetal membranes, increases cytokine levels which in turn activate matrix metalloproteinases, and ultimately leads to a cascade of events that result in the rupture of membranes.

38.6 Menopause

This is a natural event that marks the end of spontaneous ovulation in a woman's life and therefore the ability to reproduce. The average age in the western world is 51 years (http://www.endotext.org). The classical symptoms of hot flashes, vaginal irritation, sleep disturbance, fatigue, and weight gain are most likely due to oestrogen deficiency. The symptoms are unique to each individual and vary markedly, with some women experiencing few or no symptoms and other women being majorly affected.

Menopausal transition (climacteric) usually starts in the late 40s and lasts around 5–7 years, with gradually reduced ovarian function. It is characterised by erratic ovarian oestradiol production and irregular length of menstrual cycle. FSH levels increase due to reduced inhibin produced by the granulosa cells. An FSH > 10 mIU/mL measured between 2–5 days of the cycle indicates ovarian aging (http://www.endotext.org). Oestradiol levels gradually become lower and lower and eventually secretion stops. The post-menopausal ovary no longer produces oestradiol but continues to produce androstenedione and testosterone at pre-menopausal levels. Oestrone produced via peripheral aromatisation of androstenedione is then the main circulating oestrogen.

While age at menopause ranges from 49–52 years, cigarette smokers can undergo menopause 1–2 years earlier compared to non-smokers (Gold et al. 2001).

Menopausal symptoms can be alleviated by the temporary replacement of oestrogen either orally or using patches. However, unopposed oestrogen action can lead to endometrial hypertrophy and ultimately increases the risk of endometrial cancer and therefore unless a woman has undergone a hysterectomy, she should be treated with combined oestrogen and progesterone preparations or have topical progesterone administration in the form of an intrauterine device, as well as the oestrogen replacement (please refer Chap. 41 in Part VI). The typical blood results of a post-menopausal woman is low oestrogen due to primary ovarian failure and high gonadotropins (LH and FSH), as the negative feedback of oestrogen has been removed. Initially, FSH and LH are high in the neonatal period, but by the age of 2, they drop, until a gradual increase during puberty. There is cyclical release during the fertile years and increase substantially in the post-menopausal period (Fig. 38.5), due to ovarian failure which results in low levels of oestrogen and therefore loss of negative feedback.

38.7 Conclusions

This chapter presented a summary of the anatomy and physiology of the female reproduction. It describes hormonal changes and how this influences the development of sexual characteristics and ovulation in a female throughout their lifetime.

Abstract

Polycystic ovary syndrome (PCOS) is a complex, common endocrine condition affecting reproductive aged women with a reported prevalence of between 8 and 13%, depending on the diagnostic criteria and the population studied. Diagnosis, based on Rotterdam criteria, commonly requires two of the three following features: oligo/amenorrhoea, polycystic ovaries on ultrasound, biochemical/or clinical hyperandrogenism, with exclusion of other aetiologies. Nurses are ideally situated to provide evidence-based care and education within an interdisciplinary model to optimise the health outcomes of women with PCOS.

PCOS affects health and well-being over the lifespan. The presentation of PCOS can be heterogeneous with reproductive (hyperandrogenism, anovulation, and subfertility), metabolic (dyslipidaemia, type 2 diabetes, and CVD risk factors), and psychological features (depression, anxiety, and poor self-esteem). Women with PCOS are also predisposed to weight gain, which in turn increases PCOS prevalence and exacerbates its severity. PCOS is underpinned by intrinsic insulin resistance. Obesity exacerbates insulin resistance, and lifestyle modification alleviates this feature.

Despite the high prevalence of PCOS many women with PCOS remain undiagnosed, clinical practice is inconsistent, psychological issues are neglected, and there is little focus on lifestyle modification and chronic disease prevention with most services targeting fertility and offering costly assisted reproductive technology. In addition, women report dissatisfaction with diagnosis experiences, poor quality information, and inadequate support.

Given the multi-system dimensions of PCOS and duration of impact over the lifespan, PCOS places a large financial burden on health systems with affected women also suffering the social costs of stigmatisation and isolation, largely due to non-conformity with societal expectations relating to femininity and fecundity. In addition, due to the diversity of PCOS health impacts, affected women may be marginalised within the health system and often fall between the gaps in a specialty-focused health care system, with knowledge gaps among practitioners and, inconsistency in care delivered. In the primary care sector, health practitioners report feeling confused and ill equipped to manage PCOS, listing PCOS as the highest priority for education in women's health. With women feeling isolated, disempowered, and underserviced, PCOS places a personal burden on affected women and their significant others, and highlights the lack of systemic, evidence-based responsiveness to their needs. This chapter provides an overview of PCOS for endocrine nurses who can play a critical role in providing evidence-based, person-centred care, within an interdisciplinary, biopsychosocial model of care.

Keywords

Polycystic ovary syndrome · Metabolic syndrome · Subfertility · Hyperandrogenism Menstrual irregularity · Emotional well-being Lifestyle management

Abbreviations

AMH	Anti-Müllerian hormone
BMI	Body mass index
FAI	Free androgen index
FSH	Follicle stimulating hormone
GnRH	Gonadotropin-releasing hormone
LH	Luteinising hormone
OGTT	Oral glucose tolerance test
PCOS	Polycystic ovary syndrome
SHBG	Sex hormone binding globulin
T	Testosterone

Key Terms

- **Body image:** is the way a person may feel, think, and view their body including their appearance.
- **Disordered eating:** refers to eating and weight-related symptoms and can include behavioural, cognitive, and emotional factors.
- **Emotional well-being:** a broad subjective concept encompassing; feelings, behaviour, relationships, goals, and personal strengths. Well-being may manifest differently due to sociocultural and individual factors.
- **Hirsutism:** excessive hair growth (face, stomach).
- **HRQoL:** Health-Related Quality of Life is a multidimensional (physical, psychological, social) and subjective concept related to a variety of patient outcomes.
- **Hyperandrogenism:** is characterised by excessive production and/or secretion of androgens.
- **Metabolic syndrome:** is a clustering of risk factors such as excess abdominal weight, lipid abnormalities, hypertension, and elevated glucose levels that are underpinned by the pathophysiological causes of insulin resistance associated with central adiposity.
- **Psychosexual dysfunction:** encompasses sexual problems or difficulties that have a psychological basis.

Key Points

- PCOS is a highly prevalent, complex, heterogeneous condition with reproductive, metabolic, and psychological features.
- It is under-recognised with up to 70% of affected women undiagnosed. This lack of recognition leads to significant delays in diagnosis and inconsistent management practices with affected women reporting unsatisfactory diagnosis experiences and inadequate support and information provision.
- Emotional well-being and increased metabolic risks are often under-recognised in PCOS and ethnic differences are often poorly appreciated.
- Subfertility is a prevalent feature of PCOS with approximately 75% of PCOS-related subfertility due to anovulation, yet with simple medical assistance the majority of women with PCOS can attain desired family size.
- Insulin resistance is a cardinal feature in PCOS, affecting 75% of lean women and 95% of obese women, contributing to an increased risk of impaired glucose metabolism and chronic diseases such as diabetes, obesity, and CVD risk factors.
- There is a bi-directional relationship between PCOS and obesity. Weight loss is a highly effective way to reduce the severity of PCOS symptoms and reduce long-term health risks. Healthy lifestyle (diet, exercise, and reduction of harmful behaviours such as smoking) is the first-line treatment for symptom management and prevention of chronic diseases.
- A holistic, person-centred approach within a biopsychosocial model of care is recommended, with a primary focus on a healthy lifestyle, emotional well-being, and prevention of chronic diseases.

39.1 Introduction

Polycystic ovary syndrome (PCOS) is the most common endocrinopathy affecting reproductive aged women (Yilmaz et al. 2018). It is a prevalent, complex condition with a heterogeneous range of reproductive, metabolic, and psychological symptoms. The condition is undiagnosed in up to 70% of affected women and key features such as a psychological burden and metabolic risks are under-recognised. Women with PCOS report dissatisfaction with diagnosis experiences, poor quality information, and inconsistent management practices. To achieve optimal health outcomes for women with PCOS a holistic, person-centred approach implemented within a biopsychosocial model of care is recommended.

39.2 Epidemiology

PCOS is increasingly recognised as a condition affecting women across the lifespan with hyperandrogenic symptoms (acne, hirsutism) most evident in adolescents and increased metabolic risks (diabetes, central obesity, and CVD risk factors) more prominent later in life. The prevalence of PCOS ranges from 8 to 13% depending on the criteria used to diagnose the condition (March et al. 2010; Boyle et al. 2012; Yildiz et al. 2012). Women at higher risk of developing PCOS include those who are overweight, and those with a family history of PCOS or type 2 diabetes (T2DM).

39.3 Pathophysiology

The pathophysiology of PCOS is not fully understood despite the identification of a genetic predisposition (Fig. 39.1). Studies have shown women with a positive family history for PCOS are at increased risk of developing the condition, with up to 80% heritability (Kahsar-Miller and Azziz 1998). Hyperandrogenism and insulin resistance, caused by both genetic and environmental factors, are the key hormonal features underpinning the pathophysiology of PCOS (Teede et al. 2011). Insulin resistance is present in up to 85% of women with PCOS, including lean and obese women (Stepto et al. 2013) and hyperandrogenism is present in 60–80% (Teede et al. 2011). In addition, alterations in hormonal signalling is evident with increased gonadotropin releasing hormone (GnRH) and luteinising hormone (LH) pulse frequency and increased LH to follicular stimulating hormone (FSH) ratio, resulting in impaired follicular development and increased ovarian androgen production. Also, hyperinsulinaemia, through the gonadotropic action of insulin on follicular cells, further exacerbates these hormonal derangements (Azziz et al. 2016).

Note: The current name—polycystic ovary syndrome—is increasingly recognised as redundant with moves afoot to rename the condition to more accurately reflect the underpinning pathophysiology.

39.4 Diagnostic Criteria (Rotterdam Criteria)

PCOS is diagnosed based on excess androgens (clinical or biochemical hyperandrogenism), menstrual irregularity (secondary to ovulatory dysfunction), and polycystic ovarian morphology (PCOM) on ultrasound.

The Rotterdam diagnostic criteria (Fig. 39.2) highlights the refined diagnostic criteria in adolescents, which require both hyperandrogenism and irregular cycles, with ultrasound now not recommended for diagnosis within 8 years of menarche, owing to overlap with normal reproductive physiology.

Patient Quote 1

"When I found out that what was happening to me had a name and was fairly common I was greatly relieved. Up to that point, I thought I was I going crazy. When I asked my doctor she just it was nothing to worry about and just stop eating so much. I felt very isolated".

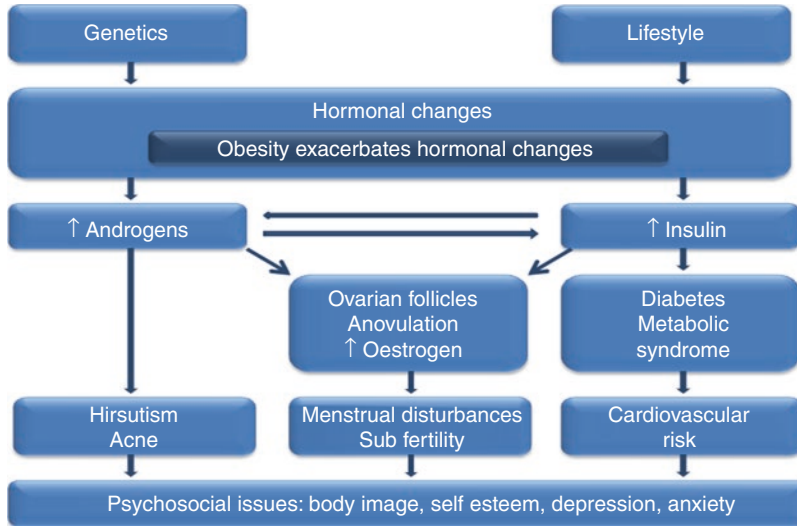

Fig. 39.1 The aetiological, hormonal, and clinical features of polycystic ovary syndrome (Teede et al. 2011)

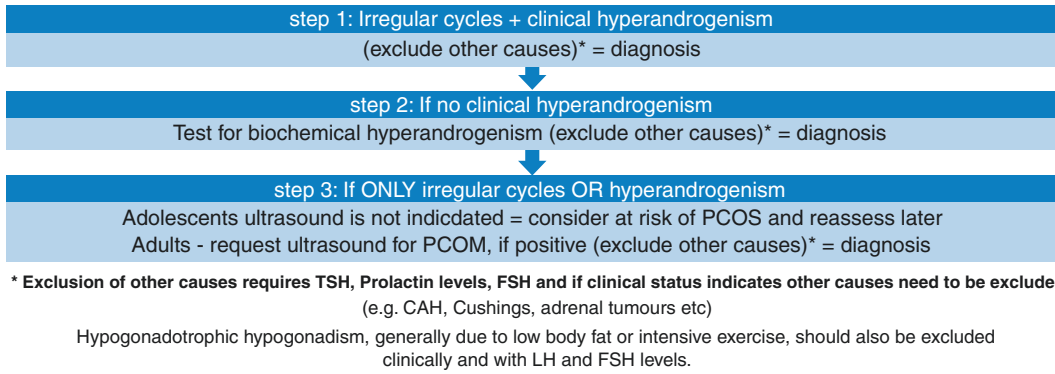

Fig. 39.2 The refined Rotterdam diagnostic criteria

39.4.1 PCOS and Obesity

There is a strong bi-directional relationship between PCOS and obesity. Whilst PCOS occurs independently of obesity, there is an increased prevalence of obesity in women with PCOS. In turn, there is an increased prevalence of PCOS as BMI increases, with obesity exacerbating metabolic, reproductive, and psychological features of PCOS (Teede et al. 2013; Lim et al. 2013). Studies have shown that women with PCOS have a higher calorie intake and a more sedentary lifestyle than women without PCOS (Moran et al. 2013). Further research is required into the biopsychosocial drivers of obesity such as increased hunger signalling and/or the impact of emotional well-being on lifestyle habits. Mechanistically, insulin resistance and hyperandrogenism are both exacerbated by obesity with adipose tissue producing pro-inflammatory signals mediating insulin resistance and hyperandrogenism. Moreover, decreased production of sex hormone binding globulin (SHBG) associated with obesity and insulin resistance results in increased levels of free circulating androgens and hyperandrogenism. Whilst a higher body mass index (BMI) is a common feature in women with PCOS, there is a need for vigilance in order not to miss the diagnosis of PCOS in lean women.

L., Kim, M. H. & Tredway, D. 1981. Hirsutism: implications, aetiology, and management. *Am J Obstet Gynecol,* 140, 815–30

39.4.2 Clinical Features

Women with PCOS may present with a constellation of symptoms that can vary according to the age at presentation. Reproductive symptoms may dominate in younger women whilst metabolic features become of great concern later in life. Clinical features can be categorised under the three domains: reproductive, metabolic, and psychological.

39.4.3 Reproductive Features

These include hyperandrogenism and oligomenorrhoea, subfertility, and pregnancy complications. Biochemical (identified by increased free androgen levels) or clinical hyperandrogenism (identified by hirsutism using the Ferriman-Gallwey (mFG) scoring tool (Fig. 39.3) [Hirsutism assessment tool - Ferriman-Gallwey (mFG)] scoring tool http://www.hirsutism.com/hirsutism-biology/ferriman-gallwey-score.shtml), and to a lesser extent acne and scalp alopecia is one of the key diagnostic and clinical features of PCOS. Menstrual irregularity (cycle length greater than 35 days or less than 21 days or fewer than eight cycles per year) and fertility issues are common reproductive manifestations of PCOS.

PCOS is the most common cause of oligo/anovulation and subfertility secondary to dysregulated reproductive hormones and follicular development (Homburg 2004). Moreover, women with PCOS were more likely to receive hormonal treatment for fertility assistance than women without PCOS (Joham et al. 2015). Importantly, family size can reach desired goals, where ovulation induction is available.

Women with PCOS are also at increased risk of pregnancy complications including pre-eclampsia, preterm delivery, and gestational diabetes (GDM). These risks are mediated by multiple factors (including genetic and environmental factors, the metabolic and reproductive characteristics of PCOS), as well as higher rates of subfertility and use of assisted fertility treatments. The aforementioned may act independently or in concert (Palomba et al. 2015). Obesity further exacerbates these risks. Therefore, women with PCOS should be recognised as having a high-risk pregnancy and have more frequent assessment of weight gain, blood pressure, and glucose tolerance during pregnancy.

There is also an association between PCOS and endometrial cancer as these women share many of the risk factors including obesity, hyperinsulinaemia, T2DM, and anovulation with unopposed uterine oestrogen exposure. However, routine ultrasound screening for endometrial thickness is not recommended unless risk factors (prolonged amenorrhoea or oligomenorrhoea) or symptoms are present.

39.4.4 Metabolic Features

Insulin resistance is a cardinal feature in PCOS, affecting 75% of lean women and 95% of obese women (Stepto et al. 2013). PCOS is associated with an increased risk of developing impaired glucose tolerance, pre-diabetes, GDM, and T2DM. It is noteworthy that these metabolic abnormalities occur at a younger age and are increased independent of body weight, but are further exacerbated by increased BMI.

Women with PCOS also have increased risk factors for cardiovascular disease including dyslipidaemia and obstructive sleep apnoea (OSA). BMI is a key driver of dyslipidaemia, which is characterised by higher triglycerides and lower high-density lipoprotein (LDL) cholesterol levels.

39.4.5 Psychological Features

PCOS is associated with higher rates of depression, anxiety, disordered eating, psychosexual dysfunction, and low self-esteem (Teede et al. 2011). Symptoms challenging feminine identity, including obesity, acne, excess hair growth, and subfertility, are associated with a higher risk for anxiety and depression. However, studies have shown this increased prevalence of psychological symptoms in PCOS also exists independent of obesity and reproductive abnormalities. Overall, quality of life is significantly reduced in women with PCOS (Barnard et al. 2007).

39.5 Diagnosis and Investigations

Nurses should have a high level of suspicion of PCOS in women who present with menstrual irregularity (2 years or more after menarche), overweight or obesity, fertility issues, acne or hirsutism, pre-diabetes, gestational diabetes, or early-onset T2DM. The Rotterdam criteria is the most universally accepted diagnostic criteria (Fig. 39.2).

In young women (<20 years) only 1 and 2 are required due to the high prevalence of polycystic ovarian morphology (PCOM) in this group.

39.6 Presentation of PCOS at Different Life Stages

39.6.1 Young Women (<20 Years)

Two years after the onset of menarche, if young women report irregular menstrual cycles (>35 or <21 days) a diagnosis of PCOS should be considered. The value and optimal timing of assessment and diagnosis of PCOS should be discussed, taking into account diagnostic challenges at this life stage and psychosocial and cultural factors. When commencing hormonal contraception in adolescents, who have presented with 12 months of irregular menstrual cycles (>35 or <21 days) following onset of menarche, take a baseline assessment of clinical and biochemical hyperandrogenism and cycle patterns before commencement of hormonal contraception. If baseline assessment is abnormal, potential increased risk of PCOS could be discussed with the patient and future reassessment planned (Need to cease oral contraception for a period of 3 months to attain an accurate assessment). Ultrasound is not recommended in this age group and not required if hyperandrogenism (clinical or biochemical) and irregular periods are present.

39.6.2 Adult Women (Reproductive Years)

Irregular menstrual cycles (>35 days of <21 days) in adult women clinically reflect ovulatory dysfunction. However, ovulatory dysfunction can still occur with regular cycles and luteal phase progesterone levels can be measured to assess ovulation when PCOS is clinically suspected and cycles are regular.

39.6.3 Peri/menopausal Women

Diagnosis at this life stage may be based on a history of oligomenorrhoea and hyperandrogenism during the reproductive years. In addition, whilst some aspects of PCOS improve at this life stage, the risk of metabolic abnormalities may persist.

39.7 Patient-Centred Care Model

Women with PCOS report delayed diagnosis and dissatisfaction with the care and information provided by health professionals. A patient focused, multidisciplinary approach targeting both short- and long-term reproductive, metabolic and psychological features is required given the complexity and chronicity of PCOS. A thorough clinical evaluation is necessary to explore all associated features and to enable the tailoring of treatment for each individual. Nurses need to actively engage women in a partnership approach to their own care. Ongoing management in primary care is the mainstay of management. However, interdisciplinary care is often required and referral to an obstetrician/gynaecologist, endocrinologist, psychologist, or a dermatologist maybe needed for targeted medical therapy of reproductive, metabolic, and psychological complications. In addition, the provision of high quality PCOS-specific education and resources are vital to optimise patient empowerment and self-management.

Patient Quote 2

"Once I received a proper diagnosis and realised that this condition was well understood and that there was a lot of help for me, I feel to much better. It was the not knowing why I had these symptoms and what I could do that was so difficult. I know now that there is a lot I can do to help myself".

39.7.1 Key Patient Messages Once Diagnosis Established

- PCOS is common.
- PCOS is a long-term condition.
- PCOS affects individuals differently and therefore treatment needs to be individualised.
- There are some long-term health risks.
- Lifestyle management improves all aspects of PCOS.
- Treatment can reduce symptoms and risk of complications.
- A great deal of support is available and education is important.
- Continue the effort to reduce the risk of health complications.

39.8 Management of Hyperandrogenism

Hyperandrogenism is mainly manifested by excessive hair growth and to some extent acne and androgen-related alopecia. Whilst various options are available for management of hirsutism, the choice of therapy depends on the severity of the condition and its impact on individual well-being, patient preference, access and affordability of the treatment, and potential side effects. Cosmetic therapy, including laser therapy and electrolysis, are considered first line in management of hirsutism.

Combined oral contraceptive pills (COCPs) are first-line management and are generally effective but need 6–12 months to work. COCPs or alternative forms of contraception can be used with antiandrogens although the evidence for these agents in limited.

Patient Quote 3

"For me the symptoms I struggle with the most are my facial hair and my weight. Also, I used to also have very severe acne which was really tough but this was cleared up by medication".

39.9 Management of Reproductive Features

Oligo/anovulation and menstrual irregularity is best managed by combined oral contraceptive pills in women who do not seek fertility. COCPs are effective in reducing ovarian androgen production by supressing GnRH. Androgen production is also inhibited by the progestins in these pills, which impairs androgen receptor binding. The oestrogen in COCPs increases production of SHBG which in turn reduces availability of free androgens. Combined oral contraceptive pills also provide progestins which protect the endometrium.

Age, BMI, metabolic and thromboembolism risk factors as well as history of smoking need to be considered when prescribing COCPs. Whilst COCPs are effective in resuming cycle regularity, providing contraception and controlling hirsutism, they may have a negative influence on venous, thromboembolic and metabolic risk factors including dyslipidaemia and insulin resistance. Therefore, a low dose COCP is preferred and evidence does not support one preparation over another.

Intermittent progestin every 3 months can be considered as an alternative to induce a withdrawal bleed and protect the endometrium from hyperplasia in women with oligo/amenorrhoea who do not wish to take the COCP, or if there is a contraindication to their use. In women with oligomenorrhoea, routine ultrasound screening for endometrial thickness is not recommended unless risk factors are present; these may include obesity, older age, and amenorrhoea.

Fertility declines as women get older and with obesity. Therefore, early family planning, when possible, and weight management should be initiated to preserve and optimise fertility. Lifestyle intervention is first-line treatment and increases spontaneous pregnancy. Early intervention is required to prevent weight gain and to engage women in intensive lifestyle programmes with regular exercise and caloric restriction to achieve a BMI of less than 30 kg/m^2. Achieving optimal body weight is beneficial for regulation of menstrual cycles, ovulation, and spontaneous pregnancy and for

prevention of potential pregnancy complications and should be initiated at the primary care level (Clark et al. 1998). First-line therapies include pharmacological ovulation induction with aromatase inhibitors, clomiphene citrate, metformin, gonadotropins, and surgical options such as laparoscopic ovarian drilling could be considered second line when appropriate. Third-line IVF is not often required in isolated PCOS. Early specialist referral for consideration of assisted reproductive techniques is warranted once infertility is established (12 months of failure to conceive). Referral should be initiated earlier in older women if infertility is suspected (6 months of failure to conceive).

39.9.1 Therapeutic Benefits of Metformin in PCOS

The role of metformin is now clearer. Metformin is not first-line treatment. In the general population with impaired glucose tolerance, metformin prevents diabetes and is known to be effective in the prevention of weight gain and restoration of menstrual cyclicity and ovulation in women with PCOS. The addition of metformin to structured lifestyle programmes may improve BMI, yet it is not recommended as a substitute for diet and exercise (Teede et al. 2011; Legro et al. 2013). In PCOS, it reduces BMI (a high priority endpoint for women) and has positive effects on ovulation and metabolic features.

Metformin does not have the same adverse metabolic or homeostatic effects of COCPs; however it does not provide contraception. It also causes mild, self-limiting gastrointestinal side effects. Metformin is not as effective as COCPs in managing symptoms of clinical hyperandrogenism. In women resistant to clomiphene, the addition of metformin to clomiphene citrate increases live birth rates when compared with clomiphene alone or laparoscopic ovarian drilling. Metformin was also effective in preventing ovarian hyperstimulation syndrome in women with PCOS undergoing IVF treatment.

Metformin is a low cost and readily available medication, its use to prevent weight gain, impaired glucose tolerance and T2DM in PCOS is primarily in those whose lifestyle programmes alone are ineffective. It also could be considered to alleviate menstrual irregularity in women who do not desire contraception or have contraindications to the use of COCPs and to assist reproduction in women who are resistant to ovulation induction with clomiphene.

39.9.2 Preconception and Early Pregnancy Care

There is an increased risk of pregnancy complications in women with PCOS. Preconception and early antenatal lifestyle intervention, assessment of BMI, blood pressure, and OGTT are recommended in all women with PCOS to reduce the risk of developing GDM, pregnancy-induced hypertension, and pre-eclampsia (Legro et al. 2013; Boomsma et al. 2006).

39.10 Early Screening and Management of Metabolic Complications

According to both national and international guidelines, all women with PCOS should undergo regular screening for early detection of metabolic complications including IGT, T2DM, and other cardiovascular risk factors including dyslipidaemia and hypertension (Teede et al. 2011).

Current guidelines recommend screening all women with PCOS for glucose intolerance using a 2-h oral glucose tolerance test (OGTT).

Health professionals and women with PCOS should be aware that, regardless of age, the prevalence of gestational diabetes, impaired glucose tolerance, and type 2 diabetes (fivefold in Asia, fourfold in the Americas, and threefold in Europe) are significantly increased in PCOS, with risk independent of, yet exacerbated by obesity. Glycaemic status should be assessed at baseline in all women with PCOS. Thereafter, assessment should be every 1–3 years, influ-

enced by the presence of other diabetes risk factors. An oral glucose tolerance test (OGTT) should be performed at baseline in high risk women with PCOS (including a BMI >25 or in Asian >23 kg/m^2, history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of type 2 diabetes, hypertension or high risk ethnicity). Fasting plasma glucose or HbA1c may be substituted in women with PCOS with no other diabetes risk factors; however, these may be less ideal for detecting impaired glucose tolerance, as a key predictor for diabetes. An OGTT should be offered in all women with PCOS who are planning pregnancy or seeking fertility treatment preconception, and if negative at <20 weeks gestation and at 28 weeks gestation, given their high risk of hyperglycaemia and the associated comorbidities in pregnancy.

Measurement of fasting insulin levels is not appropriate clinically as the commercially available assays are not adequately sensitive and accurate; therefore, results are potentially misleading and hard to interpret. Measurement of fasting glucose alone is also not recommended as this is not adequately sensitive for detection of impaired glucose tolerance and diabetes in PCOS. The mechanism underpinning insulin resistance in PCOS mainly affects the skeletal muscle and adipose tissue rather than the liver. Therefore, women with PCOS are more likely to demonstrate postprandial dys/hyperglycaemia rather than abnormal fasting glucose levels. Frequency of screening for glucose intolerance varies according to each individual's risk profile. These risk factors include age, ethnicity, parental history of diabetes, history of high glucose levels, smoking, use of COCPS or antihypertensive medications, physical inactivity, and waist circumference greater than 80 cm.

Screen and assess all women with PCOS for risk factors for cardiovascular disease at diagnosis. This includes screening for overweight and obesity, dyslipidaemia, hypertension, and taking a history for smoking. Frequency of re-screening is still under discussion; however, current guidelines recommend subsequent assessments based on each individual's overall risk profile, age, and family history of cardiovascular disease (Teede et al. 2011; Legro et al. 2013).

39.10.1 Metabolic Risk Management in PCOS (Next Section Will Be Put in Table Format)

- Encourage smoking cessation.
- Check BP once a year if BMI is less than 25 kg/m^2 and at every visit if BMI is equal to or greater than 25 kg/m^2.
- Measure fasting lipids at diagnosis and monitor based on additional obesity and cardiovascular risk factors.
- OGTT at baseline in all women with PCOS, then assess every 1–3 years, influenced by the presence of other diabetes risk factors. OGTT should be performed at baseline in high risk women with PCOS (including a BMI >25 or in Asian >23 kg/m^2, history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of type 2 diabetes, hypertension or high risk ethnicity).
- Screen all women for impaired glucose tolerance or diabetes preconception and early in pregnancy and all women at 24–28 weeks.

39.10.1.1 Weight Management

- Offer regular monitoring for weight changes and excess weight, in consultation with and where acceptable to the individual woman. Monitoring could be at each visit or at a minimum 6–12 monthly, with frequency planned and agreed between the health professional and the individual.
- Target prevention of weight gain for all and achieving at least 5–10% weight loss if overweight. Note: education alone and unachievable goals are generally unsuccessful.
- Key message: 5–10% weight loss will greatly assist in symptom control.
- Encourage simple behaviour change—prioritisation of healthy lifestyle, family support, lifestyle and exercise planning, setting of small achievable goals.
- Consider referral if appropriate to: dietitian (tailored dietary advice, education, behav-

ioural change support), exercise physiologist (exercise motivation, education), psychologist (motivational interviewing, behaviour management techniques, emotional health, and motivation), and/or group support (diet and exercise programme).

39.10.1.2 Management of Psychological Features

Given the psychological burden associated with PCOS, the assessment and monitoring of psychological well-being is essential for making lifestyle changes, to promote ongoing engagement with management strategies and to improve quality of life. PCOS guidelines recommend emotional health screening using evidence-based screening tools.

It is important to note that treatment of factors such as hirsutism and excess body weight, which can negatively affect quality of life, can be as important as conventional treatments (cognitive behavioural therapy, psychotherapy, and pharmacotherapy) available for management of mood disorders (Teede et al. 2011). It is equally critical to empathise the role lifestyle can play is improving emotional well-being (Thomson et al. 2010).

39.10.1.3 Emotional Health Simple Screening Tools

If the answers to any of the questions in any of the domains are positive, further exploration of that domain should be considered. Moreover, proper management of the problem including consideration of a mental health care plan and referral to a mental health professional is required.

In addition to the above questions, health professionals should capture and consider women's perceptions of their symptoms, impact on their quality of life, and personal priorities for care to improve patient outcomes.

Additional recommended tools:

- Modified Polycystic Ovary Syndrome Questionnaire (MPCOSQ)
- The female sexual function index Female Sexual Function Index (FSFI)
- The Arizona sexual experience scale Arizona Sexual Experience Scale (ASEX Summary of treatment strategies in PCOS

39.10.1.4 Oligo/amenorrhoea

- Lifestyle changes (5–10% weight loss through structured exercise and calorie restriction).
- COCPs (low oestrogen doses, i.e. 20 micrograms may have less impact side effects and second-generation progestins are associated with lower risk of thromboembolism).
- Cyclic progestins to induce withdrawal bleed if COCPs not desired or contraindicated (i.e. 10 mg medroxyprogesterone acetate 10–14 days every 2–3 months if no cycle in interim).
- Metformin improves menstrual cyclicity and ovulation.

39.10.1.5 Hirsutism

- Cosmetic therapy (laser or electrolysis) is considered first line.
- Consider pharmacotherapy if cosmetic therapy is ineffective, inaccessible, or unaffordable. Each medication should be tried for at least 6 months before making changes in dose or introducing a new medication.
- COCPs are first line. If ineffective after 6–9 months, an antiandrogen can be added (i.e. spironolactone or cyproterone acetate).
- Monotherapy with antiandrogens should not be considered in premenopausal women as they increase irregular vaginal bleeding and have adverse foetal outcomes should pregnancy occur.
- Ensure adequate contraception when prescribing antiandrogens.

39.10.1.6 Infertility

- Advise early family planning and initiation where possible.
- Emphasise prevention of weight gain prior to conception.
- Encourage weight loss if overweight. Lifestyle changes (5–10% weight loss through structured exercise and calorie restriction). If a significant weight loss occurs, consider a period of 3–6 months of weight stability prior to conception.
- Smoking cessation.
- Folate supplementation.
- Specialist referral for consideration of assisted reproductive techniques is essential in women who fail to conceive after 12 months and earlier in women over 35 years.

- Ovulation induction techniques include pharmacotherapy with letrozole, clomiphene citrate ± metformin, gonadotropins, or laparoscopic ovarian drilling. IVF is uncommonly needed in isolated PCOS.

39.10.1.7 Weight Management and Cardiometabolic Risk Reduction

- Encourage cessation of smoking.
- Prevention of weight gain through ongoing attention to lifestyle and weight monitoring.
- Note: no specific diet is recommended as ideal in PCPS and generally healthy principles apply.
- Encourage reduction of sedentary behaviour and increase in physical activity.
- If overweight or obese, encourage 5–10% weight loss through structured exercise and calorie restriction.
- Metformin aids prevention of weight gain, assists lifestyle induced weight loss, and prevents diabetes onset.

39.10.1.8 Psychological Symptoms

- Screen women using the emotional health simple screening tool (Box 39.1)
- Address factors which can negatively affect quality of life
- Consider a mental health care plan and referral to psychologist/psychiatrist when needed

Box 39.1 Emotional Health Simple Screening Tool

Depression and/or anxiety

1. During the last month, have you often been bothered by feeling down, depressed, or hopeless?
2. During the last month, have you often been bothered by having little interest or pleasure in doing things?
3. During the last month, have you been bothered by feeling excessively worried or concerned?

Negative body image

1. Do you worry a lot about the way you look and wish you could think about it less?
2. On a typical day, do you spend more than 1 h per day worrying about your appearance? (More than 1 h a day is considered excessive). If positive what are your specific concerns and how does it affect your life?
3. Does it make it hard to do your work or be with your friends and family?

Disordered eating and eating disorders

1. Do you worry you have lost control over your eating?
2. Do you ever feel disgusted, depressed, or guilty about eating?
3. Have you tried fasting or skipping meals in an attempt to lose weight?
4. Have you tried vomiting, laxatives, or diuretics in an attempt to lose weight?
5. Have you had significant (i.e. >5–7%), recurrent fluctuation in body weight?

Psychosexual dysfunction

1. During the last few months, have you often been bothered by problems with your sex life such as reduced satisfaction, diminished desire, pain, or any other problems?
2. Do you feel that polycystic ovary syndrome affects your sex life?
3. (If relevant) Do sexual problems affect your current relationship and/or have sexual problems affected your past relationships?

Considering the high prevalence of depression and anxiety in PCOS appropriate screening and a timely referral to psychologist/psychiatrist is important.

39.10.1.9 Use of Metformin

When indicated, metformin can be started at a low dose (500 mg daily) to enhance GI tolerance with dosage titrated (by 500 mg every 2–4 weeks as tolerated) to a maximum dose of 1500–2000 mg daily.

Metformin may also be used

- To prevent weight gain, IGT, and T2DM in PCOS where lifestyle programmes fail
- To improve menstrual irregularity in women who do not desire or have contraindications to the use of COCPs
- To assist reproduction in women who are resistant to ovulation induction with clomiphene alone

Case Studies

Scenario 1: Fei

26 year old, Chinese woman

History

– menarche at age 14 with irregular cycles (45–60 days).
– strong family history of T2DM and CVD on father's side

Presenting Symptoms

– amenorrhoea (last 4 months)—Fei concerned about this
– weight gain (7 kg over the past 2 years)—struggling to lose

Lifestyle

– currently sexually active (uses condoms)
– sedentary lifestyle, little time for exercise

Examination

– Not cushingoid
– normotensive
– BMI 28
– central adiposity, waist circumference 89 cm

On Further Questioning

– excessive facial hair growth, requires regular waxing
– self-rating of 11 on the modified Ferriman-Gallwey scoring system

Investigations

– testosterone 2.0 (0.1–1.7), SHBG 15 (18–136), FAI 13% (0.7–10.9)
– TSH, prolactin, FSH, LH, hCG—normal
– transvaginal ultrasound: multiple follicles consistent with PCOM
– OGTT normal, mild dyslipidaemia—normal total cholesterol and LDL-C, low HDL-C

Diagnosis and Treatment

– Fei chooses to start a COCP for regulation of her periods, considers laser therapy for hirsutism
– sees a dietician, attends regular aerobic exercise sessions at the local gym to achieve weight loss

Sequela

Four years later—presents to emergency department with vaginal bleeding and abdominal pain
  – pregnant and referred for an ultrasound, a live pregnancy at 8 weeks
  – bleeding stopped, Fei reassured pregnancy still viable

On Examination

– weight is 73 kg, BMI 26, normotensive
– stopped taking COCP about 6 months ago to get pregnant
– referred for early OGTT to screen for gestational diabetes—fasting glucose 5.1, 2 hourly glucose 9

Critical Thinking Questions: Scenario 1

1. How could the nursing process be used to prioritise Fei's care?
2. What would your key lifestyle messages to Fei be?
3. What other health professionals may form part of Fei's care team?

Scenario 2: Katie

29 year old, caucasian woman

History

– menarche at age 13, irregular menstruation until she started taking a COCP at age 15
– no regular medication
– works fulltime
– does not smoke, drinks alcohol occasionally

Presenting Symptoms

- presents to GP with 12 months irregular menstruation
- cycle lengths 50–70 days
- stopped COCP last year—planning to conceive
- no success after 6/12

On Further Questioning

- disappointed with weight gain of 8 kg over 9 year
- believes weight gain is disproportionate as very active

Examination

- normotensive
- BMI 29
- central adiposity, waist circumference 89 cm
- no physical features suggestive of secondary causes of weight gain
- modified Ferriman-Gallwey scores 5, reports waxing face frequently
- normal testosterone, low SHBG, elevated FAI
- thyroid function, 17-OH progesterone, and prolactin levels—normal

On Further Screening

- mildly elevated LDL, low HDL
- OGTT normal, no signs or symptoms suggestive of OSA

Emotional well-being—using simple screening tool Katie found to be concerned about weight gain but not distressed about body image.

- mood, energy levels, and social relationships—good

Diagnosis and Treatment

- diagnosed with PCOS (Rotterdam)
- advised to commence lifestyle changes, aim weight loss of 5–10% of body weight
- referred to a dietitian, calorie-restricted diet, and exercise programme (dramatic weight loss to be avoided)
- Medroxyprogesterone acetate prescribed to induce a withdrawal bleed as Katie does not want to commence COCPs
- will continue waxing (can't afford laser therapy)

Sequela

returns to GP after 3/12—lost 4 kg
cycles shorter and lipid profile normalised
advised to continue active lifestyle for 6/12
if not conceived, further examination, ovulation induction considered
will refer to reproductive/infertility specialist after 12 months of trying to conceive
after a further 2 kg weight loss—Katie conceives, although she develops gestational diabetes.

Critical Thinking Questions: Scenario 2

1. What would your key lifestyle messages to Katie be to optimise her fertility?
2. What percentage of body weight reduction has been shown to improve PCOS symptoms?
3. How does excess weight impact the symptoms of PCOS?

Scenario 3: Anju

33 year old, South-east Asian woman

Presenting Symptoms

- presents to GP with irregular menstruation <4 cycles per year
- menarche at age 14, COCP until 30
- not planning to conceive—uses condoms

Examination

- Normotensive, BMI 29, central adiposity
- waist circumference 86 cm, no features of secondary causes of obesity
- modified Ferriman-Gallwey score 4, however reports laser therapy
- normal testosterone, low SHBG, and elevated FAI
- transvaginal ultrasound—unilateral PCOM
- elevated LDL, low HDL
- OGTT–IGT
- no signs and symptoms of OSA
- thyroid function, 17-O progesterone, prolactin levels—normal

Diagnosis and Treatment

- diagnosis of PCOS (three Rotterdam criteria)
- lifestyle programmes with personal trainer 6/12
- lost 2 kg (reports being stressed about not losing weight due to effects on fertility)
- failed to lose weight on diet and exercise alone

Started metformin 500 mg daily—dose gradually titrated to 2000 mg (for IGT and weight gain prevention)

– referred to psychologist—anxiety

Sequela

– visits GP after 3/12, lost 3 kg
– cycles returned
– reports psychologist helpful—learnt behavioural techniques to overcome anxiety
– advised to plan family (risk of age-related infertility)
– starts folate, conceives naturally after 3/12
– advised to cease metformin
– referred for early screening for gestational diabetes
– advised to aim for optimal gestational weight gain to reduce risk of complications in pregnancy

Critical Thinking Questions: Scenario 3

1. Which of Anju's presenting symptoms may lead you to suspect a diagnosis of PCOS?
2. What are the pathological processes that lead to irregular menstrual cycles in PCOS?
3. How can lifestyle changes improve the regularity of menstrual cycles?

39.11 Conclusions

PCOS is a complex, prevalent, life-long endocrine condition with long-term metabolic, reproductive, and psychological features. It is independent of, yet exacerbated by, obesity. Many women remain undiagnosed because of the heterogeneity of clinical presentation. Affected women report diagnostic delays (>2 years) (Gibson-Helm et al. 2017), inconsistent practices and inadequate health practitioner knowledge (Dokras et al. 2017), poor diagnostic experiences (Gibson-Helm et al. 2017), and inadequate health system responsiveness leading to additional costs (Jason 2011; Azziz et al. 2005).

Therefore, awareness of this condition and its features is important for nurses who positively contribute to early and accurate diagnosis, raising PCOS-related health literacy and being a critical member of an interdisciplinary care team. This will avoid missing the diagnosis and assist with appropriate screening of all women with PCOS for the presence of potential metabolic, psychological, and reproductive manifestations. Nurses can play a critical role in delivering evidence-based, holistic care through the provision of targeted education, and preventative and therapeutic strategies within a biopsychosocial model of care.

Abstract

Turner syndrome affects approximately 1 in 2500 live female births and is characterised by an abnormal or missing X chromosome. It is associated with increased morbidity and mortality due to the associated phenotypic abnormalities. The commonest presentation is aged 10–16 with short stature and primary amenorrhoea, however the considerable phenotypic variation some of which is associated with a particular/mosaic karyotype may lead to delay/missed diagnosis. Girls and women with TS should be followed up for life with screening for complications, and management of short stature, primary (and more rarely secondary) ovarian failure, cardiovascular complications, and increased autoimmune and metabolic risk. Recent guidelines provide useful guidance for the successful lifelong management of girls and women. A multidisciplinary approach addressing (Fig. 40.6) all aspects of their care including expert cardiological monitoring and intervention when required, access to fertility and obstetric expertise when appropriate, expert genetic counselling if indicated, and discussion of psychosocial, education, employment issues is key to the successful outcome for all women with Turner syndrome.

Keywords

Turner syndrome · Karyotype · Fertility · Aortic dissection · Oestrogen · Autoimmunity

Abbreviations

AMH	Anti-Mullerian Hormone
APS	Autoimmune polyglandular syndrome
ASI	Aortic size index
BAV	Bicuspid aortic valve
CMR	Cardiac MRI
CoA	Coarctation of aorta
ECG	Electrocardiogram
GH	Growth hormone
HRT	Hormone replacement therapy
HTN	Hypertension
IVF	In vitro fertilisation
OR	Odds ratio
R	Recommendation of International Guidelines
SMR	Standardised mortality ratio
TS	Turner Syndrome
TTE	Transthoracic echo

Key Terms

- **Short stature:** a child or an adult is more than two standard deviations below the mean for age and gender or less than the 3rd percentile.

- **Primary amenorrhoea:** the failure of menses to occur by age 16 years, in the presence of normal growth and secondary sexual characteristics.
- **Karyotype:** the number and visual appearance of the chromosomes in the cell nuclei of an organism or species.
- **Genotype:** is the set of genes in our DNA which is responsible for a particular trait.
- **Phenotype:** is the physical expression, or characteristics, of a trait.
- **Mosaic karyotype:** one kind of karyotype in some cells, and a different karyotype in other cells.

Key Points

- Turner syndrome is the commonest sex chromosome abnormality in women characterised by an abnormal or missing X chromosome.
- Turner syndrome is associated with increased mortality due to cardiovascular disease, aortic dissection, and adverse metabolic risk profile.
- Characteristic clinical features are short stature and ovarian failure.
- The phenotype is highly variable and includes autoimmune, metabolic, hepatic, bony, cutaneous, renal, and neurocognitive abnormalities.
- Lifelong management and multidisciplinary care is key to successful outcome for girls and women with Turner syndrome.

40.1 Introduction

Turner Syndrome (TS) is the most common sex chromosome aneuploidy affecting females and is caused by the loss of part or all of an X chromosome. It is a major cause of primary hypogonadism and short stature in young girls. Girls and women with a diagnosis of TS require comprehensive multi-system assessment, active management of growth-promoting therapies, pubertal induction and maintenance, management of developing comorbidities, and ongoing health surveillance of increased lifetime risks of a number of conditions.

The clinical triad of impaired sexual development, webbed neck, and cubitus valgus was first described in the English language literature by Turner in 1938 (Turner 1938) with ovarian failure and streak gonads noted in 1944 (Wilkins and Fleischmann 1944). Much earlier in Europe, Ullrich and Bonnevie described similar case findings in a young girl and mouse in 1930 and 1934, respectively (Ullrich 1930; Bonnevie 1934).

40.2 Epidemiology

TS occurs in approximately 1 in 2000 to 1 in 2500 live births and a 45,X Karyotype is implicated in 3 of 100 female conceptuses. The prenatal prevalence is higher, with increased mortality during the first trimester leading to a high rate (7–10%) of spontaneous abortion (Stochholm et al. 2006). The diagnosis of TS still occurs across the female lifespan. The true prevalence of TS is difficult to determine as those with mild phenotypes may remain undiagnosed until late adulthood. It is important to recognise clinical and phenotypic findings and risks with specific chromosome anomalies for affected females.

Population studies show both significant delay (Fig. 40.1) and under-diagnosis of TS (Stochholm et al. 2006). A population study in Denmark of 746 girls and women with TS showed the median age of diagnosis to be 15 years, with a peak at birth and subsequent second peak age 15 secondary to evaluation for short stature and primary amenorrhea. However, it is important to be aware and recognise the potential for diagnosis throughout the entire adult life as demonstrated by cases diagnosed up to the age of 86 (Stochholm et al. 2006). The diagnosis is confirmed by karyotype analysis.

Morbidity and mortality is increased in TS. In a UK study, overall mortality was raised (SMR 3.0) (Schoemaker et al. 2008) and a Danish population study demonstrated a similar SMR of 2.86 (Stochholm et al. 2006). The increased mortality is multifactorial but is predominantly due to cardiovascular disease (41% excess mortality in UK study), aortic dissection, and metabolic disease. Some of the increased morbidity and risk for

increased death rate are amenable to treatment and emphasise the importance of both making the diagnosis and early appropriate management of associated conditions.

40.3 Diagnosis and Genetics

Diagnosis of Turner Syndrome (TS) requires complete or partial absence of the second sex chromosome with or without cell line mosaicism and the presence of characteristic features. A 30 cell karyotype identifies at minimum 10% mosaicism with 95% confidence and is recommended by the American College of Medical Genetics (Hook and Warburton 2014) (Table 40.1).

Although a specific karyotype does not necessarily predict the phenotype of an affected individual, recognised associations between clinical phenotype and underlying karyotype do exist as shown in Table 40.2 and described below.

45, X 45, X (monosomy X) is found in approximately 45% of the live births with TS.

45, X mosaicism—More than half of all patients with TS have a mosaic karyotype for example 45X/46, XX or 45,X/47, XXX, or 45,X mosaics with additional X chromosome abnormalities of isochromosome Xq (46,X,i(X)q), ring chromosome X (rX), or Xp or Xq deletion.

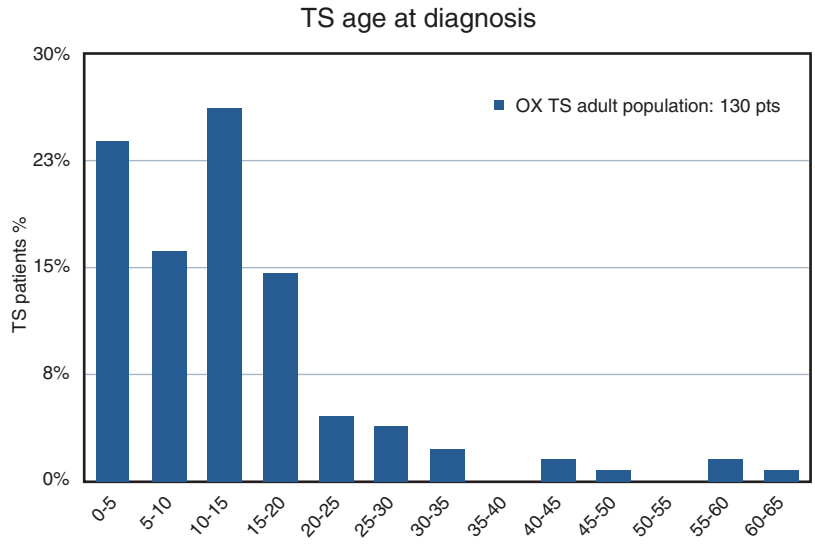

Fig. 40.1 Time of diagnosis in Turner syndrome diagnosis from birth (unpublished author's data from Oxford TS cohort 2018)

Table 40.1 Incidence of different karyotype in 410 adult women with Turner syndrome (adapted from Birkebaek et al. (2002))

45,X	49%
45,X/46,XX mosaicism	19%
45,X mosaicism with structural anomaly of second X	23%
45,X/46,Xi(Xq)	
45,X/46,Xr(X)	
45,X/47,XXX	
46,XX and structural anomaly of second X	9%
46,Xdel(Xp)	
46,Xi(Xq)	
46,Xr(X)	
45,X/46,XY mosaicism (the Y can be normal or structurally abnormal—**NB only called TS if phenotypically female**)	

Table 40.2 Common genotype/phenotype associations in women with TS (Gravholt et al. 2017)

- 45,X—classic genotype
  - Highest incidence of renal and cardiovascular anomalies
- 45,X, 46,XX cell line mosaicism
  - Lowest risk of short stature
  - Greatest incidence of spontaneous menarche
- Isochromosome X
  - Increased incidence of autoimmune disorders and deafness
  - Reduced risk of internal malformation
- Ring chromosome r(X)
  - Spontaneous menses in 33%
  - Increased incidence of cognitive difficulties
- Y material 5–10%—FISH, gonadoblastoma risk

Isochromosome Xq—represents a structurally abnormal X chromosome that consists of two copies of the long arm of the X chromosome that are connected head to head. Those with isochromosome Xq are monosomic for the short arm of the X chromosome and are believed to be at higher risks for autoimmune disorders particularly thyroiditis.

Ring chromosome X—those with a ring chromosome X (rX) are at risk for significant developmental delay and cognitive difficulties may have early severe growth failure, atypical facial dysmorphic features, and/or increased risk for irritable bowel disease syndrome.

Xp or Xq deletion—signifies a deletion of a portion of the short arm of the X chromosome [del(X)p] or long arm of the X chromosome [del(X)q] with or without cell line mosaicism. Xq deletions are associated with ovarian failure but rarely other features of TS (Maraschio et al. 1996).

45,X/46,XY affects up to 10% of TS patients with a cell line containing Y chromosome material (Jacobs et al. 1997). If sex chromosome material of uncertain origin (marker chromosome elements) is detected on karyotype, further assessment is warranted because of increased risks for gonadoblastoma. It is important to note that 45,X/46,XY karyotypes have been associated with a variety of phenotypes that range from TS to ovotesticular disorder of sex development to a normal phenotypic male with infertility. Thus, the diagnosis of TS should only be applied to individuals who have a documented abnormality of the X chromosome and phenotypic features. TS should be distinguished from Noonan syndrome, mixed and complete or pure gonadal dysgenesis (dos Santos et al. 2013).

A karyotype analysis identifying Y-chromosomal material may be present in approximately 5% of those with TS, and additionally up to 3% may have marker chromosomes, an X or Y chromosome fragment (Alvarez-Nava et al. 2013; Rivkees et al. 2011). The risk of developing gonadoblastoma, a neoplasm that occurs in dysgenetic gonads, with Y material identified ranges up to 30%. As a result, early gonadectomy is recommended when Y material has been identified. These patients may be at future risk for other malignancies.

Future directions for screening of TS may capitalise on recent advances of high throughput pyrosequencing of buccal swabs for TS (Rivkees et al. 2011; Rivkees 2012). This testing has the potential to provide a very useful non-invasive screening tool that can detect loss of an entire X chromosome or mosaicism with up to 97% sensitivity. The potential for clinical use and future mass screening or new-born screening is appealing.

40.3.1 Prenatal Diagnosis

Ultrasound findings (increased nuchal translucency, coarctation of the aorta and/or left-sided cardiac defects, renal anomalies, polyhydramnios, oligohydramnios, and growth retardation) and/or an abnormal triple or quadruple maternal serum (alpha fetoprotein, human chorionic gonadotropin, inhibin A, and unconjugated estriol) screening may suggest TS (Gravholt et al. 2017) however are not diagnostic and require karyotype confirmation. Postnatally, all infants require re-evaluation of karyotype to confirm, as the degree of mosaicism detected prenatally is not generally predictive of the severity of the TS phenotype (Gunther et al. 2004; Bondy 2007). Prenatal diagnosis of TS should include counselling regarding the wide variability of phenotype and the high probability of short stature and ovarian failure due to ovarian dysgenesis. It is very challenging to predict phenotype of infants with TS and particularly those with 45, X/46, XX mosaicism who tend to have a milder phenotype.

40.3.2 Postnatal Diagnosis

Lymphedema and/or coarctation in the new-born period are perhaps the more common reasons to screen for TS in infancy, and short stature generally leads to further evaluation and identification of the majority of cases of TS during childhood and adolescence (Pinsker 2012). The phenotype of a girl with TS after the new born period that represents the classic gestalt of TS findings is

very variable but includes short stature and delayed puberty related to ovarian failure often associated with phenotypic features such as epicanthal folds, low lying palpebral fissures, low-set and/or posteriorly placed ears, low anterior and/or posterior hair lines, webbed or shortened neck, high-arched palate, malocclusion, overcrowded dentition, pigmented nevi, shield-like or broad chest with wide spaced nipples, cubitus valgus, shortened fourth metacarpals and/or metatarsals, nail dysplasia, scooped or hyperconvex nails, puffy and broad hands and feet, Madelung deformity of the hands and wrists. Table 40.3 lists the common abnormalities adapted from Gravholt et al. (2017).

40.4 Low Level Mosaicism in Adult Women

Mosaicism may develop in adult women over the age of 50 years as part of the ageing process and those with less than 5% 45, X cells should not be diagnosed with TS. For women less than 50 years of age, there has not been a defined specific lower limit for 45, X that would confer a diagnosis of TS (Gravholt et al. 2017), however many have used 5%.

40.5 Disclosure

When a child is diagnosed with a sex chromosome aneuploidy before birth, during childhood or adolescence, parent's and clinicians face the decision of when and how to disclose the diagnosis to the child. Many with TS have reported that their diagnosis or other important information was inappropriately withheld from them. In one study conducted in the United States, up to one-third of patients with TS reported that their families and/or health providers withheld all or part of the Turner syndrome diagnosis from them (Sutton et al. 2006). Additionally, many young women with TS were not informed of the infertility associated with their diagnosis. A timely, caring and age-appropriate disclosure of diagnosis and what this means for the individual child is recommended. While every aspect or risk of TS does not have to be elucidated on first discussion, open and truthful communication is key and serves as a foundation for future interactions, discussions, and revelations. Early factual knowledge gives children time to adapt gradually in steps appropriate to their age and emotional maturity. Very young children can be told of the diagnosis in general terms with further disclosures timed or provided based on the child's own understanding and inquisitive questions, age or health needs. While some parents may strongly prefer to withhold information for a "right-time", this becomes increasingly more difficult to do particularly when signs and symptoms may progress or evolve or when comprehensive health surveillance screening or active treatment is being instituted and family and health care practitioners have to explain why they withheld timely disclosure. With the internet children can easily do their own research on symptoms they experience (Sutton et al. 2006). An atmosphere of secrecy discourages children from asking questions, knowing themselves and participating in their own health care, and it may cause child to be distrustful of parents and health care providers once disclosure has been made.

40.6 Cardiovascular Disease and Risks

The pathogenesis of cardiovascular developmental defects in TS is not well understood (Bondy et al. 2013). Structural cardiovascular anomalies affect more than 50% of individuals diagnosed with TS (Bondy and Turner Syndrome Study Group 2007) and cardiovascular disease is a major cause of morbidity and mortality in this syndrome. The presence of webbed neck, which is indicative of foetal lymphedema, is significantly associated with coarctation of the aorta (COA) and bicuspid aortic valve (BAV) (Pinsker 2012). Additionally, the presence of neck webbing and increased thoracic anterior-to-posterior diameters are predictors for cardiovascular abnormalities. The prevalence of cardiovascular malformations varies across studies and case

Table 40.3 Clinical features in Turner syndrome and reported frequency (adapted from Gravholt et al. (2017))

Clinical appearance/abnormality		Reported frequency (% affected)
Growth failure and short stature	Prenatal poor growth Childhood failure to thrive Adult height 20 cm (average) below general female population	95
Skeletal abnormalities	Decreased bone mineral content Short fourth metacarpal Cubitus valgus Genu valgum Scoliosis Congenital hip subluxation Madelung deformity	50–80 35 50 35 10 20 5
Ovarian failure with hypergonadotropic hypogonadism	Delayed/arrested/absent pubertal development Primary amenorrhoea	75 (delay; commoner in mosaic) 95
Cardiovascular abnormalities	Bicuspid aortic valve Coarctation of the aorta Pulmonary venous drainage abnormalities Increased risk of dilatation of aorta and increased risk of dissection	15–30 7–17 3–42 100-fold increased risk Mean age 35
Metabolic abnormalities	Glucose intolerance	15–50
	Type 2 diabetes mellitus	10
	Type 1 diabetes mellitus	
	Hypertension	50
	Central obesity	
	Dyslipidaemia	50
Renal abnormalities	Horseshoe kidney Abnormalities of renal pelvis, ureters, or vessels	10 15
Autoimmune disorders	Hashimoto's thyroiditis Coeliac disease	15–30; annual incidence 3% 6
Hepatic and gastrointestinal disorders	Elevated liver enzymes	50–80
	Non-alcoholic fatty liver disease	
	Cirrhosis	
	Inflammatory bowel disease	3
Phenotypic characteristics	Lymphedema hands and feet	25
	Broad neck/webbed neck	40
	Low posterior hairline	40
	Broad/shield chest	30
	Micrognathia (small lower jaw)	60
	Multiple pigmented nevi	25
Eyes	Epicanthus Strabismus	20 15
Ears	Otitis media Hearing defects	60 30
Psychological/neurocognitive	Emotional immaturity Learning disorder Visual-spatial organisation difficulties Social interaction problems and social isolation Increased anxiety Low self-esteem	40

reports based on whether echocardiography or cardiac magnetic resonance imaging (CMR) were used. There is a complex and extensive cardiovascular phenotype seen in TS and CMR has identified that many women with TS have abnormal cardiovascular anatomy (Matura et al. 2007). Following diagnosis of TS, evaluation for both *congenital* cardiac structural anomalies, (commonly left-sided heart defects including hypoplastic left heart, COA, BAV, and anomalous pulmonary veins/venous return) and *acquired* (aortic dilation) should take place (Table 40.4).

40.6.1 Acquired Cardiac Disease in Turner Syndrome

The increased morbidity and mortality in adult women with TS is most commonly due to the increased risk of acquired cardiac abnormalities as shown in Table 40.5.

40.6.2 Hypertension

Hypertension is common in TS with a prevalence of up to 30% in children and 60% in adults often beginning in mid-childhood and increasing with age. As a result, regularly monitored blood pressure and aggressive early treatment and management of hypertension is indicated. Careful assessment or reassessment for cardiac and/or renal causes should be undertaken though hypertension may be idiopathic.

Table 40.4 Estimated prevalence of congenital cardiac abnormalities with increased incidence in women with TS (Mortensen et al. 2012)

Congenital cardiac abnormalities in TS	Prevalence (%)
Bicuspid aortic valve	15–30
Coarctation of aorta	17
Atrial septal defect	1–2
Ventricular septal defect	1–4
Partial anomalous pulmonary venous drainage	13–15

Table 40.5 Acquired cardiac abnormalities in women with Turner syndrome

Acquired cardiac abnormalities in TS	
Aortic dissection	1–2%
Ischaemic heart disease	
Hypertension	50%
Prolongation of QT interval on ECG	20%

40.6.3 Aortic Dissection

The increased risks for cardiovascular malformations compounded by renal abnormalities and hypertension leads to the increased risk for aortic dilatation and dissection in TS. The risk for aortic dissection is approximately 100-fold higher than that seen in women of similar age without TS. The aetiology is ill understood. The risk of aortic dissection or rupture is felt to be related to a high rate of generalised dilatation of major vessels (aorta, brachial, and carotid artery in TS) (Granger et al. 2016). The risk factors include bicuspid aortic valve, hypertension, coarctation of the aorta, and pre-existing aortic dilation. BAV is present in approximately 30% of patients with TS (Sachdev et al. 2008) and in one TS registry in 95% of patients who experience dissection (Turtle et al. 2015). This is a risk across the lifespan as there have been reports of aortic dissection both in children and adults with TS with and without risk factors. The consequences of late recognition can be devastating. The added vascular strain in pregnancy in women with TS significantly increases this risk further (Bondy 2014).

To minimise the risk for aortic dissection all patients should have regular and continuous cardiovascular monitoring (Granger et al. 2016) and especially closer follow-up for those with dilated ascending aorta, bicuspid aortic valves, history of coarctation, and/or hypertension. Dissection is not always preceded by progressive dilatation. Aortic parameters are corrected for body surface area (BSA) as this is a major determinant of aortic size and allows standardisation of recommendations and sequential monitoring. The ascending aorta is the most affected and informative site and dissection risk is highest for those with an aortic size index (ASI) of >/=2.5 cm/m^2. Those with an ASI of >2.0 cm/m^2 require close cardiovascular

surveillance. An ASI of >2.0 cm/m^2 (>99th percentile) is considered a dilated ascending aorta (Carlson et al. 2012). Surgical intervention is recommended for coarctation of the aorta, and/or if significant aortic dilatation develops.

Women with aortic dilation need more frequent echocardiographic/CMR monitoring of change in size, aggressive management of blood pressure, advice regarding exercise, careful assessment if pregnancy is planned, and education regarding the symptoms of aortic dissection and appropriate action to take. Classic signs and symptoms of aortic dissection include sudden onset of chest or back pain and may include shortness of breath, nausea, diaphoresis, and syncope. Wearable medical alert documentation should be worn for those identified with increased risk for dissection or rupture.

40.6.4 Conduction Anomalies

Conduction abnormalities such as prolonged QT intervals have been reported in TS including in young children (Bondy et al. 2006a). Prolonged QT intervals may occur at any heart rate and is associated with reduced heart rate variability, resting tachycardia and absence of the normal nocturnal dip in blood pressure, indicating autonomic dysregulation. In those with a prolonged corrected for heart rate (QTc) on ECG, care should be taken when prescribing medication which may further prolong repolarisation. Figure 40.2 presents the protocol for monitoring women aged over 16 years old based on the international guidelines (Gravholt et al. 2017).

Thus, cardiovascular screening is essential from the time of diagnosis and continued with regularity throughout childhood and adult life. Evaluation by a cardiologist should include regular echocardiography from childhood. In addition, CMR is recommended in older girls and women as this provides a more accurate assessment and serial measurements, in addition to reducing the error due to the common chest abnormalities in women with TS (Fig. 40.3). Repeat imaging should be performed every 3–5 years and more often if aortic dilatation or other pathology is detected and/or pregnancy or fertility treatment is considered. Blood pressure should be monitored annually and hypertension treated early and vigorously, particularly in the

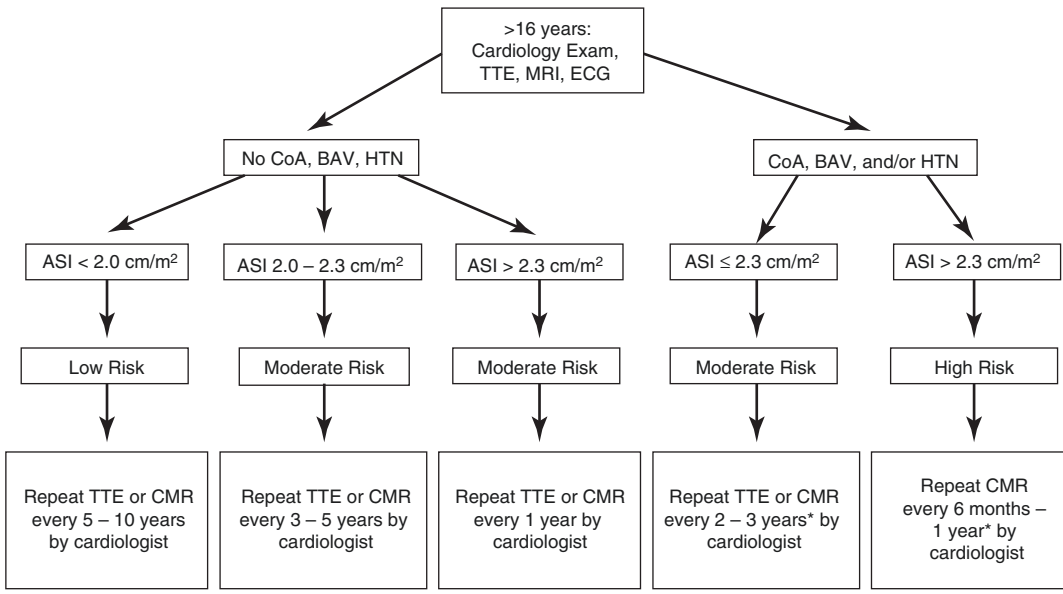

Fig. 40.2 Suggested monitoring protocol for women aged over 16. Used with permission from International guidelines 2017 (Gravholt et al. 2017). Key: *TTE* transthoracic echo, *CMR* cardiac MRI, *ECG* electrocardiogram, *HTN* hypertension, *CoA* coarctation of aorta, *BAV* bicuspid aortic valve, *ASI* aortic size index

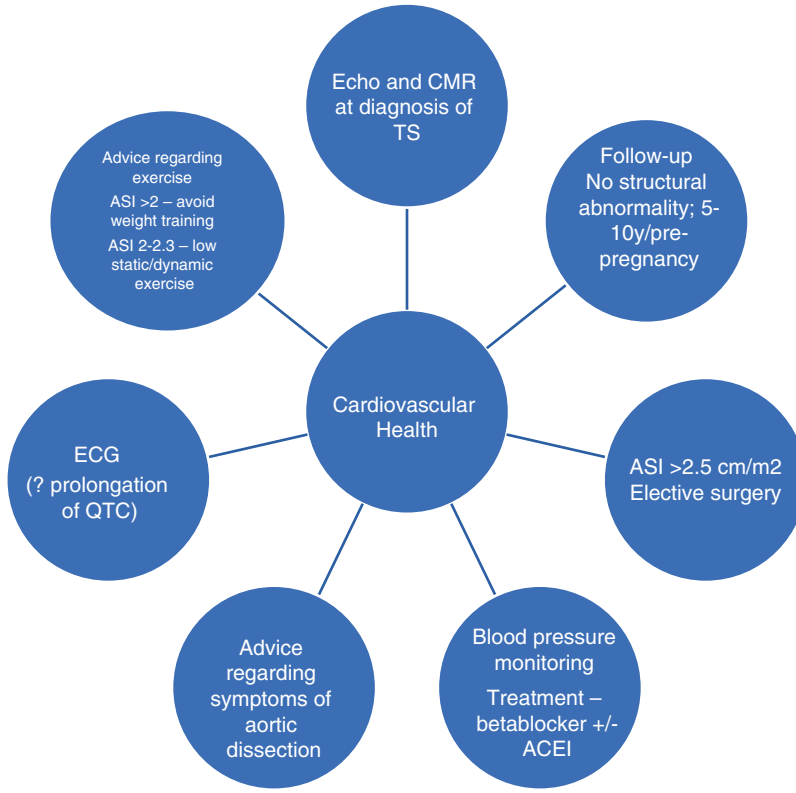

Fig. 40.3 Suggested investigations and management of cardiovascular parameters in Turner syndrome

presence of other cardiac abnormalities. According to the 2007 American Heart Association (AHA) guidelines, antimicrobial prophylaxis to prevent bacterial endocarditis is not required for valvular heart disease including those with BAV (Wilson et al. 2007).

40.7 Short Stature, Growth Failure, and Growth-Promoting Therapies

Short stature is a major clinical finding associated with 45,X karyotype and is the main phenotypic abnormality present in nearly all patients with TS. It is thought to be primarily due to haploinsufficiency (deficient expression) of the short stature homeobox (SHOX) gene expression in chondrocyte. This region does not undergo X-inactivation and it appears that two active copies of this gene are required for full expression of the protein and normal linear growth. Specific skeletal anomalies such as cubitus valgus, Madelung deformity, and shortened fourth metacarpals may also be manifestations of SHOX deficiency. Growth hormone insensitivity may also play a role in the development of short stature.

Growth failure generally begins prenatally, with eventual poor growth that may be evident within the first 3–5 years of life (Davenport et al. 1999). Final adult height is generally 20 cm below expected average female population norms. This translates to an average height of 143 cm (4′8″). It is important to note that girls and women with TS are generally not growth hormone deficient (GHD) as they have increased insulin binding protein-3 (IGFBP-3) proteolytic activity and normal to lower insulin growth factor-1 (IGF-1).

For monitoring growth, height should be tracked using a TS-specific growth curve. Lyon,

Preece, and Grant combined the growth data from four European studies representing a total of 366 patients to create the TS-specific growth chart (Lyon et al. 1985) that documents the expected growth trajectory of girls with TS on a given centile. The standard TS chart may be used from 2 years of age onward. All girls with TS should be tracked on a TS-specific growth chart which allows for the simultaneous opportunity of tracking the patterns of growth of an individual child relative to both the general female population and to other girls with TS. Of note the 50th centile of growth on the TS curve is below the fifth centile of the standard growth charts for North American females. By 5 years of age, 90% of girls with a 45,X karyotype will be below the fifth centile on non-TS female growth charts. During childhood girls with TS gain, on average, less than 5 cm of linear height each year, and this eventually translates to growth below the fifth centile, though it is not uncommon for those with mosaic and/or isochromosome karyotypes to have normal growth velocity during early childhood. For girls whose growth shows crossing of growth centiles in a downward direction on the TS growth curve consideration may be given to further assessing for growth hormone deficiency (GHD).

40.7.1 Growth Hormone Therapy in Turner Syndrome

Use of growth hormone (GH) is an approved indication of GH therapy in Europe, and North America. The optimal age of initiating GH therapy has not been firmly established and generally, treatment with GH is justified as soon as growth failure becomes evident (Davenport et al. 1999). A controlled, randomised study to final adult height of patients with TS showed a gain of 7.2 cm over a mean of 5.6 years of using higher doses of GH as compared to the usual doses used in the United States and Europe (Stephure and Canadian Growth Hormone Advisory Committee 2005). This translates into an expected approximate 1 cm of additional growth for every year on GH therapy. GH is required for a minimum of 3–4 years or more to see a meaningful impact on adult height.

Even with GH treatment, adult height remains at least 10 cm below the average height of healthy females thereby correcting up to 50% of the adult height deficit. Final adult height in TS is highest for those with a mosaic karyotype, taller stature at initiation of GH therapy, taller parents, and those that received higher dosing and longer duration of GH therapy (Hughes et al. 2011; Ranke et al. 2007; Ross et al. 2011a). Cochrane Reviews published in 2003 and 2007 reviewed four randomised control trials (RCT) using recombinant GH and noted that GH increased short-term growth in girls with TS by approximately 3 cm in the first year of treatment and 2 cm in the second year of treatment and noted the final adult height (FAH) was still more than 2 SDS below the normal population mean (Cave et al. 2003; Baxter et al. 2007).

Many jurisdictions, health systems, and/or insurance companies require evidence and documentation of growth failure or growth fall off prior to providing financial coverage, and/or initiating financially supported expensive GH therapy in TS. Subsequently, funding sources may require proof of continued enhanced growth benefit, documented in centimetres or inches over and above the pre-GH therapy growth rate.

40.7.1.1 Additional Benefits of Growth Hormone Treatment

The literature suggests that GH treatment may also confer a number of additional benefits such as improving body proportions; contributing to cardiac health by lowering diastolic blood pressure even after GH treatment has been discontinued (Bannink et al. 2009a); as well as lowering of total cholesterol and low-density lipoproteins, elevating high-density lipoproteins (Bannink et al. 2009b), and improving insulin resistance as abdominal adiposity is reduced during treatment.

40.7.1.2 Safety of Growth Hormone Treatment

The general safety of GH Treatment in the literature has been reassuring; however, observational

data indicate that when compared with children with idiopathic GHD or idiopathic short statue on GH, girls with TS appear to be at increased risk of intracranial hypertension, slipped capital femoral epiphysis, development and/or progression of scoliosis, and development of pancreatitis during treatment (Allen 1996). Data from large GH registries provide no evidence of an increase in risk of neoplasia in GH-treated patients with TS (Bell et al. 2010; Bolar et al. 2008; Tuffli et al. 1995).

The Food and Drug Administration has approved 0.375 mg/kg/week (generally given as 6 or 7 divided doses per week) for the GH treatment of TS. Higher doses of GH do not correlate with much increased height gain but do correlate with elevated insulin growth factor 1 (IGF-1) levels (van Pareren et al. 2003). As girls with TS are not GHD and may in fact be somewhat GH resistant, therapy for this population requires greater doses of GH than those used for children with GHD to impact growth. There is significant and substantial variation in GH treatment response among girls with TS, and there is no way to predict how well an individual child with TS will respond to therapy. Most will likely not achieve their genetic potential based upon mid-parental heights. In childhood, girls with TS tend to grow 2.5–4 cm or a year without GH, thus clinicians need to be mindful of this in their ongoing therapeutic assessments and not to ascribe all future growth to GH therapy if and when it has been instituted. Risks of GH therapy in TS include slipped capital femoral epiphysis and idiopathic intracranial hypertension (with persistent visual defects) that are higher than in those treated with GH for GHD and idiopathic short stature (Noto et al. 2011) and worsening scoliosis (Bell et al. 2010). Growth should be monitored every 4–6 months while on GH therapy (Gravholt et al. 2017). GH treatment is given by subcutaneous injection generally 6 or 7 days each week. This therapy requires considerable commitment by both children and families. Many families also choose not to pursue GH treatment and this is also appropriate.

The previous clinical practice of delaying pubertal development until 15 years of age with the goal of preventing earlier epiphyseal closure, to allow more time for growth to improve final adult height, is no longer acceptable as it generally failed to recognise the importance of age-appropriate pubertal development and maturation for overall general and psychosocial health.

40.7.1.3 Very Early Growth Hormone Treatment

Somewhat recent studies have reviewed the safety and efficacy of beginning GH treatment in very young girls with TS prior to the expected and eventual fall off in growth velocity. The Toddler Turner Study showed that GH rapidly normalised height standard deviation score (SDS) after 2 years of treatment for those that initiated treatment between 9 months and 4 years of age (Davenport et al. 2007). In the French Collaborative Young Turner Study Group, 80% of girls with TS who started GH at a mean age of 2.6 years of age achieved height within the normal range within 4 years (Linglart et al. 2011); however, 75% of this treatment group had elevated IGF-1 levels. The clinical implications and significance of long-term elevated IGF-1 levels in the childhood years in TS is unknown.

40.7.1.4 Early Oestrogen and Growth Hormone Treatment

Early low dose oestrogen has been studied as a way to supplement GH treatment. Some studies have trialled low dose oestrogen (oral ethinyl oestradiol) as early as 5 years of age and showed a synergistic effect of increasing adult height of 2.1 cm beyond the 5 cm of height gain expected when GH treatment was used alone (Ross et al. 2011b). However, this treatment also reported frequent findings of inappropriate early pubertal development or feminisation of young girls. The long-term consequences of early and prolonged oestrogen exposure and relation to future risk of breast cancer are unknown. At this time, use of early low dose oestrogen as a growth-promoting therapy is not supported by the literature and is not recommended (Gravholt et al. 2017).

40.7.1.5 Oxandrolone Adjuvant Therapy

The use of the synthetic anabolic steroid and derivative of testosterone, Oxandrolone, is con-

sidered to be an adjuvant therapy. Oxandralone has been shown to improve growth by acting directly at the growth plate, and by increasing IGF-I concentrations, and blocking the bone maturation effects of oestrogen which may provide up to 4 cm of growth with the use of GH therapy in TS (Rosenfeld et al. 1998). Oxandrolone is FDA-approved for treating osteoporosis, aiding weight gain, and counteracting the catabolic effect of long-term corticosteroid treatment; use of it in TS is considered off-label. Caution is required as the use of Oxandrolone may be associated with virilisation (enlargement of clitoris, deepening voice), hypertension, delay or deceleration of breast development, and liver dysfunction (Matura et al. 2007). If girls are experiencing these side effects, the doses of Oxandrolone would require reduction thereby reducing the effectiveness of the treatment. It is unclear if the taller height associated with this adjuvant treatment is due to more time for growth, more time on Oxandrolone, or more time on GH (Sheanon and Backeljauw 2015). Doses range between 0.03 and 0.05 mg/kg/day. Oxandrolone therapy would be discontinued prior to initiating hormone replacement therapy. The long-term beneficial effect of Oxandrolone on adult height in TS women has been debated due to the small sample size of studies, varied results in adult height outcomes, and the concern of virilisation due to this treatment. As it has not demonstrated a real benefit for adult height, it is not considered standard of care.

40.7.1.6 Diminished Pubertal Growth in Turner Syndrome

It is important to note that the absence of, or the generalised diminished pubertal growth spurt, with or without HRT will ultimately reduce FAH, and height predictions in TS. Ultimately, GH increases linear growth and height in the childhood years with generally rapid plateauing of height in the pubertal years. It is not uncommon to later question how much GH therapy ultimately added to FAH when tracking where a girl started (using height standard deviation scores SDS) on the TS curve, and where she ultimately ended up.

40.7.1.7 Discontinuing Growth Hormone Therapy

Discontinuing of GH therapy in TS is an individualised clinical decision. Though the literature supports the discontinuation of treatment when little growth potential remains (bone age of >/=14 years or growth velocity is less than 2–3 cm/year). Other considerations could and should sway earlier discontinuation decision-making. These include increasing body disproportion, particularly enlarged hands and feet; coarsening of facial features (rare); very elevated IGF-1; poor adherence; a voiced desire to end therapy; and contentment with current height. It should be noted that those who discontinue therapy between 14 and 15 years of age will still grow an additional 1–2 or more centimetres over the following years.

40.8 Pubertal Development, Ovarian Failure, and Ovarian Hormone Replacement Therapies (HRT)

Up to one-third of girls, especially those with mosaic karyotypes, may have normal spontaneous pubertal development (Pasquino et al. 1997). Ovarian function is generally related to underlying karyotype; those that achieve menarche or very rarely pregnancy are predominately individuals with a mosaic karyotype. Spontaneous thelarche occurs in approximately one-third of girls with TS. Normal puberty may occur and there have been some numerous reports of precocious puberty in TS underscoring the phenotypic variability that occurs whereby girls with TS may have normal functioning ovarian tissue. If gonadotropins are within the normal range for age, continued observation for the development of spontaneous puberty is appropriate.

The majority of girls with TS will have primary hypogonadism and/or primary or secondary amenorrhea related to gonadal dysgenesis. Streak gonads are seen in at least two-thirds of patients. Girls with TS have viable oocytes in foetal life however undergo accelerated oocyte degeneration that may begin as early as 18 weeks

gestation, when fibrous degeneration/erosion of ovarian follicles begins. Follicular loss continues following birth and will affect pubertal development and spontaneous menarche in a majority of individuals with TS. Elevated and/or rising gonadotropins (luteinising hormone (LH) and follicle stimulating hormone (FSH)) are associated with progressive ovarian failure. Spontaneous pregnancies are reported to be rare, in the 3–5% range. Most will require exogenous oestrogen therapy for pubertal initiation, sexual maturation and/or maintenance of secondary sexual characteristics, optimising uterine growth, attaining peak bone mass, supporting brain, and cardiovascular health.

Current recommendations encourage initiation oestrogen therapy between 11 and 12 years of age (Gravholt et al. 2017). This allows for age-appropriate secondary for those that require it here sexual characteristic development and menarche in line with peers without compromising adult height. It also supports normalised uterine and bone mineral development, improved cognitive and hepatic function and quality of life (Bannink et al. 2009b; Kanaka-Gantenbein 2006). Prolonged oestrogen deficiency in TS is linked to low BMD (Bondy 2007).

Transdermal preparations are preferred as this is more physiological and avoids excessive hepatic exposure to oestrogen (Gravholt et al. 2017). However, generally staged 17B ethinyl oestradiol use is started with 0.25 oral. 0.5 mg increased to 1.0 mg, increased to 1.5 mg, increased to 2.0 mg every 6 months then medroxyprogesterone 10 mg for 10–12 days each month once breakthrough bleeding occurs or after 2 years of oestrogen treatment (Gravholt et al. 2017). Unopposed oestrogen therapy causes uterine hyperplasia and increases risks for spontaneous and unexpected spotting and increases uterine cancer risk. Eventual transition is to monophasic oral contraceptive pill packs taken as directed or that may be used in the extended or continuous regime (using 3 or more 21 day packages sequentially before a withdrawal bleed is instituted with a no-pill or sugar-pill week). Newer continuous HRT products may be considered whereby menses occurs every 3 months or more.

Once adult replacement is reached, treatment should generally persist until menopause, around 51 years of age, unless the risk of continuation outweighs the benefits. The use of transdermal oestradiol (TDE) facilitates a more physiologic mode of delivery without hepatic first-pass metabolism effects. TDE has been reported to result in: faster bone accrual in the spine; improved uterine growth; possible increased FAH; and reduced thrombotic risk, when used. Though touted to be amenable to dose modification by cutting of the patches, to customise dosing and dose adjustment, this is not recommended by the manufactures. Transdermal gels are often well tolerated and avoid the difficulty with patches. There will be increased use of TDE in pubertal induction and adult replacement in TS in the coming years once optimal dosing has been further elucidated.

40.8.1 Hormone Replacement Therapies and Cardiac, Thrombosis, Cancer Risk

Recent studies have suggested that thrombosis may be more common than previously believed in TS raising concerns for increased thrombosis risk with HRT (Calcaterra et al. 2011). The use of transdermal oestradiol (TDE) may lower the risk of thrombosis when compared with oral oestrogens (Vrablik et al. 2008; Canonico et al. 2007). It is not uncommon for many young women with TS to have poor adherence to treatment and/or have declining use of HRT in general (Bondy et al. 2006b).

HRT treatment in TS has not been shown to increase risk for myocardial infarction or cancer risk in women with TS (Bosze et al. 2006).

A national cohort study in the UK noted that in addition to having an increased risk of gonadoblastoma, women with Turner syndrome seem to be at increased risk for meningioma and childhood brain tumours, and possibly bladder cancer, melanoma, and corpus uteri cancer. However, they were at a decreased risk for breast cancer. Reasons for these risks might relate to genetic and hormonal factors or to the effects of

hormonal treatments given to women with Turner syndrome (Schoemaker et al. 2008).

40.9 Breast Development in Turner Syndrome

Poor breast development is not uncommon in TS. This is related to the broad shield-like chest with wide spaced nipples that is remnant of foetal lymphedema whereby a tight fibrous mesenchymal layer resists growth in any or all of the breast quadrants, except at the areola which is an area of low resistance resulting in tubular breast development with large areolas for some. A paucity of medial and inferior breast tissue/skin leads to inner quadrant tightness and a tendency for areolas to face medially and inferiorly. Poor breast development may make pubertal breast staging difficult or inaccurate with or without the use of HRT. Poor breast development may have psychosocial implications for adolescents and adult women with TS affecting self-esteem and establishing intimacy. Plastic surgery consultation for breast enhancement should be considered for older teens and women who have experienced this. In many jurisdictions, surgical breast augmentation may be covered by national health systems or insurance by being categorised as a congenital anomaly or defect.

40.10 Fertility and Reproductive Assistive Technologies and Pregnancy

As a result of ovarian failure, most women with TS are infertile. The literature has noted this to be a major issue affecting quality of life (QOL). Spontaneous pregnancies occur in 4.8–7.6% of women with TS. Unfortunately, the frequency of foetal loss from miscarriage after spontaneous pregnancy is quite high and reported to be 30.8–45.1% (Gravholt et al. 2017). Also, pregnancies in TS are complicated by higher rates of foetal malformation (TS and Down syndrome). Women with TS also have higher rates of pregnancy complications including hypertension, pre-eclampsia, and aortic dissection. Delivery is frequently via caesarean section due to body habitus and complications, which increases morbidity and mortality for both the mother and foetus. In the past, TS has been categorised as a relative contraindication for pregnancy and absolute contraindication for those with documented cardiac anomaly (surgically repaired cardiovascular defect BAV, evidence of aortic dilatation, systemic hypertension) by the American Heart Association (Hiratzka et al. 2010). More recently, a risk stratification approach is accepted which involves careful assessment by a multidisciplinary team and careful cardiac imaging pre-conception (Gravholt et al. 2017).

Most women with TS are infertile due to primary ovarian failure but approximately 5% may achieve spontaneous pregnancy particularly if they have a mosaic karyotype 45X/46XX. Integrity of the long arm of the X chromosome is required for maintaining fertility (Quilter et al. 2010). Most women will therefore require assisted reproduction with in vitro fertilisation (IVF) using donor oocytes to attempt pregnancy. It is important to assess and counsel women who have not yet developed ovarian failure in order to plan pregnancy because of the risk of premature ovarian failure. Anti-Mullerian Hormone (AMH) is the best endocrine marker of the size of the population of the reserve pool of small antral follicles within the ovaries (Broer et al. 2014). In the near future, consideration of oocyte, ovarian, or embryo cryopreservation will be important in this group (Oktay et al. 2016).

Pregnancy and fertility in a woman with TS requires discussion, assessment, and education *a*. pre-conceptually, *b*. during any pregnancy, and *c*. when planning delivery of the offspring. A multidisciplinary approach with input from cardiology (including echocardiography and CMR before any pregnancy consideration), genetics, fertility, and obstetrics is essential to discuss and optimise the likelihood for safe attempts or successful outcome. Multiple embryo transfer is contraindicated. Particular risks of pregnancy for a woman with TS include progression of aortopathy with 1–3.3% risk of dissection particularly associated with assisted reproduction; due to pregnancy-associated

increased haemodynamic strain and also hormonal factors (Bondy 2014; Hadnott et al. 2011). Complications of the pregnancy itself include higher rates of spontaneous abortion, foetal anomaly, premature birth, low birth weight offspring, and cephalopelvic disproportion. Less than 40% may have an entirely normal pregnancy. While vaginal delivery may be possible delivery needs to be carefully planned with elective or emergency caesarean section anticipated for most (Hewitt et al. 2013).

40.11 Lifelong Screening and Management in Women with Turner Syndrome

Girls and women with TS need to be followed for life with regular screening not only for the management of age-appropriate issues, e.g. growth and puberty, fertility and pregnancy, but also for the development of complications, e.g. cardiovascular and autoimmune disorders (Conway et al. 2010; Culen et al. 2017) (Figs. 40.4 and 40.6).

Women with TS should be seen at an annual visit for physical examination, e.g. blood pressure, body mass index, and for biochemical investigations to assess for glucose intolerance, dyslipidaemia, liver abnormalities, and thyroid function. Education is an essential component to lifelong care with advice regarding weight management, hypertension, diabetes, hepatic steatosis, and osteoporosis.

40.11.1 Autoimmune System and Autoimmune Disorders

Many autoimmune conditions are commoner in girls and women (Table 40.6) (Bondy 2007) and their incidence increases with age. It is unclear what the underlying mechanism of the TS-associated increased risks of autoimmunity are. One theory is the higher rate of autoimmunity is related to the haploinsufficiency of immunoregulatory genes on the X chromosome, like FOXP3, which encodes a transcription factor that is critical for natural regulatory T cell control

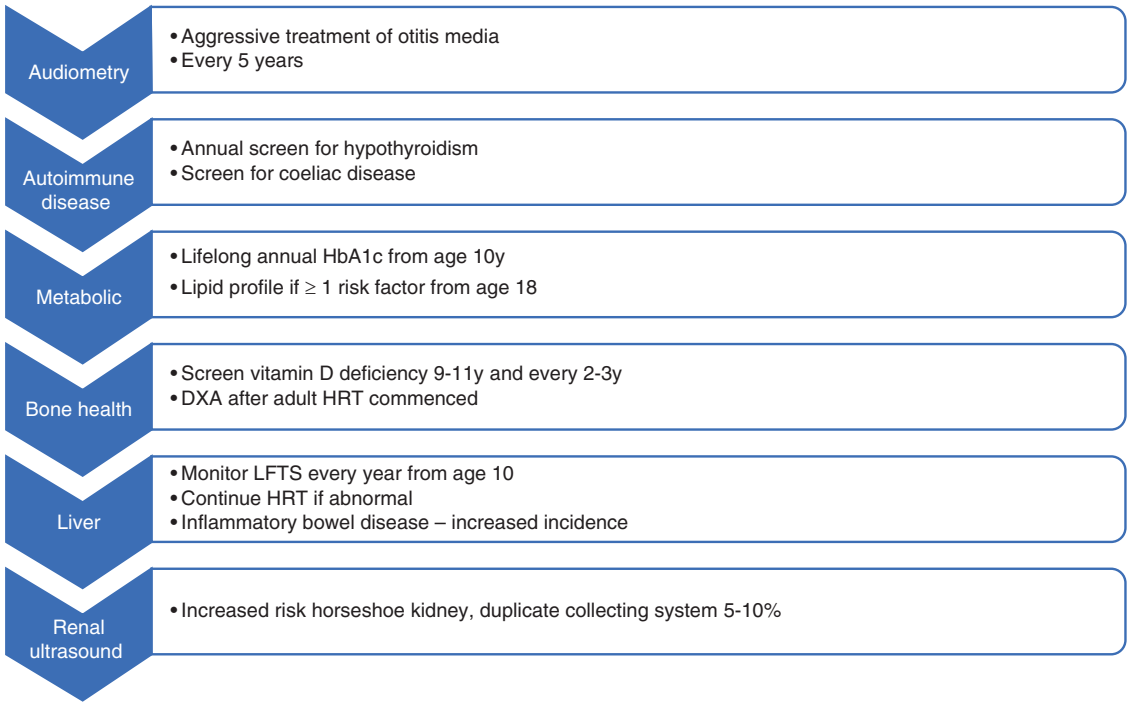

Fig. 40.4 Screening and lifelong monitoring in Turner syndrome

Table 40.6 Autoimmune conditions associated with Turner syndrome showing those which are commoner than the background female population

Increased	No increase
• Primary hypothyroidism? 3.2%	• Addison's disease
• Graves'	• Autoimmune polyglandular syndrome 1 and 2
• Coeliac disease	
• T1 DM	
• Alopecia areata • Rheumatoid arthritis	
• Uveitis	
• Inflammatory bowel disease	

(Invernizzi et al. 2005; Pessach and Notarangelo 2009) and thus may play a role in autoimmune conditions (Bakalov et al. 2012). FOXP3 deletions cause immunodysregulation, polyendocrinopathy, and enteropathy (Bakalov et al. 2012). Currently, there are at least ten genes located on the X chromosome which have been identified with possible immune regulatory functions (Pessach and Notarangelo 2009).

40.11.1.1 Autoimmune Thyroiditis

Autoimmune thyroiditis is the most common autoimmune diagnosis in TS and occurs in 10–37% with prevalence increasing with advancing age. It rarely develops in those less than 4 years of age. Hypothyroidism develops in approximately 15% of those under 18 and up to 30% in adulthood and up to 50% of adults will have positive thyroid antibodies (Elsheikh et al. 2001a). Women with the isochromosome X are at particular risk of developing autoimmune thyroid dysfunction (Elsheikh et al. 2002). Screening at diagnosis, and regular annual thyroid function screening beginning at 4 years of age, along with thyroid antibodies every 3–5 years to identify those at risk for future thyroid disease is recommended (Bondy 2007).

40.11.1.2 Coeliac Disease

Intestinal autoimmunity, such as coeliac disease (CD), is an autoimmune disease prevalent in 1–2% of Western populations. Individuals with TS are at a threefold increased risk of CD and the recommendation of active case finding for CD in TS continues to be supported by the literature (Marild et al. 2016). Regular, every 2–5 years, screening of tissue transglutaminase immunoglobulin A antibodies (tTG-IgA, usually combined with total IgA) should begin in childhood (Bondy 2007). Testing should take place regularly throughout the lifespan as classic overt symptoms of coeliac disease may not be present in TS, though tTG-IgA testing, endoscopy, and intestinal biopsy may confirm active disease.

40.11.1.3 Inflammatory Bowel Disease

The prevalence of inflammatory bowel disease (IBD) in TS approximately 3–4% whereby the rate in the general population is less than 0.5%. Onset of inflammatory bowel disease tends to be earlier with more severe symptoms in TS. Crohn's disease is more frequently diagnosed than ulcerative colitis and isoXq karyotype makes up more than half of those with IBD (Gravholt et al. 2017; Elsheikh et al. 2002).

40.11.1.4 Juvenile Rheumatoid Arthritis

An association with juvenile rheumatoid arthritis and psoriatic arthritis has been noted in TS, and it is important to have an underlying suspicion of inflammatory arthritis when there is radiologic evidence and/or clinical joint symptoms (Wihlborg et al. 1999).

40.11.2 Metabolic Issues; Diabetes, Insulin Resistance, and Glucose Intolerance

Metabolic issues, diabetes, insulin resistance, and glucose intolerance occur more frequently in TS than in the general population. Epidemiological studies have demonstrated the risk of diabetes mellitus, both type 1 and type 2, is about tenfold and fourfold higher in girls in women with TS. Annual lifelong monitoring for diabetes is essential in TS, as the risk of both type 1 and type 2 diabetes is significantly increased and occurs at a younger age, when compared to the general population (Gravholt et al. 2017). Impaired

glucose tolerance, insulin resistance, and other abnormalities of glucose metabolism are more common and found in up to one-third of women with TS. Recently presented data suggest that diabetes in TS may be different to that in the general population as TS-associated diabetes has features of both type 1 and type 2 diabetes. The association with autoimmune hypothyroidism suggests an autoimmune pathway may be more prominent than previously thought and that being overweight could compound the autoimmune risk (Cameron-Pimblett et al. 2017) (Fig. 40.5).

Overweight, obesity, and growth hormone treatment exacerbate insulin resistance. Monitoring of fasting blood glucose concentrations should be regularly completed on any who are significantly overweight, have a strong family history of type 2 diabetes mellitus, are a member of a higher risk ethnic group have signs of insulin resistance such as acanthosis nigricans and/or are on GH therapy. Annual measurement of HbA1c with or without fasting serum glucose starting at age 10 years or sooner if significant risk factors present is recommended.

40.11.2.1 Obesity

While the TS literature frequently mentions obesity associated with this syndrome, there is a paucity of literature. The prevalence of obesity in TS reflects population means in most studies. TS is a high-risk condition for complications related to the development of early cardiovascular disease and hypertension independent of obesity. Supportive active medical management is required to reduce and avoid risk factors that additionally predispose to this increased risk. Obesity increases the risk for insulin resistance in the general population and girls and women with TS should be counselled and encouraged to maintain their weight within an appropriate range for height. Girls and women with TS tend to have increased cholesterol and LDL. GH treatment and obesity exacerbate insulin resistance. Thus, counselling and guidance regarding weight control and healthy lifestyle behaviours including decreasing intake of problematic foods and fluids and maintaining increased rates of physical activity especially weight bearing exercises (Frias et al. 2003), with referral to weight management programmes if needed, should be strongly encouraged.

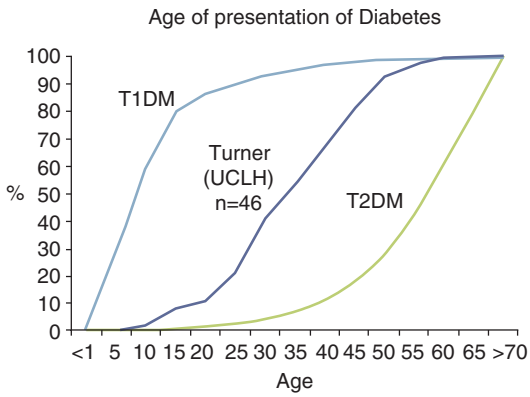

Fig. 40.5 Graph showing age of presentation of diabetes in women with TS compared with non-TS individuals (used with permission from Cameron-Pimblett et al. (2017))

40.11.3 Vascular Malformations of Gastrointestinal System

Gastrointestinal vascular malformations that may cause bleeding such as haemangiomas, telangiectasias, and venous ectasias may involve the small bowel, large bowel, or mesentery have been described in up to 7% of individuals with TS. As discussed earlier, while gastrointestinal bleeding should initially prompt an evaluation for IBD gastrointestinal vascular malformations may also need to be actively considered and evaluated.

40.11.4 Liver Function Abnormalities and Lipid Disorders

Liver function abnormalities are a common finding with increasing prevalence with age. Liver enzyme elevations (ALT, AST, GGT) tend to persist and remain stable or increase over time. The risk of cirrhosis is fivefold that of the general population (Bannink et al. 2009a). Persistent elevated liver enzyme tests warrant further investigation and referral as fibronodular disease, portal hypertension, fibrosis, or steatosis may be present. Several studies have documented improve-

ment or resolution of elevated liver enzymes with HRT regardless of the route of administration (Elsheikh et al. 2001b; Gravholt et al. 2007).

40.11.4.1 Liver Disease

Asymptomatic biochemical changes in liver function are common in TS (Fig. 40.4), and while usually benign, may in some progress to structural changes including fibrosis and cirrhosis. While obesity and insulin resistance undoubtedly lead to increased incidence of non-alcoholic fatty liver disease, more rarely vascular abnormalities and autoimmune conditions such as primary biliary cirrhosis and sclerosing cholangitis may develop (Roulot 2013). Liver biochemistry should be monitored throughout life from age 10 years with further investigation and referral to liver specialist if found to be abnormal.

40.11.4.2 Lipids

An atherogenic lipid profile is very common in TS. Hypercholesterolaemia may affect up to 50% of women with TS with higher total cholesterol, LDL cholesterol, and triglycerides than the general population. There is evidence that oestrogen modifies lipid concentrations (Taboada et al. 2011; Torres-Santiago et al. 2013).

While some studies show an elevation in cholesterol in up to 50% women with TS, others have shown no increased prevalence compared to the karyotypically normal population. The relationship with increased BMI and obesity make it difficult to establish whether TS is an independent risk for developing hyperlipidaemia. However as part of an assessment and optimisation of the potentially atherogenic metabolic profile in TS it is recommended that a lipid profile should be checked from age 18 years or earlier if there are other metabolic risk factors (Gravholt et al. 2017).

40.11.5 Ear Health

Recurrent otitis media is common in the early years in TS and is due to anatomical placement of the eustachian tubes that lie more horizontally and impede drainage. Conductive hearing loss is common due to recurrent otitis media and middle ear effusions (Davenport et al. 2010) in childhood and progressive mid-frequency sensorineural hearing loss development, in the 1500–2000-Hz range often begins in childhood and will affect up to 50% of adult women with TS. An audiological assessment should take place at diagnosis and regularly thereafter.

There is a high prevalence of the development of a cholesteatoma in Turner syndrome particularly with 45X and isochromosome Xq karyotypes (Lim et al. 2014). Early recognition, otolaryngology referral, and surgical treatment of this destructive erosive and expanding growth that consists of keratinising squamous epithelium in the middle ear and/or mastoid process is required for this persistent disease. A cholesteatoma may result in destruction of middle ear ossicles causing hearing loss and may grow through the base of the skull. These may become infected and result in chronically draining ears and conductive hearing loss, classic signs of this condition.

40.11.6 Skeletal Manifestations in Turner Syndrome

Congenital developmental dysplasia of the hip occurs more frequently in TS than in the general population (Saenger et al. 2001) and predisposes individuals to arthritis of the hips. Scoliosis and kyphosis is being increasingly recognised as affecting a larger percentage of children with TS than previously thought. Scoliosis develops in up to 40% and kyphosis in up to 50%. The use of GH in girls with TS and scoliosis may exacerbate single or double curves. While the presence of scoliosis in childhood does not preclude the use of growth-promoting therapies it does warrant close monitoring during therapy (Bondy 2007) and referral to orthopaedic specialists if or when curvature progresses. Other abnormalities of the skeleton include short neck (hypoplasia of the neck vertebrae), Madelung deformity (bayonet deformity), cubitus valgus (increased carrying angles in greater than 50%), and genu valgum (knock-knee) causing an in-toeing gait or genu

varum (bow leggedness), short fourth metacarpal or metatarsal bones.

40.11.6.1 Osteoporosis

Although there may be an element of delayed bone maturation, bone density is lower in TS than the normal population when corrected for height and skeletal maturation (Lanes et al. 1999). Women with TS have reduced bone mass associated with increased risk of fracture, and assessment of bone density and treatment of osteopenia/osteoporosis is therefore essential. Clearly, GH and oestrogen replacement during childhood and adolescence are crucial for achieving peak bone mass. Adolescents, who undergo puberty spontaneously and continue with normal pubertal development have been noted to have normal BMD into early adulthood (Carrascosa et al. 2000). Optimisation of oestrogen replacement through adulthood is essential and is associated with higher bone mineral density (BMD). Regular screening for vitamin D deficiency commencing at age 9–11 and continuing throughout the lifespan with replacement as required is a key recommendation in the recent International guidelines (R 6.14) (Gravholt et al. 2017; Granger et al. 2016). Bone densitometry assessment after transition to the adult clinic allows risk assessment, monitoring, and treatment where appropriate.

40.11.7 Renal/Urinary Findings in Turner Syndrome

Congenital malformations of the renal/urinary system are 10 times more likely to be present in TS (25–40% of patients) (Flynn et al. 1996) compared with 3–4% in the general population. Renal function tends to be normal despite the high incidence of renal tract abnormalities in TS (Nathwani et al. 2000). The common abnormalities include collecting system malformations (20%), horseshoe kidneys (10%), mal-rotated kidneys, and other positional abnormalities (5%). Anomalies associated with the obstruction of the ureteropelvic junction can produce clinically significant hydronephrosis and increased risk for pyelonephritis.

Three primary types of defects are recognised according to the stage of gestational development in which the defect occurs. Defects of the collecting system occur in the first 5 weeks of gestation and these include partial or complete duplications. Generally, renal duplications are of no clinical importance. The second type of defect occurs during the period from 5 to 9 weeks of gestation and relates to the position of the kidneys and includes horseshoe kidney, ectopic, or mal-rotated kidneys. Finally, the third type of defect develops during the end of the first trimester and involves abnormalities of the renal vascular supply.

With the renal fusion of a horseshoe kidney, the kidneys lie vertically instead of obliquely and are joined at their lower poles by midline parenchymal tissue (the isthmus). The horseshoe kidney lies lower in the abdomen (at L3 to L4 vertebral level). With a horseshoe kidney the normal rotation of the kidney is also prevented and the renal pelvis lies anteriorly with the ureters also passing anteriorly over the kidneys and isthmus however enter the bladder normally. Patients with horseshoe kidney can be reassured that these kidneys generally function normally however, symptoms such as abdominal or back pain should raise the question of urinary tract obstruction. Also, these patients require information and about the risks of trauma as there is increased risk of renal injury associated with abdominal trauma as the kidney is not protected by the ribcage.

For horseshoe kidney, the collecting system of each half is usually normally developed and the renal system is also generally normal. However, because the ureters tend to run anterior to the fused portion of the kidney, urine flow may be impeded and ureteric obstruction or secondary urinary tract infection may develop. If severe or inadequately treated, hydronephrosis or pyelonephritis may result. Patients with structural renal abnormalities are at increased risk for urinary tract infections and vesicoureteric reflux. Renal ultrasonography for examination of renal abnormalities at the time of diagnosis is indicated with referral to a Nephrologist Specialist if needed for consultation and/or management of renal disease.

40.11.8 Ocular Abnormalities

Ocular abnormalities are common in TS and the detection and surveillance of eye abnormalities is necessary in all patients diagnosed with TS. The prevalence of visual disturbances in TS is significant as near-sightedness affects 40%, farsightedness 13%, strabismus 15–30%, amblyopia >15%, epicanthal folds up to 45%, ptosis up to 30% hypertelorism 10%, and red-green colour blindness 8–10% (Chrousos et al. 1984; Wikiera et al. 2015). There is no known association between the presence of eye defects and karyotype. Case reports have also noted keratoconus, glaucoma, cataracts, and retinal detachments in TS. Regular ongoing evaluation by an eye specialist optometrist, ophthalmologist will provide surveillance, prevent irreversible deterioration of eye function and permanent poor vision and is recommended from age 12 to 18 months, at the time of diagnosis, and regularly during paediatric years annually and as indicated in adult years.

40.11.9 Lymphedema and Dermatological Related Issues

40.11.9.1 Lymphedema

Abnormal lymphatic development in utero is responsible for many of the traits and physical manifestations in TS. Lymphedema is more common in girls with 45,X karyotype, in the newborn period and tends to regress over time particularly in the first 2 years. Jugular lymphatic obstruction during embryogenesis and early gestation results in nuchal cystic hygroma (Lowenstein et al. 2004). When collateral lymphatic drainage develops, the cystic hygroma resolves leaving a webbed neck (pterygium coli) and the cystic hygroma is no longer present at birth. Referral to Plastic Surgery may be considered for surgical options for improving neck aesthetics and function if limited range of motion, due to moderate to severe webbed neck is present.

Congenital lymphedema of the hands, and feet is present in over 60% of females with TS. Lymphedema may recur or occur at any time especially during puberty or with hormonal treatment such as growth hormone or ovarian stimulation therapy (Bondy 2007) and is caused by a failure of the lymph-conducting system that may be due to failure of lymph reabsorption by the initial lymphatic capillaries (Atton et al. 2015). Lymphedema may be controlled in most cases by support stockings, lymphatic drainage massage therapy, and/or physical therapy. Aggressive therapy should be considered when prolonged swelling leads to pain, skin changes, poor circulation, and/or infections. A four-step intervention with attention to skin and nail care, compressive massage, compression bandaging, and remedial exercise programming may be required (Bondy 2007) to reduce oedema, improve circulation, and reduce risk of infection. Vascular surgery should be avoided when possible.

A low posterior hairline or hair that extends onto the back of the neck, occurs in 40% of girls in TS. Bushy eyebrows and low-set ears are also associated with congenital lymphedema. This develops secondarily to lymphedema and cell migration abnormalities and is thought to be affected by stretching of the skin by the underlying cystic hygroma at around 10–12 weeks gestation with hair follicles growing downward into the underlying tissues. The bushy eyebrows and low-set ears have been attributed to the altered tension on the skin during this same period of development.

40.11.9.2 Nail Dysplasia

Abnormal nail formation or nail dysplasia is found in approximately 70% of those with TS. Peripheral lymphedema is also implicated in the developmental abnormalities of the nails which may be small, narrow, thin, curved, and deeply inserted (Kaplowitz et al. 1993). Nail dysplasia may be particularly marked in the feet with some individuals having very small or complete absence of toenails. Good foot care and well-fitting shoes are important. Individuals with short broad feet may have difficulty purchasing properly fit shoes leading to increased susceptibility to ingrown toenails and other toe, foot, nail, skin problems, and infections. This may lead to

increased risk of infection and cellulitis especially when coupled with lymphedema.

40.11.9.3 Moles and Nevi

There is an increased number of pigmented nevi seen in TS of which the cause is unknown. These nevi have generally been reported as benign melanocytic nevi in 25–70% of individuals with TS (Becker et al. 1994). As with the general population, nevi often increase in number and size throughout childhood and particularly during puberty and adolescence. While there is increased prevalence of nevi in TS there is not an increase in melanoma, and this has led to theories about a tumour suppressive factor operating in TS (Gibbs et al. 2001). Overall, an increased number of nevi is the strongest established risk factor for melanoma (Lowenstein et al. 2004) and as such individuals with a large number of nevi should learn the ABCDEs of mole assessment and have regular assessment of their nevi by their health care provider (HCP) and/or dermatologist. Studies of GH and OHR have failed to confirm any pathologic or harmful impact of these therapies on the number and density of melanocytic nevi (Zvulunov et al. 1998; Wyatt 1999).

40.11.10 Orthodontic and Dental Manifestations in Turner Syndrome

The orthodontic manifestations of TS are well documented and require ongoing evaluation and active management. The mandible in many is positioned posteriorly and is hypoplastic compared with the rest of the face. As a result of this underdevelopment and posterior positioning of the mandible, retrognathia and micrognathia are common. Micrognathia has been reported in more than 50% of TS patients. The palate in TS has been described as high-arched, with either an inverted U-shape or narrow vault. Malocclusion with increased incidence of anterior open bite and lateral cross bite (maxillary teeth are positioned inside the mandibular teeth) when the mouth is closed may be seen. It is not uncommon for girls with TS to have advanced dental age which contrasts with the other conditions of delayed skeletal maturation. Early palatal expansion corrects lateral cross bite. Shortness of dental roots and increased risk for root resorption in TS is problematic for orthodontic movements.

Early paediatric specialty dental and orthodontic referral is indicated in TS with regular follow-up and communication regarding any active growth therapies being utilised (GH or anabolic steroid) as these therapies affect craniofacial growth. As growth hormone improves mandibular growth, it may help to improve and/or normalise retrognathia. Active orthodontic therapy is usually delayed until completion of growth-promoting therapies to avoid the need for re-treatment. As a result of the known craniofacial abnormalities in TS, these patients often benefit from meeting the inclusion criteria for evaluation, surveillance, and active treatment for dental and orthodontic services from various health systems (national, provincial, state) cleft lip and palate programmes funding. Access to these programmes may provide significant financial support for dental and/or orthodontic treatment.

40.11.11 Intelligence, Psychological, Neurocognitive, and Social Issues

Intelligence is within the normal population range; however, many with TS are at higher risk for neurocognitive, behavioural and social domain impairments (Frias et al. 2003), and educational deficits. Non-verbal IQ may be lower than verbal IQ. The learning disability profile associated with TS is unique and may require special accommodations and/or modifications in education in many cases. Verbal abilities or skills are usually quite strong. Many are described as avid early readers and perform well with spelling. There is a high degree of individual variability in the somatic, cognitive, and psychosocial phenotypes (Gravholt et al. 2017). Many are very successful with post-secondary education at colleges or universities.

Selective impairments include non-verbal or specific neurocognitive deficits or challenges particularly with visuospatial, executive function, and/or a non-verbal learning disorder. Those with a ring chromosome ring X chromosomes may have severe mental retardation because ring chromosomes fail to undergo X-inactivation.

Visuospatial deficits tend to be in spatial memory and orientation. Many will also have issues with directional sense, knowing their right and left orientation, extra-personal space perception along with spatial reasoning and visual sequencing (Hart et al. 2006). Visuospatial processing impairments are intensified when tasks require increased working memory. Tasks that involve aspects of driving, finding one's way around new or familiar places, judging distances or geometric mathematics may pose problems.

Executive functioning deficits may include difficulty on tasks of planning, fluency of communication, poor working memory and focusing, which is needed to solve complex problems in a step-by-step fashion.

Non-verbal disabilities include issues with being able to understand incoming visual and spatial information such as being able to recognise what and where an object is, and visualising objects changing position. Some may have difficulties with global processing and "seeing the whole picture".

Genomic imprinting may be relevant, as those who have maternally derived X chromosome have been shown in some studies to have deficits or impairments in social competence and in social adjustment and verbal function compared to those with a paternally derived X chromosome (Skuse et al. 1997). This implies that social functioning may be influenced by an imprinted gene on the X chromosome that is switched off when this gene is inherited from the mother.

Behavioural issues differ by age, younger girls may be very hyperactive, immature, and not particularly cognisant of social cues, and therefore socially vulnerable. In contrast older girls may exhibit continued immaturity, or be inhibited and shy, and experience anxiety, depression, and difficult or unsatisfactory peer relationships and be more socially withdrawn than their peers. There is no evidence of significant psychiatric disorder in TS.

Clinicians working with individuals with TS should be attuned to the neuropsychological phenotype in TS which may significantly impact their patients' ability to successfully navigate social, home, school, personal, and work environments (Hong and Reiss 2012). Any child who is not achieving appropriate developmental or educational milestones deserves assessment, intervention, and regular follow-up from developmental and/or educational specialist services. Neuropsychological and/or educational testing is recommended before enrolment in school or when educational issues become apparent. Re-evaluation will be needed at identified intervals throughout their education. Strengths will be recognised and identified issues and areas for development should be addressed by specific implementation of educational strategies both in the school and home setting.

Psychosocial assessment and support addressing home environment, friends and relationships, and employment should be considered at each visit. Discussions regarding ongoing health surveillance and the importance of lifelong follow-up is essential. Population studies show a broad variation in socioeconomic profile, with a reduced prevalence of TS women in relationships with a partner (Stochholm et al. 2006). While educational attainment does not vary from the background population, employment, and income tend to be lower. A recent 6-year follow-up of women with Turner syndrome showed that women with TS were more likely to live alone and have fewer sexual partners and less sexual confidence compared with controls (Fjermestad et al. 2016). In addition, they had lower self-esteem and life satisfaction. Gender dysphoria is uncommon.

Targeted clinic psychology support is beneficial and optimal for the wide-ranging problems that may exist. Support groups can be invaluable in providing peer group support, information, and practical management advice (Fig. 40.6).

Fig. 40.6 Spectrum of the many aspects of lifelong management in women with Turner syndrome

40.12 Transition to Adulthood

Adolescence and the transfer of a young woman with TS from the paediatric service to adult clinics is a critical time when many young women may be lost to the recommended targeted lifelong management and health surveillance. There is a risk of increased morbidity and mortality associated with lack of follow-up in TS. The emphasis to engage adolescents early on and develop their abilities and knowledge to actively plan and participate in their own care is needed. There are many differences between paediatric and adult health care systems. The paediatric clinic is involved in GH administration, introduction of oestrogen and induction of puberty, initiation of screening for cardiovascular health and autoimmune conditions, and management of musculoskeletal challenges all with their supportive and responsible parent(s) by their side. In contrast, the adult clinic focuses interactions and discussion with the patient themselves rather than the parent and the patient is expected to be a participating partner in her health care, arrive prepared with specific questions for her team and make decisions about treatment by herself. This may be problematic for some young women who still may require parental involvement, due to the intellectual and related functional capabilities and the complexity of number of health issues that may be affecting them. Continued discussion and education surrounding genetic, fertility, and lifestyle issues is essential, along with recognition of potential psychosocial challenges (Culen et al. 2017). It is crucial that care-givers recognise the importance of creating an open dialogue and willingness to address sensitive issues such as sexual health, risk-taking behaviours, sexuality, romantic relationships, and self-esteem in addition to the specific TS health issues and health surveillance recommendations for each individual patient.

40.13 Nursing and Team Considerations

The endocrine nurse plays a crucial role in all phases of the health care journey for the girls and women with TS, their families, and the health care team by providing the appropriate and recommended education and support across the lifespan. An individualised family-centred, multidisciplinary team approach is required to provide medically complex care and long-term surveillance. The endocrine nurse will be able to provide general, TS specific, and detailed health condition information, anticipatory guidance, education and emotional support, and mobilise psychosocial support. The endocrine nurse will participate in and facilitate the coordination and management of multidisciplinary team-related care and ongoing health surveillance and identify when additional evaluations and early interventions may be appropriate for each individual patient. The nurse will recommend and support appropriate strategies for optimal therapy adherence and reinforce the importance of wearable medical alert documentation when needed. The nurse will connect individuals and families to external information and support networks including the Turner Syndrome Support Society (TSSS). Education, information, and provision of useful resources when appropriate throughout the lifetime of a woman with TS is invaluable. The key to successful management of a woman with TS is the relationship which continues throughout their life. Continuity of follow-up, adjustment of direction of care according to the particular stage in their life, and the ability to detect and address sensitive issues is essential.

40.14 Working with Patient Advocacy Groups

Patient Advocacy Groups play a crucial role in improving education and awareness of rare conditions such as Turner syndrome. In Box 40.1, Arlene Smyth describes how the Turner Syndrome Support Society (TSSS) UK was developed and the invaluable resources they provide for patients and health care professionals.

Box 40.1 Case Study and Resources Provided by the Turner Syndrome Support Society (TSSS) UK (Published with Consent)

Sadly, one of the most common calls for supporting the Turner Syndrome Support Society [UK] [TSSS] is the late diagnosis of girls with Turner syndrome [TS] many girls are not diagnosed until they are 15–21 years old. This is a very difficult age for any girl to cope with. For girls with TS, a late diagnosis is devastating to be told that you may be infertile and that you need to choose what is most important to you "height or pubertal development" is very difficult. Parents are left feeling frustrated and guilty as many of them sought advices from their GPs and were told that she is just a late developer and thus missed out on vital timely treatment.

Parents and health care professionals need to know about normal pubertal development to act if there are no signs of breast bud development by 12 or 13 at the latest. There is a health reason and they should be referred to a Paediatric Endocrinologist. The vast majority of girls with TS are beautiful normal looking girls who are shorter than their peers and have no signs of puberty or their puberty started and then stopped. Many of the documented features are not seen in all girls, please see "Diagnosing Turner Syndrome" and other information leaflets available www.tss.org.uk.

The Turner Syndrome Support [UK] was set up to support those affected by Turner syndrome. When my daughter was diagnosed at birth with TS. I wanted her to have friends and I wanted to meet other families too. Initially, it was just friendship and support, then I started to learn more about Turner syndrome and realise what a complex condition it was. I was lucky and met many amazing girls and women

with TS. They were kind and opened up to us about how difficult life could be, in turn that allowed us to come up with strategies to help and support each other.

The TSSS has grown and developed over the years. We have worked with health care professionals to help inform girls and women with TS so they can access the best possible medical care. Ensuring they understand the reason for taking their treatments and the long-term benefits to them. We produce some of the best information on Turner syndrome all checked and approved by our Clinical Advisory Board for accuracy. We have a wonderful relationship with our members we host Open Days, Social Events, and annual conference. We have a large social media presence and regional friendship groups ran by our volunteers.

Being diagnosed with a rare condition in its self is isolating, frightening, and you have so many unanswered questions. Not always about the medical issues but often about behaviour, feelings coping with TS. By helping and supporting families, we provide a service that compliments the excellent care available to those with TS once diagnosed. Together we can help them be the best they can be. This is a quote from one of our teen members who was diagnosed at 12 years old. She was asked what the TSSS meant to her. "The people I have met a long away have changed my life in ways I could not have imagined. I am proud to say I am part of the best family in the world, the TSSS Family a bond so close it can never break. That is what the TSSS means to me".

We are proud to work closely with patients, their families, HCP, and others such as teachers. Our website contains a wealth of information free to download. We have a close bond with other TS groups throughout the world and worked collaboratively on writing guidelines and attending conferences.

The recently published *patient* directed advice and guidelines to complement the specialist medical publication is invaluable (https://tss.org.uk/downloads/patient_family_guidelines.pdf) and the Turner Syndrome Support Society (TSSS) UK and counterparts in other countries provide a very helpful resource and support. Moreover, the TSSS developed in collaboration with the author and other health care professionals a cardiac alert card (Fig. 40.7) for girls and women with TS to carry in their wallet to alert them and the emergency services, doctors, and nurses of the symptoms, investigations, and urgent management if clinical features of heart dissection develop.

40.15 Conclusion

Turner syndrome is the commonest karyotype abnormality affecting women, and associated with a broad spectrum of clinical abnormalities which present different challenges throughout a woman's life from birth to older age. Successful management requires increased ascertainment and earlier diagnosis of the condition, continuity of follow-up from childhood into and throughout adulthood, lifelong monitoring and the treatment where required of the various complications that arise in addition to the provision of appropriate social and psychological support throughout a woman's life. In the future,

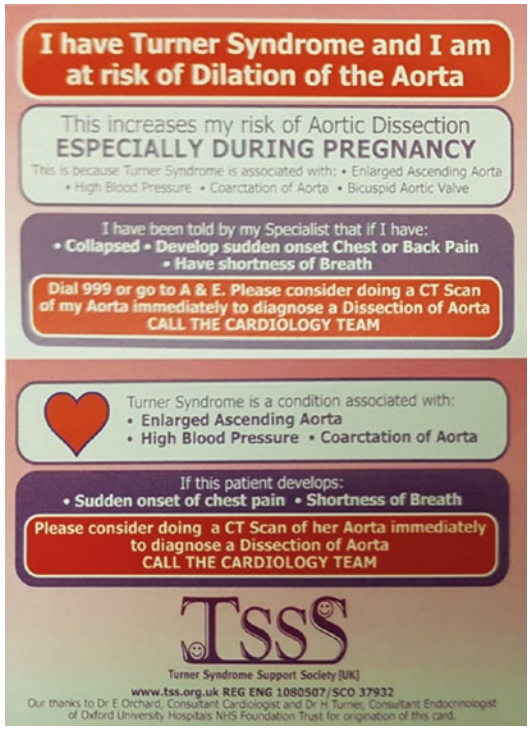

Fig. 40.7 Cardiac alert card for girls and women with TS. Used with permission from the Turner Syndrome Support Society [UK], available from https://tss.org.uk/information/healthcare

the increased use of a multidisciplinary team approach and developments in genetic understanding may help target appropriate follow-up in those at particular risk. Developments in treatment of fertility such as cryopreservation and improvements in cardiac imaging or treatment may lead to increased options for pregnancy and a reduction in the increased morbidity and mortality in women with TS.

Acknowledgments With special thanks to Arlene Smyth, Executive Officer, Turner Syndrome Support Society [UK] www.tss.org.uk for her contribution to this chapter with a case study and information on the Patient Advocacy Group.

Abstract

Menopause and the years preceding it are associated with a wide variety of symptoms that are often missed in a routine consultation. Informed choice regarding hormone replacement therapy and lifestyle options can alleviate much of the burden of the menopause when this change in life has a major impact on well-being. Premature ovarian insufficiency is one of the most difficult conditions in reproductive medicine. It occurs in 1% of women. The impact of the diagnosis can dissipate with time assisted by full evaluation and discussion of the implications of POI. The role of the nurse includes assessment of symptoms, discussion of implications for fertility as well as

assisted fertility treatment options and then to give guidance through choices of sex steroid replacement. Ongoing education is required in order to adapt the level of information and types of treatment according to life circumstances. Women with ovarian insufficiency frequently feel isolated or that there is insufficient time in a clinic visit for full discussion. Nursing input can overcome some of these limitations.

Keywords
Autoimmunity · Oestrogen and androgen treatments · Late effects of cancer · Ovum donation

Abbreviations

AMH	Antimullerian hormone
APS	Autoimmune polyglandular syndromes
BMI	Body mass index
COCP	Combined oral contraceptive pill
DXA	Dual X-ray absorptiometry
Fra-X	Fragile X
FSH	Follicle-stimulating hormone
HRT	Hormone replacement therapy
LH	Luteinising hormone
LOR	Low ovarian reserve
POI	Premature ovarian insufficiency
TS	Turner Syndrome

Key Terms

- **Premature ovarian failure:** A term describing ovarian insufficiency now considered obsolete.
- **Primary amenorrhoea:** Failure for menstruation to occur in adolescence.
- **Secondary amenorrhoea:** Absence of periods for greater than 6 months occurring after menarche.
- **Hypergonadotrophic Hypogonadism:** The finding of each deficiency in the presence of raised concentrations of LH and FSH.
- **Gonadal dysgenesis**: Early onset ovarian insufficiency causing primary amenorrhoea usually with a genetic cause such as Turner Syndrome.
- **Low ovarian reserve**: Women with regular cycles but raised FSH and low AMH usually in the context of infertility.
- **Early menopause**: Menopause before the age of 45.

Key Points

- Menopause usually occurs at the age of 51 and premature ovarian insufficiency (POI) is defined as hypergonadotrophic hypogonadism before the age of 40.
- Ovarian insufficiency requires consideration of fertility options, sex hormone replacement therapy, and psychological support. Nursing assessment should include an evaluation of the priorities in each of these domains at every clinic visit.
- Ovarian insufficiency has wide-ranging effects on quality-of-life and relationships requiring counselling and help with decision-making as well as support at the time of an often traumatic diagnosis.
- There are a number of options for sex steroid replacement comprising oestrogen, progestogen, and androgens. Assessment of optimal individualised hormone replacement treatment is based on quality of life taking careful note of details in history including mood and sexual function.

41.1 Introduction

The ovary is a unique organ in the body with a defined lifespan of approximately 50 years. The life expectancy of the ovary is determined by optimal germ cell development in utero and factors affecting programmed cell death throughout life. The peak germ cell number occurs at 6 months

gestation with >700,000 eggs. Once this maximum number has been achieved, the body is no longer able to make new oocytes and the total number gradually decline. It is estimated that nearly 50% of germ cells have been destroyed by the age of menarche, and by the onset of menopause, only 1000 remain. Throughout life, therefore, germ cell apoptosis takes place at a rate of approximately 25–150 lost per day. As the number of germ cell falls, a critical point is reached when periods stop with subsequent reduction in circulating oestrogen, and thus lesser extent testosterone, concentrations.

The menopause is defined by the last menstrual period and occurs at an average age of 50.7 years in the western world (van Noord et al. 1997). Premature Ovarian Insufficiency (POI) is defined as amenorrhoea with raised FSH before the age of 40. POI occurs in approximately 1% of females and becomes increasingly rare in younger age groups. For instance, in presence of normal karyotype, 1:1000 of women at 30 has POI, and 1:10,000 at 20 and 1:100,000 of women will present with gonadal failure and primary amenorrhoea (Fig. 41.1). POI accounts for 20–50% of females presenting with primary amenorrhoea and 10% of those with secondary amenorrhoea (Master-Hunter and Heiman 2006).

The term premature ovarian insufficiency is preferred to premature ovarian failure because it is an all-encompassing term that accounts for the variable course and occasional remission (Welt 2008a). The term hypergonadotrophic hypogonadism is also used to emphasise ovarian origin, whereby the raised concentrations of LH and FSH contrast from low gonadotrophins in hypothalamic or pituitary causes of hypogonadism. Gonadal dysgenesis refers to hypergonadotrophic hypogonadism with a known genetic cause such as an abnormal 46XY or 45X karyotype and implies that ovarian development was halted at an early stage of embryonic development. In the case of Turner Syndrome, it is thought that early ovarian development is usually normal, but that the chromosome anomaly leads to rapid germ cell apoptosis (Reynaud et al. 2004).

41.2 The Menopause

Menopause describes the end of natural reproductive life when periods stop. The process can be abrupt, but in many cases symptoms precede amenorrhoea by months or even years. The age of menopause varies between 45 and 60 with daughters tending to follow mothers in many

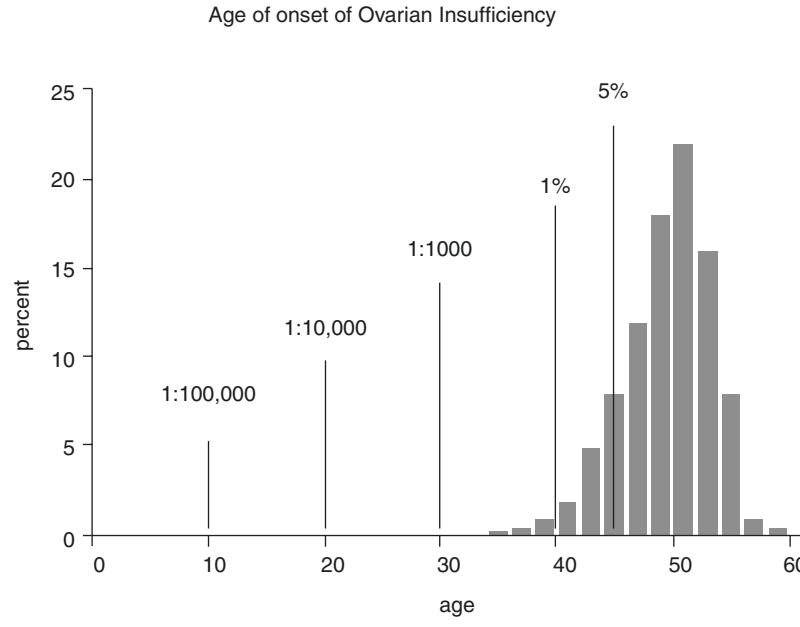

Fig. 41.1 A graph of the distribution of the age of onset of amenorrhoea according to the lifespan of the ovary

families (Davis et al. 2015). The interval between periods usually shortens as the menopause approaches from an average of 28 days often to 21 days. The diagnosis of menopause may not be obvious in women taking hormone treatments for period control or who have had a hysterectomy. In addition, nonspecific symptoms such as joint and muscle stiffness, loss of memory and concentration, or simply low mood can occur in the absence of classical symptoms. Oestrogen deficiency should be considered as a possibility for anyone experiencing new onset of symptoms after the age of 40. The diagnosis of menopause is mainly based on history and, for the majority of women, no diagnostic test is required. A measurement of FSH can be unreliable as it may not correlate with symptoms of the premenopause.

The majority of women experience some symptoms of the menopause which often gradually diminish over several years (Monteleone et al. 2018). In a proportion of women, disabling symptoms can be lifelong requiring indefinite treatment with HRT. Treatment of the menopause is individualised and may include lifestyle, hormone-based treatments, counselling, and treatments to improve sexual function. A great deal can be achieved with detailed information and advice. A discussion regarding the spectrum of symptoms that are associated with oestrogen deficiency can be reassuring and will ensure that no hidden symptom is left untreated. Symptoms relating to change of mood, libido, sexual function, and urogenital dysfunction may need to be sought by direct questioning.

The risks and benefits of hormone replacement therapy require discussion as this treatment is not essential and nonpharmaceutical alternatives are available. Studies which highlighted the risks of HRT between 2002 and 2004 resulted in a decline in the use of HRT (Sassarini and Lumsden 2015). Subsequent assessments, however, have shown that the risks of HRT may have been overestimated. In addition, the risk of stroke can be eliminated by the use of transdermal oestrogen instead of oral oestrogen, which formed the basis of most of the early HRT studies.

41.3 Premature Ovarian Insufficiency

41.3.1 Clinical Evaluation and Diagnosis of POI

The clinical presentation of POI varies depending on the age of presentation (Conway et al. 1996; Nelson 2009). Very early onset in adolescence leads to pubertal delay puberty and primary amenorrhoea. After menarche, the presentation is with symptoms of oestrogen deficiency and secondary amenorrhoea or as part of a work up for irregular periods or infertility. In addition, POI can be part of clinical syndromes that can be genetic, such as Turner Syndrome, or autoimmune.

The formal diagnosis of POI is based on the presentation of amenorrhoea with finding of elevated serum FSH concentrations (FSH > 25 IU/L) on at least two occasions separated by 4 weeks (Webber et al. 2016). The requirement for two samples takes into account the fact that ovarian function can fluctuate and end raised FSH and can be a transient phenomenon. In addition, because the diagnosis has such severe implications, certainty of the diagnosis is required. While it is the usual expectation that the condition will be permanent, some women follow an unpredictable course of relapse and remission particularly in the first year after diagnosis (Bachelot et al. 2017). There is a commonly quoted pregnancy rate of approximately 1–5% in women with POI and it is, therefore, important to inform women with POI of this phenomenon so that they use contraception when appropriate. Because of this background fertility, case reports of effective treatment of POI must be viewed with caution. Fluctuating ovarian function probably accounts for many cases where the older term ‘resistant ovary syndrome’ was applied and it is now understood that ovarian biopsy is not predictive of remission and should no longer be included as part of the work up of POI (Webber et al. 2016). Antimullerian hormone has found a place as a diagnostic marker of low ovarian reserve, but once the FSH concentration is raised, AMH offers little extra information (Visser et al. 2012).

A careful family history can identify other affected female members in as many as 30% of cases (van Kasteren et al. 1999a), and in this situation, more genetic screening is indicated and genetic counselling for relatives may be appropriate. A karyotype should be performed in anyone with a positive family history because small chromosome deletions can be inherited. Fragile X (Fra-X) premutation analysis should be offered to all women with POI because of its value in detecting a new pedigree for the prevention of fragile X syndrome (Conway 2010; Mila et al. 2018).

Oestrogen receptors are widely distributed throughout the body and the effects of oestrogen deficiency are diverse. While the classical symptoms of hot flushes, sleep disturbance, and vagina dryness are obvious, more subtle changes in mood and musculoskeletal pain are often unrecognised as part of this symptom spectrum. A careful history listing any change in well-being, no matter how minor, that coincides or precedes amenorrhoea will provide a useful guide to optimising hormone replacement therapy.

The major medical issues for health surveillance in women with POI revolve around the quality of life and bone protection offered by hormone replacement therapy (HRT). Oestrogen deficiency is a risk for osteoporosis and DXA scans should be performed at intervals to assist in the correct dosing of HRT. Options for reproduction include oocyte donation, but adoption should not be overlooked. Women also require personal and emotional support to deal with impact of diagnosis on their health and relationships. Long-term follow-up is essential to monitor HRT and to consider emerging associated autoimmune pathology.

41.3.2 Aetiology of POI

Ovarian insufficiency is the final outcome of many pathogenic mechanisms. Table 41.1 shows the main categories of pathogenic mechanisms that lead to ovarian insufficiency. Despite diagnostic advances, particularly in the identification of genetic associations, the cause of POI remains unknown in the majority of cases (Nelson 2009).

Table 41.1 Summary of pathogenic mechanisms causing premature ovarian insufficiency

Genetic	Chromosomal and genetic abnormalities causing abnormal ovarian development or accelerated apoptosis. Single gene defects—mutations in genes vital for ovarian development or function
Autoimmune	Autoimmune ovarian damage is usually presumed because of the association with other organ-specific autoimmune conditions. Thyroid and adrenal autoimmunity is common. Ovarian autoantibodies are rarely positive
Metabolic	In galactosaemia, abnormal metabolites are thought to mediate ovarian damage
Iatrogenic	Ovarian damage following pelvic surgery and radiotherapy of chemotherapy during treatment of cancer
Environmental factors	Viral infections and toxins such as pesticides are presumed. Smoking results in younger age of natural menopause

41.3.2.1 Genetic Causes of POI

A genetic aetiology for POI is suggested not only by a positive family history, but also if there are features of an associated syndrome. Cytogenetic chromosome anomalies occur in about 2% of cases with the majority involving the X chromosome (Davison et al. 1999; Baronchelli et al. 2011; Desai and Rajkovic 2017).

X chromosome defects and Turner's Syndrome: Defects of the X chromosome associated with POI include complete or partial deletion of one X (Turner syndrome), trisomy X, or X-autosome translocations. In the case of Turner Syndrome variants, there is a great deal of variability in severity of the condition and this corresponds approximately with genotype and the amount of X chromosome disruption. Ovarian histology can vary from streak ovaries to those with well-preserved structure and numerous follicles. Those with monosomy X (45X) tend to be the most severely affected, while those with partial deletions of the X chromosome or mosaic 45X/46XX karyotype often lack the typical phenotypic features of the syndrome, but may present with only ovarian insufficiency and secondary

amenorrhoea. Among women with Turner Syndrome, the prevalence of ovarian failure is between 80 and 90% with most experiencing primary amenorrhoea and complete pubertal delay (Cameron-Pimblett et al. 2017).

X chromosome deletions appear to segregate into two specific regions: POI1 at Xq26-qter and POI2 Xq13.3--Xq21.1 (Baronchelli et al. 2012). There are various proposed mechanisms by which X chromosome defects cause POI. Genes responsible for germ cell development located along the critical region may be interrupted, although break point genes that determine ovarian function have not been convincingly identified. It seems most likely that structural rearrangements of the X chromosome do not affect single genes, but rather disrupt normal pairing at meiosis, leading to meiotic arrest and subsequent atresia. It must also be noted, however, that some X chromosome break points are not associated with POI (Baronchelli et al. 2012).

Single gene defects causing POI: A growing number of genes have been linked to ovarian insufficiency, although the strength of evidence linking each anomaly with POI is variable (Desai and Rajkovic 2017; Ferrarini et al. 2013). The most clinically useful genetic association is that between carriers of the Fra-X premutation and ovarian failure. Fra-X premutations occur in 3% of women with sporadic POI and 15% of those with the familial form and this genetic test is the only one advised in the UK as part of routine work up of POI (Conway et al. 1998). In general, the phenotype of this subgroup of women with POI is indistinguishable from others, although a minority are reported to a progressive intention tremor. The pathway by which Fra-X premutations damage ovarian function is unclear as this type of expansion of exon 1 of the gene is not thought to effect protein transcription, even though the protein is expressed within the ovary.

41.3.2.2 Autoimmune Causes of POI

Autoimmune mechanisms may be involved in pathogenesis of up to 30% of cases of POI (Welt 2008b; Wilson 2011). POI has been reported to be associated with various endocrine (thyroid, adrenal, hypoparathyroidism, diabetes mellitus, and hypophysitis) and non-endocrine (chronic candidiasis, idiopathic thrombocytopenic purpura, vitiligo, alopecia, autoimmune haemolytic anaemia, pernicious anaemia, SLE, rheumatoid arthritis, Crohn's disease, Sjogren's syndrome, myasthenia gravis, primary biliary cirrhosis, and chronic active hepatitis) autoimmune disorders (La Marca et al. 2010). In many cases, non-ovarian autoimmune involvement exists only at subclinical level (Wilson 2011). POI may be part of the autoimmune polyglandular syndromes (APS) when accompanied by other autoimmune endocrinopathies. POI is more common with APS types I and III than with APS type II. The single most common autoimmune association is with hypothyroidism which occurs in 10% of women with POI.

Various pathways of autoimmune ovarian damage have been described, but a reliable ovarian specific autoimmune marker is still lacking. Several putative pathogenic autoantibodies have been explored (Melner and Feltus 1999). Anti-ovarian antibodies detected by routine *immunofluorescence* have been reported in several studies of women with POI, but their specificity and pathogenic roles are questionable. The incidence of anti-ovarian antibodies in POI in different studies has been reported to vary from 4 to 69% (Wheatcroft et al. 1997). Other candidate autoantibodies include those directed against steroidogenic enzymes (such as 3ß-hydroxysteroid dehydrogenase), gonadotropins and their receptors, the corpus luteum, zona pellucida, and oocyte. None of these, however, have been validated as a diagnostic marker of autoimmune ovarian failure. Therefore, in the clinical work up of POI, screening for an autoimmune aetiology is usually only possible by seeking coexisting autoimmune diseases.

Women with idiopathic POI show an increased number of activated T cells in peripheral blood. Similar findings have been described in other autoimmune endocrinopathies, such as recent onset Graves' disease, type 1 diabetes mellitus, and Addison's disease. However, postmenopausal women also show raised numbers of activated peripheral T cells and oestrogen substitution has been shown to lower the number of activated

peripheral T cells in women with POI. Therefore, it is difficult to be certain whether the raised numbers of activated blood T cells is the cause or the result of ovarian failure in this situation (La Marca et al. 2010).

41.3.2.3 POI Resulting from Cancer Treatments

As the number of survivors of childhood cancer increases across the world, iatrogenic POI develops in a greater proportion of women with this condition. Both chemotherapy, alkylating agents in particular, and radiotherapy used in the treatment of cancer or benign diseases are damaging to the ovary (Wallace et al. 2005; Morgan et al. 2012). The return of ovarian function after cancer treatment is commonly observed although difficult to predict. For women estimated to be at high risk of POI, oophorectomy or oocyte harvesting for cryopreservation may be considered (Wallace et al. 2012).

41.3.2.4 Miscellaneous Causes of POI

Viral oophoritis is a possible occult aetiology that could theoretically account for the many cases of idiopathic POI. There is, however, little direct evidence of viral ovarian damage beyond case reports such as mumps oophoritis (Morrison et al. 1975). Cigarette smoking is known to be associated with earlier age of natural menopause, but whether environmental effects are sufficiently strong to cause POI is not known. The available data regarding effects of endocrine disruptors, heavy metals, solvents, pesticides, plastics, and industrial chemicals on female reproduction are equivocal (Sharara et al. 1998).

41.4 Hormone Replacement Therapy

Box 41.1 presents an overview of the management and treatment of POI. Physiological replacement of ovarian steroid hormones until the age of normal menopause at 50 is generally accepted as routine for women with POI, although there is little risk/benefit data for this young population. The principle of HRT use in young women differs only slightly from that in older women with the main treatment goal being optimal quality of life. Young women may require a higher oestrogen dose than that used in an older age group. Also, expectations for sexual function

Box 41.1 An Overview of the Management of POI

Education and counselling

- Return of ovarian function may occur in 5–10% of women with POI, but it is difficult to predict when and if this may happen.
- Adoption and oocyte donation are the only realistic options for fertility, although cryopreservation of ovarian tissue is possible for those at risk of developing POI.
- Access to follow-up counselling is important as issues return with life events such as a close friend or family member becoming pregnant.

Investigations:

- Thyroid function tests, vitamin B12 and ferritin to cover associated autoimmune conditions.
- Autoantibody screen including thyroid and adrenal antibodies.
- Karyotype for early-onset POI and genetic screen for FRAXA premutation.
- Pelvic ultrasound and ovarian biopsy are not recommended.

Treatment:

- Oestrogen and progesterone replacement is usually indicated as individualised.
- Education is required regarding risks and benefits of oestrogen preparations—oral, transdermal, and vaginal.
- Inform on media HRT scares and relevance to young women.
- Consider vaginal oestrogen and testosterone supplements.

can be higher commonly requiring consideration for vaginal oestrogen and androgen replacement. An HRT regimen should be based on the individual preferences of each patient who should be encouraged to undertake a trial and error approach through the wide variety of product available.

Management of oestrogen replacement for young women presenting with primary amenorrhoea requires liaison with paediatric endocrinologists with experience in the induction of puberty in order to optimise breast and uterine development. For instance, a popular strategy is to maximise the time between the introduction of oestrogen and starting progesterone and withdrawal bleeding is thought to benefit breast development. Conversely, the common practice of starting a low dose-combined oral contraceptive in this circumstance may not offer the best outcome of uterine development.

Among ***oral oestrogen*** choices, oestradiol esters and 17 beta-oestradiol provide the mainstay of treatments (Lobo 2017). Conjugated equine oestrogens are used less frequently than in the past because of a greater risk of hypertension and thrombosis compared to oestradiol (Swica et al. 2018; Smith et al. 2014). Some young women with POF find the ***combined oral contraceptive pills*** (COCP) a more acceptable option for oestrogen replacement, but careful assessment of the pill-free week is advised. The pill-free week amounts to 3 months of oestrogen deficiency each year, which may coincide with symptoms of oestrogen deficiency or bone loss. In choosing a type of COCP, those with lower dose ethinylestradiol and second-generation progestins have the lowest risk to thrombosis (Hugon-Rodin et al. 2014). ***Transdermal oestrogen*** avoids first-pass liver metabolism and involves noninvasive self-administration and attainment of therapeutic hormone levels with low daily doses (Henzl and Loomba 2003). This route of oestrogen administration also appears to be free of an excess risk of thrombosis. ***Subcutaneous oestrogen*** replacement involves placement of 25–50 mg oestradiol pellets usually in the lower abdomen or buttocks in a minor office procedure, which is not currently available in some countries including the UK. ***Topical vaginal oestrogen*** may be used as an adjunct to systemic oestrogen. Creams, pessaries, tablets, and vaginal ring appear to be equally effective for control of symptoms (Faubion et al. 2017).

Once the choice of oestrogen has been made, separate consideration can be given to the ***progestin*** in women with an intact uterus. Progestins vary from the more potent such as norethisterone to the weaker such as dydrogesterone. Trial and error will allow the user to find the most suitable progesterone preparation. The route may be oral, transdermal, vaginal, or uterine. With the ***oral*** and ***transdermal*** routes, there is a choice between continuous or sequential (for 10–14 days each month) delivery. Sequential regimen ensures monthly menstrual bleed. Continuous regimen avoids menstrual flow, but breakthrough bleeding may be more common in young women compared to an older age group in whom there is greater uterine atrophy. ***Uterine delivery*** with the levonogestrel intrauterine device (Mirena) has the advantage of avoiding the adverse effects of oral progestins highlighted in the studies of older women (Marjoribanks et al. 2017).

Androgen replacement is useful in some instances when fatigue and loss of libido persist despite optimised oestrogen replacement (Wierman et al. 2014). Transdermal testosterone administration and dehydroepiandrosterone treatment are two of the options for androgen replacement in these women.

41.5 Fertility Options for Women with POI

Different fertility options will be appropriate for each individual with POI. It is important that discussions on this topic from a professional with experience in the field are made available not only soon after diagnosis, but at intervals throughout follow-up as the technology and opportunities in this field are continually developing. There are a number of psychological issues and ethical dilemmas that women face when considering fertility treatment options and it is very important to

discuss this with a specialist healthcare professional. Please refer to chapters on assisted fertility and psychological considerations in Part VI of this textbook for more details.

41.5.1 Spontaneous Fertility in POI

Women with POI have a 5–10% chance of spontaneous conception at some time after diagnosis, as in some cases hormone levels and disease activity fluctuate and return to biochemical normality; this is often transient and the likelihood of recovery of ovulation is not possible to predict. Pregnancy loss in those who conceive is reported at 20%, which is similar to that of the normal population. Several medical therapies have been tried to induce ovulation in women with POI; however, in a systematic review, all were reported to be equally ineffective (van Kasteren et al. 1999a). In particular, glucocorticoids have been considered for those with autoimmune markers, and although promising in early case reports, a controlled trial failed to show benefit (van Kasteren et al. 1999b).

41.5.2 Ovum Donation

Assisted conception with donated oocytes has been used to achieve pregnancy in women with POI for over 20 years and remains the only realistic fertility treatment for the majority of women with established POI (Luisi et al. 2015). The availability of donated oocytes varies from country to country and this option is not acceptable for some ethnic groups. Donated oocytes, fertilised with partner's sperm, are observed on the usually way for the integrity of the embryo. The best embryo is chosen for implantation with the recipient having been prepared with increasing doses of oral estradiol. Because of the lack of a corpus luteum, progesterone support is required which can be administered orally, virginally, or by injection. Endometrial preparation is established in earlier dummy cycles.

41.5.3 Embryo Cryopreservation

Cryopreservation of embryos is a long established technique as part of in vitro fertilization, but it will apply to only a small number of women with normal ovarian function who can anticipate imminent ovarian failure but have sufficient time to allow for controlled ovarian hyperstimulation (Wallace et al. 2005). This circumstance might arise in some cases of malignancy or in someone who is known to be at risk of ovarian failure such as those with X chromosome anomalies or Fra-X premutation who may wish to delay starting a family for some years. Donor sperm could be used for those without a partner.

41.5.4 Oocyte Cryopreservation

Cryopreservation of oocytes has become popular since the advent of vitrification, which improved the freezing process for such a large cell. Vitrification involves rapid cooling in high concentrations of penetrating cryoprotectants, which avoids formation of intracellular ice and resulting damage during cooling and warming. In vitro maturation of oocytes, where immature oocytes are retrieved from unstimulated ovaries, has also emerged as a safe and effective treatment for women with cancer who are undergoing gonadotoxic therapy.

Oocyte cryopreservation also requires controlled ovarian stimulation, but in contrast to preservation of embryos, no sperm is required. In practice, this option is only applicable to women with normal ovarian function and who are old enough for oocyte harvesting. The success rate for achieving pregnancy is likely to be lower than that for embryo cryopreservation because oocyte survival and subsequent fertilisation are impaired. This option has been used for women with Turner Syndrome who retain some ovarian function (El-Shawarby et al. 2010), but so far the overall success rate is not known for this subgroup compared to the more common application in women diagnosed with cancer.

41.5.5 Ovarian Tissue Cryopreservation

The use of ovarian tissue cryopreservation for later use has been explored in young women undergoing anticancer treatment. Cryopreservation of one ovary or strips of ovarian cortical tissue has resulted in the birth of over 12 children according to a review in 2012 (Wallace et al. 2012). This procedure has the advantage of not requiring sperm and being appropriate for prepubescent girls accepting that a laparoscopy is required. The cryopreserved tissue can be reimplanted into the pelvis with ovulation and pregnancy occurring spontaneously or after IVF. Once again, it is too early to be certain of the overall success rate of this procedure, which is only undertaken in specialist oncology centres.

41.6 Nursing Considerations in the Care of Patients with POI

POI can be a devastating condition, especially when women are diagnosed at a very early age. The nurse has a crucial role in providing holistic care and taking into consideration many aspects of patient's life as well as their treatment and management of their condition. Many women with POI require multidisciplinary approach in their care and nurses are key to coordinating and providing a seamless care across settings and disciplines. The case study in Box 41.2 describes the complexities of the condition and the emotional distress patients with POI have to face at the time of diagnosis and throughout life.

Box 41.2 Patient Case Study and Key Learning Points

I'm 20 years old and I was diagnosed with Premature Ovarian Insufficiency (POI) at the age of 16 back in December 2014. I was only 16, so it wasn't something that I thought about when I didn't progress through puberty. I never even heard of the condition until I was diagnosed! So, what happened with me was that I noticed I had never had a period and thought my body shape was not normal for a girl of my age at the time. My mum and I decided to go to my GP who then referred me to the gynaecological unit where I underwent various tests. Then, a few weeks later, the doctor simply sat us down and told us straight—"Your ovaries are not working." For me, I wasn't shocked. To me, it just sounded something unusual that I would clearly have to live with and get on with. My mum, on the other hand, was very concerned as mums would be. She cried when we got home, and I just said to her, "It's okay mum! It's not terrible! I'm like Monica from Friends!!" However, for her it was awful because earlier on that year my sister lost one of her ovaries due to a cyst, which was such a hard time for her and mum. Looking at it that way, one daughter was potentially at risk of not conceiving, whereas the other daughter couldn't, so no wonder my mum was in heartache! It all happened in 1 year to both of her girls.

2015 was the toughest year I've faced as I struggled immensely with anxiety. To this day, I still struggle a bit about my health, but not as much as I did then. I was doing my A-Levels which brought so much stress, and on top of that, I had many hospital appointments following on from my condition. I do look back at that year and think, "How did I manage?" One bad day, especially, was my 17th birthday and I was coming home from London and I remember getting on a train and just felt so shaky, sweaty, dizzy, and was having a panic attack. I told my mum that we needed to get off the train and I just cried in her arms on a bench at the station. That was the worst it got for me! I had had minor panic attacks in bed where I would sweat and shake, but having one in public made it all more concerning. This was all

brought on mainly because I was worrying about my health every second of everyday!

So, I decided to do something about it! I started yoga (today, I just do meditation, I find the physical stuff not that relaxing can I just say?! Dance instead!) which really helped! Massively! I wanted to care for myself and help myself get better in my own way. I didn't see a therapist because, honestly, I didn't think I was bad enough and understood that it was just something I needed to tackle myself. But self-help books do put you on the right track!

I could natter all day, but I really do hope this little segment of my story and experiences help other teenagers out there. **What I want my story to do is raise awareness about teen ovarian failure and the mental health that comes along with that.** It is a shock and understandably so and I want other teenagers to know that they are not alone. I want to start meeting other girls and share our experiences together, so we can learn from each other and help each other. That is my main aim for the future. After all, this condition is for life, so why not make a positive out of it?!

Key learning points:

- Having a life-changing diagnosis of POI during adolescence can be devastating for the patient and requires very careful handling and disclosing of information.
- It is important to take into consideration the home environment and other factors that may influence the outcome of accepting and coping with the diagnosis. Parents also need to be supported in this journey and not excluded from care planning and shared decision-making.
- Most patients will not require regular visits and follow-ups, but it is crucial to plan for adequate support during transition periods such as going to university or very stressful periods such as taking exams, starting a relationship, or planning for a family.
- Patients find peer support exceptionally beneficial at learning about and coping with their condition and improving their self-management and adherence to medication. Providing them with access to peer groups or patient advocacy groups can be very beneficial for patient and their families.

Patient advocacy groups play a crucial (Box 41.3) role in raising awareness of the condition and providing peer support for patients. They are also a highly valuable resource of information for patients and their families and it is important to maintain a close working relationship with the clinical teams.

Box 41.3 The Role of Daisy Network, Patient Advocacy Group, in POI

The Daisy Network is the only UK-registered charity dedicated to providing free information and support to women with Premature Ovarian Insufficiency (POI). It is run solely by volunteers. Our aim is to provide up-to-date medical information about POI and treatment options available to sufferers and to provide a support network of people to talk to for those newly diagnosed, in addition to continually raising awareness of the condition among doctors and the broader medical community.

41.7 Conclusions

The lifespan of the ovary is occasionally interrupted by pathological processes, some known but many unknown. Premature ovarian insufficiency can be a devastating diagnosis for a teenager or for someone who has yet to start a family. Knowledge of the pathogenesis of the condition as well as treatment options in terms of hormones and assisted fertility is a important skill for a nurse practitioner in endocrinology, paediatrics, and reproductive medicine.

Acknowledgments Special thanks to Marie Gerval, Co-Chair, The Daisy Network (www.daisynetwork.org.uk) for the contribution to this chapter with a case study and information on the Patient Advocacy Group.

Abstract

Healthy endocrine function is vital for fertility, normal foetal growth and development, labour and delivery, and postnatal breast feeding. In disease states such as diabetes, attention must be given to preconception planning and management of concomitant issues through a pregnancy. Both hypoglycaemia and hyperglycaemia can be teratogenic, resulting in poor maternal and/or foetal outcomes.

Likewise, maternal thyroid function must be maintained in the euthyroid range to avoid significant foetal neural damage from hyper- or hypothyroidism. Monitoring and adjustments of thyroid replacement at each trimester are recommended to parallel increasing foetal requirements.

Pituitary dysfunction may become apparent during pregnancy as the gland enlarges. Prolactin levels will normally rise in response to rising oestrogen levels, but may also stimulate the growth of a prolactinoma. Hypothalamic-pituitary-adrenal dysfunction is uncommon, but may result for other dysfunctions.

Successful pregnancy outcomes require pre-pregnancy patient counselling, planning, and ongoing monitoring of patient responses. This continues through pregnancy and the post-partum period.

Keywords

Pregnancy · Diabetes type 2 · Thyroid function · HPA axis · Parathyroid disease

Abbreviations

CSI	Continuous subcutaneous insulin infusion
DM1	Type I diabetes
DM2	Type 2 diabetes
GDM	Gestational diabetes
HA1c	Haemoglobin A1c
hCG	Human chorionic gonadotropin
MDI	Multiple daily injections
MM	Methimazole
Mnt	Medical nutrition
PPT	Post-partum thyroiditis
PTU	Propylthiouracil
RAI	Radioactive iodine
SMBG	Self-monitoring of blood glucose
T3	Tri-iodothyronine
T4	Thyroxine
TRH	Thyroid-releasing hormone
TSH	Thyroid-stimulating hormone
TSI	Thyroid-stimulating immunoglobin
μg	Micrograms

Key Terms

- **Pre-gestational Diabetes:** Maternal hyperglycaemia secondary to inadequate insulin and/or resistance to insulin action prior to pregnancy.
- **Gestational Diabetes:** Maternal blood glucose elevation of variable degree with onset or recognition during pregnancy.
- **Teratogen:** Any agent that causes an abnormality following foetal exposure during pregnancy.

- **Human Chorionic Gonadotropin (HCG):** A placental hormone that stimulates production of progesterone from the corpus luteum, supporting the placenta during the early stages of pregnancy.
- **Foetal Immunological Privilege:** Physiological condition in pregnancy in which the foetus is protected from attack from the maternal immune system.
- **Post-partum Thyroiditis (PPT):** Inflammation of the maternal thyroid gland occurring during the first few months after the birth of a baby.
- **Progesterone:** A hormone secreted by the corpus luteum and the placenta that triggers the uterine lining to thicken to accept a fertilized egg. Progesterone decreases uterine contractions, stimulates blood supply to the endometrium, and suppresses further ovulation during pregnancy.
- **Endocrine Disrupting Chemicals (EDCs):** These are chemicals and compounds that may interfere with the endocrine system producing adverse developmental, reproductive, neurological, and/or immune effects in humans and other organisms.
- **Precautionary Principle:** A foundational concept of environmental regulation in many countries emphasizing that if threats of serious or irreversible damage to the environment exist, the lack of full scientific certainty should not be used as a reason for postponing cost-effective measures to preserve the environment and protect the health of living organisms.

Key Points

- Uncontrolled diabetes pre-pregnancy and during pregnancy can have serious adverse effects on both mother and developing foetus that can be minimized with optimal blood sugar level treatment and control.
- Aggressive screening of women at risk for thyroid disorders in the prenatal period and through each trimester of pregnancy is essential to ensure normal foetal development.
- The pituitary gland enlarges during pregnancy; prolactin level increases and may impact the hypothalamic-pituitary-adrenal axis function.
- Peptide hormones produced by the placenta, hypothalamus, and the pituitary such as: gonadotropin-releasing hormone, corticotrophin-releasing hormone and growth hormone-releasing hCG, growth hormone, are important for sustaining pregnancy and regulating growth and development.
- Endocrine disruptors have been linked to reproductive dysfunction in men and women and the generational development of some diseases.

42.1 Introduction

This chapter presents current concepts related to the nursing care of pregnant woman with disorders of the endocrine system. While the emphasis is placed on the most commonly encountered clinical issues, other, less common, though clinically relevant, issues are also discussed. The significant role of the placenta as an active endocrine organ is reviewed.

Emerging data regarding exposure to endocrine-disrupting compounds and the impact of these compounds on maternal-foetal health outcomes is explored.

The most commonly occurring forms of diabetes are categorized into three major types: Type 1 diabetes, Type 2 diabetes, and Gestational diabetes. Each of these types of diabetes has distinct clinical presentations and management varies widely. There are potential complications for the pregnant woman and her baby that result from poor control of diabetes of any type. The following section discusses normal glucose metabolism in pregnancy and each of the three common types of diabetes as they relate to the pregnant woman and developing foetus.

42.2 Normal Glucose Metabolism During Pregnancy

Glucose is the primary foeto-placental fuel and its transport across the placenta is in proportion to the maternal glucose level. In order to adapt to the challenge of meeting the glucose needs of both the mother and the growing foetus, the maternal metabolism undergoes adaptations throughout pregnancy. The primary purpose of these adaptations is to prepare for the accelerated foetal growth in the last trimester when approximately 70% of foetal growth occurs. During early gestation, maternal nutrient and fat stores increase with minimal changes in insulin sensitivity, in order to prepare for the nutritional demands of late gestation and lactation.

By late gestation, insulin sensitivity decreases (increased insulin resistance) with a twofold increase in mean circulating insulin and 30% increase in hepatic glucose production from the maternal liver. The resulting increases in maternal blood glucose and fatty acids provide fuel for the developing foetus. Due to high foeto-placental fuel demands, maternal fasting glucose falls in spite of the increased hepatic glucose production (Lain and Catalano 2007). If foetal glucose demands cannot be met due to maternal malnutrition or illness, the foetus can utilize alternate fuels from breakdown of maternal fatty acids (Feldt-Rasmussen and Mathiesen 2011). Because maternal insulin does not cross the placenta, early foetal insulin production is vital for foetal utilization of fuels. Both the ambient maternal glucose level and glucose spikes stimulate foetal insulin production (Feldt-Rasmussen and Mathiesen 2011). Other specific types of diabetes exist due to causes such as cystic fibrosis, HIV/AIDS, medications, and organ transplantation. As these are relatively rare, for the purposes of this chapter, we will focus on the first three classifications: Type 1 diabetes, Type 2 diabetes, and Gestational diabetes.

42.3 Type 1 Diabetes

Type 1 diabetes (formally called juvenile diabetes) accounts for 5–10% of individuals with diabetes. It can occur at any age and is caused by cellular-mediated autoimmune destruction of pancreatic beta cells, the cells that produce insulin. The destructive process takes months, but eventually results in insulinopenia (the decreased or absent insulin levels). The signs and symptoms can be sudden and dramatic at diagnosis. Signs and symptoms include: extreme thirst, frequent urination, and weight loss. Treatment is aimed at achieving optimal glucose levels by replacing the hormone insulin that the pancreas can no longer produce.

People with type 1 diabetes require insulin replacement for survival (Guthrie and Guthrie 2004).

42.4 Type 2 Diabetes

Type 2 diabetes is caused by a loss of balance between insulin sensitivity and insulin secretion. Unlike type 1 diabetes, in type 2 diabetes the pancreas produces insulin, but peripheral tissues lose sensitivity to insulin action, a process known as insulin resistance. Early in the disease process, insulin levels are often elevated with normal glucose levels. Over a period of months or years, the beta cells cannot produce enough insulin to maintain normoglycaemia and hyperglycaemia ensues. Predisposing factors for Type 2 diabetes include obesity, sedentary lifestyle, family history, puberty, ethnicity, and advancing age. Unlike Type 1 diabetes, the onset of Type 2 diabetes is insidious and the diagnosis can be delayed for years after the onset of hyperglycaemia, setting the stage for long-term complications.

Ninety to ninety-five percent of people with diabetes have Type 2 diabetes (CDC 2011). Type 2 diabetes occurs across a wide range of ages (adolescence through advanced maturity) and disproportionately affects ethnic minorities in the U.S. Worldwide prevalence of 8.5% (WHO 2017). It is currently estimated that 12.7% of adults of African descent have Type 2 diabetes as compared to 7.4% in whites, and prevalence rates have more than doubled over in the 10 years previous to 2011, but has decreased a little in recent years (CDC 2017). Rates of Type 2 diabetes are rapidly increasing in youth who are of Latino, Native American, or Asian/Pacific Island descent. According to the

National Institutes of Diabetes and Digestive and Kidney Disease (NIDDK) in 2017, 11.7% of all women age 20 years and older have diabetes. This explosion of type 2 diabetes has resulted in a higher than expected rate of pre-gestational diabetes in women of childbearing age.

In the past, pre-gestational diabetes was usually assumed to be Type 1 diabetes. In recent years, the increasing rate of obesity and Type 2 diabetes in adolescents has resulted in an increase in the number of pregnancies complicated by pre-gestational Type 2 diabetes. Over time, as the recommendations for earlier testing are widely adopted, the number of preexisting diabetes pregnancies will climb. In any case, no matter the cause of the maternal hyperglycaemia, the resulting foetal hyperglycaemia is a potent teratogen, an agent that causes foetal malformation.

42.5 Preconception Planning

Initiating meticulous metabolic management prior to conception is critical to the successful outcome of diabetic pregnancies. The importance of preconception planning and counselling cannot be overstated in this high-risk population of women with preexisting diabetes (Type 1 or Type 2). When pregnancy is planned, many non-insulin therapies including blood pressure and cholesterol-lowering medications may need to be stopped or changed. The Endocrine Society Guidelines recommend that blood pressure control of <130/80 be achieved and angiotensin-converting enzyme (ACE) inhibitor or angiotensin-receptor blockers be stopped prior to withdrawing contraception (Blumer et al. 2013).

Pre-pregnancy counselling must include guidance regarding effective contraception and instruction and support to normalize glucose to as near normal as possible while avoiding significant hypoglycaemia. Even before the pregnancy is detected, maternal hyperglycaemia can contribute to congenital malformations in the cardiac and central nervous system. The risk for these malformations and foetal demise increases with any increase in maternal glycaemia during the first 6–8 weeks of gestation. For this reason, counselling regarding avoidance of unplanned pregnancy should begin during puberty and continue into adulthood for women with diabetes or who are in a high-risk population for developing diabetes (ADA 2018). Additionally, maternal risks of developing new or progression of existing eye and renal complications are increased during pregnancy in women with pre-gestational diabetes. Eye and renal examinations should begin prior to conception with close follow-up during pregnancy and for 1 year post-partum. Optimally, treatments for preexisting eye, renal, neuropathic, and cardiovascular disease begin prior to conception (Blumer et al. 2013).

42.6 Gestational Diabetes

It is estimated that 2–10% pregnancies are affected by gestational diabetes (GDM). Hyperglycaemia in pregnancy has been associated with high birth weight above the 90th percentile, increased rates of caesarean sections, neonatal hypoglycaemia, and foetal hyperinsulinaemia. Mothers have a higher risk for pre-eclampsia, preterm delivery. The impact on the neonate could include: shoulder dystocia, hyperbilirubinaemia, and may trigger the need for neonatal intensive care admission.

GDM has been defined as any degree of glucose intolerance first identified during pregnancy without regard to undetected pre-gestational hyperglycaemia (Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997). This long-held definition of gestational diabetes (GDM) has come under scrutiny as more women of childbearing age are diagnosed with Type 2 diabetes prior to pregnancy. In 2009, the "Hyperglycaemia and Adverse Pregnancy Outcomes" (HAPO) trial results were published. The HAPO was a large, multinational study that determined increased glucose levels during pregnancy; even levels that were below diagnostic criteria for diabetes were associated with adverse outcomes (Lapolla et al. 2011; Metzger et al. 2009). In other words, there is no safe level of hyperglycaemia during pregnancy.

With this new data from the HAPO Study, consensus panels with representatives from ten member organizations, including the American

Diabetes Association (ADA), convened to study and review the HAPO results and develop new diagnostic criteria for GDM. Due to the increasing incidence of obesity and pre-gestational diabetes in young women, new screening criteria were developed that included screening for hyperglycaemia at the first prenatal visit for women in high-risk groups. For women not previously diagnosed with diabetes, the ADA supports the new diagnostic procedures at 24–28 weeks gestation and the following diagnostic criteria:

- Performance of a 75-g oral glucose tolerance test (OGTT).
- Obtain plasma glucose measurements at fasting, 1 and 2 h
- The OGTT should be performed in the morning after an overnight fast of at least 8 h.
- The diagnosis of GDM is made when any of the following plasma glucose values are exceeded:
  - Preprandial blood glucose ≤95 mg/dL (5.3 mmol/L)
  - Fasting blood glucose target of ≤90 mg/dL (5.0 mmol/L)
  - 1 h after the start of a meal ≤140 mg/dL (7.8 mmol/L)
  - 2 h after the start of a meal ≤120 mg/dL (6.7 mmol/L)
  - HbA1C ≤7% (ideally ≤6.5%) (Blumer et al. 2013)

The diagnosis of GDM has long-term importance for the mother after delivery. Within the first 2 months post-partum, 5–10% of women with GDM develop Type 2 diabetes and over the next 10–20 years this risk increases to 35–60% (CDC 2011). This fate may be avoided through lifestyle changes that include weight loss through exercise and healthy food choices and the use of certain glucose lowering medications. The Diabetes Prevention Program (DPP) showed these interventions could lower the risk for Type 2 diabetes by 50% or more and these individuals continued to have reduced risk 10 years later (Knowler and Hamman 2009).

42.7 Management of Diabetes During Pregnancy

Management of diabetes during pregnancy is aimed at achieving normal foetal growth and development by maintaining near normal glucose levels. Diabetes self-management education (DSME) has well-established evidence for improved outcomes and cost-effectiveness when provided in age-appropriate and culturally informed manner (ADA 2018). Diabetes self-management education usually includes content related to self-monitoring of blood glucose (SMBG), rationale for maintaining optimal glucose control, medical nutritional therapy (MNT), exercise, and medication. Although emerging evidence indicates that some oral glucose lowering agents may be safe during pregnancy, these data are not sufficient to ensure the safety of oral agents during pregnancy (ADA 2018). Therefore, insulin remains the cornerstone of pharmacological interventions for diabetes during pregnancy.

Self-monitoring of blood glucose (SMBG) via finger-stick blood samples and a glucose meter is the most widely used method of monitoring maternal glycaemia. The Endocrine Society guidelines (Blumer et al. 2013) recommendations for GDM glycaemic goals are:

- Fasting blood glucose levels less preprandial blood glucose ≤95 mg/dL (5.3 mmol/L)
- 1-h postprandial blood glucose levels less than 140 mg/dL
- 2-h postprandial blood glucose levels less than 120–127 mg/dL.

For women with preexisting Type 1 or Type 2 diabetes who become pregnant, the ADA (2018) recommends the following glucose targets if these targets can be reached without excessive hypoglycaemia:

- Pre-meal, bedtime, and overnight glucose: 60–99 mg/dL (3.3–5.4 mmol/L)
- Peak postprandial glucose: 100–129 mg/dL (5.4–7.1 mmol/L)
- HbA1C ≤7% (ideally ≤6.5%)

Frequent finger-stick SMBG is crucial to achieving glycaemic targets. It is typical that a pregnant woman with diabetes will measure blood glucose up to 6–10 times daily. Continuous glucose monitoring (CGM) may be used to supplement finger-stick glucoses, especially during the first trimester, where hypoglycaemia may be problematic in Type 1 diabetes. Although CGM can be useful in persons prone to hypoglycaemia, CGM measures interstitial glucose levels and correlation between interstitial and traditional blood glucose readings has not been established (Hoeks et al. 2011).

HA1c is a lab value that estimates the percentage of red blood cells that are marked as a result of elevated blood glucose (glycosylation). Normal values can vary by assay, but are usually 4–6%.

42.7.1 Additional Surveillance

In addition to glucose monitoring, urine ketones should be monitored during illness, and at any time, the capillary glucose exceeds 200 mg/dL. The presence of urine ketones may be an indicator of metabolic derangement and should be reported promptly (Kitzmiller et al. 2008). Since maternal hyperglycaemia causes foetal abdominal adiposity, ultrasound surveillance of foetal abdominal girth starting in the second trimester or early third trimester and repeated every 2–4 weeks can provide useful information in combination with SMBG (Metzger et al. 2007).

42.7.2 Medical Nutrition Therapy

Medical Nutrition Therapy (MNT) is essential to reaching metabolic targets. A registered dietitian or other professionals with experience in managing GDM should design a plan to provide adequate nutrients and caloric intake without inducing weight loss or excessive weight gain. For overweight or obese women, a modest caloric and carbohydrate reduction may be appropriate (Metzger et al. 2007).

As with gestational diabetes, MNT is crucial to optimizing metabolic management in women with pre-gestational diabetes (Type1 or Type2 diabetes). The tailored meal plan should be based on pregravid body mass index and individual gestational weight gain goals. To be successful, the food plan must be mindful of personal food preferences, ethnic and financial considerations as well as macro- and micronutrient composition. Keeping a detailed food diary is useful for the pregnant woman to make adjustments in her food intake and for her health care team to make therapeutic modifications in her food plan (Kitzmiller et al. 2008).

42.7.3 Insulin Therapy

For women with Type 1 diabetes, insulin and healthy lifestyle are the only therapeutic options available to them from the time that the diagnosis of diabetes is established. Before and during pregnancy, the insulin regimen should be intensified to a basal and preprandial regimen if this is not her pregravid regimen. Some women with Type 2 diabetes may require intensive insulin therapy to achieve optimal blood glucose control during pregnancy. This intensive regimen can be accomplished most commonly with multiple daily injections (MDI) or, in some cases, continuous subcutaneous insulin infusion (CSII) utilizing an insulin pump.

42.7.4 Multiple Daily Injections (MDI)

In MDI therapy, insulin is given in a basal/bolus manner. Basal insulin, long-acting insulin, is administered once or twice daily and the dose is expected to increase as the pregnancy progresses. Fast-acting insulin is used for pre-meal insulin and the doses are adjusted on a meal-by-meal basis depending on the carbohydrate content of the meal and a calculated insulin sensitivity ratio, or how many mg/dL a unit of insulin will drop the glucose. Some women may require 4–6 injections daily to reach and maintain normoglycaemia. As the pregnancy progresses, these formulas will change and will require constant surveillance

and adjustments (Kitzmiller et al. 2008). Since glucose fluctuations are the norm during pregnancy, any pregnant woman who takes insulin must be prepared for both hypoglycaemia and hyperglycaemia. Hypoglycaemia is most troublesome early in pregnancy, but can occur at any time. Anyone on intensive insulin therapy, MDI or CSII, should always carry a sugar source, preferably glucose tablets or gels that deliver a more predictable glucose load than soda or candy. Glucagon emergency kits should always be available for trained family, friends, and coworkers to administer in the event of a hypoglycaemic emergency. A medical alert bracelet should be worn by anyone taking insulin, especially those on an intensive regimen that predisposes one to hypoglycaemia. On the opposite end of the glucose curve is hyperglycaemia. The only treatment for hyperglycaemia is insulin and must be (International Association of Diabetes and Pregnancy Study Groups Consensus Pane, 2010).

42.7.5 Continuous Subcutaneous Insulin Infusion (CSII)

CSII, or external insulin pump therapy, is a therapeutic option that has been utilized primarily in Type 1 diabetes, but can be an effective therapy in Type 2 diabetes. Although CSII was first used in pregnancy in 1978, there is a paucity of research data about its use in this high-risk population. Although many patients and expert practitioners prefer insulin pump therapy, it has not been shown to be superior to multiple daily injections during pregnancy (Castorino et al. 2012).

In the simplest of terms, an insulin pump is an external device that runs on batteries with electronic controls, miniature processing module, and a disposable reservoir for insulin. The insulin is delivered to the patient through a disposable subcutaneous cannula that may have tubing connecting the pump to the cannula. There are pumps available that attach directly to the skin without the use of tubing. The abdomen is usually the best site for cannula placement, but as the gravid abdomen becomes distended the cannula can be inserted into the lower flank, the upper outer buttocks, or outer thigh. The insulin, reservoir, tubing, and cannula are replaced every 2–3 days. Rapid onset insulin analogues are used in the insulin pump. As with MDI therapy, the pump is programmed to deliver the insulin both slowly as background insulin (called basal insulin) and in a burst of insulin before meals (called bolus insulin doses). Basal insulin rates can be programmed to mimic the individual's circadian insulin requirements and adjusted as necessary. Bolus insulin is delivered before meals based on a two-part formula that is programmed into the pump. The first part is the carbohydrate ratio, or how many grams of carbohydrate 1 unit of insulin cover. The second part of the formula is the sensitivity factor, or how many mg/dL will 1 unit of insulin drop the glucose. These ratios are personalized and programmed into the pump and the individual "tells" the pump how many grams of carbohydrate she will be eating and what her glucose value is. Many glucose-measuring devices communicate with the pump, so this information may not need to be entered manually. In the event of a pump malfunction, insulin injections must be available (Bernasko 2012).

With both MDI and those using CSII, women must always be prepared for hypoglycaemia and hyperglycaemia. A sugar source and glucagon emergency kit must always be available.

42.7.6 Intrapartum with CSII

The mother may choose to continue CSII during labour and delivery. This decision should be made during pregnancy and discussed with and supported by the team caring for her. The labouring mother may be distracted or medicated and not able to manage her insulin pump. She must arrange to have assistance from an experienced person to monitor her glucose and operate the insulin pump during this potentially stressful time. If CSII is not continued or abandoned, a continuous IV insulin drip can be started to control glucose during the intrapartum period. The lowest basal rate in the final days of the pregnancy is usually sufficient to keep maternal glucoses between 70 and 140 mg/dL to prevent

newborn hypoglycaemia. Maternal glucose levels should be checked every hour during the intrapartum period so that appropriate therapeutic adjustments can be made (Bernasko 2012).

42.7.7 Oral Diabetes Agents

The recommended therapy for women with pregestational Type 2 diabetes who become pregnant and those diagnosed with gestational diabetes is not as straightforward as with Type 1 diabetes. At the time of this writing, the current American Diabetes Association (ADA) recommendations are that any oral agents are to be stopped and intensive insulin therapy initiated as soon as possible. There is concern about transplacental passage of medication during organogenesis and foetal development (Kitzmiller et al. 2008).

An open label study for women with gestational diabetes treated with metformin versus insulin found that neonatal complications were similar in the two groups and the women in the metformin group would choose their treatment again (Rowan et al. 2008). In a meta-analysis study that examined the benefits and risks of oral diabetic agents versus insulin in gestational diabetes, "No substantial maternal or neonatal outcome differences were found with the use of glyburide or metformin compared with the use of insulin in women with GDM" (Nicholson et al. 2009: 193). In contrast, another trial that examined the outcomes of women with GDM treated with glyburide compared to insulin therapy had the opposite outcome. The glyburide-treated mother's neonates were more likely to be macrosomic and admitted to the ICU than those whose mothers were treated with insulin (Cheng et al. 2012). In a trial that compared efficacy of metformin with glyburide in gestational found that the failure rate of metformin-treated group was 2.1 times that of the glyburide-treated group. Glyburide was found to be more efficacious than metformin, but the safety issues were not addressed (Moore et al. 2010). Again, as safety data are inconclusive, insulin remains the drug of choice when required for treating hyperglycaemia in pregnancy.

42.8 Maternal and Foetal Complications of Diabetes in Pregnancy

There are immediate and long-term foetal and maternal consequences of diabetes during pregnancy. During pregnancy, near normal glycaemia is essential for both mother and foetus. "The relationship of maternal glucose to pregnancy outcome is a continuum, and ideal results are achieved when maternal glucose concentrations are within normal limits, but not too low" (Kitzmiller et al. 2008: 1062). Maternal hyperglycaemia, especially during the first few weeks after conception, possibly before the pregnancy, has been recognized as a significant risk for spontaneous abortions and congenital malformations. Hyperglycaemia after 12 weeks gestation promotes foetal hyperinsulinaemia, excess foetal growth, and adiposity (Ray et al. 2001). Excess adiposity often causes macrosomia which is present in 27–62% of infants born to diabetic mothers, especially common when maternal glucose were elevated. Macrosomia is associated with neonatal complications of birth trauma, hypoglycaemia, caesarean delivery, hypocalcaemia as well as long-term risk of obesity, insulin resistance, and diabetes (Kitzmiller et al. 2008). Other maternal risks of uncontrolled or poorly controlled diabetes include preterm labour, pregnancy-induced hypertension, polyhydramnios, infections, and seizures (Castorino et al. 2012).

It is important to the nursing care of women with diabetes during pregnancy to recognize that although uncontrolled diabetes can have serious adverse effects on both mother and developing foetus, maintaining optimal blood sugar levels can minimize these adverse outcomes.

42.9 The Thyroid Gland and Pregnancy

Thyroid disorders are common, especially in women, and the management issues during pregnancy are complex. Abnormalities in thyroid hormone production can have devastating effects

during pregnancy. The reported prevalence of thyroid disorders during pregnancy ranges from 2 to 3% for hypothyroidism and 0.4–1.7% for hyperthyroidism (Glinoer and Spencer 2010; Yazbeck and Sullivan 2012). Hypothyroidism is characterized by abnormally low levels of hormones produced by the thyroid and associated elevated thyroid-stimulating hormone (TSH). Hypothyroidism has been linked to many adverse outcomes in pregnancy including: premature birth, pre-eclampsia, abruption, post-partum haemorrhage, impaired foetal neuropsychological development, and low birth weight (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012). Hyperthyroidism is characterized by abnormally high levels of thyroid hormones and associated suppression of TSH. Hyperthyroidism is also linked to adverse pregnancy outcomes including: spontaneous abortion, intrauterine growth restriction, thyroid storm in the mother, and increased perinatal mortality (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012).

42.9.1 Review of Thyroid Physiology

There is an intimate connection between the hypothalamic-pituitary hormones and thyroid hormone production. The thyroid hormones, triiodothyronine (T3) and thyroxine (T4), are secreted as part of a classic negative feedback loop with TSH and thyroid-releasing hormone (TRH). TSH is produced in the pituitary via TRH signalling from the hypothalamus. TRH signals the production of TSH, which in turns signals the thyroid to synthesize and release T3 and T4. T3 and T4 require iodine trapping in the thyroglobulin of the thyroid gland for the production of these hormones. When signalled by TSH, a series of chemical reactions takes place in the thyroid synthesizing T3 and T4 from the iodine-rich thyroglobulin. T3 and T4 are then released; some of the hormone remains free hormone, but most is bound to circulating proteins for distribution. The free hormone completes the feedback loop to the HPA, decreasing TRH and TSH production. T3 is the more metabolically active hormone. T3 is converted from T4 at distal sites when needed (See thyroid chapter) (Springer et al. 2017).

During pregnancy, three important physiological events occur that are important to thyroid function. First, increased oestrogen levels increase the production of binding proteins. This increases the amount of thyroid hormone which is bound and decreases the available free hormone. This stimulates the hypothalamus and pituitary to increase TRH /TSH. Secondly, human chorionic gonadotropin (hCG) and TSH are chemically identical in some areas. With the surge in hCG in early pregnancy, TSH effects are mimicked and production of thyroid hormones increased. Third, the placenta transfers some maternal T3 and T4 to the foetus in early pregnancy to support foetal growth and development. In the second and third trimesters, the placenta participates in the chemical conversion of T4 to T3 (a process called deiodination) and supports foetal thyroid hormone activity (Springer et al. 2017).

42.9.2 Hypothyroidism

As discussed above, hypothyroidism is characterized by insufficient production of T3 and T4. Thyroid hormone production depends on adequate availability of iodine. If iodine is nutritionally deficient, thyroid hormone production will be compromised. Worldwide, maternal iodine deficiency is still a leading cause of preventable intellectual compromise in infants (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012; Zimmerman 2009). Iodine deficiency can induce enlargement of the thyroid gland, a condition known as goitre. With iodine replacement, the goitre can regress and the thyroid returns to normal size. In some cases, however, the goitre persists and may compress surrounding tissues so that surgery may be indicated. Dietary sources of iodine include saltwater fish, shellfish, seaweed, some bread products, and iodized salt (Lutz and Przytulski 2006). However, many women do not eat shellfish for religious reasons and to avoid mercury exposure from seafood. Many women are also allergic to shellfish.

Curiously, sea salt does not contain any iodine. Iodized salt has been available in the United States since 1924. Although the United States has readily available supplies of iodized salt, internationally, particularly in southeast Asia and parts of Europe, iodized salt is not readily available. Many women in the United States avoid salt to minimize the risk of hypertension, an important consideration in pregnancy as well. Women of childbearing age require 150 μg of iodine daily. During pregnancy, daily intake of iodine should be 250 μg, but not exceed 500 μg (American Thyroid Association [ATA] 2011; Fitzpatrick and Russell 2010; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012). The amount of iodine contained in prenatal vitamins is variable. Nurses need to be aware of the nutritional content of the prenatal vitamins pregnant women are taking.

Today, the leading cause of hypothyroidism in the United States is autoimmune disease. Hashimoto's thyroiditis accounts for about 95% of cases (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012). Signs and symptoms of overt hypothyroidism include: fatigue, constipation, cold intolerance, hair thinning, vocal changes, and slowed cognitive activity. Many women with hypothyroidism offer no complaints and there is overlap between common problems during pregnancy and symptoms of hypothyroidism. It is the goal of treatment to avoid clinical hypothyroidism as determined by elevated TSH level.

As thyroid hormone deficit can have adverse effects very early in pregnancy, women on treatment for hypothyroidism should have preconception counselling about thyroid hormone requirements during pregnancy. Levothyroxine (Lt4) tablets are the recommended treatment for replacing thyroid hormone. Women who are being treated for hypothyroidism with Lt4 prior to pregnancy should increase their dose by approximately 30% to mimic the physiological increase during normal pregnancy (Stagnaro-Green et al. 2011). This dose adjustment can be accomplished by taking two extra tablets per week (nine tablets instead of seven) when a menstrual cycle is missed or pregnancy test is positive (Fitzpatrick and Russell 2010; Stagnaro-Green et al. 2011). To assure consistent absorption, Lt4 tablets should be taken on an empty stomach and separated from other medications, including prenatal vitamins by at least 4 h (Carson 2009; Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012).

42.9.3 Gestational Transient Thyrotoxicosis

As discussed above, hCG is structurally similar to TSH and can physiologically mimic TSH activity, stimulating the thyroid gland and increasing thyroid hormone production. In response to elevated hCG levels in early pregnancy, approximately 1–3% of women will develop transient signs and symptoms of hyperthyroidism. This is referred to as gestational transient thyrotoxicosis (GTT). GTT is often associated with hyperemesis gravidarum. Multiple gestation, hydatiform mole, and choriocarcinoma increase the risk of developing GTT. The thyroid gland typically remains normal size in this condition. GTT usually resolves by about 18 weeks gestation and only supportive therapies are required, though some women will need to be hospitalized for fluid and electrolyte management if the hyperemesis is severe. Should symptoms persist beyond 18 weeks, if goitre or eye changes occur or if autoimmune disease is present, the mother should be screened for overt hyperthyroidism (Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012).

42.9.4 Hyperthyroidism

Hyperthyroidism is characterized by an excess of thyroid hormone. Thyroid function tests indicating relative suppression of TSH and increased levels of free T3 and T4 are consistent with hyperthyroidism. Signs and symptoms include: resting tachycardia, hypertension, tremor, enlarged thyroid gland, and ocular changes including proptosis, lid lag, and stare. Less specific symptoms include: nausea and vomiting, increased appetite, weight loss, heat intolerance,

hyperdefecation (frequent bowel movement throughout the day), fatigue, insomnia, and new onset irritability or anxious mood. Uncontrolled hyperthyroidism is associated with spontaneous abortion, some congenital anomalies, preterm birth, low birth weight, abruption, neonatal thyroid disorder, and perinatal mortality. For the mother, uncontrolled hyperthyroidism is associated with pre-eclampsia and thyroid storm (Fitzpatrick and Russell 2010). Thyroid storm is a medical emergency and can be fatal. Thyroid storm is characterized by fever, hypoglycaemia, sudden changes in mental status, hypertension, resting tachycardia, enlarged thyroid gland, and exophthalamos. Thyroid storm can result in multi-organ failure and death. This rare but serious condition can be stabilized when recognized and treated early (Chong et al. 2010).

Grave's disease accounts for 85–95% of hyperthyroidism in pregnancy (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012). Grave's disease is an autoimmune disorder occurring in about 0.5% of the general population. Autoantibody formation results in thyroid overstimulation, enlarging the thyroid gland and increasing thyroid hormone production. The diagnosis is based on clinical presentation, thyroid function tests, and often the measurement of thyroid-stimulating immunoglobin (TSI) and/or TSH-receptor antibody (TRAb). All women with known Grave's disease should have preconception counselling and evaluation to ensure optimal thyroid function. Although many women can be stabilized on oral medication, some women may require surgery to achieve metabolic stability. In non-pregnant women, radioactive iodine (RAI) for thyroid ablation may also be a therapeutic option. It is critical that women who have been treated with RAI avoid pregnancy for at least 6 months to provide sufficient time to manage the hypothyroid state that will be induced. Because of possible teratogenic effects of RAI, it is absolutely contraindicated in pregnancy and lactation (De Groot et al. 2012; Fitzpatrick and Russell 2010; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012). In Grave's disease during pregnancy, autoantibodies can cross the placenta and may cause foetal hyperthyroidism and even goitre (Fitzpatrick and Russell 2010; Yazbeck and Sullivan 2012). Maternal symptoms, as discussed above, can include: resting tachycardia, hypertension, tremor, goitre, and ocular changes. Reflecting physiologic changes in maternal immune system, preexisting Grave's disease is more likely to exacerbate in the first trimester and in the post-partum period. Improvement is often seen during the second and third trimesters, during which medication is reduced and sometimes even discontinued. Grave's disease can also occur for the first time during pregnancy. Nurses and other clinicians need to be vigilant about evolving signs and symptoms that may indicate Graves hyperthyroidism, particularly in women with other autoimmune processes such as Type I diabetes.

Grave's disease during pregnancy is treated with anti-thyroid drugs of the thionamide class. Two drugs are most commonly used to treat the disorder: propylthiouracil (PTU) and methimazole (MMI). Both medications work by inhibiting production of T4. Additionally, PTU blocks conversion of T4 to T3. MMI is more potent mg/mg than PTU and has a longer half-life. MMI is generally a once daily medication, whereas PTU is usually taken three times daily. Both PTU and MMI are associated with agranulocytosis occurring in approximately 0.1% of persons treated with these medications. There has been conflicting evidence regarding the association of MMI with foetal anomalies. For this reason, PTU is the preferred treatment in the first trimester. PTU is associated with liver failure that can occur any time during treatment. Therefore, the ATA recommends initial treatment with PTU in the first trimester and clinician consideration of switching to MMI for the second and third trimesters (Stagnaro-Green et al. 2011). As anti-thyroid drugs cross the placenta, the foetal exposure to autoantibodies will also be treated with maternal medication. Foetal ultrasonography is used to assess heart rate, growth, and development.

However, overtreatment with thionamides can cause foetal hypothyroidism which can have serious adverse effects on foetal development. Minimizing excessive exposure to anti-thyroid medication is critical. The goal of medical ther-

apy is to maintain freeT4 levels in the upper limits of the normal range with as low a dose of medication as possible (De Groot et al. 2012; Fitzpatrick and Russell 2010; Galofre and Davies 2009; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012). Beta blockers such as propanolol can be used as adjunctive treatment for hypertension, tremor, and tachycardia. However, long-term treatment (greater than 2–6 weeks) with beta blockers is associated with foetal complications including hypoglycaemia, bradycardia, and intrauterine growth restriction (Fitzpatrick and Russell 2010; Galofre and Davies 2009; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012).

42.9.5 Post-partum Thyroiditis

Post-partum thyroiditis (PPT) is another autoimmune process that may induce transient hyperthyroidism followed by transient hypothyroidism and resolution to normal thyroid function within 12 months after delivery. Not all women presenting with PPT will experience all stages of this disorder. The average prevalence of PPT in parous women is 7.5–8.1%. Up to 70% women who have had PPT in the past will develop it after subsequent pregnancies. Women with Type I diabetes have a PPT prevalence of 25% (Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012). Beta blockade is used to treat hyperthyroid symptoms which are typically mild. Anti-thyroid medication is not warranted and is not effective in PPT. Thyroid replacement with levothyroxine (LT4) can be initiated if the hypothyroid stage lasts longer than 6 months or if symptoms become severe, the woman is breast feeding, or if another pregnancy is desired (Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012).

42.9.6 Thyroid Nodules in Pregnancy and Thyroid Cancer

Thyroid nodules are relatively common, occurring in about 1–2% of young women. Most nodules are benign, some are functional (secrete thyroid hormone), some nonfunctional, and rarely some nodules are cancerous. The prevalence of thyroid cancer in pregnancy is estimated to be approximately 14/100,000 pregnant women. All thyroid nodules need to be evaluated by ultrasound and TSH measurement (Fitzpatrick and Russell 2010; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012). If a woman is found to have a nodule with atypical echo pattern on ultrasound or if the nodule is growing or larger than 10 mm, she should be referred for a fine needle aspiration (FNA) biopsy. FNA is an office procedure and is considered safe during pregnancy. If the nodule is not suspicious on ultrasound, FNA can be delayed until after delivery. Radionuclide scans and RAI commonly used for diagnosis and treatment in non-pregnant women are absolutely contraindicated during pregnancy. Outcomes for well-differentiated thyroid cancer (DTC) in pregnancy are excellent. There is 10 year survival of 99%, not different from age-matched non-pregnant women. Surgical intervention for DTC can often be delayed until after delivery. If undifferentiated cancer is detected, the tumour is large or rapidly growing, or the cancer is in advanced stages, surgery can be done during pregnancy with the second trimester considered to be the safest time (Fitzpatrick and Russell 2010; Stagnaro-Green et al. 2011; Yazbeck and Sullivan 2012).

42.9.7 Screening for Thyroid Disorders During Pregnancy

According to The Endocrine Society's [TES] Clinical Guidelines in 2007 and the 2011 American Thyroid Association Guidelines for Diagnosis and Management of Thyroid Diseases during Pregnancy and Post-partum, there is insufficient evidence to justify universal screening of all pregnant women for thyroid dysfunction. Although thyroid disorders have many serious adverse effects on pregnancy outcome, evidence based on cost-effectiveness of screening and interventions is inconsistent. Therefore, aggressive case finding of women at risk for thyroid disorders based on

specific criteria is recommended (De Groot et al. 2012; Stagnaro-Green et al. 2011). Nurses need to actively assist with or perform screening pregnant women who are at risk for thyroid disease. According to the American Thyroid Association (2011), the following groups of women should be screened by TSH measurement:

1. History of thyroid dysfunction or previous thyroid surgery
2. Age > 30 years
3. Symptoms of thyroid disorder or presence of a goitre (enlarged thyroid gland)
4. Women with known thyroid antibodies
5. Women with Type 1 diabetes or other autoimmune diseases
6. History of miscarriage or preterm delivery
7. History of head or neck radiation
8. Family History of thyroid dysfunction
9. Morbid obesity (BMI $\geq$ 40 kg/m^2)
10. Use of amiodarone, or lithium or recent administration of iodine contrast media
11. Infertility
12. Residing in an area of known moderate to severe iodine insufficiency (Stagnaro-Green et al. 2011)

42.9.8 Summary of Thyroid Disorders During Pregnancy and Nursing Considerations

The goal of nursing care of pregnant women with thyroid disorders is to support optimal thyroid function throughout the entire gestational period and post-partum. Optimal thyroid function is supported by adequate iodine intake, pregestational counselling and evaluation, aggressive screening of women at risk for thyroid disorders, and nursing interventions to facilitate adherence to medically prescribed treatment regimens. Thyroid function is assessed by clinical presentation and laboratory measurement of thyroid hormone production. Understanding thyroid physiology is foundational to professional nursing care and serves as the basis for advocacy, education, and counselling for women with thyroid disorders during pregnancy.

42.10 Other Endocrine Considerations During Pregnancy

Many endocrine disorders are related to autoimmune responses. Whenever preexisting autoimmune processes are present, endocrine disorders are more likely and must be monitored during pregnancy.

42.11 Hypothalamic-Pituitary-Adrenal Axis

The maternal pituitary gland increases markedly in size in response to increased oestrogen levels in pregnancy. A normal pituitary is approximately 6 mm size in non-pregnant women, but may enlarge to 12 mm by 1 week post-partum. This activity correlates with rising prolactin levels (Feldt-Rasmussen and Mathiesen 2011). Typically, the pituitary will return to normal size within 6 months after delivery. Cortisol, secreted from the adrenal glands, increases throughout pregnancy and surges during labour. Both the maternal hypothalamus and the placenta stimulate this increase in cortisol production through increase in adrenocorticotrophic-stimulating hormone (ACTH) from the pituitary and placental corticotrophin-releasing hormone (CRH). In the course of normal pregnancy, maternal free cortisol may increase threefold. In response to increased oestrogen, binding proteins are also increased, decreasing the amount of free cortisol that will cross the placenta (Feldt-Rasmussen and Mathiesen 2011; Smith et al. 2011) (See Chap. 12).

Of all neuroendocrine tumours, prolactinomas are by far the most common, accounting for about 40% of all pituitary tumours. The prevalence of prolactinomas in the general population is estimated to be 100 per million (Mann 2011). Prolactinomas most commonly occur in women of childbearing age. Galactorrhea and amenorrhea are common presenting symptoms. Treatment can include surgery, radiotherapy, and/or medication, depending on tumour size and presenting symptoms. The drugs most commonly

used for treatment are the dopamine-receptor agonists, bromocriptine and cabergoline. When treated with dopamine-receptor agonists, many women will respond favorably with restored fertility. Treatment may be stopped when pregnancy occurs, although bromocriptine has an excellent safety record during pregnancy and cabergoline data seem promising regarding safety during pregnancy (Molitch 2010) (See Chap. 19).

42.12 Parathyroids and Maintaining Calcium Balance

Maternal parathyroid hormone levels are relatively stable during pregnancy. In the first trimester, maternal absorption of calcitonin (vitamin D3) results in increased calcium absorption. The resulting increase in calcium may be stored in the maternal skeleton in preparation for increased demand for maternal calcium from the developing foetus later in pregnancy. This increase in calcium may also explain in part the increased risk for kidney stone in the pregnant women (Feldt-Rasmussen and Mathiesen 2011).

42.13 Placenta as an Endocrine Organ

The placenta allows both maternal and foetal circulation to be in close proximity to each, while preventing actual mixing of the two systems. During pregnancy, the respiratory, alimentary, and excretory needs of the developing foetus are addressed by the placenta. Throughout pregnancy, the placenta plays an important role in the synthesis of both steroid hormones (derived from LDL cholesterol) and peptide hormones (derived from protein precursors).

An example of placental steroid hormone synthesis is progesterone production. During gestation, progesterone secretion is predominantly associated with placental and decidual production. In conjunction with hCG and cortisol, progesterone inhibits the maternal immune system by diminishing T-lymphocyte activity, thus preventing rejection of the foetal tissue and conferring foetal immunological privilege. Progesterone is also a potent inhibitor of smooth muscle contractility and prevents contractions of the uterine myometrium until the onset of labour. Additionally, progesterone serves as a substrate for the production of foetal adrenal hormones such as cortisol and aldosterone (Feldt-Rasmussen and Mathiesen 2011).

Examples of placental peptide synthesis include hypothalaminc-like hormones (e.g. Gonandotropin-releasing hormone, corticotrophin-releasing hormone, and growth hormone-releasing hormone) and pituitary-like hormones such as hCG, growth hormone, and other growth factors including insulin-like growth factors (e.g. IgF1 and IgF2). These peptide hormones are important for sustaining pregnancy and regulating growth and development. It is of interest that there is no neuronal control of placental peptide hormones and the exact mechanism of feedback to regulate placental peptide hormones is unknown (Feldt-Rasmussen and Mathiesen 2011).

42.14 Endocrine Disruptors in Human Reproduction and Health

Over the last decade, there has been increasing awareness of the hazard posed by substances known as endocrine disruptors or endocrine disrupting chemicals/compounds (EDCs). According to The Endocrine Society's 2009 scientific statement, EDs are defined from a physiological perspective as "...a compound, either natural or synthetic, which, through environmental or inappropriate developmental exposures, alters the hormonal and homeostatic systems that enable the organism to communicate with and respond to the environment" (Diamanti-Kandarakis et al. 2009: 2). EDCs are associated with multiple reproductive and developmental problems including, but not limited to: delayed conception, infertility, spontaneous abortion, still birth/neonatal death, preterm birth, congenital anomalies, low birth weight, developmental delays, and childhood cancers (Andersson et al.

2012; Chalupka and Chalupka 2010; Diamanti-Kandarakis et al. 2009).

Sources of EDs are diverse and prevalent including many commonly encountered substances such as some plastic bottles, metal food cans, detergents, computers, cell phones, flame retardants, food, toys, cosmetics, paints, varnishes, perfumes, soil, ground water, and pesticides (Chalupka and Chalupka 2010; Diamanti-Kandarakis et al. 2009; Gilden et al. 2010; National Institute of Environmental Health Sciences [NIEHS] Website 2012). Examples of just a few specific compounds that have been linked to endocrine disruption include:

- Bisphenol A (BPA) which is found in some food and drink containers, hard plastic bottles, and some baby products
- Glycol esters used in some paint, varnishes, and perfumes
- Pesticides used to protect food in both residential and commercial settings
- Phthalates added to some PVC plastics to soften them (plasticizers); also found in some cosmetics, perfumes, toys, and pharmaceuticals (Chalupka and Chalupka 2010)

The Endocrine Society identifies five important issues in endocrine disruption:

1. Age at exposure: periods of foetal and neonatal development increase susceptibility to EDCs.
2. Latency from exposure: repercussions of developmental exposure may not be evident until many years later (e.g. puberty, adulthood, or aging).
3. Importance of mixtures: if a population is exposed to environmental contamination multiple compounds may be involved, some of which will have additive or synergistic impact.
4. Non-traditional dose-response dynamics: very low doses of EDCs may have enormous impact, mid-range doses may have enormous impact in some cases, and in other cases high doses may have enormous impact. In still other cases, the substance may be benign or possibly beneficial in low doses and hazardous in higher doses (U-shaped dose-response curve).
5. Transgenerational, epigenetic effects: EDCs may have an impact on future generations via alterations in regulation of gene expression (Diamanti-Kandarakis et al. 2009).

Naturally occurring substances may also be endocrine disrupters. For example, soy baby formula contains plant-derived oestrogens known as phytoestrogens. Soy formula feeding by infant boys has been variably associated with changes in reproductive hormones, spermatogenesis, sperm capacitation, and fertility (Cederroth et al. 2010; Diamanti-Kandarakis et al. 2009). Therefore, there may be some link between these naturally occurring compounds and future reproductive issues in men. A dilemma regarding exposure to EDCs is evident in breast and bottle feeding. If a mother has exposure to EDCs, it is possible that her breast milk may contain concentrated amounts of the hazardous compound. For infants who are fed formula, in addition to the soy issue, the cans in which formula is packaged may contain plasticizers, a potential source of EDCs. The implication to be drawn from these observations is that there is a developmental basis for adult disease. This concept is fundamental to our understanding of the impact of EDCs in human health across the life span (Diamanti-Kandarakis et al. 2009).

42.15 Precautionary Principle and Implications for Nursing Practice

As explicated by the Science and Environmental Health Network (SEHN), the Precautionary Principle implies: “When the health of humans and the environment is at stake, it may not be necessary to wait for scientific certainty to take protective action” (SEHN Website 2012). The SEHN stresses the importance of action prior to deleterious health outcomes becoming widespread. The SEHN website offers four important strategies for implementing the Precautionary Principle. These strategies include:

> "Exploring alternatives to possibly harmful actions, especially clean technologies that eliminate waste and toxic substances; placing the burden of proof on the proponents of an activity rather than on the victims or potential victims of the activity; setting and working toward goals that protect health and the environment; and bringing democracy and transparency to decisions affecting health and the environment" (SEHN 2012, FAQ).

The Endocrine Society 2009 scientific statement endorses the Precautionary Principle in addressing the issues raised by EDCs. Among the recommendations for clinical practice suggested in the scientific statement, several are particularly relevant to nursing practice. Nurses need to advise their clients, particularly women of childbearing age, about potential exposure to EDCs and ways to minimize risks of exposure. All health care professionals need to be educated about the potential impact of EDCs across the lifespan. Health care professionals need to: develop, and have access to, clear concise and accurate health education materials to share with patients. Clinicians need to be vigilant about detecting potential cases of EDCs exposure when documenting client health history (Chalupka and Chalupka 2010; Diamanti-Kandarakis et al. 2009). Nurses are in a unique professional position to advocate for health policies related to endocrine disruptors, to develop community-specific educational tools, provide health counseling, and participate in case finding. The health of future generations may depend on what we as nurses do today.

42.16 Conclusions

Endocrine function is both altered by pregnancy and is vital to the developing foetus and successful neonatal outcomes. Optimal endocrine function is vital for fertility and normal foetal growth and development. Successful pregnancy outcomes require pre-pregnancy patient counselling, planning, and ongoing monitoring of patient responses. Counselling continues throughout pregnancy and the post-partum period. Additionally, abnormalities in the endocrine system can impact labour and delivery and postnatal breast feeding. Women with diabetes, before and/or during pregnancy, must be given preconception planning and careful management to avoid adverse pregnancy outcomes resulting from hypoglycaemia and hyperglycaemia. Optimal maternal thyroid function must be maintained to avoid significant foetal neural damage from hyper or hypothyroidism. Hypothalamic-pituitary-adrenal dysfunction is uncommon, but may present during gestation or post-partum. All families should be aware of EDCs and their potential impact on human health.

Clinical Application Exercise

Case Study 1

Sonia is a 32-year-old woman with Type I diabetes. She and her husband are school teachers. They have a daughter who is a healthy 3 year old. After her daughter was born, Sonia developed Grave's disease for which she is still taking medication. Sonia is now pregnant with their second baby.

Diabetes Management

1 unit of rapid-acting insulin is needed for each 15 g of carbohydrate and 1 unit of insulin will drop the glucose 20 mg/dL.

Using these ratios, if a woman was planning to consume 45 g of carbohydrates and her glucose was 140 mg/dL and she wanted to drop her glucose to 100 mg/dL:

1. How many units would she need to cover her carbohydrate in her meal?
2. How many additional units would she need to bring her glucose down to 100 mg/dL?
3. What will the total number of units or prepandial insulin that she needs to inject (or program her pump to deliver)?
4. If your patient is using MDI or CSII, how would you prepare her for hypoglycaemia and hyperglycaemia?
5. List the three categories of diabetes that most impact pregnancy.
6. Describe the relative degree of insulin resistance during early vs. late pregnancy.
7. List the IADPSG diagnostic criteria.
8. Discuss the short- and long-term complications to the offspring of pregnancies complicated by gestational diabetes.

9. Discuss the importance of preconception planning in pre-gestational diabetes for the foetus and for the mother.
10. Describe the components of an intensive insulin regimen.
11. Discuss the pros and cons of oral diabetes agents in pregnancy

Thyroid Management

1. Does the region in which you practice have a readily available source of iodine? Read the labels of food you commonly consume. Is your iodine intake about 250 μg?
2. Explain the classic feedback loop between TRH, TSH, T3, and T4
3. Describe the potential threats to healthy pregnancy outcomes that result from hypothyroidism.
4. Describe the potential threats to healthy pregnancy outcomes that result from hyperthyroidism.
5. Discuss the concept of foetal immunological privilege.

Other Considerations in Management

1. Explain the significance of endocrine disrupting compounds in human reproduction.
2. Apply the Precautionary Principle to nursing practice with women of childbearing age.

Abstract

The hypothalamic-pituitary-gonadal (HPG) axis is central for human reproduction. This axis includes neuroendocrine networks that integrate wide ranging internal and external inputs to coordinate reproductive competence. Gonadotrophin-releasing hormone (GnRH) is the principal regulator of reproduction. GnRH controls gonadotrophin secretion and subsequently, gonadal (testicular) function. The HPG axis is activated during foetal life, neonatally and in puberty through adulthood. This developmental perspective is important as these peri-

ods contribute to the proper formation and development of sexual structures *in utero* as well as the development and function of the system enabling reproductive capacity in adulthood. The HPG axis remains silenced during childhood and neuroendocrine re-activation triggers pubertal onset. In early puberty, nocturnal sleep-entrained GnRH-induced gonadotrophin secretion stimulates testicular development and the initial rise in sex steroids resulting in the appearance of secondary sexual characteristics. Progressively, this pulsatile neuroendocrine activity extends through the day and is regulated by negative feedback. Puberty culminates in sexual maturation and the reproductive capacity of adult life. Sperm development occurs in the seminiferous tubules of the testes and requires testosterone and other testicular products for normal spermatogenesis. Effective HPG axis function is needed for normal sexual function and fertility and contributes to overall health and well-being. This chapter is a mini-review for endocrine nurses providing a summary of HPG axis development, function and regulation. This targeted summary is intended to serve as a basis for understanding key elements relating to male reproductive endocrine disorders such as hypogonadism, sexual dysfunction and infertility.

Keywords
Hypothalamus · Pituitary · Gonadotrophins
Testes · Spermatogenesis · Testosterone
Sexual function

Abbreviations

AMH	Anti-Müllerian hormone
CHH	Congenital hypogonadotrophic hypogonadism
DHEA	Dehydroepieandrostenedione
DHEAS	Dehydroepieandrostenedione sulphate
DHT	Dihydrotestosterone
DSD	Disorder of sex development
ED	Erectile dysfunction
FSH	Follicle stimulating hormone
GnRH	Gonadotrophin-releasing hormone
hCG	Human chorionic gonadotrophin
HH	Hypogonadotrophic hypogonadism
HPG	Hypothalamic-pituitary-gonadal
IB	Inhibin B
INSL3	Insulin-like peptide 3
KS	Kallmann syndrome
LH	Luteinizing hormone
PDE5	Phosphodiesterase type 5
SC	Sertoli cell
SD	Standard deviation
SHBG	Sex hormone binding globulin
ST	Seminiferous tubule

Key Terms

- **Mini-puberty:** The postnatal surge in gonadotrophins during the first 6 months of neonatal life. In male infants levels rise following the first week of life, peaking at around 3 months then progressively decline. This surge is thought to be important fertility potential in adulthood.
- **Cryptorchidism (maldescended testes):** This refers to testes that are not descended into the scrotum and may be in the inguinal canal or abdomen. It may occur unilaterally or bilaterally and has negative consequences on fertility.
- **Orchiopexy (orchidopexy):** A surgical procedure to bring maldescended testis/testes into the scrotum. Earlier surgical correction (i.e. in the first year of life) may help improve future fertility potential.
- **Secondary sexual characteristics:** These are features that develop during puberty and are outward signs of the progression towards sexual maturation. In males, these characteristics are stimulated by rising androgen levels and include changes in body habitus (increased musculature), deepening of the voice, and development of body and facial hair.

- **Spermatogenesis:** The process by which spermatogonia become mature spermatozoa. This includes forming haploid gametes via mitosis and meiosis (spermatocytes) and the maturation process (spermiogenesis).
- **Mitosis:** This is a form of cell division wherein one parent cell is transformed into two cells with a full complement of identical sets of chromosomes—each within their own nucleus.
- **Meiosis:** A form of cell division wherein a parent cell produces four haploid gametes (cells with half of the number of chromosomes as the parent cell). It is an essential process for developing sperm for reproduction.
- **Tumescence:** A state in which the sexual organs become swollen and engorged with blood in response to physical, visual or emotional stimuli. In men, this is known as a penile erection. The reverse (detumescence) is when the erectile tissue returns to its flaccid state.

Key Points

- Reproduction is regulated by the hypothalamic-pituitary-gonadal (HPG) axis. Understanding how the axis functions is fundamental to identifying the cause(s) of male reproductive endocrine disorders.
- The HPG axis functions via stimulatory effects and negative feedback effects. Male reproductive endocrine disorders can occur at the level of the hypothalamus, pituitary and/or the testes.
- The HPG axis is active in foetal life, during the mini-puberty and at puberty into adulthood. Circulating LH, FSH and testosterone hormone levels reflect GnRH secretion during these periods.
- Early HPG axis activity can have long-reaching effects on the reproductive phenotype and fertility. Accordingly, careful history-taking is an essential component of endocrine evaluation.

43.1 The Hypothalamic-Pituitary-Gonadal (HPG) Axis

Reproductive capacity is central to species survival. In humans and other higher vertebrates, this essential function is regulated by the coordinated endocrine action of the hypothalamic-pituitary-gonadal (HPG) axis. Secretion of gonadotrophin-releasing hormone (GnRH) by a small population of specialized hypothalamic neurons (<2000) initiates the neuroendocrine activity of the HPG axis. Recent research has identified signals "upstream" of GnRH (Abreu and Kaiser 2016; Boehm et al. 2015) yet classically; GnRH has been considered the "pilot light" of reproduction (Balasubramanian et al. 2010). GnRH is secreted in a pulsatile manner, meaning that it is released in discrete bursts from the median eminence into the hypophyseal portal system (the network of vessels connecting the hypothalamus with the anterior pituitary). Once GnRH is delivered to the anterior pituitary (adenohypophysis), it stimulates the gonadotrophs to secrete luteinizing hormone (LH) and follicle stimulating hormone (FSH). These two hormones are collectively referred to as gonadotrophins. Whereas GnRH has a very short half-life and as yet cannot be measured outside of the hypophyseal portal circulation, LH and FSH enter the peripheral circulation and are readily measurable in venous blood. The gonadotrophins in turn stimulate sex steroid production and gametogenesis in the gonads. In males, LH is primarily responsible for stimulating specialized cells in the testes (Leydig cells) to produce testosterone. In contrast, FSH plays a major role in regulating the seminiferous tubule and spermatogenesis via its action on the Sertoli cells (Fig. 43.1).

43.1.1 Normal Development and Function of the HPG Axis

The proper formation and function of the hypothalamus, anterior pituitary and testes require multiple coordinated developmental events demanding

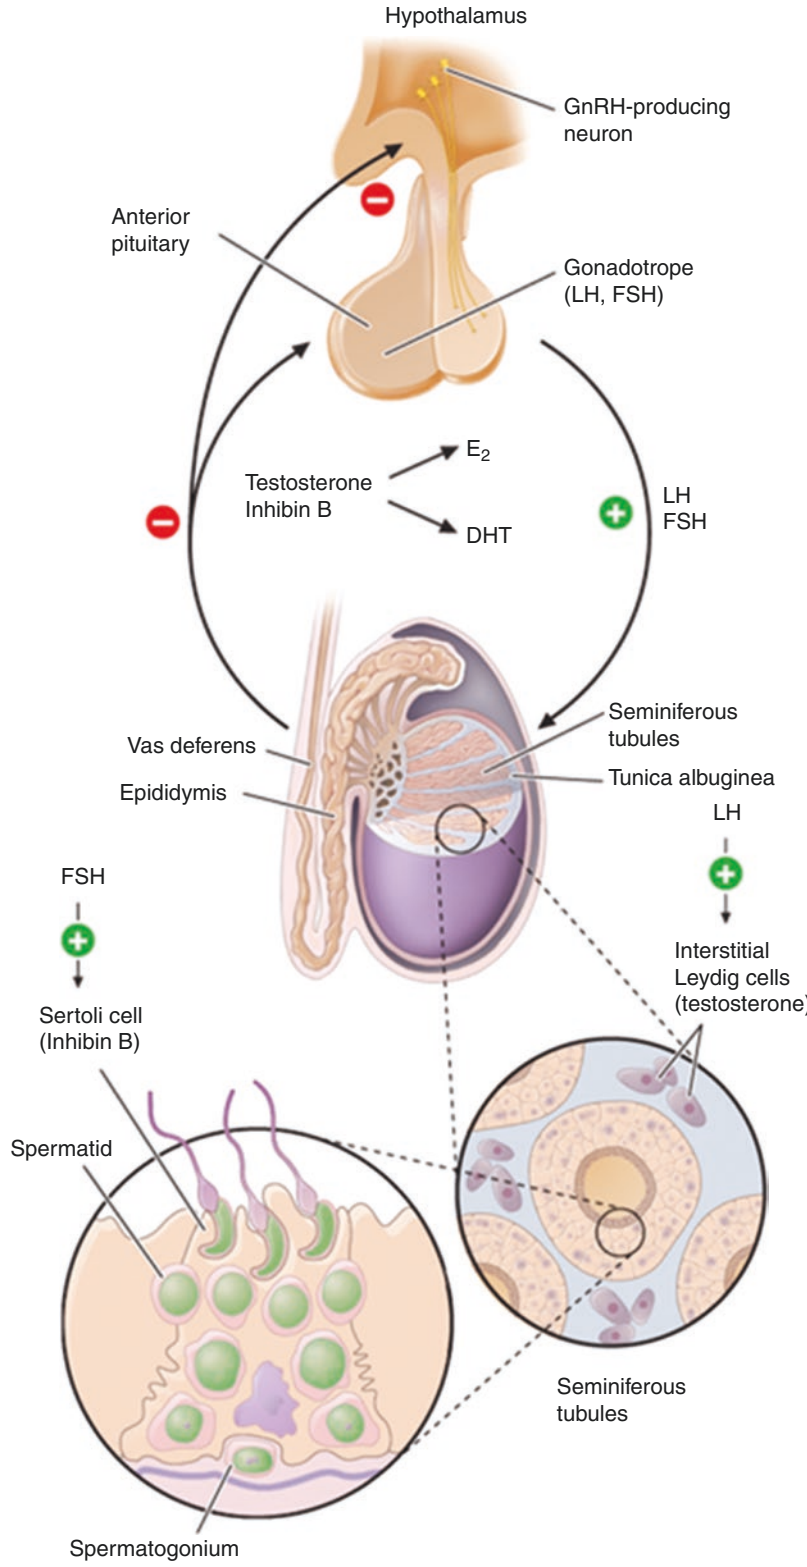

Fig. 43.1 The male hypothalamic-pituitary gonadal axis (used with permission from Bhasin S. and Jameson L.J. (2017) Disorders of the testes and male reproductive system, chapter 11. In: Jameson L.J. (Eds) Harrison's Endocrinology, 4th Edition. McGraw-Hill Education, pages 159–185.). Pulsatile secretion of GnRH from hypothalamic neurons triggers the release of LH and FSH from the pituitary and into the peripheral circulation. FSH supports spermatogenesis via stimulatory effect on the Sertoli cells in the seminiferous tubules. LH stimulates the Leydig cells in the interstitium to produce testosterone. Positive and negative feedback regulate the axis function

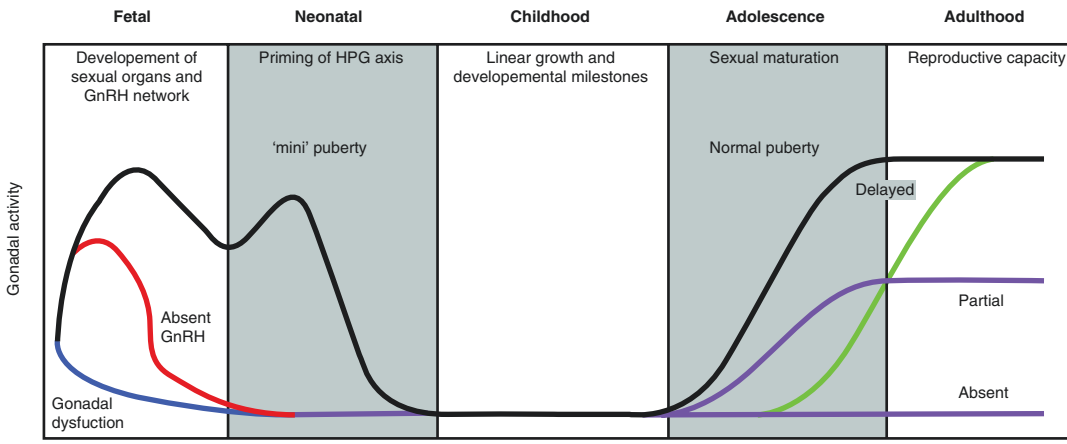

Fig. 43.2 Gonadal activation throughout development. Schematic depicting gonadal activation from foetal life through adulthood. Gonadal dysfunction (i.e. disorders of sexual development) in foetal life is depicted by the blue line while incomplete activation of the hypothalamic-pituitary-gonadal axis is shown in red (i.e. congenital hypogonadotrophic hypogonadism). The spectrum of pubertal development includes normal (grey), delayed (green), as well as partial/stalled and absent (purple)

spatiotemporal coordination under genetic and epigenetic control. Disruption of these crucial steps in development may manifest in endocrine dysfunction. Moreover, the HPG axis is active in three distinct waves during the lifespan (Fig. 43.2). Presently, the precise mechanisms controlling the activation, silencing and re-activation of the HPG axis remain largely unknown. However, recent genetic and physiologic investigations have begun to elucidate the molecular control of these processes and have identified critical signalling pathways essential for proper development and function.

43.1.1.1 Foetal and Neonatal Life

GnRH neurons are unlike other neurons in that they originate outside of the central nervous system. They primarily originate in the rudimentary nose (olfactory placode) and undergo a remarkable migration into the brain. Early in development they migrate along olfactory nerves across the base of the skull (cribriform plate) into the forebrain (arcuate nucleus). After aggregating, they begin secreting GnRH in a coordinated fashion from around 32 weeks gestation. GnRH is released from the terminal axons in the median eminence into the portal hypophyseal circulation (Boehm et al. 2015). It is notable that the activity of the HPG axis varies across development. During early foetal life, the axis is driven *in utero* by maternal hormones (i.e. human chorionic gonadotrophin, hCG) from around 7 weeks gestation and then is again active in a brief neonatal window referred to as mini-puberty (Grumbach 2005). Although gonadotrophin and testosterone levels are briefly low from birth until about 1 week of age LH, thereafter they begin to rise again, peaking between 1 and 3 months of life in neonate males (Kuiri-Hanninen et al. 2014). This HPG axis activation is significant as testosterone levels reach adult levels and it presents a unique opportunity to observe HPG function prior to puberty (Grumbach 2005). This surge in testosterone production is accompanied by rising levels of weaker androgens such as dehydroepieandrostenedione (DHEA) and its sulphated form (DHEAS) that may clinically manifest as "baby acne". However, these androgens do not result in sexual maturation or spermatogenesis as the androgen receptor is not yet expressed on the Sertoli cells; nor do they result in body hair growth as skin does not yet express 5AR enzyme to convert testosterone locally to DHT (Rey et al. 2013).

Events *in utero* and the subsequent mini-puberty during first 3 months of life in male infants may seem far removed from eventual adult reproductive capacity. However, these first two waves of HPG axis activity can significantly impact the reproductive phenotype and potential

for fertility in men (Dwyer et al. 2016). In particular early HPG activation (i.e. LH stimulated testosterone secretion) is important for normal testicular descent into the scrotum as well as further development of the penis. Accordingly, the earliest signs indicating possible deficient secretion or action of GnRH include cryptorchidism (maldescended testes) or micropenis (atypically small phallus). Notably, the hormonal surge of mini-puberty is a period of important yet clinically subtle testicular growth. This brief window of proliferation is crucial for increasing the number of Leydig cells as well as Sertoli and germ cells that are key for future spermatogenesis (Kuiri-Hanninen et al. 2014).

43.1.1.2 Childhood and Puberty

After 3 months of life, the axis is silenced and there is a relative period of quiescence during childhood prior to its re-activation in puberty. The exact mechanism(s) that control these changes are yet unknown and remain elusive. It is presumed that they are influenced by heritable (genetic) factors as well as environmental and epigenetic influences (Abreu and Kaiser 2016). There is a wide range of timing for pubertal onset. However the progression of signs is consistent across normal development. The first sign of pubertal onset in boys is increased testicular volume—typically observed between 11 and 12 years of age. This is followed by development of pubic hair (Tanner II), growth spurt (peak growth velocity), sperm in the first morning voided urine, achieving Tanner V pubic hair and a "spurt" in muscle strength. Importantly, outward signs of pubertal onset are the manifestation of the re-awakening of the HPG axis. This initially occurs with sleep-entrained GnRH pulses (Boyar et al. 1974). As frequent blood sampling to assess GnRH-induced LH secretion is not clinically feasible, a useful tool for approach for evaluating pubertal progression in male adolescents is using a Prader orchidometer to assess testicular volume as volume ≥4 mL indicates pubertal initiation (Boehm et al. 2015). Further, plotting testicular size using the puberty normogram enables a sensitive charting of pubertal development according to population-based norms (Joustra et al. 2015).

43.1.1.3 Adulthood

Puberty culminates in full reproductive capacity and the HPG axis has several important functions in adult life beyond reproduction. Importantly, normal function of the axis supports spermatogenesis and sex steroid production that have both androgenic and anabolic aspects. Testosterone is important for libido and sexual function and supports lean muscle mass. Further it has a stimulatory effect on erythropoiesis as well as bone health. Thus, normal HPG axis function is relevant for adult men long after reproductive goals have been attained. Similarly, disrupted HPG axis function can result in risk for developing health problems or overt pathology in any or all of these functions.

43.1.2 Abnormal Development

The coordinated development of the hypothalamus, pituitary and gonads means that when development does not progress normally (i.e. as a result of genetic mutations, environmental influences or toxic exposures) problems may manifest as either isolated deficiencies or as disorders affecting multiple levels of the HPG axis. Abnormal development may cause structural problems in the hypothalamus, pituitary and/or testes. Further, to exert their biologic action, hormones require a functional receptor. Therefore, changes in genes (mutations) encoding either the ligand (hormone) or the receptor can result in reproductive axis dysfunction (Boehm et al. 2015). Because the HPG axis is quiescent during much of childhood, some problems effecting of HPG axis development may not present until adolescence or early adulthood if the mini-puberty diagnostic window has been missed—as it usually is.

43.1.2.1 Hypothalamic Defects

For GnRH secretion to occur, GnRH neurons must migrate to the arcuate nucleus, form a network and release GnRH in a coordinated episodic (pulsatile) manner. Disruption of these steps may compromise effective GnRH-stimulated release of gonadotrophins from the anterior pituitary and without trophic stimulation from LH and FSH the

testes have impaired testosterone and sperm production. This is biochemically evident as hypogonadotrophic hypogonadism (HH). It is recognized that the vast majority of GnRH neurons derive from the embryonic nose (olfactory placode) and that the neurons migrate along olfactory nerves (Boehm et al. 2015). Thus, gene defects affecting craniofacial development, GnRH neuron fate specification and migration can result in the neurons never reaching their destination. Alternatively, if the signalling system upstream of the GnRH neurons is defective the GnRH neurons will not "switch on". The result of such developmental defects is isolated GnRH deficiency—congenital hypogonadotrophic hypogonadism (CHH). When it occurs with no sense of smell, it is termed Kallmann syndrome (KS). Importantly, in such cases it is clear that the defect is hypothalamic as these patients respond to pulsatile GnRH administration. In contrast, those patients with a pituitary defect typically cannot respond to exogenous GnRH. It is important to note that in addition to their hypothalamic defect, some patients with CHH/KS also have defects at the level of the pituitary and/or testes (Sykiotis et al. 2010).

43.1.2.2 Pituitary Defects

The anterior pituitary arises from the adenohypophyseal placode and is a combination of two ectodermal tissues: Rathke's pouch from the oral ectoderm (forming the anterior pituitary) and the infundibulum from neural ectoderm. Pituitary development is a complex process regulated by a number of genes, transcription factors and other signalling molecules (Bancalari et al. 2012). The anterior pituitary has five specific endocrine cell types (prolactins, somatotropes, thyrotropes, corticotropes and gonadotrophs); abnormal development may result in deficits in any or all of these hormones (i.e. panhypopituitarism). Indeed, patients with developmental defects such as combined pituitary hormone deficiency, and septo-optic dysplasia may exhibit reproductive defects. Indeed, genetic overlaps have been documented between these conditions and CHH/KS (Raivio et al. 2012). Similarly, gene defects encoding the pituitary gonadotroph receptor for GnRH (*GNRHR*) make the gonadotrophs less responsive to hypothalamic GnRH, thus presenting as HH (although in many cases this can be overcome with very high doses of exogenously administered GnRH) (Boehm et al. 2015).

43.1.2.3 Testicular Defects

At birth, hallmark signs of an inactive HPG axis include micropenis and cryptorchidism (maldescended testes) (Grumbach 2005). Micropenis is defined as stretched penis 2.5 standard deviations smaller than normal (i.e. ≤2.5 cm among term infants) (Hatipoglu and Kurtoglu 2013). Cryptorchidism may be unilateral or bilateral and typically classified in relation to the inguinal ring—either above (abdominal) or below (inguinal) (Ritzen et al. 2007). Just as mutations in *GNRHR* result in insufficient GnRH action at the level of the pituitary, mutations in gonadotrophin receptors (*LHR*, *FSHR*) render the testes unable to respond to high circulating gonadotrophin levels (Boehm et al. 2015). Klinefelter syndrome (47XXY) is a common chromosomal defect in males affecting approximately 1:600 males and is characterized by a testicular defect that often manifests in adolescence or adulthood (Groth et al. 2013). Disorders of sex development (DSD) may be indicated at birth by ambiguous genitalia and/or non-palpable gonads (Ahmed et al. 2016). DSD include a wide range of rare conditions of testicular defects including congenital anorchia, vanishing testes syndrome, dysgenetic gonads, persistent Müllerian duct syndrome, ovotestis and others. While not a testicular defect, complete or partial androgen insensitivity syndrome is a DSD resulting from mutations in the androgen receptor. These patients are genetically male (46XY) yet are infertile and phenotypically female as they cannot become virilized despite very high testosterone levels.

43.2 Hormonal Control of the HPG Axis

The reproductive functions of the testes include sex steroid production and gametogenesis. These are under neuroendocrine control from hormones secreted by hypothalamus (GnRH)

and the anterior pituitary (LH, FSH). Over the past decade research has identified factors, notably the kisspeptin/neurokinin B/dynorphin pathway, upstream of GnRH that contribute to the regulation of hypothalamic GnRH section (Skorupskaite et al. 2014).

43.2.1 Gonadotrophins

GnRH is the stimulus for the release of gonadotrophins into the peripheral circulation from the anterior pituitary. Importantly, LH and FSH trigger the production of sex steroids and other peptides (notably inhibin B) in the testes. These gonadal products in turn provide negative feedback regulating the neuroendocrine activity of the HPG axis. Gonadotrophin secretion may be regulated upstream (i.e. by decreased frequency or amount of GnRH secretion) or directly by direct inhibition of the pituitary gonadotophes. Testosterone produced by the interstitial Leydig cells slows GnRH pulse frequency at the level of the hypothalamus and dampens pituitary release of LH from the pituitary. Further, aromatized T in the form of oestradiol also plays an important role in negative feedback in men by reducing LH pulse amplitude and diminishing pituitary responsiveness to GnRH (Pitteloud et al. 2008). The control of FSH secretion is predominantly regulated by inhibin B secreted by testicular Sertoli cells (Boepple et al. 2008) and to a much lesser extent by sex steroids (oestradiol and testosterone). This negative feedback control of the HPG is a critical aspect that helps clinicians identify the level of a particular defect in the male reproductive axis differentiating primary (i.e. testicular) from secondary (neuroendocrine) defects (see Sect. X, Chap. XX).

43.2.2 Gonadal Sex Steroids

LH stimulates the interstitial Leydig cells to produce testosterone, the predominant sex steroid in men. The enzyme aromatase converts a portion of circulating testosterone into oestradiol (Neto et al. 2016). Aromatase is present in adipose tissue and as such, increased aromatase activity observed in states of obesity may become clinically evident as gynaecomastia (development of glandular breast tissue in men) resulting from increased oestradiol levels. Oestradiol exerts its effects (i.e. on the bone) by binding with the oestrogen receptor. Notably, recent evidence points to a threshold effect wherein men suffer declines in bone health when serum oestradiol levels drop below 10 pg/mL (36.7 pmol/L) or when serum T levels are less than 200 ng/dL (6.9 nmol/L) (Finkelstein et al. 2016). Another enzyme, 5-alpha reductase transforms testosterone to dihydrotestosterone (DHT) which is much more potent in binding to the androgen receptor. Importantly, DHT does not undergo aromatization. By and large, circulating testosterone is bound in the peripheral circulation. Approximately 44% is strongly bound to sex hormone binding globulin (SHBG) and unavailable, about 54% is weakly bound to albumin and only about 2% is freely circulating (Neto et al. 2016). Testosterone bound to SHBG is unavailable so conditions that increase circulating SHBG (such as ageing) decrease the amount of available testosterone. Overall androgen action results from the combined effects of available testosterone and its metabolites. These hormones are critical at different points in development, from sexual development in foetal life to the outward signs of puberty (i.e. virilization, deepening of the voice) and sexual maturation to benefits on bone health and lean muscle mass in adulthood (Table 43.1).

43.2.3 Other Gonadal Peptides

The testes secrete a number of different peptides, the function of which has not been completely elucidated. A complete description of all these products is beyond the scope of this chapter so we will focus on three: insulin-like peptide 3 (INSL3), anti-Müllerian hormone (AMH) and inhibin B (IB). In addition to producing T, Leydig cells also produce INSL3 during periods of HPG axis activation (Rey et al. 2013). The

[a]It is hypothesized that testosterone in neonatal life contributes to the so-called "masculinization" of the brain yet definitive evidence is lacking

precise physiologic role of INSL3 is unclear but it is important for normal testicular descent and has been used as a marker of interstitial function and Leydig cell activity. Similarly, the Sertoli cells (SCs) produce two important peptides, AMH and IB (Rey et al. 2013). AMH is critical for sexual differentiation while IB is a key regulator of FSH secretion. Early in testis differentiation (embryonic week 5), SCs secrete AMH resulting in regression of Müllerian ducts—thus preventing the formation of a uterus and fallopian tubes. In concert, androgens masculinize the external genitals and trigger differentiation of male genitourinary system as the Wolffian ducts become the epididymis, seminal vesicle and vas deferens. AMH remains high until the onset of puberty when rising T secretion stimulates SC maturation, down-regulating AMH (Rey et al. 2013). Because AMH is secreted by immature SCs, serum levels can be used as a distinctive surrogate marker of testes for infants with ambiguous external genitalia. IB is the predominant negative feedback regulator of FSH. As the seminiferous tubules account for the vast amount of testicular volume, it is well established that SC number correlates testicular size. Moreover, SCs support a species-specific, finite number of germ cells and so SC population correlates well with sperm output. Therefore, as a secreted product of SCs, serum IB levels have been used as a surrogate marker of SC population. Accordingly, serum measurements can also provide insight into spermatogenesis and cases of infertility.

43.3 Testicular Function

The two primary functions of the testes include spermatogenesis—the process of forming gametes for reproduction and sex steroid (androgen) production. These tasks occur in two different parts of the testes. Sperm is developed in the seminiferous tubules while testosterone production occurs between the tubules in the interstitial compartment.

43.3.1 Seminiferous Tubules

The seminiferous tubules (STs) are the site for spermatogenesis, a complex multistep process that is controlled by number of endocrine, paracrine and autocrine factors (Neto et al. 2016). The STs are veritable sperm factories that comprise two-thirds of the total testicular volume (the normal adult testis is 15–25 mL in volume). STs are the functional units of sperm production. They are tightly coiled and each individual tubule is approximately one metre in length (Neto et al. 2016). This means that the cumulative length of the tubules is approximately 250 m per testis—the equivalent of 2½ football fields. The structure of the tubule involves an exterior basement membrane lined with densely packed SCs followed by germ cells at varying stages of development progressing towards the lumen of the tubule.

The purpose of germ cells is to develop to spermatozoa and capable of transmitting genetic (and epigenetic) information to the next genera-

tion. They are the only type of human cell type capable of undergoing meiosis—dividing into two cells (gametes) with half of the number of chromosomes for reproduction. Notably, the process of spermatogenesis, from germ cell to sperm, is both complex and lengthy, demanding approximately 74 days (Neto et al. 2016). First, primordial germ cells (gonocytes) differentiate into two types of spermatogonia: inactive (A dark) and active (A pale). The A dark spermatogonia are reserves, they are stem cells that remain in a quiescent state awaiting activation. The A pale are proliferative. They may regenerate in a self-renewing manner or undergo mitosis to spermatogonium B. These subsequently undergo mitosis to produce primary spermatocytes (Fig. 43.1). Factors secreted by SCs determine whether A pale spermatogonia will either regenerate or differentiate. The self-renewing mechanism means that spermatogonia are the progenitors for all other germ cells and account for the entire sperm development throughout life. In brief, spermatogenesis involves three phases: mitosis, meiosis and spermiogenesis. The mitotic phase included initial proliferation from A pale to B spermatogonium then a second mitosis from B to primary spermatocyte. First meiosis marks the transition from primary to secondary spermatocyte and the second meiosis produces round spermatids. Spermiogenesis is the final phase and refers to the transformation of haploid germ cells (spermatids) to spermatozoa (Fig. 43.1, for a detailed review see Key Reading at the end of the chapter). Subsequently, the mature spermatozoa are released into the lumen of the ST.

This entire process of spermatogenesis takes approximately 74 days and is continually ongoing (Neto et al. 2016). It is estimated that a healthy adult male produces anywhere from 150–275 million spermatozoa per day. Spermatogenesis is not only dependent upon FSH stimulation but qualitatively and quantitatively normal sperm development demands androgen action—particularly for meiotic progression and maturation of the spermatids (gametes). STs are surrounded by peritubular myoid cells that together with the SCs form the blood–testis barrier. Peritubular myoid cells have properties akin to smooth muscle cells and help move testicular fluid secreted by SCs and spermatozoa from the tubules to the efferent ducts. These ducts form the epididymis where mature sperm are stored prior to ejaculation.

Spermatogenesis is a multistep process yet delivering sperm in the ejaculate requires additional products from male accessory sex organs. Indeed, the spermatozoa comprise a very small portion of the ejaculate, approximately 2–5%. In humans, the ejaculate is a mixture of secretions from the seminal vesicles (65–75%), the prostate (25–30%) and the bulbourethral glands (<1%).

43.3.2 Interstitial Compartment

The interstitial compartment of the testes represents only a small part of the entire testicular volume, yet its functional role is critical. The Leydig cells reside outside of the STs and are the primary source of testosterone production in males. Healthy adult males produce 3–10 mg of testosterone per day, accounting for >95% of the total circulating amount (Neto et al. 2016). As noted above testosterone is essential for sex development *in utero*, penile growth in mini-puberty, the development of secondary sex characteristics (virilization, deepening of the voice) in puberty as well as supporting lean muscle mass, erythropoiesis, bone health and libido/sexual function in adulthood. Notably, intra-testicular testosterone concentration is approximately 100-fold higher than peripheral circulation (Neto et al. 2016). This is important as such high concentrations are needed to support normal spermatogenesis.

43.4 Endocrine Aspects of Sexual Function

The seventeenth century mathematician, scientist and philosopher René Descartes proposed the famous "Cartesian" separation of the mind and body. Certainly, few would likely consider our modern view of sexuality as falling within such conceptual framework. However, for ease of presenting the topic, we propose that male sexual function can be broadly thought of as having two

central components: the sexual brain and the sexual body. The two are inherently connected. Indeed, male reproduction depends on coordinated endocrine hormonal factors and physiologic response that are influenced by psychosexual factors.

43.4.1 Sexual Desire

The concept of sexual desire can be expressed using a variety of terms. Sexual motivation, libido, sex drive, lust and sexual appetite address the same notion—albeit with slightly different connotations. All these terms relate to desire (including fantasy) for sexual activity. It has been proposed that gonadal sex steroid levels and external (visual) stimuli combine to create sexual incentives that are subsequently reinforced by sexual reward emotional pleasure and dopamine release (Georgiadis et al. 2012). Sexual desire is strongly linked with individual (psychological) attitudes towards sexuality, yet there are significant biological (organic) and endocrine influences. Testosterone has long been associated with virility. Importantly testosterone is a major hormonal contributor stimulating sexual desire while DHT and oestradiol play relatively small parts and weak adrenal androgens (DHEA, DHEAS) do not appear to contribute (Corona et al. 2016). There is a significant amount of evidence for this based on the fall in libido observed in studies involving men undergoing androgen deprivation therapy as well as male contraceptive studies. Similarly, a number of interventional studies have noted increased sexual desire concurrent with exogenous testosterone administration (Corona et al. 2016).

Prolactin also plays a suppressive role in sexual desire. Hyperprolactinaemia is associated with decreased libido yet the mechanism(s) is not entirely clear. It could be acting via prolactin-induced hypogonadism or via effects on the neurotransmitter dopamine which is important for sexual behaviour. Psychological stress has long been identified as having a negative effect on libido. Interestingly, there is a growing body of literature to suggest that stress may also negatively impact male fertility (spermatogenesis) via decreased testosterone production as well as by the inhibitory effects that cortisol has on the HPG axis (Nargund 2015). The sexual brain is influenced by a number of neurotransmitters and hormonal inputs that affect sexual desire—namely testosterone in males. Accordingly, a functioning HPG axis and eugonadal status (normal serum testosterone levels) contribute to maintaining healthy sexual desire in men.

43.4.2 Erectile Function

Broadly, erectile function refers to the ability to achieve and maintain an erection suitable for satisfactory sexual performance (Yafi et al. 2016). This function is essential for reproduction and includes two types of erections, reflex and psychogenic. The reflex erection is controlled by peripheral nerves and the lower spinal cord in response to tactile stimuli. The psychogenic aspect of erection involves the limbic system of the lower brain and is stimulated by erotic or emotional stimuli. The penis remains in a flaccid state as long as smooth muscle is contracted. A variety of inputs from the nervous system (adrenergic input via noradrenaline), the muscle itself (myogenic control) as well as circulating factors released from the endothelium (e.g. prostaglandins) regulate smooth muscle contraction. In the presence of sexual stimulation, erections occur when the smooth muscle relaxes. Blood flow fills the corpora cavernosa blocking venous outflow (veno-occlusion) creating a tumescence (erection). Release of nitric oxide from nonadrenergic noncholinergic nerve fibres stimulating increased cyclic GMP is critical in initiating this process of tumescence. This is reversed as phosphodiesterase type 5 (PDE5) works to break down (hydrolyse) cyclic GMP resulting in detumescence. The contribution of testosterone to erectile function appears to be through its modulating effects on smooth muscle. While studies indicate a threshold effect on erectile function (Corona et al. 2016), this does not seem to be an absolute requirement as some men are able to sustain near-normal sexual activity despite levels well below this cut-off (Yafi et al. 2016).

43.4.3 Sexual Dysfunction

Problems with sexual function may include problems with libido and desire or erectile dysfunction (ED) that caused by psychogenic, organic or endocrine factors. Among psychogenic factors stress, anxiety and depression are well-documented factors (Yafi et al. 2016). This can result in progressive loss of self-confidence and avoidance behaviour stemming from concerns about sexual performance that further exacerbate the situation and may strain intimate relationships. Importantly this is amenable to intervention and also important for the partner as there is a clear bi-directional component to sexuality, satisfaction and quality of life (Yafi et al. 2016). It is estimated that approximately 80% of ED results from an organic aetiology. Large population based studies have demonstrated strong associations between ED and age, overall health status and emotional well-being (Yafi et al. 2016). Indeed, ED has emerged as an indicator of cardiovascular health and endothelial dysfunction as reduced blood flow and arterial insufficiency/stenosis can underlie ED. Similarly, diabetes, dyslipidaemia and smoking promote atherosclerosis and can contribute to ED. Additional organic causes include neurogenic resulting from pelvic trauma or surgery.

A variety of endocrine factors contribute to sexual dysfunction. Low testosterone has been associated with decreased libido (hypoactive sexual desire), ED and delayed ejaculation (Buvat et al. 2010). This may stem from dysfunction within the HPG axis resulting in hypogonadism or indirectly as a result of axis suppression via elevated cortisol or prolactin levels (Corona et al. 2016). Stress and fasting can suppress the HPG axis as well yet it appears that men are much more resistant to such suppression compared to women who commonly develop hypothalamic amenorrhoea triggered by stress and caloric deficits. In contrast, men are susceptible to HPG axis suppression secondary to obesity, which has no evident counterpart in women. Serum T decreases with age, approximately 1% per year after age 40 and it is widely accepted that sexual dysfunction increases with age. However, there is a lack of convincing evidence that the hormonal changes associated with ageing are a direct, primary driver of changes in sexual function among otherwise healthy ageing men (Corona et al. 2013). Rather it seems that ill health (i.e. chronic disease, obesity) are much stronger contributors to sexual dysfunction (Yafi et al. 2016).

Questions about sexual function are common items in questionnaires developed to screen for testosterone deficiency. These instruments are often sensitive yet lack specificity, thus making a biochemical diagnosis essential (Dean et al. 2015; Bhasin et al. 2010). For details on diagnosing hypogonadism, please refer to Chap. 45. Notably, a recent meta-analysis indicated that T treatment is beneficial for improving libido and a variety of aspects of erectile function in men when serum T levels <12 nmol/L (345 ng/dL) (Corona et al. 2014). Importantly, the management of sexual dysfunction is based on the accurate identification of aetiology. By and large it involves an empirical, step-wise approach that may include lifestyle modifications and counselling (i.e. smoking cessation, weight loss, exercise, stress management, sex/couples therapy), medications (e.g. adjusting medications with ED as a side effect, hormone treatment, PDE5 inhibitors, intra-urethral prostaglandin suppositories) or surgical interventions (e.g. penile implants, penile revascularization) (Yafi et al. 2016).

43.5 Conclusions

Male reproduction capacity is orchestrated by the dynamic hypothalamic-pituitary-gonadal axis. The development of the axis occurs in three distinct waves that contribute to normal adult reproductive function. Neuroendocrine control of reproduction involves the hormonal interplay at the level of the hypothalamus and pituitary. GnRH-induced gonadotrophin secretion stimulates spermatogenesis and testosterone production (the dominant male sex steroid). The axis is controlled via intricate negative feedback loops and disruption of the axis can result in hypogonadism, sexual dysfunction and infertility. Understanding the basic structure and physiology

of the male reproductive endocrine system is a fundamental competency for endocrine nurses caring for patients in this domain.

Abstract

The proper function of the hypothalamic-pituitary-gonadal (HPG) axis is needed for full pubertal development, normal androgen production and full reproductive capacity. Congenital or acquired disorders at any level of this system can produce characteristic signs and symptoms of testosterone (T) deficiency and disrupt fertility. Organic problems at the level of the hypothalamus and/or pituitary can be differentiated from testicular disorders by measurement of serum gonadotrophins (luteinizing hormone and follicle stimulating hormone). Primary hypogonadism results from testicular defects and is evidenced by elevated gonadotrophins, whereas secondary hypogonadism is central in origin and characterized by low (or abnormally normal) gonadotrophins. Epidemiologic studies have demonstrated a progressive decline in serum T with age. However, the increased rates of hypogonadism seen in advanced age primarily relate to obesity and chronic disease burden. Androgen deficiency may result from a wide range of causes including tumours, medications and systemic illness that directly affect the testes or suppress the HPG axis. Regardless of aetiology, untreated hypogonadism has significant negative consequences on health and quality of life. T deficiency not only contributes to poor bone health but is also linked to increased risk for metabolic problems such as the metabolic syndrome and diabetes and has been associated with all-cause cardiovascular mortality. Understanding the pathophysiology underlying hypogonadism is the foundation for appropriately assessing, diagnosing and treating androgen deficiency. This chapter is a mini-review for endocrine nurses providing a summary of disorders affecting the HPG axis with specific attention given to the nursing process in relation to testosterone deficiency.

Keywords

Hypogonadism · Androgen deficiency
Testosterone · Sexual dysfunction · Obesity
Testes

Abbreviations

AMH	Anti-Müllerian hormone
AOH	Adult-onset hypogonadism
AR	Androgen receptor
BBS	Bardet–Biedl syndrome
BMI	Body mass index
CAH	Congenital adrenal hyperplasia
CHH	Congenital hypogonadotropic hypogonadism
CPHD	Combined pituitary hormone deficiency
DSD	Disorder of sex development
ED	Erectile dysfunction
EDCs	Endocrine disrupting chemicals
EMAS	European Male Ageing Study
FSH	Follicle stimulating hormone
GnRH	Gonadotrophin-releasing hormone
HIV	Human immunodeficiency virus
HPG	Hypothalamic-pituitary-gonadal
IB	Inhibin B
INSL3	Insulin-like peptide 3
LH	Luteinizing hormone
LOH	Late-onset hypogonadism
SHBG	Sex hormone binding globulin
SOD	Septo-optic dysplasia
SSRIs	Selective serotonin reuptake inhibitors
T	Testosterone
TDS	Testicular Dysgenesis Syndrome

Key Terms

- **Hypogonadism:**: The combination of repeated, unequivocally low serum testosterone levels combined with clinical signs and symptoms of androgen deficiency, typically within the framework of a recognized clinical syndrome.
- **Gynaecomastia:** The development of glandular breast tissue in men resulting from an imbalance of testosterone and oestradiol. Pseudogynaecomastia refers to the superficially similar appearance resulting from excess fat accumulation; in practice, many men exhibit a combination.
- **Sexual dysfunction:** The inability to engage in normal, pleasurable sexual activity resulting from diminished desire (libido), arousal difficulties (erectile dysfunction) and/or problems with orgasm (ejaculation).
- **Metabolic syndrome:** A condition comprising a constellation of risk factors that increase risk for cardiovascular disease and diabetes. Definitions vary across organizations yet key elements include insulin resistance, hypertension, abnormal lipid profile (i.e. elevated triglycerides, low high-density lipoprotein levels) and obesity (particularly central).
- **Late-onset hypogonadism:** This is clinically characterized by decreased sexual interest, morning erections and erectile dysfunction in the setting of serum testosterone levels below the normal adult range in older men. However, in practice, obesity and cumulative burden of ill health are more powerful predictors than biological age per se.

Key Points

- Disorders at the level of the hypothalamus or pituitary result in hypogonadotropic hypogonadism (secondary hypogonadism). Effective treatments are available for correcting testosterone deficiency and for inducing fertility in these classic forms of hypogonadism.
- Testicular defects can result in hypergonadotropic hypogonadism (primary hypogonadism). Primary hypogonadism is readily identified by elevated serum gonadotrophin levels. Testosterone treatment can ameliorate hypogonadism but fertility treatment for these disorders remains challenging.
- Apart from the small percentage of older men who exhibit some age-related testicular dysfunction, the increased prevalence of low testosterone levels in ageing men is largely due to obesity and other chronic health problems, causing suppression of gonadotrophin levels, rather than ageing per se. It remains unknown whether this phenomenon is adaptive, maladaptive or neutral in its effects.
- There is a bi-directional interaction between obesity and testosterone. Weight loss is highly effective way for obese men to simultaneously reduce their cardio-metabolic risk and increase their testosterone levels.
- Regardless of aetiology hypogonadism, sexual dysfunction and infertility can severely impact quality of life. Nursing assessment should include evaluation of psychological and interpersonal aspects.

44.1 Introduction

In men, hypogonadism is a state defined by insufficient testicular androgen (testosterone) production. Testosterone (T) deficiency may occur at any point from puberty through adult life. Hypogonadism is evidenced biochemically by low circulating serum T levels and clinically by a wide range of signs and symptoms of T deficiency (Table 44.1) (Bhasin et al. 2010). Hypogonadism can have consequences on health and well-being and contributes to male factor infertility. Among infertile couples, it is estimated that male factors contribute (fully or partially) to 20–70% of cases (Tournaye et al. n.d.). The prevalence of hypogonadism is rather difficult to pin down as

Table 44.1 Signs and symptoms suggestive of androgen (testosterone) deficiency

Clinically observable signs	Patient-reported symptoms
More specific:	
• Incomplete/delayed sexual development • Eunuchoidal proportions[a] • Gynaecomastia, breast tenderness/discomfort • Small testes (TV < 5 mL) or ↓ in volume • Oligospermia or azoospermia (infertility) • ↓ in height, ↓ BMD, or low-trauma fracture	• ↓ sexual desire (libido) • ↓ sexual activity • ↓ spontaneous erections • ↓ morning erections • Sexual dysfunction (erectile and/or orgasmic) • Hot flushes, ↑ in sweating • ↓ shaving or ↓ in body hair (axillary/pubic)
Less specific:	
• Mild anaemia (normochromic, normocytic[b]) • ↑ body mass index (BMI), ↑ body fat	• Fatigue, ↓ energy and motivation • Irritability, ↓ sense of wellbeing • Depressed mood, feeling down • Difficulty concentrating, impaired memory • Sleep disturbance/ insomnia • ↓ strength or muscle bulk • ↓ physical or work performance • ↑ frailty (impaired balance and coordination)

Bhasin et al. J Clin Endocrinol Metab 2010, Dean et al. J Sex Med 2015

[a]Altered body proportions in which armspan exceeds height by ≥7 cm. *TV* testicular volume, *BMD* bone mineral density

[b]Anaemia of chronic disease wherein the average red blood cell size and haemoglobin content are within normal limits

this depends on whether estimates are based on a diagnosis of a hypogonadism-related disease (i.e. congenital hypogonadotropic hypogonadism), as part of a clinical syndrome (i.e. diabetes) or based on a defined biochemical cut-off (i.e. serum T < 10 nmol/L). Epidemiologic data have identified an age-related decline in serum T, particularly the circulating free fraction, yet much of the increased hypogonadism with age results from concurrent health issues such as obesity, chronic disease, medications and frailty (Bhasin et al. 2010; Dean et al. 2015; Morgentaler et al. 2016; Khera et al. 2016).

44.2 Signs and Symptoms of Testosterone Deficiency

The 2010 Endocrine Society clinical Practice Guideline on testosterone therapy in men with androgen deficiency syndromes delineated two specific groups of signs and symptoms (Bhasin et al. 2010). The expert panel identified more specific signs and symptoms of hypogonadism as: incomplete/delayed sexual development, reduced sexual desire/libido, decreased spontaneous erections and erectile dysfunction, gynaecomastia, diminished facial/axillary/pubic hair, small testes (volume < 5 mL), infertility, low bone mineral density and hot flashes. These more specific signs and symptoms tend to be evident in young men with classic forms of hypogonadism. Less-specific signs and symptoms include decreased energy level, diminished motivation or initiative, feeling down or blue, difficulty concentrating, poor memory, disturbed sleep, anaemia, reduced muscle strength, increased body fat and diminished physical or work performance (Table 44.1). Notably, the correlation between signs, symptoms and serum T levels is weak as best—as underscored by a recent systematic review (Millar et al. 2016).

Indeed, the clinical presentation of hypogonadism greatly depends on age of onset, the severity of androgen deficiency, rapidity of onset and genetic and host factors. Herein, we will describe the classification of male endocrine disorders resulting from disruption of the hypothalamic-pituitary-gonadal (HPG) axis.

44.3 Testicular Disorders (Primary) Hypogonadism

A number of conditions cause insufficient testicular production of testosterone and Leydig cell dysfunction. Primary gonadal failure (hypogonadism) is characterized by elevated serum gonadotrophin levels in the setting of low T levels. Some testicular disorders underlying hypo-

Table 44.2 Causes of testosterone deficiency

Congenital disorders	Acquired disorders
Primary (1°) hypogonadism (hypergonadotropic) resulting from gonadal defects	
• Cryptorchidism Uncorrected maldescended testes (bilateral) • Chromosomal abnormalities Klinefelter syndrome (47XXY) • Disorders of sex development (DSD) 46XY gonadal dysgenesis Vanishing testes/testicular regression syndrome Steroid synthesis defects Partial/complete androgen resistance syndromes Swyer syndrome Noonan syndrome • Inactivating mutations LH receptor	• Gonadectomy • Trauma Bilateral trauma/torsion Orchiectomy • Infection/inflammation (bilateral) Mumps/viral orchitis Autoimmune polyglandular syndrome • Iatrogenic Chemotherapy (alkylating agents) Radiotherapy (pelvic irradiation) • Systemic disease HIV infection, sickle cell disease
Secondary (2°) hypogonadism (hypogonadotropic) resulting from hypothalamic-pituitary defects	
• Isolated GnRH deficiency Congenital hypogonadotropic hypogonadism Kallmann syndrome	• Tumours Pituitary adenoma (prolactinoma), craniopharyngioma, gliomas, germinomas, meningiomas, astrocytomas • Trauma/vascular Pituitary stalk dissection, pituitary apoplexy • Infiltrative disease Haemochromatosis, histiocytosis, sarcoidosis, granulomatous disease • Iatrogenic/medications Cranial irradiation, glucocorticoid therapy, high-dose corticosteroids, opioids, antipsychotics, androgen deprivation therapy, illicit drug use: marijuana, narcotics, anabolic androgenic steroids • Functional Critical illness, hyperprolactinaemia, stress, eating disorders, weight loss, excessive exercise, obesity • Systemic disease COPD, rheumatoid arthritis, chronic liver disease, chronic renal disease, diabetes
• Syndromic forms Combined pituitary hormone deficiency Septo-optic dysplasia CHARGE syndrome Bardet–Biedl syndrome Prader–Willi syndrome Congenital adrenal hypoplasia	
(*NR0B1*) • Inactivating mutations GnRH receptor Gonadotrophins	

HIV human immunodeficiency virus; *CHARGE* Coloboma, *H*eart defect, *A*tresia of nasal choanae, *R*etarded growth/development, *G*enital abnormalities and *E*ar abnormalities/deafness; *COPD* chronic obstructive pulmonary disease

gonadism are exceedingly rare such as congenital anorchia (e.g. vanishing testes, XY gonadal dysgenesis, Swyer syndrome) or Leydig cell hypoplasia secondary to inactivating mutations of the LH receptor (Salvi and Pralong 2010). Other contributors to primary hypogonadism, notably cryptorchidism and Klinefelter syndrome are much more common (Table 44.2).

44.3.1 Cryptorchidism

The lower temperature of the scrotum (compared to the abdomen) is critical for spermatogenesis. Thus, maldescended testes can have far reaching negative impact on fertility. Approximately 1–2% of males are born with cryptorchidism and the vast majority (80–90%) of cases are unilateral (Lee and Houk 2013). Importantly, testes remaining in the inguinal canal (or abdomen) have little or no function and if left uncorrected, men have increased risk of infertility, T deficiency (if bilateral) and testicular cancer. Thus, the current recommendation is that surgical correction of undescended testes be performed in the first year of life (Ritzen et al. 2007). In normal initial testicular descent between 10 and 15 weeks gestation in a process is largely driven by androgens and insulin-like peptide 3 (INSL3) as well as anti-

Müllerian hormone (AMH) (Lee and Houk 2013). As such, GnRH deficiency resulting in decreased LH-induced T secretion or gene mutations in *INSL3*, *AMH* or the androgen receptor (*AR*) can cause cryptorchidism. It is worthwhile noting that, even in cases of unilateral cryptorchidism, the contralateral testis is not completely normal suggesting that cryptorchidism is a bilateral disease (Chan et al. 2014). Similarly, so-called "retractile testes that intermittently move into the inguinal canal are not completely normal on histology. Current recommendations favour surveillance as opposed to orchiopexy (surgical correction), which is recommended for congenital undescended testes within the first year of life (Ritzen et al. 2007). Notably, there is growing concern that endocrine disrupting chemicals (EDCs) may be contributing to growing rates of cryptorchidism (Juul et al. 2014) which is discussed later in this chapter.

44.3.2 Klinefelter Syndrome (KS)

Klinefelter syndrome (47, XXY) is the most common form of male hypogonadism and the most frequent male chromosomal anomaly occurring in approximately 1:660 males (Groth et al. 2013). First described in 1942 by eminent endocrinologist Harry Klinefelter, the syndrome is clinically characterized by small testes, gonadal failure (hypergonadotropic hypogonadism), disrupted spermatogenesis (infertility), gynaecomastia and eunuchoidal proportions (armspan exceeds height by ≥7 cm). Importantly, few patients are diagnosed before puberty (<10%) and it is estimated that only about 25% of men with Klinefelter syndrome (KS) are ever diagnosed (Groth et al. 2013). While the reason for this remains unclear, it is thought that number of undiagnosed cases results from mosaic forms of KS with a milder clinical phenotype. Serum LH, FSH and inhibin B (IB) levels are typically normal until puberty at which point Leydig cells begin to hyalinize and testicular function declines (Groth et al. 2013). Testicular function progressively degenerates and testicular volume typically does not exceed 5–6 mL in KS. In light of the progressive decline in sperm, there has been recent growing interest in the possibility that early sperm extraction could potentially preserve fertility for these men (Aksglaede and Juul 2013). With access to modern assisted fertility techniques such as microdissection, testicular sperm extraction (TESE) combined with intracytoplasmic sperm injection (ICSI), men with KS are no longer categorically infertile. However, experience with and outcomes from these new techniques are limited and carry considerable ethical and emotional concerns particularly for adolescents. Professional genetic counselling is recommended for such case as well as discussion of prenatal diagnostic techniques.

Importantly, T replacement therapy is recommended once serum gonadotrophins begin to rise in early puberty, or at the very least, when serum T levels become hypogonadal (Groth et al. 2013). This can ensure full development of secondary sexual characteristics and help support bone health. Some reports have identified increased risk for mediastinal tumours, autoimmune disorders, vascular disease, thromboembolism and cancer in cohorts of patients with KS, some of which may relate to lifestyle issues. Strong evidence supports an increased risk for metabolic complications including obesity, the metabolic syndrome and type 2 diabetes. Accordingly, lifestyle coaching should be part of regular consultations along with ongoing monitoring of bone health (i.e. densitometry) and regular assessment of adherence to T replacement (Box 44.1).

Box 44.1 Nursing Process: Hypogonadism

1. Assess

Evaluate all aspects of patient health status, including aspects relating to health promotion, protection and disease prevention including signs and symptoms of testosterone deficiency (see Table 44.1).

- Take a detailed medical and family history including specific questions on pubertal timing. Perform a careful review of past and current medications.

- Examine clinically relevant signs with particular attention to degree of sexual maturation and testicular volume.
- Identify potential contributors to T deficiency such as chronic illness, medications or illicit drug use.
- Inquire about sexual function.

2. Diagnose

Work collaboratively to plan appropriate screening tests (and examinations) based on recommendations, i.e. patients presenting with infertility, sexual dysfunction, gynaecomastia diseases of the seller region, men taking medications effecting T biosynthesis or metabolism, men with HIV and weight loss, osteoporosis or low-trauma fracture.

- Identify patient knowledge deficits as areas for therapeutic education.
- Coordinate relevant radiologic examinations.
- Ensure appropriate, accurate reproductive hormone profiling, i.e. morning blood draw (between 08:00 and 12:00) in a fasting state.
- Collaborate with endocrine colleagues to determine if the patient warrants treatment based on evidence-based guidelines.
- Facilitate additional specialist referrals as needed (i.e. urology).

3. Plan

Interpret test results, recognize abnormal findings and help communicate results and implications to the patient/family.

- Prepare teaching points to address identified patient knowledge deficits.
- Review potential treatment modalities and gather materials to engage the patient in shared decision-making.
- Identify patient resources including websites, patient support groups, contacts for narcotics anonymous, weight loss programmes (nutrition and physical therapy consultations) or research studies/clinical trials as appropriate.
- Coordinate plan of care with the primary care provider to ensure continuity and collaboration if they will be overseeing treatment.

4. Implement

Initiate treatment and inform the patient of appropriate monitoring and follow-up.

- Teach proper medication administration technique with return demonstration as appropriate (i.e. sterile self-injection).
- Provide therapeutic education to ensure comprehension of the term effects of the diagnosis and key principles for management.
- Provide emotional support to patient/family based on condition-specific psychological issues and provide resource materials.
- Assess readiness for change in cases of substance abuse (rehabilitation) and obesity (initiating lifestyle modifications for weight loss).
- Reinforce the importance of therapeutic adherence for health and well-being.
- Provide prescriptions for medication and materials (i.e. syringes, needles, sharps container).
- Facilitate transition to primary care as is relevant to the plan of care.
- Plan and coordinate initial and subsequent follow-up appointments.

5. Evaluate

Assess the effectiveness of interventions and revise the plan of care as appropriate.

- Evaluate biochemical response to treatment (i.e. serum T level) paying particular attention to peak-trough pharmacokinetics based on treatment modality.
- Inquire about potential unwanted side effects of treatment.
- Monitor adherence to the treatment: Was treatment initiated? Were any doses missed either intentionally or unintentionally? Is the treatment ongoing?
- Assess actual and potential effects on patient-reported outcomes (i.e. energy level, sleep quality, sexual function).
- Inquire about sexual function and satisfaction and fertility plans or concerns.
- Monitor for other psychological comorbidities (i.e. anxiety, depression, body image concerns) and coping behaviours.
- Assess patient's ability to navigate the healthcare system including transition and financial concerns.
- Reformulate the plan of care as needed in collaboration with the healthcare team.

In addition to these health problems and the physical stigmata of KS, affected boys often have poor motor skills, behavioural problems and may exhibit neurocognitive deficits (Skakkebaek et al. 2015). While highly variable, patients with KSD may have problems with cognition and language acquisition (i.e. dyslexia), learning disabilities and difficulties with executive function. These difficulties often require speech-language therapy, special education programmes and/or psychological counselling. The combination of cognitive behavioural problems and hypogonadism can negatively affect quality of life and the effective adaptation to living with KS (Turriff et al. 2015). Impulsivity and anger-management issues may be inherent to the condition and are very unlikely to be caused or exacerbated by physiological testosterone replacement. Accordingly, comprehensive holistic nursing care includes assessment of psychosocial concerns, discussing these aspects with patients and families, identifying educational and coping resources, and making appropriate interprofessional referrals as needed (Box 44.1).

44.3.3 Disorders of Sex Development (DSD)

Disorders of sex development (DSD) include a wide range of conditions spanning a broad spectrum of phenotypic features and pathophysiology (Hughes et al. 2006). Most cases of DSD are identified at birth as atypical or ambiguous genitalia are the impetus for evaluation. Atypical genitalia (i.e. hypospadias, a condition when the urethra opens on the ventral side of the penis rather than at the tip) at birth can be common occurring in 1:300 births. However, truly ambiguous genitalia, most often caused by congenital adrenal hyperplasia (CAH), are quite rare and occur in roughly 1:5000 births (Hughes et al. 2006). In some cases, adolescents may present because of lack of pubertal development. There are a number of 46XY DSD wherein the gonads are in fact testes, yet serum T is pathologically low. Many of these conditions are autosomal recessive genetic disorders resulting in defective enzymes (comprehensively summarized in Hughes et al. 2006). Patients with DSD deserve care by an inter-professional team (i.e. endocrinology, radiology, surgery, psychology, psychiatry and nursing) (Hiort et al. 2014). These patients and families need psychological support and should be connected with available patient support groups (Brain et al. 2010). Nurses can play a key role in supporting patients and families, facilitating communication within the multidisciplinary team and providing patient-centred, coordinated care (Box 44.1).

44.3.4 Acquired Primary Hypogonadism

Acquired forms of primary hypogonadism (testicular failure) may result from trauma, infection/inflammation (i.e. mumps orchitis), iatrogenic or secondary to systemic disease (Table 44.2). One type of traumatic injury, testicular torsion, has an

incidence of 4.5 cases per 100,000 (Ross and Bhasin 2016). It occurs when the testes become twisted on the spermatic cord cutting off blood flow to the testes. If not corrected urgently (i.e. within 6–8 h), necrosis can permanently damage the testes resulting in infertility and T deficiency. Testicular inflammation (orchitis) may be secondary to viral infection. Among post-pubertal men, orchitis occurs in roughly a quarter of mumps infections (Ross and Bhasin 2016). Unilateral inflammation occurs in about two-thirds of cases and may result in diminished testicular size yet 75% maintain fertility. Bilateral cases are more severe as only a third of men recover spermatogenesis (Ross and Bhasin 2016).

44.4 Hypothalamic and Pituitary Disorders (Secondary) Hypogonadism

As reviewed in the previous chapter, testosterone production is contingent upon adequate gonadotrophin stimulation (i.e. luteinizing hormone, LH) of the Leydig cells. Hypogonadism resulting from inadequate gonadotrophin stimulation is biochemically evident in low (or inappropriately normal) serum gonadotrophin levels—thus hypogonadotropic hypogonadism. Secondary hypogonadism may be congenital (from birth) or acquired (Table 44.2). Hypogonadotropic hypogonadism may result from defects at the level of the hypothalamus (i.e. isolated GnRH deficiency), pituitary defects causing inadequate gonadotrophin release, genetic mutations resulting in inadequate action of GnRH/gonadotrophins as well as via functional suppression of the neuroendocrine axis (Boehm et al. 2015).

44.4.1 Congenital Hypogonadotropic Hypogonadism

Congenital hypogonadotropic hypogonadism (CHH) is a rare disorder (1/4000–10,000) caused by isolated GnRH deficiency and clinically characterized by absent or incomplete puberty and infertility (Boehm et al. 2015). When CHH occurs with anosmia (lack of sense of smell), it is termed Kallmann syndrome. While sense of small and reproduction may appear to be unrelated functions, the embryonic origins of GnRH neurons in the olfactory placode provide the development link. More than 20 genes have been identified as underlying CHH and Kallmann syndrome either alone or in combination (Boehm et al. 2015; Stamou et al. 2015). Some gene mutations disrupt GnRH neuron development and migration—manifesting as Kallmann syndrome. Other mutations may disrupt GnRH homeostasis and secretion and clinically present as cases of normosmic CHH (Boehm et al. 2015). In some cases, mutations in the gene encoding the GnRH receptor (*GNRHR*) result in decreased GnRH action and CHH ensues (described below). CHH may occur with other associated phenotypes such as cryptorchidism with/without micropenis, renal agenesis, hearing loss, midline defects (cleft lip/palate) and skeletal anomalies. CHH is difficult to diagnose and many patients are diagnosed late with significant psychosocial impact (Dwyer et al. 2014). These patients are in need of psychological support and may benefit from peer-to-peer support (Box 44.1). Effective treatments are available for inducing secondary sexual characteristics and fertility in most cases (Boehm et al. 2015; Rastrelli et al. 2014). Spontaneous reversion of CHH is observed in about 10–15% of cases following treatment, but may not be sustained permanently and thus warrant ongoing monitoring (Dwyer et al. 2016).

44.4.2 Syndromic Forms of Secondary Hypogonadism

Developmental defects can result in hypothalamic-pituitary dysfunction and hypogonadotropic hypogonadism. Many problems present with a constellation of features and thus are referred to as syndromic forms. These cases are typically identified during childhood as anterior hormone deficiency, adrenal failure, obesity of neurologic aspects command attention far before absent puberty is clinically evident (Brioude

et al. 2010). Given the complexity of these cases, patients and families need purposeful planned transitional care to ensure continuity and ongoing support (Box 44.1).

44.4.2.1 Combined Pituitary Hormone Deficiency (CPHD) and Septo-Optic Dysplasia (SOD)

Patients with combined pituitary hormone deficiency (CPHD) often are identified early in childhood and treated for the respective pituitary hormone deficiencies, yet gonadotrophin deficiency may not become apparent until the failure of puberty to commence spontaneously. Importantly, these patients are responsive to treatment inducing secondary sexual characteristics and fertility (Mao et al. 2015). A number of genes have been identified to underlie this condition yet the majority of cases remain without an identified genetic cause (Castinetti et al. 2016). Septo-optic dysplasia (SOD) is a developmental brain malformation that may occur with pituitary hormone deficiency as well as severe visual impairment, neurocognitive disability and developmental disorders on the autism spectrum (Ryabets-Lienhard et al. 2016). Notably, genetic overlap has been reported between SOD, CPHD and Kallmann syndrome (Raivio et al. 2012).

44.4.2.2 CHARGE, Bardet–Biedl and Prader–Willi Syndromes

The constellation of coloboma (ocular malformation of the lens, iris or retina), congenital heart defects, choanal atresia (abnormal formation of the nasal cavity), retardation of growth and development, genital hypoplasia, and ear anomalies associated with deafness define CHARGE syndrome (Bergman et al. 2011). In addition to additional immunologic problems, patients with CHARGE syndrome may exhibit hypogonadotropic hypogonadism necessitating treatment. Approximately two-thirds of cases are explained by mutation Chromodomain-helicase-DNA-binding protein 7 (*CHD7*) (Bergman et al. 2011) a gene also involved in CHH and Kallmann syndrome (Boehm et al. 2015). Bardet–Biedl syndrome (BBS) is a recessive genetic disorder of the cellular cilia that may present with a wide range of clinical features (obesity, mental retardation, renal anomalies, polydactyly, retinal degeneration, hypogonadism, as well as cardiovascular, hepatic and metabolic problems (Khan et al. 2016). In addition to being clinically heterogeneous, BBS is genetically diverse with 19 identified loci and complex genetics (i.e. digenicity, oligogenicity) (Khan et al. 2016) akin to CHH and Kallmann syndrome (Boehm et al. 2015). Prader–Willi syndrome (PWS) is a rare genetic disorder (1/10,000–25,000) on chromosome 15 that causes physical, mental and social disability. During infancy, PWS is characterized by hypotonia and poor feeding (failure to thrive). Subsequently, additional features such as developmental delays, cognitive disability, short stature, hyperphagia, obesity and behavioural problems (i.e. obsessive food seeking) emerge (Angulo et al. 2015). Multiple endocrine deficiencies are not uncommon. Patients typically receive growth hormone and sex steroid treatment (Deal et al. 2013).

44.4.2.3 Congenital Adrenal Hypoplasia

A rare form of hypogonadotropic hypogonadism occurs in the setting of congenital adrenal hypoplasia. Mutations in Nuclear receptor subfamily 0, group B, member 1 (*NR0B1*, formerly *DAX1*) result in early adrenal failure and subsequently absent/incomplete puberty is the initial sign of hypogonadotropic hypogonadism (Jadhav et al. 2011).

44.4.3 Inactivating Mutations

Much like a lock and key, proper signalling requires both functional ligand and receptor. Mutations in genes encoding the ligands upstream of GnRH (*KISS1*, formerly *GPR54*), GnRH itself (*GNRH1*), LH (*LHβ*) and FSH (*FSHβ*) are exceedingly rare causes of secondary hypogonadism (Salvi and Pralong 2010; Boehm et al. 2015; Chan 2011). The receptors of these ligands (*KISS1R, GNRHR, LHR, FSHR*) belong to the G-protein coupled receptor super-family

and mutations are very rare (but for *GNRHR*). Mutations in *FSHR* cause disrupted albeit not complete infertility, and non-functioning LHR can result in hypospadias, micropenis and/or Leydig cell hypoplasia (i.e. 46XY disorder of sex development, DSD) (Salvi and Pralong 2010). Typically the serum levels of the mutated hormone are undetectable while the other gonadotrophin is elevated. Interestingly, mutations in GNRHR underlie approximately 4–5% of CHH cases and may be overcome by high doses of GnRH (Boehm et al. 2015) and have been identified in a number of CHH reversals (Dwyer et al. 2016).

44.4.4 Acquired Forms

Acquired hypogonadism refers to T deficiency in adult life subsequent to full pubertal development. T deficiency of neuroendocrine origin can result from trauma (i.e. skull fracture, pituitary stalk dissection), vascular events (i.e. pituitary apoplexy), infiltrative disorders (i.e. hemochromatosis) or from illicit drug use (i.e. marijuana, opiates or anabolic androgenic steroids) suppressing the HPG axis as well as iatrogenic caused or secondary to systemic disease (Ross and Bhasin 2016). Anabolic androgenic steroids are used without medical supervision to enhance athletic performance and appearance and the estimated lifetime prevalence of abuse is approximately 6% of men (Nieschlag and Vorona 2015). The extremely high circulating androgen levels suppress the HPG axis resulting in testicular atrophy and infertility. These consequences are reversible yet products are typically used in very high doses and as some products have an extended half-life, recovery of HPG axis function may take several months and in some cases up to a year or longer (Nieschlag and Vorona 2015).

Another form of acquired secondary hypogonadism occurs in men with adult-onset isolated GnRH deficiency. These men complete puberty then present in adulthood with decreased libido, poor sexual function and infertility secondary to a crash of their HPG axis (Nachtigall et al. 1997). Notably, detailed hormone profiling with blood draws every 10 min reveals pulsatile LH secretion patterns with frankly hypogonadal T levels. The men have no other apparent underlying cause of their hypogonadism and defect is identified as hypothalamic as these men respond to physiologic pulsatile GnRH replacement. Long-term follow-up studies suggest that the neuroendocrine defect is permanent as these men do not subsequently recover HPG axis function (Dwyer et al. 2010).

44.4.5 Functional Causes

Secondary hypogonadism can also result from physiologic causes. Such cases of functional hypogonadism are much more common in females, wherein physical, emotional or nutritional stressors can result in suppression of menses (functional hypothalamic amenorrhea) (Fourman and Fazeli 2015). Males appear to be much more resistant to hypothalamic suppression from either excessive exercise or energy deficits as only small series have been reported to date (Chavan et al. n.d.). Typically, such cases are restricted to patients with eating disorders (i.e. anorexia nervosa) or endurance athletes on highly very low-fat diets. A much more common form of functional hypogonadism results from hyperprolactinaemia suppressing hypothalamic GnRH secretion. Elevated serum prolactin levels may result from physiologic causes (e.g. stress, illness, sleep deprivation), pathophysiologic (i.e. prolactin-secreting tumour) or iatrogenic causes (i.e. medications) (Ajmal et al. 2014). Notably, dopamine negatively regulates prolactin while serotonin has a stimulatory effect on prolactin. Thus, antipsychotic medications that block dopamine action and anti-depressants (i.e. selective serotonin reuptake inhibitors, SSRIs) can cause elevated prolactin levels and may induce hypogonadism (Ajmal et al. 2014). Importantly, eugonadal function returns with the removal of the underlying cause of hyperprolactinaemia. A key component of identifying the root cause of hypogonadotropic hypogonadism is ruling out potential causes. This demands a detailed history taking with a careful medication review and biochemical assessment (Box 44.1).

44.5 Ageing and Testosterone Deficiency

Serum LH and FSH levels define hypo- and hypergonadotropic forms of hypogonadism. However, a certain percentage of men present in adulthood with low testosterone as well as signs and symptoms of hypogonadism (Table 44.1). These men often have elements of both presentations with both pituitary and testicular hyposecretion—thus mixed hypogonadism. This is characteristic of the presentation of many ageing men. There have been four key epidemiologic studies examining testosterone deficiency in ageing men (summarized in Dean et al. 2015): the Massachusetts Men's Aging Study (n > 1600, aged 40–70 years), Boston Area Community Health Survey (n > 1400, aged 30–79 years), Hypogonadism in men (n > 2100, aged >45 years) and the European Male Ageing Study (EMAS) (n > 3000, aged 40–79 years). These studies point to a progressive decline in serum T with age as well as alterations in sex hormone binding globulin (SHBG). Historically, a number of vague terms have been used to describe the age-related fall in serum T including male menopause, andropause, and androgen deficiency syndrome of the ageing male. Recently, more precise definitions have provided much-needed clarity to this phenomenon. EMAS was a multicentre European cohort study of years that defined "late-onset hypogonadism" (LOH) as at least three sexual symptoms (decreased sexual interest, morning erections and erectile dysfunction [ED]) in the setting of a total serum T level < 11 nmol/L (317 ng/dL) and free T < 220 pmol/L (Wu et al. 2010). Presently, a number of international organizations agree that LOH (the preferred European term) (Wang et al. 2008) and adult-onset hypogonadism (AOH, the term put forth by the Sexual Medicine Society of North America) (Khera et al. 2016) include both laboratory and symptom-based criteria.

Importantly, actual symptomatic testosterone deficiency occurs in a small minority of ageing men and is only in the range of 2–6% (Dean et al. 2015). Notably this can be largely attributed to comorbidities, and in particular obesity (described below) (Morgentaler et al. 2016). Moreover, EMAS investigators found that with age 2% of men had a primary hypogonadism and that approximately 10% had a compensated hypogonadism meaning that they were able to maintain normal serum T levels via increased pituitary LH secretion (Tajar et al. 2010). These men with primary and compensated hypogonadism were older than their eugonadal counterparts. Regardless of age, T therapy effectively resolves signs and symptoms of testosterone deficiency including libido and sexual function particularly when levels are <8 nmol/L (231 ng/dL) (Morgentaler et al. 2016). While older men are more prone to erythrocytosis and prostate problems than younger counterparts, these are not reasons for withholding T treatment if monitored appropriately (Aversa and Morgentaler 2015) (Box 44.1).

44.6 Obesity-Related Testosterone Deficiency

There are consistent data showing a negative correlation between obesity and T (free, albumin bound and total) regardless of age (Kelly and Jones 2015). Some have proposed that obesity is the most common cause of T deficiency in the developed world (Dean et al. 2015) as obesity is the single most powerful predictor (Tajar et al. 2010). Obese men with T deficiency often exhibit low-normal serum gonadotropins suggestive of a mixed cause. Importantly, it is reversible and studies using lifestyle modification (i.e. diet and exercise) or bariatric surgery show that the increase in serum T is proportional to the amount of weight loss (Kelly and Jones 2015). The relationship between T and fat (obesity) is bi-directional. For instance, T deficiency results in decreased lean muscle mass and increased fat mass, this increased fat mass spurs aromatase activity in the adipocytes, higher aromatase increases the conversion of T to oestradiol, thereby directly decreasing circulating T as well as indirectly via oestradiol-mediated suppression of GnRH secretion. This creates a vicious cycle. The exact mechanism has yet to be fully

elucidated. It is notable that the variety of contributing factors is diverse, ranging from excess aromatization to oestradiol and the subsequent suppressive effect of oestradiol on GnRH secretion to the inhibitory effects of leptin, adiponectin, and gut hormones ghrelin, peptide YY, the effects of pro-inflammatory adipocytokines (i.e. tumour necrosis factor alpha, interleukin 6) and physiologic stressors accompanying obesity (i.e. chronic disease, sleep apnoea, arthritis) (Kelly and Jones 2015).

It is widely known that obesity increases the risk for developing metabolic problems such as hypercholesterolemia and type 2 diabetes. Abdominal obesity (visceral) in particular is a major factor in the metabolic syndrome that includes a constellation of abnormalities (Alberti et al. 2009) that heighten metabolic and cardiovascular risk as well as all-cause mortality. Both large-scale studies and meta-analyses demonstrate that T deficiency is strongly linked with increased risk for developing obesity, the metabolic syndrome and type 2 diabetes (Khera et al. 2016). Therefore, it is prudent to take a two pronged approach to obesity-related hypogonadism: promote lifestyle modification to achieve weight loss and treat confirmed T deficiency. Nursing plays a key role in educating patients about health risks, identifying resources for enhancing self-management, coaching and guiding patients on lifestyle modification and evaluating adherence to treatment and providing positive reinforcement as patients work to meet their individual goals (Box 44.1).

44.7 Tumours

Tumours such as craniopharyngiomas, pituitary adenomas, gliomas, germinomas and meningiomas can cause secondary hypogonadism through different mechanisms. As space-occupying lesions, compression and destruction of the hypothalamic-pituitary region can impair GnRH-induced gonadotrophin secretion causing hypogonadism. Such lesions are more apt to perturb gonadotrophin secretion, and so these patients typically present with hypogonadism with normal adrenal and thyroid function. Alternatively, prolactin-secreting pituitary adenomas (prolactinomas) cause hyperprolactinaemia and suppress the neuroendocrine axis (Ross and Bhasin 2016). In adults, prolactinomas (pituitary adenomas) are the most frequent tumours causing hypogonadotropic hypogonadism.

44.8 Iatrogenic

In certain cases, hypogonadism may be secondary to medical intervention. This is typically an unwanted side effect of chemotherapy, radiation treatment, long-term glucocorticoid therapy, high-dose corticosteroid treatment or subsequent to narcotics use for chronic pain management. In contrast, T deficiency is the goal of androgen deprivation therapy (ADT) and is an alternative to surgical castration for the treatment of prostate cancer.

44.8.1 Post Chemotherapy or Radiation Therapy

Several different medical treatments may cause hypogonadism as an unwanted secondary effect including chemotherapy/radiation therapy, long-term glucocorticoid treatment and chronic opioid use for pain management (Ross and Bhasin 2016). The late effects of childhood cancer are reviewed extensively in an accompanying chapter yet it is worthwhile to note that hypogonadism and infertility are potential sequelae in adolescence and young adults (Dwyer et al. 2015). The late effects depend on multiple factors including sex, age and degree of pubertal development at the time of treatment, as well as the type of cancer and the specific therapeutic regimens employed (Rose et al. 2016). In particular, alkylating agents (e.g. mechlorethamine, cyclophosphamide, ifosfamide, procarbazine, busulfan, melphalan and cisplatin) and platinum compounds used in chemotherapeutic regimens can be particularly damaging to the gonads (Kenney et al. 2012). The hypothalamus is more sensitive to irradiation than the pituitary. Head

and/or brain radiotherapy (≥30 Gy) can result in secondary hypogonadism and pelvic irradiation (≥2 Gy) often causes primary gonadal failure and patients are invariably infertile following doses exceeding 4–6 Gy (Rose et al. 2016; Kenney et al. 2012). Broadly speaking, testes are more sensitive to damage from adjuvant treatment compared to ovaries (Kenney et al. 2012). Given the impact that T deficiency can have on bone health, sexual function, psychological well-being and quality of life of these patients warrant ongoing surveillance and a planned purposeful transition to adult endocrine care (Dwyer et al. 2015) (Box 44.1).

44.8.2 Medications

Chronic glucocorticoid treatment or high-dose corticosteroids may lead to hypogonadism (Ross and Bhasin 2016; Rose et al. 2016). The absence of a compensatory increase in LH among patients on long-term glucocorticoid therapy suggests that this acts via a central mechanism. Chronic opiate use for pain management (or methadone treatment for narcotic addiction) causes T deficiency (De Maddalena et al. 2012). Like the functional medication-induced hypogonadism caused by antipsychotics and SSRIs (see Sect. 43.1.4), opioid-induced hypogonadism is reversible with cessation of treatment. However, it can be a particularly challenging form of reversible hypogonadism to treat as the narcotics are typically essential for pain management. These medication-induced causes of hypogonadism underscore the necessity of careful medical history taking and medication review.

44.8.3 Androgen Deprivation Therapy

Androgen deprivation therapy (ADT) is an approach for treating prostate cancer that medically induces hypogonadism to reduce androgen action on the prostate. Long-acting GnRH analogues are used to block GnRH secretion resulting in biochemical castration. By definition, this causes T deficiency with its corresponding symptoms (Table 44.1) as well as a number of adverse effects including loss of bone density and lean muscle mass, increased risk for developing type 2 diabetes and cardiovascular disease and diminished quality of life (Ostergren et al. 2016). Men receiving ADT should be closely monitored for complications and appropriate measures including exercise can be employed to mitigate the fatigue, body composition changes, and maintain function during treatment (Ostergren et al. 2016). Nurses can play a key role in the ongoing care of these patients by assessing changing in status, discussing how therapy is impacting quality of life (including sexual function) as well as planning, implementing and encouraging physical exercise (Box 44.1).

44.9 Systemic Disease

Stress from acute illness can suppress the HPG axis causing temporary periods of reversible hypogonadism. Surgery, burn injuries, myocardial infarction, stroke and sepsis have all been noted to suppress the HPG axis (Kalyani et al. 2007). When stress becomes prolonged as in the case of chronic illness, central suppression of GnRH-induced gonadotrophin secretion can produce hypogonadotropic hypogonadism. Hypogonadism is frequently observed in patients with chronic obstructive pulmonary disease (approximately 40% of cases) and human immunodeficiency virus (HIV) infection (between 30 and 50%). Androgen deficiency is also associated with cancer, rheumatoid arthritis, sickle cell disease, chronic liver and renal disease as well as diabetes (Kalyani et al. 2007). Notably, T deficiency is observed in 50% of obese men with diabetes (Kelly and Jones 2015). While current recommendations do not call for systematic screening of men with diabetes for T deficiency (Bhasin et al. 2010), the endocrine nurse should be aware of prevalence among obese men with diabetes and can play an integral role in the ongoing assessment and monitoring for symptoms of hypogonadism (Table 44.1).

44.10 Endocrine Disrupting Chemicals

Endocrine disrupting chemicals (EDCs) are substances in foods, consumer products and the environment that interfere with hormone action and disrupt health or reproduction (Diamanti-Kandarakis et al. 2009). There is mounting concern that EDCs pose a significant public health concern. EDCs are heterogeneous and widespread in the environment, consumer goods and food. Many synthetic chemicals and solvents as well as their byproducts contain EDCs, i.e. dioxins or polychlorinated biphenyls (PCBs). Some pharmaceutical agents include harmful substances (i.e. diethylstilbestrol, DES) as do plasticizing agents (phthalates). Environmental and food exposures may result from pesticides (dichlorodiphenyltrichloroethane, DDT), fungicides (i.e. vinclozolin) or even in naturally occurring chemicals in some foods (i.e. phytoestrogens) (Diamanti-Kandarakis et al. 2009). EDCs may exert their effect through varied mechanisms including direct action on hormone receptors (i.e. diethylstilbestrol [DES] acting on oestrogen receptor α, bisphenol A [BPA] acting on oestrogen receptor β), direct/indirect interference with hormone synthesis or metabolism, altering hormone receptor expression, or by epigenetic mechanisms (Sweeney et al. 2015).

Interestingly, epigenetic modifications (i.e. DNA methylation, non-coding RNAs, histone modification, altered chromatin structure) can be passed via sperm resulting in transgenerational inheritance of diseases that include behavioural effects, obesity and reproductive disorders (Skinner 2016). There is growing evidence for early life origins of some adult diseases. The premise is that the foetal environment and environmental exposures can alter cellular, stem cell and tissue development predisposing one to obesity or reproductive disorders later in life. Lifestyle factors, notably, maternal smoking has been linked with preterm and low birth-weight infants and these children are at increased risk for developing obesity later in life (Heindel et al. 2015). Moreover, some have posited that early exposure to wide ranging environmental chemicals (i.e. bisphenol A, flame retardants, phthalates) and so-called "obesogens" predispose individuals to obesity and have helped fuel the growing obesity epidemic (reviewed in (Heindel et al. 2015)). Thus, it is tempting to speculate that such obesogen exposures could indirectly contribute to male T deficiency via obesity.

Epidemiologic data from the past 50 years demonstrate progressively earlier pubertal onset and falling fertility rates with concomitant decreasing sperm quality as well as increasing rates of cryptorchidism, hypospadias and testicular germ cell cancer (Juul et al. 2014). The Testicular Dysgenesis Syndrome (TDS) has been proposed as a potential explanation for these observations (Juul et al. 2014). This model posits that adverse environmental exposures combined with genetic defects, and the foetal environment (i.e. placental function, intrauterine growth disorders) influence testicular development and function later in life. Epidemiologic and clinical data as well as research in animal models provide support to this model. However, research clearly identifying causality between EDCs and human developmental defects and disease (i.e. cancer) is limited by a number of methodological challenges. In particular, real-world conditions are difficult to replicate using cell-based or animal models given inter-species differences and the ubiquity of EDCs (Sweeney et al. 2015). In the laboratory environment, one can study the effects of a single substance while strictly controlling the route of administration, dosage and the duration of exposure. However, this is quite different from a real-life context in which age, developmental stage, mixtures of exposures and latency from exposure likely play significant contributing roles. Certainly, more research and scientific evidence is needed to elucidate the precise mechanisms and risks associated with EDCs. In the meantime, a cautionary and preventive approach to limiting human exposure to EDCs seems warranted and is advocated (Diamanti-Kandarakis et al. 2009).

44.11 Conclusions

Congenital and acquired disorders of the hypothalamus, pituitary or testes can cause androgen deficiency eliciting signs and symptoms of hypo-

gonadism. Measuring serum gonadotrophins is a means to dissect the axis separating primary from secondary forms of hypogonadism. T deficiency can have deleterious effects on bone health, places men at higher cardio-metabolic risk and can negatively impact well-being and quality of life. Hypogonadism can be effectively managed, yet treatment should only be initiated after appropriate evaluation and unequivocal biochemical confirmation on at least two morning measurements (Bhasin et al. 2010). Endocrine nurses can play an important role for patients with hypogonadism by helping to provide comprehensive coordinated care and promoting health and well-being.

Abstract

Among male adolescents, lack of spontaneous pubertal development is a common reason for presenting for endocrine evaluation. Among adult men, symptoms of androgen deficiency, sexual dysfunction and/or infertility are chief complaints that often motivate patients to seek reproductive endocrine consultation. Obtaining a comprehensive medical history, performing a clinical examination and conducting laboratory diagnostic testing are cornerstones for evaluating the hypothalamic-pituitary-gonadal (HPG) axis. Sexuality and

reproduction can be sensitive topics and some patients may find it challenging to discuss such matters. Herein we present best nursing practices for history taking and review the clinical competencies for physical examination. The rationale and value of specific hormone assays and the role of stimulation testing will be reviewed in relation to clinical decision-making as well as the appropriate use of imaging studies. Male reproductive disorders may span several domains including endocrinology, andrology, urology and genetics. Thus, appropriate referrals and coordination of care are important factors for management. This chapter is a mini-review for endocrine nurses providing a synopsis of the approach to and evaluation of patients with hypogonadism, sexual dysfunction and infertility. Particular emphasis is placed on providing comprehensive coordinated care that includes patient education, anticipatory guidance and addressing patients' psychosocial concerns.

Keywords

Androgen deficiency · Gonadotrophins Hypogonadism · Infertility · Sexual dysfunction · Testes · Testosterone

Abbreviations

BMI	Body mass index
CBAVD	Congenital bilateral absence of the vas deferens
CDGP	Constitutional delay of growth and puberty
CFTR	Cystic fibrosis transmembrane regulator
CGH	Comparative genomic hybridization
CHH	Congenital hypogonadotrophic hypogonadism
CT	Computed tomography
DSD	Disorder of sex development
DXA	Dual X-ray absorptiometry
ED	Erectile dysfunction
EMAS	European Male Ageing Study
FSH	Follicle stimulating hormone
GnRH	Gonadotrophin-releasing hormone
HbA1c	Glycated haemoglobin
HIV	Human immunodeficiency virus
HPG	Hypothalamic-pituitary-gonadal
IPSS	International Prostate Symptom Score
LH	Luteinizing hormone
LOH	Late-onset hypogonadism
LUTS	Lower urinary tract symptoms
MRI	Magnetic resonance imaging
SHBG	Sex hormone binding globulin
T	Testosterone
TV	Testicular volume

Key Terms

- **Hypogonadism:** The combination of repeated, unequivocally low serum testosterone levels with clinical signs and symptoms of androgen deficiency.
- **Sexual dysfunction:** The inability to engage in normal, pleasurable sexual activity resulting from diminished desire (libido), arousal difficulties (erectile dysfunction) and/or problems with orgasm (ejaculation).
- **Infertility:** The inability to achieve pregnancy following regular unprotected intercourse for 12 months. Factors may be male, female or mixed (both) in origin.
- **Testicular volume:** A measure of testicular size. Volume predominantly reflects the development of the seminiferous tubules and is an important predictor of fertility potential. It is most frequently measured via Prader orchidometer or via calculation of ultrasound measurement in three planes.

Key Points

- The clinical presentation of androgen deficiency differs according to the underlying cause, age of onset and prior treatment(s).
- A thorough diagnostic evaluation is warranted prior to initiating testosterone replacement therapy. The decision to initiate treatment should be based on at

least two low morning serum testosterone levels and signs/symptoms of testosterone deficiency.
- Regardless of aetiology, hypogonadism, sexual dysfunction and infertility can severely impact quality of life. Nursing assessment should include evaluation of psychological and interpersonal aspects.
- Endocrine nurses can play an important role in providing clear patient communication to set appropriate expectations, effectively counsel and engage them in shared decision-making.

45.1 Introduction

The evaluation of the hypothalamic-pituitary-gonadal (HPG) axis is guided by the presenting symptoms of the patient. Therefore, a significant part of a consultation includes a careful review of systems, taking a detailed history and reviewing medications. Findings from a focused clinical examination can provide key additional information yet diagnosing endocrinologic disorders is largely based on serum hormone measurement that may be complemented by dynamic endocrine testing and imaging studies. This chapter provides the endocrine nurse with an overview of the approach to evaluating male patients presenting with complaints of hypogonadism, sexual dysfunction and/or infertility. This will include a synthesis of best practices for history taking and eliciting symptoms, a summary of skills needed to identify clinical signs on examination, a discussion of clinical judgement and decision-making related to diagnostic testing, and a review of elements contributing to comprehensive coordinated nursing care of these patients.

45.2 Medical History

The medical history is a key clinical tool that serves two important functions. First, it is typically the initial patient interaction and the first step in developing a therapeutic relationship, thus setting the tone for subsequent interactions. Second, it provides essential information on the chief complaint and guides subsequent aspects of the evaluation. History taking is a structured process following a certain logical progression beginning with open-ended questions to elicit the chief complaint and the chronology of the present problem and their reason for seeking care. While it seems completely obvious, it is worthwhile to underscore that common courtesy (i.e. introducing yourself), having good eye contact and active listening are important for developing trust (Ball et al. 2014; Keller and Carroll 1994; Brega et al. 2015) (Box 45.1).

Box 45.1 Approach to Fostering Effective Communication with Patients

- Be courteous, introduce yourself to the patient and any others accompanying them
- Ensure physical comfort for the patient in a quiet, private setting
- Take the history with the patient fully clothed
- Ask the patient about their reason for the consultation—don't simply assume that you know
- Make eye contact, don't let your face be obscured by a computer monitor or paper chart.
- Begin the encounter with open-ended questions and progress towards more directed questioning
- Try to avoid leading questions
- Use simple language
- Show empathy
- Use active listening techniques (i.e. eye contact, nodding, re-framing statements)
- Keep a neutral tone, avoid being judgemental
- Respect silent pauses, try not to interrupt unless necessary
- Do not trivialize any concerns or complaints

Box 45.1 (continued)

- For sensitive topics,
  - don't apologize
  - be direct
  - use clear language (i.e. no slang)
  - encourage them to be open and honest
  - affirm confidentiality
- Inquire how the present condition is making them feel, if it is causing them stress or impacting their quality of life
- Provide a brief summary at the end and give the patient the opportunity to elaborate or correct any points

These practices can help put patients at ease and facilitate discussion of sexuality and reproduction.

Frequent reasons for presenting for reproductive endocrine consultation include absent or incomplete puberty in adolescents (Sedlmeyer and Palmert 2002), sub-fertility in adult men (Anawalt 2013) and symptoms of androgen deficiency in older adults (Khera et al. 2016). Hypogonadism can contribute to all of these situations yet the clinical presentation depends largely on the age of onset, the severity of androgen deficiency, rapidity of onset, as well as genetic factors. A number of questionnaires have been developed to assess symptoms of hypogonadism. However, the currently available instruments lack specificity and thus are not recommended for use as a screening tool (Bhasin et al. 2010; Dean et al. 2015). Rather, a detailed medical and family history as well as a careful review of symptoms is required. Medical history should include attention to any congenital defects, growth and development, pubertal history as well as any medical problems, diagnoses and chronic health problems, surgeries and medications (including vitamins and nutritional supplements). Findings will help direct subsequent clinical and laboratory inquiry. For instance, midline defects, cryptorchidism and micropenis can be associated with congenital hypogonadotrophic hypogonadism (CHH) (Boehm et al. 2015) and learning disabilities and scholastic problems may be manifestations of Klinefelter syndrome (Skakkebaek et al. 2015). A detailed medication review is essential as a variety of medications and illicit drugs can contribute to developing hypogonadism and erectile dysfunction (ED). Additionally, probing social history may provide clues for potential contributing lifestyle factors such as illicit drug use, high alcohol consumption, tobacco use, stress or excessive exercise that can disrupt the reproductive endocrine axis function (Table 45.1) (Bhasin

Table 45.1 Conditions and medications implicated in men's reproductive health (Bhasin et al. 2010; Dean et al. 2015; Foote et al. 2015; Young 2012)

Androgen deficiency	Erectile dysfunction	Decreased semen quality
Associated factors		
Obesity Metabolic syndrome Diabetes HIV infection Sickle cell disease Eating disorders	Obesity Metabolic syndrome Diabetes Hypertension/CV disease Hyperlipidemia Androgen deficiency Lower urinary tract symptoms Depression Tobacco use	Obesity Tobacco use Heavy alcohol use
Medications and drugs		
Opioids Glucocorticoids 5-aplha reductase inhibitors, Sulfasalazine GnRH agonists (androgen deprivation therapy) Spironolactone Ketoconazole Anabolic androgen abuse Marijuana	Antidepressants Beta blockers Aldosterone receptor antagonists Thiazide diuretics	antidepressants anabolic androgen abuse marijuana

et al. 2010; Dean et al. 2015; McCabe et al. 2016; Tournaye et al. 2016a).

Family history is an important contributing factor and construction of a genogram can be particularly useful for visualizing patterns within families (Au et al. 2011). Questions about infertility in the family, difficulty conceiving, miscarriages, midline defects, chronic diseases, delayed puberty or so-called "late-bloomers" and abnormal or lack of sense of smell (anosmia) are important points to elicit. Consanguinity (when members of the family are related by blood) is not taboo in all cultures and this should be assessed using straightforward direct questioning. Notably, pubertal timing has a strong hereditary component as 50–75% of patients with delayed puberty have a family history (Wehkalampi et al. 2008). Interestingly, family pedigrees of patients with CHH are enriched for delayed puberty and recent genetic studies have begun to unravel the genetic contribution to pubertal timing (Boehm et al. 2015). However, it still remains clinically challenging to differentiate common causes of delayed puberty (i.e. constitutional delay of growth and puberty, CDGP) from much less common forms of permanent hypogonadism such as CHH (discussed in detail later in this chapter).

Lastly, an age-appropriate review of systems is effective for evaluating general health and identifying potential underlying problems. In reviewing the genito-urinary system, it is important to assess for lower urinary tract symptoms (LUTS) as these symptoms are closely associated with erectile dysfunction (Seftel et al. 2013). Using a validated instrument such as the International Prostate Symptom Score (IPSS) can be useful in quantifying the degree and severity of symptoms experienced by the patient. Sexual dysfunction warrants specific inquiry including assessing for changes in sexual desire (libido), difficulties achieving or maintaining an erection (erectile dysfunction [ED]) and problems with ejaculation, as well as for eliciting other signs and symptoms suggestive of androgen deficiency that warrant hormonal screening (Bhasin et al. 2010).

The Endocrine Society Clinical Practice Guideline (Bhasin et al. 2010) identifies a range of patient symptoms associated with androgen deficiency, some of which are considered to be more specific (See Chap. 44, Table 44.1). Importantly, the correlation between signs, symptoms and serum testosterone (T) levels is relatively weak (Millar et al. 2016). However, some general principles exist for middle-aged and older men as symptoms typically become increasingly prevalent with lower serum T levels such as decreased libido and vigour (T < 15 nmol/L), depressive symptoms and type 2 diabetes (<10 nmol/L) and ED (<8 nmol/L) (Zitzmann et al. 2006). The European Male Ageing Study (EMAS) used a systematic investigation of a large random sampling of ageing men from the general population to define "late-onset hypogonadism" (LOH) as at least three sexual symptoms in the setting of low serum total and free T (<11 nmol/L [317 ng/dL], <220 pmol/L respectively). This study provides quite good evidence that three symptoms in particular (decreased sexual interest, decreased morning erections, ED) are quite reliable for identifying testosterone deficiency among middle-aged and older men (Wu et al. 2010).

45.3 Physical Examination

45.3.1 Approach to the Patient

Depending on role and scope of practice, nurses in endocrinology may perform a physical assessment. The proper clinical assessment of pubertal disorders, signs/symptoms of androgen deficiency and/or sub-fertility requires the clinician to be knowledgeable and competent in specific skills and techniques (Box 45.2).

Box 45.2 Clinical Skills Related to Men's Reproductive Health

Taking a comprehensive medical history
Conducting a detailed review of systems
Recording current and past medications

Box 45.2 (continued)

Accurately assessing:

- height and weight
- body mass index (BMI)
- waist to hip ratio (WHR)
- eunuchoidal proportions

Differentiating lipomastia from gynaecomastia
Performing a genital examination:

- Tanner staging
- testicular exam
- testicular volume (Prader orchidometer)
- stretched penis length

Prostate examination

Before going into specific aspects of the clinical examination, a few points on approach merit comment. One of the central aspects of the focused examination is the genital exam. This may be anxiety provoking for many patients. Adolescents in particular are likely to feel nervous and uncomfortable about this part of the consultation. Providing patient-centred care demands that one is sensitive to these patient concerns. It is important for the clinician to explain briefly, yet clearly what will be done during the exam and explain any materials (i.e. orchidometer) that will be involved. Additionally, washing your hands in warm water is helpful as performing the exam with cold hands may be uncomfortable for patients. Occasionally patients may develop an erection during a genital exam. This can be an involuntary response to touch in the genital area and does not necessarily indicate sexual arousal. However it may be embarrassing for the patient and may make some clinicians uncomfortable. Should this situation arise, one should maintain a professional attitude and complete the exam without specific comment. Being direct, using clear professional language, maintaining a neutral expression and avoiding jokes will help patients maintain their dignity.

45.3.2 Patients with Absent or Incomplete Puberty

The specific components of a focused examination will be based on findings revealed during the history and review of systems. Examining adolescents and young adults typically focuses on identifying the cause of failure to initiate or complete puberty. Any obvious clinical signs suggestive of a syndromic presentation should be noted as this may warrant further molecular investigation (i.e. genetic or cytogenetic screening) (Boehm et al. 2015). Accurately measuring height (using a stadiometer) and weight to calculate body mass index (BMI) is essential and provides insight in relation to predicted mid-parental height (Foote et al. 2015). Additionally, a skeletal survey is useful for identifying scoliosis (abnormal curvature of the spine) as well as the presence of any anomalies. The body habitus should be assessed for eunuchoidal proportions as evidenced by an armspan exceeding height by >7 cm or an upper: lower segment ratio <0.9 (upper segment: symphysis pubis to crown, lower segment: symphysis pubis to floor) (Boehm et al. 2015). Visual inspection is used to identify virilization and other signs of puberty. Breast tissue may need to be palpated to differentiate lipomastia from true gynaecomastia (i.e. disc-like shaped glandular tissue under the areola) resulting from imbalanced T and oestradiol levels. Both eunuchoidal proportions and gynaecomastia are common clinical findings among patients with Klinefelter syndrome (Groth et al. 2013). Synkinesia, mirror movements of the contralateral hand/foot, is a neurologic finding observed in some patients with CHH as is anosmia (absent sense of smell) that may be elicited in the history and confirmed via cranial nerve exam or formal smell testing. Anosmia is a "red flag" sign suggesting permanent hypogonadism (i.e. Kallmann syndrome = CHH + anosmia) (Boehm et al. 2015).

45.3.3 Clinical Evaluation Related to Complaints of Sexual Dysfunction and/or Infertility

Erectile dysfunction is associated with a number of factors including psychological (stress, anxiety, depression) as well as obesity, the metabolic syndrome, hypertension and cardiovascular disease

(Table 45.1) (McCabe et al. 2016). Accordingly, physical examination should include assessment of central adiposity (assessed by waist circumference), survey for signs of insulin resistance (i.e. acanthosis nigricans), blood pressure, peripheral pulses and reflexes to assess for possible neurologic aetiology that could underlie ejaculatory dysfunction.

45.3.4 Examining the Penis and Testes

Arguably, the most important part of the physical assessment for a reproductive endocrine consultation is the genital (testicular) exam (Anawalt 2013; Tournaye et al. 2016a; Young 2012). First, visual inspection of the character and distribution of pubic hair should be done to determine Tanner staging (P1–P5). Many young men with CHH will exhibit Tanner II to III pubic hair as a result of adrenarche and the resulting production of weak adrenal androgens. However, gonadal sex steroids are needed for full pubic hair development (i.e. Tanner V) (Palmert and Dunkel 2012). Evidence of scars may indicate prior surgery (i.e. orchiopexy). The penis should be examined for placement of the meatus and assess for hypospadias—a condition when the urethra opens on the ventral side of the penis rather than at the tip. Hypospadias may be glanular, mid-shaft, or penoscrotal and falls within the spectrum of disorder of sex development (DSD). In obese patients, the suprapubic fat pad may obscure the penis and may need to be manipulated to perform a proper examination. Any lesions or ulcerations should be noted and if the penis appears atypically small, a stretched penis length should be measured and compared to age-based norms (reviewed in (Hatipoglu and Kurtoglu 2013)).

Men presenting for evaluation of infertility should have the presence of the *vasa deferentia* (spermatic cord) confirmed by palpation as congenital bilateral absence of the vas deferens (CBAVD) is a cause of azoospermia associated with cystic fibrosis (Fig. 45.1) (Tournaye et al. 2016a).

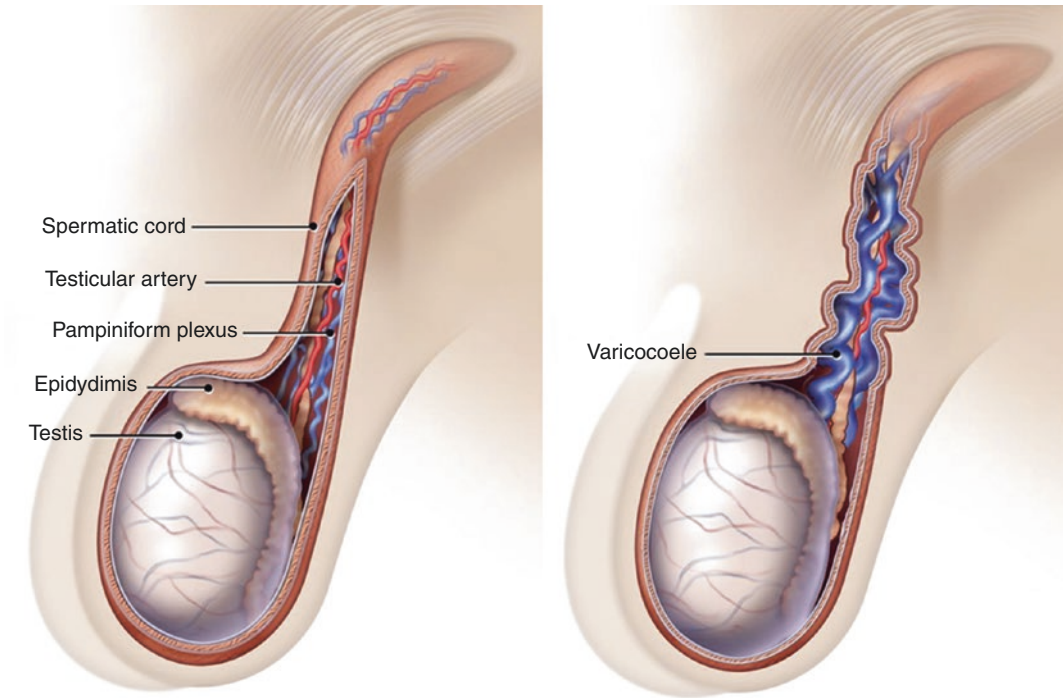

Fig. 45.1 Examination for the vasa deferentia and large varicoceles. The vasa extend from the base of the epididymi that lie posterior to each testis and run cephalad in the spermatic cord. The vas feels like a pull cord inside of the pliable tubular spermatic cord. Varicoceles feel like a "bag of worms" and enlarge when the patient stands. Published in: Bradley D. Anawalt; *The Journal of Clinical Endocrinology & Metabolism* **2013,** 98, 3532–3542. DOI: https://doi.org/10.1210/jc.2012-2400. Copyright © 2013

The spermatic vein should be palpated with the patient standing to assess for dilatation of the pampiniform venous plexus (indicated by a texture comparable to a bag of worms) indicating varicocele. Compared to the overall population, varicocele is more frequently observed in men presenting for infertility compared to the general population (40% vs. 12%) (Tournaye et al. 2016b). The epididymis and testes should be palpated with particular attention to any masses, swelling, asymmetry and testicular volume measured using a Prader orchidometer (Boehm et al. 2015). Small, firm testes (<6 mL) is a hallmark sign of Klinefelter syndrome (Groth et al. 2013). In situations of inguinal testes, hydrocele, epididymitis or thick scrotal skin, an ultrasound is useful for assessing the testes (Lotti and Maggi 2015). Testicular examination can be challenging in men with a highly reactive cremasteric reflex—a response causing the testes to retract (this response is typically absent in cases of testicular torsion). To facilitate examination, examination can be enabled by having the patient support himself on his elbows and bend his knees (i.e. mimicking frog legs) during the exam. Testicular volume (TV) of 4 mL or larger indicates onset of puberty (Palmert and Dunkel 2012) and the 50th percentile TV for an 18 year-old male is approximately 25 mL (Goede et al. 2011). Using the puberty normogram (Joustra et al. 2015) can be a valuable tool for gauging if an adolescent has a significant delay (i.e. 3+ SDs form normal) in testicular development consistent with CHH (see Chap. 44).

45.4 Laboratory Investigations

The Endocrine Society recommends against broad screening of the general population for androgen deficiency and has identified groups of patients warranting evaluation (Bhasin et al. 2010). In particular, men with sexual dysfunction, infertility, gynaecomastia, sellar mass (or prior sellar irradiation), human immunodeficiency virus (HIV) positive men with weight loss, osteoporosis (or low-trauma fracture) as well as men on certain medications are at increased risk of being androgen deficient (Bhasin et al. 2010). Further, in the setting of signs and symptoms of testosterone deficiency (See Chap. X, Table 1 in Sect. X) serum T measurement is warranted. While liquid chromatography-tandem mass spectroscopy is the gold standard for measurement, most clinical settings utilize commercially available immunoassay platforms (Taylor et al. 2015). As the initial screen, total T should be measured in a morning sample (i.e. 08:00–11:00) using a reliable assay (Bhasin et al. 2010). As men with obesity and/or diabetes may exhibit decreased levels of sex hormone binding globulin (SHBG), measurement of SHBG may be useful to aid in interpreting results (Bhasin et al. 2010). While different societies have suggested varying laboratory T cut-offs, patients exhibiting an unequivocally low serum T level based on local reference ranges (i.e. lower limit for healthy young men—approximately 9.8–10.4 nmol/L) should have a repeat confirmatory measurement. This is important as T levels can vary throughout the day and up to 15% of healthy men can have a low serum T level during the course of 24 h (yet without symptoms) and values can vary depending on whether patients are fasting or fed (Caronia et al. 2013).

If androgen deficiency is confirmed, then the next step is to differentiate primary from secondary forms of hypogonadism according to serum gonadotrophin levels (See Chap. X, Sect. X). Elevated levels are indicative of a gonadal cause such as Klinefelter syndrome. If Klinefelter syndrome is suspected (i.e. TV < 6 mL), a karyotype or comparative genomic hybridization (CGH) array is helpful in making (or ruling out) the diagnosis (Groth et al. 2013). In contrast, low levels of luteinizing hormone (LH) and follicle stimulating hormone (FSH) point to a neuroendocrine (hypothalamic-pituitary) aetiology and suggest the need for additional workup such as measurement of iron saturation, serum prolactin, pituitary function and imaging (Bhasin et al. 2010; Boehm et al. 2015) (Table 45.2).

For men with CHH, a serum inhibin B measurement can be useful as a predictor of outcome to treatment as well as a baseline measure for

Table 45.2 Biochemical evaluation of hypogonadotrophic hypogonadism (Bhasin et al. 2010; Dean et al. 2015; Boehm et al. 2015)

Test	Rationale for investigation
Prolactin	Elevated prolactin/ prolactinoma
TSH, free T4	Thyroid disorder
Cortisol	Adrenal insufficiency
IGF-1, IGFBP3	Growth hormone deficiency
LFTs, BUN, electrolytes, CBC	Overall health, systemic disease
CRP, ESR and faecal calprotectin	Inflammatory disease
Coeliac screen	Malabsorption
Ferritin, TIBC% saturation	Iron overload/ haemochromatosis
Inhibin B	Assess Sertoli Cell population

Initial screening may be complemented by dynamic endocrine testing. *TSH* thyroid stimulating hormone, *IGF-1* insulin-like growth factor-1, *IGFBP3* insulin-like growth factor binding protein 3, *LFTs* liver function tests (liver transaminases), *BUN* blood urea nitrogen, *CBC* complete blood count, *CRP* C-reactive protein, *ESR* erythrocyte sedimentation rate, *TIBC* total iron binding capacity

evaluating response to FSH monotherapy as part of sequential treatment to induce fertility (see Chap. X, Sect. X) (Dwyer et al. 2015).

45.5 Semen Analysis

Approximately 15% of couples experience difficulty conceiving and roughly half of these cases result from either male factor or mixed (male and female) aetiology of sub-fertility (Anawalt 2013). In combination with hormone profiling, seminal fluid analysis (spermiogram) is useful to help categorize sub-fertility as either pre-testicular, testicular or post-testicular. Spermatogenesis takes between 69 and 80 days (see Chap. 42), so a single seminal fluid analysis is not always informative (Tournaye et al. 2016b). The Endocrine Society recommends that men undergoing evaluation for infertility have at least two seminal fluid analyses (Bhasin et al. 2010). Important patient teaching elements include that semen samples should be provided via masturbation following a period of abstinence (2–7 days), *coitus interruptus* is not an acceptable means to collect a sample for analysis and that the lab should be informed if there were difficulties such as incomplete collection or if there was any spillage (World Health Organization 2010). If semen collection is done at home, temperature extremes should be avoided (i.e. remaining between 20 and 37 °C) and the sample should be transported within an hour for analysis to facilitate accurate interpretation.

Perhaps the two most important components of semen analysis are the ejaculate volume and sperm concentration. The most recent reference values from the World Health Organization indicate that ejaculate be >1.5 mL in volume and contain ≥39 million sperm (World Health Organization 2010). Approximately 50–80% of the ejaculate volume is comprised of the alkaline secretions from the seminal vesicles. Therefore, low ejaculate volume and low pH (<7.4) suggest an obstructive (post-testicular) cause (Anawalt 2013; Tournaye et al. 2016b). A normal sperm concentration is considered $\geq 15 \times 10^6$/mL, while adequate motility is set at 40% of total sperm and morphology ≥4% is considered normal (World Health Organization 2010). A low sperm concentration (i.e. $<10 \times 10^6$/mL), also termed oligospermia, in the setting of elevated serum FSH levels points to a primary (testicular) failure as the cause of sub-fertility. Pre-testicular causes of male sub-fertility, such as hypogonadotrophic hypogonadism, are indicated by azoospermia (no sperm) and low to normal serum gonadotrophins (Anawalt 2013; Tournaye et al. 2016b).

45.6 Imaging Studies

Several radiologic investigations may be employed as part of a reproductive endocrine consultation. Scrotal ultrasound is informative in situations when the testes are difficult to assess clinically and such imaging may also help identify obstructive causes of sub-fertility such as agenesis of the vasa or varicocele in obese patients (Tournaye et al. 2016a). Importantly, for patients with CHH or Kallmann syndrome, a renal ultrasound is warranted to identify potential unilateral renal agenesis which can occur in a

portion of these patients (Boehm et al. 2015). In young adults being evaluated for incomplete or absent puberty a wrist X-ray reveals if the epiphyses have fused and is used to determine bone age for comparison to chronologic age (Palmert and Dunkel 2012). Young adults with CHH who have yet to receive exogenous T treatment will exhibit marked differences between chronologic age and bone age (e.g. bone age of 13 years for chronologic age of 18). Androgens play an important role in bone health so men with severe androgen deficiency (i.e. CHH or Klinefelter syndrome) and men with a history of low-trauma fracture warrant measurement and monitoring of bone density using dual X-ray absorptiometry (DXA) (Bhasin et al. 2010). While most adult men presenting for evaluation of androgen deficiency will not require cranial imaging, part of a workup for severe hypogonadotrophic hypogonadism (i.e. T $\leq$ 5.2 nmol/L) includes imaging to rule out potential tumours/space occupying lesions (Bhasin et al. 2010). Magnetic resonance imaging (MRI) of the sella turcica (hypothalamopituitary) region is necessary in such instances. MRI or computed tomography (CT) can be informative for evaluating hypoplasia or agenesis of the olfactory structures (olfactory bulbs, tracts, grooves) in the setting of anosmia (a red flag for Kallmann syndrome). Similarly, when signs suggestive of CHARGE syndrome are apparent (coloboma, heart defects, atresia of choanae, retarded growth/development, genital anomalies and ear abnormalities/deafness) imaging should be performed to visualize the semicircular canals (a diagnostic criteria of CHARGE syndrome) (Boehm et al. 2015).

45.7 Other Investigations

Based on the history, clinical presentation and serum hormone measurements, other tests may be relevant. Certainly for patients who are overweight/obese and who may exhibit characteristics of the metabolic syndrome, a standard 75 g oral glucose tolerance test and/or measurement of glycated haemoglobin (HbA1C)/fasting glucose/fasting insulin levels can be used to identify glucose intolerance and diabetes (American Diabetes Association 2016). Based on patient history, exam and initial hormone profiling, additional stimulation testing may be ordered to evaluate pituitary function (i.e. cortrosyn stimulation or insulin tolerance test) (see Chap. X Dynamic Endocrine Testing). In evaluating incomplete or absent puberty in adolescents and young adults (i.e. isolated GnRH deficiency), it would presumably follow that GnRH stimulation testing would be useful. However, results are only informative in cases of a flat response (indicating severe GnRH deficiency) as there is a broad overlap between CHH and delayed puberty (Harrington and Palmert 2012). At present there is no single gold-standard test to clearly differentiate CHH from constitutional delay of growth and puberty.

Diagnosing CHH in adolescence remains challenging (Boehm et al. 2015). One potential avenue for facilitating this is via genetic screening. However, more than 25 genes have been identified to date, thus making it challenging to select a single gene for screening—which is why next-generation sequencing is becoming increasingly prevalent for such investigations (Boehm et al. 2015). Moreover, the identified CHH loci only account for about half of cases and the condition is characterized by incomplete penetrance and variable expressivity posing further challenges interpreting test results. However, when mutated CHH genes are identified, this can be informative for guiding genetic counselling should the patient desire fertility-inducing treatment (Au et al. 2011) (see Chapters X and X, Sect. X).

Elevated serum gonadotrophins indicating hypergonadotrophic hypogonadism should raise the suspicion of Klinefelter syndrome, the most common chromosomal abnormality in men (1:660 men) (Groth et al. 2013). Cytogenetic testing such as a karyotype or CGH array (which provides much higher resolution) should be performed to confirm or alternatively rule out a diagnosis. Similarly, cytogenetic screening and testing for Y chromosome microdeletions should be conducted in azoospermic men with a presumed non-obstructive cause (i.e. normal ejaculate volume, normal pH, normal serum FSH)

(Tournaye et al. 2016a). Men with no palpable vasa should have screening for the cystic fibrosis transmembrane regulator (*CFTR*) gene as this is associated with congenital absence of the vas deferens (CBAVD) (Tournaye et al. 2016a).

Genetics and genomics are becoming increasingly part of endocrine practice. Testing not only has implications for making a diagnosis, but also for setting expectations for treatment and results can impact fertility decisions for patients and couples. Importantly, limited patient literacy and numeracy can hinder patients' understanding of genetics and genomics (National Academies of Sciences Engineering, and Medicine 2016). Therefore, it is important for health professionals to be familiar with and utilize best practices in communicating with patients (Box 45.1, 45.3) (Brega et al. 2015).

Box 45.3 Reflection on Patient-Centred Care: Patient Quotes

Healthcare professionals are expected to understand the pathophysiology, evaluation and treatment of disorders of the HPG axis. However, we may not fully appreciate how patients feel about living with their condition day-to-day. Important elements of providing patient-centred care include understanding these viewpoints, providing effective lay language education and engaging patients in shared decision-making.

These quotes are drawn from focus group discussions with men diagnosed with congenital hypogonadotrophic hypogonadism (CHH):

"It's like you are the only one going through it. How can anyone else understand? I mean, if you don't understand it completely yourself, how can anyone else?"

- Patients may not fully understand their condition contributing to feelings of isolation. What types of nursing interventions could be employed to lift the veil of isolation and empower these patients?

"After you get into treatment, you get treated like an idiot. You know? 'We'll give you this… this is what you have to do…' They tell you nothing, I knew nothing".

- Patients at all ages are capable of understanding their condition. Effective communication and coaching includes being developmentally appropriate and culturally sensitive while using lay language (i.e. avoiding medical jargon) and employing the "teach back" method. How might your approach differ between a 16 year-old adolescent presenting for evaluation of absent puberty versus a 40 year-old man with the metabolic syndrome presenting with complaints of erectile dysfunction?

"when you see the doctor, the endocrinologist, you don't get anything that comes your way that has anything remotely to do with them wanting to understand. Or asking if you have anything that you need to say or need to ask or actually how you feel".

"I think we have to find more people who are willing to take the time to understand and to explain to new people… because it's scary no matter what you get diagnosed with".

- As a healthcare professional, seeing the same chief complaints week after week it is understandable that some become "the norm". However, while the patient's condition may be routine to you, the patient likely has a vastly different perspective. Indeed, their health status may be causing them significant stress and worry. What are some simple ways you can foster a caring, therapeutic relationship during a brief consultation or medical encounter?

Remember that the consultation is not solely about identifying a problem and offering a solution. For chronic conditions, patients provide most of their own care so the 4 Es: engaging the patient, showing empathy, educating them and enlisting them in self-care are key elements of the clinical encounter that can foster effective communication and support self-management (Keller and Carroll 1994). Endocrine nurses should also be proactive and identify colleagues specializing in genetic counselling so that appropriate timely referrals can be made to adequately support patient decision-making.

45.8 Conclusions

Androgen deficiency, sexual dysfunction and subfertility are common reasons why men seek reproductive endocrine consultation. Endocrine nurses should be aware of the aetiology of these problems and practise in line with available guidelines (Bhasin et al. 2010; Dean et al. 2015; Boehm et al. 2015). Depending on the nurse's scope of practice, there are specific clinical competencies needed to effectively care for men with reproductive endocrine disorders. Because reproductive endocrine disorders can impact patient health, well-being and quality of life approach to nursing care should include aspects beyond pathophysiology and evidence based guidelines. Nursing's role also includes employing transversal skills such as giving attention to patient concerns, delivering education and anticipatory guidance in clear plain language, and providing psychosocial support. Patients with infertility may require care by multiple specialists including urologists, experts in assisted reproductive technologies, genetic counsellors and others. Navigating these specialty silos can be challenging for patients and nurses can play an important role in coordinating care and providing timely patient advocacy.

Abstract

This chapter discusses the management of male hypogonadism and focuses on the diagnosis and treatment of testosterone replacement therapy (TRT). Available TRT formulations will also be discussed by providing a rationale on their benefits and disadvantages to support the endocrine nurse in developing a tailored treatment plan in consultation with their patients.

Clinical guidelines and empirical evidence for diagnosis, long-term monitoring and management of adverse events are also discussed. Emphasis is given on patient education and shared decision making to support patients' self-management. Education and continuation of care for patients should be the mainstay of the role of the endocrine nurse. This aspect of the role distinguishes nursing from other health professionals within a multidisciplinary team and it is hoped that this chapter will provide an insight on the endocrine nurse practising at an advanced level and areas of involvement in caring for patients with hypogonadism treated with testosterone replacement therapy.

Keywords
Hypogonadism · Testosterone deficiency · Testosterone replacement therapy · Polycythaemia · Erythrocytosis

Abbreviations

FSH	Follicle stimulating hormone
FT	Free testosterone
GnRH	Gonadotrophin releasing hormone
LH	Luteinising hormone
LOH	Late-onset hypogonadism
PSA	Prostate specific antigen
SHBG	Sex-hormone binding globulin
T	Testosterone
TRT	Testosterone replacement therapy

Key Terms

- **Androgen** is responsible for sexual development in males and is produced by the testes and partly the adrenal glands.
- **Testosterone** is the most important androgen produced by the Leydig cells under the influence of LH. Testosterone plays a vital role in the differentiation of the male sexual organs and development of secondary sex characteristics. In the adult male, in addition to regulation of spermatogenesis, testosterone has androgenic, anabolic and psychological/psychotropic effect.
- **Gonadotrophin Releasing Hormone (GnRH)** is produced and secreted by the hypothalamus to the anterior pituitary, where it stimulates the production of follicle stimulating hormone (FSH) and luteinising hormone (LH).
- **Follicle Stimulating Hormone (FSH)** is released by the anterior pituitary for pubertal development. In males, FSH acts on the Sertoli cells of the testes to stimulate sperm production (spermatogenesis).
- **Luteinising Hormone (LH)** is a gonadotropic hormone produced in the anterior pituitary. In males, LH stimulates Leydig cells in the testes to produce testosterone.
- **Hypergonadotrophic Hypogonadism** refers to testosterone deficiency in the presence of raised concentrations of LH and FSH.
- **Hypogonadism** is the combination of repeated, unequivocally low serum testosterone levels combined with clinical signs and symptoms of androgen deficiency, typically within the framework of a recognised clinical syndrome.
- **Infertility**: The inability to achieve pregnancy following regular unprotected intercourse for 12 months. Factors may be male, female or mixed (both) in origin.
- **Sexual dysfunction**: the inability to engage in normal, pleasurable sexual activity resulting from diminished desire (libido), arousal difficulties (erectile dysfunction) and/or problems with orgasm (ejaculation).

Key Points

- Hypogonadism is a common condition in men causing adverse health effects.
- Treatment in hypogonadism involves testosterone replacement therapy.
- Replacement of testosterone normalises serum levels which can improve physical performance, sexual function, well-being and quality of life.
- Regular and appropriate monitoring is required to avoid adverse events.

46.1 Introduction

Testosterone deficiency due to male hypogonadism is a common disorder in men and requires testosterone replacement therapy. Hypogonadism is the medical term used to describe any conditions developed from the inadequate function of the testes in a man. This is normally associated with decreased or total deficiency in androgens, mainly testosterone, and sperm production. It is caused either by hypothalamic, pituitary, testicular or target organ disorders and this can be congenital (born with the disorder) or acquired later in life. Male hypogonadism is categorised into two groups according to the cause of abnormality; if the abnormality lies in the testes, this is referred to as *primary hypogonadism* (or hypergonadotrophic hypogonadism). If the cause of the testicular abnormality originates from the hypothalamus and/or the pituitary, this is referred to as *secondary hypogonadism* (or hypogonadotrophic hypogonadism).

Hypogonadism is a very common condition estimated to affect 5 in 1000 men. Hypogonadism is also common in elderly men as the function of the organs affecting testosterone production declines with age. When hypogonadism occurs in older age, it is called late-onset hypogonadism (LOH). The clinical presentation of hypogonadism in the adult male can vary and is often misdiagnosed. The most common complaints that adult patients present with are decreased sexual potency, loss of libido and impaired fertility (Allan and McLachlan 2016; Bhasin and Jameson 2017; Bhasin 2007). A detailed and careful case history and physical examination is very important in determining differential diagnosis and requesting the appropriate laboratory investigations. Please read Chaps. 44 and 45 for details on classification and diagnostic evaluation of male hypogonadism.

46.2 Testosterone Function

46.2.1 Testosterone Production and Metabolism

Testosterone is produced by the testes which lie within the scrotum and have dual action as endocrine (hormone-producing) and exocrine (sperm-producing) glands. The adult testes have a volume of 15–35 mL each and are divided in two morphologically and functionally distinct compartments: the tubular compartment where spermatogenesis occurs (seminiferous tubules and Sertoli cells) and the interstitial compartment consisting of the Leydig cells which produce testosterone. The function of the testes is controlled by the hypothalamic and the anterior pituitary hormones. In the hypothalamus, the gonadotrophin releasing hormone (GnRH) is produced under the stimulating and inhibiting influence of neurotransmitters and promotes the production of the two pituitary gonadotrophins, the luteinising hormone (LH) and the follicle stimulating hormone (FSH). GnRH is secreted in regular pulses every 90–120 min and continuous administration of GnRH causes gonadotrophin production to cease completely. This is important to remember in specific conditions requiring treatment with GnRH (Allan and McLachlan 2016).

Testosterone is the most important androgen produced by the Leydig cells under the influence of LH; 3–10 mg of testosterone is produced each day from healthy adult testes, accounting for 95% of the total circulating amount of testosterone (Neto et al. 2016). Each testis contains 500 million Leydig cells constituting about 5% of the mature testis volume (Bhasin and Jameson 2017; Traish 2018). The negative feedback of testosterone has an inhibitory effect on the neurons producing GnRH and a suppressant effect on the LH production, maintaining this way the balance of testosterone production. FSH binds to receptors on the Sertoli cells and stimulates the production of seminiferous tubule fluid and other substances important for spermatogenesis (sperm production). The hormones inhibin and activin are formed in the Sertoli cells under the influence of FSH and form an important component in the feedback system controlling FSH secretion. The enzyme aromatase which converts testosterone to oestradiol (oestrogen) is also present in the Sertoli cells (please refer to Chap. 43 for more details).

Testosterone is synthesised through a total of five enzymatic stages from cholesterol in the Leydig cells. It enters the blood circulation by diffusion and is transported to the target cell

receptor where it exerts its action. In certain target cells, testosterone is metabolised to 5α-dihydrotestosterone (DHT) by the enzyme 5α-reductase (prostate gland, hair follicles) and to oestradiol by the enzyme aromatase (adipose tissue, bone cells, prostate). Only 2% of total testosterone is free and 98% is bound to transport proteins. Of the latter, 44% is bound with high affinity to the β-globulin sex-hormone binding globulin (SHBG) and 54% is loosely bound and transported by albumin. The binding affinity of testosterone to SHBG is about 100-fold compared to albumin. However, since albumin concentration is far higher than that of SHBG, the binding capacity of both proteins for testosterone is approximately the same (Luetjens and Weinbauer 2012). Owing to the increased nightly production of LH, testosterone production follows a circadian rhythm (24 h cycle) with the highest concentration in the early morning hours (Allan and McLachlan 2016; Jockenhovel 2004).

46.2.2 Diagnosing Testosterone Deficiency

In the presence of clinical features and symptoms suggestive of possible hypogonadism, the measurement of serum total testosterone, in an early morning specimen when testosterone is at its highest, and using a reliable assay, is crucial to the diagnosis of testosterone deficiency. Total testosterone concentrations, including bound and unbound testosterone, are affected by the pulsatile, circadian and circannual rhythms of testosterone secretion, assay variability and levels of SHBG (Bhasin 2007). The timing of blood samples is more important in younger than older men as the circadian rhythm becomes less significant with increasing age (Jockenhovel 2004). Sampling for testosterone should be done when the patient is fasting as testosterone may also be suppressed by food intake or glucose. Acute illness or short-term use of medications such as opioids also suppresses testosterone. The lower limit of the normal total testosterone (TT) harmonised to the CDC standard in healthy non-obese young men is 264 ng/dL (9.2 nmol/L) (Bhasin et al. 2018a). Two separate morning fasting samples should be taken to confirm low serum testosterone concentrations, because 30% of men with an initial diagnostic low testosterone have a normal testosterone concentration on repeat measurement (Brambilla et al. 2007). This, however, can vary depending on the assay used in each laboratory and it is, therefore, important to interpret each result based on the local reference range. If there is a clinical indication or suggestive features of hypopituitarism, evaluation of LH, FSH and other pituitary hormones should be performed. Similarly, evaluation of LH and FSH can distinguish between primary and secondary hypogonadism.

Testosterone has a high affinity for sex-hormone binding globulin (SHBG) which means that less free testosterone is available in raised SHBG levels. Only 2% of total testosterone is free (unbound) and SHGB and albumin should be measured in order to calculate free testosterone (the *free androgen index* calculator can be accessed at http://www.issam.ch/freetesto.htm). The testosterone that binds loosely to albumin can be biologically readily available (bio-available or non-SHBG testosterone). Free testosterone (FT) is costly to measure and, as it correlates well with total testosterone, the latter is used as the method of choice in clinical practice, except for specific disorders such as extreme obesity and hyperthyroidism. FT should be used for diagnostic purposes in men who have conditions that alter the SHBG or whose initial testosterone concentrations are near the lower limit of the normal range (Bhasin et al. 2018a). Table 46.1 lists the conditions associated with low or high SHBG (Bhasin et al. 2018b).

46.2.3 Functions of Testosterone and Symptoms of Testosterone Deficiency

Testosterone plays a vital role in the differentiation of the male sexual organs and development of secondary sex characteristics. Its effect on the body development before the end of puberty has been discussed in Chap. 4 and will not be referred to in detail here. In the adult male, apart from regulation of spermatogenesis, testosterone plays

Table 46.1 Conditions in which FT should be used to confirm testosterone deficiency

Conditions that are associated with decreased SHBG concentrations
Obesity
Diabetes mellitus
Use of glucocorticoids, some progestins and androgenic steroids
Nephrotic syndrome
Hypothyroidism
Acromegaly
Polymorphisms in the SHBG gene
Conditions associated with increased SHBG concentrations
Ageing
HIV disease
Cirrhosis and hepatitis
Hyperthyroidism
Use of some anticonvulsants
Use of oestrogens
Polymorphisms in the SHBG gene
Total testosterone concentrations in the borderline zone around the lower limit of the normal range (*e.g.* 200–400 ng/dL)

Used with permission from BHASIN, S., TRAVISON, T. G., O'BRIEN, L., MACKRELL, J., KRISHNAN, V., OUYANG, H., PENCINA, K. & BASARIA, S. 2018b. Contributors to the substantial variation in on-treatment testosterone levels in men receiving transdermal testosterone gels in randomized trials. *Andrology,* 6**,** 151–157

a key role in a large number of other bodily functions. Its effects on the adult male body, detailed in Table 46.2, can be defined as androgenic, anabolic and psychological/psychotropic. Symptoms and clinical presentation of testosterone deficiency are also presented in Table 46.2 (Bhasin et al. 2018a; Jockenhovel 2004; Traish 2018).

46.3 Testosterone Therapy and Importance of Patient Education and Adherence to Treatment

The objective of TRT is to reverse or prevent the symptoms and long-term effects of male hypogonadism and to maintain general well-being (Bhasin et al. 2018a). More specifically, if administered properly, testosterone can:

- Improve libido and sexual function.
- Improve mood and emotional well-being.
- Improve muscle mass and strength as well as physical stamina.
- Prevent osteoporosis and treat low bone density mass.

Table 46.2 Effects of testosterone on the adult male body

Action	Physiological action	Effect of testosterone deficiency
Androgenic	Testicular maintenance	Decrease in the volume and consistency of testes
	Prostate gland and ejaculate	Atrophy of prostate, reduced ejaculate volume
	Pubic, axillary and body hair	Reduced density in pubic, axillary and body hair
	Beard growth	Reduced beard growth and frequency of shaving
	Regulation of spermatogenesis	Reduced sperm count or infertility
	Erectile potency	Reduced frequency of morning erections
		Difficulty in getting and maintaining an erection
		Erectile dysfunction
	Male pattern baldness	No development or progression of male pattern balding once testosterone deficiency occurs
Anabolic	Bone mineral density mass	Decrease in bone mass, osteopaenia or osteoporosis
		Increased risk of fractures
	Muscular mass and strength	Muscular weakness and reduced muscle bulk
	Distribution of adipose tissue	Increase in fat mass, pronounced hips (female-like)
	Lipid metabolism	Increase in HDL and decrease in LDL
	Promotion of erythropoiesis	Low haematocrit, anaemia
	Thickening of skin and function of sebaceous glands	Decreased sebum production, hot flashes
		Skin appears dry, thin, pale and wrinkly
Psychological/ psychotropic	Libido and sex drive	Loss of libido and lack of sexual desire
	Aggression and motivation	Loss of motivation, irritability
	Emotional well-being	Mood swings, depression
	Energy levels, physical stamina	Tiredness and fatigue
	Mental and cognitive ability	Lack of concentration, reduced spatial cognition

Patient education is imperative to optimising treatment outcome from TRT. The endocrine nurse plays a key role in supporting patients and their families to develop an individualised treatment plan, to understand their treatment and condition and to adhere to their medication. There is evidence to suggest that non-adherence to TRT can compromise the patient's quality of life, physical and cognitive performance and bone density (Dwyer et al. 2014; Zitzmann 2008; Beauchet 2006).

Low persistence with treatment gaps of more than a year and high discontinuation rates at 6 months were reported for testosterone replacement by 37% (Dwyer et al. 2014) and 65% (Schoenfeld et al. 2013) of patients, respectively. Similar high discontinuation rates for TRT were reported by Donatucci et al. (2014). This was higher for patients on daily topical TRT with 52% of patients discontinuing treatment after 3 months compared to 31% of patients on short-acting TRT injections. The latter group, however, did not include long-acting testosterone undecanoate injections. The gap between stopping and restarting TRT tended to decrease over time, suggesting that patients who experienced a benefit from TRT remained on treatment (Donatucci et al. 2014). The endocrine nurse should reinforce for the patient and their family that the treatment benefit from TRT may not be immediate and should support them to recognise and manage potential side effects. Dissatisfaction with the information received about treatment and perceived impaired communication with clinicians was reported by patients as a significant barrier to treatment non-adherence (Dwyer et al. 2014). Another survey of 99 men on TRT found that almost half of respondents had inadequate knowledge and were not satisfied with their testosterone treatment. Respondents' level of knowledge was highly correlated with their satisfaction with treatment ($r = 0.646$; $p < 0.001$), suggesting that patients who were well informed of their treatment and condition were able to select a suitable TRT option for their needs (Llahana and Conway 2006).

Individual patients' needs will often guide the treatment option for TRT; factors that influence this are ease of use, ability to raise testosterone levels, improvement in symptoms, convenience and cost (Kovac et al. 2014). Determining which TRT product is preferred by patients may be challenging, given the number of options for route of administration, i.e. injection, implant, topical and oral. Optimal patient experience and satisfaction with the treatment selected is most likely to occur when patient preferences are factored in the treatment planning and choice of TRT (Szeinbach et al. 2012). The endocrine nurse should take into account the patient's needs and individual preferences when discussing TRT treatment initiation.

46.3.1 Testosterone Replacement Therapy Options

A number of treatment options are available (Table 46.3) (Behre and Nieschlag, 2012; Bhasin and Jameson, 2017; Bhasin et al, 2018a) and, despite their disadvantages, with appropriate education and shared-decision making, the endocrine nurse should be able to develop a person-tailored TRT treatment regime to suit patients' individual needs.

46.3.1.1 Testosterone Pellet Implants

Implants are the oldest form of testosterone treatment available since 1940. These are small half-inch cylindrical pellets which are inserted in the fat tissue of the body (usually in the abdomen, thigh or buttock) following a surgical procedure under local anaesthetic. Their dose is 100 or 200 mg and 3–6 pellets are inserted every 4–6 months. The low frequency of dosing and maintenance of normal testosterone levels for up to 6 months are positive features of this method. However, as this is a minor surgery, it is related with a higher risk of infections and implant rejection from the body. It is also a painful procedure and may leave scars following each implantation. The levels of testosterone fluctuate between each implantation with higher levels, which can be associated with relevant clinical symptoms. During the first months (peaks) and low levels towards the end of the dose interval (troughs).

Table 46.3 Testosterone therapy formulations and their characteristics

Formulation and dose	Administration method	Advantages	Disadvantages
Subcutaneous implants *Testosterone pellets 100 or 200 mg to a total of 600–1200 mg T per dose*	3–6 pellets every 4–6 months. Pellets implanted in the subcutaneous adipose tissue with surgical incision under local anaesthetic.	Serum T peaks at 1 month and is sustained in normal range for up to 6 months; Convenience—twice or thrice a year application.	Painful procedure with high risk of infection at the insertion point and scar tissue; Risk of spontaneous extrusion after implantation.
Oral testosterone undecanoate capsules 40 mg *1–3 capsules (40–120 mg) twice or thrice daily with meals*	Taken orally; absorption is improved when taken with fatty meal. Swallow without chewing.	Easy and convenient administration; Suitable for patients who cannot tolerate other forms of treatment and those who require low levels of T, not a preferred treatment option.	Low bioavailability and inter- and intra-individual variability in absorption resulting in insufficient serum T levels. Normal serum T level attained for only up to 3–5 h.
Intramuscular testosterone: 1. *Combination of testosterone esters 250 mg/mL IM every 3–4 weeks (propionate 30 mg, phenylpropionate 60 mg, isocaproate 60 mg, decanoate 100 mg);* 2. *Testosterone enanthate or cypionate 150–200 mg IM every 2 weeks of 75–100 mg/week*	Administration every 1–4 weeks depending on dose and patient needs; Oily preparation (1 mL) injected slowly deep into the gluteal muscle or upper thigh; warm ampoule to body temperature before injection.	Dose flexibility and convenient administration—relatively inexpensive. Can be self-injected. Improves symptoms of androgen deficiency; mostly noticeable in the first days after the injection Maintenance of normal level serum T for 2–4 weeks following administration.	Initially supraphysiological T levels which decline to hypogonadal range by the next injection may result in unpleasant "peak & trough" symptoms between doses; Risk of polycythaemia due to high abnormal T levels Pain, discomfort at injection site; Lifestyle restrictions for patients not self-injecting; risk of reaction to excipients (such as peanut oil).
Transdermal non-genital testosterone patches of 5 mg or 10 mg	1–2 patches once daily; patches may be removed for up to 2 h a day. Stick-on patches contain T in an alcohol gel reservoir; apply on clean, dry, healthy skin (abdomen, back, buttock, upper arms and thighs).	Convenient and easy application; Effective, provides T levels within physiological range; Steady levels of serum T with no "peak & troughs" between applications.	Skin irritation at the application site; Unsightly, discomfort at removal; "sticky" marks on skin, easily detachable; More than one patch may be required.
Transdermal topical testosterone gels and axillary solution *50–100 mg of 1%, 40–70 mg of 2% or 20.25–81 mg of 1.62% transdermal gel applied once daily* *60 mg of T solution applied in the axillae once daily*	Available in sachets, tubes and pumps; refer to each formulation for application site and package instructions. Clear alcohol gel containing T; apply on dry, clean skin on shoulders, abdomen upper arms or thighs (avoid genital area), preferably after shower; allow to dry for 5 min before dressing; wash hands with soap after applications. Have to be reapplied if swimming or showering within 3–5 h of application.	Convenient, flexible and easy application; good skin tolerability. Effective, provides T levels within normal range for 24 h; Steady physiological levels of serum T with no "peak & troughs" between applications; Dose easily adjustable to individual needs; No pain of injections.	May cause skin dryness and irritation for some patients; Takes time to apply; can be "messy"; Potential of transfer to a female partner or child by direct skin-to-skin contact. Fear of transfer may inhibit intimacy—patient education minimises potential of transfer; Increased DHT levels due to presence of 5α-reductase in the skin. Considerable inter- and intra-individual T levels require close dose titration.

(continued)

Table 46.3 (continued)

Formulation and dose	Administration method	Advantages	Disadvantages
Bioadhesive, Buccal oral T tablet *30 mg controlled-release tablets applied to the upper gum twice daily*	T is absorbed gradually from the buccal mucosa over 12 h; Place rounded side of tablet on the gum and below the lip; apply on healthy, clean gum; the solid tablet softens and moulds to the shape of the gum; replace tablet if it detaches within the 12 h dosing interval or with next dose if due.	Easy and fast to apply; Effective; serum T levels remain within physiological range with twice daily application without significant peaks and troughs; "easy to remember" administration with teeth brushing daily routine.	Risk of gum-related adverse events reported by 16% of treated men. May detach when eating shortly after application; Takes time to get used to; Instructions should be followed carefully for application; patient education is vital in increasing the success of treatment.
Long-acting T undecanoate injections *1000 mg in 4 mL ampoule of oily preparation*	1000 mg every 10–14 weeks following the initial injection at 6 weeks interval (loading dose); Weekly monitoring of serum T levels starting at 10 weeks after the third injection helps determine the frequency of injections based on trough T level; Injected very slowly deep into the gluteal muscle; warm ampoule to body temperature before injecting.	Effective, maintains physiological serum T levels for up to 3 months or longer for some men. Does not have the supraphysiological profile of serum T level seen in other intramuscular T injections and "peak and trough" symptoms are less noticeable. Convenient, 3-monthly application without the side effects seen with T implants.	Pain, discomfort and adverse reaction at injection site; Requires large muscle bulk for injection; lifestyle restrictions as it cannot be self-administered; Not recommended as first-line treatment option due to inability of withdrawal in case of adverse events (AE). Rare AE of pulmonary microembolism presenting with severe coughing episode during injection. Risk of reaction to preservative (castor oil).

Note: TRT options in this table may not be available in every country

46.3.1.2 Oral Testosterone Undecanoate (Capsules)

These capsules are taken by mouth. While oral route of delivery is very popular, these capsules have a short half-life (they maintain normal testosterone levels only for a few hours) and need to be taken three to four times a day with a fatty meal. Only a small part of the medication is absorbed and, therefore, large doses of up to eight capsules a day are required to restore testosterone levels within normal range. Oral therapy is more suitable for patients who cannot tolerate other forms of treatment or do not require large doses of testosterone. Some oral preparations (e.g. 17a-methyltestosterone and fluoxymesterone) may cause liver toxicity; these preparations, however, have been discontinued from most European countries.

46.3.1.3 Testosterone Injections

These injections are given deep into the gluteal muscles or upper thigh (intramuscular injections). They are oily preparations (such as peanut or castor oil) which allow slow release over a long period after being injected. Most patients have their injection given by their GP or practice nurse; however, this may cause restrictions in lifestyle, i.e. regular appointments, difficulty in planning holidays, etc. This form of treatment provides high levels of testosterone (peaks) immediately after the injection, which tend to drop below normal range (troughs) towards the end of the injection interval. As a result of these, some patients have symptoms of high and low testosterone levels between the injections, such as mood swings, difference in energy levels and sexual drive.

There are two options of testosterone injections:

1. Short acting
   Short-acting testosterone injections are administered IM every 1–4 weeks depending on formulation and patient's response. Education is important to support and consult patients and their families on how to monitor improvement in well-being and response to treatment and any potential side effects as well as peak and trough levels between injections. This treatment has been around since the 1950s and has been the most widely used option until other preparations became available.
2. Long-acting testosterone undecanoate 1000 mg /4 mL IM injections every 10–14 weeks. This has similar texture to short-acting injections (thick oil) but is four times larger in volume (4 mL) and should be injected very slowly into the gluteal muscle. The second injection should be given at 6 weeks (loading dose) and thereafter every 12 weeks. After the third injection, a testosterone level measured at 4, 8, 10 and 12 weeks can be helpful to monitor the TRT profile and determine the frequency of future injection intervals.

46.3.1.4 Testosterone Patches

The patch contains testosterone in an alcohol gel reservoir which is absorbed gradually through the skin. This form of treatment is quite effective as it avoids metabolism through the liver and raises testosterone to normal range within a few hours after application. Patches are applied once a day, ideally, at bed-time so that the pattern of testosterone release is closest to the normal body rhythm. They can be removed for up to 2 h a day before applying a new one. Some patients require two or more patches to get sufficient dose of testosterone. For best absorption, patches should be placed on body areas with minimal body hair, back, abdomen, upper arm, thigh or upper buttock. Skin reaction or rash is quite frequent with this form of treatment; rotation of application sites (use of different site every day) can help to minimise any skin reactions. The body patches are quite large and some patients find them unsightly and socially embarrassing.

46.3.1.5 Testosterone Gel

This is a clear alcohol gel applied once a day, preferably in the morning, to dry, clean and healthy skin, excluding the genital area, with no open sores. The gel is absorbed rapidly through the skin within 5–10 min and testosterone level rises into normal range within 2–4 h after application. Testosterone is released slowly into the blood circulation for about 24 h. Full absorption of the gel may take up to 6 h and, therefore, showering or swimming within that time should be avoided or the gel reapplied. It is important to advise patients on the potential risk of direct skin-to-skin transfer of testosterone and how to avoid this. Transfer of testosterone gel to pregnant women may cause abnormalities or harm to the unborn baby. To minimise risk of transfer advise patients to:

- Wash hands thoroughly immediately after applying the gel.
- Cover the application site (shoulders, upper arms, abdomen) with clothing once the gel has dried.
- Shower before any situation involving close skin-to-skin contact with someone else, especially if that happens within 6 h after applying the gel.

46.3.1.6 Testosterone Buccal Tablets

This, when taken twice daily, provides testosterone levels within normal range for up to 24 h. The buccal tablet is placed on the gum of the incisor tooth on either side and below the lip (just to the left and right of the two front central teeth). They should not be chewed or swallowed. Men, naturally, have an inwards curved area on their gum; the tablet has such a form to fit perfectly into that area without risk of dislodgment. The solid tablet absorbs moisture from the mouth and

begins to soften and mould to the shape of the gum about an hour after application and remains in place until next application. Testosterone is absorbed slowly through the gum into the blood circulation for up to 12 h; tablets should be replaced approximately every 12 h. The application surface must be clean; ideally after brushing the teeth. If the tablet fails to adhere properly to the gum or falls off during the 12-h dosing interval, the old tablet should be removed and a new one applied. If the tablet is swallowed, it is harmless and will be rendered ineffective as the stomach enzymes will not allow its absorption. Similarly, there is no risk of transferability to other people. The buccal tablet may occasionally cause gum irritation especially at the start of the treatment.

Box 46.1 Patient Case Study: Importance of Self-Management and Peer-Support in Testosterone Therapy

My diagnosis of Klinefelter's Syndrome (KS), at the age of 35, was as a result of fertility investigations and while it came as a shock, it was a great relief as it explained many of my limitations from childhood through to adulthood. Upon starting testosterone replacement therapy (TRT) I decided to have an outlook of "*use TRT as a catalyst to improve my life and work with it for my betterment!*". However, I learnt that TRT alone was not an answer, while it can improve life, one must work *with* it and be willing to adapt and embrace a change in life-long habits. My life pre-treatment and post-treatment are very different. I lacked confidence, had social anxiety, low self-confidence, had difficulty concentrating at times and staying fit was challenging. All these have improved significantly since starting on TRT.

Successful self-management of TRT involves patients working with their clinicians and being aware and well informed about their condition, their treatment and how to monitor their progress and well-being. Observations such as the effects of TRT on moods, energy levels and appetite can assist in the management of patient-specific care. My current TRT is long-acting testosterone undecanoate injections. I recommend using a patient diary to note when the dose begins, when the next is due, side effects experienced and how one feels in-between doses at different weeks. I found after a point, lethargy would begin, and it impacted my day-to-day life.

Development of the Peer Support Group

In 2014, I organised my first KS Support group and meet-up. This was borne out of a need for support and to gain accurate and up-to-date information regarding KS. It gave attendees the opportunity to learn more about their condition in an informal, friendly, understanding and safe environment. Support groups help bring people together to ask questions, offer advice or simply to listen to one another and make friends. To date I have organised ten events, some of which have included workshops facilitated by clinicians to educate patients about their condition and how to better manage it. Attendees can ask questions in an informal environment without the time restrictions and medical environment of a clinical appointment. For clinicians, it gives an opportunity to meet a large group of patients in a single session and to gain an understanding of the issues frequently experienced by patients from which common themes can arise and may highlight overlooked personal experiences.

I regularly liaise with patients to discuss their concerns or key questions and feed this back to healthcare professionals to increase awareness of concerns and enable presentations to be tailored accordingly to give attendees "take home advice". Clinicians can also assist patients with KS to form a support group by organising open patient education events in their Centre and, thereafter, further facilitation can be undertaken by a group member. For further information on educational resources, please refer to my website "*The Klinefelter's Network*" www.klinefelters.net.

46.4 Benefits of Testosterone Therapy

The objective of testosterone replacement therapy is to reverse and/or prevent the effects of low testosterone described above. In particular, testosterone therapy aims to:

- Improve sex drive, libido and sexual function.
- Improve mood and well-being.
- Improve muscle mass and strength.
- Restore or maintain masculine characteristics such as facial and body hair.
- Maintain bone strength and prevent osteoporosis.

Testosterone replacement therapy does not restore fertility. Effects of testosterone therapy are not immediate and can often take up to 18 months (Bhasin and Jameson 2017; Saad et al. 2011). It is important for the endocrine nurse to consult the patient on what to expect from TRT and the estimated time periods when he will experience the benefits of TRT. Effects on sexual interest appear after 3 weeks plateauing at 6 weeks, with no further increments expected beyond. Changes in erections/ejaculations may require up to 6 months (Saad et al. 2011) (Fig. 46.1). Effects on quality of life manifest within 3–4 weeks, but maximum benefits take longer. Effects on depressive mood become detectable after 3–6 weeks with a maximum after 18–30 weeks. Effects on erythropoiesis are evident at 3 months, peaking at 9–12 months. Prostate specific antigen and volume rise, marginally, plateauing at 12 months; further increase should be related to ageing rather than therapy. Effects on lipids appear after 4 weeks, maximal after 6–12 months. Insulin sensitivity may

improve within few days, but effects on glycemic control become evident only after 3–12 months. Changes in fat mass, lean body mass and muscle strength occur within 12–16 weeks, stabilise at 6–12 months, but can marginally continue over years (Fig. 46.2). Effects on bone are detectable already after 6 months while continuing at least for 3 years (Saad et al. 2011).

46.5 Contraindications and Adverse Effects of Testosterone Therapy

The recent clinical practice guidelines issued by the Endocrine Society (Bhasin et al. 2018a) recommend that TRT should not be used in patients with:

- Prostate or breast cancer.
- Prostate benign hyperplasia and unexplained elevated prostate specific antigen (PSA) without further urological investigation.
- Polycythaemia (elevated haematocrit and haemoglobin).
- Untreated obstructive sleep apnoea.
- Uncontrolled severe heart failure.

The suitability of each treatment option and any formulations-specific side effect (listed in Table 46.4) should be assessed and addressed in each consultation. The most frequent side effects seen with TRT are acne, gynaecomastia, fluid retention, mood swings and male pattern baldness (Bhasin et al. 2018a).

The following side effects may occur from the testosterone replacement therapy. The patient should be advised to discuss any of these symptoms with their endocrine team to review the treatment regimen:

- Irritability, nervousness, aggressiveness
- Mood swings, depression (more noticeable with testosterone injections)
- Weight gain, water retention

Table 46.4 Potential adverse effects of testosterone therapy

Adverse events for which there is evidence of association with T administration
Erythrocytosis
Acne and oily skin
Detection of subclinical prostate cancer
Growth of metastatic prostate cancer
Reduced sperm production and fertility
Uncommon adverse events for which there is weak evidence of association with T administration
Gynaecomastia
Male pattern balding (familial)
Growth of breast cancer
Induction or worsening of obstructive sleep apnea
Formulation-specific adverse effects
Intramuscular injections of T enanthate, cypionate or undecanoate
Fluctuation in mood or libido
Pain at injection site
Coughing episodes immediately after the intramuscular injection[a]
Transdermal patches
Frequent skin reactions at application site
Transdermal gels and solutions
Potential risk for T transfer to partner or another person who is in close contact (need to remind patient to cover application sites with clothing and to wash skin and hands with soap before having skin-to-skin contact with another person)
Skin irritation and odour at application site
Stickiness, slow drying, dripping
Buccal T tablets
Alterations in taste
Irritation of gums
Pellet implants
Infection, expulsion of pellet
T nasal gel
Rhinorrhea, epistaxis, nasal discomfort, nasal congestion, parosmia
Oral tablets (methylT)—not recommended
Effects on liver and cholesterol[b]

Used with permission from BHASIN, S., BRITO, J. P., CUNNINGHAM, G. R., HAYES, F. J., HODIS, H. N., MATSUMOTO, A. M., SNYDER, P. J., SWERDLOFF, R. S., WU, F. C. & YIALAMAS, M. A. 2018a. Testosterone Therapy in Men With Hypogonadism: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab,* 103, 1715–1744

[a]The mechanism of cough, which has been reported rarely after intramuscular injections of T undecanoate and even more rarely after T enanthate and cypionate, is unknown, but it has been attributed to pulmonary oil microembolisation

[b]Liver toxicity has been reported mostly with oral 17α-alkylated androgens

- Prolonged painful or frequent erections
- Headache
- Acne
- Elevated haematocrit and haemoglobin on blood test—raised red blood cell count
- Increase of prostate gland (prostatic hyperplasia) and elevated PSA on a blood test
- Male pattern baldness
- Breast enlargement

Testosterone stimulates erythropoiesis (red cell production) and can lead to polycythaemia or erythrocytosis characterised by increased haematocrit and haemoglobin and long-term risk of thrombosis. The effects of erythrocytosis, defined by a haematocrit >54%, are related to T doses and circulating concentrations and is more prevalent in older men than in younger men (Bhasin et al. 2018a; Haddad et al. 2007). For men on TRT, the risk of developing erythrocytosis is well established, with short-acting testosterone IM injections having the highest risk (Ohlander et al. 2018). Pastuszak et al. (2015) reported a raised haematocrit >50% in 67% of men treated with short-acting IM T injections and in 35% treated with subcutaneous T pellets but only in 13% of men treated with T transdermal gels ($P < 0.0001$). Erythrocytosis was also found in men with higher trough serum testosterone levels treated with T pellets (Ip et al. 2010).

A study of men treated with long-acting T undecanoate IM injections ($N = 347$) showed a low prevalence of erythrocytosis with 7% of men having haematocrit >0.50 and 1% >0.54 (Middleton et al. 2015), although there is no evidence from this group of patients in relation to trough T levels and risk of erythrocytosis. It is therefore important to monitor trough serum T after the third injection of T undecanoate and yearly thereafter to adjust the frequency of injections appropriately in order to minimise the risk of erythrocytosis. The impact of testosterone on erythropoiesis is delineated in Fig. 46.3.

Androgens (testosterone and DTH) stimulate prostatic growth and therefore the long-term effects of their elevated levels on the prostate is often a cause for concern. Circulating levels of

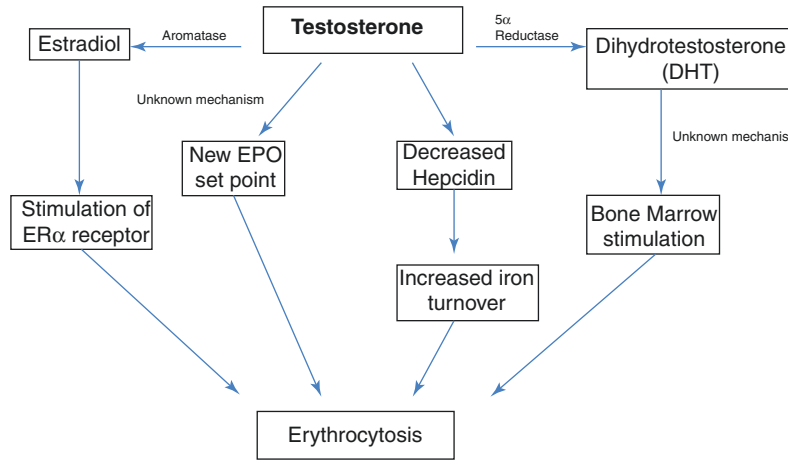

Fig. 46.3 Impact of testosterone on erythropoiesis. Key: *EPO* erythropoietin, *ERa* estrogen receptor-a. **Used with permission from** OHLANDER, S. J., VARGHESE, B. & PASTUSZAK, A. W. 2018. Erythrocytosis Following Testosterone Therapy. *Sexual Medicine Reviews,* 6**,** 77–85

androgens have not been found to be strongly related to prostate cancer, but it is suggested that high levels of testosterone may promote the growth of an existing cancer (Gould et al. 2006; Walsh et al. 2018; Kang and Li 2015; Osterberg et al. 2014). The side effects can be minimised with strict treatment surveillance. The endocrine nurse has a vital role in developing and applying treatment monitoring protocols as well as educating patients on recognising and reporting the side effects from this treatment.

46.6 Testosterone Therapy in Men with Age-Related Testosterone Deficiency

A decline in the testicular and pituitary function is associated with ageing in men resulting in reduced testosterone levels and hypogonadism. Clinical symptoms along with low testosterone level confirm diagnosis of LOH. However, it is difficult to diagnose LOH based on clinical presentation as symptoms are often similar to those found in other conditions prevalent in older men and a careful and detailed clinical history taking is vital. The use of validated questionnaires (Heinemann 2005; Morley et al. 2000) can assist the endocrine nurse in screening for testosterone deficiency in older age. It has also been suggested that low levels of serum T in healthy older men are associated with reduced cognitive performance, particularly spatial ability and memory (Beauchet 2006). Therefore, hypogonadism and testosterone deficiency should be included in the differential diagnosis of older men reporting cognitive dysfunction. Testosterone replacement therapy can reverse hypogonadal symptoms and is commenced once prostate cancer has been excluded (Bhasin et al. 2018a; Wang et al. 2008). Initiation of treatment with half of the standard dose and frequent monitoring is recommended (Bhasin et al. 2018a; Wang et al. 2008; Osterberg et al. 2014).

46.7 Monitoring of Testosterone Therapy

Long-term monitoring involves assessment of hypogonadal symptoms and measurement of testosterone, LH and FSH (in primary hypogonadism), prostate specific antigen (PSA) and rectal examination of the prostate, haematocrit and haemoglobin, and serum lipids at 3 months after initiating TRT and then 6–12 monthly (Traish 2018; Bhasin et al. 2018a). Bone mineral density examination should be undertaken at the start of treatment and then repeated at intervals indicated by the bone density and the risk fracture score (Bhasin et al. 2018a). Table 46.5 presents an overview of the long-term monitoring for patients on testosterone replacement therapy (TRT).

Table 46.5 Monitoring of patients on testosterone therapy

Explain the potential benefits and risks of monitoring for prostate cancer and engage the patient in shared decision making regarding the prostate monitoring plan.
Evaluate the patient at 3–12 months after treatment initiation and then annually to assess whether symptoms have responded to treatment and whether the patient is suffering from any adverse effects.
Monitor T concentrations 3–6 months after initiation of T therapy:
Therapy should aim to raise serum T concentrations into the mid-normal range.
Injectable T enanthate or cypionate: measure serum T concentrations midway between injections. If mid-interval T is >600 ng/dL (24.5 nmol/L) or <350 ng/dL (14.1 nmol/L), adjust dose or frequency.
Transdermal gels: assess T concentrations 2–8 h following the gel application, after the patient has been on treatment for at least 1 week; adjust dose to achieve serum T concentrations in the mid-normal range.
Transdermal patches: assess T concentrations 3–12 h after application; adjust dose to achieve T concentration in the mid-normal range.
Buccal T bioadhesive tablet: assess concentrations immediately before or after application of fresh system.
T pellets: measure T concentrations at the end of the dosing interval. Adjust the number of pellets and/or the dosing interval to maintain serum T concentrations in the mid-normal range.
Oral T undecanoate[a]: monitor serum T concentrations 3–5 h after ingestion with a fat-containing meal.
Injectable T undecanoate: measure serum T levels at the end of the dosing interval just prior to the next injection and aim to achieve nadir levels in low-mid range.
Check haematocrit at baseline, 3–6 months after starting treatment, and then annually. If haematocrit is >54%, stop therapy until haematocrit decreases to a safe level; evaluate the patient for hypoxia and sleep apnea; reinitiate therapy with a reduced dose.
Measure BMD of lumbar spine and/or femoral neck after 1–2 years of T therapy in hypogonadal men with osteoporosis, consistent with regional standard of care.
For men 55–69 years of age and for men 40–69 years of age who are at increased risk for prostate cancer who choose prostate monitoring, perform digital rectal examination and check PSA level before initiating treatment; check PSA and perform digital rectal examination 3–12 months after initiating T treatment, and then in accordance with guidelines for prostate cancer screening depending on the age and race of the patient.
Obtain urological consultation if there is:
An increase in serum PSA concentration >1.4 ng/mL within 12 months of initiating T treatment
A confirmed PSA >4 ng/mL at any time
Detection of a prostatic abnormality on DRE
Substantial worsening of LUTS
Evaluate formulation-specific adverse effects at each visit as per Table 46.3.

46.8 Patient Education and Role of Patient Advocacy Groups

Most of the endocrine reproduction disorders are chronic in nature and continuation of care for these patients is the most important aspect of maintaining and enhancing their well-being. From discussions in this chapter it is apparent that the use of certain medication can be quite complex and lifestyle changes may be required depending on the patient's age at diagnosis and the severity of each case. Patients are not always familiar with the purpose of and how to use these medications. Barber et al. found that a significant percentage of patients newly started on a chronic medication quickly became non-compliant, mainly due to lack of knowledge of their treatment (Barber et al. 2004). A survey which involved 99 men on testosterone replacement therapy found that patients taught by the endocrine nurse reported a high level of knowledge and satisfaction with the control of their condition and their treatment (Llahana and Conway 2006), emphasising once again the important role of nursing in patient education (Llahana 2005).

Patient advocacy groups (PAGs) play an essential role in raising awareness of conditions that can lead to male hypogonadism and providing patients with reassurance that they are not alone. PAGs work closely with health-

care professionals to develop evidence-based information leaflets and educational resources. The Klinefelter's Syndrome Association (KSA) in the UK, as described below, is a great example of a PAG with a vital contribution in the support and self-management of patients with hypogonadism.

46.8.1 The Klinefelter's Syndrome Association (KSA)

After her infant son was diagnosed with Klinefelter's Syndrome (KS/XXY) (please refer to Chap. 44 for more details on KS), Sue Cook found it very difficult to find good information out about the condition. She was given no support. Determined that others wouldn't have to struggle as she had, in the late 1980s, with the support of Contact a Family, Sue, her husband David, and an XXY adult, Steve Hammett, started The Klinefelter Syndrome Association (KSA) to provide reliable information and support for others affected.

The KSA has a worldwide membership. It organises an annual conference, produces a quarterly newsletter for members and hosts an excellent website. It runs several hidden Facebook groups and is building a network of social events across the country to allow those affected to have contact with others. It organises Activity Weekends twice a year which have prompted several members to say that they now feel part of a "second family" of people who understand how they feel, the challenges they face and amongst whom they can relax and truly be themselves. The KSA also produces various booklets and a Members' Handbook most of which can be downloaded from the website. It runs a Helpline and offers free membership to medical professionals—available from the website.

The KSA is presently working with medical professionals to identify the many areas—such as gender identity issues, the effects of testosterone replacement on muscle and bone development, the causes of excessive abdominal weight distribution—where information is lacking, with a view to commissioning further research.

The KSA is encouraging the production of guidelines for the treatment of KS/XXY to ensure that all affected receive appropriate treatment.

Below are two case studies which highlight the importance of the work carried out by the KSA.

- A. contacted the helpline when her husband was told that he would have to stop testosterone treatment as his blood count was too high. She was concerned that he was in a physically demanding job and couldn't remain alert without his medication. After A. sent over her husband's blood test results, the call handler realised that he needed urgent venesection. The KSA contacted an experienced endocrinologist who gave A's husband an emergency appointment.
- KSA was contacted by a male in his 30s who had recently discovered, when going through his deceased mother's papers, that he had been diagnosed with karyotype XXY in childhood. He had never been told and was very confused and upset. The KSA volunteer talked with him for an hour, answering many of his questions and allaying some of his fears, and advised him to talk to his general practitioner to arrange a referral to an Endocrinology Clinic for specialist diagnosis and follow-up. Peer support was also offered and he was advised that when he was ready, he could ask to join one of the Facebook groups which the KSA supports.

Please pass our details to all KS/XXY patients:
Website: www.ksa-uk.net.
Contact for information: Email: Chair@ksa-uk.net

46.9 Conclusions

Male hypogonadism is a frequent, but also underdiagnosed, endocrine condition. Testosterone replacement therapy, treatment option, long-term monitoring and adverse effects were discussed in this chapter with a focus on the aspects relevant to endocrinology nursing. It is widely recognised

that when patients have adequate understanding of their condition, they are more empowered and able to choose an individualised treatment tailored to their needs. The endocrine nurse is the most important member of the team, in providing patients and their families with education, continuous support and consultation on new treatments and coping strategies necessary following diagnosis.

Acknowledgments With special thanks to Alison Bridges, Chair of Trustees, Klinefelter's Syndrome Association (KSA) (www.ksa-uk.net) and Zahir Barmania from The Klinefelter's Network, Greater London (www.klinefelters.net) for their contribution to this chapter with case studies, patient resources and information on the Patient Advocacy Group.

Abstract

Approximately 15% of couples are affected by infertility and it is estimated that male factors contribute to roughly half of cases. Careful history and clinical assessment is warranted in men presenting with infertility. Genetic defects such as Klinefelter syndrome and iatrogenic causes such as exogenous testosterone treatment are not uncommonly identified causes of infertility in men presenting for endocrine consultation. Importantly, neuroendocrine aetiologies of male infertility such as congenital hypogonadotrophic hypogonadism (CHH) are more amenable to treatment compared to gonadal defects causing hypergonadotrophic hypogonadism. Assessing predictors of outcomes is an important aspect of setting appropriate patient expectations prior to beginning fertility-inducing treatment. Tailored hormonal therapies can effectively develop sperm in approximately 75% of men with CHH. Additionally, assisted reproductive technologies can be a helpful complement in challenging cases. This chapter is intended to give the endocrine nurse context for the approach to male infertility and provides an overview of hormonal treatments and relevant assisted reproductive technologies. Emphasis is given to setting realistic patient expectations, delivering coordinated care including appropriate referral to fertility specialists and elements related to therapeutic education and psychosocial support relevant for this patient population.

PCAs	Permeable cryoprotective agents
PESA	Percutaneous epididymal sperm aspiration
PGD/PGS	Pre-implantation genetic diagnosis/screening

SHBG	Sex hormone binding globulin
T	Testosterone
TARTs	Testicular adrenal rest tumours
TV	Testicular volume

Key Terms

- **Assisted reproductive technologies (ART):** Procedures employed to achieve pregnancy such as hormonal stimulation followed by in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI).
- **Autonomy:** Respect for persons, allowing for fully informed decision-making free of coercion.
- **Azoospermia:** The absence of sperm in the ejaculate.
- **Beneficence:** Doing good, providing the maximum benefit for a patient.
- **Infertility:** The inability to achieve pregnancy following regular unprotected intercourse for 12 months. Aetiologies may be male, female or mixed (both).
- **Justice:** Insuring equal distribution of resources, risks and benefits,
- **Nonmaleficence:** Doing no harm, or preventing/minimizing harm whenever possible.
- **Oligospermia:** Decreased number of sperm in the ejaculate. The World Health Organization considers oligospermia as the fifth percentile for fertile men (15 million/mL). Severe oligospermia is considered as <5 million/mL.
- **Spermatogenesis:** The process of producing spermatozoa. Both mitosis and meiosis are involved in the complex development from spermatogonia to spermatozoa in the ejaculate. The entire process takes between 69 and 80 days.
- **Testicular volume:** A measure of testicular size. Volume reflects predominantly the development of the seminiferous tubules and is an important predictor of fertility potential. It is most frequently measured via Prader orchidometer or via calculation of ultrasound measurement in three planes.

Key Points

- Hypogonadotrophic hypogonadism is a treatable form of male infertility.
- Testosterone treatment suppresses spermatogenesis and is contraindicated in men seeking fertility.
- Predictors of outcome should be thoroughly evaluated to appropriately gauge patient expectations for response to treatment.
- Hormonal treatment should be tailored and supervised by clinicians experienced with these specialized treatment regimens.
- Assisted reproductive technology can be used to complement hormonal treatments and enhance fertility outcomes.

47.1 Introduction

Infertility is common and is estimated to affect 15% of couples. Estimating the prevalence of male infertility is challenging since a female partner with normal fertility may still conceive if their male partner has mild infertility; however, male factor infertility is reported as contributing to 20–70% of infertility (Tournaye et al. 2016).

Broadly, male fertility problems fall into several categories: abnormal spermatogenesis (quantitative/qualitative), problems with sperm transport (i.e. ductal obstruction), gonadal disorders (e.g. hypergonadotrophic hypogonadism) or neuroendocrine dysfunction (e.g. hypogonadotrophic hypogonadism). Quantitative and qualitative spermatogenic problems are identified via seminal fluid analysis (see Chap. 45) (World Health Organization 2010) (Fig. 47.1 and Box 47.1).

Aetiologies may be genetic (e.g. Y chromosome microdeletions, Klinefelter syndrome), mumps

infection, cancer related (chemotherapy or localized radiotherapy), or secondary to maldescended testes (cryptorchidism) or varicocele (Tournaye et al. 2016). Sperm transport problems may result from sexually transmitted infections (STI, e.g. chlamydia, tuberculosis), pelvic trauma or neurologic problems (e.g. diabetes mellitus) as well as retrograde ejaculation and erectile dysfunction (see Chap. 46). Men harbouring mutations in the cystic fibrosis gene (cystic fibrosis transmembrane regulator, *CFTR*) may have congenital bilateral absence of the *vas deferens* (CBAVD) despite having no other clinical features of cystic fibrosis. This problem can be identified by clinical examination of the testes and scrotum and may be manifested in a low volume, low pH, azoospermic seminal fluid analysis (Tournaye et al. 2017).

Primary gonadal failure (i.e. Klinefelter syndrome) results in hypergonadotrophic hypogonadism and infertility. The most common chromosomal anomaly in males, 47, XXY occurs in approximately 1:660 and adults are infertile in 90–99% of cases (Groth et al. 2013). There is evidence that testicular failure and progressive hyalinization of seminiferous tubules occur in mid-puberty (Rohayem et al. 2016). Hormonal treatments are not effective for such cases yet advances in assisted reproductive technologies (ART) provide new possibilities for potential fertility in these men as sperm can be retrieved surgically in about half of cases (Corona et al. 2017).

For men with infertility arising from a hypothalamic or pituitary origin (e.g. congenital hypogonadotrophic hypogonadism, CHH) treatment options are quite effective in developing fertility. This chapter will focus primarily on the hormonal treatment regimens for such patients as well as providing an overview of relevant ART and discussion of appropriate urologic consultation and referral to an infertility specialist.

47.2 Approach to Fertility Treatment

As reviewed in Chap. 45 (evaluation of HPG axis), careful evaluation is needed to identify the underlying aetiology of infertility so treatment can be appropriately targeted. Importantly, iatrogenic causes must be ruled out. Exogenous testosterone (T) treatment suppresses the hypothalamic-pituitary-gonadal (HPG) axis and spermatogenesis. The Endocrine Society and the American Society and the International Society for Sexual Medicine both consider testosterone therapy as contraindicated in men seeking fertility (Bhasin et al. 2010; Dean et al. 2015); unfortunately this clinical guidance is not always adhered to. A 2012 survey of nearly 400 practising urologists revealed that 1 in 4 (25%) would prescribe T treatment to infertile men actively trying to conceive (Ko et al. 2012).

Recovery of spermatogenesis following cessation of testosterone therapy can be protracted. Indeed, an integrated analysis of male contraception studies by Liu and colleagues found that roughly two-thirds of men recover normal sperm counts (20 million/mL) within 6 months (95% CI: 61–72%) and all men recovered within 2 years (95–93% at 12 months, 92–98% at 16 months) (Liu et al. 2006). However, recent clinical data suggest that age and sperm count prior to starting testosterone treatment are predictive of spermatogenic recovery (Kohn et al. 2017). Notably, men who use performance enhancing drugs such as anabolic androgenic steroids can suppress their HPG axis for extended periods of time and may remain infertile long after cessation of use (Christou et al. 2017).

It is worthwhile to note that among the most common causes of male factor infertility is idiopathic (Anawalt 2013). These men typically exhibit sperm counts of 10 million/mL (or less) and often abnormal sperm morphology and/or motility. Such cases should be referred for consultation with a fertility specialist to discuss ART options. Of men presenting with very low sperm counts or azoospermia, approximately 15% have chromosomal anomalies (Hofherr et al. 2011) (Table 47.1). Among the most frequent is Klinefelter syndrome—which can be identified by karyotype or comparative genomic hybridization (CGH). Advances in surgical techniques, specifically microsurgical testicular sperm extraction (micro-TESE), provide the possibility for these men to have fertility. A recent meta-analysis found that sperm extraction was possible in approximately half of cases (44%, 95% CI: 39–48%) (Corona et al. 2017), although the live birth rate following micro-TESE for Klinefelter syndrome remains under-reported. Notably, as the gonadal failure is progressive, some have proposed to perform extraction during adolescence for long-term cryopreservation and potential fertility in adulthood using ART. However, there is considerable controversy regarding this and it

Table 47.1 Aetiological factors in male infertility

Abnormal spermatogenesis	Sperm transport problems	Hypogonadotrophic hypogonadism (HH)
Varicocele Mumps infection Maldescended testes (cryptorchidism) Cancer therapy Genetic Y chromosome microdeletions Klinefelter syndrome	Congenital bilateral absence of the *vas deferens* (2° to *CFTR* mutations) Sexually transmitted infections (e.g. chlamydia) Pelvic trauma Neurologic problems e.g. diabetes mellitus Retrograde ejaculation Erectile dysfunction	Congenital GnRH deficiency Normosmic HH Kallmann syndrome Combined pituitary hormone deficiency

should be considered on a case-by-case basis given ethical concerns related to non-essential invasive procedures in minors as well as potential confounding issues related to the young adult's comprehension and ability to weigh risk-benefit (Ramstein et al. 2017; Franik et al. 2016). It is advisable that discussions occur with adolescents 16+ years to review the option as part of shared decision-making and management (Dwyer et al. 2015a). In the event that patients are interested in pursuing this option, a referral to a urologic surgeon with expertise in micro-TESE should be made in a timely manner.

A number of endocrine disorders can disrupt spermatogenesis. Hyper- and hypothyroidism can disrupt sperm morphology and motility—yet thyroid disorders are rarely the sole cause of male factor infertility (Krassas et al. 2010). While a relatively rare endocrine cause of male infertility, hyperprolactinaemia can underlie some cases (see also Chap. 45). Accordingly, sub-fertile males should have a thorough medication history taken to identify possible contribution of antipsychotic drugs or dopamine agonists to elevated serum prolactin levels (Patel et al. 2016). Severe cases of congenital adrenal hyperplasia (CAH) are usually diagnosed in infancy yet milder forms of 21 hydroxylase deficiency may not be identified until adolescence to early adulthood. Males with congenital adrenal hyperplasia (CAH) have impaired fertility related to hypogonadotrophic hypogonadism and gonadal failure related to testicular adrenal rest tumours (TARTs) (King et al. 2016).

Rising obesity rates are contributing to a growing number of consultations evaluating subfertility in overweight men. A meta-analysis of 21 observational studies including over 13,000 men demonstrates that obese men have a doubled risk of sperm abnormalities when compared with men of normal weight (Du Plessis et al. 2010). The precise mechanism of how obesity impairs fertility remains unclear and it may result from several interacting factors. Contributors include thermal effects of increased scrotal temperature (secondary to a scrotal adiposity or a panniculus—overhanging belly), the pro-inflammatory state of obesity and oxidative stress that can impair sperm quality, as well as altered adipokines (e.g. adiponectin, leptin) and hormonal disturbances (Cabler et al. 2010). Obesity-induced hormonal alterations including decreased sex hormone binding globulin (SHBG) increased aromatization of T to oestradiol with a resulting decrease in serum gonadotrophins via oestradiol-induced negative feedback at the hypothalamus/pituitary (Pitteloud et al. 2008). Thus, first-line interventions include lifestyle interventions for weight loss—yet this can be challenging to maintain in the long term. Bariatric surgery has a potent impact on sex steroids and a recent meta-analysis indicates that serum T levels increase by 8.1 nmol/L (95% CI: 6–11 nmol, 173–317 ng/dL) and this normalizes serum levels in 87% of men (95% CI: 76–95%) (Escobar-Morreale et al. 2017). Such increases likely impact fertility yet well-designed studies examining the ultimate effect on conception and pregnancy outcomes are lacking (Abiad et al. 2017). A pharmacologic approach to improve sub-fertility in obese men has been to use either aromatase inhibitors (AIs) or selective oestrogen receptor modulators (SERMs) to reduce the negative hypothalamic-pituitary feedback of oestradiol (Rambhatla et al. 2016). However, caution is warranted as these applications are unapproved (so-called "off-label" treatments), increase the risk of thrombosis, and recent meta-analyses reveal limited supporting data that are often from single-centre, methodologically weak studies (Chua et al. 2013; Ribeiro et al. 2016).

For men with a hypothalamic aetiology such as isolated gonadotrophin-releasing hormone (GnRH) deficiency (i.e. CHH) or a pituitary gonadotrophin deficiency (combined pituitary hormone deficiency, CPHD), infertility can be effectively treated with hormonal regimens to induce spermatogenesis (Dwyer et al. 2015b). In cases when limited sperm production (or poor quality sperm) hinders conception, ART may be employed to enhance chances for achieving a biologic pregnancy.

47.3 Predictors of Outcome

47.3.1 Testicular Volume

To date, several predictors of fertility outcomes have been identified (Table 47.2). Testicular

Table 47.2 Predictors of outcome for fertility induction in men with hypogonadotrophic hypogonadism

Report	Sample size	Treatment (duration)	Sperm positive	Time to sperm	Negative predictor	Comments
Burris et al. (1988) J Clin Endocrinol Metab	22	hCG: 2′000 U 3×/wkly (24 mos)	15/22 (68%)	n/a	TV <4 mL	Larger initial TV → better outcomes for hCG mono-therapy
Pitteloud et al. (2002a, b) J Clin Endocrinol Metab	76	Pulsatile GnRH 25–600 ng/kg Q 2 h (12–24 mos)	57/76 (75%)	2–24 mos	TV <4 mL Cryptorchidism IB <60 pg/mL	Cryptorchidism more common with absent puberty (TV <4 mL) 50% of bilateral cryptorchidism remained azoospermic Sperm by 12 mos: 24/31 (77%), by 24 mos: 42/51 (82%)
Miyagawa et al. (2005) J Urol	18	hCG: 3′000 U 2× weekly FSH: 75 IU 2× weekly (12–24 mos)	9/18 (50%)	n/a	TV <4 mL	Cryptorchidism more common with absent puberty (TV <4 mL) Initial TV was positively correlated with sperm count
Liu et al. (2009) J Clin Endocrinol Metab	75	hCG: 1′500–2′000 U 2×/wk FSH (post 6 mos hCG): 75–150 IU 3×/wk (23 ± 2 mos)	85–90%	7 mos 95% CI: 6–10	TV <4 mL Prior TRT	Time to response effected by initial TV Positive effect of prior cycles
Warne et al. (2009) Fertil Steril	81	hCG: 1′000 U 3×/wk or 2′000 U 2×/wk FSH (post 3–6 mos hCG): 150–300 3×/wk (18 mos)	68/81 (84%)	6 mos 95%CI: 3–18	TV <4 mL BM I > 30	Time to response effected by initial TV No effect of prior gonadotrophin treatment All non-responders had absent puberty (TV <4 mL)
Liu et al. (2016) Medicine (Baltimore)	223	hCG: 2′000–5′000 U 2×/wk FSH (post 6 mos hCG): 75–150 U 2×/wk (23 ± 13 mos)	143/223 (64%)	14 ± 8 mos	TV <4 mL Cryptorchidism	Higher LH levels on GnRHa stimulation → positive predictor No effect of prior TRT or BMI
Rohayem et al. (2016) Andrology	51	hCG: 1′500 U 2×/wk FSH (post 3 mos hCG): 150 U 3×/wk (27 ± 18 mos)	50/51 (98%)	11 ± 8 mos	TV <4 mL Cryptorchidism	Cryptorchidism more common with absent puberty (TV <4 mL) Initial TV and IB positively correlated with final TV No effect of BMI

hCG human chorionic gonadotrophin, *FSH* follicle stimulating hormone (purified urinary formulation or recombinant), *GnRH* gonadotrophin-releasing hormone, *mos* months, *TV* testicular volume, *IB* inhibin B, *BMI* body mass index, *TRT* testosterone replacement therapy

volume (TV) is an important predictor of spermatogenesis (Dwyer et al. 2015b) and pregnancy (Liu et al. 2002). Men with CHH/CPHD may have either partial pubertal development or no spontaneous development at all. Those with a complete absence of puberty (TV <4 mL) lack the important proliferative window of mini-puberty (Dwyer et al. 2016) (see Chap. 43) and consistently have poorer fertility outcomes. As such careful assessment of TV via Prader

orchidometer is a key aspect of evaluation. Importantly, one must take into consideration any prior gonadotrophin exposure may confound interpretation of current TV.

47.3.2 Cryptorchidism

Maldescended testes, either unilateral or bilateral, is another prognostic factor for men with CHH/CPHD (Table 47.2) (Dwyer et al. 2015b). Cryptorchidism is evident in 2–5% of full-term neonates (Chan et al. 2014) yet testes subsequently descend spontaneously by 6 months in three quarters of cases. If this does not resolve, and surgical correction is not done in the first year of life, the long-term impact on fertility can be significant (Chan et al. 2014). Indeed, men with bilateral cryptorchidism are six times more likely to be infertile compared to men with a history of either unilateral cryptorchidism or normally descended testes (Lee et al. 1996). A study suggested that orchiopexy at 9 months (current recommendation) (Chan et al. 2014; Ritzen et al. 2007) was associated with significant higher TV and numbers of germ and Sertoli cells when compared with later correction at 3 years—thus making a compelling case for early surgical intervention to correct maldescended testes (Kollin et al. 2012).

47.3.3 Inhibin B (IB)

Sometimes used as a surrogate measure of Sertoli cell number, IB is correlated with a number of fertility measures such as TV and sperm count (Pitteloud et al. 2002a). Indeed, lack of spontaneous puberty is biochemically manifested as low serum inhibin B (IB) levels (i.e. <60 pg/mL) (Pitteloud et al. 2002b). While IB is indirectly related to the other two predictors, it can be a useful biomarker to examine response to treatment during fertility-inducing treatment (Dwyer et al. 2013). There are some remaining questions related to how modifiable the predictors of outcome are. For instance, small pilot studies administering gonadotrophins to neonates lacking mini-puberty offer some promise for improving potential fertility in the future (Bouvattier et al. 2012). While long-term follow-up and definitive data are pending, these initial studies raise important questions regarding the optimal timing for hormonal intervention. There has been some suggestion that prior T treatment may have detrimental effects on later fertility induction (Liu et al. 2009). A recent meta-analysis by Rastrelli and colleagues did not find evidence of this (Rastrelli et al. 2014). However, caution is warranted in interpreting their findings as a number of studies examined in the meta-analysis excluded men with prior T treatment—thus raising a potential source of bias in these data. More data are needed to address this unanswered question.

In summary, a careful history and clinical examination can provide important information for tailoring hormonal treatment and maximizing potential fertility outcomes. This information should be contextualized for the patient and partner. Clear communication on this topic is a key element for helping to establish appropriate expectations for response to treatment. This should not be ignored as conception, clinical pregnancy and birth of a child is not achieved in all cases.

47.4 Spermatogenesis Induction

47.4.1 Pulsatile GnRH Therapy

For patients with hypothalamic defects and isolated GnRH deficiency (CHH), pulsatile GnRH therapy is an effective treatment for both normalizing serum T levels and for inducing spermatogenesis (Hoffman and Crowley 1982; Delemarre-Van de Waal 1993). This treatment involves a subcutaneous bolus of GnRH every 2 h via microinfusion pump and the dose is titrated to achieve normal serum T levels. Three quarters of men are able to develop sperm in their ejaculate on long-term treatment (Rastrelli et al. 2014). Typically, men with some spontaneous puberty (TV ≥4 mL) develop sperm more rapidly than men with absent puberty (6–12 months compared to 18–24 months) (Pitteloud et al. 2002a).

Pulsatile GnRH is a physiologic approach but it is limited by two main factors. First, there are limited options for the microinfusion pump. The device must deliver programmed boluses without a basal rate—this is a feature that is not a design feature in insulin pumps where delivering a basal rate is a central aspect of treatment. Second, managing men on pulsatile GnRH therapy requires particular expertise and thus is typically only available at specialized centres (Dwyer et al. 2015b; Boehm et al. 2015). Thus, it may not be a feasible treatment option for many patients.

47.4.2 Human Chorionic Gonadotrophin (hCG) Mono-therapy

Unlike pulsatile GnRH, exogenous gonadotrophin treatment is a treatment approach that is effective for men with hypothalamic and pituitary aetiologies alike (Finkel et al. 1985). However, mono-therapy with hCG is best reserved for men with a larger TV (Dwyer et al. 2015b). It is a viable option for men with suppressed spermatogenesis following T treatment and for men on the milder end of the CHH phenotypic spectrum (e.g. "fertile eunuch" variant, see Chap. 44). Mono-therapy is much less successful in men who lack testicular development (Rastrelli et al. 2014), as only approximately half of men with no testicular development are able to develop sperm in the ejaculate in long-term hCG mono-therapy (Dwyer et al. 2015b). Treatment regimens vary according to the available formulation yet typically involve subcutaneous injections every other day or three times per week of 1000–1500 units (titrated to achieve mid-normal serum T) (Boehm et al. 2015) (Table 47.3).

47.4.3 Combined Gonadotrophin Treatment

Spermatogenesis outcomes are improved for men with TV <4 mL with the use of combined gonadotrophin therapy, i.e. hCG + follicle

Table 47.3 Treatment regimens for fertility induction in men with hypogonadotrophic hypogonadism

Treatment	Type(s) of patients	Regimen	Titration targets	Notes
Pulsatile GnRH therapy	• Isolated GnRH deficiency	GnRH (25–600 ng/kg) via SC bolus every 2 h	GnRH adjusted to reach low-mid normal serum T	• Sperm in 75% of cases • Can be used as part of sequential treatment
hCG mono-therapy	• Partial puberty (TV >4) or full pubertal development	SC injection 1′000–2′000 U 2 or 3×/week	Trough T adjusted to low-mid normal range	• Monitor haematocrit and gynaecomastia • hCG dose can often be decreased once T is normalized
Combined gonadotrophins (hCG + FSH[a])	• Isolated GnRH deficiency • Pituitary LH/FSH deficiency	hCG via SC injection 1′000–2′000 U, 2 or 3×/week FSH* via SC injection 75–150 IU, 2 or 3×/week	hCG: Trough T adjusted to low-mid normal range FSH: Trough serum level of 4–6 IU/L	• FSH can be started immediately or following 3 or 6 mos hCG alone • Serum FSH level of 9 IU/L or higher should be avoided
Sequential treatment (FSH priming)	• Absent puberty (TV <4 mL)	FSH* via SC injection 75–150 IU, daily or 3×/week (for 2–4 months) → then GnRH or hCG + FSH	FSH: Trough serum level of 4–6 IU/L GnRH/hCG as above	• Ultrasound is helpful for monitoring TV • Growth during FSH priming • Post-priming both pulsatile GnRH and combined gonadotrophins are effective

GnRH gonadotrophin-releasing hormone, *hCG* human chorionic gonadotrophin, *FSH* follicle stimulating hormone, *LH* luteinizing hormone, *T* testosterone, *TV* testicular volume, *SC* subcutaneous

[a]Refers to either purified urinary forms or recombinant FSH

stimulating hormone (FSH) (Rastrelli et al. 2014). Combined treatment outcomes are comparable to pulsatile GnRH therapy (75%, 95% CI: 69–81% vs. 75%, 95%CI: 60–85% with sperm, respectively). Formulations come as either a highly purified urine FSH preparation or recombinant form. FSH is delivered via subcutaneous injection and the choice of FSH preparation does not appear to influence outcome (Rastrelli et al. 2014). Notably, the development of long-acting FSH preparations (Nieschlag et al. 2017) may be highly relevant for treating men as the frequency of FSH injections could be reduced and this could conceivably have beneficial impact on adherence to treatment. Approaches vary in the literature yet most often hCG and FSH are initiated simultaneously or FSH is added following 3–6 months of hCG mono-therapy (Table 47.3).

A large study of 75 men with CHH/CPHD identified that the median time to develop sperm in the ejaculate was 7 months (Liu et al. 2009). Notably, in a separate analysis the authors identified that half of the treatment cycles result in pregnancy with a median time to conception of 28 months (Liu et al. 2002). However, caution is warranted in interpreting findings regarding pregnancy and live births as not all study participants are not always actively seeking to conceive. Mean sperm concentration on long-term combined therapy is 5.9 million/mL (95% CI: 4.7–7.1 × 10^6) (Rastrelli et al. 2014). While 6–7 months of treatment may be sufficient to develop sperm in the ejaculate among men with partial pubertal development (Pitteloud et al. 2002a; Liu et al. 2009), maximal TV (and chances for having sperm in the ejaculate) is reached following 12–18 months of treatment (Dwyer et al. 2015b). However, in men with a history of bilateral cryptorchidism extended treatment of up to 24 months (or longer) may be required (Dwyer et al. 2015b). Importantly, analysis of patients receiving multiple rounds of gonadotrophin treatment reveals that regaining spermatogenesis is achieved two to threefold faster in subsequent courses compared to the initial induction (Liu et al. 2009).

47.4.4 Sequential Treatment

Men with prepubertal testes (TV <4 mL) have sub-optimal outcomes to both pulsatile GnRH and combined gonadotrophin treatment (Rastrelli et al. 2014). Some have posited this is because they lack the proliferative benefits of mini-puberty (Bouvattier et al. 2012; Boehm et al. 2015). Importantly, the androgen receptor on Sertoli cells is not active during this neonatal window so there is unopposed FSH stimulation which has proliferative effects (Grinspon et al. 2014). Similarly, in early puberty, FSH increases ahead of rising serum testicular androgen levels that mature the Sertoli cells (Boehm et al. 2015; Boyar et al. 1974). Based on these physiologic observations, sequential treatments have been developed in an effort to maximize the potential for fertility in men with severe gonadotrophin deficiency caused by CHH, CPHD or following surgical intervention of intracranial tumours in the most severe cases (Dwyer et al. 2013; Raivio et al. 1997, 2007). Essentially, FSH treatment is initiated unopposed to recapitulate the hormonal dynamics of these proliferative periods during development (Table 47.3).

A 2007 study by Raivio and colleagues reported outcomes for 14 young men who received pre-treatment with recombinant FSH using varied regimens prior to pubertal induction with the addition of hCG (Raivio et al. 1997). Notably, some patients with prepubertal testes and a history of cryptorchidism were able to develop sperm in their ejaculate suggesting that FSH priming may have a role in treating such severe cases. Subsequently, a randomized open-label study outcomes between two groups of men with CHH and prepubertal testes (without cryptorchidism or prior gonadotrophin treatment). The control group (n = 6) received 24 months of standard pulsatile GnRH therapy (i.e. LH + FSH) while the intervention group (n = 7) received 4 months of FSH pre-treatment followed by 2 years pulsatile GnRH (Dwyer et al. 2013). The 4-month FSH priming induced normal serum IB levels, a doubling of TV and proliferation of Sertoli cells/spermatogonia evident on histological examination. All the men

in the FSH pre-treatment arm developed sperm in their ejaculate and they trended toward higher maximal sperm counts. However, the pilot was underpowered to definitively determine the optimal treatment and a large, multicentre international study would be required to fully address this question (Boehm et al. 2015). Despite these small numbers, these data demonstrate that pre-treatment with FSH successfully induces testicular development and positive fertility outcomes in CHH who have a complete absence of puberty and may be beneficial for those with a history of cryptorchidism. It is important to underscore that such tailored approaches be monitored by clinicians with experience with these specialized regimens.

47.4.5 Patient Education and Monitoring During Treatment

Patient education and anticipatory guidance is extremely important for fertility induction. Following careful assessment of predictors of outcome patients should be counselled on findings in clear language to help them understand the nature of their infertility and the likelihood of fertility. It is a good practice to include the partner in such conversations as relevant. Second, genetic counselling is recommended for these patients (Boehm et al. 2015; Au et al. 2011). In some cases, genetic testing can be informative. However, when considering genetic testing for CHH it is worthwhile to note that the 25+ loci identified to date only account for approximately 50% of cases (Boehm et al. 2015; Stamou et al. 2015). So it is relevant to discuss with patients that while genetic testing may not reveal the molecular cause of their CHH, hormonal profiling of their child in the neonatal window of mini-puberty can identify if CHH has been passed to the offspring (Dwyer et al. 2016; Quinton et al. 2017). This can allay concerns as appropriate sex steroid therapy can be initiated so as to induce the development of secondary sexual characteristics in line with peers. Thus, the child can avert the psychological effects of not spontaneously starting puberty that is so common among patients with CHH (Dwyer et al. 2014, 2015c, 2017).

Infertility is stressful on couples and the endocrine nurse can be a key source of support and can suggest psychological referral as appropriate. Additionally, fertility treatments are expensive and treatment duration may be lengthy in certain cases. As such, ongoing monitoring for adherence and appropriate therapeutic education (with teach-back) should be done to ensure patients have the appropriate knowledge, know-how and confidence (self-efficacy) to reconstitute medications and deliver self-administered subcutaneous injections (intramuscular injections are not necessary). During fertility induction, regular assessment of TV is warranted (Anawalt 2013). This is typically done using a Prader orchidometer, but ultrasound measurement in three planes can provide accurate information for those severe cases when FSH pre-treatment is used (Dwyer et al. 2015b; Boehm et al. 2015). Typically a TV of 8–10 mL is consistent with active spermatogenesis yet some men are fertile with less robust development (i.e. 4–5 mL) (Dwyer et al. 2015b). While it may seem completely evident, it is good practice to educate patients on the fertile part of the menstrual cycle so that timed intercourse around the time of ovulation can enhance chances for conception.

Nurses should be aware of, and assess for untoward effects of gonadotrophin therapy. Gynaecomastia can develop in up to one-third of men on treatment (Boehm et al. 2015). It is presumed the growth of this glandular tissue results from excessive LH-induced oestrogen secretion and this can be minimized by using the lowest dose of hCG able to maintain trough serum T levels in the low-mid normal range (Dwyer et al. 2015b; Boehm et al. 2015). In terms of pharmacokinetics, the half-life of hCG is roughly 36 h so serum T should be monitored during trough levels (i.e. prior to the subsequent injection) to adjust dose and avoid overly high serum T excursions. Falling T levels can indicate problems with adherence or, in rare cases, may suggest the development of hCG antibodies

secondary to intermittent/sporadic adherence (Boehm et al. 2015). This is an important teaching point to underscore that poor adherence can undermine successful fertility treatment on several levels.

Serum IB levels can be useful from a prognostic point of view (Pitteloud et al. 2002a) as well as a means to monitor the response to treatment (Dwyer et al. 2013). In the randomized study employing FSH pre-treatment (75 IU daily), serum IB levels plateaued after 2 months—suggesting that this might be a sufficient amount of priming prior to adding hCG or pulsatile GnRH (Dwyer et al. 2013). For sequential or combined gonadotrophin treatment, target serum FSH levels are 4–6 IU/L and levels 9 IU/L or higher should be avoided (Dwyer et al. 2013). Additionally, a marker of Leydig cell function, insulin-like 3 (INSL3) may have a role in assessing response to hCG treatment—just as IB is sometimes used as a proxy for Sertoli cells (Trabado et al. 2014).

Most men will not attain sperm counts that are normal as defined by the World Health Organization (Box 47.1) (World Health Organization 2010). Median sperm counts for gonadotrophin and pulsatile GnRH therapy are similar—in the range of 4–6 million/mL (Rastrelli et al. 2014). Importantly, such low sperm counts do not preclude fertility (Burris et al. 1988). Typically serial seminal fluid analyses are initiated after a few months of treatment. As patients with negative predictors (i.e. maldescended testes) may require extended treatment, it is recommended to initiate treatment well in advance (i.e. 6–12 months) of the time which fertility is desired. Treatment is typically continued after conception and well into the second trimester in the event of miscarriage. Mono-therapy with hCG can maintain spermatogenesis yet sperm counts tend to progressively fall over time (Boehm et al. 2015). While previous gonadotrophin treatment accelerates the process of restarting spermatogenesis on subsequent cycles (Liu et al. 2009), this does not guarantee success later cycles and patients may opt to bank samples (see section below on cryopreservation).

47.5 Assisted Fertility

The past decades have witnessed remarkable advances in the field of assisted reproductive technology (ART) and it is now possible for men with even severely impaired number or quality of sperm to have conceive (Cissen et al. 2016). Typically approaches begin with less invasive approaches and progress to more invasive techniques, i.e. intra-uterine insemination (IUI), in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI) and microsurgical testicular sperm extraction (micro-TESE). For men with low sperm counts or motility problems, IUI can be useful. The principle is to inject spermatozoa into the uterus to bring them in closer proximity to the oocyte to enhance chances for fertility (Bahadur et al. 2016; Veltman-Verhulst et al. 2016). This is less invasive and less costly than IVF and success rates are approximately 13% per cycle (Bahadur et al. 2016). In IVF, the female undergoes hormonal treatment to induce ovarian hyperstimulation (superovulation) for subsequent harvesting of oocytes (Pandian et al. 2015). The oocyte is then fertilized in a laboratory setting and grown in a culture medium for several days then one (or more) blastocyst stage embryos are implanted in the uterus. Unused embryos can be frozen and stored for possible future use.

47.5.1 Surgical Sperm Retrieval

For men with obstructive forms of azoospermia (e.g. STI, CBAVD), sperm can be effectively aspirated from the epididymis using percutaneous epididymal sperm aspiration (PESA) or the more invasive microsurgical epididymal sperm aspiration (MESA) (Verheyen et al. 2017). Outcomes are excellent following PESA/MESA for obstructive azoospermia. Men with non-obstructive azoospermia have a problem with spermatogenesis, so sperm must be harvested from the testes. Both sperm retrieval and live birth rates are lower with micro-TESE compared to PESA/MESA (Tournaye et al. 2017). Testicular sperm recovery requires conventional (open) testicular sperm extraction (TESE) or microsurgical

testicular sperm extraction (micro-TESE) (Tournaye et al. 2017). This is an invasive procedure performed under general anaesthesia and sperm recovery is possible in approximately 40–50% of cases (Verheyen et al. 2017). There is mounting evidence suggesting that micro-TESE is more effective option and a recent meta-analysis identified that sperm retrieval is 1.5 times more likely with a microsurgical approach compared to conventional TESE (Bernie et al. 2015). Sperm can then be used for immediate use in combination with oocyte retrieval ("synchronous sperm retrieval") and/or frozen for future use by their partner, usually with ICSI.

47.5.2 Intracytoplasmic Sperm Injection (ICSI)

In contrast to IVF, ICSI is a procedure wherein a single sperm is selected and used to fertilize an oocyte. For men with CHH, this approach was initially used as a means to shorten the duration of hormonal treatment (Yong et al. 1997). However, it has become increasingly clear that outcomes are improved when intervention is delayed until maximal testicular development has been reached. Overall, success rates of ICSI in men with CHH are high with fertilization rates in the range of 50–60% and pregnancy occurs in approximately 30% of cases per cycle (93–96). While the numbers of patients limit analysis, one published report on sperm quality concluded that CHH per se does not appear to impair DNA integrity nor does it elevate the risk of chromosomal aberrations (Krabchi et al. 2011).

Potential risk for birth defects has been raised as a possible result of ART. Several meta-analyses demonstrate that ART-conceived children have a 30–40% increased risk of birth defects compared to fertile counterparts who conceive spontaneously (Chen and Heilbronn 2017). However this is a complicated issue to tease apart as women undergoing IVF tend to be older, have more pre-existing health conditions and at baseline are at higher risk for complications (Luke et al. 2017). Interestingly, there is growing attention to the epigenetic aspects of ART as there is emerging evidence that ART impacts methylation and imprinting (Lazaraviciute et al. 2014). Consequently, some have raised questions regarding the potential long-term risk for certain types of cancers, cardiovascular disease, and metabolic problems such as obesity and diabetes mellitus in children conceived using ART (Chen and Heilbronn 2017). However, this area of investigation is still relatively nascent and there is no clear consensus regarding risk for birth defects or long-term health consequences for children born to ART. Indeed, while remarkable technologic advances have been made, many questions remain (Box 47.2).

Box 47.2 Unanswered Questions and Future Directions

Is there a role of neonatal treatment to optimize potential for developing future fertility?

What is the optimal treatment regimen(s) for inducing spermatogenesis?

What is the best way to optimize fertility potential in those men with a history of maldescended testes?

Does prior testosterone treatment impact the success of subsequent spermatogenesis induction?

How will the evolving understanding of genetics and genomics alter our approach to treatment and counselling of these patients?

Do assisted reproductive technologies have long-term health consequences for the children conceived via these procedures?

47.5.3 Sperm Cryopreservation

Cryopreservation is the storage of cells or tissues at ultra-low temperatures for future use and is a well-established and widely used procedure in the fertility field. It is based on the principle that biological activity ceases below −135 °C (Benson et al. 2012) and therefore, thawed cryopreserved cells will continue to function as

before, providing the damage caused by the freezing and thawing processes is minimized. Sperm cryopreservation is used for several reasons. First, it is used to ensure availability of sperm for fertility treatments. Second, it can serve as an "insurance policy" for those with testicular failure, following treatment to induce spermatogenesis, or prior to certain some surgical interventions/gonadotoxic or gonado-suppressive treatments. Importantly, cryopreserved sperm may represent a man's only opportunity for fatherhood, and laboratories employ methodologies for cryopreservation that maximize sperm cell survival and therefore, maximize fertility options for men at risk of infertility.

Current cryopreservation practices involve the storage of cells in liquid nitrogen or nitrogen vapour (−196 °C) and provide sperm survival rates of around 30–60%, with the remainder being lost to cryo-injury. Cells are considered inert during storage so the damage to cells is caused during the cooling and warming processes when ice crystal formation and high intracellular solute concentrations can rupture cell membranes (Benson et al. 2012; Gao and Critser 2000). Accordingly, successful cryopreservation and thawing depends on a careful balance of cooling and warming rate as well as intracellular solute concentration resulting from osmosis secondary to ice crystal formation. As the cell suspension cools below −5 °C, water crystallization begins in the extracellular medium. This draws water out of the cells increasing their internal concentration of solutes. If this happens too slowly, cell damage can occur as a result of osmotic shock (or extreme cell shrinkage). If cells are cooled too quickly, the water in the cells cannot leave, and instead freezes into crystals within the cell membrane rupturing the cell (Gao and Critser 2000; Woods et al. 2004). Surviving cells must then endure the repeat stressors during thawing process.

When referring a patient for sperm cryopreservation, it is important to counsel the patient that a strict consent process and viral screening must be fulfilled before a sample can be obtained. Current minimum European standards require valid consent for sperm storage as well as screening for blood-borne pathogens including human immunodeficiency virus (HIV), Hepatitis B and Hepatitis C. Ejaculated sperm samples should be produced directly into an approved sterile container that has been tested for toxicity to sperm. Surgically retrieved sperm (e.g. during micro-TESE) should be obtained under sterile conditions, and handled by trained scientists to minimize contamination by potentially toxic agents. Samples must be transported to the laboratory in secure, sterile containers at 37 °C to maintain their viability, and should be processed within 1 h.

An analysis of sperm quality must be carried out before cryopreservation begins. This ensures the suitability of the sample for storage i.e. that there are viable sperm present; however, the pre-freeze analysis, along with post-thaw survival data, provides important information for the future of the samples, in particular for the suitability for use in certain types of fertility treatment and the number of attempts at the fertility treatments that may be afforded by the quantity stored. This is an important factor when considering "how much is enough" and how many samples should be stored, especially in cases of fertility preservation where the availability of more sperm in the future is uncertain. Accordingly, it is generally recommended that patients attend on multiple occasion to produce a sample, to ensure that adequate sperm are cryopreserved for future treatment.

Most European countries have strict regulations surrounding the storage of gametes and embryos. Although the specific rules will vary from country to country, each will have specific rules on the requirements for consent in relation to stored material. The maximum duration of storage, the permissible use of the samples and what actions should be taken in the event of death or mental incapacity of the gamete or embryo provider represent the minimum requirements for consent to storage.

47.6 Ethics of Assisted Fertility

Medical ethics is guided by four principles proposed by Tom Beauchamp and James Childress (2008): autonomy, beneficence, nonmaleficence

and justice. These principles are applied to ethical questions to better understand which principles may be in conflict. Autonomy is often described as respect for persons. Involving patients in decision-making is a common example of promoting autonomy. Doing good is the definition of beneficence, while nonmaleficence is preventing harm. The principle of justice applies to questions of fairness, equality and allocation of resources.

47.6.1 Ethical Issues Related to Future Children

Assisted reproduction presents some unique medical ethics challenges. Perhaps the most fundamental issue, however, involves beliefs about the presence or absence of personhood status held by an embryo or foetus. These beliefs are informed by cultural, religious and personal factors (and personal practices surrounding) assisted reproduction and termination of pregnancy. For example, whether a couple or family believe that personhood of an embryo begins at conception may dramatically impact assisted reproduction decisions based on their perceived beneficence or nonmaleficence, e.g. not pursuing in vitro fertilization (IVF) or creating unused embryos. Beyond personal choices, these beliefs also influence the regulatory landscape. In the United States, so-called personhood amendments to several state constitutions (Oklahoma, Virginia, Colorado, Nevada, Missouri) have sought to legally establish personhood from the moment of conception (fertilized egg) to birth. To date, many such campaigns have not been enacted as law (Suckow and Yates 2015).

Practitioners who offer assisted reproductive services may be asked to consider beneficence and nonmaleficence toward a child created through these techniques. This could potentially conflict with the autonomy of the individual seeking fertility treatment. The United Kingdom, via the Fertility and Embryology Act and European Society of Human Reproduction and Embryology (ESHRE) practitioners are required to consider the welfare of the future child and not contribute to the creation of a child at high risk for psychological and physical harm (Harper et al. 2014). Though children created with assisted reproduction are usually healthy, there may be some increased risk for epigenetic/imprinting disorders (i.e. Beckwith-Wiedemann syndrome, Angelman syndrome). These risks have been most associated with conception using intracytoplasmic sperm injection (ICSI). Risk for other genetic conditions (e.g. chromosomal abnormalities, cystic fibrosis) and birth defects may also be increased, and possibly related to the cause of one's infertility (Kurinczuk and Bhattacharya 2014). Screening patients for chromosome rearrangements, Y chromosome microdeletions, and CFTR gene mutations prior to treatment facilitates a better understanding of a family's specific risk for these conditions.

47.6.2 Ethical Issues Related to Patients

Promoting autonomy, beneficence, and nonmaleficence in assisted reproduction toward the patient alone is constantly evolving as new technologies emerge and our understanding grows regarding risks and outcomes. The American Society of Reproductive Medicine (ASRM) and the ESHRE offer some practice guidelines (Practice Committee of the American Society for Reproductive Medicine et al. 2014) for clinicians to provide the most effective, safe and ethical care. The guidelines, however, are dependent on the completeness and consistency of outcomes data derived from numerous sources and are limited by the paucity of solid evidence regarding long-term outcomes, particularly for newer treatments. An informed consent process that addresses the capabilities, limitations and risks of assisted reproduction and a clear delineation between clinical and experimental/research protocols is essential. This may be more challenging when the patient is a child. Fertility preservation has been proposed as an option for

children facing cancer treatment, as well as those with Klinefelter and Turner syndromes. For the latter conditions, extraction of gonadal tissue at young ages may be needed to obtain viable gametes (Franik et al. 2016; Londra et al. 2014).

47.6.3 Ethical Issues Related to Gamete Donors

When sperm or egg donors are added to the equation, additional considerations must be made. Donor programmes/banks have obligations to both families and gamete donors. Donors should be advised of potential associated risks, limitations to their anonymity, and their rights and even responsibilities. Families who use gamete donors should have some mechanism to report adverse outcomes (birth defects, genetic disease) to donor programmes as this information can benefit other recipients as well as the donors themselves. Donors have an obligation to provide truthful information about their health and family history and update donor programmes with changes to that information (Ethics Committee of the American Society for Reproductive Medicine 2014). Egg donors in particular face health risks associated with ovulation induction and egg retrieval. Concerns regarding coercion from excessive payment beyond compensating donors for their time and discomfort, and perhaps based on other features (education, race, physical traits) have also been raised (Londra et al. 2014). Infectious disease and genetic screening of gamete donors is not uncommon in the United States and Europe. Currently, genetic screening focuses on carrier status for recessive conditions and Fragile X Syndrome. Increasing accessibility to larger-scale genomic testing will make it possible to test donors for a wider range of genetic conditions. Importantly, such testing may reduce some, but not all, risk for recipient families. Indeed, providing adequate pre- and post-test genetic counselling for donors is needed to promote autonomy, maximize the benefits, and minimize harms (Dondorp et al. 2014).

47.6.4 Access to Assisted Reproduction

Access to assisted reproduction remains a significant ethical and social issue. Local restrictions in the form of regulatory and/or financial barriers to accessing assisted reproduction have led some families to seek these services abroad. In many European countries, families must meet specific criteria (age, medical necessity, marital status and sexual orientation) to be eligible for IVF. However, these criteria vary across countries. Similarly, the availability of public funding for IVF and regulation of gamete donors also vary widely by country (Berg Brigham et al. 2013). In the United States, infertility treatment is often not covered by health insurance and given the needed financial resources required, assisted fertility treatment is out of reach for many families. One response to this has been to seek services outside one's home country or so-called "medical tourism". Yet concerns have been noted regarding safety and quality of services, both for patients and gamete donors, as well as barriers for sharing outcome data (Harper et al. 2014).

47.6.5 Assisted Reproduction and Pre-implantation Genetic Testing

People undergoing assisted reproduction treatment may elect to have pre-implantation genetic screening/testing (PGS/PGD) of embryos for specific conditions. Benefits of PGS/PGD include a decreased risk of miscarriage in women over age 35, likely the result of aneuploidy screening (Chang et al. 2016), avoiding pregnancy termination, and avoiding a fully penetrant life-limiting genetic disease. The use of PGD to create "saviour siblings" via human leukocyte antigen typing and testing for less penetrant and/or serious genetic conditions has raised concerns about rights and welfare of the child. Such cases present a potentially slippery slope toward genetic designer babies. To date there is no clear consensus. However, in these instances, determining the

necessity of PGD and the "seriousness" of a particular condition may be best understood by evaluating each situation in its unique context (Harper et al. 2014). Examining potential principles in conflict is also helpful in these situations. For example, autonomy and beneficence/nonmaleficence as defined by the patient versus the autonomy and beneficence/nonmaleficence toward the potential child. Sex selection and the potential for gender discrimination, the destruction of embryos with genetic disorders, as well as limited knowledge of risks to children created with PGD are all potential concerns (Londra et al. 2014). While PGD provides a great service to many families, patients should be properly consented, offered genetic counselling, and informed of the known risks and benefits—including the possibility of false positive and negative results. The Society for Assisted Reproductive Technology and ASRM recommend follow-up prenatal diagnostic testing with chorionic villus sampling or amniocentesis is recommended to confirm the PGD result (Practice Committee of Society for Assisted Reproductive Technology and Practice Committee of American Society for Reproductive Medicine 2008). Given the growing availability of multi-gene panels and whole exome sequencing in the postnatal setting, it seems plausible that such approaches may be applied for PGD. However, consideration of the necessary pre-test counselling, criteria for selecting embryos, and goals for outcomes (healthy child and/or no predisposition for adult-onset disorders) is warranted and necessary for such testing approaches to be implemented (Harper et al. 2014).

Ever-changing technology in reproductive technology adds to the complexity of the ethical issues. The interests of patients, future children and gamete donors must be examined with the realization that these may sometimes conflict. The rapidly changing landscape of reproductive technologies means that recommendations and regulations may not be up to date with current practices and are not consistent across countries. Barriers to obtaining fertility treatment still exist, primarily due to cost and regulations. Ongoing evaluation of risks and long-term outcomes is needed to provide appropriately informed consent and to promote and support the tenets beneficence and nonmaleficence.

47.7 Conclusions

Male factors contribute to approximately half of all couples presenting for evaluation of infertility. Thorough history, clinical examination and biochemical profiling can help identify iatrogenic causes of male infertility (i.e. T treatment) and cases that require referral for urologic consultation with a specialist in ART. Men with obstructive azoospermia, sperm transport problems and gonadal failure require this type of consultation. Hypogonadotrophic hypogonadism with a hypothalamic or pituitary aetiology is amenable to hormonal therapy to induce spermatogenesis. Based on the presence of negative predictors of outcome (i.e. TV <4mL, history of cryptorchidism, serum IB <60 pg/mL), treatment can be tailored and appropriate expectations for treatment can be set. Fertility-inducing hormone treatments are best managed by clinicians with experience and expertise with these specialized regimens. The majority of men (75%) will be able to develop sperm in their ejaculate (Rastrelli et al. 2014), and low sperm counts do not preclude fertility in these men (Burris et al. 1988). ART can complement hormonal therapies for those men with severely compromised sperm counts and/or motility problems. A rational approach is to progress from less invasive to more invasive measures with ICSI and micro-TESE reserved for poor responders.

While remarkable technologic advances have made fertility a possibility for many, reproduction has humanistic meaning. Infertility is not simply a physiologic problem—it also has psychological, emotional and social meaning and consequences. Thus, a holistic approach is central to the care of patients with infertility. The endocrine nurse can play an important role in caring for and managing men presenting with infertility. Infertility can be a stressful situation for

couples and many find it challenging to navigate the health system given that care may involve endocrinology, urology, andrology labs, psychology and genetic counselling as well as payers (i.e. health insurers). Appropriate, timely referrals are a critical aspect of care coordination and nurses can have an important role in coordinating care and providing psychological support for patients and couples. Additionally, therapeutic education, assessing adherence, monitoring response to treatment (i.e. hormonal, TV, spermatogenesis) and effective interprofessional communication and collaboration are all part of comprehensive care for these patients.

Abstract

Erectile Dysfunction (ED) has been defined as a persistent inability to attain or maintain erection adequate to permit satisfactory sexual function (National Institute of Health 1993). It is estimated that a third of men will be affected by ED at some point during their lives (Heidelbaugh 2010). Whilst published figures provide an indication of the prevalence of ED, they are likely to underestimate the true number as many men will not seek help either due to embarrassment or through acceptance that ED is inevitable with advancing age (Hatzimouratidis et al. 2010).

The pathophysiology of ED may be neurogenic, hormonal, vasculogenic, drug-induced, anatomical, and/or psychogenic. However, regardless of the pathological basis for ED, the condition can have a profoundly negative psychological impact on relationships, quality of life and overall affect self-esteem (Gruenwald 2012). Therefore, to establish an

effective ED management plan in a timely fashion is of paramount importance for the well-being of the sufferer and partner.

By the end of this chapter we hope that you will have a better understanding of the pathophysiology and management of ED.

Keywords

Key Terms

- An **erection** is reliant upon a complex interplay of arterial, venous, neurological, hormonal and psychological elements. The erectile tissue comprises two cylinders of smooth muscle (corpus cavernosum) which become engorged with blood when sexually aroused and during sleep (nocturnal erections). The increase in arterial inflow through the cavernosal arteries into cavernosal tissue and occlusion of venous outflow results in penile rigidity and erections.
- **Erectile dysfunction (ED)** is a common male sexual disorder which describes the inability to achieve or maintain an erection to enable satisfactory sexual function.
- **Infertility:** the inability to achieve pregnancy following regular unprotected intercourse for 12 months. Factors may be male, female or mixed (both) in origin.
- **Sexual dysfunction:** the inability to engage in normal, pleasurable sexual activity resulting from diminished desire (libido), arousal difficulties (erectile dysfunction) and/or problems with orgasm (ejaculation).

Key Points

- To describe and present evidence on the definition, prevalence and pathophysiology of erectile dysfunction (ED).
- To describe the clinical presentation, symptoms and investigations to diagnose ED.
- To present latest evidence on the management of ED with medical treatment, surgical pathway and additional therapies.

48.1 The Physiology of Erections

The erectile tissue comprises two cylinders of smooth muscle (corpus cavernosum) which become engorged with blood when sexually aroused and during sleep (nocturnal erections). The increase in arterial inflow through the cavernosal arteries into cavernosal tissue and occlusion of venous outflow results in penile rigidity. Pelvic nerves that run intermittently around the prostate and end within the penis facilitate this complex process (Fig. 48.1). Testosterone has effect on every component required for erectile function (Isadori et al. 2014).

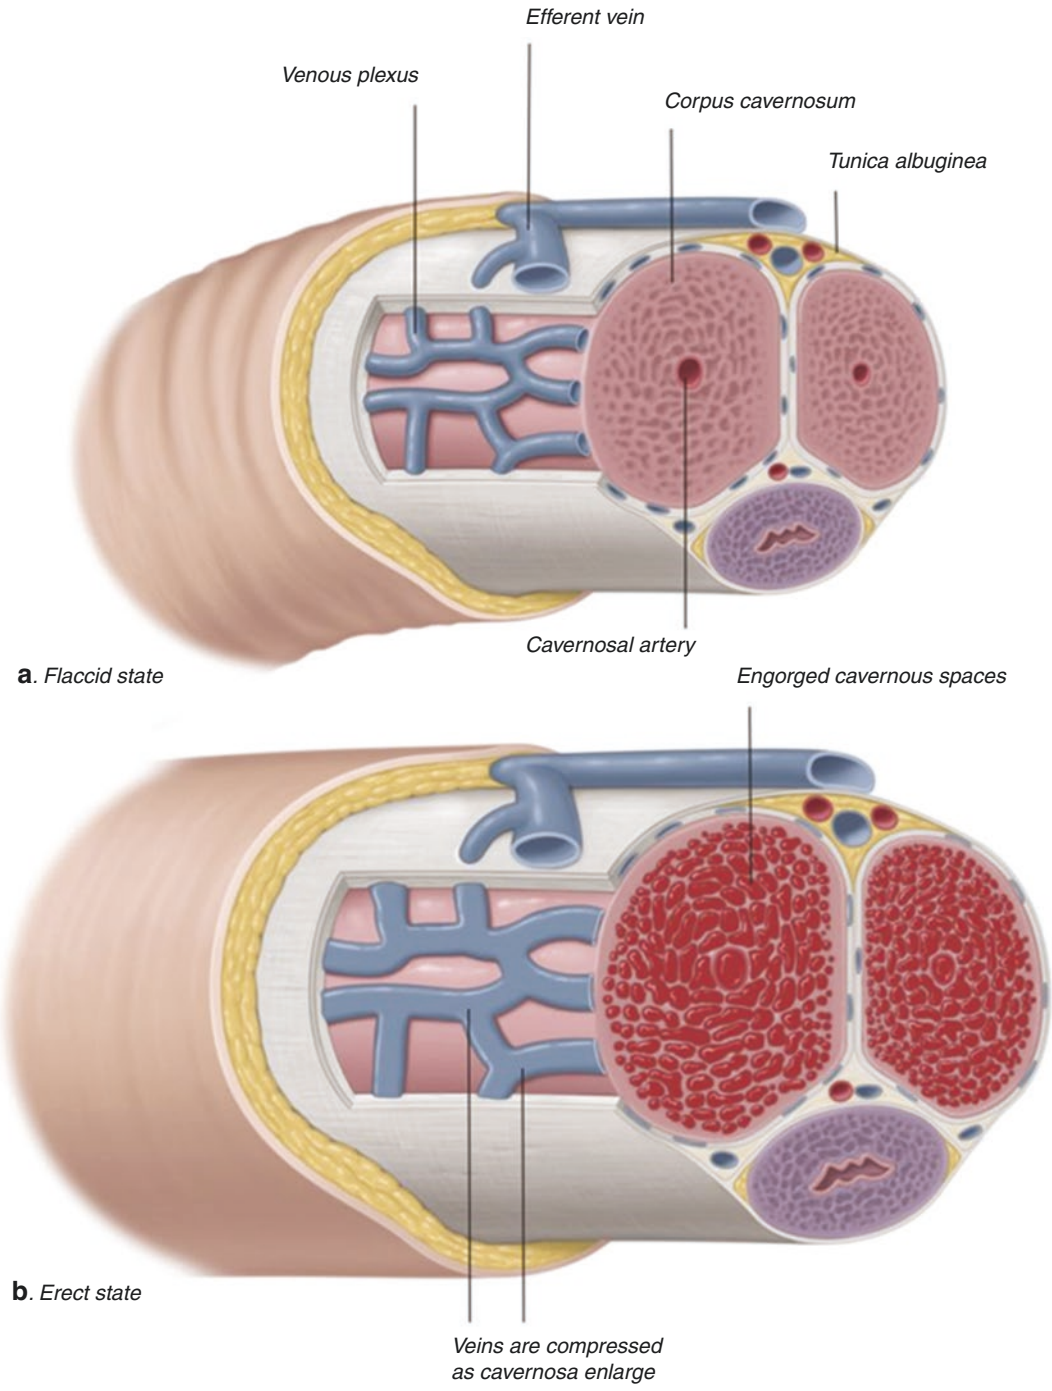

Fig. 48.1 Physiology of erectile function and erections. Used with permission from the European Association of Urology Patient Information http://patients.uroweb.org/erectile-dysfunction/

Table 48.1 Common medical conditions or medications associated with erectile dysfunction

Vascular	Neurogenic	Hormonal
• Diabetes • Congestive heart failure • Peripheral vascular disease • Hypertension • Hypercholestraemia • Kidney disease • Atherosclerosis • Pelvic trauma (fracture) • Smoking	• Radical prostatectomy • Spinal cord injury • Cerebrovascular accident (CVA) • Multiple sclerosis (MS) • Peripheral neuropathy • Diabetes • Pelvic radiotherapy • Parkinson's disease	• Increased prolactin • Low testosterone • Low luteinising hormone (LH)
Psychological	**Medications**	
• Depression • Anxiety • Schizophrenia • Bipolar disorder • Substance abuse	• Anti-androgens • Anxiolytics • Tobacco • Alcohol • Recreational drugs • Antihistamines • Antidysrhythmics • Antihypertensives • Antidepressants • Antipsychotics • Anticonvulsants	

In the normal erection process, sexual stimulation triggers the local release of nitric oxide (NO) which has long been recognised as the most important mediator for smooth muscle relaxation (Sullivan et al. 1999). NO effects intracellular activation of guanylate cyclase which regulates conversion of guanosine triphosphate to cyclic guanosine monophosphate (cGMP). cGMP mediates intracellular signal transduction which leads via protein activation mechanisms to a reduction in intracellular calcium, resulting in dilatation of the cavernosal arteries and relaxation of the smooth muscle (Moreland et al. 2001). This process enables an increase of blood flow into the cavernosal tissues resulting engorgement, and ultimately erection.

As described above, an erection is a complex phenomenon reliant upon a complex interplay of arterial, venous, neurological, hormonal and psychological elements and any disturbance to this process can result in erectile dysfunction (Montague et al. 2005). Erectile dysfunction (ED) is a common male sexual disorder which describes the inability to achieve or maintain an erection to enable satisfactory sexual function.

Medical risk factors for ED include diabetes, hypertension, cardiac disease, hypogonadism, dyslipidaemia, neurological disease including multiple sclerosis and Parkinson's disease, spinal injury, and depression renal failure, chronic liver disease, chronic respiratory disease (Hackett et al. 2008). It is not unusual for men to possess multiple risk factors, therefore establishing the exact cause of ED is not always possible (Dean and Lue 2005).

Lifestyle factors that can predispose men to ED include sedentary lifestyle, smoking, obesity and alcoholism (Hackett et al. 2008; Hatzimouratidis et al. 2010). Iatrogenic causes for ED include medications such as anti-androgens, antihypertensives and antidepressants (Table 48.1). Pelvic radiotherapy can also result in ED (Hackett et al. 2008). Direct trauma to the nerves of the penis either through injury or as a consequence of pelvic/genital surgery can result in ED. In men who have undergone radical prostatectomy surgery for cancer (nerve sparing and non-nerve sparing), the incidence ranges between 40 and 85% (Nandipati et al. 2006).

48.2 Diagnosing Erectile Dysfunction

The first and most important stage in diagnosing the cause of ED is to undertake a detailed medical history of patients including a history of their

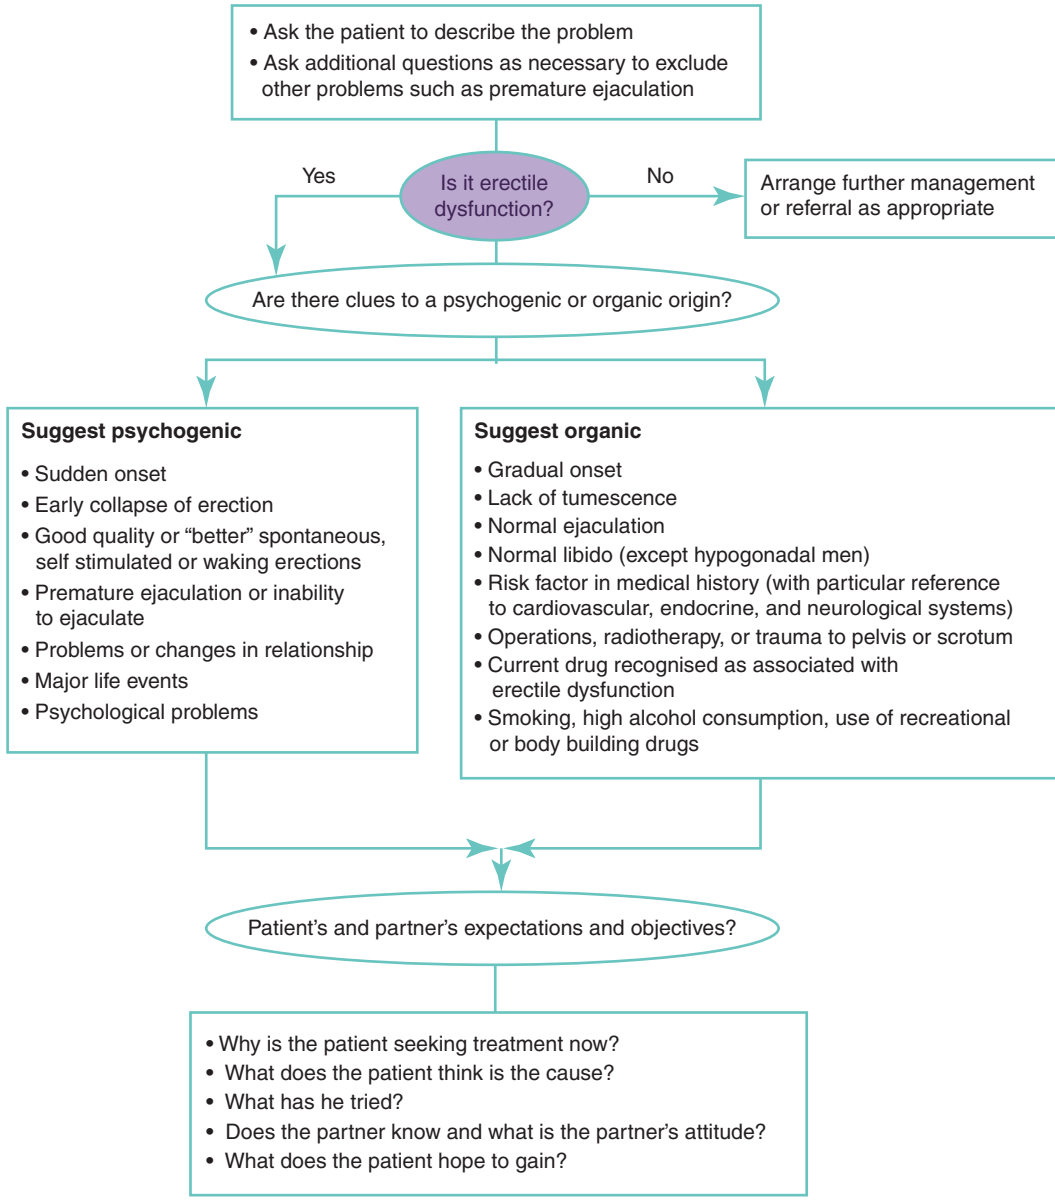

Fig. 48.2 History-taking in erectile dysfunction. Source: Ralph, D and McNicholas, T (2000) UK management guidelines for erectile dysfunction. *Bmj,* 321, 499–503. (link for copyright https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1118395/figure/F1/)

erectile function (Davis-Joseph et al. 1995; Hatzichristou et al. 2002). If the initial assessment indicates the possibility of an important psychiatric problem, this should be addressed before treatment for erectile dysfunction (Ralph and McNicholas 2000) (Fig. 48.2).

The pathophysiology of ED may be neurogenic, hormonal, vasculogenic, drug-induced, anatomical and/or psychogenic, thus obtaining a comprehensive medical history may elicit one of the conditions typically associated with ED. ED may be associated with modifiable risk factors, including lifestyle, medications or undiagnosed illness/conditions.

These issues may be addressed either before, or at the same time as specific treatments are used.

Medical conditions such as endocrine and metabolic disorders (e.g. hypogonadism, hyperprolactinaemia and diabetes) should always be treated and well controlled as the first step of ED treatment.

Treatment options for ED should be tailored according to patient (and partner) satisfaction, QoL factors and treatment-related safety and efficacy. The management algorithm for ED recommended by the European Association of Urology (EAU) (Hatzimouratidis et al. 2016) is presented in Fig. 48.3.

The physician–patient (partner) dialogue is essential throughout the management of ED. It is important to create a relaxed atmosphere during history-taking, ideally involving the patients' partner if possible. This will make it easier to ask personal questions regarding the patient's erectile function which will also include other aspects of sexual history.

48.2.1 Sexual History

This should include information regarding duration of the erectile problem and whether onset was gradual or sudden. Details relating to previous treatments trialled and information on any previous or current relationships, including current emotional status must also be documented. Additional information to be sought includes rigidity and duration of both sexually stimulated, morning or nocturnal erections, and any problems with ejaculation, arousal or orgasm.

Psychometrically validated questionnaires, such as the International Index for Erectile Function (IIEF) (Rosen et al. 1997), are useful tools to assist the clinician to measure the patient's different sexual function domains (i.e. sexual desire, erectile function, orgasmic function, ejaculation, intercourse and overall satisfaction), as well as the effect of a specific treatment. Patients should be questioned for symptoms of possible hypogonadism, for example, decreased libido, energy, fatigue and cognitive impairment, as well as for symptomatic lower urinary tract symptoms (Hatzimouratidis et al. 2016).

48.2.2 Physical Examination

Every patient should undergo a physical examination focusing on the genitourinary, vascular, endocrine and neurological systems (Davis-Joseph et al. 1995), as this could divulge signs suggesting hypogonadism (e.g. small testes) or penile disorders such as Peyronie's disease (Hatzichristou et al. 2002). In addition, the EAU guidelines stipulate the need for rectal examination in men over 40 years to identify prostatic problems (Hatzimouratidis et al. 2016), and blood pressure and heart rate should be checked in those men who have not had this assessed within the past 6 months to elicit possible cardiovascular causes.

48.2.3 Blood Tests

Fasting blood glucose, lipid profile and early morning testosterone are essential laboratory tests that must be obtained in males presenting with ED. Additional tests that should be considered include prostate-specific antigen (PSA) for detection, or suspicion, of prostate cancer (Heidenreich et al. 2011), and hormonal tests, including prolactin and luteinising hormone, when low testosterone levels are discovered. Indeed, for these males, referral to an endocrinologist may be appropriate (Lue et al. 2004a).

48.2.4 The Cardiovascular System and Sexual Activity

Patients who pursue treatment for sexual dysfunction have a high incidence of cardiovascular disease (Montorsi et al. 2010); in addition, the cardiac risks coupled with sexual activity are well established. It is imperative that clinicians can identify those men who may require additional cardiological workup, and additionally ensure that each man's cardiovascular health is harmonious with the physical demands of sexual activity before prescribing ED treatment (Nehra et al. 2012). For men determined as 'high risk',

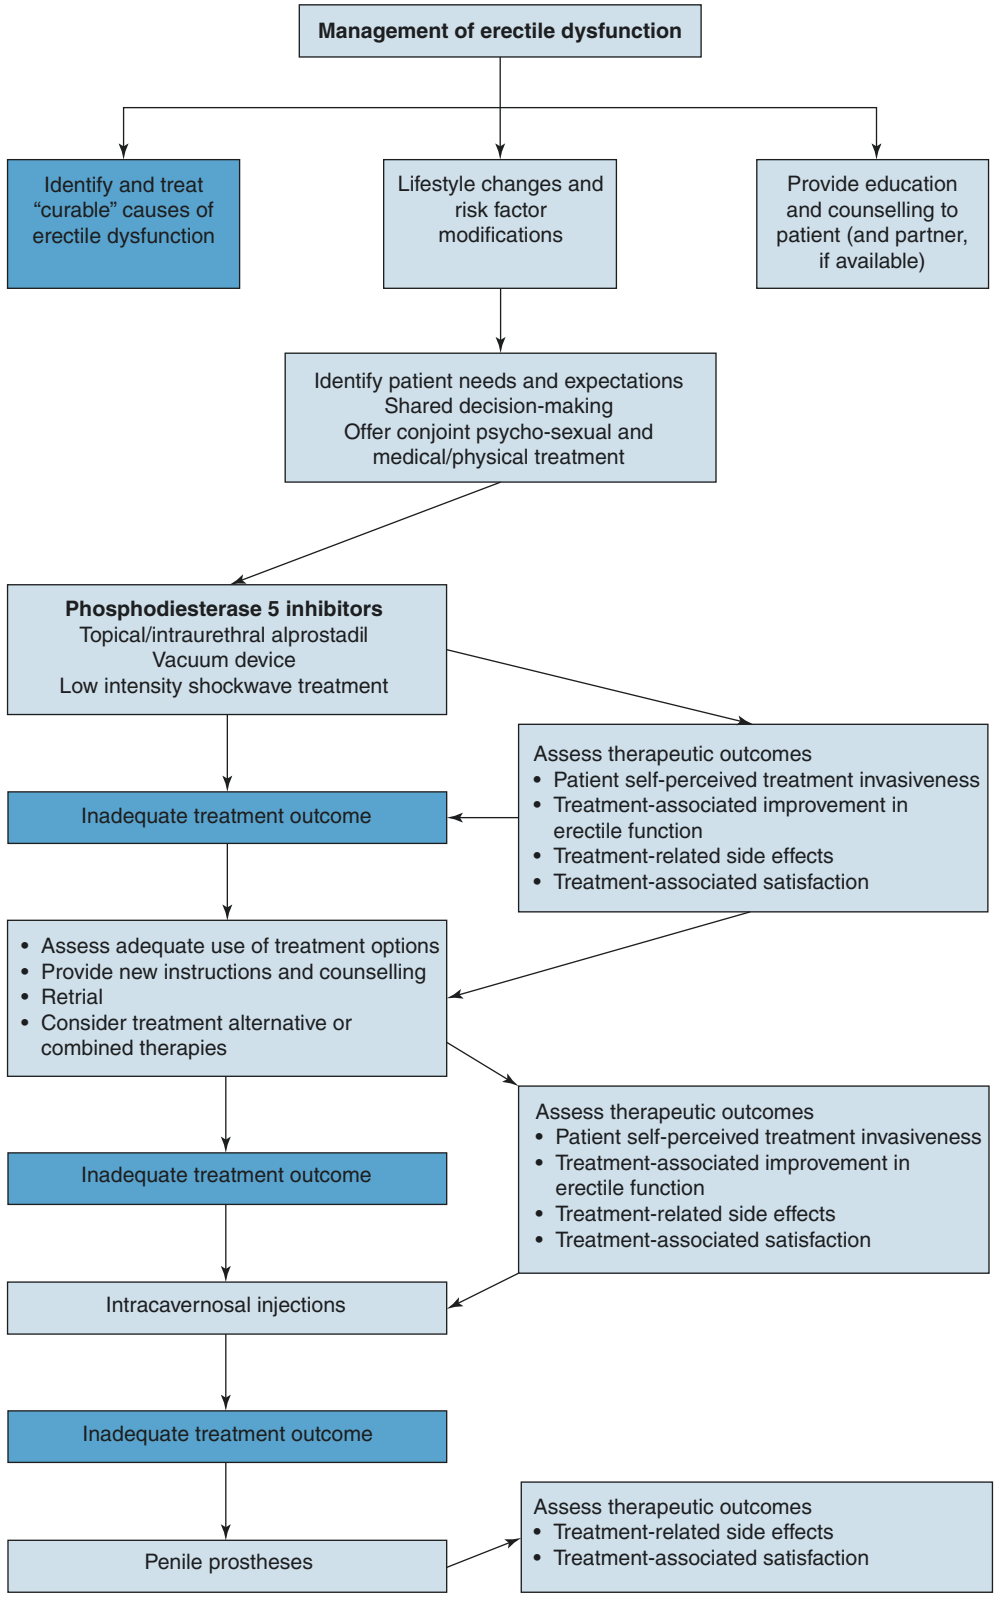

Fig. 48.3 Algorithm for the evaluation and management of patients with ED (used with permission from the European Association of Urology, accessed via http://uroweb.org/guideline/male-sexual-dysfunction/#3)

referral should be made to a cardiologist for assessment, possible treatment and an opinion that it is safe to resume sexual activity.

48.2.5 Specialist Diagnostic Tests

Although not essential, it may be pertinent to perform specialist tests on some males with erectile dysfunction.

These include:

- **Nocturnal penile tumescence (NPT) study**
  This sleep study is used to determine nocturnal penile tumescence and rigidity, with an erectile event indicated by a minimum of 60% rigidity recorded on the tip of the penis, lasting for >10 min (Hatzichristou et al. 1998). A positive NPT result (where strong erectile activity is recorded) indicates psychogenic erection dysfunction and a physical cause can be excluded.
- **Duplex ultrasound of the penis**
  The aim of Doppler ultrasound is to assess the inflow and outflow of blood through the cavernosal arteries after an intracavernosal injection of a pharmaco-stimulant (e.g. alprostadil) a peak systolic blood flow >30 cm/s, an end-diastolic velocity of <3 cm/s and a resistance index >0.8 are generally considered normal (Meuleman and Diemont 1995). In such circumstances where a normal duplex ultrasound is reported, further vascular investigation is unnecessary.
- **Cavernosography**
  The purpose of cavernosography is to identify veno-occlusive dysfunction in men with suspected organic ED (Glina and Ghanem 2013), thus it should only be performed in patients who are being considered for vascular reconstructive surgery (Wespes and Schulman 1993). This test is rarely offered today, even in specialist UK andrological centres.

48.3 Treatment Options for ED

Guidelines on the Management of Erectile Dysfunction (Hackett et al. 2008) were developed to standardise ED care. The standards describe the ED pathway as a three-stage process, commencing with first line oral phosphodiesterase 5 inhibitors (PDE5i's), followed by more invasive second line pharmacological injectables/intraurethral pellets, and lastly for refractory ED cases, penile prosthesis surgery (Fig. 48.4).

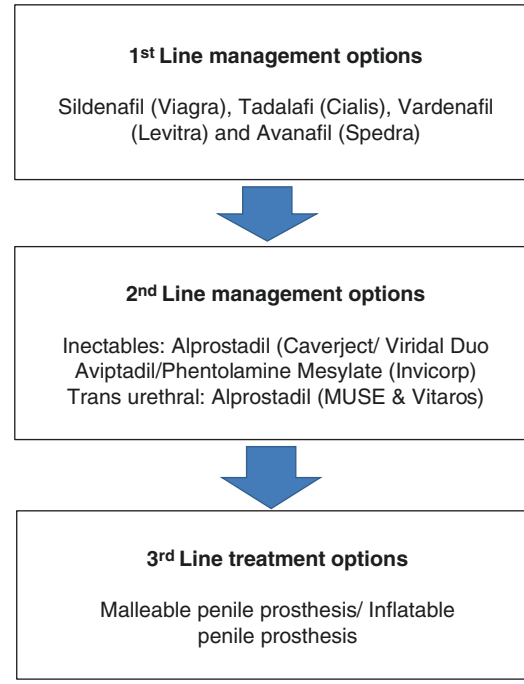

Fig. 48.4 Treatment algorithm for ED (adapted from Hackett et al. 2008)

48.3.1 First Line Treatment

48.3.1.1 PDE5 Inhibitors

Evidence suggests that phosphodiesterase 5 (PDE5) is the most important isoenzyme in the physiological control of normal penile activity (Gresser and Gleiter 2002), although tissue distribution of PDE5 also includes vascular smooth muscle, kidney, CNS, platelets and digestive smooth muscle (Lue et al. 2004b). In the penis, PDE5 is responsible for the breakdown of cGMP which leads to an increase in the tone of the cavernosal vessels resulting in contraction of the smooth muscle which induces de-tumescence usually after ejaculation or when sexual stimuli has been removed (Lue et al. 2004b).

PDE5i's selectively inhibit PDE5 to reduce breakdown of cGMP. They do not exert relaxant effect directly on the cavernosal tissue but can augment the relaxant effect of NO on the tissue which is released during sexual stimulation (Sussman 2004), therefore, in order to optimise the effect of a PDE5i, stimulation is necessary.

PDE5i oral tablets are recommended as the first line therapy for men with ED as they are well tolerated and non-invasive. These include sildenafil (Viagra), vardenafil (Levitra), tadalafil (Cialis) and avanafil (Spedra). Although components of each PDE5i are slightly different, all PDE5i's are considered relatively similar in efficacy and tolerability (Hackett et al. 2008). The most significant difference to the drugs relates to their pharmacokinetics in that sildenafil, vardenafil and avanafil are relatively short acting with a half-life of 4–6 h, whereas tadalafil has a considerably longer 17.5 h half-life (Electronic Medicines Compendium 2017f) (Table 48.2).

The shorter acting PDE5i's sildenafil and vardenafil are more readily absorbed with higher plasma concentration in the fasted patient, whereas tadalafil is better absorbed with food (Electronic Medicines Compendium 2017e). Avanafil can be taken with or without food. Adherence to administration advice is essential to maximise efficacy potential, and standard protocol indicates that a PDE5i should be trialled at maximum dose on at least eight separate occasions before it can be deemed a failure (Hackett et al. 2008).

As previously discussed, expression of PDE5 is present in other structures including the vascular and digestive smooth muscle and therefore side effects including headache, flushing and dyspepsia are common. Particular to sildenafil is its effect on inhibition of phosphodiesterase 6 inhibitor (PDE6) in the cones of the retina which may cause visual disturbance including 'blue vision'.

With their known effects on the NO/cGMP pathway, all PDE5i's have been shown to significantly potentiate the hypotensive effects of nitrates. As a result, PDE5i's are contraindicated in men using nitrates in any form (Electronic Medicines Compendium 2017d). Special caution must be employed to those with cardiovascular disease which could be compromised further by vaso-dilatory effects. Men with recent

Table 48.2 Characteristics of PDE-5I medications (adapted from McVary 2017)

Medication	T-max	Half-life	Duration	Dose (mg)	Adverse effects	Affected by	Contraindications
Sildenafil	30–120 min	2–5 h	4 h	25–100 mg (starting dose 50 mg)	Headaches, flushing, dyspepsia, nasal congestion, altered vision	High fat meal decreases absorption; alcohol may affect efficacy	Nitrates Hypotension Cardiovascular risk factors Change dose with some antiretrovirals Should be on stable dose for alpha blockers
Vardenafil	30–120 min	4.5 h	4–5 h	5–10 mg	Headaches, flushing, rhinitis, dyspepsia	High fat meal decreases absorption; alcohol may affect efficacy	Same as sildenafil May have minor prolongation of QT interval Concomitant use of Class I antiarrhythmic
Tadalafil	30–60 min	17.5 h	12–36 h	10, 20, 2.5, or 5 mg for daily dose	Headaches, dyspepsia, back pain, nasal congestion, myalgia	Plasma concentration NOT affected by food or alcohol	Same as sildenafil
Avanafil	30 min	3–5 h	2 h	50, 100, or 200 mg	Headache, flushing, nasal congestion, nasopharyngitis, back pain	Plasma concentration NOT affected by food	Same as sildenafil

Abbreviations: *T-max* time to maximum plasma concentration, *min* minutes, *h* hours

history of cerebrovascular accident or myocardial infarction should also refrain from using PDE5i's until deemed fit by a physician or cardiologist (Hackett et al. 2008; Hatzimouratidis et al. 2010). PDE5i's are predominantly metabolised by the enzyme CYP3A4 in the liver, therefore concomitant use of CYP3A4 inhibitors can increase exposure to PDE5i's, therefore these should be avoided (Electronic Medicines Compendium 2017a).

48.3.2 Second Line Treatment

48.3.2.1 Intracavernosal Injection

In the event PDE5i's prove ineffective, intolerable or are contraindicated, second line pharmacological options are offered (Hackett et al. 2008).

Worldwide, a number of injectable drugs for ED are available. In the UK, the first line injectable drug is alprostadil which is available as Caverject or Viridal Duo. Alprostadil is not dependent on NO or an intact nervous system, therefore making it a viable treatment option for a range of ED aetiologies including peripheral nerve injury, severe vascular disease, and diabetes associated with neuropathy, vasculopathy and myopathy (Nehra 2007).

Chemically identical to prostaglandin E1 (PGE1), alprostadil targets an enzyme called adenylate cyclase, which converts adenosine triphosphate (ATP) into cyclic adenosine monophosphate (cAMP). cAMP is the active second messenger that lowers intracellular calcium, resulting in smooth muscle relaxation (Lue et al. 2004b). It is associated with vasodilation which facilitates increased cavernosal arterial flow resulting in engorgement of the tissue.

Intracavernosal injections are administered by the patient; however for purpose of safety, the initial injection must be given following training and under supervision in the clinical setting (see Fig. 48.5 and Box 48.1). Different doses of alprostadil are required for each individual to achieve a satisfactory response. The starting dose is either 1.25 or 2.5 μg with dose titration up to a maximum of 60 μg (Electronic Medicines Compendium 2017b), in 2.5 or 5 μg increments until the patient achieves a satisfactory response.

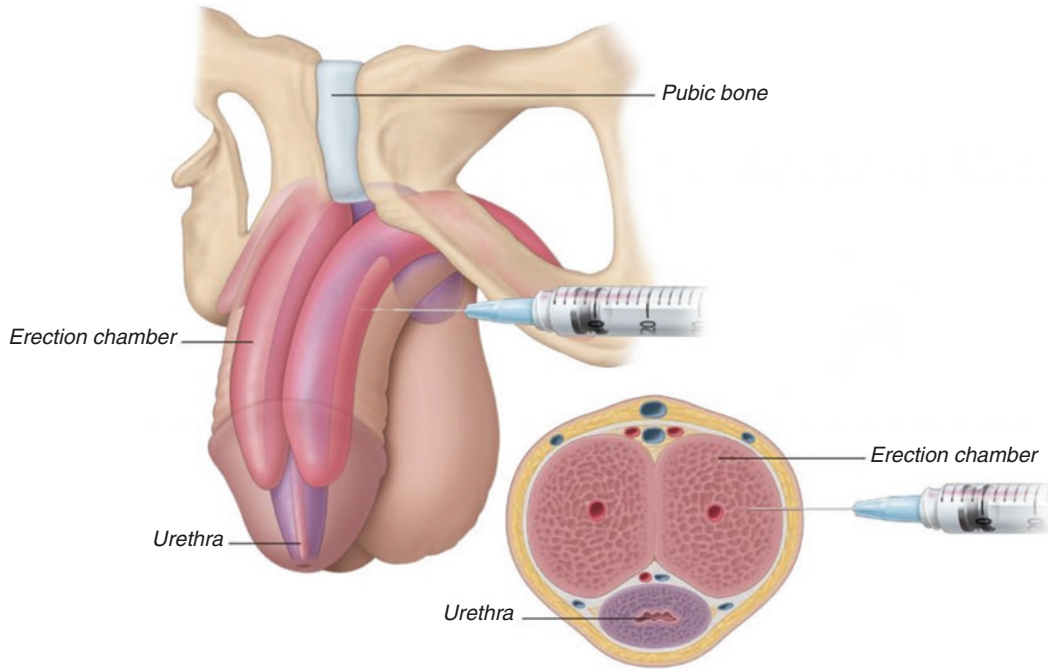

Fig. 48.5 Administration of intracavernosal alprostadil (used with permission from the European Association of Urology Patient Information, accessed via http://patients.uroweb.org/erectile-dysfunction/)

Box 48.1 Instructions on Administration of Intracavernosal Alprostadil

How to Administer Intracavernosal Alprostadil

- Patients may wish their partner to be involved in administering the medication and may need to attend the hospital in order to be taught. This may be essential in men whose body habitus does not allow direct visualisation of the penis.
- After washing hands, patients are shown how to prepare the medication for administration.
- The usual site for injection is within the proximal third of the penis along the dorsolateral aspect of the shaft (Electronic Medicines Compendium 2017b). This is to ensure the patient injects in the corpus cavernosum.
- Patients are advised to inject in both sides of the penis to prevent fibrosis and potential penile curvature development and to avoid the underside (risk of injecting into urethra) or the top (to avoid nerves).
- Visible veins are avoided to prevent bruising.
- Following administration patients are advised to massage the penis for 10 min sitting or standing in order to elicit a response.
- Erection occurs within 10–15 min of administration and should last between 30 and 60 min.
- Intracavernosal alprostadil should not be used more than once in 24 h or more than three times a week.

Common side effects include headache, dizziness and localised discomfort/pain. More serious systemic effects such as syncope and hypotension are rare due to minimal levels of alprostadil in the peripheral venous circulation. However concomitant use of antihypertensives with alprostadil can enhance hypotension, therefore caution should be employed when trialling the drug. Repeated injections into the corporeal tissue can lead to fibrosis, therefore varying the injection site is important. An important but uncommon side effect of the alprostadil injection is priapism (Electronic Medicines Compendium 2017b). Priapism is a prolonged full erection lasting in excess of 4 h without spontaneous resolution. Urgent medical attention is vital because of the potential detrimental effects on the viability and function of the corporal tissue if intervention is delayed (Bassett and Rajfer 2010).

Alprostadil use for ED is well tolerated and has a good safety profile; however, it is contraindicated in some men including those with known hypersensitivity to alprostadil or any of its excipients. It is contraindicated in men with severe penile deformity as well as those with unstable cardiovascular or cerebrovascular status. Men with sickle cell disease, multiple myeloma and leukaemia have an increased potential for priapism, therefore alprostadil should either be avoided in this group or used with extreme caution (Electronic Medicines Compendium 2017b).

Men who abandon alprostadil because of penile pain or who fail to respond at maximum dose can be offered other second line injectable agents. Although not licensed for ED, papaverine and phentolamine used in low dose combination known as ‘bi-mix’, and ‘tri-mix’ (with the addition of alprostadil) have been shown to be effective (Bechara et al. 1997; McMahon et al. 1999).

In the UK, the aforementioned drug combinations are rarely used, but another combination intracavernosal injection Invicorp is available and is licensed for ED. Invicorp comprises aviptadil (Vasoactive Intestinal Peptide—VIP), a naturally occurring amino acid neuro-transmitter, and phentolamine, an alpha blocker. When injected directly into the cavernosal tissues, the drug relaxes the smooth muscle of the penis (Dinsmore and Wyllie 2008).

Invicorp is available in only one dose, 25 μg/2 mg, therefore dose titration is not possible. The most common adverse reaction is facial flushing. Other potential side effects include dizziness, tachycardia/palpitations, and headache. As with all intracavernosal injections, the development of cavernosal fibrosis is a risk. Contraindications for Invicorp use mirror that of alprostadil.

48.3.2.2 Intraurethral Alprostadil

Intraurethral administration of alprostadil is considered less invasive than hypodermic injection (Mulhall et al. 2001; Dinsmore et al. 2014), and for the needle phobic, it is the preferred mode of delivery. There are two available intraurethral alprostadil preparations namely the medicated urethral system for erection (MUSE) and Vitaros.

MUSE comes in the form of a 3 mm pellet which is administered via the urethral meatus into the penile urethra using a small polypropylene instillation applicator (Electronic Medicines Compendium 2017c). In accordance with national guidelines (Hackett et al. 2008), the first dose of 500 μg is administered in the clinical setting. Response to this will determine subsequent prescription to trial at home. MUSE is available in 125 μg, 250 μg, 500 μg and 1 mg pellets. In order to facilitate easy introduction of the applicator and to expedite breakdown of the pellet, urination is recommended prior to insertion. The penis should be held in an upright position until the pellet has dissolved. At this point the penis can be dropped down and massaged to encourage distribution of the drug into the penile tissues and increase gravitational engorgement of blood. Erection occurs within 10–15 min of administration and should last between 30 and 60 min (MEDA 2011).

Vitaros is an intraurethral cream which is available in two strengths 200 and 3 mg/g. A preloaded syringe is used to administer the cream into the urethra via the urethral meatus (Ferring 2016). Erection is usually achieved 5–30 min following instillation and duration of effect ranges between 1 and 2 h (Electronic Medicines Compendium 2017g).

Intraurethral alprostadil in whichever form is readily absorbed through the urethral mucosa. It is metabolised both locally and within the cavernosal tissue via the lungs. Metabolites of intraurethral alprostadil are excreted primarily via the kidney (90%) within 24 h and the remainder in the faeces (Electronic Medicines Compendium 2017g).

The most common adverse effects associated with intraurethral alprostadil are transient urethral and penile burning/pain affecting around 7% of men (Electronic Medicines Compendium 2017g). Other side effects include dizziness and headache. The contraindications associated with ICI alprostadil pertain to intraurethral alprostadil. In addition, MUSE should be avoided in those with distal urethral stricture. Due to its vasodilating properties, men who have partners with possible or confirmed pregnancy should avoid intraurethral alprostadil, unless with condom protection (Electronic Medicines Compendium 2017c).

48.3.3 Third Line Therapy

48.3.3.1 Penile Prostheses

Penile prosthesis (Fig. 48.6) has become effective surgical treatment for patients who have failed or declined other available treatments, including oral pharmacotherapy, a vacuum erection device, intraurethral suppositories or intracavernosal injection (Hellstrom et al. 2010). Consequently, it is classified as a third line or 'end stage' ED treatment, as during placement the corpus cavernosa is damaged.

The two available types of penile implants include inflatable (2- and 3-piece) and malleable devices (Montague 2011; Martinez-Salamanca et al. 2011). Three-piece implants are the most preferred device due to the patient's ability to maintain a more 'natural' erection. These implants include a separate reservoir placed in the abdominal cavity, allowing the user to inflate the device by continuous squeezes of a pump located in the scrotum until erection is achieved, thus affording men the opportunity to achieve spontaneity for intercourse. Overall, three-piece devices provide the best rigidity and the best flaccidity; however, the two-piece inflatable prosthesis can be a viable option for patients who are deemed high risk of complications with reservoir placements, such as those who have undergone major pelvic surgery. Malleable prostheses are the least invasive implant but result in a firm penis and men must be coun-

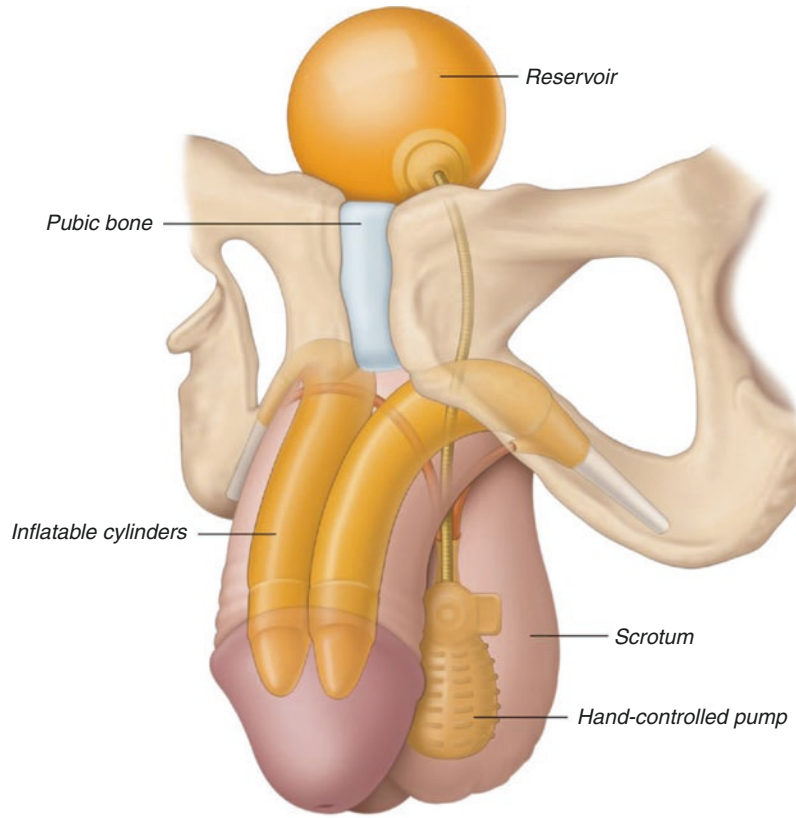

Fig. 48.6 A common type of inflatable penile implant (used with permission from the European Association of Urology Patient Information, accessed via http://patients.uroweb.org/erectile-dysfunction/)

selled of the need to conceal the device. Placement of a penile prosthesis will not increase the patient's libido, change his ability to ejaculate, or orgasm, and it does not alter penile sensations (Le and Burnett 2015).

It is proffered that satisfaction rates following prosthesis insertion are high, with researchers citing patient and partner satisfaction above 80% (Vitarelli et al. 2013). Pre-operative counselling at a specialist centre is imperative to ensure that patient expectations are not disproportionate, as this could lead to lower satisfaction rates. Patients should be afforded the opportunity to see and handle the different devices. They should also be informed that the procedure is irreversible and associated with significant procedural risks such as infection, erosion and mechanical failure (Vitarelli et al. 2013). It is essential that patients have realistic expectations in terms of erect penile length post implant insertion.

48.3.4 Other Available Treatments

48.3.4.1 Vacuum Erection Devices (VEDs)

Vacuum erection devices (VEDs) are clear plastic chambers, tightened against the lower abdomen with a mechanism to create a vacuum insider the chamber. This action provides passive engorgement of the corpora cavernosa, and the use of a constriction ring at the base of the penis will enable the user to retain blood within the corpora. Due to this action, erections with these devices are abnormal as there is no initial relaxation of the sinus smooth muscle in the corpora cavernosa. Instead all penile tissue becomes engorged with trapped blood, which is drawn into the penis by the action of negative pressure. In some men, the size of the penis is larger than that obtained with a normal erection, during use the penis may feel cooler, slightly numb or blueish in colour due to tissue cyanosis (Lewis and Witherington

1997). It is crucial for men to be appropriately consulted on this adverse effect.

The most common side events of VEDs include pain, inability to ejaculate and bruising, particularly in those patients with bleeding disorders or those on anticoagulant therapy. Users are reminded to remove the constriction ring within 30 min to avoid skin necrosis. Satisfaction for intercourse has been reported as to be as little as 27% and as high as 94% (Levine and Dimitriou 2001). Men who have an understanding and motivated partner report the highest rates and the feeling of coolness of the penis and the need to use lubrication gel have been cited as reasons for partner dissatisfaction. Long-term use decreases to 50–64% after 2 years (Cookson and Nadig 1993) and most men, who discontinue use, do so within the first 3 months.

VEDs may be the preferred treatment for older patients who practise infrequent sexual intercourse and those with comorbidities requiring non-invasive, drug-free management of ED (Levine and Dimitriou 2001). VEDs are also used by men to practise penile rehabilitation to prevent penile shrinkage such as those recovering from radical prostatectomy (Hoyland et al. 2013).

48.3.4.2 Shockwave Therapy

Recently, low intensity extracorporeal shock wave therapy has been considered a potential innovative treatment for the management of ED (Vardi et al. 2010). Since the 1980s when it was first introduced for renal lithotripsy, shock wave therapy has been adopted around the world for various conditions. The shock wave produces a wave of energy and when delivered through a medium, can be targeted non-invasively to affect a desired anatomical region. When low intensity shock wave therapy is applied to an organ, the shock waves interact with the tissues that have been targeted and stimulate a cascade of biological reactions. This results in the release of growth factors, which in turn activates neovascularisation of the tissue with successive improvement of the blood supply (Rassweiler et al. 2011). Still in its infancy for erectile dysfunction, the mechanism by which this treatment improves the symptoms of sufferers is not fully understood. Current research is limited and certainly more trials are needed to fully determine its safety and efficacy. However, initial reports suggest this has the potential to be a safe and alternative non-invasive treatment for ED sufferers.

A Patient Case Study

John a 52-year-old accountant, presents to the nurse-led ED clinic with his wife Mary. Throughout their marriage they report to having a healthy sexual relationship until 12–18 months ago where gradually his erections became weak. They are now unable to have penetrative sexual intercourse although they still desire it. John is becoming depressed that he is no longer able to 'satisfy' his wife, and has been to see his GP regarding the possibility of commencing an antidepressant.

The nurse takes a full medical history and notes John has an 8-year history of type 2 diabetes controlled with metformin, and gliclazide. The gliclazide is a recent addition as John's HbA1c has been deteriorating and he admits that his diabetes has been poorly controlled. He has gained 10 kg due to a change in his job and has a body mass index of 33 and a waist circumference of 42 in. (106 cm). In addition to diabetes, he suffers with hypercholesterolemia for which he is prescribed atorvastatin and ramipril for hypertension. Physical examination is unremarkable. His blood pressure and pulse are within normal limits.

The nurse notes that John has several organic and psychological factors (diabetes, cardiovascular disease, obesity, lack of exercise and depression) that have the potential to contribute to his decrease in erectile function.

In clinic, the nurse formulates a plan to improve John's physical and psychological well-being and he reports to feeling more positive now he has sought help. Mary is happy that a cause for his erectile dysfunction has been established and plans to work with her husband to improve his diabetic control and maintain a healthier lifestyle.

The nurse gives John an overview of the available treatments for erectile dysfunction, including the advantages and disadvantages of

each treatment and possible side effects. A plan is made to commence treatment with sildenafil 50 mg on demand increasing to 100 mg if necessary. John is advised to take this 1 h prior to sexual activity on an empty stomach. He is advised that sexual stimulation is required to be effective. John is supplied with eight tablets and a plan is made to see John in 3 months for follow-up. John is advised to try all eight tablets before his next review. In addition, an early morning testosterone is requested for completion and John will bring this with him when he attends his next appointment.

48.4 Conclusions

Penile erection is a complex phenomenon which is reliant upon a delicate balance of vascular, neurological, hormonal and psychological elements. ED is caused by disequilibrium within this process. There are a multitude of cause and risk factors associated with ED which can be categorised as unmodifiable or modifiable. A thorough diagnostic evaluation should elicit any modifiable risk factors, including lifestyle, medications or undiagnosed illness/conditions and these should be addressed in the first instance to optimise erectile function and improve general health. ED can have a devastating psychological impact on the sufferer and partner and therefore, it is imperative that access to treatment is not delayed.

The ED management algorithm developed by an expert panel promotes best practice in the management of this condition and should be adhered to ensure men are offered appropriate management/treatment options.

Abstract

The chapter starts with a focus on the issues associated with genetic counselling. The process of genetic counselling is described, followed by a discussion of inheritance patterns commonly observed in reproductive disorder. Current genetic testing options with considerations for their benefits, limitations, and possible results are reviewed. The second section starts by briefly describing current theories of psychosexual development as well as highlighting some issues which suggest the limit of their utility. We then move to consider the psychogenic aspects of sexual function for men focusing mostly on those issues likely to be experienced by those with endocrine disorders. We also consider the problems men face when consulting with healthcare professionals about sexual function and make the case for the use of tools and techniques to aid the process.

Key Terms

- **Exome sequencing:** Examining the nucleotide sequence within the protein-coding regions (exons) of all genes in the genome.
- **Genome sequencing:** Examining the nucleotide sequence of the entire genome, including the exons (protein-coding regions) and introns (segments between exons) of all genes, as well as segments of the genome between genes.

Key Points

- Reproductive disorders demonstrate a wide range of inheritance patterns. Collecting a detailed family history with a focus on reproductive and associated traits guides risk assessment and genetic test selection.
- Genetic testing can assist with confirming the aetiology of and recurrence risk for reproductive disorders. Consideration regarding appropriate test selection and possible results, including incidental findings, is an important part of pre-test genetic counselling.
- Psychosexual development is a complicated process still not completely understood. Given the increasingly fluid nature of gender identity, each person needs to be treated as an individual.
- Men face a number of obstacles to being able to seek help with problems related to sexual functioning. We need to get better at enabling men to access healthcare and psychological support.

49.1 Genetic and Ethical Considerations

49.1.1 Definition and Practice of Genetic Counselling

Genetic counselling has been defined as the process of helping others make meaning of the medical, familial, and psychosocial consequences of disease through understanding and adaptation. Key components of genetic counselling include: gathering an individual's medical history/phenotype, documenting their family history, genetic test selection, result interpretation, risk assessment, resource gathering, and psychosocial counselling. Though specific genetic counselling training programmes and certifications exist in some areas, nurses are well suited to provide many genetic services. Whether one is trained as a geneticist, genetic counsellor, physician, or nurse, key aspects of working with patients and families around genetics involve effective communication and detailed history taking (Benjamin et al. 2015; Delikurt et al. 2015).

49.1.2 Inheritance Patterns

Reproductive disorders demonstrate a wide range of inheritance patterns, so obtaining detailed medical and family histories is essential in the process of determining differential diagnoses and recurrence risk. A family history should include three generations whenever possible and constructing a family pedigree (genogram) can allow for visualization and documentation of inheritance patterns. In a pedigree, circle symbols are used for females, squares for males, and diamonds for individuals of

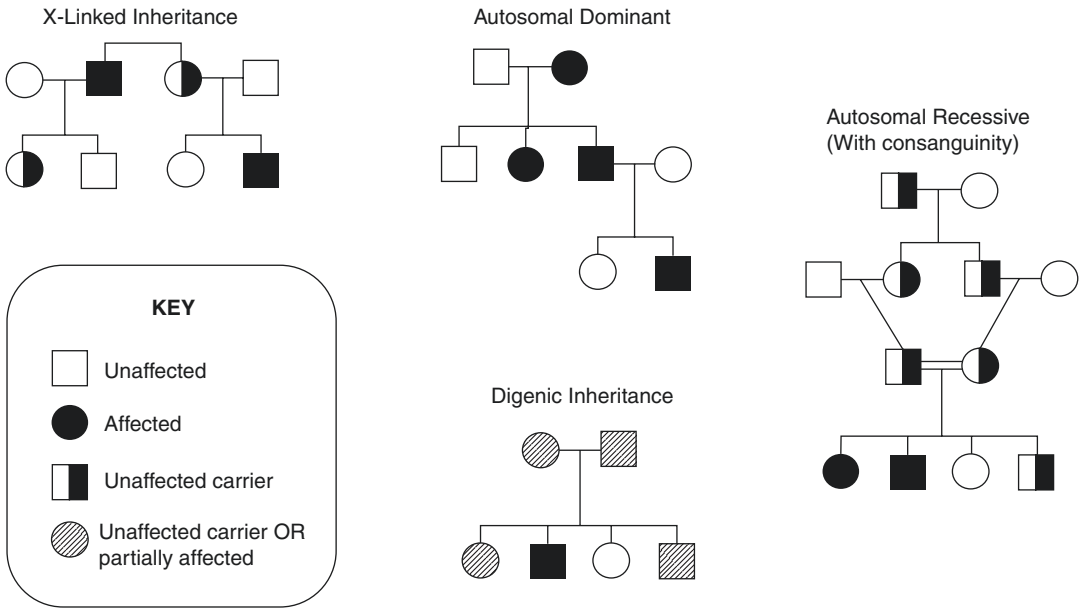

Fig. 49.1 Pedigrees demonstrating common inheritance patterns

Table 49.1 Example questions to assess family history of reproductive disorders

Fertility status	Timing of puberty	Non-reproductive phenotypes
Does a family member have biological children? If not, is it by choice?	Were any family members considered "late bloomers"?	Are there family members with congenital abnormalities (cleft lip/palate, renal abnormalities/agenesis, skeletal defects, missing or extra teeth)
Is there a family history of infertility?	At what age did women have their first menstrual period (menarche)? Did menarche occur for any female family member after the age of 16?	Does a family member have an absent or reduced sense of smell?
Has a family member required fertility treatment to conceive? If so, what treatment was used?	Did any male family members continue growing after age 18?	Any history of hearing loss among family members?
Is there a family history of recurrent miscarriage, spontaneous abortion, or stillborn babies?	Was treatment, such as oral contraceptives or testosterone, used to initiate puberty in a family member?	

unspecified gender. A male and female partner are connected in the middle with horizontal relationship line, with resulting children shown below the parents and connected with a vertical line of descent (Bennett et al. 2008). See Fig. 49.1 for example pedigrees. Relevant questions for family history focusing on reproductive conditions can be found in Table 49.1.

Reproductive disorders may present as familial cases or in sporadic forms. Familial means that more than one member of the family is affected, whereas sporadic refers to situations in which only the patient (proband) is affected. Inheritance, or how the condition is transmitted throughout a family, can take several forms.

49.1.2.1 X-Linked

Disorders related to genes on the sex chromosomes (i.e. X, Y) display a characteristic pattern of transmission as females have two X chromosomes

while men only have one X in addition to a Y chromosome. A classic X-linked family history shows affected males related through unaffected or sometimes mildly affected females. There is no male to male transmission of the condition. Examples of this include Kallmann syndrome resulting from mutations in anosmia 1 (*ANOS1,* formerly *KAL1)*, and disorders of sex development resulting from gene defects in the androgen receptor (*AR*). Affected men will have likely unaffected carrier daughters and unaffected, non-carrier sons. Female carriers of X-linked conditions have a 25% chance of having an affected son, a 25% chance of having a carrier daughter, and 50% chance of an unaffected son or non-carrier daughter.

49.1.2.2 Autosomal Recessive

Males and females are equally affected in a typical autosomal recessive pedigree. Affected individuals are often siblings with unaffected carrier parents. Parental consanguinity (meaning that the parents are related, i.e. cousins or closer) can also be a clue to support recessive inheritance. A number of genetic loci underlying congenital hypogonadotropic hypogonadism (CHH) follow an autosomal recessive inheritance pattern: *GNRHR*, *KISS1R*, *TAC3*, *TAC3R*, *PROK2*, *PROKR2*, and *GNRH1*. Mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR)* is an autosomal recessive cause for azoospermia due to congenital bilateral absence of the vas deferens (CBAVD). Carrier parents have a 25% chance of having an affected child, 25% chance of having a child who is neither affected nor a carrier, and a 50% chance of having a child who is an unaffected carrier. People with recessive conditions are only at risk of having an affected child if their partner is either affected with that condition or a carrier.

49.1.2.3 Autosomal Dominant

Autosomal dominant conditions also typically present equally in males and females. Male to male transmission occurs. Each generation can show affected individuals, though the presentation may vary (described as variable expressivity), OR a person with a pathogenic gene variant may show no signs of disease if the condition demonstrates incomplete penetrance. For CHH, *FGFR1*, *PROKR2*, *PROK2*, *CHD7*, *SEM3A1*, *NELF*, *HS6ST*, *WDR11*, and *FGF8* demonstrate autosomal dominant inheritance. CBAVD can also be due to a heterozygous pathogenic variant in *CFTR* and demonstrate dominant inheritance. An individual with an autosomal dominant condition has a 50% chance of passing on the condition/gene variant to each child and a 50% chance of having a child without the condition/gene variant.

49.1.2.4 Digenicity and Oligogenicity

Some endocrine disorders, namely Bardet–Biedl syndrome and CHH/Kallmann syndrome have been identified to include digenic and oligogenic forms. For CHH, in particular, determining the inheritance pattern can be complicated by di-/oligogenicity. This occurs when variants in two or more genes in combination appear to contribute to disease. Many of the genes associated with CHH have been reported in di-/oligogenic states, but *SEM3A1*, *NELF*, *HS6ST*, and *WDR11* variants are predominantly found in combination with other gene variants (Buck et al. 2013). The contribution of variants in multiple genes may help explain observations of incomplete penetrance and variable expressivity in family members carrying the same mutation. In some cases, the aggregation of gene defects helps explain the more severe clinical presentation (phenotypes) (Miraoui et al. 2013).

See Fig. 49.1 for pedigrees demonstrating X-linked, autosomal recessive, autosomal dominant, and digenic inheritance patterns.

49.1.2.5 Chromosomal and Cytogenetic Causes

Chromosomal/cytogenetic aetiologies of male infertility include Klinefelter syndrome (two or more X chromosomes in addition to a Y chromosome), which is typically sporadic and not seen in other family members. Microdeletions of the AZFa or AZFb regions of the Y chromosome can result in male infertility due to azoospermia. And 46, XX testicular disorders of sex development are also usually due to chromosome rearrangements involving genes that are critical for early gonadal development i.e. *SRY*, *SOX9*, or *SOX3*. Chromosome microdeletions and rearrangements

can be inherited or the result of a parental balanced chromosome rearrangement (translocation or inversion) or occur as a new (de novo) change in an affected individual.

Determination of inheritance may be derived from several sources including discussions with the patient, interviewing family members, and/or medical record review. Indeed, detailed medical record review is important for both selecting an appropriate genetic test and confirming a diagnosis. Often specific phenotypes may be useful for guiding the selection of a genetic test. For instance, CHH-associated phenotypes can be useful for targeted gene screening (Costa-Barbosa et al. 2013; Boehm et al. 2015). Similarly, clinical palpation of the vasa (i.e. absence) can help guide screening for variants in *CFTR*. Health history questions such as those noted for family history can be asked of the patient. Review of health records, including laboratory results (endocrine profiling may include testosterone, LH, FSH, prolactin, and ferritin in particular), imaging studies (pituitary MRI, ultrasound), and physical exam findings is also necessary. More regarding the evaluation and types of male reproductive disorders can be found in Chaps. 43 and 44.

49.1.3 Genetic Testing

A genetic aetiology for male infertility may be identified in up to 15% of cases (Krausz and Chianese 2014), though this number may increase with wider use of genomic testing. Clues from a patient's medical and family histories can assist in the selection of the appropriate genetic test. For CHH, a testing algorithm driven by family history and patient phenotype has been suggested (Costa-Barbosa et al. 2013; Boehm et al. 2015; Au et al. 2011). However, with increased availability and reduced cost associated with next-generation sequencing panels and exome sequencing, it may be equally economical to take a "genotype first" approach and sequence all genes associated with a particular disorder, if not the entire exome or genome (Baetens et al. 2014). Sequencing is appropriate as first-line genetic testing for CHH genes, androgen insensitivity (via the *AR* gene), and *CFTR* as sequence variants are the most common genetic aetiology. Deletion/duplication testing for these genes may be considered if sequencing is not informative. A panel of the 25 most common pathogenic *CFTR* variants is available, but the detection rate is dependent on patient race/ethnicity (i.e. it is higher in people of European and Ashkenazi Jewish descent). If the R117H pathogenic variant in *CFTR* is identified in the setting of CBAVD, further evaluation of the poly T (thymidine bases) tract is indicated (Grody et al. 2001). For individuals with possible Klinefelter syndrome or 46, XX testicular disorder of sex development, a karyotype is indicated with follow-up florescence in situ hybridization (FISH) for *SRY* or a chromosome microarray (CGH array) study if the karyotype shows 46, XX in someone with male external genitalia. CGH array could be performed instead of a karyotype as it will detect aneuploidies (like Klinefelter syndrome) and chromosome microdeletions and duplications. It may be more expensive than a traditional karyotype and will not detect balanced chromosome rearrangements (translocations, inversions). Y chromosome microdeletions of specific AZF regions may be completed with polymerase chain reaction (PCR) based copy number studies.

49.1.3.1 Inconclusive and Incidental Findings

Even with powerful genetic testing tools and careful phenotyping, results of genetic testing may be negative or uncertain. A negative genetic test result does not exclude the possibility of a genetic aetiology in many cases. Among individuals with a clinical diagnosis of CHH, the genetic cause will be identified 50% of the time (Buck et al. 2013). Genetic testing will identify SRY, SOX9, or SOX3 copy number abnormalities in ~90% of people with 46, XX testicular disorders of sex development if normal male genitalia is present, but <10% in those with ambiguous male genitalia (Baetens et al. 2014; Délot and Vilain 2015). Expanded genomic testing also increases the likelihood of identifying variants of uncertain significance. These variants may have limited or conflicting evidence that prevents them from being interpreted as either benign (normal) or

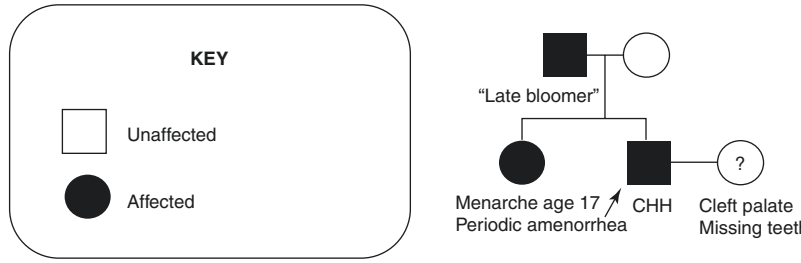

Fig. 49.2 Pedigrees demonstrating the family inheritance patterns for this patient

pathogenic (disease-causing). In some cases, studying family members to determine if the variant tracks (referred to as "segregation") with disease can be helpful to potentially resolve uncertainty. Large-scale genomic testing such as exome or genome sequencing also presents the possibility of learning unrelated or unexpected information. The American College of Medical Genetics and Genomics recommends all families proceeding with exome sequencing be given the option to learn about the presence of any disease-causing mutations in a list of 59 genes associated with conditions for which some action (mostly preventive) is available. For the most part, these conditions are related to hereditary cancer predisposition or hereditary cardiovascular diseases. This information is usually not related to the primary indication for testing and is sometimes referred to as "secondary" or "incidental" findings (Kalia et al. 2017). The European Society of Human Genetics does not have a similar policy statement at this time, but instead suggests the future guidelines take into account legal, cultural, familial, and personal factors when considering reporting incidental findings (Heihir-Kwa et al. 2015). Notably, non-paternity and parental consanguinity or possible incest can potentially be identified in the course of genetic testing. Thus, careful consideration is warranted in dealing with such sensitive issues that may reflect family secrets or culturally challenging situations.

Case Study

A 25-year-old man clinically diagnosed with CHH and his 26-year-old female partner seek genetic counselling and testing to understand their risk for having a child with a CHH. The pedigree shows the man's sister to have late menarche at age 17 and amenorrhea during stressful periods. Their father was described as a late bloomer who reached his adult height after age 18 years. The partner's personal history is significant for cleft palate and three missing adult teeth. Her family history is unremarkable. The couple are not known to be related to each other (Fig. 49.2).

1. What inheritance pattern does this pedigree suggest?
   (a) The man's family history is suggestive of autosomal dominant inheritance with variable expressivity. The woman's history of cleft palate and missing teeth could be due to sporadic congenital abnormalities OR the result of variants in genes related to CHH.
2. What genetic testing would be indicated and who would be tested first?
   (a) Testing with a panel of genes known to contribute to CHH would be most efficient. The 25-year-old man with CHH is the ideal candidate for genetic testing as he has a clinical diagnosis of CHH and appears to be the most significantly affected in his family. If other syndromic causes of cleft palate, in particular, have been ruled out in the female partner, it may also be helpful to test her for variants in genes related to CHH due to the possibility of digenic inheritance.
3. What is this couple's recurrence risk for CHH?
   (a) Based on the man's family history alone, the risk to have a child with some degree of a reproductive disorder could be as high as 50%. It will be difficult to predict how sig-

nificantly a child would be impacted by the condition due to variable expressivity. If the female partner also has a pathogenic variant in a CHH gene (and assuming an autosomal dominant genetic cause in the man), they would have a 25% chance of having a child with both genetic factors and possibly more severe phenotype, a 25% chance of having a child with the father's genetic cause of CHH only, a 25% chance of having a child with the mother's CHH-related variant only, and a 25% chance of having a child with neither CHH gene variant.

If the mother's cleft palate and missing teeth are NOT due to CHH-related factors or other syndrome, the couple would have an increased risk to have a child with a cleft palate compared to the general population risk. They may consider having a high-level foetal ultrasound after 20 weeks gestation for prenatal diagnosis of cleft palate, though cleft palate is much more difficult to detect by prenatal ultrasound than cleft lip.

49.2 Psychosexual Considerations

49.2.1 Psychosexual Development

Psychosexual development seems to flow out of theories aimed at explaining dichotomous gender identity (i.e. male/female) especially in relation to early childhood. Widely criticized for a number of failings, Boyd and Bee (Boyd and Bee 2014) describe how Freud's psychoanalytic theory has now been joined by four other theories they list as: (1) social learning (where the role of parents/caregivers is considered key); (2) cognitive-developmental (a three part process of learning about gender as being fixed); (3) information-processing (learning about gender by the generation and development of categories); and (4) biology-based (acknowledging that sex hormones can play a part in psychological functioning across the lifespan). The different theories emphasize that there are many aspects to the processes that play a part in children getting to grips with the idea of gender. Translating the theories into simpler terms, as young children we start the process of learning who we are and how we are allowed to express ourselves in the presence of others.

Children learn from their direct experience of whether they like something or not, but their caregivers also help the child to learn both what is and what is not acceptable behaviour in exploring and interacting with their environment. This trial and error approach with guidance from caregivers arguably continues throughout childhood and on into adolescence. In addition, children can be encouraged to behave in ways that are seen as gender congruent with males in particular being permitted to be lively, encouraged to be confident and play with gender appropriate toys. Males who do not do so may face serious censure or even punishment within their family and/or immediate community. Children may find these experiences to be very confusing. For many, gender is not fixed until relatively late in childhood (Kreukels et al. 2014).

Children not only learn about what is acceptable about them and their behaviour within their families, but also from their wider community, for example, at school. Junior school years are the time when children start trying out different roles, for example, playing games such as "mummies and daddies" and "doctor and nurse". Usually these are innocent enough and tend to involve hand-holding and inept kissing. Children at this age tend to be fairly blunt in their communications and will ostracize others who are perceived as being different. Such public and private experiences of censure about self-expression can lead the affected child to feel anxiety about whether they are acceptable to others. Such anxiety can grow to the point where the child will have few friends and may experience overt or covert bullying from peers.

Both age-inappropriate sexualized behaviour and non-conformity of behaviour to gender norms in young children can take many forms. In respect of the former, sensitive investigations will need to be undertaken to determine the cause of

the troubling behaviour; while in respect of the latter the book by Kruekels, Steensma, and de Vries (2014) has many useful chapters detailing the methods by which issues of gender identity can be identified in children. Their book is an ode to caution, however, as they make clear that gender confusion in children's behaviour is not necessarily indicative of anything that requires something as serious as sex-reassignment surgery. Their chapter authors provide examples of children's presentation at clinic, their care over time by the multi-disciplinary team with details of the outcomes, as well as the various questionnaires and methods employed both with the children and their caregivers to determine the extent of the issues to be addressed.

There is a certain amount of debate about the extent to which sexual identity and gender congruent behaviour are socially constructed (Giordano 2014), a key issue in adolescence when the public world starts to matter more than that of the family. It is the period of time when young people are trying out different ways of being in the world, and these can be at odds with their family/community values and lead to a great deal of conflict. For adolescents, finding a tribe/group with whom they belong is an important part of this life stage, and it is important that their behaviour fits with this tribe/group for them to be accepted and remain involved. Boyd and Bee (2014) suggest that the formation of romantic relationships at this age is dependent on the individual's self-perceived sexuality, with heterosexual and homosexual patterns of relationship formation being distinctly different and occurring on different timescales. Aron (1999) has suggested that for some adolescents the whole area of relationships can feel so daunting, that they couple up with one partner very early and stay in that relationship which then functions as a bulwark against the sexual experimenting that is common at this age. There are growing concerns that with access to the internet the experiences and expectations of young males are informed initially by pornography.

In research with males with Klinefelter's Syndrome (KS), it was clear that adolescence was a key time for them in terms of recognizing that their condition made them significantly different from the prevailing norms (Morris et al. 2009). This was both in terms of appearance (males with KS tend to look physically different to other males) and behaviour (males with KS tend to lack confidence). The research resounds with experiences of adolescent males being beaten by their fathers (to toughen them up) all the way up to reports of rape in situations where other males did not think they were sufficiently masculine enough and decided to use them as sexual subordinates. Such experiences led to a variety of responses, with some males able to learn how to act in more masculine ways, some becoming confused about their sexuality, while others experienced confusion over their gender identity. The report makes clear the ramifications of these experiences lasted a lifetime in terms of both identity and mental health issues.

49.2.2 Psychogenic Aspects of Sexual Function

Brown (2015) has written about the strait jackets that each gender wears in Western culture and how difficult, but how necessary it is, for us to recognize and move beyond them. She cites research which shows that the attributes associated with masculinity in the USA are: winning, emotional control, risk-taking, violence, dominance, playboy, self-reliance, primacy of work, power over women, disdain for homosexuality, and pursuit of status. The author (SJ) has seen many men who struggle with their identity and mental health because they do not recognize themselves in this list of masculine attributes. Their struggle is arguably made worse because men, unlike women, are not socialized to talk about their issues and compare experiences. The most common question the author (SJ) hears is, "Is this normal or am I weird?" The men quite often talk about feeling ashamed of themselves, and research by Pennebaker et al. (2001) suggests that anything associated with shame and guilt is unlikely to be talked about and the behaviour associated with it is also unlikely to be disclosed. Where there is confusion about sexual

function or gender identity, avoidance can be a common coping strategy. It can be effective to the extent that it reduces the risk of rejection and the associated stress, guilt and shame.

There are common societal discourses about Western male sexuality—shown the right visual stimulus, and assuming a suitable environment, there should be a predictable physical response. However, in men with low libido, such stimuli may be unwelcome and actively avoided. To be subjected to it unwillingly can result in feelings of entrapment and high anxiety. Some men with pituitary conditions talk about the disconnection they have from sexual feelings and sexual responses generally which can lead to tension and pressure within relationships as men try to communicate their feelings at the risk of alienating their partner who may feel they are somehow to blame for the lack of sexual desire. In men with erectile dysfunction the problem may also be associated with feelings of anxiety, in this case the stimulus is wanted, but anxiety about performance issues may create a vicious cycle where physical functioning is inhibited by the stress of the situation. Testosterone replacement therapy given to men can sometimes have unexpected outcomes, such as involuntary erections where the perceived lack of control associated with profound distress and embarrassment can lead to social anxiety, social avoidance, and in some cases profound social isolation.

If your basic relationship with your body is one of distrust because it is not performing its functions in expected ways, the levels of anxiety experienced are likely to affect any communication with others including healthcare professionals. Humans are not good with uncertainty, and anxiety will increase in the absence of explanations for occurrence, the likely duration of the problem, and the likely prognosis. The anxiety increases when we feel at odds with ourselves and are experiencing something that is socially confusing or outright unacceptable. Additionally, anxiety can be related to control; the less control you feel you have, the greater the anxiety you experience and this can lead to a strong feeling of frustration (especially if you feel you are not being heard and/or supported) which can eventually lead to feelings of anger and disappointment.

The stress, shame, and guilt associated with being different to norms of appearance, function, or behaviour activate the threat system which is associated with feelings of anxiety, anger, and depression. In such a state, as Gilbert (2010) has so well described, it is next to impossible to access the part of the brain associated with rational thought and problem-solving. The threat system requires effective soothing, but for lots of men, while they may be good at restorative hobbies and interests the soothing skills remain unlearned and they quite often rely on female family members and friends for their (mental) healthcare and support. Except when very young or much older, and unlike women, men typically do not have much contact with healthcare services which tends to reinforce the reliance on female family and friends for healthcare issues.

In primary mental health services there is a reliance on standardized questionnaires to assess need and to signpost to relevant services. Men can have problems here, too. On a lot of the standard measures used, men score significantly lower than do women. An eminent endocrinologist in discussing some research results where this pattern had been observed (yet again), commented that men are realists and women clearly exaggerate. However, an alternative interpretation is that women are realistic while men are socialized to minimize their problems (remember they are supposed to be strong and have good emotional control) and hence underreport. The short appointments in primary care mean that you have to be prepared to just "jump in" with your concerns, but medical services are predicated on the biomedical model where physical functioning takes priority over mental distress. The situation is complicated by a situation where healthcare professionals are generally not trained in the identification, assessment, or support of mental health related issues. Added to which sex has to be one of the most difficult topics to talk about. The definitions of what count as sexual behaviour can be individually or culturally very broad or very narrow, and can be gender dependent. Sex can refer to the label attached to a

particular genital configuration (i.e. penis and tests = male), it can refer to reproduction, or even a form of self-expression. For some individuals there are no differences between these things, but for others, they can be very different, for example, those involved in the world of BDSM where sexual activity might not involve penetrative sex at all. Individuals can have profound fears about how to frame their concerns in such a way as to elicit the information they need from healthcare professionals without exposing themselves to negative judgement.

In such a situation, it can be helpful for healthcare professionals to use tools and techniques aimed at empowering patients to identify their broader concerns as well as enabling a discussion about appropriate intervention and support. An example of a tool to achieve this is the Pituitary Distress Thermometer (developed by the author SJ with the Pituitary Foundation), while BATHE is an example of an appropriate consultation technique (Stuart and Lieberman 2008). Many healthcare practitioners use ICE (Ideas, Concerns and Expectations) but ICE is predominantly about data gathering and tends to relate to the first stage of the consultation (determining the presenting issue). ICE and BATHE can be used effectively together to provide a full picture of the presenting issue(s), arguably moving away from the biomedical model of symptoms and physical problems, to a biopsychosocial model where the psychological is also recognized and potentially supported.

Finally, it is important to note that we are living in a time of great change, as Pfäfflin (2014) has noted the increasingly fluid nature of gender identity means that we need to treat each person as an individual rather than relying on the outmoded dichotomously focused theories and models of psychosexual development.

49.3 Conclusions

The process of genetic counselling includes the exploration of psychosocial factors that emerge when discussing highly sensitive reproductive conditions and genetic risk. People with reproductive conditions may feel embarrassed about their altered sexual development or fertility status. Discussions of genetic/inherited disease risk also bring about feelings of guilt and shame, particularly when considering risk to children and other family members. Additionally, genetic testing may not yield an informative result, potentially leading to anxiety because the cause of disease and risk for family members remains uncertain. On the other hand, determining a genetic cause may alleviate some uncertainty. Listening, acknowledging expressed and implied feelings, sharing potentially empowering information, and clarifying as much uncertainty as possible can benefit individuals and families obtaining genetic counselling.

Psychosexual development is a complicated process still not completely understood. We should not expect that there will ever be a theory that can adequately describe and account for the variety of experiences that people have as they grow and mature. This, coupled with the increasingly fluid nature of gender identity, means that we need to have the time to treat each person as an individual. Men face a number of obstacles to being able to seek help with problems related to sexual functioning. We need to remember that their social conditioning tends to lead them to minimize their problems so we need to use tools and consultation techniques to empower them to speak up.

Abstract

Parathyroid hormone and active vitamin D control calcium homeostasis; dysregulation of this system leads to abnormal calcium measurements and a spectrum of clinical disorders. Primary hyperparathyroidism can present clinically with abdominal pain from peptic ulceration or renal calculi, mood disorders, fractures and loss of height from osteoporosis or on blood tests with reduced kidney function and hypercalcemia in the setting of normal or elevated parathyroid hormone. It is managed primarily with surgery although asymptomatic patients may elect to have serial monitoring for deterioration or clinical sequelae of hyperparathyroidism. International consensus guidelines are regularly updated to reflect research on the benefits of surgery or medical management of asymptomatic patients with primary hyperparathyroidism. Parathyroid carcinoma is a rare cause of primary hyperparathyroidism that is associated with a genetic mutation causing hyperparathyroidism-jaw tumour syndrome. Secondary hyperparathyroidism is usually a complication of chronic kidney disease or vitamin D deficiency. Hypoparathyroidism is a complication of thyroid or parathyroid surgery, a manifestation of one of a number of genetic disorders or may be one of a number of autoimmune diseases in an individual patient. Patients with hypoparathyroidism suffer from lower quality of life; undertreatment manifests as symptomatic hypocalcemia and overtreatment can result in renal calculi or reduced kidney function. Pseudohypoparathyroidism is a condition of resistance to circulating PTH, which is high; this can co-exist with skeletal abnormalities described collectively as Albright's hereditary osteodystrophy. A case history, a patient perspective and clinical notes on two particular aspects of care of patients with parathyroid disorders are included with this chapter.

Keywords

Parathyroid hormone · Vitamin D · Calcium · Hyperparathyroidism · Hypoparathyroidism

Abbreviations

25OHD	25 hydroxy vitamin D
AHO	Albright's hereditary osteodystrophy
BMD	Bone mineral density
CaSR	Calcium-sensing receptor
CKD	Chronic kidney disease
CKD-MBD	Chronic Kidney Disease-Mineral Bone Disorder
DXA	Dual-energy X-ray absorptiometry
eGFR	Estimated glomerular filtration rate
FGF-23	Fibroblast growth factor 23
FHH	Familial hypocalciuric hypercalcemia
GI	Gastrointestinal
HPT-JT	Hyperparathyroidism-jaw tumour syndrome
KDIGO	Kidney Disease Improving Global Outcomes
MEN	Multiple Endocrine Neoplasia
PHPT	Primary hyperparathyroidism
PPIs	Proton pump inhibitors
PTH	Parathyroid hormone
PTHrP	Parathyroid hormone-related peptide

SERM	Selective estrogen receptor modifier
SHPT	Secondary hyperparathyroidism
SPECT	Single photon emission computed tomography
VFA	Vertebral Fracture Assessment

Key Terms

- **Hyperparathyroidism:** A disorder causing an excess of parathyroid hormone in the blood leading to elevated blood calcium levels and adverse bone, kidney, musculoskeletal, and GI effects.
- **Hypercalcemia:** an abnormally high serum calcium level.
- **Hypoparathyroidism:** A disorder causing an under-functioning of the parathyroid glands leading to low parathyroid hormone levels and low serum calcium.
- **Vitamin D:** a fat soluble vitamin responsible for increasing absorption of calcium in the intestines and essential for normal bone structure.

Key Points

- Primary hyperparathyroidism is diagnosed in the setting of hypercalcemia with high or inappropriately normal PTH measurement; it is primarily managed with surgery and there is guidance available for those asymptomatic patients who may benefit from surgical intervention.
- Hypoparathyroidism is diagnosed in the setting of hypocalcemia with low or inappropriately normal PTH; serum magnesium should be measured and hypomagnesemia corrected before the diagnosis is confirmed.
- Hypoparathyroidism is sometimes challenging to manage and requires careful assessment for complications of over- or undertreatment; it is associated with reduced quality of life.
- In recent years, more information has become available about underlying genetic disorders which predispose to parathyroid pathology including parathyroid carcinoma; consideration of genetic screening in younger patients, those with family histories suggestive of a genetic endocrinopathy and those with atypical presentations or parathyroid histology should be considered as a positive result may change clinical follow-up.

50.1 Normal Parathyroid Metabolism

Many physiologic processes depend on the precise regulation of calcium including muscle and nerve function and contractility, bone metabolism, cell signalling, and hormone release and regulation (Fraser 2009). The parathyroids, four pea-sized glands located behind the thyroid, are the master regulators of calcium homeostasis. In healthy people, these glands control calcium metabolism by releasing parathyroid hormone (PTH) in response to a fall in circulating calcium levels sensed by the calcium-sensing receptor (CaSR). PTH, an 84-amino acid peptide, is upregulated or downregulated based on the serum calcium and mediates an increase in serum calcium by its actions at bone, kidneys and gut. In bone, PTH stimulates osteoclasts to increase bone resorption to release calcium from the skeleton. In the kidneys, PTH increases reabsorption of calcium and increases excretion of phosphate from the renal tubules. In the GI tract, PTH increases the conversion of 25-hydroxyvitamin D (25OHD) to 1,25-dihydroxyvitamin D to increase calcium absorption from the gut (Fraser 2009). This is illustrated in Fig. 50.1 and discussed in more detail in Chap. 48.

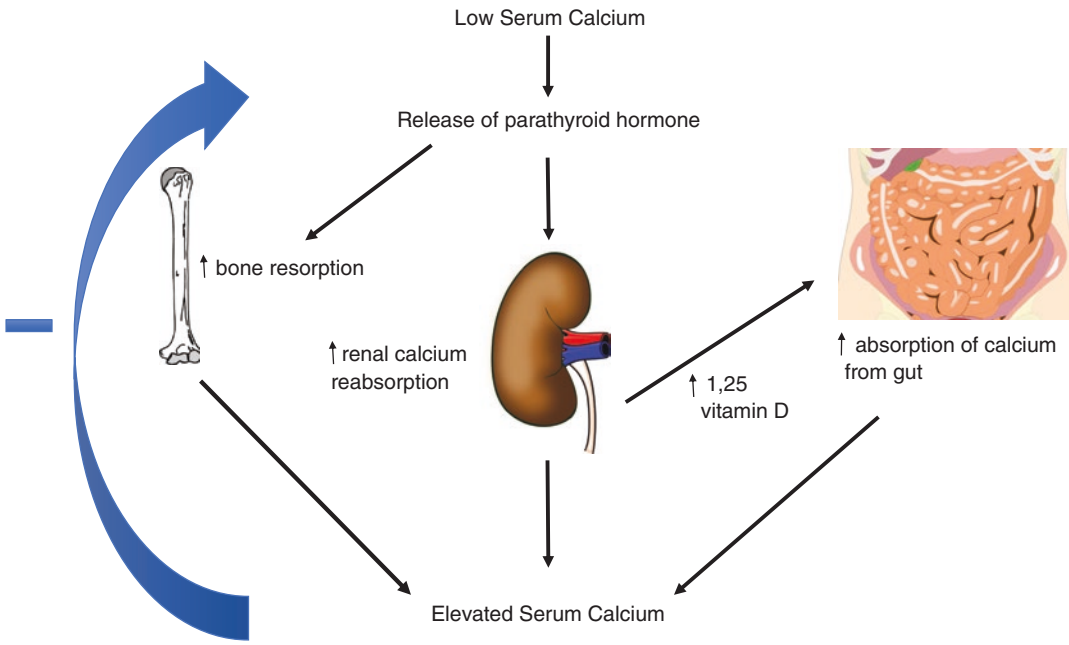

Fig. 50.1 Normal parathyroid physiology. When serum calcium is low, PTH is released from the parathyroid glands. PTH stimulates osteoclasts in the bones which releases calcium. In the kidneys, there is an increase in reabsorption of calcium from the urine. The kidney also increases the conversion of 25(OH) vitamin D to 1,25(OH) vitamin D which stimulates calcium absorption in the gut. The normalized calcium level serves as a negative feedback to stop this process

50.2 Primary Hyperparathyroidism

50.2.1 Epidemiology, Pathophysiology, Presentation

Primary hyperparathyroidism (PHPT) is the most common cause of hypercalcemia in the outpatient setting and is the third most common endocrine disorder. Women are affected about twice as often as men and the incidence increases with age. The peak incidence of PHPT is in women between 50 and 60 years old likely related to menopause. Oestrogen prior to menopause is thought to exert an inhibitory effect on the parathyroid glands. The increasing use of thiazide diuretics in this age group can also unmask the condition (Fraser 2009). The prevalence of PHPT varies based on the population studied, parameters defined and methods used, but is estimated to affect up to 5% of the general population (Crowley and Gittoes 2013).

Approximately 80% of cases of PHPT are caused by a single benign parathyroid adenoma, but there can be multiple adenomas or hyperplasia of multiple glands (Bilezikian et al. 2005). Parathyroid carcinoma is a very rare cause of PHPT occurring in only about 0.5% of cases (Bilezikian et al. 2005). Most PHPT cases are sporadic; recognised genetic causes, such as Multiple Endocrine Neoplasia (MEN) 1 and MEN 2, account for about 5% of cases. Ninety percent of patients with MEN 1 will develop 4-gland parathyroid hyperplasia and PHPT.

In the 1970s, the availability of routine laboratory chemistry gave easy access to calcium measurements and created an increase in the number of patients diagnosed with PHPT. The majority of patients in the modern day are asymptomatic and are diagnosed with mild or moderate hypercalcemia before they develop any signs or symptoms. Prior to the availability of simple biochemical screening, patients had much higher serum calcium at presentation and were often symptomatic, presenting with the classic signs and symptoms of

PHPT as described in the mnemonic 'stones, bones, groans and moans'. The most common renal manifestation of PHPT is a kidney stone, occurring in about 15–20% of patients (Mackenzie-Feder et al. 2011). Renal insufficiency, nephrogenic diabetes insipidus and nephrocalcinosis (calcium deposits in the renal parenchyma) can also occur. Bone disease associated with PHPT includes osteoporosis—particularly in cortical bone such as at the wrist—fragility fractures and osteitis fibrosa cystica. Although rarely seen in developed countries today, osteitis fibrosa cystica was once a common occurrence among those with PHPT and caused bone pain due to cyst formation in areas of subperiosteal bone resorption, 'salt and pepper' appearance of the skull, fractures and deformities. The 'Groans' of the PHPT mnemonic refer to gastrointestinal symptoms such as constipation, abdominal pain, peptic ulcers and rarely pancreatitis (usually associated with severe hypercalcemia). Neuropsychiatric symptoms or 'moans' include lethargy, impaired concentration, confusion, depression, anxiety and muscle weakness; in modern-day patients with PHPT this can manifest as subtle low mood or reduced quality of life. The cardiovascular system can also be affected by hypercalcemia, which may contribute to hypertension, cardiac and vascular calcifications, a shortened QT interval, and rarely conduction abnormalities or arrhythmias.

50.2.2 Diagnosis of PHPT and Its Complications

In patients with PHPT, serum PTH is elevated or inappropriately normal in the setting of hypercalcemia. Other causes of hypercalcemia such as malignancy, thyrotoxicosis, granulomatous diseases and immobility are usually associated with suppressed PTH measurements. A review of all the patient's medications and supplements should be performed; thiazide diuretics, vitamin D, lithium, calcium antacids and vitamin A can exacerbate hypercalcemia. Other causes of elevated PTH with or without hypercalcemia include renal insufficiency, vitamin D deficiency and familial hypocalciuric hypercalcemia (FHH).

The biochemical diagnosis of PHPT is made by measurement of serum calcium, PTH, 25OHD and urinary calcium. A finding of hypercalcemia should be confirmed by repeat laboratory testing. Thiazide diuretics should be discontinued for at least 2 weeks prior to repeating bloodwork. Calcium measurement results should be corrected to account for any abnormal measurement of albumin, since albumin is the main plasma protein that binds to calcium. Calcium correction can be provided by the local laboratory, by use of available online calculators, or by the following formula: corrected calcium = measured calcium (mg/dL) + 0.8 (4.0 − measured albumin in g/dL) or measured calcium (mmol/l) + 0.02(40 − measured albumin in g). Alternatively, an ionised calcium can be measured, but since most facilities do not have sufficient capabilities to perform this test, the corrected serum calcium is recommended (Crowley and Gittoes 2016).

Measurement of 25OHD is the estimation of choice for assessment of vitamin D status. When PHPT occurs with vitamin D deficiency, the serum calcium is often normal or lower than expected. Replacement of vitamin D is indicated in PHPT associated with vitamin D deficiency and does not cause further marked elevation in calcium in the majority of cases (Crowley and Gittoes 2013). After vitamin D replacement, and in the absence of a thiazide diuretic, 24-h urine calcium should be done to (1) exclude FHH from the differential diagnosis and (2) establish whether an elevation in urinary calcium is high enough to indicate referral for surgery (see below). In FHH, the calcium to creatinine clearance ratio is less than 0.01 mmol; it is normal or elevated in PHPT (Mackenzie-Feder et al. 2011). Ca/Cr clearance ratio is calculated by [24-h urine Ca × serum Cr] ÷ [serum Ca × 24-h urine Cr]. Confirmation of the diagnosis of FHH is by genetic testing for mutations in the *CaSR* gene.

PHPT is now most often discovered incidentally by identification of hypercalcemia on routine blood screenings, thus 80% of patients are asymptomatic on diagnosis. Those patients with asymptomatic PHPT require an additional workup to identify end-organ effects of PHPT, in

order to plan management of their disease. Some asymptomatic PHPT patients may progress over time and eventually develop symptoms—**see patient case study** (Bilezikian et al. 2005). Normocalcemic PHPT is another variant of PHPT in which calcium is normal but PTH is elevated. It is often found during the biochemical investigation of osteoporosis; surveillance of these patients over 3–8 years reveals development of hypercalcemia in 20% cases (Crowley and Gittoes 2016). Screening for end-organ disease and management planning in normocalcemic PHPT is similar to that of asymptomatic PHPT (Crowley and Gittoes 2016).

The evaluation of asymptomatic PHPT should include measurement of renal function including estimated glomerular filtration rate (eGFR), imaging for kidney stones and measurement of bone mineral density (BMD) (Table 50.1). A 24-h urine calcium level should be collected at diagnosis to exclude FHH; the degree of calciuria also informs the management plan in asymptomatic patients. Marked hypercalciuria of >400 mg/day (>10 mmol/day) is an indication to refer asymptomatic patients for surgery because of the anticipated risk of nephrolithiasis. Asymptomatic nephrolithiasis or nephrocalcinosis identified by abdominal imaging (X-ray, ultrasound, or CT scan) are indications to refer asymptomatic patients for surgical management (Bilezikian et al. 2014). Bone mineral density is evaluated by dual-energy X-ray absorptiometry (DXA) which should include measurement of the distal 1/3 radius; this area is composed of cortical bone that has a higher turnover than trabecular bone and is thus more likely to be adversely affected by PHPT (Bilezikian et al. 2014). Measurement of bone turnover markers (bone-specific alkaline phosphatase activity, CTX or urine NTX) is an optional test to evaluate skeletal involvement in asymptomatic PHPT (Bilezikian et al. 2014). Asymptomatic patients who decide not to undergo surgery at diagnosis should be monitored over time for progression of the disease.

Table 50.1 2013 guidelines for surgery in asymptomatic PHPT (Bilezikian et al. 2014)

Serum calcium measurement	1.0 mg/dL (0.25 mmol/L) above the upper limit of normal
Bone involvement	BMD with of <−2.5 at lumbar spine, total hip, femoral neck, or distal 1/3 radius **or** Vertebral fracture seen on X-ray, CT, MRI or VFA
Renal involvement	Creatinine clearance of <60 cm^3/min **or** 24-h urine calcium >400 mg/day (>10 mmol/day) and increased stone risk by laboratory stone risk analysis **or** Presence of kidney stone on X-ray, ultrasound or CT
Patient age	<50 years
Patient preference	Patient prefers to pursue surgery despite not meeting guidelines **or** Patient is unable or unwilling to undergo medical surveillance

Adapted from Bilezikian JP, Brandi ML, Eastell R, Silverberg SJ, Udelsman R, Marcocci C, et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Fourth International Workshop. J Clin Endocrinol Metab 2014 Oct;99 (10):3561–9

50.2.3 Treatment

Patients with symptomatic PHPT should be referred for surgery because the only definitive cure for PHPT is excision of the parathyroid adenoma or adenomas. After surgery, the risk of kidney stones is decreased, bone mineral density improves, fracture risk may decline, and some quality of life measures may improve. Surgery may not benefit all patients with asymptomatic PHPT. One long-term observational study showed that most patients with asymptomatic PHPT could be monitored safely over a period of 15 years (Rubin et al. 2008). However, the same study showed that over 30% of asymptomatic PHPT patients had disease progression and met one or more surgical criteria at some point during the study. Additionally, decline in the BMD at the femoral neck and distal radius were present in about 60% of the untreated group (Rubin et al. 2008).

50.2.3.1 Surgical Treatment

Localising studies before parathyroid adenoma resection usually consist of two modalities such as a sestamibi single photon emission computed tomography (SPECT) scan and a neck ultrasound; the type of imaging varies between centres (Glynn et al. 2011). If an adenoma is found and imaging is concordant, a minimally invasive parathyroidectomy (combined with intraoperative PTH monitoring in some centres) can be performed. In cases of equivocal or negative imaging, either a minimally invasive surgical technique with intraoperative PTH monitoring (targeting a post-resection PTH decrement of 50%) or a bilateral neck exploration can be considered (Khan et al. 2016). Patients should be referred to an experienced endocrine surgeon for either procedure. Post-excision intraoperative PTH measurement can be falsely elevated in the setting of impaired renal function, in which case circulating PTH is cleared more slowly after excision, or if the adenoma has been stimulated to release PTH by intraoperative manipulation.

Complications of parathyroid surgery are rare but include recurrent laryngeal nerve injury, infection, hematoma and post-operative hypocalcemia. In patients with high bone resorption before parathyroid surgery, post-operative hypocalcemia can be caused by a positive bone remodelling balance as the bones recover from prolonged exposure to high PTH; this is called hungry bone syndrome and is also associated with post-operative hypophosphatemia and a rise in bone alkaline phosphatase. Post-parathyroidectomy hypocalcemia can also be secondary to hypoparathyroidism which can be transient or permanent, and is associated with higher phosphate levels than hungry bone syndrome (see section on post-operative hypoparathyroidism). Formerly, in about 5% of patients who had parathyroidectomy for PHPT, hypercalcemia recurred due to inadequate removal of diseased parathyroid tissue. However, cure rates are 96–99% with current surgical techniques (Bilezikian et al. 2005). A discussion of the risks and benefits of surgery should take place between the surgeon and the patient prior to surgery.

In 2014, an international consensus statement for the surgical management of asymptomatic PHPT was published (Bilezikian et al. 2014). These guidelines aimed to identify those asymptomatic patients with PHPT at risk for progression of the disease if untreated, or who may improve after parathyroidectomy. Patients with asymptomatic PHPT should be referred for surgery if they meet the following criteria, which are also listed in Table 50.1: under the age of 50 years, serum calcium ≥1 mg/dL (≥0.25 mmol/L) above the upper limit of normal for the local reference range; peri- or post-menopausal women and men over 50 years with *T*-score of −2.5 or less at the lumbar spine, femoral neck, total hip, or distal 1/3 radius; pre-menopausal women and men under 50 years old if *Z*-score of −2.5 or less; vertebral fracture; creatinine clearance <60 cm^3/min, 24-h urinary calcium greater than 400 mg (10 mmol)/day, presence of kidney stones, or evidence of nephrocalcinosis. Patients with asymptomatic PHPT who do not meet these criteria at the first evaluation but satisfy the referral criteria during long-term monitoring should also be referred (Bilezikian et al. 2014). If an asymptomatic patient does not meet the above criteria, but prefers to have parathyroidectomy rather than surveillance, it is acceptable to refer them for surgical management. Those patients with familial causes of PHPT, such as MEN1, have a more aggressive form of PHPT; in these cases surgery is not curative without causing hypoparathyroidism and such patients should be managed in a specialist centre.

50.2.3.2 Medical Treatment

Patients who have asymptomatic PHPT and do not meet surgical criteria should be monitored for any deterioration in their biochemistry, bone or renal status, as listed in Table 50.2. Monitoring includes serum calcium measurement every 1–2 years. BMD should be monitored, but there are no official guidelines on the interval between scans; therefore this is a decision based on the individual characteristics of the patient. Vitamin D should be supplemented to maintain a 25OHD level of at least >20 ng/dL (50 nmol/L), although

Table 50.2 2013 guidelines for observation of patients with asymptomatic PHPT who do not undergo surgery

Serum calcium	Yearly
Bone	BMD every 1–2 years and/or X-ray or VFA of spine if clinically indicated
Renal	Yearly eGFR, serum creatinine **and** If kidney stones suspected, 24-h urinary stone profile or renal imaging by X-ray, ultrasound or CT

Adapted from Bilezikian JP, Brandi ML, Eastell R, Silverberg SJ, Udelsman R, Marcocci C, et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Fourth International Workshop. J Clin Endocrinol Metab 2014 Oct;99(10):3561–9

there is some evidence to suggest levels >30 ng/mL may be associated with lower PTH levels (Bilezikian et al. 2014).

Patients with PHPT should meet the daily intake of dietary calcium recommended for their age. Adequate hydration should be encouraged. Drugs that may exacerbate hypercalcemia such as thiazide diuretics and lithium should be avoided. Patients should stay physically active and periods of prolonged bedrest should be avoided.

Pharmacologic treatment may be appropriate for those who meet criteria for surgery but are deemed to be poor surgical candidates or prefer to avoid surgery. However, there are insufficient long-term studies on any pharmacologic therapy in PHPT and most agents are not approved for treatment of PHPT (Bilezikian et al. 2014). Bisphosphonates improve bone density in patients with PHPT but do not significantly lower serum calcium or PTH; a reduction in fracture risk in PHPT patients has not been demonstrated (Crowley and Gittoes 2013). A discussion with the patient about the expectations for bisphosphonate therapy in PHPT is advisable. Cinacalcet reduces serum calcium and therefore may relieve symptoms in patients with symptomatic PHPT who are not fit for surgery, but does not lower PTH level, demonstrate improved BMD or reduce fracture risk. Cinacalcet is a calcimimetic which activates the calcium-sensing receptor in the parathyroid glands to decrease PTH secretion. Cinacalcet is FDA and EMA approved for treatment of severe hypercalcemia in adults with PHPT who meet criteria for surgery but are unable to undergo parathyroidectomy. It is also approved for treatment of secondary hyperparathyroidism in patients with CKD on dialysis and for the treatment of parathyroid carcinoma. It is recommended to start cinacalcet at a dose of 30 mg twice daily and titrate every 2–4 weeks as needed to normalise serum calcium. Serum calcium should be monitored within a week of initiation or dose adjustment and then every 2 months after maintenance dose is established. It is not known whether cinacalcet improves nephrolithiasis or neuropsychiatric problems associated with PHPT (Crowley and Gittoes 2013). More research is needed about the use of combination therapy bisphosphonate with cinacalcet.

Oestrogen or combination of oestrogen with progestin can improve bone density in PHPT but is not recommended as first line medical therapy for women with PHPT due to the risks for thromboembolic events, heart disease and stroke. However, if a woman with PHPT opts to take hormone replacement therapy for menopausal symptoms, it may help treat the PHPT. With raloxifene, a selective estrogen receptor modifier (SERM) that is a potential alternative to oestrogen. Neither of these drugs is approved as treatment of PHPT.

50.3 Secondary Hyperparathyroidism

Secondary Hyperparathyroidism (SHPT) occurs when elevated circulating PTH is not sufficient to maintain serum calcium in the normal range due to an underlying problem with a target organ (such as liver, kidney or gut) or because of reduced calcium availability. Causes of SHPT include malabsorption or malnutrition (celiac disease, bariatric surgery, cystic fibrosis), liver failure, vitamin D deficiency, pseudohypopara-

thyroidism, and most commonly, chronic kidney disease (CKD).

50.3.1 Secondary Hyperparathyroidism in CKD

Secondary HPT in CKD is part of a wider disorder of electrolyte and skeletal metabolism called Chronic Kidney Disease-Mineral Bone Disorder (CKD-MBD) by the Kidney Disease Improving Global Outcomes (KDIGO) group, and is associated with increased morbidity and mortality (KDIGO 2009). PTH secretion in CKD is stimulated by hyperphosphatemia and vitamin D deficiency, and a rise in PTH can be measured as early as CKD stage 3. Hyperphosphatemia increases PTH in several ways as illustrated in Fig. 50.2, direct stimulation of the parathyroid glands to produce PTH, precipitation with calcium to cause a mild hypocalcemia that stimulates further PTH secretion, and stimulation of fibroblast growth factor 23 (FGF-23) secretion, the primary regulator of phosphorus. FGF-23 produced by osteocytes in response to hyperphosphatemia increases clearance of phosphorus from the proximal renal tubule and inhibits 1-alpha hydroxylase activity, thus it decreases circulating active vitamin D. Initially, this is an adaptive mechanism to maintain normal phosphate and calcium, with PTH and FGF-23 persistently elevated.

With progressive CKD and loss of nephron function, the kidney loses its ability to excrete phosphate which further stimulates PTH secretion. Although the kidney has become resistant to the effect of PTH, bone remains sensitive and continues to release calcium and phosphorus in response to PTH. The end result is a vicious cycle of escalating PTH and phosphorus in circulation which leads to bone problems such as osteitis fibrosis cystica, adynamic bone disease, osteomalacia; parathyroid hyperplasia; and is associated with vascular calcification and left ventricular hypertrophy.

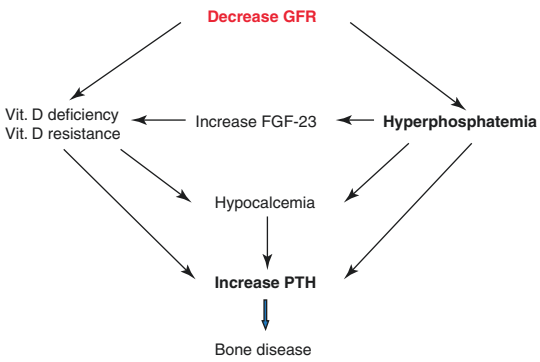

Fig. 50.2 Secondary hyperparathyroidism in renal failure. Saliba W, El-Haddad B. Secondary Hyperparathyroidism: Pathophysiology and Treatment. J Am Board Fam Med 2009 Sep; 22(5):574–581. Calcium and phosphorus metabolism in renal failure. *PTH* parathyroid hormone, *FGF-23* fibroblasts growth factor 23

50.3.2 Management of Secondary Hyperparathyroidism

Secondary HPT is managed medically in the majority of cases. For patients with CKD who do not require dialysis, the optimal target PTH for treatment is not known (KDIGO 2009). Patients with CKD who have a PTH measurement above the reference range should have measurement of calcium, phosphate and 25OHD, and any abnormality of these should be addressed. Hyperphosphatemia is managed with a low phosphate diet and phosphate binders. Vitamin D deficiency is treated with supplementation with vitamin D2 or D3. If these measures are not sufficient to maintain PTH within the normal reference range, then a vitamin D analogue or calcitriol could be added. Measurement of PTH, calcium, phosphate and 25OHD should be monitored routinely, to assess the effect of these treatments and to avoid overtreatment, for example, the development of hypercalcemia with vitamin D or calcium-based phosphate binders. Routine measurement of FGF23 is not recommended in current guidelines. Patients with CKD that have progressed to require dialysis may require cinacalcet in combination with these therapies,

although for such patients it is recommended to target a PTH within a range of twice to nine times the upper limit of the local reference range (KDIGO 2009). When medical therapy fails, parathyroidectomy may be necessary. Bone-specific therapy for renal osteodystrophy is aimed at prevention of fractures which are 2–4 times more frequent in patients with end-stage renal disease than in an age-matched population (KDIGO 2009). Patients with low BMD and advanced CKD should have replacement of calcium and vitamin D before treatment with denosumab or other anti-resorptives; the combination of CKD-MBD, untreated vitamin D deficiency and denosumab is associated with severe hypocalcemia. It can be challenging to assess the potential benefit of pharmacologic therapy for fracture prevention in CKD patients; KDIGO advises consideration of bone biopsy after correction of the abnormalities already detailed in this section (KDIGO 2009).

50.4 Tertiary Hyperparathyroidism

Tertiary HPT is a state of autonomously functioning parathyroid tissue and is usually the result of long-standing secondary HPT due to CKD. For example, a patient who undergoes successful kidney transplant but continues to have increased PTH and calcium measurements may have developed tertiary HPTH. Typically it is treated surgically.

50.5 Parathyroid Carcinoma

Parathyroid carcinoma is an extremely rare cause of primary hyperparathyroidism. It is suspected in cases with severe hypercalcemia and higher levels of PTH than are seen in benign disease, particularly when these are associated with a palpable neck mass which is unusual in benign hyperparathyroidism (McClenaghan and Qureshi 2015). The incidence of parathyroid carcinoma is equal in men and women. A small portion of carcinomas may not produce functional PTH and present with invasive local disease. Hyperparathyroidism-Jaw Tumour syndrome (HPT-JT syndrome) is caused by germline mutations in the cell division cycle 73 (*CDC73*) gene and is inherited in an autosomal dominant pattern (Li and Simonds 2015). Penetrance is incomplete therefore there is no family history in some cases. Suspected cases of HPT-JT syndrome should be discussed with the genetics laboratory conducting the genetic analysis because conventional testing may miss a complete *CDC73* gene deletion. Fibro-osseous tumours of the mandible and maxilla, Wilms tumours of the kidney and uterine fibroids are associated with this mutation. The primary management of parathyroid carcinoma is surgical, including bilateral neck dissection and cinacalcet can be used to control hypercalcaemia (Li and Simonds 2015). For members of families with known *CDC73* germline mutations, serum calcium and PTH measurement is recommended every 6–12 months with jaw imaging and renal imaging every 5 years (Li and Simonds 2015).

PHPT Case Study

Mr. S is an 80-year-old male who has been followed for asymptomatic PHPT for the last 13 years. His medical history is significant for pulmonary fibrosis, coronary artery disease, Type 2 Diabetes, hyperlipidemia and gout. He denies kidney stones or hematuria, falls or fractures, memory or mood disturbances, constipation or abdominal pain. In fact, Mr. S feels quite well. He worked up until 6 months ago as a contractor. He stays very active and appears younger than stated age.

His most recent BMD showed osteopenia with a *T*-score of −1.6 in the femoral neck but was normal at the other sites. However, BMD did show a decline from his baseline BMD several years prior.

While he remained without physical symptoms, his renal function had been worsening with a creatinine of 1.7 mg/dL (150 μmol/L), up from his baseline of 1.3 (115) (normal 0.5–1.3 mg/dL)

and calcium had risen—the highest value recorded was 11.7 mg/dL (2.93 mmol/L) (normal 8.5–10.1 mg/dL). PTH was 100 pg/mL (normal 15–88). Vit D was normal at 34 ng/mL (85 nmol/L). 24-h urine calcium was within normal limits.

The patient was sent for parathyroid SPECT which showed: 'Faint persistent uptake in the inferior posterior left thyroid bed on SPECT imaging only may represent parathyroid adenoma or hyperplasia'. Thyroid ultrasound was unremarkable.

Based on the serum calcium and the declining creatinine, the patient was counselled regarding the choice of parathyroidectomy or starting medical therapy with cinacalcet. However, he was not interested in another long-term medication and opted for surgery.

He underwent one gland parathyroidectomy with interoperative PTH monitoring. His recovery was complicated by pneumonia. He also lost weight that he has been unable to re-gain. At his 2 month post-surgery follow-up, his creatinine had improved to 1.1 mg/dL and calcium to 9.9 mg/dL.

50.5.1 Nursing Role/Key Learning Points from the Case

Renal impairment as a complication of PHPT may be missed; careful follow-up of the patient can ensure that an evolving complication is identified without delay. Co-morbidities that may influence the decision to proceed to surgery should be assessed. The specialist nurse should be aware of the individual patient's risks and indication for surgery, so that he or she can counsel the patient appropriately.

50.6 Hypoparathyroidism

Hypoparathyroidism is a disease state in which the parathyroid glands fail to produce active PTH in response to hypocalcemia or hyperphosphatemia. Some causes for hypoparathyroidism are listed in Table 50.3.

Table 50.3 Causes of hypoparathyroidism (for detailed list, see Clarke et al.) (Clarke et al. 2016; Bollerslev et al. 2015)

Congenital/genetic	Associations	Mutation
DiGeorge syndrome	Immune deficiency; congenital heart defects; ENT defects	*TBX1; NEBL*
APECED; also known as autoimmune polyglandular syndrome type 1	Addison's; chronic mucocutaneous candidiasis; malabsorption; dental abnormalities; gonadal failure; hepatitis; anaemia	*AIRE*
Sanjad-Sakati and Kenny Caffey syndromes	Short stature; cognitive impairment; seizures	*TBCE*
X-linked hypoparathyroidism	Neonatal tetany	Xq26-q27
Familial isolated hypoparathyroidism	Autosomal recessive and dominant inheritance	*PTH; GCM2*
Autosomal dominant hypocalcaemia 1 (with hypercalciuria)	Can be asymptomatic. High risk renal complications	*CASR*
	Sensorineural deafness; renal	*GATA3*
Acquired		
Surgery (damage to, or removal of parathyroid glands)	Younger age; female patients; surgery for Graves' disease or malignancy; number of parathyroids left in situ	
Infiltration	Iron/copper deposition; malignancy; sarcoid	
Neck irradiation		
Autoimmune (also see APECED, above)		
Hypomagnesaemia	PPI use; alcohol excess	

50.6.1 Assessment of the Patient with Suspected Hypoparathyroidism

Patients are diagnosed with hypoparathyroidism when albumin-adjusted serum calcium or ionised calcium concentration is less than the local lower

limit of normal, in the setting of low or inappropriately normal PTH concentration. Magnesium concentration should be measured because hypomagnesemia impairs both release of PTH from parathyroid glands and PTH action in target tissues; therefore magnesium should be replaced and bone biochemistry re-assessed in those with a low serum magnesium result. The most common aetiology of chronic hypoparathyroidism is post-surgical—up to 7% of patients who undergo total thyroidectomy develop permanent hypoparathyroidism which is defined as hypoparathyroidism persisting more than 6 months after surgery (Shoback et al. 2016). In a patient with evidence of chronic hypoparathyroidism who has no history of neck surgery or irradiation, consider an autoimmune cause followed by genetic screening (see Table 50.3) (Clarke et al. 2016). Almost half of the cases of non-surgical hypoparathyroidism are idiopathic (Astor et al. 2016). Patient and family history and clinical examination are used to guide further investigations.

50.6.2 Clinical Assessment of the Patient with Potential Acute Post-surgical Hypoparathyroidism

Hypocalcemia in the first post-operative day occurs in 30–60% of patients who undergo total thyroidectomy; this is more likely in those undergoing surgery for underlying thyroid malignancy, because they tend to have more extensive surgical clearance including lymph node dissection. Acute hypoparathyroidism can also occur after parathyroidectomy. Most centres where these procedures are performed have a protocol for monitoring patients on the post-operative ward; these protocols usually include a combination of clinical and biochemical monitoring, as outlined below.

After thyroidectomy or parathyroidectomy patients should be asked about tingling or 'pins-and-needles' sensations, usually felt in the hands, feet or face. Nursing staff should check for neuromuscular irritability by assessing Chvostek's and Trousseau's signs at the time of measurement of patient vital signs. Chvostek's sign is facial twitching elicited by lightly tapping over the patient's facial nerve. Trousseau's sign is carpopedal spasm elicited by inflating a blood pressure cuff on the upper arm to greater than the patient's systolic blood pressure for 3 min. A useful video of these signs and description of their clinical use was provided by Jesus and Landry (2012). These signs are indicators of severe hypocalcemia and should trigger urgent measurement of calcium, but do not replace routine measurement of calcium at least twice daily in this post-operative cohort of patients.

50.6.3 Treatment of Hypoparathyroidism

Hypoparathyroidism is the only endocrine deficiency state that is not routinely treated by replacement of the relevant deficient hormone. The aim of treatment of acute hypoparathyroidism is to prevent symptoms, laryngospasm and cardiac arrhythmia. It is possible that for patients with acute post-operative hypoparathyroidism, maintenance of calcium in the middle to higher end of the normal calcium reference range increases their chance of parathyroid recovery in the long term (Bollerslev et al. 2015). The aim of treatment of chronic hypoparathyroidism is to avoid symptoms of hypocalcemia, avoid complications of overtreatment and preserve a normal quality of life; in order to achieve this the biochemical targets are to keep serum calcium in the low normal or slightly low range while the patient remains free of signs and symptoms of hypocalcemia; to keep 24-h urinary calcium in the normal reference range (<0.1 mmol/kg/24 h or 4 mg/kg/24 h); to keep serum phosphate and magnesium in the normal reference range and to keep serum calcium-phosphate product less than 4.4 $mmol^2/L^2$ (55 mg^2/dL^2); this requires an individualised approach for each patient.

Standard treatment is with active vitamin D analogues and calcium supplementation, and with supplementation of cholecalciferol 400–800 IU/day to levels of at least 50 nmol/L (20 ng/mL). The vitamin D analogues commonly used are calcitriol and alfacalcidol. Oral calcium

supplements relieve mild symptoms of hypocalcemia such as fatigue. Some patients feel better at a higher serum calcium level, and it is reasonable to maintain calcium at this level if they do not develop hypercalciuria or renal stones. Oral calcium supplements also bind phosphate. The guidelines for dietary calcium intake for the general population apply to patients with hypoparathyroidism (1000 mg/day). The capacity of the intestine to absorb calcium is saturated at 500 mg at any one time, therefore it is advisable to spread out dietary and supplement calcium intake across the day in divided doses. For patients on proton pump inhibitors, see Clinical Note 1. Dose adjustment of calcium supplementation is according to symptoms, serum calcium and phosphate and urinary calcium clearance. Dietitian review for advice about dietary calcium, phosphate and sodium is advisable (Brandi et al. 2016).

Some patients benefit from use of either teriparatide, which is PTH 1–34 (the N terminal active fragment of PTH), or intact parathyroid hormone (1–84). In 2015, the FDA approved Natpara (intact PTH 1–84) with orphan drug designation for management of hypocalcemia in hypoparathyroidism (Brandi et al. 2016). Concern about the risk of osteosarcoma has limited its use to patients with hypoparathyroidism who cannot achieve normocalcemia on activated vitamin D analogues and calcium supplementation alone. American guidelines suggest consideration of PTH 1–84 replacement therapy in the setting of difficulty maintaining stable calcium measurements; high dosing requirements for calcium (>2.5 g/day) or vitamin D (>1.5 μg for active form or >3.0 μg for 1α analogue); history of hypercalciuria, calculi or reduced eGFR; increased calcium-phosphate product or hyperphosphatemia; malabsorption and reduced quality of life (Brandi et al. 2016). If PTH 1–84 is commenced, vitamin D dose must be reduced.

50.6.4 Follow-up of the Patient with Hypoparathyroidism

Patients with hypoparathyroidism receiving stable doses of calcium, vitamin D, magnesium or diuretics should undergo measurement of serum-adjusted (or ionised) calcium, magnesium, phosphate and creatinine (for estimated GFR) every 3–6 months and this frequency should be increased in the event of prescription changes. The frequency of testing after a calcium or vitamin D dose change depends on how high the dose of the supplement was prior to change (higher doses require longer time to achieve steady-state and electrolyte response), and upon the clinical status of the patient. Measurement of 24-h urinary calcium should be done annually or every second year, and renal imaging should be considered if urinary calcium is high or if estimated glomerular filtration rate is decreasing. Bone imaging is not routinely indicated during follow-up.

50.6.5 Complications of Treatment of Hypoparathyroidism

Undertreatment of hypoparathyroidism can result in symptomatic hypocalcemia which manifests as mood disorders, cognitive problems, paresthesiae, muscle cramp, sleep disturbance, fatigue, cardiac arrhythmia and laryngospasm. Some of these symptoms may go un-noticed or their significance may not be recognised by the patient—for example the authors have seen life-threatening laryngospasm present initially as an irritating cough—therefore patient education is extremely important. Patients with post-surgical hypocalcemia who experience a rapid drop in calcium may be quite symptomatic while those with hypocalcemia of more insidious onset can tolerate lower serum calcium levels without symptoms. In patients with non-surgical hypoparathyroidism, an increased risk of cataract, intracerebral calcification, ischemic heart disease and proximal humeral fracture has been reported (Bollerslev et al. 2015).

Over-replacement of calcium leading to hypercalcemia may also present with cognitive problems, muscle pain, nephrogenic diabetes insipidus and arrhythmia, as well as renal colic from nephrolithiasis where hypercalciuria is long-standing. Both hypo- and hypercalcemia can be acute emergencies, and both electrolyte

imbalances can complicate acute illness in patients with hypoparathyroidism. Hypercalciuria is a risk factor for renal stone formation in patients with hypoparathyroidism; this may be managed by reduction of calcium supplementation (with compensatory increase in vitamin D replacement), restriction of dietary sodium and use of high-dose thiazide diuretics. Patients with hypoparathyroidism who are known to have renal stones should be managed as per guidelines for the general population with renal calculi.

50.6.6 Quality of Life with Hypoparathyroidism

Patients with hypoparathyroidism report lower quality of life than members of the general population, and those with post-surgical hypoparathyroidism appear to suffer more than those with a non-surgical aetiology; this has recently been confirmed in a Norwegian study which reported lower quality of life in post-surgical patients using the Short Form 36 and Hospital Anxiety and Depression scale (Astor et al. 2016). Patients with combined post-surgical hypothyroidism and hypoparathyroidism report more physical symptoms than patients with hypothyroidism alone (Sikjaer et al. 2016). An open-label Italian study of twice daily PTH(1–34) in 42 patients with post-surgical hypoparathyroidism demonstrated improvement in quality of life measured by the SF36 (Santonati et al. 2015), and a study of PTH(1–84) therapy in patients with hypoparathyroidism of mixed aetiologies also demonstrated improvement in SF36 domains (Cusano et al. 2013); these suggest that poor quality of life is treatable in this patient cohort. See Patient Experience.

50.7 Pseudohypoparathyroidism and Pseudopseudohypoparathyroidism

Pseudohypoparathyroidism is resistance to PTH, characterised by low calcium and high phosphorus in the setting of high PTH measurements. Serum hypomagnesaemia should be excluded before the diagnosis of pseudohypoparathyroidism is made. Careful examination and biochemical assessment of response to PTH is required to diagnose the subtype of pseudohypoparathyroidism (Levine 2012). Albright's hereditary osteodystrophy (AHO) is a clinical syndrome that includes short stature, round face, obesity, heterotopic ossification, shortening of the third, fourth and fifth metacarpals and shortening of the distal phalanx of the first digit and can be observed both with and without endocrinopathy.

AHO, pseudohypoparathyroidism and the coexistence of other endocrine resistant states (thyroid stimulating hormone/gonadotrophin resistance) suggests pseudohypoparathyroidism type 1a or 1c. Type 1a and 1c can be differentiated by molecular testing of the *GNAS* gene. Type 1b is usually associated with renal PTH resistance alone and with mild brachydactyly. Pseudohypoparathyroidism type 2 is a renal resistance to PTH in which cyclic AMP is generated in response to PTH infusion but PTH does not cause phosphaturia; this is associated with severe hypocalcemia and vitamin D deficiency.

Patients with a clinical examination consistent with Albright's hereditary osteodystrophy who have normal endocrine function and PTH action have a condition called pseudopseudohypoparathyroidism caused by mutations in the GNAS gene inherited from the patient's father.

Detailed description of the genetic basis for these conditions is reported elsewhere (OMIM) (Levine 2012).

Treatment of type 1 pseudohypoparathyroidism is with calcium and either calcitriol or alfacalcidol supplementation. Correction of underlying vitamin D deficiency is also recommended. Other endocrine disorders should be identified and treated appropriately.

50.8 Clinical Note 1: Proton Pump Inhibitors (PPIs)

PPIs are associated with hypomagnesemia which can cause reduction in PTH release or resistance to PTH at the level of target tissues. PPI use

should be checked in the medication history of patients with newly diagnosed hypoparathyroidism and serum magnesium should be measured.

In patients receiving calcium supplementation for hypoparathyroidism, it should be remembered that PPIs raise the gastric pH, which interferes with absorption of calcium carbonate. If it is not possible to change the patient's antacid prescription, calcium supplementation should be given in the form of calcium citrate.

50.9 Clinical Note 2: Pregnancy in Hypoparathyroid Patients

Pregnant women with hypoparathyroidism require special consideration because of the changes in calcium metabolism that occur during pregnancy. The placenta produces 1,25 $(OH)_2D$ which drives increased intestinal absorption of calcium; parathyroid hormone-related peptide (PTHrP) production in later pregnancy and breastfeeding drives increased calcium resorption from the bone. The combined increased activity of 1,25 $(OH)_2D$ and PTHrP can lead to hypercalcemia complications for the mother and hypocalcaemia in the neonatal period for the infant. Conversely untreated maternal hypocalcemia can lead to foetal loss or skeletal abnormalities in the infant. Treatment of hypoparathyroidism with calcium and vitamin D analogues should continue in pregnancy but women with hypoparathyroidism should have serum calcium measurement (adjusted or ionised) every 2–3 weeks during pregnancy and breastfeeding, and the obstetrician should be aware of the diagnosis of hypoparathyroidism (Bollerslev et al. 2015).

50.10 Patient Experience of Hypoparathyroidism

A hypopara patient can feel both physically and emotionally at odds with a 'normal' blood test result so the key to management is to maintain calcium levels high enough to be symptom-free but low enough to prevent kidney damage. Good levels of serum magnesium and Vitamin D3 are important to help reduce symptoms and maintain stability. Patients with brittle hypopara or patients having their medication adjusted will need extra support and more frequent and accessible blood tests. Hypopara clinical guidelines should be consulted.

Hypopara is a very complicated condition to live with (especially without a home tester), so patients and their medical teams need to work together for best results. Self-management is also essential to avoid crises. Calcium levels fluctuate in response to many factors throughout the day and can affect the patient at every level—physical, emotional and neurological. Understanding how certain factors such as exercise, menstrual cycles and sleep levels affect levels; how to get calcium from dietary sources; and how and when to take medication can help the patient to feel better. Hypopara patient support groups also play a great role in educating and supporting hypopara patients and their families and raising awareness of patient needs to the medical profession.

The hardest part about being a hypopara patient is the invisibility of the illness. There is an assumption that because you look OK on the outside and your bloods might come back in the OK range that everything is fine. Family and friends can forget that you have the illness (and make unreasonable demands on your energy levels) and well-meaning people underestimate the seriousness of the illness and advise you to drink more milk!

50.11 Hypopara UK (Hypoparathyroidism and Primary Hyperparathyroidism)

Hypopara UK is a national patient organisation working to improve the lives of people living with conditions caused by parathyroid gland disorders.

Hypopara UK was founded in 2005 by Liz Glenister, a former teacher, after a 12 year search for information about her unnamed and unacknowledged condition following her operation for thyroid cancer in 1992. Liz continues to run

Hypopara UK today with the help of a committed band of patients, all volunteers like herself and a clinical advisory team of specialist healthcare professionals. Hypopara are proud founders of the World Hypopara Awareness Day and the Hypopara Europe Network and we continue to set up new groups around the world.

Hypopara UK offers support and information to empower patients and their families to become involved and active in the management of their condition through its informative website, award winning patient information leaflets, telephone helplines and online support groups. Making contact is often a life changing moment for patients who may have been struggling alone to understand their condition or find appropriate treatment, as Sarah's story describes.

Hypopara UK works closely with our Clinical Advisory Team in the UK and Ireland, as well as international HCPs with a particular interest in calcium homeostasis and bone metabolism. Together they work to raise awareness, develop new protocols and advance research into more effective treatment.

Hypopara UK is honoured to have been involved in some ground-breaking work including the BTA guideline for the 'Management of Thyroid Cancer' Guidelines (2014), the ESE guideline on the 'Treatment of Chronic Hypoparathyroidism in Adults' (2015), 'Living with Chronic Hypoparathyroidism'(2017) and 'Burden of Illness Among Patients With Chronic Hypoparathyroidism Not Adequately Controlled With Standard Therapy by Self-Perception' (2018).

Hypopara UK is very keen to work with nurses (particularly those in endocrine clinics, A&E, post-surgical wards and GP practices) wishing to learn more about supporting and educating patients with these challenging conditions. Hypopara UK attends meetings and training events to network and share information, and provides free resources for clinics and surgeries available to order or download from our website.

For further information, please visit our website at www.hypopara.org.uk, email us on mailto:info@hypopara.org.uk or call us on +44 (0)1342 316315.

50.12 Patient Story

Currently 75% of our membership (and 6–7% of all thyroid surgery cases in the UK) are living with permanent post-surgical hypoparathyroidism due to thyroid, parathyroid or laryngeal surgery. The problems of achieving calcium homeostasis, particularly without monitoring, are very challenging and, being a rare condition, symptoms may not be recognised or properly treated, even in a crisis.

Sarah H is a 51-year-old registered nurse who had a total thyroidectomy to remove a large multinodular goitre in London, in October 2017. Two days later she was readmitted with hypocalcaemia (and a haemorrhage and tracheal tear) and was finally diagnosed with permanent post-surgical hypoparathyroidism in April 2018.

Sarah writes: It has been an emotional and physical struggle, mainly because my endocrinologist had little experience of this rare condition. She couldn't understand why I was so symptomatic despite my serum calcium being within 'normal' range and did not monitor me after increasing my medication. This led to dangerously high calcium levels (>3.2) but, despite feeling extremely ill, I was told to continue on the same medication just cut the calcium slightly and retest in 3 days.

Hypopara UK was invaluable in giving me the confidence to disregard this dangerous advice and to go to A&E for urgent care. I did this and was immediately admitted for a week for IV fluids and potassium replacement. Hypopara UK later advised me to take magnesium supplements which has dramatically reduced my symptom burden further.

I have since asked Hypopara UK to recommend a specialist in calcium metabolism which they did and he is now expertly planning and monitoring my condition. I am thrilled. They also advised me to ask for altered employment hours and am now back at work with only one night shift a week.

I don't know where I'd be now without the help and support from Hypopara UK. They gave me the tools to educate myself about the condition, and above all, the confidence to be my own advocate in order to receive appropriate care. I'm in a much better place now.

50.13 Conclusions

1. Primary hyperparathyroidism (PHPT) is diagnosed in the setting of hypercalcemia with high or inappropriately normal PTH measurement; it is primarily managed with surgery. Some asymptomatic patients may benefit from surgical intervention.
2. PHPT can be complicated by osteoporosis and fractures; by nephrolithiasis, nephrocalcinosis and reduced renal function; by peptic ulcer disease and by psychiatric disturbance.
3. Hypoparathyroidism is diagnosed in the setting of hypocalcemia with low or inappropriately normal PTH; serum magnesium should be measured and hypomagnesemia corrected before the diagnosis is confirmed. The most common aetiology of hypoparathyroidism is post-surgical.
4. Hypoparathyroidism requires careful assessment for complications of over- or under-treatment with monitoring of serum and urinary calcium and imaging in certain patients; it is associated with reduced quality of life.
5. Genetic disorders which predispose to parathyroid pathology including parathyroid carcinoma have been identified in recent years; consideration of genetic screening in younger patients, those with family histories suggestive of a genetic endocrinopathy (e.g. MEN) and those with atypical presentations or atypical parathyroid histology should be considered as a positive result may change clinical follow-up.

Acknowledgements Special thanks to Liz Glenister, Chief Executive Officer, HypoparaUK (www.hypopara.org.uk), for her contribution to this chapter with case studies, patient resources, and information on the Patient Advocacy Group.

Abstract

The plasma levels of calcium and inorganic phosphate are controlled by homeostatic mechanisms. The plasma level of calcium is particularly tightly controlled. Parathyroid hormone (PTH) raises calcium via actions on: bone cells (osteoclasts and osteocytes) to promote mineral resorption; the renal distal tubule to enhance calcium reabsorption; and renal proximal tubule cells to promote 1,25-dihydroxyvitamin D synthesis. Calcium-sensing receptors lower calcium dependent on plasma membrane expression in cells of: the parathyroid gland to suppress PTH secretion and thus serum PTH levels; the renal cortical thick ascending limb to promote urinary calcium losses; and other tissues including thyroid calcitonin-secreting C-cells and osteoclasts. Hypocalcaemia arises as a consequence of a failure of one of the normal homeostatic mechanisms that act to raise the plasma calcium level. Hypocalcaemia may be symptomatic or asymptomatic. Key early clinical features of hypocalcaemia include perioral or peripheral paresthesiae or numbness, and various manifestations of neuromuscular excitation including carpo-pedal spasm. Later, more severe manifestations of hypocalcaemia include convulsions, including febrile convulsions in children. Dietary calcium requirements for adults are around 1–1.5 g/day, reflecting relatively low levels of intestinal absorption efficiency, even in vitamin D replete individuals. Calcium supplements are of particular benefit in patients with osteoporosis on anti-resorptive medications, which impair calcium release from bone, thereby promoting the risk of hypocalcaemia. Hypercalcemia arises as a consequence of a failure of one or more of the normal homeostatic mechanisms that act to lower the plasma calcium level.

Keywords

Calcium metabolism · Calcium-sensing receptor · Hypercalcemia · Hypocalcaemia Hypophosphatemia · Parathyroid hormone Phosphate metabolism

Abbreviations

ADH	Autosomal dominant hypocalcaemia
ATP	Adenosine 5′-triphosphate
CaSR	Calcium-sensing receptor
DXA	Dual energy Xray absorptiometry
FGF-23	Fibroblast growth factor-23
FHH	Familial hypocalciuric hypercalcemia
NSHPT	Neonatal severe hyperparathyroidism
PTH	Parathyroid hormone

Key Terms

- **Hydroxyapatite:** is a key bone mineral composed of Calcium and phosphate.
- **Ionized calcium:** is free calcium in blood that is not attached to proteins.
- **Calcium sensing receptor:** regulates calcium metabolism by regulating parathyroid hormone secretion and urinary calcium excretion.
- **Osteomalacia:** an end-stage bone disease of chronic and severe vitamin D or phosphate depletion of any cause.

Key Points

- Bone is composed of collagen protein fibres strengthened by a mineral phase. Calcium and inorganic phosphate are the two key chemical components of bone mineral, also known as crystalline hydroxyapatite.
- Calcium ions via both the extracellular and several intracellular pools are critical for various important cell functions including interactions between key proteins. Inorganic phosphate ions are also critical for normal cell function.
- The metabolisms of calcium and inorganic phosphate are subject to homeostatic control mechanisms. One key element of the control mechanism is parathyroid hormone (PTH) from the parathyroid gland, which elevates the plasma calcium concentration and suppresses the plasma phosphate concentration. The calcium-sensing receptor lowers the plasma calcium concentration by mediating negative feedback control of PTH secretion and promoting urinary calcium excretion.
- Vitamin D exists in several forms in the body, primarily as metabolites of vitamin D_3 (cholecalciferol). 25-Hydroxyvitamin D is the primary circulating form and is used to assess the whole body vitamin D store. 1,25-Hydroxyvitamin D is the active hormonal form, which stimulates calcium absorption from the small intestine and renal distal tubule.
- Disorders of calcium metabolism leading to hypercalcemia or hypocalcaemia arise from disturbances of the homeostatic mechanisms.

51.1 Introduction

Calcium and phosphate are the two main components of the key bone mineral, hydroxyapatite. In addition, the extracellular ionised Ca^{2+} concentration is a key determinant of neuromuscular excitability and is required for coagulation, and control mechanisms that up- or down-regulate the intracellular Ca^{2+} concentration drive or suppress key cell functions including muscle contraction and the secretion of key hormones including insulin and even digestive enzymes. Inorganic phosphate, on the other hand, plays major roles in reactions that are critical for human biochemistry acting, for example, to enable the storage of chemical energy as ATP, facilitate many of the reactions of intermediary metabolism, and shift the activation states of enzymes and proteins via reversible phosphorylation. For these reasons, the plasma levels of both calcium and phosphate are subject to tight regulation. The plasma ionised Ca^{2+} concentration is subject to particularly tight control. In this chapter, we consider the normal plasma levels of both calcium and phosphate as well as causes of disturbances in their levels, focusing in particular on key mechanisms that underlie hyper- and hypocalcaemia.

51.2 Calcium and Phosphorus Metabolism and Testing

51.2.1 Calcium

The normal range for the plasma total calcium concentration in humans is around 2.2–2.6 mmol/L, distributed between three major fractions:

1. One in which calcium is bound to plasma proteins, chiefly albumin (representing around 45%).
2. One taking the form of filterable complexes including calcium citrate (around 5%).
3. A free, ionised fraction (i.e. Ca^{2+} ions; around 50%).

As a result the normal range for plasma ionised Ca^{2+} concentration, which may be measured by a suitable Ca^{2+}-selective electrode, is 1.1–1.3 mmol/L. It is the ionised Ca^{2+} concentration that controls the coagulation cascade and modulates cell and tissue function. For example, low extracellular Ca^{2+} concentration enhances excitability at the neuromuscular junction. Thus, any factor that perturbs the ionised Ca^{2+} concentration can perturb cell function. One important factor is a change in pH leading to a change in Ca^{2+} binding to albumin; an increase in pH increases Ca^{2+} binding to albumin and thereby acutely lowers the ionised Ca^{2+} concentration. A drop in the plasma albumin concentration is typically accompanied by a drop in the total plasma calcium concentration so that the ionised Ca^{2+} concentration does not change.

The ionised Ca^{2+} concentration is protected by several key factors (review: Brown and MacLeod 2001):

1. Ca^{2+} ion sensing by cells of the parathyroid gland to suppress the secretion of a peptide hormone parathyroid hormone (PTH) that promotes calcium transfers into the extracellular fluid and, thus, the blood.
2. Ca^{2+} ion sensing by cells of the thick ascending limb of the renal tubules to suppress Ca^{2+} reabsorption from the tubular fluid.
3. Ca^{2+} ion sensing by parafollicular C-cells of the thyroid to activate the secretion of a peptide hormone, calcitonin that suppresses osteoclastic-dependent bone resorption.
4. Ca^{2+} ion sensing by the proximal tubule to suppress the synthesis of 1,25-dihydroxyvitamin D_3.

51.2.2 Phosphate

The plasma inorganic phosphate concentration lies in the range 0.8–1.4 mmol/L present as the free ion distributed between two main species HPO_4^{2-} and $H_2PO_4^-$, dependent upon the pH. At normal plasma pH 7.40, the ratio of HPO_4^{2-}:$H_2PO_4^-$ is around 5:1. The ratio falls as the pH drops and increases as the pH rises. $CaHPO_4$ is poorly soluble and, as might be expected, the problem is exacerbated at high pH as the concentration of HPO_4^{2-} increases.

Table 51.1 Causes of hypophosphatemia

Primary disturbances of mineral metabolism
1. Acquired
• Primary hyperparathyroidism
• Vitamin D deficiency
2. Inherited
• Autosomal dominant hypophosphatemic rickets (mutant stable form of FGF-23)
• X-linked (dominant) hypophosphatemic rickets (mutant PHEX; defective negative regulation of FGF-23 production)
• X-linked recessive hypophosphatemic rickets (various forms including mutations in renal Na-phosphate co-transporters)
Nutritional causes
• Acute alcoholism
• Refeeding after prolonged under nutrition
• Diabetic ketoacidosis (recovery phase)
Miscellaneous
• Severe burns
• Diuretic use

51.2.3 Disorders of Phosphate Metabolism

Hypophosphatemia is associated with proximal myopathy and cardiomyopathy. It is also associated with various forms of rickets and osteomalacia. Hypophosphatemia arises in some important nutritional disorders. A number of inherited and acquired conditions are also associated with hypophosphatemia (see Table 51.1).

Hyperphosphatemia typically occurs in chronic kidney disease and contributes to vascular mineralisation and associated peripheral, coronary and cerebral vascular disease. In this setting, the plasma calcium level may be low. Hyperphosphatemia also occurs in hypoparathyroidism and parathyroid hormone resistance states (pseudohypoparathyroidism) as well as disorders of FGF-23 metabolism, in which the serum levels of FGF-23 are suppressed and the serum levels of 1,25-dihydroxyvitamin D are elevated (review: Conigrave 2012).

51.3 Dietary Calcium and Calcium Supplementation

Dietary calcium intakes vary considerably dependent on dietary composition. Foods rich in calcium include various dairy products including

Table 51.2 Calcium-rich foods

• Dairy products (including milk, yoghurt, cheese and ice cream)
• Salmon or sardines (containing edible bones)
• Tofu (set with calcium salts)
• Almonds
• Broccoli, cabbage, soy-beans, tahini (sesame seeds), bok-choy, celery
• Dried figs, dried apricots, oranges

whole milk, skim milk, yoghurt and cheese. Some forms of fish, nuts, vegetables and fruit are also rich sources of calcium (see Table 51.2).

Recommended daily allowances of calcium are based on balance studies and suggest that optimal calcium intakes are around 1.0 g/day during childhood and around 1–1.5 g/day during adolescent growth, and during pregnancy and lactation. Lower calcium intakes are required in adult men and in women post-lactation and in the peri- and postmenopausal stages but are still around 1.0 g/day. The relatively high levels of recommended calcium intake reflect, in part, the low efficiency of intestinal calcium absorption, which is around 10–20% even when vitamin D levels are replete (Conigrave 2012).

Until recently, almost all patients, men and women, with osteoporosis have been prescribed both calcium and vitamin D supplements at doses of around 1.0–2.0 g/day and 1000–2000 IU/day, respectively. In the presence of anti-resorptive therapy with one of the oral or intravenous bisphosphonates, subcutaneous denosumab, selective estrogen receptor modulator (SERM) raloxifene or even oestrogen therapy, the benefits of supplementation with calcium and vitamin D are relatively straightforward. They prevent the development of acute symptomatic hypocalcaemia. Hypocalcaemia can develop in this setting as a result of anti-resorptive-induced impairment of osteoclastic bone resorption and the unopposed formation and mineralisation of new bone. In patients taking anti-resorptive therapy, increased intakes of calcium and vitamin D prevent acute hypocalcaemia by increasing the amount of calcium absorbed by the small intestine each day.

In the absence of anti-resorptive therapy, the value of calcium and vitamin D supplements in adults is less certain and benefits in terms of improved bone mineral density and muscle mass and function are at best modest. Two additional circumstances in which calcium and vitamin D supplements should be considered even in the absence of therapy with anti-resorptive agents are:

1. Low serum vitamin D levels (<40 nmol/L). Defining the normal range for serum 25-hydroxyvitamin D_3 in adults has proved difficult. However, the risk of osteomalacia increases markedly at serum concentrations below 30 nmol/L and serum PTH levels are suppressed at serum 25-hydroxyvitamin D_3 levels up to 80 nmol/L.
2. Evidence of secondary hyperparathyroidism and high bone turnover (high serum PTH in the presence of a low plasma calcium concentration with elevated bone turnover markers including the pro-collagen breakdown product P1NP and ostase reporting bone formation and the plasma CTX and urinary level of deoxypyridinoline cross-links reporting bone resorption).

51.4 Hypocalcaemia

51.4.1 Diagnosis of Hypocalcaemia

Two main sources of information are: (1) the plasma calcium levels reported by the biochemistry laboratory and (2) the patient's clinical state. The former requires careful consideration of key related information including the plasma albumin concentration and plasma pH. The latter can be somewhat unpredictable: patients who experience a relatively small but acute drop in plasma calcium concentration can be symptomatic and exhibit many of the clinical features of hypocalcaemia. On the other hand, patients with long-standing moderate-severe hypocalcaemia can be asymptomatic or only mildly symptomatic and display only modest clinical features indicating that appropriate physiological adjustments are made in the presence of persistently low calcium levels (Brown and MacLeod 2001).

The clinical features of hypocalcaemia include enhanced neuromuscular excitability including fasciculations and tetanic contractions of isolated muscle groups, which may be either spontaneous or elicited by tapping directly over nerves, e.g. the facial nerve at the angle of the mandible

(Chvostek's sign), or by inflating a blood pressure cuff to a level above the systolic pressure for 2–3 min to induce local hypoxemia (Trousseau's sign). Other clinical features include perioral or peripheral numbness, bronchospasm and even convulsions.

51.4.2 Laboratory Contribution to Diagnosis of Hypocalcaemia

As noted above, hypocalcaemia is defined by two ranges: one for plasma total calcium concentration (2.2–2.6 mmol/L) and one for plasma ionised Ca^{2+} concentration (1.1–1.3 mmol/L). In terms of pathophysiological significance, a low ionised Ca^{2+} concentration is more important but assays for ionised Ca^{2+} are not always available. In the presence of hypoalbuminemia (e.g. in the context of uncompensated chronic liver disease), the plasma ionised Ca^{2+} concentration is frequently normal despite the presence of a low plasma total calcium concentration. This arises from a significant reduction in the plasma protein calcium binding capacity. To confirm that the plasma calcium concentration is normal in this setting either (1) the plasma ionised Ca^{2+} concentration can be measured and/or (2) a correction can be made to the total calcium concentration using an appropriate formula (Payne et al. 1973).

An example of such a formula is as follows:

$$\text{Plasma total Ca}\left(\text{corrected; mmol / L}\right) = \text{plasma total Ca}\left(\text{measured; mmol / L}\right) + [0.025\ \text{mmol / g} \times \left(40\text{g / L}^{*} - \text{plasma albumin concentration g / L}\right]).$$

* plasma albumin concentration (mid-normal range)

In a case in which a plasma total calcium concentration was 2.0 mmol/L, for example, the value would be hypocalcemic if the plasma albumin concentration was in the mid-normal range, around 40 g/L. However, in the presence of a low plasma albumin concentration (30 g/L), the corrected plasma total calcium concentration would be 2.25 mmol/L, i.e. normal.

51.4.3 Causes of Hypocalcaemia

The most common cause of acute hypocalcaemia is post-operative hypoparathyroidism, typically in the context of major thyroid surgery. Untreated, the plasma total and ionised calcium concentrations both drop, typically into the plasma total calcium range 1.8–2.0 mmol/L (ionised 0.9–1.0 mmol/L) and the patients exhibit acute symptoms and clinical features of hypocalcaemia. Other causes of hypocalcaemia are provided in Table 51.3.

51.5 Hypercalcemia

As noted above, the normal range for the plasma total calcium concentration is 2.2–2.6 mmol/L (8.8–10.2 mg/dL). Therefore, hypercalcemia is defined by a total calcium concentration >2.6 mmol/L and an ionised Ca^{2+} concentration >1.3 mmol/L. The clinical features of mild hypercalcemia include lethargy, anorexia and constipation. More severe features include muscle weakness, abdominal pain that may be associated

Table 51.3 Causes of hypocalcaemia

Nutritional or metabolic
• Severe vitamin D deficiency
• Chronic kidney disease
Parathyroid dysfunction
• Hypoparathyroidism (surgical or primary)
• Autosomal dominant hypocalcaemia
• PTH resistance states (pseudohypoparathyroidism)

Milk Alkali syndrome
Pituitary/adrenal failure

with peptic ulcer disease or pancreatitis, polyuria, and even confusion, convulsions and coma.

In practice, there are two main clinical scenarios according to whether the serum PTH concentration (normal range 1–6 pmol/L) is elevated. If the serum PTH level is elevated, the patient has primary hyperparathyroidism (see Chap. 47) due most commonly to a benign adenoma of a single parathyroid gland (see Table 51.4). If the serum PTH is normal or low, the patient has one of a relatively large number of uncommon causes of hypercalcemia (see Table 51.5). Appropriate investigations for hypercalcemia in the context of (1) raised or (2) normal or low serum PTH levels are provided in Box 51.1 and Box 51.2, respectively. Immobilisation and dehydration can exacerbate hypercalcemia in various contexts including primary hyperparathyroidism.

Box 51.1 Investigations for Hypercalcemia Associated with Elevated Serum PTH Levels

Plasma biochemistry: sodium, potassium, calcium, phosphate, bicarbonate, creatinine, 25-hydroxyvitamin D_3

Urine biochemistry: calcium: creatinine (Ca/Cr ratio)

Serum hormones: PTH

Bone density: DXA

Imaging for parathyroid tumour: Sestamibi scan (neck and thorax); Ultrasound of neck; 4D CT scan (neck and mediastinum)

Box 51.2 Investigations for Hypercalcemia Associated with Normal or Low Serum PTH Levels

Plasma biochemistry: sodium, potassium, calcium, phosphate, bicarbonate, creatinine, 25-hydroxyvitamin D_3. 1,25-dihydroxyvitamin D_3, Angiotensin Converting Enzyme (ACE), ACTH, Cortisol

Urine biochemistry: calcium: creatinine (Ca/Cr ratio)

CXR: granulomas or tumour

Bone density: DXA

51.5.1 Familial Hypocalciuric Hypercalcemia

Familial Hypocalciuric hypercalcemia (FHH) is an uncommon condition that should be considered in patients who present with mild-moderately severe hypercalcemia (total plasma calcium 2.7–3.0 mM) and serum PTH levels that are either normal or at the upper limit of normal. The calcium disturbance is typically benign and does not require medical or surgical intervention. It arises in the context of hyperplasia of all four parathyroid glands. Parathyroid surgery is not indicated. Two key disturbances of calcium metabolism are: (1) impaired inhibitory feedback control of PTH secretion and (2) impaired inhibitory control of renal calcium reabsorption. The elevated serum PTH level arises from impaired calcium-sensing receptor-mediated inhibition of PTH secretion from the parathyroid glands. Hypocalciuria (most easily assessed as the

urinary calcium: creatinine ratio) arises from impaired calcium-sensing receptor (CaSR)-mediated inhibitory control of renal calcium reabsorption. The inappropriately elevated serum PTH concentration and enhanced rate of renal calcium reabsorption act together to raise the plasma calcium concentration. Most commonly, impaired calcium-sensing receptor function in FHH arises from an inactivating mutation of the receptor (Brown et al. 1998).

51.5.2 Forms of FHH That Do Not Arise from Mutations of the CaSR

Recently, two additional genes have been linked to FHH: the alpha subunit of G11 (FHH2) and the sigma subunit of the endosomal sorting protein AP2 (FHH3) (Hannan et al. 2016). FHH has also been described in the context of circulating anti-CaSR antibodies that suppress receptor function.

51.6 Other Disorders of the Calcium-Sensing Receptor

51.6.1 Neonatal Severe Hyperparathyroidism (NSHPT)

Whereas FHH typically arises in individuals who are heterozygous for inactivating mutations of the CaSR, individuals that are, very rarely, homozygous or compound heterozygous for inactivating mutations of the CaSR present early in postnatal life with severe hypercalcemia (plasma total calcium >3.5 mmol/L) and markedly elevated serum PTH concentrations arising from near total failure of Ca^{2+}-dependent feedback control of PTH secretion. This disorder, neonatal severe hyperparathyroidism (NSHPT), requires early four gland parathyroidectomy to correct the disturbance in calcium metabolism, reverse skeletal demineralisation and prevent pathological fractures in the first weeks of life.

51.6.2 Autosomal Dominant Hypocalcaemia

Autosomal dominant hypocalcaemia (ADH) arises from heterozygous activating mutations of the CaSR, which promote renal Ca^{2+} excretion and inappropriately suppress PTH secretion in the context of hypocalcaemia (Brown et al. 1998). Plasma total calcium concentrations typically fall into the range 1.0–1.8 mmol/L (plasma ionised Ca^{2+} 0.5–0.9 mmol/L). Untreated, this condition is usually benign and patients typically report only mild symptoms of hypocalcaemia. Some will report a history of one or more episodes of childhood convulsions. In asymptomatic adults, correction of the plasma calcium concentration into the normal range is not required and is potentially very harmful. Aggressive treatment with oral calcium supplements and active forms of vitamin D such as calcitriol (1,25-dihydroxyvitamin D_3) to restore the plasma calcium to normal, results in marked elevations in renal calcium and phosphate excretion, nephrocalcinosis and associated chronic kidney disease. Some patients treated in this way progress to dialysis and even renal transplantation. For this reason, it is generally accepted that the plasma calcium concentration in patients with ADH should be adjusted, if possible with calcium salts alone, to lie just below the normal range, e.g. between 1.8 and 2.0 mmol/L.

51.6.3 A Form of ADH That Does Not Arise from Mutations of the CaSR

Recently, activating mutations of the alpha subunit of the G-protein G_{11} have been linked to a form of ADH (ADH2) (Hannan et al., 2016).

51.7 Hypercalcemia of Malignancy

51.7.1 Hypercalcemia in the Context of Bone Metastases

Hypercalcemia occurs in the context of osteolytic metastases from various cancers including notably breast cancer and certain forms of leukemia. It arises primarily from markedly enhanced osteoclastic bone resorption in response to cytokines released by the tumour cells in the bone microenvironment. In this context hypercalcemia responds to anti-resorptive therapy, e.g. with the bisphosphonates pamidronate or zoledronate. A similar situation arises in patients with multiple myeloma, a malignancy of plasma cells that arises in the bone marrow and drives enhanced osteoclastic bone resorption.

51.7.2 Humoral Hypercalcemia of Malignancy

In addition to the impact of cancer cells via locally derived cytokines to drive osteoclastic bone resorption in the bone microenvironment, enhanced bone resorption also arises in response to certain cancers that do not metastasise to bone. In these cases (e.g. associated with certain squamous cell carcinomas, renal carcinoma, carcinoma of the ovary, and some lymphomas) markedly enhanced production of cytokines by tumour cells converts peptides that have restricted local roles in certain tissues under normal physiological conditions to factors with endocrine effects. One of these, parathyroid hormone related protein (PTHrP) induces osteoblast-dependent osteoclastic bone resorption via type-1 PTH receptors on osteoblasts (McCauley and Martin 2012). In part, the mechanism involves enhanced osteoblast expression of RANK-ligand and decreased expression of its decoy receptor osteoprotegerin. Under these conditions, RANK-ligand induces osteoclastogenesis, a process in which the number of mature bone-resorbing osteoclasts markedly increases together with the bone-resorbing surface.

51.8 Calcium Disorders in Renal Disease

As chronic kidney disease (CKD) develops there is progressive loss of glomerular filtration, disturbances of renal tubular function and impaired synthesis of key hormones including 1,25 dihydroxyvitamin D_3 and erythropoietin. Elevated plasma phosphate concentration is one early mineral disturbance that arises in the context of the CKD and the plasma phosphate level continues to rise as renal function deteriorates. This is partially offset by increases in the serum FGF-23 and PTH concentrations, at least initially, since FGF-23 and PTH both promote renal phosphate excretion (Uribarri 2007). The plasma calcium concentration is normal initially but falls as the disorder progresses. This promotes the development of secondary hyperparathyroidism, which takes the form of markedly elevated serum PTH levels, including intact PTH as well as various inactive C-terminal fragments, and hyperplasia of all four parathyroid glands. The low plasma calcium concentration, low serum 1,25-dihydroxyvitamin D_3 concentration, high serum PTH levels, and retention of toxic N-containing metabolites, act together to promote the development of renal osteodystrophy, a form of skeletal disease with features of osteoporosis and osteomalacia. Cinacalcet, a positive modulator of the calcium-sensing receptor is used to lower serum PTH levels in CKD to reduce the severity of renal osteodystrophy and reduce bone resorption. To avoid the development of inappropriately low bone turnover rates and thus reduced bone formation rates and repair (‘frozen bone’), the doses of cinacalcet are selected to lower serum PTH concentrations to around 100 pmol/L but not lower. In some CKD patients, hypercalcemia develops late in the disorder (tertiary hyperparathyroidism). In some cases, this arises due to uncontrolled hyperplasia of all four parathyroid glands. In others, single parathyroid adenomas develop.

51.9 Milk Alkali Syndrome

This condition arises typically in the context of high oral dosing with calcium carbonate salts (calcium intakes >4 g/day) (Medarov, 2009). The prevalence of the condition has fallen due to the replacement of calcium carbonate antacids with histamine H_2 receptor antagonists, proton pump inhibitors, and anti-*Helicobacter pylori* antibiotic therapy in the treatment of peptic ulcer disease.

Key features of the condition are hypercalcemia, which can be severe (plasma total calcium concentration >3.0 mmol/L), high plasma bicarbonate levels (>35 mmol/L), alkalosis (arterial or venous pH >7.5), low plasma chloride levels, and renal impairment (plasma creatinine >120 μmol/L). Plasma inorganic phosphate levels are normal rather than low, thereby enhancing the conditions for ectopic mineralisation, and renal calcium excretion levels are inappropriately normal or low, thereby promoting hypercalcemia. Serum PTH and 1,25-dihydroxyvitamin D_3 levels are typically low. The condition may present either acutely or chronically. While the link to the ingestion of both calcium and alkaline salts is clear, the pathogenesis is not well understood. High pH promotes small intestinal Ca^{2+} absorption via the epithelial Ca^{2+} channel Trpv6 and renal Ca^{2+} reabsorption via the epithelial Ca^{2+} channel Trpv5. In addition, high plasma Ca^{2+} levels are reported to suppress glomerular filtration and to promote proximal tubular reabsorption of water and bicarbonate. Finally, chronically elevated plasma concentrations of calcium and bicarbonate together promote the deposition of calcium salts in various tissues including the arterial system, the brain, various structures in the eye including the cornea and lens, and in the kidneys (nephrocalcinosis). Nephrocalcinosis can progress to end-stage renal failure requiring dialysis or renal transplantation.

51.9.1 Management

The approach is relatively simple:

- Stop the calcium and alkaline salts.
- Promote hydration.
- Use frusemide to induce calciuresis if the plasma calcium level is markedly elevated.

In acute cases, the renal function can completely recover. In chronic cases, renal function may be permanently impaired and progression to end-stage kidney disease may occur.

51.10 Nursing Process

51.10.1 Assess

Evaluate all aspects of patient health status, including aspects relating to health promotion, protection and disease prevention, as well as signs and symptoms of calcium disorders.

Hypocalcaemia

– Take a detailed medical history, including specific questions on recent thyroid surgery, osteoporosis and a family history of known calcium disorders or parathyroid dysfunction.
– Assess patient's nutritional state and dietary intake of calcium or vitamin D, sun exposure or recent use of anti-resorptive therapy.
– Inquire about enhanced neuromuscular excitability including fasciculation and tetanic contractions of muscles.
– Examine clinically relevant signs, such as fasciculation and tetanic contractions of isolated muscle groups, by tapping directly over the facial nerve at the angle of the mandible (Chvostek's sign) or by inflating a blood pressure cuff to a level above the systolic pressure for 2–3 min to induce local hypoxemia (Trousseau's sign).

Hypercalcemia

– Assess first on symptoms, especially confusion and lethargy as they are signs of sudden-onset and severe hypercalcemia effecting the nervous system (acute care is needed!)
– Take a detailed medical history including specific questions on kidney stones, chronic kidney disease or renal insufficiency, malignancies and a family history of known calcium disorders.

- Assess patient's nutritional state and dietary intake of calcium or vitamin D and use of supplements or use of calcium and alkaline salts.
- Assess on the mnemonic 'stones, bones, abdominal moans, and psychic groans' (kidney stones, osteoporosis or fractures, pain in abdomen, obstipation and/or depression (and use of lithium)).
- Inquire about urine output, fluid intake and increased thirst.
- Examine clinically relevant signs such as hypotonic muscles, weight loss, dehydration, faecal impaction (from constipation), arrhythmias and or hyper/hypotension.

51.10.2 Diagnose

Work collaboratively to plan appropriate screening tests based on recommendations in patients presenting with calcium disorders.

- Identify patient knowledge on deficits as areas for therapeutic education.
- Ensure appropriate, accurate collection of urine or blood samples for diagnostic or evaluation purpose.
- Ensure appropriate guidance if there is a suspicion of a malignant disease.
- Collaborate with endocrine colleagues to determine if treatment is conform evidence-based guidelines.
- Facilitate additional specialist referrals as needed.

51.10.3 Plan

Interpret test results, recognise abnormal findings and help communicate results and implications to the patient and family.

- Provide disease-specific education to the patient on the long-term effects of the diagnosis and management.
- Advise patient of risks and benefits associated with the various treatment options, including medical and surgical management, and engage the patient in shared decision-making.
- Monitor calcium levels, encourage taking oral fluids, weight-bearing exercises and smoking cessation.
- Instruct what symptoms to report.
- Discuss the expectations of the therapeutic interventions on patient related outcome (what are the patients goals of the treatment) and explain the medical goals.
- Identify patient resources including websites, refer to patient support groups if appropriate.

51.10.4 Implement

Initiate treatment and inform the patient of appropriate monitoring and follow-up.

- Provide therapeutic education (holistic approach) to ensure comprehension of the effects of the diagnosis and management.
- Provide education, support and practical arrangements regarding pre- and post-operative care, make additional referrals as needed (e.g. pre-operative assessment).
- Provide emotional support to patient and family based on condition-specific psychological issues.
- Teach proper administration of medication.
- Plan and coordinate initial and subsequent follow-up appointments.

51.10.5 Evaluate

Assess the effectiveness of interventions and revise the plan of care as appropriate.

- Evaluate biochemical response to treatment.
- Inquire about potential unwanted side effects of the treatment.
- Monitor adherence and compliance to the treatment.
- Assess actual and potential effects on patient-reported outcomes (patients goals, medical goals).
- Monitor for other psychological comorbidities (e.g. anxiety, depression) and coping behaviours.

– Monitor condition-specific issues such as constipation, abdominal pain and fractures.
– Evaluate dietary fluid and calcium intake.
– Evaluate achievement of goals regarding weight-bearing exercises and cessation of smoking.

Case Study Hypercalcemia

A 53-year-old postmenopausal woman who experienced a distal radius fracture was referred to the Fracture Liaison Service (FLS) for investigation of increased fracture risk due to osteoporosis. As part of the screening a DXA scan was performed. She had a consultation with a FLS nurse who took a detailed medical history, explained the results of the DXA scan, assessed the risk for fractures and inquired about other health problems.

Medical history: Kidney stones. Mild depression. Mild hypertension.

Patient-reported health problems: obstipation, dry mouth, anxiety attacks and fear of falling.

Risk factors for fracture (non-modifiable) are:

– Recent fracture
– Age > 50 years
– Mother with hip fracture

Modifiable risk factors:

– Sedentary lifestyle
– Smoking

The results of the DXA scan:

Lumbar spine L1–L4	*T* score −3.2
Femoral neck	*T* score −2.6
Vertebral fracture assessment (Th4-L5)	No significant vertebral fractures

Diagnosis conform WHO criteria: Severe osteoporosis

The nurse explains the implications of having an increased fracture risk and the need for further investigation. She orders a chemistry panel to screen for underlying causes of osteoporosis, including: electrolytes, 25OH vitamin D, Serum calcium, Albumin, Creatinine, PTH, TSH, Alkaline phosphatase and Serum phosphate. And refers the patient to the endocrinologist (who is participating in the FLS programme).

Lab results:

Electrolytes, albumin, creatinine, TSH: within normal range
25OH vitamin D: 97 nmol/L,
Serum calcium: 2.93 mmol/L
PTH: 17 pmol/L
Alkaline phosphatase: 130 IU/L
Serum phosphate: 2.6 mg/dL

Additional investigation of calcium excretion in 24H urine sample shows increased levels of calcium. Physical investigation shows no abnormalities besides a mild hypertension. There are no signs of malignant diseases.

These results suggest primary hyperparathyroidism.

The next step in the diagnostic process is to perform a sestamibi scan and an ultrasound. These diagnostic imaging tests show hyperplasia of one of the parathyroid glands diagnosed as a solitary parathyroid adenoma.

Because there is a symptomatic primary hyperthyroidism and (secondary) osteoporosis, the patient is referred to the head-neck surgeon who performs an extirpation of the parathyroid gland. The PTH levels normalise completely after surgery. The osteoporosis is treated with a weekly dosed oral bisphosphonate.

The patient experienced difficulties coping with these three diagnoses (fracture, osteoporosis and hyperparathyroidism) and their treatment (surgery, medication). Although she was thankful for finding the probable cause of multiple health problems, it was a lot to deal with. The patient is guided by a Nurse Practitioner (NP) who provides practical and emotional support. Three months after surgery the patient reports an increased quality of life and is completely symptom free. The patients next challenges are cessation of smoking and staying compliant to the bisphosphonates.

51.11 Conclusions

Calcium and phosphate are subject to homeostatic control mechanisms due to their importance as key chemical components of the bone mineral hydroxyapatite and key roles as important ionic species in physiologically important cell functions. In plasma calcium is present in three main forms, its ionised form Ca^{2+} (normally around 50% of the total), an albumin-bound form that is pH-sensitive (around 45% of the total), and as complexes with small organic molecules such as citrate (around 5% of the total). For this reason, the ionised Ca^{2+} concentration (normal range 1.1–1.3 mM) is only around half of the total plasma calcium concentration (normal range 2.2–2.6 mM). Inorganic phosphate is present in plasma in two main forms, the dibasic form HPO_4^{2-} and the monobasic form $H_2PO_4^-$ in a ratio of around 5:1 at physiological pH, 7.4. The calcium concentration in plasma is tightly regulated dependent on the operation of calcium-sensing receptors (CaSRs) in the parathyroid gland and in several tubular segments in the kidneys. The key role of CaSRs in both parathyroid and kidney is to lower the plasma calcium concentration. The key role of PTH is to prevent and/or correct hypocalcaemia. Once activated, the key role of vitamin D is to promote calcium and phosphate absorption from the intestine and to promote calcium reabsorption from the kidneys. The daily requirements of calcium approximate 1.0 g for adults but this increases in certain circumstances, e.g. pregnancy and lactation.

There are a large number of causes of hypocalcaemia and hypercalcemia. Careful investigation is required to identify the cause and select an appropriate plan of management. In general, acute disturbances of the plasma calcium concentration require early intervention. Acute *hypocalcaemia* arises chiefly in the context of thyroid or parathyroid surgery due to the inadvertent removal/damage of normal parathyroid tissue, or in the context of anti-resorptive therapy in patients with osteoporosis, who are vitamin D deficient (serum 25-hydroxyvitamin D <40 nmol/L). Acute pancreatitis is another important cause. Acute *hypercalcemia* arises in the context of malignancy (bone metastases or HHM), vitamin D toxicity and milk alkali syndrome. Factors that can exacerbate hypercalcemia include immobilisation, dehydration and treatment with thiazide diuretics.

Abstract

Congenital and acquired bone disorders generally increase the risk of low trauma fractures due to their impact on the formation and maintenance of bone microarchitecture. Bone deformity can also develop which can result in symptoms such as pain. The formation of the collagen bone matrix can be disrupted, as in osteogenesis imperfecta (OI) or replaced in focal areas by fibrous tissue, as seen in fibrous dysplasia. Alternatively the mineralization of the bone matrix can be affected in conditions such as rickets or there could be marked changes in bone turnover, as in Paget's disease and osteopetrosis. Chronic kidney disease-mineral and bone disorder can manifest as a wide spectrum of bone abnormalities ranging from low to high turnover states, impaired mineralization of bone, and or reduced bone volume.

The diagnosis of congenital and acquired bone disorders is made through a combination of clinical, radiological, genetic, and laboratory investigations. Management may simply involve vitamin D replacement in the case of rickets, or may involve anti-resorptive therapy to decrease bone turnover, improve bone strength, and reduce pain. Management may be symptompatic if there is no known cure. This chapter is a review for endocrine nurses, providing a summary of congenital and acquired bone disorders and the potential role of nurses in the care of these patients.

Keywords

Bone fragility · Anti-resorptive therapy Monostotic · Polyostotic · Osteoid mineralization · Bone deformity

Abbreviations

AD	Autosomal dominant
ALP	Alkaline phosphatase (bone marker)
AR	Autosomal recessive
BMD	Bone mineral density
CKD	Chronic kidney disease
COL1A	Mutation in the alpha chains of collagen gene
FD	Fibrous dysplasia
GFR	Glomerular filtration rate
HSCT	Hematopoietic stem cell transplantation
IPMN	Intra-ductal pancreatic mucinous neoplasia
MAS	McCune–Albright Syndrome
OI	Osteogenesis imperfecta
PTH	Parathyroid hormone

Key Terms

- **Chronic Kidney Disease-Mineral and Bone Disorders**: mineral and bone abnormalities associated with chronic kidney disease.
- **Fibrous dysplasia**: an excessive formation of fibrous tissue in bone marrow and destruction

of normal bone in conjunction with abnormal bone formation and increased osteoclast activity.
- **McCune-Albright syndrome**: triad of fibrous dysplasia of bone, endocrine hyperfunction and café-au-lait skin hyperpigmentation.
- **Osteogenesis imperfecta**: genetic disorder of increased bone fragility and low bone mass.
- **Osteopenia**: is a loss of bone mass by bone densitometry and expressed as a *T* score −1 to −2.0.
- **Osteopetrosis**: genetic condition characterized by increased bone mass.
- **Osteoporosis**: is a loss of bone mass by bone densitometry and expressed as a *T* score >−2.0.
- **Paget's disease**: disease with marked increase in bone turnover in localized part of skeleton.
- **Rickets**: Disorder of mineralization of the bone matrix.

Key Points
- Bone is a metabolically active tissue that responds to congenital and environmental triggers in various ways.
- Bone disorders, whether congenital or acquired usually result in increased bone fragility, potential bone deformity, and an increased risk of fractures.
- Rickets is an example of an acquired bone disorder which results from a deficiency of vitamin D and is mostly preventable.
- Osteogenesis imperfecta is a congenital bone disorder of increased bone fragility and low bone mass, with a broad clinical phenotype, depending on the genes involved.

52.1 Part A: Congenital and Acquired Bone Disorders in Adults

52.1.1 Introduction

The skeleton is a metabolically active unit, which is critical for an individual to maintain optimal health. It consists of acellular components, i.e., the bone matrix (collagen), mineral (hydroxyapatite) and cellular components, i.e., osteoblasts, osteoclasts, and osteocytes, which all interact to culminate in an integrated unit that functions to protect organs and enable a person to mobilize. Although osteoporosis is the most common disorder affecting bone, there are a number of less common acquired and congenital conditions, which affect bone strength and quality. Acquired disorders include Chronic Kidney Disease-Mineral and Bone Disorder as well as vitamin D deficiency leading to rickets in children and osteomalacia in adults. Genetic/congenital disorders include osteopetrosis, osteogenesis imperfecta, and fibrous dysplasia. The pathogenesis of Paget's disease is likely due to a combination of acquired and heritable mechanisms. These disorders will be discussed in the following sections.

52.2 Chronic Kidney Disease-Mineral and Bone Disorder

Chronic Kidney Disease-Mineral and Bone Disorder (CKD-MBD) is a term coined by the KIDOQI group in 2009 (Kidney Disease: Improving Global Outcomes (KDIGO) CKD–MBD Work Group 2009) in order to encompass the spectrum of mineral and bone abnormalities associated with chronic kidney disease that is usually seen in stage IV and V CKD (eGFR <30 mL/min). Thus, patients with CKD-MBD could manifest bone fragility through fractures but have very different underlying pathologies such as a low turnover state (characterized by low or normal PTH, low bone specific ALP), i.e., adynamic bone disease. Alternatively it may present as a high turnover state (characterized by high bone specific ALP, PTH more than 6× the upper limit of normal), i.e., osteitis fibrosa cystica, and/or osteomalacia.

52.2.1 Diagnosis and Pathophysiology

The diagnosis of osteoporosis amongst patients with CKD requires exclusion of the aforementioned conditions, especially in the setting of stage IV

(GFR 15–29 mL/min) and stage V CKD (<15 mL/min). CKD is associated with elevated PTH due to an elevated serum phosphate, a degree of PTH resistance, and elevated metabolites of PTH, which are detected in the PTH assay. These biochemical abnormalities, in particular the changes in PTH are correlated with the presence of different types of bone disorders and are most often seen amongst those with stage IV and V CKD. Ultimately however the gold standard for the exclusion of adynamic bone disease and osteomalacia is a bone biopsy with tetracycline labeling.

52.2.2 Management

Osteoporosis management should be similar to those without CKD amongst those with stage I–III CKD and absence of evidence of mineral disorders, i.e., normal calcium, phosphate, and PTH. On the other hand, in the setting of CKD stage IV and V, anti-resorptive therapy (bisphosphonates, denosumab, selective estrogen receptor modulators) should be used with caution and after the exclusion of adynamic bone disease and osteomalacia in particular. The latter conditions could be exacerbated by anti-resorptive therapy. Furthermore, treatment of osteoporosis with anti-resorptive agents is problematic as bisphosphonates are contraindicated in the setting of an eGFR <30 mL/min due to the possibility of acute kidney injury. Furthermore, there is a paucity of data from RCTs relating to treatment of osteoporosis with anti-resorptives in Stage IV and V CKD. Denosumab therapy has been used in those with stage IV and V CKD in a limited number of patients, with no effect on renal function. It has been thought of a useful agent in this setting as it is not excreted by the kidneys (unlike bisphosphonates). However denosumab should be used with caution as there have been several case reports of hypocalcemia post-denosumab therapy despite normal 25-OH-vitamin D levels. Anabolic therapy with teriparatide has not been studied in those with stage IV and V CKD and therefore any use would be off-label. However, in clinical practice, it may be worth considering amongst those with adynamic bone disease.

Nurses can play a key role in the management of this condition, supporting patients and families, facilitating communication within the multidisciplinary team, providing educational resources and patient-focused, coordinated care.

52.3 Paget's Disease

Paget's disease is a disorder in which there is a marked increase in bone turnover in localized parts of the skeleton. Subsequently, over a period of many years this results in enlarged weakened bone, manifesting with chronic pain, bone deformity, and fracture.

Since the initial report from Sir James Paget in the nineteenth century, knowledge of the disorder has grown considerably. Paget's disease occurs most frequently in the skull, pelvis, lower spine, and long bones of the leg. One (monostotic) or more (polyostotic) sites may be involved, but any bone can be involved and any number of sites can be affected at the same time. It starts from a single focus in each bone and is thought to advance about 1 cm per year (Hooper and Lang, n.d.). Patients with Paget's disease are usually diagnosed over the age of 50 years, which is consistent with the slow evolution of the disease (Singer 2015).

52.3.1 Prevalence

The prevalence of Paget's disease is highest in the UK and in countries where a large number of residents have ancestors from the UK. Currently in many countries, the prevalence of the disorder has decreased in recent decades. In addition to the reduction in prevalence, the severity of the disorder has been observed to be decreased, as revealed by a reduction in the extent of skeletal involvement and an increasing age of onset (Singer 2015).

Although the cause is not yet fully understood, it appears to be the result of both a genetic predisposition and a factor from the environment, possibly a virus. Some researchers consider that this virus may be related to a group of viruses that includes measles. The decreasing prevalence of Paget's could be attributed to measles vaccination over the past 40–50 years. A considerable

number of affected patients have a family history of Paget's disease. A large number of mutations in the SQSTM1 gene seem to account for susceptibility in some families. That gene and others are currently under investigation (Singer 2015).

52.3.2 Clinical Features

In mild cases of Paget's disease, people may have few or no symptoms and frequently these may be vague and difficult to distinguish from other conditions. Many people do not know they have the disease and attribute their symptoms to arthritis or other conditions. The most common symptom is pain, usually localized to the affected bone. A sensation of heat over the affected bone may occur, which is caused by an increase in blood flow through the abnormal bone. Deformity of the bone may lead to fracture or bowing of a limb, especially weight bearing limbs. With enlargement of the skull, compression of various nerves may cause symptoms such as hearing loss and headache (Hooper and Lang, n.d.).

52.3.3 Management

The diagnosis is usually made on the results of X-rays, bone scans, and biochemical markers of bone turnover. X-rays confirm that there is Paget's disease in a particular bone, to assess how much bone is involved and to look for complications. Isotope bone scans are more sensitive than X-ray in the identification of pagetic lesions. This test is used primarily to establish the full extent of skeletal involvement for a patient (Hooper and Lang n.d.). Paget's disease is associated with increased bone turnover. It is therefore expected that markers of bone turnover (such as ALP) will be increased in active disease (Selby et al. 2002).

The aim of treatment of Paget's disease is to relieve pain, to prevent or reduce future complications (deformity, fractures, and nerve compression by pagetic bone), and to maintain mobility (Selby et al. 2002). Treatments have advanced considerably following the introduction of bisphosphonates, in particular intravenous zoledronate. Bisphosphonates are the treatment of choice in Paget's disease and are capable of inducing suppression of the disease which may persist for years after treatment is stopped. Suppression of disease activity is expected to minimize the development of complications. The goal of treatment is to achieve remission, which is generally defined as a bone turnover result below the midpoint of the reference range of the specific bone turnover marker (Healy et al. 2015). Influenza-like side effects associated with a patient's first dose of intravenous bisphosphonate are relatively common (about 1 in 3 patients), but usually mild and transient. Influenza-like symptoms usually occur within the first 48 h but are temporary and can usually be managed with regular paracetamol. It is unusual for these effects to happen again with later doses (Hooper and Lang, n.d.).

Nurses are often part of the multidisciplinary team caring for these patients, supporting patients and their families, providing educational resources and administering intravenous bisphosphonates (Fig. 52.1).

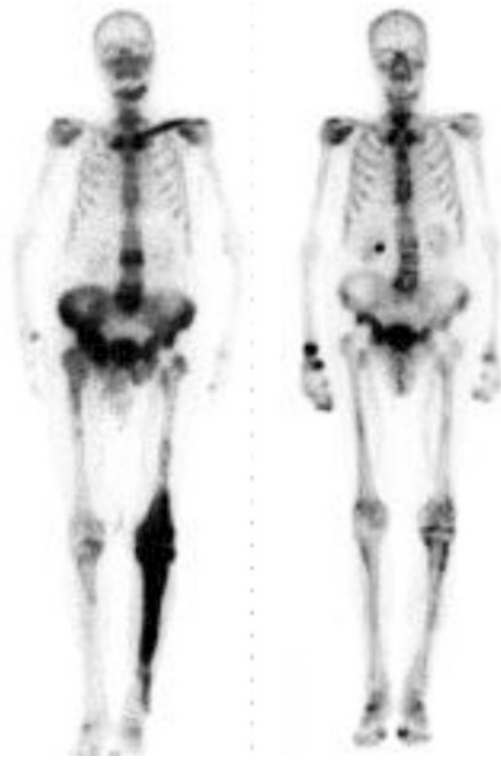

Fig. 52.1 Radionucleotide scan appearance in a patient with polyostotic disease affecting the left clavicle, spine, pelvis, femora, and tibia before (left) and after (right) bisphosphonate therapy

Case Study 1 (Fig. 52.2)

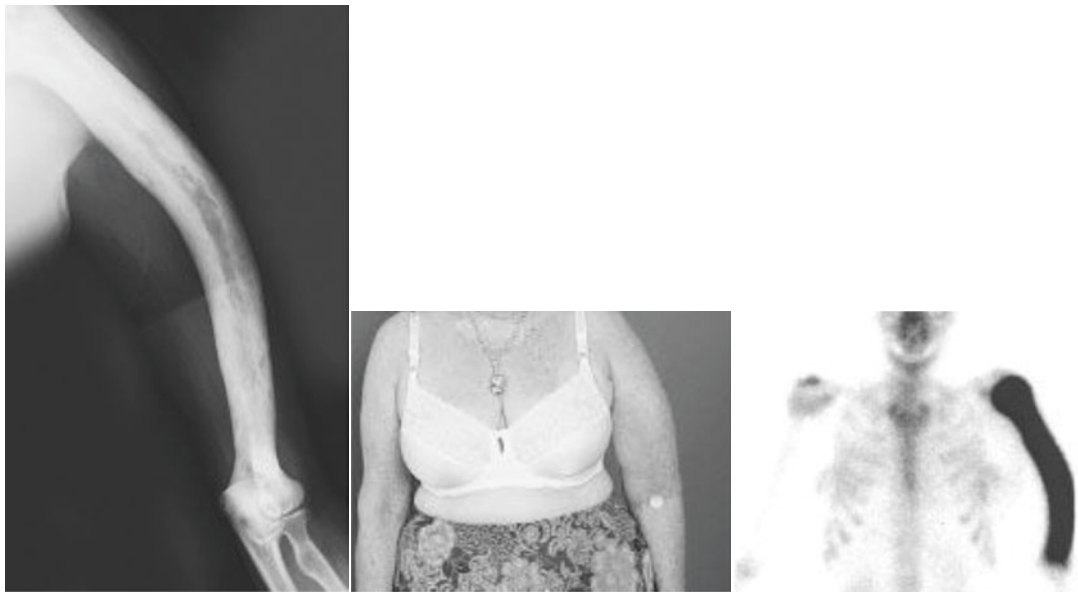

Fig. 52.2 The left humerus is extensively involved with Paget's disease. There is gross deformity and there is loss of the normal bone architecture. The disease extends from the elbow joint to the upper end of the humerus. It is unusual for Paget's not to involve the end of a long bone if other areas are diseased. Effective early treatment with bisphosphonates can be expected to prevent deformity and other complications

Case Study 2 (Fig. 52.3)

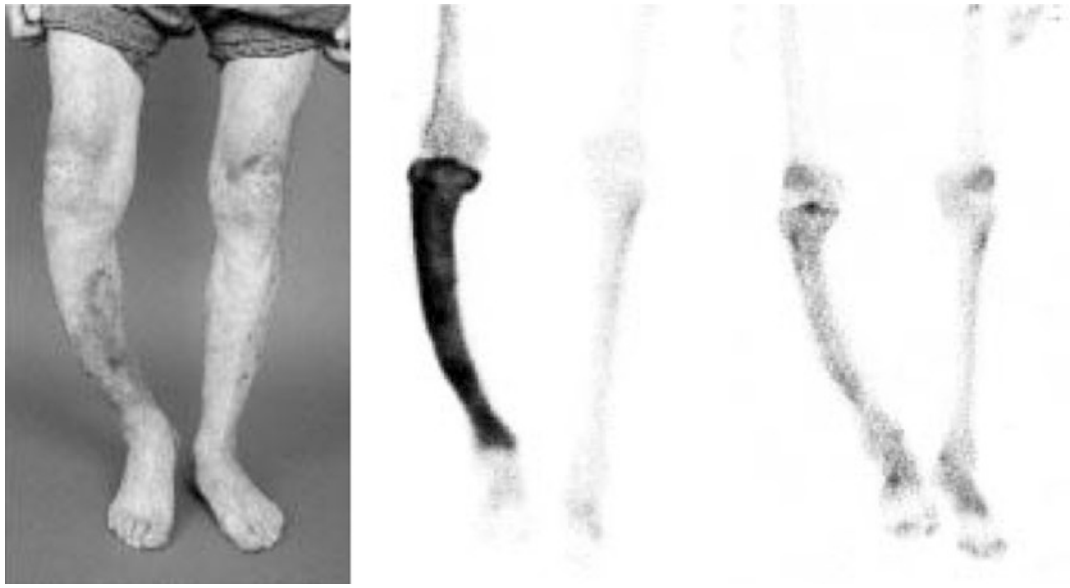

Fig. 52.3 Right tibia—effect of disease and treatment. The tibia is extensively deformed by Paget's disease which extends throughout the bone. The bone is expanded and bowed. Severe pain was a feature of the disease and the overlying skin was hot and the bone tender to pressure. With bisphosphonate therapy, the patient's pain resolved, the skin temperature returned to normal, the biochemical indices of activity of the disease returned to normal, and there was marked improvement on the bone scan

52.3.3.1 Learning Key Points/Nursing Role

Effective early treatment with bisphosphonates can be expected to prevent deformity and other complications.

52.4 Osteopetrosis

Osteopetrosis is a genetic condition characterized by increased bone mass. It has an autosomal dominant (AD) and recessive (AR) form, which have different clinical phenotypes (Sobacchi et al. 2013; Del Fattore et al. 2008). The underlying pathogenesis involves reduced bone resorption due to decreased osteoclast activity and/or function with a number of causative genetic mutations identified.

52.4.1 Clinical Features

The AR form is often fatal in children (aka malignant infantile osteopetrosis) while the AD form is more commonly present in adulthood (previously known as Albers-Schonberg disease). However, there is a wide degree of heterogeneity in the clinical presentation with both forms.

The AD form is generally less severe than the AR form; however, there is wide heterogeneity in the clinical presentation from asymptomatic to rarely fatal. It has prevalence of 5 in 100,000. Notably, a condition formerly known as ADO type I, which manifests with osteosclerosis only, due to increased bone formation from a gain-of-function mutation in the LRP5 gene, is no longer classified as osteopetrosis as it is an osteoblast defect.

The autosomal recessive form is often lethal during infancy or childhood but has a high degree of clinical and genetic heterogeneity. It is also rare with an prevalence of 1 in 250,000. The major clinical features of osteopetrosis include increased BMD on X-ray with loss of bone marrow cavity, yet increased risk of low trauma fractures, extra-medullary hemopoiesis, hypocalcemia, neurological defects (e.g., brainstem herniation), blindness, growth retardation, impaired tooth eruption and neurodegenerative manifestations. The underlying pathogenesis can vary according to the specific gene affected, which can be divided into two broad categories: from the absence of osteoclasts ("osteoclast poor") or the presence of non-functioning osteoclasts ("osteoclast rich").

52.4.2 Diagnosis

The diagnosis is made through a combination of clinical, radiological, and genetic features.

52.4.3 Treatment

The management of patients with AD osteopetrosis is symptomatic as there is no known cure. However, if the ARO is detected early, hematopoietic stem cell transplantation (HSCT) is a potential therapeutic option amongst infants without neurological involvement. Notably, HSCT is only effective amongst those with primary osteoclast defects as osteoclasts are hematopoietic in origin. On the other hand, in a form of AR osteopetrosis, which is due to a gene defect in RANK-L (produced from osteoblasts) which is of mesenchymal origin, HSCT would be ineffective. Therefore, early diagnosis and detection of the specific gene and molecular defect is critical.

52.5 McCune–Albright Syndrome

McCune–Albright Syndrome (MAS) is characterized by a triad of fibrous dysplasia (FD) of bone, endocrine hyperfunction, and café-au-lait skin hyperpigmentation (Albright et al. 1937; Dumitrescu and Collins 2008).

52.5.1 Epidemiology

MAS is rare in that it has a prevalence of 1 in 100,000 to 1 in 1,000,000.

52.5.2 Pathogenesis

The pathogenesis involves a non-inherited mutation (which occurs during the lifespan) in the gene encoding for the alpha-subunit of stimulatory G-protein resulting in osteoblast dysfunction. The type and extent of tissue involvement is dependent upon the stage of development in which the mutation occurs. Thus, there is a wide spectrum of clinical manifestations. In fibrous dysplasia there is excessive formation of fibrous tissue in bone marrow and destruction of normal bone in conjunction with abnormal bone formation and increased osteoclast activity.

52.5.3 Clinical Features

FD may present with bone pain, fragility fracture, deformity affecting the spine (i.e., scoliosis), face, upper or lower limbs, or neurological compromise. Hyperfunctioning endocrinopathies can manifest as hyperthyroidism, growth hormone excess, Cushing's syndrome, urinary phosphate wasting (with or without rickets/osteomalacia), and/or precocious puberty. A recently described association is intra-ductal pancreatic mucinous neoplasia (IPMN).

52.5.4 Investigations

In the initial assessment of a patient with possible MAS, investigations for endocrine hyperfunction should be performed. Radiological investigations to look for fibrous dysplasia include X-rays and/or CT scans of the affected area/s. A bone scan would reveal areas of intensely increased uptake in the affected bones. Bone biopsy may be required to make a diagnosis of fibrous dysplasia; however, the diagnosis is often based upon the combination of clinical, biochemical, and radiological assessments.

52.5.5 Management

Fibrous dysplasia of the bone can cause pain. Bisphosphonate therapy may be of benefit in reducing pain; however, evidence is limited due to the rarity of the disorder. Surgical management may be necessary in the case of fracture, or for cosmetic reasons. Management of the endocrinopathies is similar to those without MAS. Endocrine nurses can play a role in the diagnosis and management of associated endocrine disorders. Nurses can also play a part in the ongoing care of these patients via education and support (Fig. 52.4).

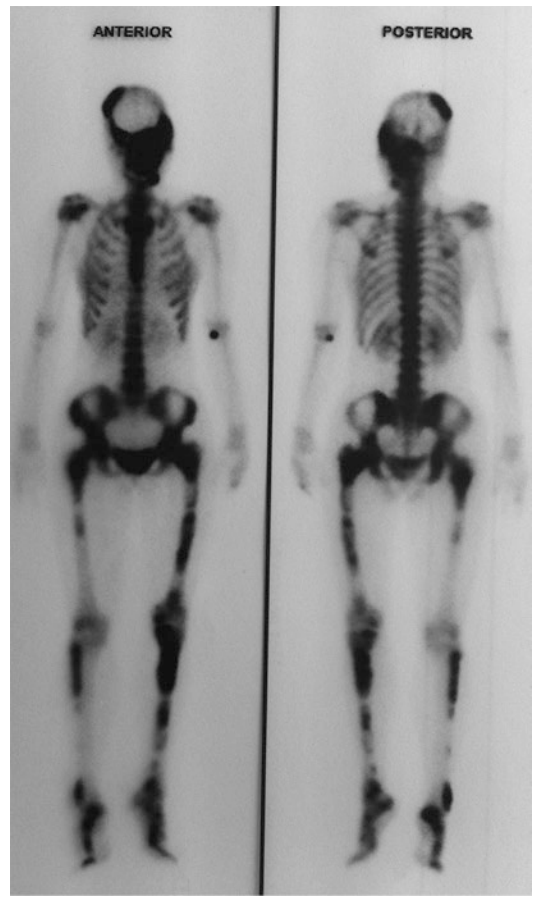

Fig. 52.4 Bone scan of a patient with polyostotic fibrous dysplasia demonstrating intense uptake in the skull, spine, ribs, femora, and tibiae

52.6 Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a genetic disorder of increased bone fragility and low bone mass.

52.6.1 Prevalence

With a prevalence of 1 in 12,000 to 15,000 children, it has a broad clinical phenotype, ranging from interuterine fractures and perinatal lethality to mild clinical forms with fractures.

52.6.2 Clinical Features

Clinical characteristics may include blue sclera, brittle teeth, and joint hypermobility. Most patients have a clinical mutation in 1 or 2 genes that encode the alpha chains of collagen type 1 (COL1A1 and COL1A2) (Rauch and Glorieux 2004). Autosomal dominant mutations in COL1A1 and COL1A2 account for approximately 90% of cases and they include OI type 1 to OI type IV. There is also rarer autosomal dominant and recessive mutations causing other forms of OI (Harrington et al. 2014).

Understanding the individual's OI type provides a starting point for understanding the person's health care needs. But due to all of the variable features, care for each person needs to be individualized. The fragility of bones in type I patients may be severe enough to limit physical activity, or so slight that individuals are unaware of any disability. Type II is lethal in the perinatal period. Type III is the most severe form in children. These patients are very short and have limb and spinal deformities due to multiple fractures. Patients with mild to moderate bone deformities and variable short stature are classified as OI type IV (Rauch and Glorieux 2004).

52.6.3 Diagnosis

The diagnosis of OI is based on typical clinical characteristics and radiological findings (including fractures and low bone density). Diagnosis can be straightforward in individuals with a positive family history or in whom several typical features are present. Though in the absence of affected family members and when bone fragility is not associated with obvious extra skeletal abnormalities, the diagnosis can be difficult. Furthermore child abuse is a frequent cause of fractures, with the highest incidence in the first year of life. Indeed clinical differentiation of mild OI from abuse can be problematic if there is no family history (Rauch and Glorieux 2004). Genetic testing can help confirm the diagnosis, though with more than 1500 dominant mutations, genetic sequencing is required (Harrington et al. 2014).

52.6.4 Management

The goals of treatment in OI are to maximize mobility, decrease bone pain and fractures. The degree of intervention needed depends on the severity of the clinical phenotype. Management should be multidisciplinary and includes surgical management, rehabilitation, and consideration of bisphosphonate therapy (Harrington et al. 2014). Endocrine nurses can play an important role for patients (and their families) with OI by helping to provide comprehensive coordinated care and promoting health and well-being.

52.7 Rickets

Although rickets was probably described some 2000 years ago, it was not until the industrial revolution and the swift movement of rural communities into heavily air-polluted and overcrowded cities of Europe that the disease became

a public health problem. The disease was rare in infants younger than 6 months of age, but with a peak prevalence of around 18 months. Early in the twentieth century the roles of cod liver oil and sunlight in the prevention and treatment of rickets was well recognized and in 1922, vitamin D was named as the factor responsible for preventing the condition (Pettifor 2005)

52.7.1 Clinical Features

Rickets is a disorder of mineralization of the bone matrix (osteoid) in growing bone before epiphyseal closure. It involves both the growth plate (epiphysis) and newly formed trabecular and cortical bone. Deficiencies of vitamin D, calcium, or phosphorus can result in defective bone mineralization (Favus 1999). The lack of mineralization results in typical appearances at the growth plate and in the gradual softening of bone, which leads to deformity in association with weight bearing (Wharton and Bishop 2003).

Signs and symptoms of rickets include muscle weakness, limb pain, increased tendency for fractures, dental problems, and skeletal deformities (esp. bowed legs once the child is walking). Changes in the skull can also occur causing frontal bossing and a distinctive "square headed" appearance (Wharton and Bishop 2003).

52.7.2 Pathophysiology

Simple nutrient deficiency, particularly of vitamin D is the most common cause of rickets. The major pathophysiological effect of vitamin D deficiency is a reduction in intestinal calcium absorption below that level need to maintain the child in a positive calcium balance large enough to meet the demands of a growing skeleton. The dietary content of vitamin D is generally insufficient to prevent vitamin D deficiency. Production of vitamin D in the skin under the influence of UV radiation is essential to maintain an adequate vitamin D status, unless foods are fortified, or supplements are taken (Pettifor 2005). Decreased calcium intake or intestinal absorption has been associated with rickets and the clinical manifestations are similar to those described for vitamin D deficiency. Phosphate deficiency has also been reported to cause rickets (Favus 1999).

The newborn infant is protected from vitamin D deficiency for the first few months of life if born to a vitamin D-replete mother as it crosses the placenta readily and has a half-life of approximately 3 weeks (Pettifor 2005). However many mothers of children with rickets have poor vitamin D status and such a mother gives her baby a low endowment of vitamin D. Her breast milk provides little of the vitamin and therefore in this situation, exclusive breast feeding can be a significant risk factor (Wharton and Bishop 2003). Children living in countries of high latitude are more at risk than those living near the equator. Additional factors include the degree of atmospheric pollution, the extent of skin coverage by clothing, the amount of skin pigmentation, and the time spent outside (Pettifor 2005).

52.7.3 Management

Prevention of rickets centers around vitamin D supplementation, public awareness, and vitamin D fortification (infant formula). These measures have been effective in dramatically reducing the prevalence of nutritional rickets in most developed countries. The mainstay of treatment for infants and children with nutritional rickets is the prompt correction of vitamin D deficiency and ensure sufficient calcium intake. As a result, symptoms can subside and healthy bones grow. Educating families at risk is critical to eradicate this preventable disease and certainly nurses have a key role in this regard with their work in community and hospital settings (Hartman 2000).

52.8 Part B: The child with a Congenital Bone Disorder

Anne L. Ersig

52.8.1 Pathophysiology and Genetics of Congenital Bone Disorders

Care of the child with a congenital bone disorder aligns with care for other conditions affecting bone and connective tissue. However, because congenital disorders are due to gene mutations, and have an earlier onset compared to other bone conditions (Bartl and Bartl 2017), there are additional considerations. Clinical signs and symptoms are not limited to bone and skeletal tissue, since the mutations causing congenital bone disorders can also affect cartilage and other connective tissue (Krakow 2015). Individuals with congenital bone disorders may present with symptoms affecting tissues other than bone, requiring careful attention to all body systems when establishing a diagnosis or evaluating the patient's current status. With earlier age at onset, congenital disorders may also have longer-term effects on growth and development, requiring additional monitoring and treatment.

Initial diagnosis typically occurs through radiologic examination, with confirmation provided by genetic analysis, particularly in families with established diagnoses and known mutations (Krakow 2015). Along with the genetic analysis, a thorough and careful history of the patient with a suspected congenital bone disorder is essential, to obtain important information on the clinical course of the patient and other potentially affected family members (Shapiro 2016). Although some signs and symptoms are common to multiple diagnoses, phenotypic variability is substantial, reflecting the specific condition and causative mutation. Mutation location and type are particularly important determinants of the clinical presentation. Phenotypes that are clinically grouped as one disease may be caused by mutations with different effects, resulting in different symptoms and presentation (Krakow 2015).

Even in families with known mutations and an established diagnosis, clinical severity and specific symptoms can vary. This requires careful evaluation of all family members at risk, since clinical manifestations in one may be more subtle compared to others. A minimum three-generation family history will provide essential information on the clinical phenotype of a family, providing guidance for future evaluations and clinical surveillance (Krakow 2015).

Somatic mosaicism, in which only a percentage of the body's cells carry the relevant mutation, is common in bone disorders, and may be one cause of variation in signs, symptoms, and severity within families (Krakow 2015). Parents who are somatic mosaics for a disease-causing mutation identified in an affected child often display more subtle clinical signs and symptoms. Gonadal mosaicism, in which a percentage of the germ cells have the mutation, is also seen. The percentage of cells with the mutation will affect risk to future pregnancies, with higher risk associated with a higher percentage of affected cells (Krakow 2015).

52.8.2 Genetic and Clinical Evaluation

While genes have been identified for many bone disorders, they are not often included in common prenatal genetic testing panels and tests; thus, when a child is the first to present with a possible congenital bone disorder, clinical identification typically occurs first, followed by genetic testing. Identifying the disease-causing mutation allows for confirmation of clinical diagnosis, and screening of potentially affected family members. One exception to this order of evaluation is in families with known mutations and a history of a congenital bone disorder; in

these cases, prenatal genetic and ultrasound screenings can help determine if a fetus is affected (Krakow 2015).

Although many cases of congenital bone disorders are seen in families with established histories, a substantial number of cases are caused by new mutations. Careful clinical evaluation and diagnosis, confirmatory genetic testing, mutation identification, and identifying a pattern of inheritance will provide essential information for the affected child and other family members. Management should also include referral to a genetic counselor.

52.8.3 Evaluation of Congenital Bone Disorders

Congenital bone disorders share some common clinical signs and symptoms, including short stature, abnormally shaped bones, and propensity to fracture (Shapiro 2016). Establishing a clinical diagnosis requires a thorough history and physical examination of all body systems. Important elements include fracture history, other skeletal and connective tissue signs and symptoms (e.g., scoliosis, hyperextensibility), pain, the neurological system, and the skin and cardiovascular systems. Neonates with a suspected congenital bone disorder will often have disproportion and skeletal abnormalities, including macrocephaly, rhizomelia, mesomelia, and brachydactyly (Krakow 2015). While fractures are common across disorders, providers should consider all possible causes, including accidental and non-accidental trauma (Bronicki et al. 2015). The shape of the skull, history of headaches, and examination of the jaw, teeth, sclerae, and ears are essential elements of the HEENT evaluation (Krakow 2015). The skin may exhibit fragility, propensity to bruise or scar easily, and changes in texture. Careful attention should also be paid to the cardiovascular system, as mutations may affect cardiac connective tissue and cause subtle signs and symptoms.

Radiological examination and evaluation provides information to support clinical diagnosis and ongoing management of a congenital bone disorder. Baseline X-rays of the entire skeleton should be acquired, for both initial evaluation and future comparison in case of injury or fracture. The spine and extremities should be examined for fractures in various states of healing, evidence of scoliosis in both planes, and growth plate abnormalities.

52.8.4 Treatment and Management of Congenital Bone Disorders

Treatment is targeted to the specific condition and its manifestations; given the wide variability in clinical presentation, there is similar variability in treatment choice and application. Treatment is often supportive and focuses on symptom and fracture management; curative treatment is not possible given the genetic cause of these conditions (Bartl and Bartl 2017). Many children with congenital bone disorders will have surgeries to correct chronic and acute bone problems; surgery may also be necessary following traumatic fracture or other events. Other common treatments across disorders include pain management, rehabilitation, physical therapy, occupational therapy, orthotic support, and gait evaluation. Depending on the specific diagnosis, referrals to other specialists (e.g., cardiovascular, pulmonary) may also be needed. In addition to pain medication, bisphosphonates are amongst the most frequently used medications for congenital bone disorders. These potent IV and oral drugs effectively raise bone density for most patients, although the clinical impact varies substantially.

52.8.4.1 Nursing Care of the Child with a Congenital Bone Disorder

Nurse practitioners play a key role in ensuring coordinated and comprehensive care for all children with chronic health conditions, including those with congenital bone disorders. Careful management by the multidisciplinary care team will support comprehensive and coordinated care for children with congenital bone disorders.

When assessing and examining a child with a congenital bone disorder, nurses and other clinicians should be aware of the high rate of fracture in these patients. Careful attention should be paid to patient position and any manipulation of the body or limbs; allowing the parent or child (depending on age) to move into a requested position will allow the nurse to avoid unanticipated movements that could result in fracture. As pain is a hallmark of many congenital bone disorders, proper positioning and cushioning during physical exams and other assessments is critical.

52.9 Exemplar Congenital Bone Disorders

Three congenital bone disorders are reviewed here as exemplar diagnoses, representing the breadth of phenotypes amongst congenital bone disorders: Paget's disease of bone, osteopetrosis, and osteogenesis imperfecta (OI). Beyond the three conditions that will be discussed in more detail below, other congenital bone disorders include Bruck syndrome, Cole-Carpenter syndrome, hypophosphatasia, idiopathic juvenile osteoporosis, and rickets (Bronicki et al. 2015).

Paget's disease of bone is typically an adult-onset condition; however, a rarer familial, inherited form of the disease presents in children. The phenotype is often severe, requiring careful management. Paget's disease is characterized by increased bone turnover due to high osteoclast activity. This leads to bone fragility and tendency to fracture; most adult cases of Paget's disease are diagnosed following fracture workup (Cundy 2016; Indumathi et al. 2009). Lytic wedges resulting from bone resorption are often evident on radiographs (Cundy 2016). High alkaline phosphatase levels also reflect higher osteoclast activity and bone resorption. Other clinical signs and symptoms include fissures and bone enlargement or other deformity; a smaller percentage of patients will experience hearing loss, leg length discrepancy, bowing of limbs, and an enlarged head (Michou and Brown 2016). Adult cases report significant impact on quality of life, usually due to pain and resulting diminished physical activity (Cundy 2016; Michou and Brown 2016). In addition to referral to rehabilitation and physical therapy, affected individuals may require assistive devices (e.g., canes). Bisphosphonates are frequently prescribed to increase bone density and reduce the number of fractures; an additional effect is relief of bone pain, which may be critical to help individuals with Paget's disease maintain movement and functionality (Michou and Brown 2016). In most cases, the number of affected bones is limited, although disease activity may increase slowly over time.

Osteopetrosis, in contrast to the other two conditions detailed here, is marked by significantly *increased* bone density. Reduced bone resorption by osteoclasts leads to high bone mass; resulting skeletal abnormalities predispose affected individuals to fractures, despite high bone density (Wu et al. 2017). Clinical presentation is similar to other bone disorders, and includes fractures, skeletal deformity, and dental abnormalities. Unique features of osteopetrosis are the associated narrowing of the marrow cavity and foramina due to bony overgrowth, potentially affecting hematologic and neurologic function (Wu et al. 2017). The highly variable clinical presentation of osteopetrosis is reflected in the clinical classifications, ranging from malignant autosomal recessive infantile to benign adult autosomal dominant, with an intermediate type also possible (Wu et al. 2017). As with many congenital bone disorders, clinical presentation can vary amongst affected family members due to incomplete mutation penetrance and variable expressivity.

Diagnosis requires, at a minimum, a skeletal survey to identify the extent of osteosclerosis. Genetic analyses should also be pursued due to the short- and long-term effects of various mutations (Wu et al. 2017). Mutation data also provide critical information on prognosis and potential clinical complications and sequelae. Additional non-genetic testing includes baseline laboratory evaluation and vision assessment. Bone density assessment is not required, nor is bone biopsy except in extreme cases.

As with other congenital bone disorders, a multidisciplinary team is best suited to manage the diverse symptoms and effects of osteopetrosis. Endocrine, ophthalmology, genetics, dentistry, orthopedic surgery, and other specialists as needed (e.g., otolaryngology, hematology, infectious disease, nephrology) should be consulted for their expertise. Other than supportive and symptom-driven treatment, most patients receive calcium and vitamin D supplementation, with transfusions only in cases of symptomatic low hemoglobin. Patients experiencing bone marrow failure due to narrowing of the marrow cavity may be considered for bone marrow transplant; however, this procedure will not be effective in all patients (Wu et al. 2017).

The final exemplar, ***osteogenesis imperfecta***, is a generalized connective tissue disorder with major manifestations in bone and a wide range of possible phenotypes. The hallmark features of OI are significant bone fragility, low bone density, and a tendency to fracture from minimal trauma. Recent advances have identified autosomal dominant and recessive mutations in multiple genes. Most cases (85–90%) are caused by mutations in one of the genes encoding type I collagen, which lead to either structural or quantitative changes in collagen, bone fragility, and high risk of fracture. The remainder are caused by mutations encoding genes that have substantial interactions with collagen, as well as genes supporting osteoblast differentiation (Forlino and Marini 2016). Mutation detection should follow a cascade pattern, starting with the genes for type I collagen, and expanding to include other genes if no mutation is identified (Forlino and Marini 2016). An exception to this is when there is more than one affected child in the family, as this indicates a greater likelihood of autosomal recessive inheritance of a non-collagen mutation. The most common structural defects in OI are caused by glycine substitution mutations in the type I collagen genes; these have varying phenotypic effects, depending on the mutation location and charge status of associated side chains. Other cases are caused by mutations in non-collagen genes that affect collagen processing and modification. While the clinical presentation may be similar, genetic analysis is critically important for family planning.

Clinical classification of OI is evolving beyond the original four types to include genetics, bone histomorphometry, and radiograph findings, and currently includes types I–VII (Biggin and Munns 2014). OI has a wide range of severity, from mild with limited impact on ambulation or stature, to lethal in the perinatal period. Regardless of clinical classification or type, careful and thorough clinical assessment is required, given the effects of OI on multiple body systems. Patients often demonstrate generalized osteopenia and other skeletal abnormalities (e.g., long bone bowing, rib deformities, vertebral compressions), blue sclerae, hearing loss, dentinogenesis imperfecta, and decreased pulmonary function (Forlino and Marini 2016). Differential diagnosis for mildly affected adults includes early-onset osteoporosis; for children with mild forms, non-accidental trauma must be considered.

As with other congenital bone disorders, the multisystem effects of OI require a multidisciplinary approach to management, including rehabilitation, physical and occupational therapy, pulmonary, cardiac, and otolaryngology specialists (Forlino and Marini 2016; Biggin and Munns 2014). Appropriate fracture management is critical, with referrals to a pediatric orthopedic surgeon for surgical intervention as needed. In addition, many patients are now treated with oral or intravenous bisphosphonates to improve bone density with positive effects on vertebral compression fractures but lack of support for prolonged use (Biggin and Munns 2014).

52.10 Conclusions

In conclusion, this chapter has detailed the wide spectrum of bone disorders, which are less common than osteoporosis; however, they need to be recognized in order to tailor appropriate therapy for the individual. While CKD-MBD has a wide spectrum of underlying pathophysiology with variable levels of bone turnover, demineralization

and quantity of bone, other disorders have a more homogenous pathophysiology, such as OI, Paget's disease, and fibrous dysplasia. The latter conditions can be managed with anti-resorptive therapy to manage associated pain in the case of Paget's and fibrous dysplasia and potentially fractures in the case of OI; however, there is a paucity of high quality evidence due to low numbers of patients with congenital disorders in particular. Thus, despite often presenting with bone pain or fractures, it is important to understand the underlying basis for the particular bone disorder, which can help tailor appropriate therapy for individuals with congenital or acquired bone disorders.

Abstract

Osteoporosis is considered as the most common bone disease in humans and represents a major public health issue as its prevalence is increasing with an aging population. Osteoporosis leads to nearly nine million fractures annually worldwide. It is a silent disease and its clinical significance lies in the fractures that arise from it. These fractures are usually sustained following minimal trauma also known as fragility fractures. It is estimated that more than one-third of adult women and one in five men will sustain one or more fragility fractures in their lifetime. Osteoporotic fragility fractures can cause substantial pain and severe disability, often leading to reduced quality of life. Additionally, hip and vertebral fractures are associated with decreased life expectancy. Hip fractures in particular, always requires hospitalization, is fatal in 20% of cases and causes permanent disability in 50% of those affected with only 30% of patients fully recover.

The substantial cost of fragility fractures is causing a significant toll on the already limited healthcare budget. In America, the cost of osteoporosis-related fractures was estimated at $17 billion in 2015 and is estimated to double and even triple by the year 2040. There are a number of effective therapies available for the prevention of fragility fracture in people thought to be at risk, or to prevent further fractures in those who have already sustained one or more fragility fractures. However, in order to effectively reduce the personal, medical, and economic burden of osteoporosis-related fractures, a robust system of fracture prevention, identification, and treatment of those who are at risk should be implemented.

Key Terms

- **Bone formation**: osteoblastic activity in the formation of new bone.
- **Bone remodeling**: the process of bone growth and development involving shape and size changes.
- **Bone resorption**: osteoclastic bone breakdown with release of calcium into the blood.
- **Mineralization**: laying down minerals on a matrix of the bone.
- **Osteopenia**: is a loss of bone mass by bone densitometry and expressed as a *T* score −1 to −2.0 (NB. − is minus).
- **Osteoporosis**: is a loss of bone mass by bone densitometry and expressed as a *T* score > −2.0.
- **Reversal**: this couples bone resorption to bone formation by generating an osteogenic environment at the site of bone remodeling.
- **Vitamin D deficiency**: levels determined to increase the risk of osteoporosis and bone fracture.
- **Vitamin D insufficiency**: levels lower than recommended by endocrine clinical guidelines.

Learning Objective

This chapter focuses on the evaluation, management, and monitoring of patient with osteoporosis. Through the course of this chapter, the reader will be able to:

1. Understand the epidemiology, etiology, and basic pathophysiology of osteoporosis.
2. Identify and explore the different criteria used in assessing and diagnosing osteoporosis.
3. Understand and use the FRAX assessment tool.
4. Compare the different methods used in assessing bone mineral density.
5. Understand the currently available pharmacological and non-pharmacological therapies used in clinical practice for the management of osteoporosis.

53.1 Background

The World Health Organisation (WHO) defines osteoporosis as a "progressive skeletal disease characterised by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture" (Kanis et al. 1994). It is a systemic skeletal disease which leads to compromised bone strength and a consequent increase in bone fragility and risk of fractures. The term osteoporosis has become synonymous with decreased bone mineral density (BMD) however; this feature is not always present. Bone strength is determined by several factors, including bone mass, size and shape of the bone, bone turnover, microarchitecture, cortical porosity, viability of osteocytes, and bone mineralization (BMJ 2018; Manolagas 2017a, b) (Fig. 53.1).

Osteoporosis is often overlooked and undertreated due mainly to the fact that it is so often clinically silent before manifesting in the form of fracture. In 2000, the Gallup survey by the National Osteoporosis Foundation found that 86% of women with osteoporosis had never discussed its prevention with their physicians, and not surprisingly, 91% wish they had known more

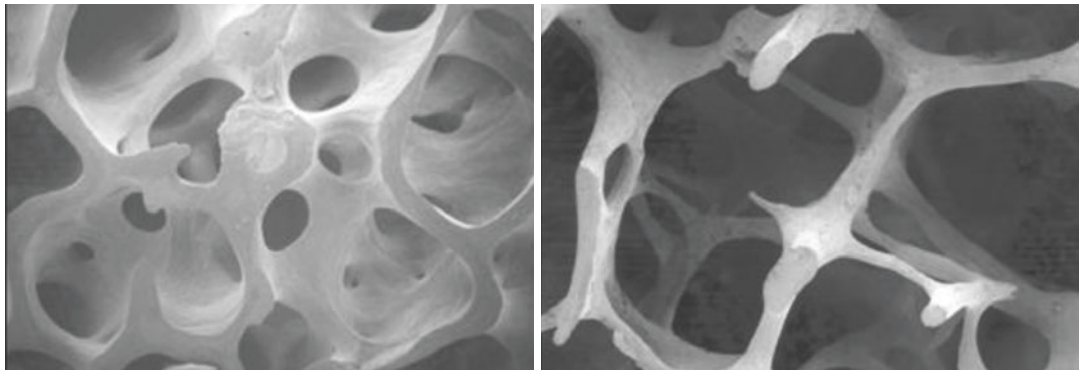

Fig. 53.1 Three-dimensional computed tomography images of cancellous bone from a normal individual (left picture) and a patient with osteoporosis (right picture). The picture illustrates how the trabeculae in patients with osteoporosis are thinner, disconnected, and further apart. Courtesy of Prof. David Dempster

Table 53.1 Types of primary osteoporosis (Source: Bethel 2017)

	Characteristics
Juvenile osteoporosis	• Usually occurs in children or young adults of both sexes • Normal gonadal function • Age of onset: usually 8–14 years • Hallmark characteristics: abrupt bone pain and/or fracture following trauma
Idiopathic osteoporosis	
(a) *Postmenopausal osteoporosis (type I osteoporosis)*	• Occurs in women with estrogen deficiency • Characterized by a phase of accelerated bone loss, primarily from trabecular bone • Fractures of the distal forearm and vertebral bodies are common
(b) *Age-associated or senile osteoporosis (type II osteoporosis)*	• Occurs in men and women as BMD gradually declines with advancing age • Represents bone loss associated with aging • Fractures occur in cortical and trabecular (wrist, vertebral, and hip)

steps to prevent this highly debilitating, yet avoidable disease (Marbury 2002). Failure to identify and educate patients at risk, and to implement preventive measures could lead to both tragic and costly consequences.

53.1.1 Etiology of Osteoporosis

Osteoporosis has been classified according to etiology and localization in the skeleton. In 1983, Riggs and Melton suggested that there are two distinct osteoporotic syndromes: type I or postmenopausal osteoporosis and type II or senile osteoporosis. Type 1 osteoporosis presents between the ages of 51 and 75 and is usually associated with vertebral crush fractures, forearm fractures, and accelerated trabecular bone loss mainly due to menopause. On the hand, type II osteoporosis presents over the age of 70 with vertebral wedging and femoral fracture, and is characterized by cortical and trabecular bone loss due to age-related factors (Riggs and Melton 1983).

While Riggs and Melton's classification may be useful in the studies of the pathogenesis and treatment of osteoporosis, its use is of limited value in the current clinical practice due to the heterogeneity and complexity of the condition. The most commonly used categories of osteoporosis are primary and secondary osteoporosis. Primary osteoporosis is the most common form of the disease and includes Rigg and Melton's type I and type II actors that can cause secondary osteoporosis as idensis (Table 53.1).

Table 53.2 Causes of secondary osteoporosis

Lifestyle factors	• Alcohol abuse • Anorexia nervosa/bulimia • Excess vitamin A • Falling • High salt intake • Immobilization • Inadequate physical activity • Low calcium intake • Malnutrition • Smoking (active or passive) • Vitamin D deficiency
Genetic factors	• Cystic fibrosis • Ehlers–Danlos syndrome • Gaucher's disease • Glycogen storage diseases • Hemochromatosis • Homocystinuria • Hypophosphatasia • Idiopathic hypercalciuria • Marfan syndrome • Menkes steely hair syndrome • Osteogenesis imperfecta • Parental history of hip fracture • Porphyria • Riley–Day syndrome
Hypogonadal state	• Androgen insensitivity • Athletic amenorrhea • Hyperprolactinemia • Klinefelter's syndrome • Premature menopause • Premature ovarian failure • Turner's syndrome
Endocrine disorders	• Adrenal insufficiency • Diabetes mellitus (Type 1 and 2) • Cushing's syndrome • Hyperparathyroidism • Central adiposity • Thyrotoxicosis
Gastrointestinal disorders	• Celiac disease • Gastric bypass • GI surgery • Inflammatory bowel disease • Malabsorption • Pancreatic disease • Primary biliary cirrhosis
Hematologic disorders	• Hemophilia • Leukemia and lymphomas • Monoclonal gammopathies • Multiple myeloma • Sickle cell disease • Systemic mastocytosis • Thalassemia
Rheumatologic and autoimmune diseases	• Ankylosing spondylitis • Lupus • Rheumatoid arthritis • Other rheumatic and autoimmune diseases
Central nervous system disorders	• Epilepsy • Multiple sclerosis • Parkinson's disease • Spinal cord injury • Stroke
Miscellaneous conditions and diseases	• Alcoholism • Amyloidosis • Chronic metabolic acidosis • Chronic obstructive lung disease • Congestive heart failure • Depression • End stage renal disease • Human immunodeficiency virus infection or AIDS • Hypercalciuria • Idiopathic scoliosis • Muscular dystrophy • Post-transplant bone disease • Sarcoidosis • Weight loss
Medications	• Aluminum (in antacids) • Anticoagulants (heparin) • Anticonvulsants (e.g., phenobarbital, phenytoin) • Aromatase inhibitor • Barbiturates • Cancer chemotherapeutic drugs • Cyclosporine A • Depo-medroxyprogesterone (Depo-Provera) • Glucocorticoid • Gonadotropin releasing hormone (GnRH) antagonists and agonists • Lithium • Methotrexate • Parenteral nutrition • Proton pump inhibitors • Selective serotonin reuptake inhibitors • Tacrolimus • Tamoxifen • Thiazolidinediones (e.g., pioglitazone [Acos]) • Thyroid hormone (in excess)

Secondary osteoporosis is characterized by having a clearly identifiable etiologic mechanism such as underlying disease, deficiency, or drug causes. There are several factors that can cause secondary osteoporosis as identified in Table 53.2.

53.1.2 Epidemiology

Osteoporosis is a major public health problem which leads to nearly nine million fractures annually worldwide (Johnell and Kanis 2006). In the United States of America (USA), the National Osteoporosis Foundation (NOF) estimated that more than ten million Americans have osteoporosis in 2004 (Cosman et al. 2014). In the UK, more than 500,000 new fragility fractures occur each year (Svedbom et al. 2013) while in Europe, all osteoporotic fractures account for 2.7 million fractures in men and women (Hernlund et al. 2013). In Australia, it was estimated that around two million people were affected by osteoporosis in 2001 (O'Neill et al. 2004).

Osteoporosis is a silent disease and its clinical significance lies in the fractures that arise. It is estimated that around 50% of white women and 20% of white men have osteoporosis-related fracture during their lifetime (Cosman et al. 2014). However, even though the risk of osteoporosis is lower amongst black men and women, the fracture risk is similar amongst those with osteoporosis (Cosman et al. 2014). In both men and women, the fracture risk increases with age (Khosla 2010). By age 60, half of white women have osteopenia or osteoporosis (Looker et al. 1997). Osteoporosis is a preventable disease and must be diagnosed and treated before any fracture occurs. Furthermore, effective treatments are available to reduce the risk of subsequent fractures following the first fractures. In primary care, prevention, diagnosis, and treatment should be the mandate when dealing with osteoporosis (Cosman et al. 2014).

Fragility fracture, also known as "low-level" or "low energy" trauma, is defined as fracture that results from mechanical force that would not normally result in fracture (Kanis et al. 2001b; NICE 2012). These fractures most commonly occur in the spine (vertebrae), hip (proximal femur), and wrist (distal radius). Fragility fractures may also occur in the arm (humerus), pelvis, ribs, and other bones. More than 20% of postmenopausal women have prevalent vertebral fractures (Melton et al. 1993). Osteoporotic fractures are fractures associated with low bone mineral density (BMD) and usually occur in the spine, forearm, hip, and shoulder (NICE 2012). In women, the lifetime probability of a fracture at any one of these sites is around 12% which exceeds that of breast cancer (Kanis et al. 2000). Collectively in Europe, all osteoporotic fractures account for 2.7 million fractures in men and women (Kanis et al. 2005a). In the USA, more than two million osteoporosis-related fractures occur annually and 70% of which occur in women (Burge et al. 2007).

53.1.3 Health and Economic Impact of Osteoporosis

Osteoporotic fragility fractures place an enormous medical and personal burden on individuals as well as economic toll on the nation. Often, patients with osteoporotic fractures suffer from substantial pain and disability which usually lead to reduced quality of life (NICE 2012). It is also well established that osteoporosis and the consequent fractures are associated with increased mortality, with the exemption of forearm fracture (Cooper et al. 1993). In Europe, in 2010, 43,000 deaths were thought to be causally related to osteoporotic fractures. It is estimated that 50% of fracture-related deaths in women were due to hip fractures, 28% to clinical vertebral and 22% to other fracture (Hernlund et al. 2013). Additionally, in Europe, osteoporosis accounts for more disability-adjusted life years compared with many non-communicable diseases including rheumatoid arthritis, Parkinson's disease, breast cancer, and prostate cancer (Johnell and Kanis 2006).

Hip fractures are associated with an 8.4–36% excess mortality within 1 year of fracture, with mortality higher in men than in women (Abrahamsen et al. 2009). Hip fractures nearly always lead to hospitalization, permanently disable 50% of those affected and are fatal in 20% of cases with only 40% of patients fully regaining their pre-fracture level of independence (USDHHS 2004; Sernbo and Johnell 1993). Most deaths following hip fracture occur in the first 3–6 months of which 20–30% are causally related to the fracture event itself (USDHHS 2004; Sernbo and Johnell 1993).

Furthermore, following a hip fracture, the risk of future fracture increases by 2.5-fold (Colón-Emeric et al. 2003). In the UK, projections suggest that the incidence of hip fracture will rise from 91,500 per year in 2015 to 101,000 in 2020 (DH 2006).

In the USA, the cost of osteoporosis-related fractures to the healthcare system was estimated at $17 billion in 2005 with hip fractures accounting for 14% of incident fractures and 72% of the total fracture costs (Burge et al. 2007). This cost is estimated to double and even triple by the year 2040. In the UK, the costs of fragility fractures to the healthcare economy were estimated at £1.8 billion in 2000, with the potential to increase to £2.2 billion by 2025, and with cost mainly relating to hip fracture care (Burge et al. 2001). In Europe, the cost of osteoporotic fractures was estimated at €38.7 billion in 2010 in 27 EU countries (Hernlund et al. 2013).

53.2 Basic Pathophysiology

The skeleton consists of specialized bone cells, water (which represents at least 25% of its wet weight), mineralized and unmineralized connective tissue matrix, and spaces that include the bone marrow cavity, vascular canals, canaliculi, and lacunae containing osteocytes. It is a highly dynamic organ that constantly undergoes changes and regeneration.

There are two major types of bone in the adult skeleton:

- Cortical bone constitutes the outer part of all skeletal structures. It is dense and compact and comprises 80% of the skeletal weight. The major function of cortical bone is to provide mechanical strength and protection. Additionally it also plays a part in metabolic responses, particularly when there is severe or prolonged mineral deficit.
- Trabecular, also known as cancellous, bone is found inside the long bones, particularly at the ends, throughout the bodies of the vertebrae, and in the inner portions of the pelvis and other large flat bones. Its main function is to provide mechanical support, particularly in the vertebrae. Compared with cortical bone, it is more metabolically active and provides the initial supplies of mineral in acute deficiency stated (Fig. 53.2).

Though dense cortical bone differs in architecture compared with spongy trabecular bone, they have the same molecular composition. Both types of bones have an extracellular matrix with mineralized and nonmineralized components. The composition and architecture of the extracellular matrix of cortical and trabecular bones determine their mechanical properties. In particular, bone strength is determined by collagenous proteins (tensile strength) and mineralized osteoid (compressive strength). The greater the concentration of calcium, the greater the compressive strength (Bono and Einhorn 2003).

53.2.1 Bone Modeling and Remodeling

The skeleton is sculpted to achieve its shape and size during growth and development. This is achieved through the process called modeling which involves complex processes that are influenced by locally and systemically produced factors and mechanical forces. Primarily, bone modeling involves the removal of bone from one site and deposition at a different site (Frost 1973). . During childhood and adolescence, linear growth occurs by the growth of cartilage at the end plates, followed by endochondral bone formation. The skeletal mass increases steadily through a combination of linear growth and changes in bone density and dimensions during childhood. During pubertal growth, there is a marked acceleration in bone mass acquisition, with 25–50% of the peak bone mass of adulthood accumulated during the pubertal growth spurt (Bailey et al. 1999, 2000). This is illustrated in Fig. 53.3, which shows the dramatic increase in the rate of bone mineral accrual in both sexes during the years of most rapid longitudinal growth.

Following skeletal maturity, the regeneration of bone continues in the form of a periodic replacement of old bone with new bone at the same location. This process is called remodeling,

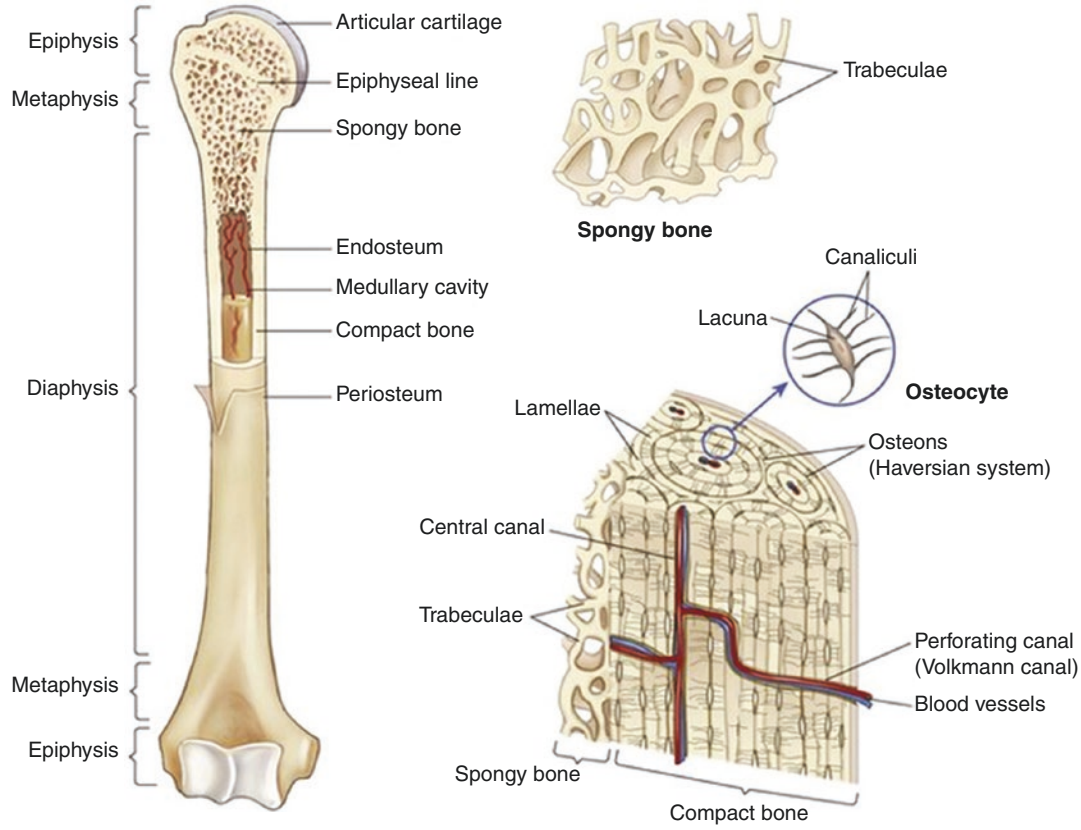

Fig. 53.2 Cortical bone and trabecular (cancellous) bone

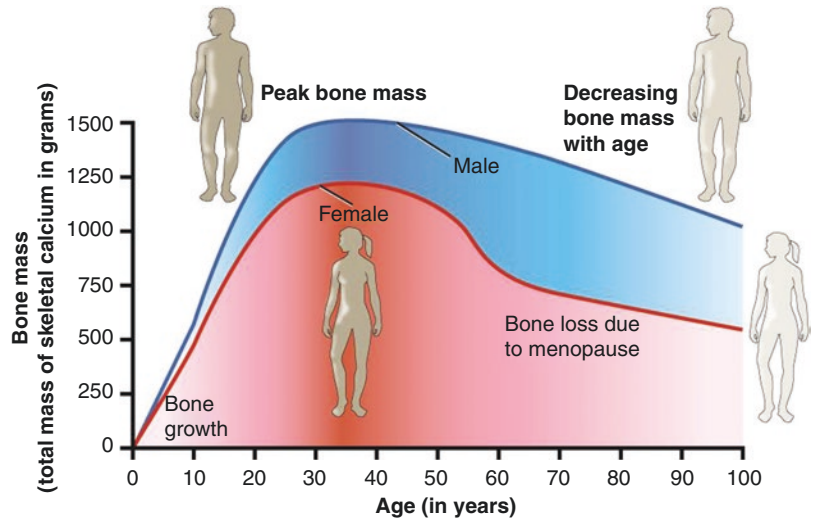

Fig. 53.3 General pattern of bone development (Bailey et al. 1999, 2000)

a complex process which is responsible for the complete regeneration of the adult skeleton every 10 years (Manolagas 2017a). The remodeling process is considered a preventive maintenance program responsible for: removing dead osteocytes; maintaining oxygen, nutrient supply and the appropriate level of matrix hydration; and repairing fatigue and damaged bone, thus preventing excessive aging and its consequences. During growth and development, remodeling also occurs in the growing skeleton with positive balance. The purpose of remodeling during this

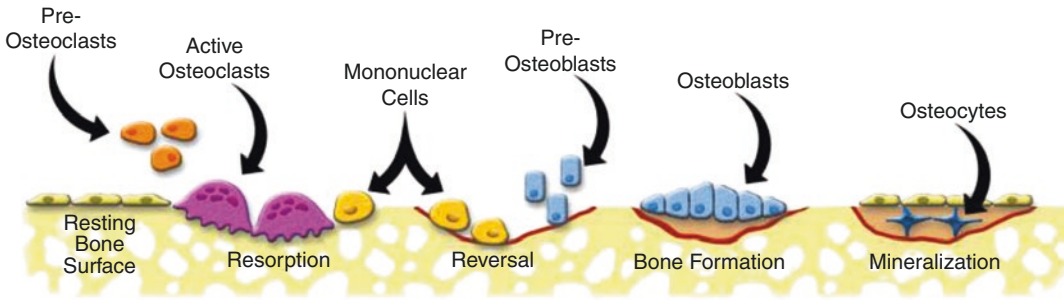

Fig. 53.4 Bone remodeling cycle

state is to expand the marrow cavity while increasing trabecular thickness (Parfitt 1994).

The remodeling cycle involves four stages: ***resorption, reversal, formation, and mineralization*** (Fig. 53.4). Each stage has different length. Resorption probably continues for about 2–3 weeks. The reversal phase may last up to 4 or 5 weeks, while formation can continue for 3–4 months until the new bone structural unit is fully formed. Bone remodeling occurs at discrete sites within the skeleton and proceeds in an orderly fashion with bone resorption always followed by bone formation, a phenomenon also known as coupling.

There are three main types of cells responsible for the bone remodeling process: ***osteoclast, osteoblast, and osteocytes***. Osteoclasts, derived from hematopoietic precursors, are responsible for bone resorption (removal of bone), whereas osteoblasts, from mesenchymal cells, are responsible for bone formation. Both of these processes are controlled by the osteocytes. Osteocytes, which are terminally differentiated osteoblasts embedded in mineralized bone, direct the timing and location of bone remodeling. Unlike osteoclasts and osteoblasts, osteocytes are deployed throughout the skeleton, are long-lived, and are far more abundant than either osteoclasts (1000 times) or osteoblasts (10 times) (Manolagas and Parfitt 2010).

There are several systemic hormones, cytokines, growth factors, and local signals that influence the birth, death, and function of bone cells. The major systemic regulators are the calcium-regulating hormones, parathyroid hormone (PTH), calcitriol, growth hormone/insulin-like growth factor-1 (IGF-1), glucocorticoids, thyroid hormones, and sex hormones. Other factors, such as IGFs, have both systemic and local effects, and some have mainly or solely local effects, particularly prostaglandins, transforming growth factor (TGF)-beta, bone morphogenetic proteins, and cytokines. The following act as Systemic and Local Regulators of Bone Cells: Parathyroid hormone, Calcitriol, Sex steroids, Calcitonin, Growth hormone and IGFs, TGF-beta, Glucocorticoids, Thyroid hormones, Cytokines, Fibroblast growth factors and other factors such as Prostaglandins, leukotrienes, and nitric oxide (Manolagas 2017a)

In osteoporosis, there is an imbalance in the coupling mechanism between osteoclasts and osteoblasts (Raisz 2005). Bone loss occurs when the balance in bone resorption and bone formation is altered, resulting in greater bone removal than replacement. Osteoclasts take weeks to resorb and osteoblasts require months to produce new bone which results in a net bone loss over time (Fig. 53.4). Rapid remodeling occurs with menopause and advancing age. During menopause, fracture risk is significantly increased because the newly produced bone is less densely mineralized, the resorption sites are temporarily unfilled, and the isomerization and maturation of collagen are impaired (Bono and Einhorn 2003).

Bone loss, together with other aging-related decline in functioning, leads to an increased risk of fracture. Fractures usually occur when weakened bone is overloaded, often caused by falls or certain activities of daily living. Figure 53.5 shows the pathogenesis of osteoporosis-related fractures which includes factors that relate to aging and sex steroid deficiency, as well as specific risk factors such as use of glucocorticoids which can cause decreased bone formation and bone loss, reduced bone quality, and disruption of micro-architectural integrity (Cosman et al. 2014).

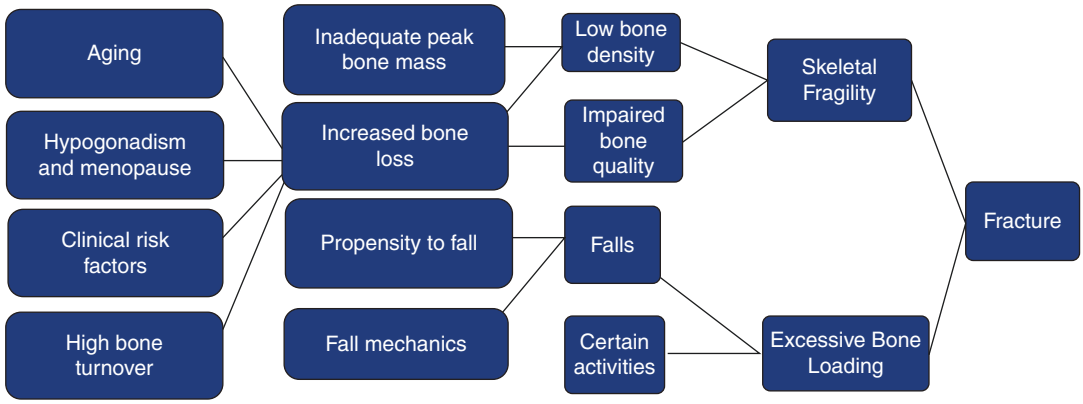

Fig. 53.5 Factors leading to osteoporosis-related fractures (Source: Cooper and Melton (2014) Epidemiology of osteoporosis. Trends Endocrinology and Metabolism. 3(6): 224–229)

53.3 Diagnosis of Osteoporosis

53.3.1 Diagnostic Criteria

Osteoporosis is diagnosed radiographically based on BMD assessment. BMD is most often described as a *T*- or *Z*-score, both of which represent units of standard deviation (SD). The *T*-score describes the number of SDs by which the BMD in an individual differs from the mean value expected in young healthy individuals. The *Z*-score on the other hand describes the number of SDs by which the BMD in an individual differs from the mean value expected for age and sex. The operational definition of osteoporosis is based on the *T*-score for BMD. Based on the WHO criteria, osteoporosis is defined as a BMD, assessed at the femoral neck, that lies 2.5 standard deviations or more below the young female adult mean (*T*-score of less than or equal to −2.5 SD) (WHO 1994) (Table 53.3). These criteria, however, should not be applied in men younger than 50 years, children, or premenopausal women. The International Society for Clinical Densitometry recommends the use of the *Z*-score for these groups of individuals and *Z*-scores of −2.0 or less are considered below the expected range for age (Schousboe et al. 2013).

Clinically, osteoporosis can also be diagnosed if there is a low-trauma (e.g., fragility) fracture in the absence of other metabolic bone disease and independent of the BMD (*T*-score) value (Camacho et al. 2016).

Table 53.3 WHO criteria for classification of osteopenia and osteoporosis based on BMD

Category	BMD	*T*-score[a]
Normal	Within 1 SD of a young-adult reference population	−1.0 or above
Low bone mass (osteopenia)	Between 1.0 and 2.5 SD below that of a young-adult reference population	Between −1.0 and −2.5
Osteoporosis[b]	2.5 SD or more below that of a young-adult reference population	−2.5 or below
Severe or established osteoporosis	2.5 SD or more below that of a young-adult reference population	−2.5 or below with one or more fractures

[a]These definition and reference ranges are necessary to establish the presence of osteoporosis; however, it is important to note that they should not be used as the sole determinant of treatment decisions

[b]The category of "osteopenia" is useful for epidemiology studies and clinical research but is problematic when applied to individual patients. Decision regarding appropriate treatment should therefore be combined with clinical information as the fracture rates within this category vary widely

53.3.2 Clinical Features and Complications of Osteoporosis

Low BMD and fractures are the main clinical features of osteoporosis. As noted in the earlier section, there is a strong inverse relation between BMD and fracture risk with low BMD being the

major indicator for fracture risk. However, low BMD and/or bone loss are not associated with symptoms prior to fracture. Fracture is the single most important manifestation of postmenopausal osteoporosis (Camacho et al. 2016). In patients with osteoporosis, fractures are usually precipitated by low-energy injuries such as fall from standing height, otherwise known as fragility fracture. However, vertebral fractures may occur without a specific fall or injury even during routine daily activities.

Osteoporosis-related fractures can have serious consequences including pain, disability, deformity, and reduced quality and quantity of life (Johnell and Kanis 2006). Most major osteoporotic fractures are associated with reduced relative survival, with an impact persisting more than 5 years after the index event (Bliuc et al. 2009; Harvey et al. 2010). Hip fractures are the most serious consequence of osteoporosis with more than 50% of survivors unable to return to independent living and many require long-term nursing home care. Furthermore, women with hip fracture have an increased mortality of 12–20% during the following 2 years (Orwig et al. 2006). In Europe, osteoporosis accounts for more disability-adjusted life years than many non-communicable disease including rheumatoid arthritis, Parkinson's disease, breast cancer, and prostate cancer (Johnell and Kanis 2006).

53.3.3 Bone Densitometry

BMD is a measure of the amount of bone mass per unit volume (volumetric density), or per unit area (areal density), and both can be measured in vivo by densitometric techniques. There is a wide variety of techniques used to assess bone mineral and the most commonly used are based on X-ray absorptiometry (DXA). This technique is most widely used as the absorption of X-rays is very sensitive to the calcium content of the tissue of which bone is the important source. In bone DXA scan, the areal density (in grams per square centimeter) is measured rather than the true volumetric density as the scan is two dimensional. As determined in vitro on isolated bones, such as the vertebral body or proximal femur, areal BMD accounts for about two-thirds of the variance of bone strength (Kanis et al. 2013).

BMD measurements can provide diagnostic criteria, prognostic information on the probability of future fractures and a baseline on which to monitor the natural history of the treated or untreated patient. Table 53.4 summarizes the potential uses of BMD measurements in postmenopausal women.

DXA is versatile as it can be used to assess bone mineral density/bone mineral content of the whole skeleton as well as specific sites, including those most vulnerable to fractures (Blake and Fogelman 2007). DXA can also be used for vertebral fracture assessment (VFA) as it can detect deformities of the vertebral bodies from T4 to L4. In research, DXA is also used to measure BMD of the whole bone as well as measurement of fat and lean mass. The use of DXA involves less radiation and more so, it is also less expensive compared with a conventional X-ray examination. In osteoporosis assessment, the use of bone mass measurement for prognosis depends upon accuracy. All densitometric techniques generally have high specificity but low sensitivity which varies with the cut-off chosen to designate high risk.

BMD testing is considered as the gold standard in diagnosing osteoporosis (Camacho et al. 2016). BMD has been clearly shown to correlate with bone strength and low BMD is the single best predictor of fracture risk (Camacho et al. 2016; Cosman et al. 2014). The risk of fracture increases approximately by twofold for each SD

Table 53.4 Potential uses of BMD measurements in postmenopausal women (Source: Camacho et al. 2016)

• Screening for osteoporosis
• Establishing the severity of osteoporosis or bone loss in patients with suspected osteoporosis (e.g., patients with fractures or radiographic evidence of osteopenia)
• Determining fracture risk (especially when combined with other risk factors for fractures)
• Identifying candidates for pharmacological intervention
• Assessing changes in bone density over time in treated and untreated patients
• Enhancing acceptance of, and perhaps adherence with, treatment
• Assessing skeletal consequences of diseases, conditions, or medications known to cause bone loss

Table 53.5 Indications of BMD testing (Adapted from: AACE/ACE Guidelines, 2016) (Camacho et al. 2016)

• All women ≥65 years old
• All postmenopausal women:
(a) with history of fracture(s) without major trauma
(b) with osteopenia identified radiographically
(c) starting or taking long-term systemic glucocorticoid therapy (≥3 months)
• Other peri- or postmenopausal women with risk factors for osteoporosis if willing to consider pharmacologic interventions:
(a) low body weight (<127 lb or body mass index of <20 kg/m^2)
(b) long-term systemic glucocorticoid therapy (≥3 months)
(c) family history of osteoporotic fracture
(d) early menopause (40 years old)
(e) current smoking
(f) excessive alcohol consumption
• Secondary osteoporosis

Table 53.6 Diagnostic evaluation of individuals with osteoporosis (Adapted from: Cosman et al. 2014)

A. Routine
• History and physical examination.
• Bone densitometry (DXA).
• Laboratory tests: blood cell count, sedimentation rate or C-reactive protein; serum calcium, albumin; creatinine; electrolytes; phosphate; liver enzymes; alkaline phosphatase; serum vitamin D, and thyroid function test.
B. Other test if clinically indicated may include:
b.1 Radiographic investigations:
• Lateral radiographs of lumbar and thoracic spine or DXA-based lateral vertebral imaging (VFA)
• Isotope bone scan
b.2 Laboratory investigations:
• Serum intact parathyroid hormone concentration (for possible primary or secondary hyperparathyroidism)
• Serum protein immunoelectrophoresis and urinary Bence Jones proteins (for possible myeloma)
• Serum testosterone, sex hormone binding globulin, follicle stimulating hormone, luteinizing hormone (may indicate hypogonadism)
• Endomysial and/or tissue transglutaminase antibodies (may indicate celiac disease)
• Markers of bone turnover
• 24 h urinary free cortisol/overnight dexamethasone suppression test (for suspected cortisol hypersecretion)
• Serum tryptase, urine *N*-methylhistidine, or other tests for mastocytosis
• Genetics testing for unusual features that suggest rare metabolic bone diseases (e.g., osteogenesis imperfecta)
b.3 Bone biopsy (usually restricted to specialist centers).

decrease in BMD (Johnell et al. 2005). However, the low sensitivity of DXA is one of the reasons why widespread population-based screening with BMD is currently not widely recommended in postmenopausal women (WHO 1994). Therefore, it is crucial that the decision to measure BMD should be based on the individual's clinical risk factors and skeletal health assessment (Kanis et al. 2007). BMD measurement is not recommended in children, adolescents, or healthy young men or premenopausal women, unless there is a significant fracture history or there are specific risk factors for fracture or bone loss (e.g., long-term glucocorticoid therapy) (Camacho et al. 2016) (Table 53.5).

The preferred measurement sites for DXA are the total hip, femoral neck, and/or lumbar spine. These areas provide accurate and reproducible BMD measurements at important osteoporosis-associated fracture sites. Furthermore, most therapeutic studies, diagnostic criteria, and cost-effectiveness data have been based primarily on DXA measurements from these sites (Johnell et al. 2005; Stone et al. 2003). It is recommended that both hips are measured to prevent misclassification and to have a baseline for both hips in case a fracture or replacement occurs in one hip (Camacho et al. 2016). The distal one-third radius can also be used as a diagnostic site, especially when other preferred sites are not available. For optimal and most reliable comparative results, it is also recommended that BMD measurements are carried out using the same instruments and, ideally, by the same technician (ISCD 2015). Like any technologies, DXA has a number of limitations which should be recognized (Watts 2004). Additionally, DXA can provide inaccurate BMD readings due to several factors.

There are several other techniques available for BMD measurement, including quantitative computed tomography (QCT) for measurement of both central and peripheral sites, quantitative ultrasonometry (QUS), radiographic absorptiometry, peripheral dual-energy X-ray absorptiometry (pDXA), and single-energy X-ray absorptiometry (Table 53.6).

53.3.4 Diagnostic Evaluation

Assessment of individuals with osteoporosis should not only include BMD evaluation but also a comprehensive medical history, physical examination, exclusion of diseases that mimic osteoporosis, elucidation of the cause of osteoporosis, and the management of any associated morbidity. Some of the disorders contributing to bone loss/osteoporosis may be asymptomatic and require laboratory testing for confirmation. Due to the high prevalence of causes of secondary osteoporosis, laboratory testing should be considered for individuals diagnosed with osteoporosis (Gallagher and Sai 2010). If medical history, physical examination, or laboratory investigations suggest causes of secondary osteoporosis, additional confirmatory tests should be considered as listed in Table 53.6.

Bone turnover markers (BTMs), although cannot be used to diagnose osteoporosis, can provide a dynamic assessment of skeletal activity and can be useful predictors of fracture risk (Camacho et al. 2016). The bone formation osteoblast-derived products and the bone resorption products of collagen degradation are the most useful BTMs. BTMs are typically ordered to: aid in the decision of whether to start, continue, or stop treatment; determine medication compliance; or evaluate drug absorption or therapeutic efficacy (Vasikaran et al. 2011; Allende-Vigo 2007).

Summary

Key Points in Clinical Practice

- The diagnosis of osteoporosis is based on the BMD T-score of ≥−2.5 SD.
- BMD testing is considered the gold standard for diagnosing osteoporosis.
- The diagnostic criteria for BMD are the same in men and women because for any age and BMD at the femoral neck, the risk of hip fracture or major osteoporotic fracture is the same in both groups (De Laet et al. 1998; Johnell et al. 2005; Kanis et al. 2011).
- The T-score cannot be used interchangeably with different techniques and at different sites as the prevalence of osteoporosis, the risk of fracture, and proportion of individuals allocated to any diagnostic category vary.
- Osteoporosis in men younger than 50 years cannot be diagnosed based on BMD assessment alone (Schousboe et al. 2013).
- Low BMD and fractures are the main clinical features of osteoporosis.

53.4 Fracture Risk Assessment

53.4.1 Assessment of Risk

There is currently no universally accepted policy for population-based screening to identify patients with osteoporosis or those at high risk of fracture. Majority of patients are identified opportunistically using a case finding strategy on the discovery of a previous fracture or the presence of significant risk factors. The risk factors used for clinical assessment, as summarized in Table 53.7, are useful in assessing risk but in principle, any risk factor that alerts the clinician to the possibility of osteoporosis is a candidate (e.g., height loss, thoracic kyphosis, etc.).

Kanis et al. (2008) have proposed an approach to fracture risk assessment as shown in Fig. 53.6. The process starts with identification of clinical risk factors followed by assessment of fracture probability by FRAX®. Using this approach, patients who are categorized as high risk can be considered for treatment without the need for BMD testing. Therefore, not all individuals require BMD testing. Several guidelines in Europe and America recommend treatment in the absence of information on BMD in women with a previous fragility fracture (a prior vertebral or hip fracture in North America) (Camacho et al. 2016; Kanis et al. 2013; Papaioannou et al. 2010). Similarly, there will be instances where the probability of fracture is so low that a decision not to treat can be made without BMD. In clinical practice, BMD measurements are often requested by clinician for reasons other than to decide on treatment intervention, for example, as a baseline to monitor treatment.

Table 53.7 Clinical risk factors for fracture that are independent of age and BMD (Adapted with modification from: Compston et al. 2017)

A. Low body mass index (BMI) • Low BMI is a significant risk factor for hip fracture, but the value of BBMI in predicting other fracture is very much diminished when adjusted for BMD.
B. History of prior fracture • A history of prior fracture at a site characteristic for osteoporosis is an important risk factor for further fracture. • Fracture risk is approximately doubled in the presence of a prior fracture, including morphometric vertebral fractures. • The increase in risk is even more marked for more than one vertebral fracture.
C. Parental history of hip fracture • A parental history of hip fracture is a significant risk factor that is largely independent of BMD.
D. Smoking • Smoking is a risk factor that is part dependent on BMD.
E. Use of glucocorticoids • Glucocorticoids increase fracture risk in a dose-dependent manner. • The fracture risk conferred by the use of glucocorticoids is, however, not solely dependent upon bone loss and BMD-independent risk has been identified.
F. Alcohol • The relationship between alcohol intake and fracture risk is dose-dependent. • Where alcohol intake is on average two units or less daily, no increase in risk has been identified. • Intakes of three or more units daily are associated with a dose-dependent increase in fracture risk.
G. Rheumatoid arthritis • Rheumatoid arthritis increases fracture risk independently of BMD and the use of glucocorticoids
H. Diabetes mellitus • Recent evidence suggests that diabetes mellitus (particularly type 2) may also exert BMD-independent effects on fracture risk

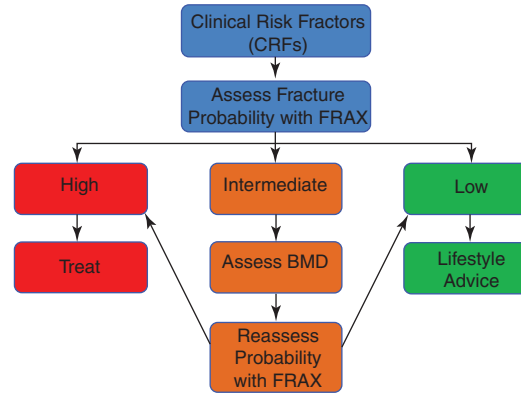

Fig. 53.6 Algorithm for the assessment of individuals at risk of fracture. (Adapted from: Kanis et al., 2008). Case finding for the management of osteoporosis with FRAX®—assessment and intervention thresholds for the UK. *Osteoporosis International* [online], **19**(10), pp. 1395–1408

53.4.2 Clinical Risk Factors

Osteoporosis is a preventable and treatable condition. However, as there are no warning signs prior to a fracture, majority of individuals with the condition are not diagnosed in time and therefore not given effective treatment during the early phase of the disease. A large number of risk factors for fracture have been identified but the focus of interest lies in those factors that contribute significantly to fracture risk over and above that provided by BMD and age (Table 53.7). In the case of causes of secondary osteoporosis (Table 53.2), the increase in fracture risk is presumed to be mediated by low BMD with the exception of glucocorticoid exposure and rheumatoid arthritis for which risks have been identified that are independent of BMD. Recent evidence also suggests that type 2 diabetes mellitus is an important independent risk factor (Kanis et al. 2012; Schwartz et al. 2011).

The following clinical risk factors for fracture are independent of age and BMD (Compston et al. 2017):

- Low body mass index (BM)
- History of prior fracture
- Parental history of hip fracture
- Smoking
- Use of glucocorticoids
- Alcohol
- Rheumatoid arthritis
- Diabetes mellitus

While BMD provides the foundation for the diagnosis of osteoporosis, its value in determining intervention threshold is less than optimal for several reasons. Firstly, the fracture risk varies markedly in different countries, but the *T*-score varies only by a small amount. Secondly, the signifi-

cance of any given *T*-score to fracture risk in women from any one country depends on age and the presence of clinical risk factors. Lastly, intervention thresholds will also be determined in part by the cost and benefits of treatment. These limitations have prompted the development of risk calculator engines that integrate several risk factors for fracture including the Garvan fracture risk calculator, QFracture™ and FRAX®. FRAX® is the most commonly used tool in clinical practice.

53.4.3 The FRAX Tool

FRAX is a computer-based algorithm (http://www.shef.ac.uk/FRAX) developed by the WHO Collaborating Centre for Metabolic Bone Disease in Sheffield, UK. It calculates the 10-year probability of a major fracture (hip, clinical spine, humerus, or wrist fracture) and the 10-year probability of hip fracture. Fracture risk is calculated from known risk factors (Table 53.8) and

Table 53.8 Clinical risk factors used for the assessment of fracture probability in FRAX Tool (Source: https://www.sheffield.ac.uk/FRAX)

Age	The model accepts ages between 40 and 90 years. If ages below or above are entered, the program will compute probabilities at 40 and 90 year, respectively.
Sex	Male or female. Enter as appropriate.
Weight	This should be entered in kg.
Height	This should be entered in cm.
Previous fracture	A previous fracture denotes more accurately a previous fracture in adult life occurring spontaneously, or a fracture arising from trauma which, in a healthy individual, would not have resulted in a fracture. Enter yes or no (see also notes on risk factors).
Parent fractured hip	This enquires for a history of hip fracture in the patient's mother or father. Enter yes or no.
Current smoking	Enter yes or no depending on whether the patient currently smokes tobacco (see also notes on risk factors).
Glucocorticoids	Enter yes if the patient is currently exposed to oral glucocorticoids or has been exposed to oral glucocorticoids for more than 3 months at a dose of prednisolone of 5 mg daily or more (or equivalent doses of other glucocorticoids) (see also notes on risk factors).
Rheumatoid arthritis	Enter yes where the patient has a confirmed diagnosis of rheumatoid arthritis. Otherwise enter no (see also notes on risk factors).
Secondary osteoporosis	Enter yes if the patient has a disorder strongly associated with osteoporosis. These include type I (insulin dependent) diabetes, osteogenesis imperfecta in adults, untreated long-standing hyperthyroidism, hypogonadism or premature menopause (<45 years), chronic malnutrition, or malabsorption and chronic liver disease
Alcohol three or more units/day	Enter yes if the patient takes three or more units of alcohol daily. A unit of alcohol varies slightly in different countries from 8 to 10 g of alcohol. This is equivalent to a standard glass of beer (285 mL), a single measure of spirits (30 mL), a medium-sized glass of wine (120 mL), or one measure of an aperitif (60 mL) (see also notes on risk factors).
Bone mineral density (BMD)	(BMD) Please select the make of DXA scanning equipment used and then enter the actual femoral neck BMD (in g/cm^2). Alternatively, enter the *T*-score based on the NHANES III female reference data. In patients without a BMD test, the field should be left blank (see also notes on risk factors) (provided by Oregon Osteoporosis Center)

Notes on risk factors

- Previous fracture
  A special situation pertains to a prior history of vertebral fracture. A fracture detected as a radiographic observation alone (a morphometric vertebral fracture) counts as a previous fracture. A prior clinical vertebral fracture or a hip fracture is an especially strong risk factor. The probability of fracture computed may therefore be underestimated. Fracture probability is also underestimated with multiple fractures.
- Smoking, alcohol, glucocorticoids
  These risk factors appear to have a dose-dependent effect, i.e., the higher the exposure, the greater the risk. This is not taken into account and the computations assume average exposure. Clinical judgment should be used for low or high exposures.
- Rheumatoid arthritis (RA)
  RA is a risk factor for fracture. However, osteoarthritis is, if anything, protective. For this reason reliance should not be placed on a patient's report of "arthritis" unless there is clinical or laboratory evidence to support the diagnosis.
- Bone mineral density (BMD)
  The site and reference technology is DXA at the femoral neck. *T*-scores are based on the NHANES reference values for women aged 20–29 years. The same absolute values are used in men.

Fig. 53.7 FRAX—Fracture Risk Assessment Tool. Available at: https://www.sheffield.ac.uk/FRAX/

the femoral neck BMD can be optionally input to enhance the fracture risk prediction. The use of clinical risk factors in conjunction with BMD and age improves the sensitivity of fracture prediction without adverse effect on specificity (Kanis et al. 2007). Furthermore, the fracture probability is computed by taking into account both the risk of fracture and the risk of death. The tool has also been externally validated in independent cohorts. As the fracture probability differs markedly in different regions of the world, FRAX has been calibrated to those countries where the epidemiology of fracture and death is known. It is currently available for use in 63 countries (Table 53.8 and Fig. 53.7).

53.4.4 Assessment Threshold for BMD Testing

In clinical practice, the use of FRAX demands a consideration of the fracture probability at which to intervene, both for BMD testing (assessment threshold) and for treatment (intervention threshold). Due to the wide variation in the availability of DXA facility from country to country, most adopt a case finding strategy where individuals with clinical risk factors are identified for further assessment. However, most countries set their assessment threshold for BMD testing differently hence there is no unified recommendation for assessment threshold strategy.

53.4.5 Intervention Threshold

Similar to the assessment threshold, several strategies have been used to set the intervention thresholds with FRAX (Fig. 53.8). The intervention thresholds vary from country to country as the population risks (of fracture and death) vary and also due to several local factors including reimbursement issues, health economic assessment, willingness to pay for health care in osteoporosis, and access to DXA (Kanis et al. 2001a, 2002, 2013; Ström et al. 2011). Several guidelines recommend that women with a prior fragility fracture may be considered for intervention without the necessity for a BMD test as a prior fracture can be considered to carry sufficient risk that warrant treatment. Using this premise, the intervention threshold can therefore be set at the "fracture threshold," an approach used in several countries including France, Switzerland, and the UK. For men, the same intervention threshold is recommended as the effectiveness and cost-effectiveness of intervention are broadly similar to that in women for equivalent risk (Kanis et al. 2011; Tosteson et al. 2008).

53.4.6 Assessment of Vertebral Fracture

Vertebral fracture is the most common osteoporotic fracture and indicates a high risk for future fractures, even when the *T*-score does not meet the threshold for osteoporosis. Hence, it is important to assess for prevalent vertebral fractures in high risk individuals as it can significantly change the diagnostic classification, estimated risk of future fractures, and clinical management (Camacho et al. 2016). However, the majority of vertebral fracture remains undetected unless specifically pursued by radiographic assessment (spine X-ray or VFA using DXA) (Lewiecki and Laster 2006). Assessment of vertebral fractures can be done using a standard lateral spine imaging or VFA by DXA. The latter delivers a significantly lower

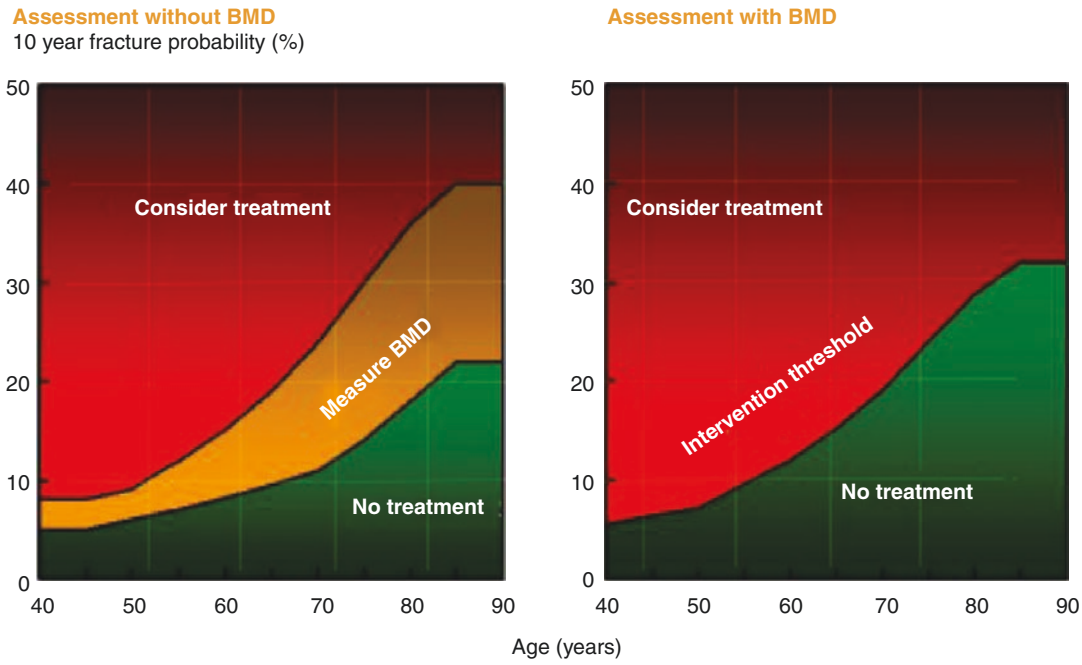

Fig. 53.8 Assessment and treatment thresholds with or without BMD (Source: Compston et al. 2009). Compston, J., Cooper, A., Cooper, C., Francis, R., Kanis, J.A., Marsh, D., McCloskey, E.V., Reid, D.M., Selby, P., Wilkins, M. and National Osteoporosis Guideline Group (NOGG) (2009) Guidelines for the diagnosis and management of osteoporosis in postmenopausal women and men from the age of 50 years in the UK. *Maturitas* [online], **62**(2), pp. 105–108

dose of radiation but performs comparably to traditional radiographs (Lewiecki 2010).

Vertebral fracture assessment should be considered in postmenopausal women and older men with:

(a) A history of ≥4 cm height loss.
(b) Self-reported but undocumented prior vertebral fractures.
(c) Kyphosis.
(d) Recent or current long-term oral glucocorticoid therapy (equivalent to ≥5 mg prednisolone per day for ≥3 months).
(e) BMD *T*-score of ≤−2.5 (In the USA, *T*-score of <−1.0 and one or more of the above as defined in a–d).

Assessment of vertebral fracture is also recommended in individuals with a history of non-vertebral fracture after the age of 50 years (Gallacher et al. 2007). In patients with back pain or unexplained height loss, vertebral fracture assessment should be considered if prevalent vertebral fractures would alter the clinical management. It is important to note that the sensitivity and reliability of standard radiography to assess BMD are poor and therefore, the technique should not be used to diagnose osteoporosis in routine clinical practice.

Summary

Key Points in Clinical Practice

- Assessment of fracture risk should be undertaken through comprehensive medical history and physical examination.
- Assessment of clinical risk factors should be completed including: history of prior fracture without major trauma after the age of 50, age ≥65, low BMI (<57.6 kg [127 lb]); family history of osteoporosis or fractures; smoking; early menopause, excessive alcohol intake (≤3 units daily); height loss or kyphosis, and risk for falling.
- Laboratory investigation to screen for secondary causes should be completed.
- Assessment of vertebral fractures by standard lateral spine imaging or VFA by DXA should be considered in high risk patients.
- BMD measurement by DXA should be considered in those at increased risk for osteoporosis and fractures and willing to consider pharmacological interventions.

53.5 Universal Recommendations for the Management of Osteoporosis

Several lifestyle interventions can be recommended to the general population to improve musculoskeletal integrity and balance, preserve bone strength, and prevent future fractures. These lifestyle measures include increasing the level of physical activity, stopping smoking, reducing alcohol intake, reducing the risk of falls, and ensuring adequate intake of calcium and vitamin D. Some patients with osteoporosis may also benefit from physical therapy or other activities or even other non-pharmacological measures to improve strength and reduce the risk of falls and fractures.

53.5.1 Calcium Intake

Adequate calcium intake either through the diet or supplementation is a fundamental aspect of any osteoporosis management program and has been shown to result in small increase in BMD (Tai et al. 2015). However, convincing evidence that calcium alone reduces fracture risk is lacking (Bolland et al. 2015). A balanced diet rich in low-fat dairy products, fruits, and vegetables can provide the necessary calcium as well as other nutrients essential for good health. If adequate calcium cannot be achieved through dietary intake, supplementation is indicated up to the recommended daily intake. Prior to recommend-

ing calcium supplementation, it is important to obtain a dietary history to assess calcium intake. There are several simple dietary calcium intake calculators available online.

There are several preparations of calcium supplements. Generally, calcium carbonate tablet is the most commonly used in clinical practice as it requires the smallest number of tablets due to its substantial calcium content (40%). However, it is known to cause more gastrointestinal (GI) side effects (e.g., constipation and bloating) compared with calcium citrate (Camacho et al. 2016). The absorption of calcium carbonate is dependent on gastric acid concentration and is best absorbed when taken with food. Calcium citrate is usually more expensive compared with calcium carbonate and it also requires more tablets to achieve the desired dose due to its lower calcium content (21%). The absorption of calcium citrate, however, is not dependent on gastric acid and therefore less likely to cause GI side effects. It is recommended that calcium supplementation should not exceed 500–600 mg per dose to ensure optimal absorption (Camacho et al. 2016). For individuals requiring more than 600 mg calcium supplementation daily, the dose should be split accordingly. Calcium supplements are also available in chewable or soluble preparations.

53.5.2 Vitamin D Intake

Vitamin D plays a major role in calcium absorption, bone health, balance, muscle performance, and risk of falling. Evidence also suggests that optimal vitamin D status may enhance the response to bisphosphonate treatment, increase BMD, and prevent fractures (Bischoff-Ferrari et al. 2004). The recommended intake of vitamin D, as proposed by many international scientific organizations, is between 800 and 1000 IU per day for adults aged 50 years and older (Camacho et al. 2016; Compston et al. 2017; Cosman et al. 2014). For the general population, a reference intake of at least 400 IU daily for adults of all ages is recommended with 4000 IU as the safe upper limit (Ross et al. 2011; SACN 2016).

Vitamin D status is assessed by measuring serum 25-hydroxyvitamin D (25[OH]D). There is currently no international consensus on the optimal level of 25(OH)D. The American Endocrine Society recommends a serum 25(OH)D of ≥30 ng/mL (75 nmol/L) (Camacho et al. 2016) while the UK National Osteoporosis Guideline Group (NOGG) recommends a serum 25(OH)D of ≥20 ng/mL (50 nmol/L) (Compston et al. 2017). There remains a controversy as to the optimal upper limit for serum 25(OH)D and the evidence of the safety of higher levels in different populations is not conclusive. The American Endocrine Society recommends a reasonable upper limit of 50 ng/mL (125 nmol/L), a level based on the sun-exposed healthy young adults. The Institute of Medicine (IOM) and the National Osteoporosis Society, UK have proposed the following vitamin D thresholds in respect to bone health (Aspray et al. 2014; Ross et al. 2011):

- Serum 25(OH)D <30 nmol/L (12 ng/mL) is ***deficient***.
- Serum 25(OH)D of 30–50 nmol/L (12–20 ng/mL) ***may be adequate in some people.***
- Serum 25(OH)D of >50 nmol/L (20 ng/mL) is ***sufficient for almost the whole population***.

Many individuals are at high risk of vitamin D deficiency including those with malabsorption (e.g., celiac disease), other intestinal disease, chronic renal insufficiency, patient on medications that increase the breakdown of vitamin D (e.g., some anti-seizure medications), those who are housebound, chronically ill patients, with limited sun exposure, individuals with very dark skin, and obese individuals. Additionally, vitamin D deficiency is also common in patients with osteoporosis and hip fractures (Holick et al. 2005; LeBoff et al. 2008). Individuals who are vitamin D insufficient/deficient (serum 25[OH]D of <20 ng/mL [50 nmol/L]) may be treated with 50,000 IU of vitamin D_2 or vitamin D_3 once a week for 6 weeks or 3200–5000 IU vitamin D_2 or vitamin D_3 daily for 8–12 weeks (Aspray et al. 2014; Holick et al. 2011; Ross et al. 2011). This regime should be followed by appropriate maintenance dose to maintain adequate target of

25(OH)D level. The usual maintenance dose of vitamin D is 800–2000 IU daily (Aspray et al. 2014; Camacho et al. 2016). Occasionally, a higher dose may be required of up to 4000 IU daily (e.g., obese individuals or those with malabsorption problem). When rapid correction of vitamin D deficiency is required, such as patients with symptomatic disease or those who are about to start treatment with potent antiresorptive agent (e.g., zoledronate or denosumab), a single fixed loading dose of 300,000 IU vitamin D may rapidly correct deficiency and improve vitamin D status for up to 3 months (Aspray et al. 2014; Kearns et al. 2013). This should be followed by appropriate regular maintenance therapy.

53.5.3 Smoking and Alcohol Intake

There is a strong body of evidence that proves cigarette smoking increases osteoporotic fracture risk and should therefore be avoided (Daniell 1976; Giampietro et al. 2010; Kanis et al. 2005b). All smokers should be advised to stop tobacco smoking as it is detrimental to the skeleton and to the overall health.

Excessive alcohol intake has also been associated with increased fracture risk (Kanis et al. 2005c). Patients with excessive alcohol intake should be recognized and treated. Moderate alcohol intake has been shown not to have negative effect on bone and may even be associated with slightly higher bone density or lower risk of fracture in postmenopausal women (Cosman et al. 2014). Postmenopausal women at risk of osteoporosis should be advised to consume not more than three units of alcohol daily. A unit of alcohol varies slightly in different countries from 8 to 10 g of alcohol per unit with one unit equivalent to 120 mL of wine, 30 mL of liquor, or 260 mL of beer (Kanis et al. 2005c).

53.5.4 Exercise

Strength training has been shown to result in small yet significant improvement in BMD from studies on early postmenopausal women. Regular weight-bearing and resistance exercise has several other health benefits including improving agility, strength, posture, and balance, which may also reduce the risk of falls. Therefore, regular weight-bearing exercise (e.g., walking for 30–40 min per session, 3–4 days a week) should be advocated lifelong at all ages. Other weight bearing exercises include jogging, Tai-Chi, stair climbing, dancing, and tennis (Cosman et al. 2014). Those individuals with severe osteoporosis should be advised to use caution when engaging in activities that involve forward spine flexion and rotation, lifting heavy weights, or even side bending of the trunk as these maneuvers exert compressive forces on the spine that can lead to fracture (Camacho et al. 2016).

53.5.5 Falls Prevention

Falls are the most common cause of fractures. Therefore, all patients should be assessed for falls risk and advised on fall prevention. An effective osteoporosis management program should include assessing and addressing modifiable risk factors for fall such as correcting visual impairment, minimizing the use of medications that alters alertness and balance, and improving the home environment (anchoring rugs and using non-skid mats, removing obstacles/clutter, improving lighting, installing handrails). Hip protectors may reduce the risk of hip fractures by protecting the individual in the event of a fall. However, its effectiveness due to poor acceptance and adherence by older people has not been established and evidence on its anti-fracture benefits is inconclusive (Gillespie et al. 2010).

Summary

Key Points in Clinical Practice

- Life style measures should be promoted to improve bone health including increasing the level of physical activity, smoking cessation, minimizing alcohol intake to not more three units per day, reducing the risk of falls, and ensuring

adequate dietary calcium intake and vitamin D status.
- Daily calcium intake of 700–1200 mg daily should be advised, either through diet or in the form of supplementation.
- Daily vitamin D dose of 800–1000 IU is recommended in postmenopausal women and men ≥50 years who are at increased risk of fracture.
- Falls risk assessment should be part of every osteoporosis management program including the provision of appropriate measures to reduce the risk of falling.

53.6 Pharmacological Therapy

Several pharmacological agents have been shown to be effective in reducing fracture risk in postmenopausal women with osteoporosis. Most agents used for the prevention and/or treatment of osteoporosis have been studied in women with postmenopausal osteoporosis with very limited data in glucocorticoid-induced osteoporosis and in men. Prior to initiating pharmacological treatment, clinician should counsel patient about the potential benefits as well as the potential risks of therapy. Table 53.9 summarizes the list of approved medications for the prevention and treatment of osteoporosis.

53.6.1 Bisphosphonates

Bisphosphonates are analogues of inorganic pyrophosphate that inhibit bone resorption. It was first introduced in the 1990s and is the most widely used drugs for treating osteoporosis.

53.6.1.1 Alendronate

- *Indications*: it is approved for the treatment of postmenopausal osteoporosis, prevention of postmenopausal osteoporosis, in men with osteoporosis, and for prevention and treatment of glucocorticoid-induced osteoporosis.
- *Dose and Preparation*: 70 mg tablet or effervescent/soluble tablet once weekly.
- *Special Instructions:* alendronate should be taken after an overnight fast and at least 30 min before the first food or drink (other than water) of the day or any other oral medi-

cations or supplementations (including calcium). Tablet should be swallowed whole with a glass of plain water (~200 mL) while the patient is sitting or standing in an upright position. Patient should not lie down for 30 min after taking the tablet.
- *Side effects:* upper gastrointestinal symptoms, bowel disturbance, headaches, and musculoskeletal pain.
- *Contraindications:* hypersensitivity to alendronate or to any of the excipients, hypocalcaemia, patient unable to follow the dosing regimen for oral use (e.g., inability to remain upright for 30 min), the presence of anatomic or functional esophageal abnormalities (e.g., active esophageal disease, achalasia, stricture, or dysmotility), and the presence of documented or potential GI malabsorption (e.g., gastric bypass procedures, celiac disease, Crohn's disease, infiltrative disorders, etc.).

53.6.1.2 Ibandronate

- *Indications*: it is approved for the treatment of postmenopausal osteoporosis. Oral preparation is also approved for the prevention of postmenopausal osteoporosis.
- *Dose and Preparation*: 150 mg tablet once a month or 3 mg as an intravenous injection every 3 months.
- *Special Instructions:* ibandronate should be taken after an overnight fast and 1 h before the first food or drink (other than water) of the day or any other oral medications or supplementations (including calcium). Tablet should be swallowed whole with a glass of plain water (180–240 mL) while the patient is sitting or standing in an upright position. Patient should not lie down for 1 h after taking the tablet. Patient should note chew or suck the tablet due to the potential risk of oropharyngeal ulceration. In case of a missed dose, patient should be instructed to take one ibandronic acid 150 mg tablet the morning after the tablet is remembered, unless the time to the next scheduled dose is within 7 days. If the next scheduled dose is within 7 days, patient should be advised to wait until their next dose and continue taking one tablet once a month as originally scheduled.
- *Side effects:* side effects with the oral preparation include upper gastrointestinal symptoms and bowel disturbance. Intravenous administration may be associated with an acute phase reaction, characterized by an influenza-like illness; this is generally short-lived and typically occurs only after the first injection.
- *Contraindications:* hypersensitivity to ibandronic acid or to any of the excipients, hypocalcaemia, abnormalities of the esophagus which delay esophageal emptying such as stricture or achalasia, and inability to stand or sit upright for at least 60 min.

53.6.1.3 Risedronate

- *Indications*: it is approved for the treatment of postmenopausal osteoporosis to reduce the risk of vertebral fracture, for the treatment of established postmenopausal osteoporosis, prevention of postmenopausal women with increased risk of osteoporosis, and for the treatment of osteoporosis in men at high risk of fractures.
- *Dose and Preparation*: 5mg tablet once daily or 35 mg tablet once weekly.
- *Special Instructions:* risedronate absorption is affected by food, thus it should be taken at least 30 min before the first food or drink (other than water) of the day or any other oral medications or supplementations (including calcium). If taking the tablet before breakfast is not practical, risedronate should be taken at least 2 h before and at least 2 h after any food, medicinal product, or drink (other than plain water), or at least 30 min before going to bed. The tablet should be swallowed whole in an upright position with a glass of plain water (≥120 mL). Patient should be advised not to lie down for 30 min after taking the tablet.
- *Side effects:* side effects with the oral preparation include upper gastrointestinal symptoms and bowel disturbance. Intravenous administration may be associated with an acute phase reaction, characterized by an influenza-like

illness; this is generally short-lived and typically occurs only after the first injection.
- *Contraindications:* hypersensitivity to risedronate acid or to any of the excipients, hypocalcaemia, pregnancy and lactation, and severe renal impairment (creatinine clearance of <30 mL/min).

53.6.1.4 Zoledronic Acid

- *Indications*: it is approved for the treatment of osteoporosis in postmenopausal women and adult men at increased risk of fracture (including those with a recent low-trauma hip fracture) and treatment of osteoporosis associated with long-term systemic glucocorticoid therapy in postmenopausal women and adult men at increased risk of fracture.
- *Dose and Preparation*: 5 mg as intravenous infusion once yearly.
- *Special Instructions:* zoledronic acid should be administered by intravenous infusion over a minimum period of 15 min. The incidence of post-dose acute phase reaction can be reduced with the administration of paracetamol or ibuprofen shortly following zoledronic acid administration.
- *Side effects:* acute phase reaction characterized by an influenza-like illness; this is generally short-lived and typically occurs only after the first infusion, and gastrointestinal symptoms.
- *Contraindications:* hypersensitivity to zoledronic acid, to any bisphosphonate, or to any of the excipients; hypocalcaemia; severe renal impairment with creatinine clearance of <35 mL/min; pregnancy; and breast-feeding.
- should be evaluated for an incomplete femur fracture.

53.6.2 Denosumab

Denosumab is a fully humanized monoclonal antibody that prevents Receptor Activator of Nuclear factor Kappa-B Ligand (RANKL) from binding to its receptor, RANK, thereby reducing the differentiation of precursor cells into mature osteoclasts and decreasing the function and survival of activated osteoclasts.

- *Indications*: it is approved for the treatment of osteoporosis in postmenopausal women and men at increased risk of fracture, and for the treatment of bone loss associated with hormone ablation in men with prostate cancer at increased risk of fractures.
- *Dose and Preparation*: 60 mg as subcutaneous injection once every 6 months.
- *Special Instructions:* administration should be performed by an individual who has been adequately trained in injection techniques.
- *Side effects:* skin infection, predominantly cellulitis, and hypocalcaemia.
- *Contraindications:* hypersensitivity to the active substance or to any of the excipients and hypocalcaemia.

53.6.3 Raloxifene

Raloxifene is a selective estrogen receptor modulator and inhibits bone resorption.

- *Indications*: it is approved for the treatment and prevention of osteoporosis in postmenopausal women and for the reduction of risk of breast cancer in women with postmenopausal osteoporosis or at high risk of breast cancer.
- *Dose and Preparation*: 60 mg tablet once daily.
- *Special Instructions:* raloxifene may be taken at any time of the day without regard to meals.
- *Side effects:* leg cramps, edema and vasomotor symptoms.
- *Contraindications:* hypersensitivity to the active substance or to any of the excipients, women with child-bearing potential, active or past history of venous thromboembolic events (VTE) (including deep vein thrombosis, pulmonary embolism, and retinal vein thrombosis), hepatic impairment (including cholestasis), severe renal impairment, unexplained uterine bleeding, and patients with signs and symptoms of endometrial cancer.
- *Special Precautions and Warning:* raloxifene should be used with caution in women with a history of stroke or with risk factors for stroke.

53.6.4 Teriparatide

Teriparatide is a recombinant human parathyroid hormone (PTH) [1-34]. When administered intermittently, it has anabolic skeletal effects which are most marked in cancellous bone.

- *Indications*: it is approved for the treatment of osteoporosis in postmenopausal women and men at high risk of fracture, and for the treatment of osteoporosis associated with systemic glucocorticoid therapy in women and men at increased risk of fracture.
- *Dose and Preparation*: 20 μg as subcutaneous injection once daily. Maximum total duration of treatment is 24 months.
- *Special Instructions:* Patient must be trained to use the proper injection techniques.
- *Side effects:* nausea, pain in limb, headache, and dizziness.
- *Contraindications:* hypersensitivity to the active substance or to any of the excipients, pregnancy and breast-feeding, pre-existing hypercalcemia, severe renal impairment, metabolic bone disease (including hyperparathyroidism and Paget's disease of the bone) other than primary osteoporosis or glucocorticoid-induced osteoporosis, unexplained elevations of alkaline phosphatase, prior external beam or implant radiation therapy to the skeleton, and patients with skeletal malignancies or bone metastases.
- *Special Precautions and Warning:* in normocalcemic patients, slight and transient elevations of serum calcium concentrations have been observed following teriparatide injection. Serum calcium concentrations reach a maximum between 4 and 6 h and return to baseline by 16–24 h after each dose of teriparatide. If blood samples for serum calcium measurements are taken, this should be done at least 16 h after the most recent injection. Routine calcium monitoring during therapy is not required.

53.6.5 Strontium Ranelate

Strontium ranelate is approved for treatment of osteoporosis in some countries but not in the USA. Due to evidence of increased cardiovascular risk and occurrence of severe Stevens–Johnson reaction, the European Medicines Agency (EMA) has recommended that strontium ranelate use be restricted to patients who cannot be treated with other medicines approved for osteoporosis, and that these patients be evaluated regularly by their doctor and that treatment is stopped if patients develop heart or circulatory problem such as uncontrolled high blood pressure or angina (EMA 2014).

53.6.6 Calcitriol

Calcitriol (1,25-dihydroxyvitamin D) is the active form of vitamin D and is approved for the treatment of established osteoporosis in an oral dose 0.25 μg twice daily. It acts mainly by inhibiting bone resorption. It has been shown to reduce vertebral fracture risk in postmenopausal women with osteoporosis but effects on non-vertebral and hip fractures have not been demonstrated. It is contraindicated in patients with hypercalcemia or with metastatic calcification. Serum calcium and creatinine levels should be monitored at 1, 3, and 6 months after starting treatment and at 6 monthly intervals thereafter.

53.6.7 Calcitonin

Injectable and nasal spray recombinant salmon calcitonin are approved by the FDA for the treatment of postmenopausal osteoporosis. The approved dosage of injectable calcitonin for treatment of postmenopausal osteoporosis is 100 IU daily given subcutaneously or intramuscularly. The approved dose of nasal spray calcitonin is 200 IU (1 spray) daily. The main contraindication is drug hypersensitivity and skin testing is recommended before use in patients with suspected sensitivity to the drug.

53.6.8 Hormone Replacement Therapy (HRT)

HRT is available in a wide variety of oral preparations including estrogen only, progestin only, and combination estrogen-progestin. Some of

these agents are approved for the prevention of osteoporosis in postmenopausal women at high risk of fracture. Conjugated equine estrogens 0.625 mg daily ± 2.5 mg/day of medroxyprogesterone acetate have been shown to reduce vertebral, non-vertebral, and hip fracture in postmenopausal women not selected on the basis of low bone density or high fracture risk (Rossouw et al. 2002). Due to the unfavorable risk/benefit balance in older postmenopausal women, the use of HRT for osteoporosis is generally restricted to younger postmenopausal women who are at high risk of fracture and also have menopausal symptoms (NCCWCH 2015). In women who are appropriately treated with long-term estrogen (or combination estrogen/progestin) therapy, these agents be sufficient, but they can also be used in conjunction with other medications for osteoporosis (e.g., bisphosphonate, denosumab, or teriparatide) based on clinical needs and judgment (Camacho et al. 2016).

Summary

Key Points in Clinical Practice

- There is a range of pharmacological agents currently used in clinical practice for the prevention and treatment of osteoporosis.
- The most commonly used agents are the bisphosphonates (e.g., alendronate, ibandronate, risedronate, zoledronic acid), raloxifene, agents derived from parathyroid hormone (teriparatide), RANK ligand inhibitor (denosumab), and HRT.
- Strontium ranelate is still available in some countries but its use is restricted to patients who cannot be treated with other medicines approved for osteoporosis.
- Teriparatide is the only pharmacological agent currently used that offers an "anabolic effect."

53.7 Monitoring of Osteoporosis Treatment

53.7.1 Treatment Monitoring

The goal of pharmacological therapy in a patient with osteoporosis is to significantly increase bone strength and ultimately, to prevent fractures. However, there is no treatment that can completely eliminate the risk. As discussed in the previous section, BMD is one of the major determinants of bone strength, and low BMD is an important predictor of fracture. However, there remains a controversy as to whether the long-term anti-fracture efficacy of anti-osteoporotic drugs depends on the extent to which treatment can increase or maintain BMD (Rabenda et al. 2011). A fracture during therapy with bone-targeted medication does not necessarily mean a treatment failure. The occurrence of fracture should trigger re-evaluation of risk factors for fracture and possibly a change in treatment strategies (Camacho et al. 2016).

It is important to monitor patients while receiving pharmacological therapy in order to identify those who have significant bone loss (Camacho et al. 2016). Serial BMD is commonly used to monitor the response to osteoporosis treatment. In patients on treatment, stable or increasing BMD at the spine and hips indicates a satisfactory response (Lewiecki and Watts 2008). In patients with significant reduction in BMD while on treatment should be evaluated for noncompliance, secondary causes of osteoporosis, or use of medications that might cause bone loss (Lewiecki and Rudolph 2002). The frequency of BMD testing should be individualized depending on the patient's clinical state. It is recommended that BMD monitoring occur at the same facility, using the same machine and, if possible, the same technologist as with the previous DXA. Additionally, DXA scan should involve the same regions of interest for both the spine and hip or the distal one-third radius when the spine and hip sites are not evaluable.

The definition of treatment failure remains controversial and complex. However, there is a consensus that treatment failure should be considered in patients with significant decrease on

BMD or recurrent fractures and are compliant to therapy (Lewiecki and Rudolph 2002) For this group of patients, it is recommended that they are re-evaluated for compliance with medication, secondary causes of bone loss, new medications or diseases that can cause bone loss. Particular emphasis should be given to monitoring of compliance to treatment as poor compliance usually occurs early (after 6–7 months) (Tosteson et al. 2003).

53.7.2 Bone Turnover Markers

In the last 25 years, several bone turnover markers (BTMs) have been developed that reflect the overall rate of bone formation and/or bone resorption. However, the utility of BTMs in clinical practice is limited by high in vivo and assay variability, poor predictive ability in individual patients, and lack of evidence-based thresholds for clinical decision-making (Camacho et al. 2016). Nonetheless, BTMs can provide a dynamic assessment of skeletal activity and are useful modalities for skeletal assessment. Significant reductions in BTMs are seen with antiresorptive therapy (e.g., bisphosphonates) and have been associated with fracture reduction, and significant increases indicate good response to anabolic therapy (e.g., teriparatide) (Lewiecki and Watts 2008). The most useful bone turnover markers for the monitoring of osteoporosis are procollagen I N-terminal extension peptide (P1NP) for assessing bone formation and C-telopeptide breakdown products (especially serum CTX) to assess bone resorption (Kanis et al. 2012).

53.7.3 Osteonecrosis of the Jaw (ONJ)

Osteonecrosis of the jaw occurs only very rarely in patients receiving bisphosphonate or denosumab therapy for osteoporosis. It was first reported in patients with advanced cancer receiving high-dose bisphosphonate therapy (at an annual dose ten times higher than that used to treat osteoporosis). The estimated incidence of ONJ is much lower with oral or intravenous bisphosphonate therapy for osteoporosis, on the order of 1/10,000 to 1/100,000 patients per year (Bilezikian 2006; Khan et al. 2015; Khosla et al. 2007; Woo et al. 2006). Its incidence is also low with denosumab for osteoporosis at 1–90 per 100,000 patient-years of exposure (Khan et al. 2016). Risk factors for osteonecrosis of the jaw include poor oral hygiene, dental disease, dental interventions, cancer, chemotherapy, or glucocorticoid therapy (Khan 2015).

Patients being considered for bisphosphonate or denosumab treatment should be advised to have oral examination by a dentist. For patients with significant dental issues, delaying the initiation of bisphosphonate or denosumab therapy until the dental issues have been corrected should be considered. For patients already receiving bisphosphonates or denosumab who require invasive dental procedures, there is no evidence that discontinuing or interrupting treatment will change the outcome or reduce the risk of ONJ. Nonetheless, stopping treatment should at least be considered for patients undergoing extensive invasive dental procedures (e.g., extraction of several teeth) (Camacho et al. 2016).

53.7.4 Atypical Femoral Fracture (AFF)

AFF, mainly of the subtrochanteric and diaphyseal regions of the femoral shaft, is another rare adverse event seen with long-term bisphosphonate therapy (>5 years duration) but is rarely (if at all) seen with the higher doses used in advanced cancer (Bauer et al. 2000; Lenart et al. 2009; Shane et al. 2014). Because of their radiologic appearance, such fractures are sometimes described as “chalk stick.” AFF usually occurs after little or no trauma and significant number of cases occur bilaterally (Shane et al. 2014). In a review by the American Society for Bone and Mineral Research (ASBMR) Task Force on the management of osteoporosis in patients on long-term bisphosphonates, a systematic search of the literature revealed wide variation in the

relative risk of atypical femoral fractures associated with bisphosphonate use (between 2- and 128-fold), but the absolute risk was consistently low, ranging between 3.2 and 50 cases/100,000 person-years (Shane et al. 2010). This estimate appeared to double with prolonged duration of bisphosphonate use (>3 years, median duration 7 years), and declined with discontinuation (Gedmintas et al. 2013; Shane et al. 2010, 2014).

All patients receiving bisphosphonate or denosumab therapy who present with persistent unexplained thigh, groin or hip pain should have imaging studies of the femur (X-ray, isotope scanning or MRI) (Camacho et al. 2016; Compston et al. 2017). If an atypical fracture is present, the contralateral femur should also be evaluated radiographically. In patients with confirmed AFF, bisphosphonate or denosumab therapy should be discontinued; weight-bearing activity should be restricted and alternative options considered where appropriate (Compston et al. 2017). In most cases, surgical treatment with intramedullary nailing is recommended.

53.7.5 Osteonecrosis of External Auditory Canal

In recent years, another rare side effect of long-term bisphosphonate and denosumab treatment, osteonecrosis of the external auditory canal, has been reported. This rare adverse event is not very well-known and there are currently no diagnostic methods or treatments for the condition. The previously reported cases were diagnosed based on the patients' medication history and computed tomography (CT) findings and were surgically treated via the removal of inflammatory granulation tissue and necrotic bone and the reconstruction of the ear canal with cartilage (Takahashi et al. 2017). The possibility of osteonecrosis of the external auditory canal should be considered in patients receiving bisphosphonates or denosumab who present with ear symptoms, including chronic ear infections, or in patients with suspected cholesteatoma. Possible risk factors include steroid use and chemotherapy, with or without local risk factors such as infection or trauma. Patients should be advised to report any ear pain, discharge from the ear, or an ear infection during bisphosphonate/denosumab treatment.

Summary

Key Points in Clinical Practice

- It is important to monitor patients while receiving pharmacological therapy in order to identify those who have significant bone loss.
- BMD testing and BTMs measurement are useful tools during treatment monitoring.
- In patients with significant reduction in BMD or those who continue to fracture while on treatment, should be re-evaluated for noncompliance, secondary causes of osteoporosis, or use of medications that might cause bone loss.
- Osteonecrosis of the jaw (ONJ), atypical femoral fracture (AFF), and osteonecrosis of auditory canal have been seen following long-term treatment with bisphosphonate and denosumab. Signs and symptoms associated with these rare complications of antiresorptive treatment should be assessed and monitored on all patients during therapy.

53.8 Duration of Osteoporosis Treatment

Due to the rare adverse effects of long-term bisphosphonate and denosumab therapy, particularly osteonecrosis of the jaw and atypical femoral fractures, the optimal duration of pharmacological therapy remains controversial. It is known that bisphosphonates are retained in bone for varying periods of time, therefore "treatment holidays" may be considered as its beneficial effects may persist for some time after cessation

of treatment. Treatment holidays involves stopping the treatment for some years and the need to reinstitute therapy is reassessed regularly (Compston et al. 2017). As most pivotal clinical trials on the use of bisphosphonate in postmenopausal women have been limited to a duration of 3 years, recommendations for longer term use and for "treatment holidays" are based on limited evidence from extension studies (Adler et al. 2016). As for men, there is currently no evidence on which to base recommendations from.

The ASBMR Task Force has proposed an algorithm for the monitoring of long-term bisphosphonate therapy in postmenopausal women. It is important to note that the optimal duration of a "treatment holiday" has not been established and guidelines vary from different countries. The UK NOGG for instance has proposed a slightly different management approach. Nonetheless, all guidelines stressed the importance of patient selection and monitoring during "treatment holidays." During "treatment holidays," consider resuming therapy in patients who experience fracture or show significant BMD decline. In some cases, the rise in bone resorption markers (e.g., CTX) to pre-treatment levels might be a signal that the "holiday" should be over; however, this may not apply to patients with osteoporosis who had low bone resorption markers before treatment initiation (Camacho et al. 2016).

Abstract

Vitamin D deficiency (hypovitaminosis D) has a very high prevalence worldwide. Over the last decade, there has been a growing interest in the research of vitamin D deficiency, its' metabolites and repletion regimen. Vitamin D plays an important role in maintaining human physiologic process such as calcium and phosphate homeostasis, adaptive and innate immunity. Vitamin D deficiency can cause metabolic bone diseases such as rickets in children and osteomalacia in adults, and may have a major impact on extraskeletal conditions such as diabetes, cancer, mortality, autoimmune and inflammatory disorders. Specific attention must be paid to high-risk groups such as the elderly, especially those living in institutional homes, people with limited sun exposure for various reasons such as religion, and people with darker skin. There are increasing numbers of children living with medical conditions in which either the condition or the treatment predisposes them to poor bone health and threatens their ability to attain peak bone mass. An understanding of calcium homeostasis and normal bone growth and development is essential for the paediatric endocrine nurse to be able to provide advice on lifestyle, supplement, and treatment options to this heterogeneous patient group. In adults, endocrine nurses need to understand the effects and recognise the importance of vitamin D deficiency on various organs and ensure appropriate assessment and management of vitamin D deficiency and assist in educating patients in how to improve their quality of life.

Keywords

Vitamin D deficiency · 25(OH)D $1,25(OH)_2D_3$ · Vitamin D repletion · Vitamin D metabolites

Abbreviations

$1,25(OH)_2D$	1,25 dihydroxyvitamin D
1α(OH)ase	1-Hydroxylase
24(OH)ase	24-Hydroxylase
25 (OH)D	25-Hydroxyvitamin D
BMD	Bone mineral density
CKD	Chronic kidney disease

DBP	Vitamin D binding protein
FGF23	Fibroblast growth factor 23
Pi	Phosphate and/or phosphorus
PTH	Parathyroid hormone
RCTs	Randomised controlled trials
RXR	Retinoid X receptor
VDRs	Vitamin D receptors

Key Terms

- **BMD**: Bone mineral density, bone mass per unit volume.
- **Cortical bone**: Outer part of all skeletal structures.
- **Osteoblast**: Responsible for bone formation.
- **Osteoclast**: Responsible for bone resorption.
- **Osteoporosis**: Skeletal disease with low bone mass with a consequent increase in bone fragility.
- **Trabecular**: The bone inside long bones, also known as cancellous bone.
- **T-score**: SDs by which BMD in an individual differs from the mean value expected in young healthy individuals.
- **Z-score**: SDs by which the BMD in an individual differs from the mean value expected for age and sex.
- **DXA**: Dual X-ray absorptiometry, measure bone areal density.

Key Points

- Vitamin D repletion is important and has many potential health benefits in skeletal and extra-skeletal health.
- Vitamin D deficiency is caused by limited sunlight exposure, decreased dietary intake, malabsorption, and other disorders.
- Vitamin D deficiency can be corrected with a repletion regimen to normalise serum vitamin D levels.
- Vitamin D metabolites such as 25(OH)D_3 and 1,25$(OH)_2D_3$ have important functions in many body organs.
- Endocrine nurses play an important role in the care of people with vitamin D deficiency.

54.1 Part A: Vitamin D Deficiency and Treatment in Adults

54.1.1 Vitamin D Repletion and Its Potential Benefits

54.1.1.1 Definition of Vitamin D

Vitamin D is a hormone, a fat-soluble vitamin, and a steroid like molecule derived from cholesterol which has two forms: ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3). Ergocalciferol (vitamin D_2) can be obtained from food such as shitake mushrooms, whereas cholecalciferol (vitamin D_3) is produced in the skin from ultraviolet light after sun exposure alters the ring of cholesterol molecule (Holick 2006; Holick et al. 2011). The circulating form of vitamin D in the blood is 25-hydroxyvitamin D (25(OH)D) which is commonly used as the indicator of the vitamin D status (The Royal College of Pathologists of Australasia, n.d.).

54.1.1.2 Recommended Daily Intake (RCI)

Normal healthy subjects produce about 4000 units of vitamin D daily, after obtaining vitamin D from various sources such as sunlight and diet (Heaney et al. 2003). According to the US Institute of Medicine in 2010, it is recommended that an 'adequate daily intake of vitamin D' is: from birth to 50 years old—200 IU; 51–70 years old: 400 IU; and >70 years old—600 IU (Dawson-Hughes et al. 2010).

Based on the 'Vitamin D and health in adults in Australian and New Zealand: A Position Statement' in 2012, it is suggested that to prevent vitamin D deficiency requires an intake of Vitamin D daily: ≥600 IU for ≤70 years old; and ≥800 IU for >70 years old (Nowson et al. 2012).

54.1.1.3 Sources of Vitamin D

54.1.1.3.1 Sunlight

It has been noted that >90% of the vitamin D body requirement comes from causal sunlight exposure (Holick 2004). The production of vitamin D_3 in the skin is affected by skin colour, application of sunscreen, time of the day, season, and latitude (Holick 2004; Holick 2007).

It's essential to have adequate sunshine exposure to maintain an optimal vitamin D level in the body. However, one must bear in mind the increased risk of skin cancer from excess sun exposure. The sun will not cause vitamin D toxicity and it is suggested that daily sunlight exposure of 15–20 min between 10:00 am and 3:00 pm will be enough for synthesis of vitamin D metabolism. It has also been found that a single body dose of ultraviolet radiation can produce 10,000 IU of vitamin D (Heaney 2005).

54.1.1.3.2 Dietary Sources

Vitamin D rich foods are presented in Table 54.1.

54.1.1.3.3 Vitamin D Supplementation

Vitamin D repletion can use either vitamin D_2 or vitamin D_3. A meta-analysis found that vitamin D_3 produces higher serum 25(OH)D levels as compared to vitamin D_2 (Hossein-nezhad and Holick 2012). Vitamin D_3 was used for vitamin D repletion since it is considered to be more effective in the prevention of non-vertebral fractures (Bischoff-Ferrari et al. 2009). Holick et al. (2008) demonstrated that a repletion regimen for 11 weeks with 1000 IU/day of vitamin D_2, 1000 IU/day of vitamin D_3, or a combination of 500 IU of vitamin D_2 and 500 IU of vitamin D_3 daily yielded the same outcome with an equal increase in serum total 25(OH)D levels in both groups (Biancuzzo et al. 2013). People taking vitamin D_2 supplements increase serum 25(OH)D levels and maintain total serum $1,25(OH)_2D$ levels compared to those taking the same dose of vitamin D_3 (Biancuzzo et al. 2013).

In Australia and New Zealand, virtually all oral vitamin D supplementation is vitamin D_3.

In clinical practice, vitamin D can be given daily or weekly or even monthly depending on the severity of vitamin D deficiency and patient preferences.

Table 54.1 Sources of Vitamin D (Holick 2007)

Source	Vitamin D_2 (D_2)/Vitamin D_3 (D_3)
Sunlight/UVB radiation	About 20,000 IU (D_3) = exposure to 1 minimal erythemal dose (MED) in a bathing suit, i.e. exposure of arms and legs to 0.5MED = ingesting about 3000 IU vitamin D_3
Cod liver oil	About 400–1000 IU/teaspoon (D_3)
Salmon, fresh	About 100–1000 IU/3.5 oz. (D_3)
Salmon, canned	About 300–600 IU/3.5 oz. (D_3)
Sardines, canned	About 300 IU/3.5 oz. (D_3)
Mackerel, canned	About 250 IU/3.5 oz. (D_3)
Tuna, canned	About 230 IU/3.5 oz. (D_3)
Shitake mushrooms, fresh	About 100 IU/3.5 oz. (D_2)
Shitake mushrooms, sundried	About 1600 IU/3.5 oz. (D_2)
Egg yolk	About 20 IU/yolk (D_2/D_3)
Fortified milk	About 100 IU/8 oz. (usually D_3)
Fortified yogurts	About 100 IU/8 oz. (usually D_3)
Fortified margarine	About 430 IU/3.5oz (usually D_3)
Fortified cheese	About 100 IU/3 oz. (usually D_3)
Fortified cereals	100 IU/serving (usually D_3)

1 oz = 30 mL

54.1.1.4 Potential Health Benefits

Over the last decade, there have been a plethora of studies assessing vitamin D and general health benefits, in addition to bone health. The skeletal and extra-skeletal health benefits in relation to vitamin D will be discussed below:

54.1.1.4.1 Skeletal Benefits

According to many randomised controlled trials (RCTs) and other studies, it has been suggested that serum 25(OH)D levels should be kept >30 ng/mL (74 nmol/L) for optimal bone health and >20 ng/mL (50 nmol/L) for normalisation of parathyroid hormone levels to ensure optimal muscle and bone health (Holick 2007; Bischoff-Ferrari et al. 2006). Similarly, it is observed that the antifracture efficacy of 25(OH)D level occurs at 30 ng/mL (74 nmol/L) suggesting a threshold for fracture protection with this optimal level (Tangpricha et al. 2006).

Hip and Non-vertebral Fractures

A meta-analysis (Boonen et al. 2007) examined postmenopausal women and men ≥50 years old taking oral vitamin D supplementation together with calcium and found that this cohort had an 18% reduction of hip fractures independent of

calcium supplementation. Research studies have demonstrated that treatment of vitamin D insufficiency can reduce the risk of hip and non-vertebral fractures (Chapuy et al. 1992; Trivedi et al. 2003).

A meta-analysis of RCT studies with 33,265 older people >65 years old taking vitamin D_3 (483–770 IU), Vitamin D_2 (800–1000 IU) or placebo (with or without calcium supplementation), after 1–7 years follow-up, showed the group taking vitamin D_3 was associated with a significant decrease (>20%) in non-vertebral fractures (Bischoff-Ferrari et al. 2009). A pooled analysis of eight RCTs indicated that serum 25(OH)D level >24 ng/mL (60 nmol/L) may be required to decrease fracture risk (Bischoff-Ferrari 2012).

Osteoporosis

Vitamin D repletion has been shown to be effective in improving bone mineral density (BMD) as illustrated in a population-based study showing a positive correlation between serum 25(OH)D and BMD (Bischoff-Ferrari et al. 2004). Another report (Adams et al. 1999) suggested that there was an increase in BMD in subjects previously with both low BMD and vitamin D deficiency after normalisation of 25(OH)D levels. Similar findings were reported in a small study of 229 subjects given vitamin D repletion of vitamin D_2 50,000 IU twice weekly with calcium supplementation for 5 weeks who normalised serum 25(OH)D and showed a significant increase in BMD (Kantorovich et al. 2000).

Fall and Muscle Strength

One of the main features of vitamin D deficiency is proximal muscle weakness (Holick et al. 2011; Holick 2007). In a systemic review and meta-analysis study, it has been shown that there is an association between muscle strength and vitamin D supplementation in older adults with significant reduction in postural sway and improved lower extremity strength (Muir and Montero-Odasso 2011). Interestingly, a recent study demonstrated that vitamin D supplementation has a small positive effect on muscle strength (Beaudart et al. 2014). In a nursing home study, the intervention group taking 800 IU of vitamin D daily together with calcium supplementation for 5 months had a 72% reduction in the risk of falls compared to the placebo group (Broe et al. 2007).

54.1.1.4.2 Extra-Skeletal Benefits

With the discoveries of vitamin D receptors (VDRs) and the 1 α-hydroxylase enzyme (CYP27B1) in various tissues, there has been growing research interests in the area of the relationship to immunity, macrophages, colon, pancreas, breast, stomach, and placenta (Plum and DeLuca 2010). Within these tissues, 25(OH)D is converted to $1,25(OH)_2D$ without changing the serum $1,25(OH)_2D$ concentrations while $1,25(OH)_2D$ affects gene expression. VDRs are a critical determinant of the ability of proliferating cells to regulate their response to various stimuli. Many observational studies have shown a reduction in risk of many disorders such as cancer, cardiovascular disease, autoimmune disease, diabetes mellitus, mental illness, and infectious disease, associated with a blood level of 25(OH) D > 28–32 ng/mL (70–80 nmol/L) (Holick et al. 2011; Nowson et al. 2012; Holick 2007).

Many research studies have been published recently in relation to extra-skeletal benefits with some still ongoing; however, the evidence of association and magnitude of the effects of these studies are not as strong as the skeletal benefits. Currently there is no consensus on the 25(OH)D levels that should be maintained for the best non-skeletal outcomes (Holick 2007).

Diabetes

There is a high prevalence of vitamin D deficiency in people with diabetes (Alam et al. 2012). The risk of type 1 and type 2 diabetes may be increased due to vitamin D insufficiency (Holick 2004; Mathieu et al. 2005).

VDRs can be found in pancreatic B cells and vitamin D may increase insulin secretion and improve insulin sensitivity. An observational study described that subjects taking vitamin D supplementation with calcium had a reduced risk of type 2 diabetes (Pittas et al. 2006). Recently a US study with a sample size of 2877 found a weak positive association between serum vitamin D levels and fasting and 2-h plasma glucose and HbA1c levels and a negative association with beta-cell function (Nielsen et al. 2016). Some small studies found that vitamin D supplementation in adults has shown an improvement of insulin sensitivity

(Mathieu et al. 2005); however, this outcome is debatable. In a recently published randomised double-blind placebo-controlled hyperinsulinemic-euglycemic glucose clamp study, taking ergocalciferol 50,000 IU weekly for 8 weeks in subjects with low vitamin D levels improved 25(OH)D levels but did not improve insulin sensitivity (Simha et al. 2012). It is still questionable whether normalisation of serum vitamin D levels with vitamin D supplementation will alter diabetic microvascular complications (Alam et al. 2016).

Infection/Autoimmune Disorder

The mechanism of the association between vitamin D deficiency and infection is thought to be due to the pleiotropic effects of 25(OH)D on human immunity with T-cell proliferation, immunoglobulin claws switching, and cytokine release (Mora et al. 2008).

Some studies findings suggested that vitamin D plays a potential role in the pathogenesis of some organ-specific autoimmune disorders such as rheumatoid arthritis (RA), Crohn's disease (CD), multiple sclerosis (MS), and type 1 diabetes. This is likely due to interference with genes, transcription factors, and signalling pathways which mediate inflammatory responses (Szekely and Pataki 2012). A systematic review and meta-analysis of 647 studies found that vitamin D deficiency (a serum 25(OH)D level <15–20 ng/mL (38–50 nmol/L)) is associated with a higher risk of infection (Upala et al. 2015).

Mortality and Cardiovascular Mortality

A meta-analysis of 18 RCTs examining all-cause mortality in postmenopausal women with vitamin D supplementation from 2000 to 3000 IU daily showed a 7% relative risk reduction of death in the intervention group of women (Autier and Gandini 2007). A Cochrane Review of 50 RCTs with a sample size of 94,000 subjects (mainly elderly women) illustrated that vitamin D_3 supplementation reduced mortality (Bjelakovic et al. 2011). It has also been reported that hospital in-patients with severe vitamin D deficiency (25(OH)D < 10 ng/mL or 25 nmol/L) and acute coronary syndrome had an increased in-hospital mortality (Correia et al. 2013).

Reduced Risk of Cancer

A meta-analysis of 11 studies has shown no association between prostate cancer and serum 25(OH)D levels. For breast cancer, a meta-analysis showed the risk of breast cancer is lower in the group with higher serum 25(OH)D levels compared to the group with the lower levels (Correia et al. 2013). A US meta-analysis suggested that every increase of 4 ng/mL (10 nmol/L) of serum 25(OH)D levels was associated with a 6% decrease in the risk of colorectal cancer (Chung et al. 2011). A RCT found a 60% decrease in all cancers, in postmenopausal women taking vitamin D_3 of 1100 IU and 1500 mg calcium daily for a duration of 4 years (Lappe et al. 2007).

Reduced Risk of Depression and Dementia

A RCT placebo trial study with obese and overweight subjects taking 20,000 or 40,000 IU vitamin D versus placebo for 12 months found the intervention group had higher serum 25(OH)D concentrations and significant improvement in depression scores (Jorde et al. 2008). In a study examining the risk of depression, there was a lower risk of depression in the middle adulthood group with serum 25(OH)D levels of 20–34 ng/mL (50–85 nmol/L) (Maddock et al. 2013). A vitamin D rich diet in animals has shown a decrease in the risk of Alzheimer's disease, and a decrease in the number of amyloid plaques and inflammation in the brains. This may imply $1,25(OH)_2D$ to have a neurological protective role (Yu et al. 2011).

Periodontal Disease

Vitamin D deficiency may be a risk factor for periodontal disease due to the effect of vitamin D on immunomodulation or bone mineral density. Periodontal disease involves inflammation with loss of periodontal attachment in the alveolar bone and ligaments. This is one of the major causes of tooth loss in the elderly. A study has shown that vitamin D supplementation with calcium decreased tooth loss and may reduce the risk of periodontal disease (Krall et al. 2001). A cross-sectional study with more than 1000 subjects concluded that in people aged ≥50 years, there is an association between lower serum 25(OH)D levels and periodontal disorders independent of BMD (Dietrich et al. 2004).

54.1.2 Vitamin D Deficiency

54.1.2.1 Epidemiology

Vitamin D deficiency is common across all ages around the world. In the USA, around 32% of the population had a serum 25(OH)D levels <20 ng/mL (50 nmol/L) (Looker et al. 2011). Whereas in the Canadian population, 60.7% of females and 57.5% of males had serum 25(OH)D levels <30 ng/mL (75 nmol/L) (Greene-Finestone et al. 2011). Australia has a similar rate as the USA, with 31% of people with vitamin D deficiency (serum 25(OH)D <50 nmol/L or 20 ng/mL) and 73% with serum 25(OH)D levels <30 ng/mL (<75 nmol/L) (Nowson et al. 2012).

In Sweden and Norway, there are higher serum 25(OH)D levels which is likely due to a higher consumption of cod liver oil and fatty fish. In contrast, there are lower serum 25(OH)D levels in Greece, Italy, and Spain, which is probably due to sun-avoiding behaviour, darker skin pigmentation, and air pollution with ozone and nitrogen dioxide (van Schoor and Lips 2011).

In a multi-centre study with 2173 adults from five cities in China, a high prevalence of hypovitaminosis D was observed, with 55.9% of subjects with serum 25(OH)D levels <20 ng/mL (50 nmol/L) and 94.6% with serum 25(OH)D levels <30 ng/mL (75 nmol/L). In addition, vitamin D deficiency was higher in inland cities compared to coastal cities such as Dalian. The reasons may be like that of Norway where people living in the coastal region of Dalian have higher daily intake (Yu et al. 2015). It has been reported that vitamin D deficiency has a high prevalence of 70–100% across the Indian subcontinent (Ritu and Gupta 2014). The reasons for this include darker skin, low dietary sources of vitamin D, such as usual unfortified milk with only 2 IU/100 mL and high phytate content in the Indian diet. Phytate is indigestible and reduces intestinal absorption of calcium due to chelation. In addition, there is a high lactose intolerance in India.

54.1.2.2 Pathophysiology

The skin absorbs vitamin D via ultraviolet B (UVB) radiation (wavelengths 290–315 nm) from sunlight. As illustrated in Fig. 54.1, 7-dehydrocholesterol in the skin is then converted to pre-vitamin D_3 which is quite unstable so then quickly undergoes thermal isomerisation to the form of vitamin D_3. Vitamin D_3 is then transported to the dermal capillary bed in the extracellular space via the vitamin D binding protein (DBP). It then enters the blood stream. DBP is a circulating alpha globulin in the same protein group as albumin and is primarily produced by the liver (Holick 2006).

Vitamin D_2 and D_3 from dietary sources after ingestion are incorporated into chylomicrons and then enter into the lymphatic system. Thereafter, the chylomicrons are transported to venous circulation, where they bind with lipoproteins and DBP.

Both vitamin D_2 (from the skin) and vitamin D_3 from the diet can then be stored in and released from fat cells. In the liver, DBP releases vitamin D which undergoes hydroxylation and is converted to 25-hydroxyvitamin D ($25(OH)D_3$) (calcidiol).

25(OH)D is the main circulating form of vitamin D. In the kidneys, 25(OH)D binding to DBP is then reabsorbed in the proximal renal tubules (Negri 2006). 25(OH)D undergoes sequential hydroxylation in the kidneys to produce 1,25 dihydroxyvitamin D [$1,25(OH)_2D$]. The hydroxylation in the kidneys is strongly regulated and is also augmented by hypocalcaemia, hypophosphatemia, and PTH; and repressed by FGF23, hyperphosphatemia, and $1,25(OH)_2D$ itself as well (Holick 2007; Nair and Maseeh 2012).

$1,25(OH)_2D$ has a half-life of 6 h, whereas 25(OH)D has 2 weeks in the circulation. This explains why the measurement of serum 25(OH)D level is used to determine vitamin D status. For non-skeletal function, 25(OH)D is also metabolised to $1,25(OH)_2D$ in other body tissues to regulate cellular growth (Holick 2007).

$1,25(OH)_2D$ is the active form of vitamin D that facilitates bone mineralisation and binds to VDRs to enhance absorption of calcium and phosphate in the intestine. It also binds to VDRs in osteoblasts which activate immature preosteoclasts as a result of the formation of mature bone-absorbing osteoclasts (Fig. 54.1). The mature osteoclasts then move calcium and phosphorous from the bone so as to maintain normal calcium and phosphorous levels in the blood stream (Holick 2006).

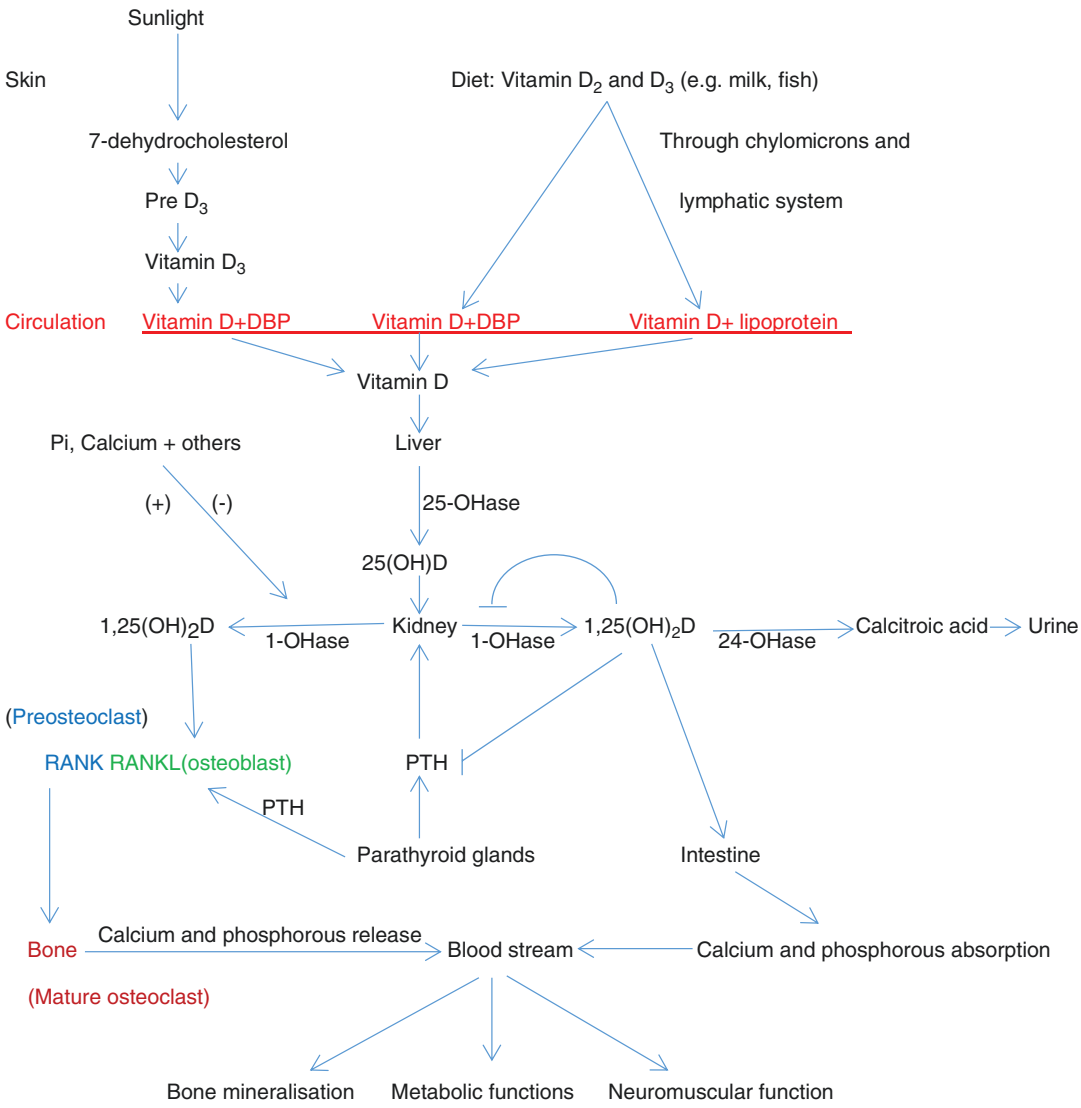

Fig. 54.1 The metabolism of vitamin D and the biologic effects of $1,25(OH)_2$ D on calcium, phosphorus, and bone metabolism (Holick 2006)

As noted early on, vitamin D plays an important role on calcium homeostasis through major interaction with bone and intestines. When serum calcium or phosphorous levels are low, the parathyroid hormone (PTH) stimulates and regulates the synthesis of $1,25(OH)_2D$ so as to: increase calcium absorption in the intestine, increase resorption of calcium by the kidneys, and stimulate the release of calcium from the bone. Apart from this, FGF23 from osteocytes inhibits the synthesis of $1,25(OH)_2D$.

Dysfunction in any of these pathways results in osteomalacia and hyperparathyroidism (Holick 2006). People with chronic kidney disease do not synthesise this active metabolite which results in hyperphosphatemia, and further impairs renal synthesis of the hormone contributing to secondary hyperparathyroidism. Alternatively, hypophosphatemia can cause osteomalacia, arising from excess FGF23 or primary renal tubule phosphate wasting disorders (Biancuzzo et al. 2013; Nair and Maseeh 2012; Shimada et al. 2004).

54.1.2.3 Diagnosis of Vitamin D Deficiency (Hypovitaminosis D)

In clinical practice, the best measurement of vitamin D status is the serum concentration of 25-hydroxyvitamin D (25[OH]D). There has not been a consensus on the cut-off points of serum 25[OH]D levels for the delineation of vitamin D deficiency. In general, it is agreed that vitamin D deficiency is defined as a serum level of 25(OH)D with <20 ng/mL (50 nmol/L) (Holick et al. 2011; Nowson et al. 2012). In clinical practice, it is common that patients with vitamin D deficiency also have an increase in PTH which indicates secondary hyperparathyroidism. An elevated serum PTH will provide a signal of the diagnosis of vitamin D insufficiency. According to The Endocrine Society's clinical practice guidelines (2011) in the USA: vitamin D insufficiency: 21–29 ng/mL (52.5–72.5 nmol/L) and vitamin D deficiency: <20 ng/mL (50 nmol/L). In addition, the guidelines also suggested that in order to prevent the risk of fracture and falls in older people, a serum level of 25[OH]D >30 ng/mL (75 nmol/L) is required (Holick et al. 2011). According to a position statement on **vitamin D and health in adults in Australia and New Zealand**: vitamin D adequacy: ≥50 nmol/L at the end of winter (level may need to be 10–20 nmol/L higher at the end of summer, to allow for seasonal decrease), mild vitamin D deficiency: 12–20 ng/mL (30–49 nmol/L), moderate vitamin deficiency: 5–12 ng/mL (12.5–29 nmol/L), and severe vitamin D deficiency: <5 ng/mL (12.5 nmol/L) (Nowson et al. 2012). Lastly according to the Institute of Medicine (IOM), Food and Nutrition Board (2011): vitamin D deficiency: <8–10 ng/mL (20–25 nmol/L) results in osteomalacia if untreated (Institute of Medicine (US) Committee to Review Dietary Reference Intakes for Vitamin D and Calcium et al. 2011).

54.1.2.4 Clinical Presentation

Initial symptoms can be subtle or asymptomatic until they become severe. Clinical presentation depends on the causes, e.g. adults with osteomalacia may experience chronic muscle aches and pains.

54.1.2.5 Screening

It has been recommended to screen for vitamin D deficiency in the following high-risk individuals (Holick et al. 2011):

- Osteoporosis
- Malabsorption syndrome
- Dark skinned individuals
- Obese persons (body mass index >30 kg/m^2)
- Disorders affecting the metabolism of vitamin D and phosphate (e.g. chronic kidney disease)

54.1.3 High-Risk Groups for Deficiency and Special Populations

54.1.3.1 Age >65 Years

Older people (age >65 years of age) are one of the high-risk groups for developing vitamin D deficiency, because they make vitamin D less efficiently due to less substrate (7-dehydrocholesterol in the skin) and reduced production rates of vitamin D from high levels of UV radiation exposure (Holick 2007). In addition, older people live in high-level residential care with chronic illness and have limited time outdoors. A study has shown that limited sun exposure in older people contributes to vitamin D deficiency (Durvasula et al. 2010).

54.1.3.2 Skin Colour

People with darker skin are also at higher risk of vitamin D deficiency due to the presence of thick layer of melanin pigment in skin and UVB does not penetrate well to the skin (Springbett et al. 2010). A study of healthy subjects illustrated vitamin D deficiency in 40% of black women (N = 1500) compared to only 4% of their white counterparts (Nesby-O'Dell et al. 2002). People with darker skin are likely to need 3–6 times longer sun exposure (Nowson et al. 2012).

54.1.3.3 Obesity

Obese people are likely to have vitamin D deficiency compared to those with normal weight. This is because vitamin D in adipose tissue may not be readily released, unless there is fat break-

down, so obesity results in lower vitamin D levels after receipt of oral or cutaneous synthesised vitamin D (Wortsman et al. 2000). Another study depicted that obese women with low 25(OH)D had suppression of PTH compared to the normal population. The lower average serum 25(OH)D level in the obese group may have a different physiologic significance compared to the normal population (Shapses et al. 2013).

54.1.3.4 Cultural/Religious Group

Research studies have found that UVB radiation doesn't penetrate through clothing. People with cultural norms/religions of wearing clothes covering most of their skin are also at high risk of vitamin D deficiency (Grover and Morley 2001; Kimlin et al. 2007). Some ethnic groups with fair skins use extreme sun protection which places them at risk of vitamin D deficiency Glass et al. 2009; van der Mei et al. 2007).

54.1.3.5 Limited Time Outdoor/ Environment

People with limited time outdoors such as office workers, factory or warehouse workers, taxi drivers, night-shift workers, those taking photosensitising medications (such as tetracyclines), and those who are sun avoidant (e.g. history of skin cancer) are also at risk of vitamin D deficiency due to decrease in sun exposure (Nowson et al. 2012). Sunscreen application affects vitamin D synthesis, with SPF 8 by 92.5% and SPF15 by 99% (Holick 2006).

54.1.3.6 Vitamin D Malabsorption Problems

People with the following conditions are at risk of vitamin D deficiency:

- Resection of the small intestine
- Coeliac disease, short bowel syndrome (Tangpricha et al. 2006)
- Cystic fibrosis (Hall et al. 2010)

54.1.3.7 Medications

Phenytoin and phenobarbital are associated with vitamin D deficiency since they can increase Vitamin D metabolism (Tangpricha 2016).

54.1.4 Dosing Options

In the USA, vitamin D supplementation is usually in the form of ergocalciferol (vitamin D_2) whereas in Australia, it is mainly cholecalciferol (vitamin D_3) orally (Nowson et al. 2012). Some evidence suggests that vitamin D_3 is more bioavailable than Vitamin D_2 (Holick 2007). Recommended doses based on the US Endocrine Society Guideline, the Canadian Society of Endocrinology and Metabolism, and the National Osteoporosis Foundation in 2011, for vitamin D deficiency are: 50,000 IU/week of vitamin D_2 or D_3 weekly for 8 weeks *or* 6000 IU of vitamin D_2 or D_3 daily for 8 weeks. If serum 25(OH)D level >30 ng/mL (74 nmol/L), maintenance treatment of 1500–2000 IU/day. For people who are obese, have malabsorption syndromes e.g. coeliac disease, or are taking medications that affect vitamin D metabolism, the recommendation is for 6000–10,000 IU/day of vitamin D and if serum 25(OH)D level >30 ng/mL (74 nmol/L), maintenance treatment of 3000–6000 IU/day. If the 25(OH)D concentration remains persistently low despite several attempts at correction with oral vitamin D, a trial of ultraviolet B light therapy (i.e. by tanning lamps) may be considered to improve vitamin D status.

54.1.4.1 Older Populations

Both vitamin D and calcium deficiencies are not uncommon in older people especially for those living in high-level residential care. The following suggestion is aimed at achieving optimal bone health and muscular function, to reduce the risk of falls and fractures in this group: vitamin D 1000 IU daily and calcium 1000–1300 mg daily preferably from diet (Table 54.2), or a combination of diet and supplementation (Avenell et al. 2009).

54.1.4.2 Toxicity

Vitamin D toxicity due to drug overdoses is uncommon. Most cases are due to accidental overdose. There is limited data in vitamin D supplementation and toxicity. One study showed that subjects using 10,000 IU of vitamin D daily for up to 5 months did not show toxicity (Vieth 1999,

Table 54.2 Foods high in calcium content (Osteoporosis Australia 2014)

Food	Calcium/serve (mg)	Standard serve	Grams/serve	K.J/serve
Milk, reduced fat, calcium fortified	520	Cup 250 ml	–	382
Skim milk	341	Cup 250 mL	–	382
Reduced fat milk	367	Cup 250 mL	–	551
Regular milk	304	Cup 250 mL	–	762
Reduced fat evaporated milk	713	Cup 250 mL	–	908
Regular soy milk	309	Cup 250 mL	–	660
Reduced fat soy milk	367	Cup 250 mL	–	702
Tofu firm	832	Cup 250 mL	260	1378
Regular natural yogurt	386	Tub	200	734
Low fat natural yogurt	488	Tub	200	498
Cheddar cheese	160	1 slice	21	349
Reduced fat cheddar cheese (15%)	209	1 slice	21	233
Shaved parmesan	204	–	21	355
Edam cheese	176	1 slice	21	312
Pecorino	156	1 slice	21	318
Reduced fat mozzarella	200	1 slice	21	258
Camembert	121	1 wedge	25	322
Sardines, canned in water, no added salt	486	Can	90	649
Sardines, canned in oil, drained	330	Can	90	824
Pink salmon, canned in water, no added salt	279	Small can	90	552
Pink salmon, canned in brine	183	Small can	90	575
Red salmon, canned in water, no added salt	203	Small can	90	734
Red salmon, canned in brine	175	Small can	90	688
Mussels, steamed or boiled	173	–	100	503
Snapper, grilled, with olive oil	163	1 fillet	100	635
Oysters, raw	132	–	100	303
Dried figs	160	6 figs	80	866
Cheesecake	163	1 slice	125	1786
Vanilla custard, reduced fat	130	1 tub	100	359
Soy beans, canned	106	Cup	200	844

2004). In clinical practice, the cut-off for vitamin D toxicity is a serum level >100 ng/mL (250 nmol/L) for a reasonable safety margin. When serum 25(OH)D level is >150 ng/mL (375 nmol/L), renal stones and hypercalcemia may occur due to intoxication.

Early symptoms of hypercalcemia include nausea, vomiting, and anorexia, followed by polyuria, polydipsia, weakness, fatigue, somnolence, headache, dry mouth, metallic taste, vertigo, tinnitus, and ataxia. Increased serum calcium levels are a constant finding when intoxication occurs and serum 25(OH)D levels may be normal in the early stage.

Prolonged sunlight exposure will not cause vitamin D toxicity because during sun exposure, isomerised vitamin D_3 is converted from previtamin D_3 (Fig. 54.1) and does not enter the circulation. Photoproducts are believed to have little effect on calcium metabolism (Holick 2004). Management of vitamin D toxicity includes ceasing vitamin D, stopping/decreasing the dietary intake of calcium foods, and restoring intravascular volume deficits; and for severe vitamin toxicity, corticosteroids or bisphosphonates (Vieth 1999).

54.1.5 Vitamin D Metabolites

The vitamin D metabolite, $1,25(OH)_2D$, has been well demonstrated in studies to have anti-proliferative, pro-differentiating, anti-inflammatory, and pro-apoptotic activities in cells and tissues. In addition, it has growth inhibitory effects on cancer cells in the breast, lung, liver,

prostate, colon, and pancreas, which express VDRs (Chiang et al. 2011).

54.1.5.1 Role of Vitamin D Binding Protein (DBP) in Vitamin D Metabolism

DBP is one of the specific serum carrier proteins for transportation of 25(OH)D and its active metabolite $1,25(OH)_2D$ to target tissues. About 90% of 25(OH)D binds to DBP in the circulation (Chun 2012). In vitro studies depict that DBP: protects 25(OH)D from degradation, prolongs its half-life, and protects against vitamin D deficiency (Safadi et al. 1999). Some animal studies illustrated that DBP is pivotal for total serum $1,25(OH)_2D_3$ levels but did not affect the amount of $1,25(OH)_2D_3$ entering into the cells or target tissues. If this is correct, the measurement of serum $1,25(OH)_2D_3$ may not truly reflect the biologically active $1,25(OH)_2D_3$ in the circulation (Bikle et al. 1986). Some studies show that DBP has potential direct action on bone resorption affecting bone density (Papiha et al. 1999).

54.1.5.2 24-Hydroxylase (24(OH)ase)

As noted previously, vitamin D has undergone liver and then kidney hydroxylation to form its active form (Fig. 54.1). 1,25-Dihydroxyvitamin D3 ($1,25(OH)_2D_3$) is the active metabolite of vitamin D and responsible for most of the biological actions after entering target organs (Fig. 54.2). In the kidney, apart from$1,25(OH)_2D_3$, 24, 25 dihydroxyvitamin D3 (24, $25(OH)_2D_3$) is also produced which is a relatively inactive metabolite as compared to $1,25(OH)_2D_3$. 24-Hydroxylase (24(OH)ase) is a mitochondrial enzyme that controls the amount of $1,25(OH)_2D_3$ in target tissues via 2 pathways (Fig. 54.2): increasing the catabolism of $1,25(OH)_2D_3$ to $1,24, 25(OH)_3D_3$, then leading to the product of calcitroic acid for excretion; and forming 24, $25(OH)_2D_3$ resulting in the reduction of 25(OH) D_3. Animal studies found that a reduction in 24(OH)ase causes an impairment of mineralisation in intramembranous bone suggesting that the main function of 24(OH)ase is vitamin D inactivation (Priemel et al. 2010).

54.1.5.3 Regulation of Renal Vitamin D Hydroxylases

54.1.5.3.1 Via Calcium, Phosphate, PTH, and 1,25(OH)2D3

Low serum calcium will increase serum PTH resulting in two outcomes: the production of $1,25(OH)_2D_3$ in the kidney and stimulation of the transcription of 1α(OH)ase. 1α(OH)ase is also negatively regulated by $1,25(OH)_2D_3$. 24(OH) ase is inhibited by low calcium and PTH, and is stimulated by $1,25(OH)_2D_3$ (Murayama et al. 1999).

54.1.5.3.2 Via FGF23

Fibroblast growth factor 23 (FGF23) is a phosphaturic factor that promotes renal phosphate excretion via decreasing phosphate reabsorption in the renal proximal tubules. FGF23 plays an important role in regulation of vitamin D metabolism in bone. The production of FGF23 in bone is stimulated by $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ binds to VDR. The ligand-bound VDR forms a heterodimer with nuclear retinoid X receptor (RXR) resulting in increased expression of FGF23 in osteocytes. Secreted FGF23 activates the FGF receptor bound by a transmembrane protein in renal tubular cells. FGF signalling suppresses expression of 1α(OH)ase and induces 24(OH) ase, thereby inhibiting synthesis and promoting catabolism of $1,25(OH)_2D_3$. Thus, FGF23—the transmembrane protein—results in decreased levels of $1,25(OH)_2D_3$ (Kuro-o 2008). It has been suggested that overactivity of FGF23 may cause phosphate wasting disorders such as hypophosphatemia, osteomalacia, and low serum 1,25(OH) D levels.

54.1.5.4 Extrarenal 1-Hydroxylase (1α(OH)ase)

54.1.5.4.1 Placenta

The trophoblast and maternal decidua in the placenta serves as a functional interface for exchange between mother and foetus. It has been reported that in early gestation, 1α(OH)ase is most abundant in decidua, and is expressed in foetal trophoblast and maternal decidual cells (Zehnder et al.

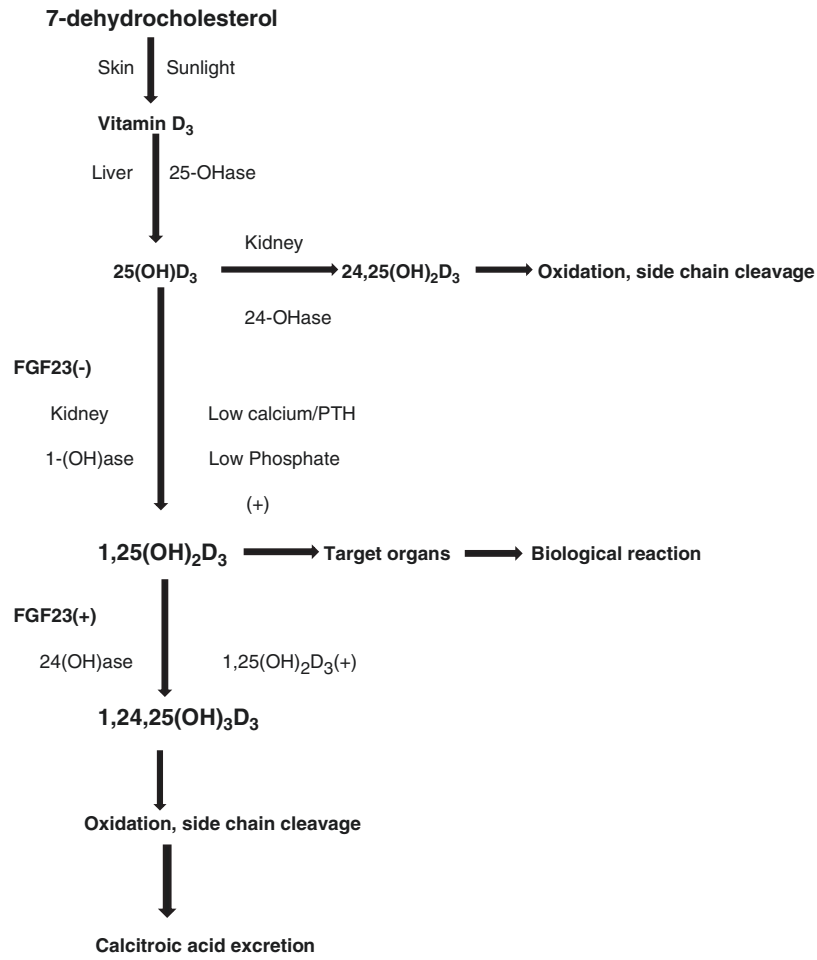

Fig. 54.2 Metabolic pathway for vitamin D (Christakos et al. 2010; Omdahl et al. 2002)

2002). The production of 1α(OH)ase is 8 times higher in the first trimester in decidual cells compared to the third trimester (Evans et al. 2006). $1,25(OH)_2D_3$ regulates the production of hormones during pregnancy and affects the trophoblast immunological, anti-inflammatory, and anti-microbial responses. In addition, trophoblasts produce $1,25(OH)_2D_3$ as well as respond to $1,25(OH)_2D_3$ (Ma et al. 2012).

54.1.5.4.2 Monocytes/Macrophages

It has been shown that 1α(OH)ase is expressed by macrophages and monocytes which also manufacture $1,25(OH)_2D_3$. However, it was observed that renal 1α(OH)ase has a different regulation compared to monocyte/macrophage 1α(OH)ase (Stoffels et al. 2007). From clinical evidence in patients with sarcoidosis, despite hypercalcemia, there is increased production of $1,25(OH)_2D_3$ by activated macrophages (Sharma 2000).

54.1.5.5 Vitamin D Metabolites and Chronic Kidney Disease (CKD) in the Elderly

With advancing age, there is a decline in the function of the conversion $25(OH)D_3$ to $1,25(OH)_2D_3$ in the kidney, and an increase in 24(OH)ase gene expression and clearance of $1,25(OH)_2D_3$. Age-related bone loss may be exacerbated by a decrease in kidney function and production of $1,25(OH)_2D_3$ and an increase in renal metabolism of $1,25(OH)_2D_3$.

For people with CKD, there is a decrease in vitamin D metabolism due to loss of renal mass and a decrease in the production of 1α(OH)ase

and an increase in FGF23 levels in early CKD as a result of decreased activity of 1α(OH)ase (Gutierrez et al. 2005).

Case Study: Osteomalacia

A 43-year-old woman presented with an unsteady gait. Her history included: childhood rickets, fractured right neck of femur, early menopause, and hypothyroidism (after hemithyroidectomy). She had an unsteady gait, bowing of the legs (Fig. 54.3), and scoliosis. She lived alone with social support from a carer.

Investigations

Serology showed a low calcium, phosphate and 25-hydroxyvitamin D, elevated alkaline phosphatase, and elevated PTH. 24-hour urine collection showed low calcium and low phosphate. X-ray of her lower limbs in Fig. 54.4 shows a fracture of the left proximal femur, with deformity and bowing of the legs which are typical features of osteomalacia (Holick 2007). X-ray of the spine showed an S-shaped spinal scoliosis with loss in vertebral body height and an extensive heterogeneous appearance of the bony skeleton. Bone biopsy with dynamic histomorphometry confirmed osteomalacia. She was treated with Calcitriol 3 capsules daily, phosphate tablet 1000 mg daily, and cinacalcet 30 mg daily.

The Role of the Endocrine Nurse

Vigilance in maintaining a normal vitamin D level via various measures is crucial to ensure adequate nutritional level for bone mineralisation. These measures include: adequate sun exposure (exposure of their arms and/or face in winter for about 15 min), compliance with vitamin D supplementation, foods high in vitamin D and calcium. If necessary, the patient and family members are referred to a dietitian for appropriate nutritional support to achieve optimal bone health.

Care of patients with osteomalacia involves multidisciplinary team members such as a nurse, endocrinologist, GP, physiotherapist, occupational therapist, dietician, and social worker. The endocrine nurse can provide edu-

cation and encourage compliance with vitamin D and calcium supplementation and education about correct use of tetracycline medications prior to a bone biopsy as errors in compliance render the test useless. The endocrine nurse can ensure regular follow-up of appointments and investigations with reminders and support for medical appointments and investigations including blood and/or urine tests (24-h collection) and BMD.

Appropriate referrals to other multidisciplinary team members are crucial and include occupational therapists for appropriate aids and equipment for daily living to prevent further fragility fractures. The physiotherapist provides ongoing assessment and exercises to strengthen muscles and improve physical function, with weight-bearing exercises to strengthen muscles and bones to maintain bone health and to reduce the risk of falls.

The vitamin D deficiency epidemic affects people of all ages, races, and religions worldwide. Vitamin D repletion has been found to be beneficial for both musculoskeletal and general health. The endocrine nurse plays an important role in maintaining the patient's bone and general health in hospital and community settings. Specific education is provided by the endocrine nurse in high vitamin D and calcium rich foods and appropriate sunlight exposure. Compliance with vitamin D supplements for a repletion regimen in the acute and maintenance phase with follow-up blood testing of serum 25(OH)D levels to maintain optimal musculoskeletal and general health is essential for treatment to be successful. Over the last decades, much research has emerged exploring Vitamin D metabolites, FGF23 and DBPs in relation to the benefits of vitamin D repletion for bone and extra-skeletal health. Endocrine nurses must keep up to date with the knowledge and skills to achieve optimal vitamin D levels in patients at risk of deficiency resulting in better health outcomes and quality of life.

54.2 Part B: Vitamin D Deficiency and Treatment in Children[1]

Key Points

- Vitamin D is essential for the absorption of calcium from the small intestine.
- Children need proportionately more calcium in relation to body size than adults; this is required for both longitudinal and appositional bone growth.
- Vitamin D deficiency in children is prevalent worldwide; the most severely affected present with hypocalcaemia or rickets. Many are asymptomatic.
- The endocrine nurse should play a key role in identifying children at risk, their assessment and treatment.
- Education of parents, patients, and other health care professionals is essential to improve concordance with treatment and prevent recurrence.

54.3 Bone Growth and Strength

Far from being an inert framework, bone is a dynamic structure, responding to factors including nutrition, hormones, and the stresses placed on it from physical activity. During childhood and adolescence, linear growth results from bone formation at the epiphyseal (growth) plates in the metaphysis of long bones. Chondrocytes divide by mitosis in the proliferative zone, mature, and then undergo apoptosis and calcification, finally being replaced by calcified bone by the action of osteoclasts and osteoblasts (Tortora and Derrickson 2011). This is referred to as bone modelling.

[1]Written by: Pauline Musson, Paediatric Clinical Nurse Specialist, Southampton Children's Hospital, Southampton, UK.

The mechanical load on the skeleton of physical activity leads to areas of micro stresses in the bone. At these sites, there is resorption of bone by osteoclasts and deposition of new bone by osteoblasts. This is known as remodelling and continues throughout life. In the long bones, bone resorption occurs in the medullary cavity and bone deposition beneath the periosteum, which increases bone thickness and strength and is referred to as appositional growth (Tortora and Derrickson 2011).

The rate of remodelling is influenced by the action of parathyroid hormone, 1,25 hydroxyvitamin D, Insulin like Growth factor (IGF-1), calcitonin, and local cytokines. During childhood, the rate of bone formation needs to exceed that of resorption in order to facilitate both longitudinal and appositional growth and ensure peak bone mass is achieved. Identification of and treatment of poor bone health/osteoporosis as early as possible is essential; a child's skeleton is able to reshape during remodelling, restoring mobility and function. This ability to reshape bones is not seen in adults (Ward et al. 2016).

An essential element of bone strength is conferred by the mineral content. Calcium and phosphate are deposited in the bone matrix throughout childhood, with approximately 50% of this being accrued during adolescence. The sex hormones (testosterone/oestrogen) and IGF-1 play an essential role in this process. Peak bone mass, or acquiring the maximum mineral content of bone, is achieved by around 25 years of age (Golden et al. 2014).

54.4 Calcium

In addition to being an essential component of healthy bone, calcium plays an important role in many other physiological processes in the human body. Calcium acts as a secondary messenger in cell signalling pathways, is needed for muscle fibre contraction, and is a co-factor in several processes including clotting.

In normal circumstances, the level of plasma calcium is tightly regulated to maintain it between 2.2 and 2.6 mmol/L, as levels outside this range have adverse effects. Hypocalcaemia gives rise to irritability, paresthesia (pins and needles type of tingling), muscle cramps and spasms, including tetany and convulsions. Clinical examination will elicit positive Chvostek and Trousseau signs. In infants, prolonged hypocalcaemia affects function of the cardiac muscle and can lead to left ventricular failure (Shaw and Mughal 2013).

Symptoms of hypercalcaemia include nausea, dizziness, and polyuria. In the longer term, this can also lead to renal calculi.

Plasma calcium levels are maintained by the actions of parathyroid hormone, vitamin D and calcitonin (Shaw and Mughal 2013).

Calcium is obtained from diet. The main food group containing calcium is dairy products such as milk and cheese. Other sources include green leafy vegetables, legumes, nuts, and fortified cereals. In clinical practice, the use of a tool such as proposed by Nordblad et al. (2016) can be helpful in assessing whether a child is having adequate calcium in their diet. Any child who is on a restricted diet or has malabsorption should be referred to a dietitian for a more in-depth assessment.

54.5 Vitamin D

Vitamin D is essential for the active absorption of calcium from the small intestine; without vitamin D, approximately only 10–15% of calcium intake is absorbed. This is not sufficient to meet physiological requirements at times of rapid growth such as infancy or adolescence and if not addressed can lead to symptomatic hypocalcaemia, osteomalacia, and rickets.

Muscle weakness is also seen in children with vitamin D deficiency and can give rise to non-specific muscle pains, proximal myopathy can lead to difficulty climbing stairs, delayed walking and in extreme cases, infants can present with life-threatening cardiomyopathy (Golden et al. 2014).

The main source of vitamin D in humans is from the action of ultraviolet B waves on the skin. UVB stimulates the manufacture of pre-vitamin D from 7-deoxycholesterol. Pre-vitamin D3 is isomerised into cholecalciferol (vitamin D3) and then

transported to the liver. Here the cholecalciferol undergoes hydroxylation into 25 OHD and this is then stored in the liver or adipose tissue.

Although most vitamin D is obtained from sun exposure, there are some dietary sources of vitamin D. However, there are only small amounts found in foods such as oily fish, egg yolks, some mushrooms, fortified spreads and cereals—so dietary intake alone would not be adequate.

54.6 Maintaining Serum Calcium

In response to a decrease in plasma calcium, parathyroid cells secrete Parathyroid Hormone (PTH). PTH directly stimulates osteoclast activity in bone, which releases calcium and phosphate into the circulation. PTH also stimulates further hydroxylation of 25OHD to 1,25 OHD in the kidney by 1α hydroxylase.

1,25 OHD increases the serum calcium levels by increasing both the absorption of calcium from the intestine and the resorption of calcium in the renal tubules. It also increases the renal excretion of phosphate to prevent hyperphosphataemia.

54.7 Rickets

Rickets only occurs in children who have not completed their linear growth, and is most commonly seen in younger children. The vitamin D deficiency will result in persistently elevated levels of PTH required to maintain serum calcium within the normal range. PTH also increases the renal excretion of phosphate and over time this results in serum phosphate levels falling to below normal. Bone formation at the growth plates is impaired, as phosphate levels within the normal range are required for apoptosis of the chondrocytes prior to mineralisation. New bone formed in these circumstances is inadequately mineralised osteoid. This is softer than healthy mineralised bone and deforms when under load—so as the child walks or crawls the long bones in the legs or arms become bowed. On X-ray, the osteoid bone is less dense and clearly undermineralised with splaying and cupping of the ends of the bones (Allgrove and Shaw 2015).

Vitamin D deficiency leading to persistently raised PTH in children and adults who have completed linear growth results in inadequate mineralisation during bone remodelling, this is known as osteomalacia.

54.8 Assessment of Vitamin D status

Assessment of vitamin D sufficiency is made by a blood test measuring the serum levels of 25OHD. Measurements of 1,25 OHD are not useful in this context—levels fluctuate in response to changes in plasma calcium and it has a very short half-life of 4 h (Allgrove and Shaw 2015).

In most areas of clinical practice, the currently accepted thresholds of 25OHD for assessment of vitamin D status are those agreed by the Institute of Medicine (2011).

- Deficiency <30 nmol/L
- Insufficiency 30–50 nmol/L
- Sufficiency >50 nmol/L

54.9 Factors Increasing Risk of Vitamin D Deficiency

Vitamin D deficiency is prevalent across the world in spite of public health awareness campaigns (Golden et al. 2014). Factors known to increase the risk of deficiency include:

- Area of residence: At latitudes below 37° there are sufficient UVB rays reaching the earth to enable vitamin D synthesis all year round. In the northern and southern hemispheres (latitudes above 37°), UVB rays are only sufficient for vitamin D synthesis during the middle of the day in the summer. There is insufficient UVB for any vitamin D synthesis during the winter.
- Increased use of sunscreen—In response to campaigns to raise awareness and reduce incidence of skin cancer, sunscreen use has significantly increased and is mandatory in many

schools and preschools. Sunscreen of factor 15 or above reduces the ability of the skin to produce vitamin D by approximately 95%.
- Skin colour—Because melanin absorbs UVB, people with darker pigmented skin need significantly longer sun exposure to generate enough vitamin D than those with fair skin.
- Wearing garments that cover the skin. This may be for cultural or religious reasons.
- Limited sun exposure—People with disabilities or those living in care institutions spend less time outside than their able-bodied peers.
- Obesity—factors that contribute to obesity, such as reduced time outside also increase risk of Vitamin D deficiency. 25OHD is also sequestered in body fat reducing the amount available.

54.10 Screening for Vitamin D Deficiency

Screening for vitamin D in the general population is not cost effective and historically advice has been to give supplements to all at risk groups. This has had only limited success, with poor implementation and uptake in many countries. Recognising this The Scientific Advisory Committee on Nutrition has now issued updated guidance advising universal supplementation should be given all year round in the UK (SACN 2016).

54.11 Vitamin D Supplementation

There is no universal agreement on the dose of daily supplements required to prevent vitamin D deficiency worldwide. The IOM (2011) recommends 400 IU daily for those under 1 year and 600 IU daily for those over 1 year. The guidance from the SACN (2016) for the UK is for lower amounts of 340–400 IU daily for infants under 1 year and 400 IU daily for everyone over this age.

Although this seems fairly straightforward, achieving concordance with these recommendations can be challenging with marked variations in clinical practice (Gupta and Warner 2011). Obtaining vitamin D supplementation on prescription from primary care is not possible in many areas and there are a small number of licensed products containing only vitamin D available. Multi-vitamin preparations available on prescription are often unpalatable and not all contain the recommended daily amount of vitamin D. The amount of a multi-vitamin preparation given should not be increased above the stated dose as these usually contain 100% of the recommended daily intake (RDA) of vitamin A; giving higher amounts can lead to vitamin A toxicity.

Vitamin D supplements are widely available as ‘over the counter’ (OTC) preparations from pharmacies and supermarkets. They are either as vitamin D3 known as cholecalciferol or vitamin D2 known as ergocalciferol. Cholecalciferol is formulated from animal product such as lanolin, whereas ergocalciferol is from plant sources. They are both effective at increasing 25OHD levels but cholecalciferol will not be acceptable for those following a strictly Halal or vegetarian diet. It is also important to be aware that many of the chewable pastilles contain gelatin, which would make them unacceptable to these groups.

The amount of vitamin D contained in available OTC preparations is variable. Further confusion is engendered by the dose being given in different units, with some labelled in IU and others in micrograms. 1 μg = 40 IU.

It is important to acknowledge that for some families the cost of the brand named chewable versions means they cannot afford to purchase these regularly. Products with added calcium are chalky and quite unpalatable for children. Additional calcium is not routinely required for children with vitamin D deficiency, but should be considered if the child has an inadequate dietary intake.

54.12 Treatment of Vitamin D Deficiency

The aim of treatment of vitamin D deficiency is to restore 25OHD levels to greater than 50 nmol/L in a safe manner without causing side effects.

This can be given as cholecalciferol or ergocalciferol in doses of 1550–10,000 units daily, depending on age, for 8–12 weeks (Cheung 2015). Care should be taken to ensure that 1,25 dihydroxyvitamin D is not prescribed in error as this will not replenish vitamin D stores and may cause hypercalcaemia and nephrocalcinosis (Gupta and Warner 2011).

Vitamin D is a fat-soluble vitamin and is best absorbed when taken with or after food. If daily administration is difficult then it can be given weekly as a larger dose, which some families find easier to manage. If gaining good concordance with daily or weekly dosing is not possible, then it can also be given as a large single dose (150,000–600,000 IU, depending on age) either by mouth or by intra-muscular injection; this is known as stoss therapy. In clinical practice, stoss therapy should be used cautiously, vitamin D toxicity is rare but has been seen in children given high dose treatment. Signs and symptoms include nausea, vomiting, constipation, and anorexia. It can also lead to hypercalcaemia and hypercalciuria (Cheung 2015).

Children being treated for rickets will need to be given additional calcium supplements to enable bone healing. They will have a high requirement for calcium and if not adequately supplemented are likely to experience symptomatic hypocalcaemia, which can be painful and distressing.

54.13 Excluding Other Causes of Rickets

Although hypophosphataemic rickets is rare, it is important that this is excluded as this requires specialist and long-term management to prevent severe deformity. This can be assessed following completion of treatment of the vitamin D deficiency by a blood test measuring inorganic phosphate. Once levels of 25OHD are within the normal range, the phosphate level should also be restored to normal; an ongoing low phosphate level should prompt further investigation.

54.14 Other Factors That Affect Bone Health

54.14.1 Nutrition

The child/young person needs nutrition that is adequate to achieve a healthy Body Mass Index (BMI). Adolescents with a very low BMI may have suppression of the hypothalamic-pituitary-gonadal axis resulting in sex hormone deficiency (Thornton and Gordon 2016).

In addition to calcium and vitamin D, the diet should also contain protein and elements including magnesium, copper, iron, zinc and vitamins A, C and K. Treatment/management of any condition that reduces the availability of nutrients is required to ensure there is no adverse impact on bone health. Conditions include: coeliac disease, cystic fibrosis, inflammatory bowel disease, anorexia nervosa, bulimia. Higher doses of Vitamin D than usual may be required to maintain sufficiency.

54.14.2 Physical Activity

As discussed, remodelling is essential for appositional growth of the bones. High impact physical activities that involve running or jumping are the most effective. It is also imperative to address this aspect of management in children whose mobility is limited, such as those with cerebral palsy or progressive diseases such as Duchenne's. Ensuring their mobility is preserved for as long as possible and using standing frames for periods of time has been shown to have a positive impact on bone health for those with Duchenne's (Buckner et al. 2015) but less effective for those with cerebral palsy (Fehlings et al. 2012).

54.14.3 Sex Steroids

Oestrogen and testosterone have a positive effect on bone health by increasing bone formation and inhibiting bone resorption. Lack of sex steroids during adolescence has a marked impact on the rate of bone deposition and if not replaced

reduces peak bone mass attained. Conditions that are likely to be associated with delayed puberty include Turner syndrome, anorexia nervosa, cerebral palsy, Duchenne Muscular Dystrophy, and others, requiring high dose glucocorticoid treatment (Golden et al. 2014).

54.14.4 Inflammatory Disorders

In conditions such as inflammatory bowel disease and juvenile idiopathic arthritis, the increased levels of cytokines have a direct effect on bone—causing increased resorption and affect absorption of the key nutrients required for healthy bone formation. Additionally, the treatments given for these conditions may also have a detrimental effect on bone turnover and health (Fehlings et al. 2012).

54.14.5 Liver and Renal Disease

Both of these conditions can impair the ability to synthesise vitamin D. In liver disease, there is reduced hydroxylation of vitamin D3 to 25OHD and in renal disease insufficient 1α hydroxylase to enable further hydroxylation to the active form 1,25 OHD.

54.14.6 Drug Treatment

Glucocorticoids have potent anti-inflammatory properties and are given in high doses as an essential part of treatment regimens for many conditions such as Duchenne Muscular Dystrophy, leukaemia, rheumatoid arthritis, kidney disease, and inflammatory bowel disease. However, treatment with high dose glucocorticoids for longer than 3 months has adverse effects on bone health and if this is not addressed results in osteoporosis (Högler and Ward 2015).

Glucocorticoids impair bone health by:

- Increasing the rate of bone absorption
- Reducing the rate of bone formation
- Inhibiting the absorption of calcium from the small intestine
- Suppression of gonadotrophins leading to sex hormone deficiency

The effect of glucocorticoids is most pronounced on trabecular bone resulting in vertebral collapse fractures, these can often be asymptomatic; adolescents at risk should be screened regularly by dual energy X-ray absorptiometry (Golden et al. 2014).

54.14.6.1 Drugs Increasing Levels of Cytochrome P450

Taking a complete drug history is an important part of assessment of this group of patients. Some herbal remedies such as St Johns Wort and some drugs including the older forms of anticonvulsants such as carbamazepine, phenobarbital, and phenytoin increase the levels of the liver enzyme cytochrome P450. This increases the metabolism of 25OHD. In clinical practice, this means that increased doses of vitamin D supplements are likely to be needed to maintain vitamin D sufficiency in children taking these drugs.

From the information above, it is clear that to maximise the potential of every child to attain peak bone mass requires attention to detail of all the factors that can affect this process. The two case studies below identify some of the issues seen in clinical practice and discuss ways of managing these.

Case Study 1

Jake was referred to the paediatric endocrine service at the age of 12 years for assessment of his bone health. Jake was diagnosed with Duchenne muscular dystrophy at the age of 8. Jake had no other health concerns and there was no significant family history of any medical conditions. Both parents were well and had experienced puberty at a 'normal' time.

At the time of his first appointment with the endocrine team, Jake was still fully ambulant and had been prescribed oral prednisolone for just over 4 years. A DEXA scan was arranged and Jake commenced on a multi-vitamin preparation to maintain vitamin D sufficiency. The results of

the DEXA showed that Jake's bone mineral density was −1 SDS below the mean (corrected for age & size). A lateral X-ray of his spine revealed asymptomatic vertebral fractures. Following discussion with the family, treatment with intravenous bisphosphonate was commenced.

Jake was reviewed in clinic at approximately 6 monthly intervals. Aged 14 years he remained prepubertal with Tanner staging of 1 for both pubic hair and genitalia and testicular volumes of 3–4 mL. Jake was commenced on treatment with testosterone at a dose of 50 mg by monthly intramuscular injection. Assessment of 25OHD revealed levels of 41 nmol/L, which is classified as insufficiency. In view of this Jake's prescription was changed to a combined product containing 400 IU of cholecalciferol and 500 mg calcium.

During this year Jake became wheelchair dependent, although still able to stand with aids. At the age of 15 years, there had been some pubertal progression to Tanner stage 3 for pubic hair and 2–3 for genitalia. A small increase in testicular volumes was noted to 4 mL on the left and 5 mL on the right. The treatment with testosterone was stopped to see if further progress was made without this. At this time 25OHD was measured and found to have improved to 70 nmol/L.

By the age of 16 years there had been no further progression through puberty and treatment with testosterone was recommenced at an increased dose of 100 mg monthly. This increased dose caused Jake to have persistent and frequent penile erections. This caused him some discomfort as well as embarrassment and difficulty in using the penile sheath system for collecting urine. The dose was reduced back to 50 mg for a further 6 months and then increased back to 100 mg with no further problems.

The effectiveness of the bisphosphonate treatment was assessed by serial DEXA scans showing continued improvement in bone density. At the age of 17 years, Jake opted to change his bisphosphonate treatment to oral risedronate. At this time Jake's 25OHD was again in the insufficient range at 44 nmol/L. He was then prescribed a treatment course of 10,000 IU daily for 12 weeks. This was inadvertently continued for approximately 9 months before changing back to the 400 IU daily preparation. A blood test at this time revealed a 25OHD of 162 nmol/L.

At the age of 18 years Jake's pubertal development was assessed at Tanner stage 4 for both pubic hair and genitalia. The dose of testosterone was increased to 250 mg monthly. At this time, the 25OHD was measured at 52 nmol/L.

54.15 Learning Points/Nursing Role

For Jake both the disease process (increased cytokines and immobility, increased likelihood of vitamin D deficiency) and treatment with glucocorticoids (increased bone resorption, reduced bone formation, reduced absorption of calcium and vitamin D, suppression of gonadotrophins) contributed to his reduced bone health. The role of the nurse is important in supporting and educating Jake and his family about the treatment options and the importance of good concordance with these.

The variations in 25OHD results mirror variable concordance with supplements, as there were no other changes in treatment that would account for this. Additionally, if he had taken the 10,000 units daily consistently for the 9 months incorrectly prescribed then a 25OHD greater than 162 nmol/L would have been expected. It may have been helpful for the endocrine nurse to have discussed this in more detail with the family going through the available products and dosing schedules that would have been suitable. However at this time there were only a few licensed products available and most of these were combinations of cholecalciferol and calcium, so the choice was limited. There were suitable OTC products available and perhaps a discussion with parents to see if they would be willing to purchase these instead of having a less palatable one on prescription would have been beneficial. Improving concordance may have eliminated the need for the period of high dose treatment and reduced the risk of prescription errors. If there is no improvement in vitamin D levels following treatment, poor compliance with the prescribed treatment is the most likely cause. It is however

important to ensure that there is no evidence of malabsorption.

From the history above, it is clear that Jake also had delayed puberty and if not addressed then this would also negatively impact on his bone health by reducing the peak bone mass attained. It is also clear that induction of puberty seems to have been managed more slowly than would be usual given that Jake did not commence on adult doses of testosterone until he was 18 years of age. In common with many other children with a chronic and disabling condition, Jake's parents were involved in his personal care, hygiene, and toileting, and Jake did not have any independence or privacy. The effects of testosterone were evident to all and made some aspects of his care harder to complete and increased both his and his parents' embarrassment. Additionally, his parents found it difficult to accept the changes in behaviour that occur during teenage years—the attempts at rebellion, temper outbursts, and moodiness. It was difficult for them to accept that the testosterone was vital to maximise his bone health and that going through puberty could not be avoided. This is a common issue faced by parents of children with disabilities and the input of the endocrine nurse in supporting these families and ensuring they understand the issues and choices around treatments is essential.

Case Study 2

Jayesh is the second son born to parents of Indian origin now living in the UK.

On a visit to their extended family in India he was taken to a doctor with concerns about bowing of his lower legs. The doctor told the family he did not have rickets but needed treatment with vitamin D. The dose prescribed is not known but this was administered, as directed, by his parents for approximately 4 months.

After returning to the UK he was seen at a local hospital for further assessment including blood tests. At this time his PTH and bone profile were in the normal range and the 25OHD was 87.3 nmol/L. Parents were told this level was high and to stop giving Jayesh cholecalciferol.

Four months later Jayesh was seen by the paediatric orthopaedic team for assessment of genu varum. Following clinical and X-ray assessment it was confirmed that there was no evidence of rickets; however, blood tests confirmed vitamin D deficiency with a 25OHD of 24 nmol/L. PTH was normal at 4.2 pmol/L and bone profile was also within the normal range.

These results prompted a referral to the paediatric endocrine clinic with concerns that vitamin D deficiency had recurred so quickly following very robust level 4 months previously.

By the time of the appointment with the endocrine nurse Jayesh was 23 months old. He was otherwise well with no underlying chronic illness or signs/symptoms to suggest malabsorption. His height and weight were on the 25th centile. Jayesh was active and moving around normally during the consultation and had no joint swelling or tenderness. Jayesh ate a vegetarian diet and was still breastfed. He did not drink milk or like dairy products and ate very little of these.

The drop in 25OHD levels from 87.3 to 24 nmol/L in a period of 4 months was an unexpected finding and parents were concerned this meant there was something more serious causing this and that the vitamin D deficiency was causing harm. From the history it was clear that Jayesh's intake of calcium was extremely low and this was most likely to be contributing significantly to the persistent and severe vitamin D deficiency.

This was explained to parents and Jayesh was prescribed cholecalciferol 3000 IU daily for 12 weeks and calcium supplements. It was also recommended to parents that Jayesh should continue on supplementation of cholecalciferol at a dose of 400 IU daily throughout his childhood while resident in the UK. Three months later the genu varum had completely resolved and Jayesh was discharged from the orthopaedic service. A referral was made to the local dietician for ongoing follow-up and managing his calcium supplementation until such time as this is no longer required.

54.16 Learning Points/Nursing Role

Jayesh had previously been prescribed cholecalciferol daily, which had increased his 25OHD levels to within the normal range; this indicates

that absorption is not an issue. The decision to stop any supplements and his parents being told that the level of 87.3 nmol/L was too high reflects the poor understanding of some health care professionals regarding normal levels and national recommendations regarding universal supplementation of children under 4 and 'at risk' groups.

In physiological terms Jayesh's calcium deficiency would lead to persistent secretion of PTH to prevent hypocalcaemia. PTH increases serum calcium in two ways, by stimulating osteoclast activity releasing calcium and phosphate into the circulation and increasing the amount of calcium absorbed from the small intestine by stimulating the hydroxylation of 25OHD to the active form 1,25OHD by 1α hydroxylase.

As there was so little calcium in Jayesh's diet, increased amounts of 1,25 OHD were necessary to maximise the absorption. In simple terms, this would mean that Jayesh's stores of 25OHD would be hydroxylated at a much faster rate than is usual resulting in the marked fall in levels seen prior to referral. Rickets has been reported in children with normal vitamin D levels but with inadequate calcium intake—both of these should be considered during patient assessment.

54.17 Conclusions

Vitamin D deficiency in children is entirely preventable and there are policies or guidelines in place in most of the world regarding supplementation for those groups known to be at risk. Unfortunately the lack of knowledge and understanding by both the public and health care professionals contributes to the poor uptake of supplementation. This results in Vitamin D deficiency remaining prevalent worldwide with children continuing to present to secondary care with vitamin D deficiency, hypocalcaemia, and rickets. As well as the short-term effects there are concerns about the impact this may have on bone health in adulthood.

By demonstrating a thorough understanding of the physiology of calcium homeostasis, bone formation, and factors that may impact on bone health, the endocrine nurse will be able to identify children at risk and provide education and advice on the most appropriate treatment or supplement for their patient group.

Abstract

Obesity is a chronic, often progressive disease, with a complex web of psychological, social, and biological factors underpinning why people overeat, struggle to be active, and gain excess body weight and adiposity. As such its management is not simply about eating less and exercising more, rather there is a need to understand the drivers to excess weight gain with comprehensive assessment identifying modifiable factors. Multicomponent programmes including dietary treatment, physical activity, and behaviour modification are more effective than interventions focusing on one aspect alone (Avenell et al. 2004). Rather than one superior dietary intervention

there are a range of effective evidence-based treatments that can be matched to patient preferences and the presence and/or severity of comorbid disease. Behavioural modification focuses on patient-centred care, incorporating motivational, behavioural, and cognitive elements and recognizes that nurse's attitudes and skills can have a profound effect on patient outcomes.

Nurses are on the frontline of obesity management raising the issue of weight where appropriate, undertaking assessment of patient's complex needs, signposting to services and providing education and support for weight loss and maintenance. Given the escalating prevalence of obesity, it is essential that nurses have a comprehensive understanding of how best to treat this condition. Obesity management is particularly relevant in the endocrine setting given the range of conditions closely linked with excess weight, such as type 2 diabetes mellitus (T2D) or polycystic ovarian syndrome, and in which comprehensive management may improve associated symptoms and risks.

Qualitative research exploring nursing beliefs about their role in managing obesity identify its assigned importance but highlight the desire for more obesity training, an infrastructure which supports high quality care, a greater understanding of evidence-based treatments, and improved access to resources (Nolan et al. 2012).

This chapter addresses some of these concerns, presenting an overview of the evidence base related to dietary and behavioural modification in obesity management, considers the assessment process, and highlights training opportunities and educational resources where appropriate.

Keywords

Weight bias · Multicomponent Comprehensive assessment · Dietary interventions · Self-monitoring · Motivation Expectations

Abbreviations

BMI	Body mass index
CBT	Cognitive behavioural therapy
CVD	Cardiovascular disease
DSM-5	Diagnostic and Statistical Manual of Mental Disorders
GI	Glycaemic index
GL	Glycaemic load
HbA1c	Glycated haemoglobin
IER	Intermittent energy restriction
LC	Low carbohydrate
LDL	Low density lipoprotein
LED	Low energy diet
MI	Motivational interviewing
MR	Meal replacements
NICE	National Institute for Health and Clinical Excellence
PAL	Physical activity level
T2D	Type 2 diabetes
TDR	Total diet replacement
VLED	Very low energy diet

Key Terms

- **Behavioural therapy**: uses techniques derived from behaviourism to modify learned behaviours.
- **Binge eating disorder**: Eating abnormally large amount of food, feeling loss of control during eating.
- **Cognitive restructuring**: learning to identify and change patterns of thinking.
- **Formula diets**: Liquid shakes, soups, bars replace food for a specific period.
- **Glycaemic Index (GI)**: Relative ranking of carbohydrate in foods according to how they affect blood glucose levels. Carbohydrates with a low GI value (55 or less) are more slowly digested, absorbed and metabolised and cause a lower and slower rise in blood glucose.
- **Low carbohydrate diets**: Less than 130 g/day.

- **Severe obesity**: BMI (body mass index) >35 kg/m^2.
- **The Mediterranean diet**: High intake of fruits, vegetables, nuts, seeds, olive oil.

Key Points

- The nurse's experience of obesity treatment and the associated treatment outcomes.
- Previous weight bias may impact on the patient's response to assessment and treatment.
- Comprehensive assessment is the foundation of tailored weight management support.
- Multicomponent programmes, including dietary change, physical activity, and behaviour modification are more effective than isolated interventions.
- There are a range of evidence-based dietary interventions rather than one superior dietary treatment.

55.1 Aims of Dietary and Behavioural Treatment

The aims of dietary and behavioural treatment are to

- Make and sustain changes to eating behaviour
- Consider needs and expectations
- Make acceptable long-term changes
- Improve health and quality of life
- Modify weight, where possible

Encouraging patients to strive for their ideal body weight can be unhelpful, particularly for those with severe and complex obesity. Modest weight change of 5–10% has been associated with improvements in metabolic health and reduced risk of obesity-related diseases (The Look Ahead Research Group 2014). However, once comorbidities are present modest weight loss is unlikely to provide sustained benefit.

For patients with a BMI <35 kg/m^2 with no medical, functional, or psychological consequences of obesity, modest weight loss of 5–10%, and/or prevention of further weight gain may be appropriate. In instances of severe and complex obesity, often BMI >35 kg/m^2, although this may occur at lower BMI in certain ethnic groups, a 15–20% weight loss may be needed to see metabolic benefit (Scottish Intercollegiate Guidelines Network 2010) and reverse intractable complications and this often requires intensive dietary treatment.

55.2 Dietary and Behavioural Assessment

55.2.1 Negative Attitudes to Obesity

Reflecting on patient's experiences of weight bias, the nurse's attitudes to obesity and how this may influence the patient's response to assessment and management can be helpful.

Many obese patients will have experienced negative attitudes with widespread stereotypes suggesting they are lazy, weak-willed, and lacking in self-discipline (Brown 2006). Indeed obesity is often portrayed as self-inflicted with many patients experiencing high levels of shame and self-blame (Puhl and Brownell 2003). Research suggests health professionals draw on these negative beliefs to justify inaction in treating obesity, and this may be linked with negative clinical practices (Frank 1993). It is important to reflect on how past experiences of weight bias may detrimentally impact the patient's confidence and willingness to, for example, discuss eating habits or attend appointments following treatment relapse.

Online training: Preventing weight bias: helping without harming in clinical practice www.uconruddcenter.org.

Explore your own attitudes: http://biastoolkit.uconruddcenter.org/module1.html.

55.2.2 Raising the Issue of Weight

Broaching the topic of body weight with a patient can be challenging. A number of barriers have been identified including a lack of time, uncertainty over treatment effectiveness and concern over offending people (Michie 2007). However, starting the conversation is essential if appropriate care is to be provided. Reassuringly, research suggests most people find brief conversations about weight instigated by health professionals very helpful particularly if they are provided with assistance and support (Aveyard et al. 2016).

Refer to "Let's talk about weight: a step by step guide to brief interventions with adults for health and care professionals" 2017 www.gov.uk.

If signposting to treatment rather than managing "in house", knowledge of local services and their referral criteria and processes is essential. See publichealthmatters.blog.gov.uk for further advice on identifying local services and local obesity care pathways.

55.2.3 What to Assess

The aim of assessment is to identify behaviours or conditions that may hinder management and specific modifiable factors that can form the basis of tailored advice. Dietary assessment usually forms part of a broader clinical assessment exploring the impact of excess weight on the presence and/or severity of medical, functional, and/or psychological comorbidities. Some medical symptoms or conditions may need treatment prior to commencing lifestyle modification in order to increase the likelihood of success. For example, extreme sleepiness linked with obstructive sleep apnoea may benefit from initial symptom control before implementing lifestyle changes.

55.2.3.1 Exploring Importance and Motivation

Not all patients want to treat their obesity or commit to treatment so exploring the importance of change and the reasons for addressing their weight is critical (Miller and Rollnick 2002). Discussing these reasons will strengthen and build motivation and help facilitate change.

Some common examples of specific, quality of life-related reasons

- To feel healthier
- To reduce joint pain and improve my ability to move about
- To be a better role model to my children
- To have a healthier relationship with food

Motivation or "willpower" is at times perceived as something you either have or you don't. However in reality, it is far more complex and influenced by the importance attached to a change and the confidence to implement it. This will help identify whether there needs to be a focus on increasing importance, improving confidence, or both.

Scoring systems can be used to assess the importance and confidence a patient may feel towards changing a particular behaviour although these need to be integrated into the broader conversation about weight and used by skilled practitioners with the associated behavioural skills. (on a scale of 0–10, where 0 is not important/not confident at all and 10 is extremely important/confident, where would you place yourself? (Rollnick et al. 1999)).

55.2.3.2 Expectations of Treatment

There is often a mismatch between the practitioner and the patient's expectations of what can be achieved with obesity treatment (Linne et al. 2002). This may relate to the extent of weight loss, the associated benefits (health, social, psychological), and the level of support available. Identifying and discussing these discrepancies particularly those relating to expected weight loss is one of the most challenging aspects of obesity management and needs to be considered at initial assessment.

With uncomplicated obesity, weight losses of 5–10% over 6–12 months are defined as success; however, research suggests patients want considerably greater losses with a recent study reporting over 90% of participants selected a goal ≥10% (Lent et al. 2016), with these disparities increasing with BMI (Foster et al. 2001; White et al. 2007). Although this magnitude of change is possible with intensive dietary treatments, very few achieve it using standard interventions. Research remains unclear about the most effective way of addressing these disparities, so practitioners are encouraged to provide information on the usual weight loss outcomes achieved with treatment.

It may also be helpful to explore broader expectations such as the hope weight loss will automatically improve self-esteem, body image, or psycho-social outcomes. Although these may be positively affected, they are influenced by a broad spectrum of factors unrelated to weight and discussing this at the start of treatment and linking with treatment goals is important.

55.2.3.3 Weight History

Weight history may identify contributing factors to obesity and give an indication of genetic predisposition. There are individuals strongly predisposed to excessive weight gain and discussing this can help convey understanding, empathy, and help address self-blame or shame about size.

Early onset childhood obesity and a strong family history suggest genetics may be making a significant contribution to weight control (Whitaker et al. 1997). Concern has been expressed that discussing differences in genetic risk may lead to fatalism and reduced motivation to address lifestyle. However, research suggests conveying genetic information to participants actually enhances motivation to alter lifestyles (Meisel and Wardle 2014). Balancing this message is challenging but focuses on acknowledging weight control is harder for some people than others but lifestyle change and successful weight management remains possible.

55.2.3.4 Dieting History

Discussing previous dieting attempts allows the time, effort, and frustration patients may have experienced to be acknowledged. Exploring triggers to previous attempts, the quantity and speed of weight loss and the helpful (e.g. group environment, regular weighing) and unhelpful elements of previous approaches are important and may help guide advice.

55.2.3.5 Eating Patterns

There are various maladaptive eating behaviours commonly found in this group (Peneau et al. 2013) including:

- Skipping meals
- Chaotic, disorganized eating
- Mindless eating
- Emotional eating
- Grazing
- Stress-related eating
- Night eating

To help identify relevant eating patterns consider exploring

- Time of day/context of eating/what else doing
- Frequency of eating meals/snacks
- Physical hunger, food cravings
- Fullness, satiety before and after food
- Speed of eating
- Physical state—e.g. daytime sleepiness, stress
- Feelings before, during, and after eating

Observational studies suggest regular eating improves dietary quality and weight control (Kirk and Hill 1997). Breakfast eating is a common habit recorded in the US National Weight Control Registry, a database of individuals successful at sustaining significant weight loss (Wyatt et al. 2002). However, randomized controlled trials examining breakfast eating and weight change do not show a clear effect (Schlundt et al. 1992; Dhurandhar et al. 2014). Given there is no consensus on optimal eating frequency, a flexible approach is needed during management. However, some opportunistic and emotional eating often occurs against a backdrop of excessive physical hunger from extended fasting, so here structure may be needed.

Binge eating disorder is present in up to 30% of obese people (Bruce and Wilfley 1996; Spitzer et al. 1993), so vigilance for possible symptoms is important. If concerned, a referral to psychological services may be appropriate and the use of assessment questionnaires can be helpful.

Binge cessation is the primary goal in managing this disorder, so deferring weight loss treatments until eating behaviours are stable is generally recommended. National Institute for Health and Clinical Excellence (NICE) eating disorder guidance outlines a stepped approach to treatment with self-help cognitive behavioural therapy (CBT) the first step (National Institute for Clinical Excellence 2017). If ineffective after 4 weeks, referral to a group or an individual CBT programme should be considered. Be aware that local eating disorder services may not accept referrals for binge eating disorder, and therefore specialist funding might need to be accessed.

Binge eating disorder is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (American Psychiatric Association 2013) but be vigilant for the symptoms given below:

- Eating an abnormally large amount of food in a discrete time period
- Feeling a loss of control during eating
- Eating quickly
- Eating until uncomfortably full
- Eating when not physically hungry
- Secret eating
- Feeling guilty and distressed after eating
- No compensatory behaviours, e.g. self-induced vomiting, excessive exercise, or laxative abuse

Given individuals with obesity often have disordered eating, it is important to distinguish between this and a clinical diagnosis of binge eating to avoid unnecessary referral. If unsure, refer to appropriately trained colleagues.

55.2.3.6 Current Dietary Intake

It is important to assess what and how much is eaten while acknowledging this may be difficult for some patients, particularly those experiencing shame about their eating.

Dietary assessment relies on self-report and can only provide an overall impression of eating habits and nutritional intake. Studies have shown obese subjects can under-report energy intakes by 30 and 70% compared with lean controls; therefore, trying to achieve greater accuracy through intensive questioning can be counter-productive and risks increasing patient resistance.

Diet histories or 24-h recalls have traditionally been used to evaluate dietary intake although the questioning style is important. The aim is to gather an overview of eating habits, exploring timings of meals, where food is eaten, hunger levels and associated thoughts and feelings. Discussing these issues before the types and quantities of foods may prove helpful and self-monitoring may provide further quantitative information.

Consider exploring the frequency of:

- Sugary drinks
- Take away meals
- Fruit and vegetable intake
- Alcohol intake
- High calorie snack foods

Questionnaires are another possible assessment method although the time taken to complete, analyse, and interpret findings should be considered.

- Check out this summary of brief assessment tools for use in clinical practice (England et al. 2015)
- Patient self-assessment—How Are You Quiz www.nhs.uk
- Rapid eating assessment questionnaire [REAP] (Gans et al. 2003)—designed for use in primary care by nursing staff

55.3 Dietary Approaches

There is no one superior dietary treatment for obesity management (Johnston et al. 2014) rather a range of evidence-based diets that can be matched to patient preferences, past experiences, and the presence of comorbidities. The focus of

treatment needs to be broadened beyond simply considering *what* and *how much* is eaten, towards helping patients consider *why* and *how* they are eating, so treatment can address these underlying issues (Grace 2011).

55.3.1 Low Fat Diet

Low fat diets remain the most researched treatment choice for obesity, with various theories linking high fat foods with weight gain including its high energy density, hedonic (reward) properties, and preferential storage (Blundell and Stubbs 1999; Drewnowski 1997; Flatt 1995).

Several large systematic reviews comparing lower with usual fat intake have shown consistent but small effects when reducing dietary fat (Hooper et al. 2012, 2015). The Look AHEAD (Action for Health in Diabetes) trial, a study exploring the impact of intensive lifestyle intervention on the development of cardiovascular disease (CVD) used a low fat diet (<30% energy from fat, <10% energy from saturated fat) as part of treatment in the intervention group with clinically meaningful weight loss of 8.6% at 12 months and 4.7% at year 8 observed (The Look Ahead Research Group 2014) A number of other large studies such as the Diabetes Prevention Trial (The Diabetes Prevention Program Research Group 2002) and the Finnish Diabetes Prevention study (Tuomilehto et al. 2001) have also observed weight losses with low fat approaches although these were all used as part of multicomponent programmes.

Most research exploring dietary fat and weight have considered different types of fat as equivalent in energy regulation. Limited research suggests possible differences in how saturated, unsaturated and trans-fats effect fatty acid oxidation rates, adipose tissue deposition, and other mechanisms involved in weight regulation with unsaturated fats associated with the most benefit (Piers et al. 2002, 2003; Soares et al. 2004).

The effect of modifying dietary fat on CVD risk reduction is also important. Despite ongoing controversy, a recent review concluded lowering saturated fats and partial replacement with polyunsaturates reduced CVD by ~30% although replacement with refined carbohydrates did not lower risk (Sacks et al. 2017). This recommendation on modifying fat intake should occur alongside the broader promotion of a healthy dietary pattern.

Although evidence supports modest weight loss with low fat diets, there is interest in whether other dietary treatments produce better results. In 2015, a systematic review comparing low fat with low carbohydrate diets found greater weight loss, albeit a modest 1.15 kg in the low carbohydrate group (Tobias et al. 2015). Although some concluded "low fat diets don't work", this review also noted those adopting low fat diets in place of usual eating lost 5.4 kg. Careful interpretation of this review is needed given the variation in sample populations and the diverse intervention and control diets.

55.3.2 The 600 kcal Deficit Approach

Basing dietary advice on reported food intake can be challenging when severe under-reporting of energy intake occurs (Lichtman et al. 1992; Prentice et al. 1986). This 600 kcal deficit approach bases agreed changes on an estimate of the energy requirements for weight loss rather than on reported intake. This requires the prediction of resting metabolic rate and an estimate of energy expended through physical activity as described below (Lean and James, 1986; Frost et al. 1991). A review of the effectiveness of this approach found weight losses of 5.31 kg at 12 months (Avenell et al. 2004).

55.3.2.1 How the 600 kcal Deficit Diet Is Calculated

- Calculate resting metabolic rate using Mifflin St. Joer predictive equation (Mifflin et al. 1990) (Table 55.1).
- Multiple results by a factor for physical activity called a PAL (Physical Activity Level) value.
- Subtract 600 kcal to give an estimate of energy needs for weight loss.
- Food group portion control charts can be used to help patients develop a meal plan based on this information.

Table 55.1 Mifflin St. Joer equations for predicting resting metabolic rate (Mifflin et al. 1990)

Men:	RMR = [10 × weight] + [6.25 × height] − [5 × age] + 5
Women:	RMR = [10 × weight] + [6.25 × height] − [5 × age] − 161

Equations use weight in kg, height in cm

Table 55.2 Physical activity level [PAL] descriptions (Scientific Advisory Committee on Nutrition 2009)

Typical activity = 1.63
Less active = 1.49
More active = 1.78

The PAL value is a numerical number given to describe levels of activity and is derived from studies where measures of resting metabolic rate are combined with total energy expenditure from doubly labelled water (Table 55.2).

Theoretically, this can produce 0.5 kg weight loss per week, given the weekly deficit of 3500 kcal is equivalent to 0.5 kg of fat. This is however an oversimplified model and has been shown to not reflect the weight losses seen in reality (Hall 2008). Over 6 months, losses of 10–12 kg should occur but in practice only half this predicted value is observed (Heymsfield et al. 2007) highlighting the compensatory mechanisms activated by weight loss, difficulties in compliance, and the complexity of obesity management.

This approach suits individuals seeking detailed guidance on portion sizes, or who find counting and exchange systems helpful. It should be noted that this approach only provides an estimate of energy needed for weight loss and the skill of the practitioner is required in tailoring the calculated energy prescription to the needs of the individual.

55.3.3 The Mediterranean Diet

The Mediterranean diet is an amalgamation of dietary practices from across a range of European countries including Crete, Greece, and Southern Italy and features a high intake of fruits and vegetables, legumes, nuts and seeds, olive oil, moderate consumption of wine, and low intakes of red and processed meats and refined sugars (Keys and Keys 1975). Nutritionally, this translates into increased consumption of fibre and whole grains, unsaturated fats, and anti-oxidants. The association of these dietary patterns with longevity and lower rates of cancer and CVD is well recognized (Sofi et al. 2008; Trichopoulou et al. 2003).

A pivotal trial, the Prevention of Cardiovascular Disease with a Mediterranean Diet (PREDIMED) study randomized participants at high risk of CVD to either a Mediterranean diet supplemented with olive oil or nuts or a low fat diet. After 4.8 years, the results showed both Mediterranean diets were comparable, achieving a 30% risk reduction in myocardial infarction, stroke, or death and were superior to the low fat diet in the primary prevention of CVD (Martinez-Gonzalez et al. 2015). Despite benefiting CVD risk, further analysis of the PREDIMED cohort found there was no clinically significant beneficial effect on weight loss found within this cohort, with adjusted 5-year change between −0.08 and −0.43 kg (Estruch et al. 2016).

Given the higher fat content of the Mediterranean diet (ranges from <25 to >35%) (Willett et al. 1995), there has been some uncertainty about its role in weight management. There have been inconsistent findings in research exploring whether the Mediterranean diet promotes weight gain or leads to weight loss (Buckland et al. 2008). However, a recent systematic review which included people with obesity and a follow-up beyond 12 months found modest weight loss in the Mediterranean diet group (mean changes ranged from −3.8 to −10.1 kg) and in three of the trials produced greater weight loss than the low fat diet (Mancini et al. 2016). The review concluded the Mediterranean diet was an effective intervention but was not superior to other dietary treatments.

This is an important treatment approach to consider in obesity management particularly given its known CVD benefits. Further clarity on its relationship with weight is needed and whether

in practice energy restricted or ad libitum Mediterranean diets are more appropriate.

55.3.4 Low Glycaemic Index Diets

Glycaemic index (GI) is a method of ranking carbohydrate-containing foods according to their capacity to raise blood glucose levels after a meal and glycaemic load (GL) is the amount of carbohydrate in a portion of food and the speed with which it will raise blood glucose levels (Jenkins et al. 1980, 1981).

Whether low GI or low GL diets are helpful, dietary treatments in obesity management remain controversial (Brand-Millar 2005; Sloth et al. 2005). In theory, high GI diets increase postprandial hyperglycaemia and hyperinsulinaemia leading to altered fuel partitioning and increased body fat storage (Brand-Miller et al. 2002). Conversely, low GI diets may support weight loss through effects on increasing satiety and reducing hyperinsulinaemia after meals (McMillan-Price and Brand-Miller 2006). Although these theories are supported by animal research in humans findings are mixed (Sloth and Astrup 2006), with appetite influenced only in the short term (Ford and Frost 2010). There have been two reviews of low GI diets in obesity management. A Cochrane review in 2007 concluded a 1.09 kg greater difference in weight loss between the low GI and high GI group although the clinical relevance of this has been questioned (Thomas et al. 2007). However, treatment was short term with brief follow-up and less than half of the studies included those with obesity (Thomas et al. 2007). More recently, a systematic review considering only research in obese participants found no effect of the low GI intervention on weight change compared to control treatments (Braunstein et al. 2016).

It is also important to consider the impact of low GI diets on cardiovascular risk reduction and glycaemic control given the risk profile of this population. Three recent Cochrane reviews contrasting low and high GI diets in the prevention of CVD, dietary fibre for primary prevention of CVD, and whole grain cereals in primary and secondary CVD all concluded that there was insufficient evidence to recommend low GI or fibre diets (Clar et al. 2017; Hartley et al. 2016; Kelly et al. 2017). In terms of glycaemic control, using low GI diet has been shown to reduce HbA1c by 0.5% and also reduce hypoglycaemic episodes (Thomas and Elliott 2009).

As such it seems premature to routinely recommend this strategy as an evidence-based obesity management approach until further findings from large scale, high quality, long term randomized controlled trials are available.

55.3.5 Low Carbohydrate Diets

Low carbohydrate (LC) diets, officially defined as less than 130 g/day, are a popular approach for managing weight. Diets providing less than 50 g/day are termed very low carbohydrate ketogenic diets (Feinman et al. 2015).

Although there have been numerous reviews comparing LC diets with control interventions, the variations in study design, duration, the composition of intervention, and control diets have limited the interpretations drawn. In most of the reviews, greater short-term weight loss is found in the LC versus comparison diet although the clinical relevance is questionable given the differences range from 0.1 to 2.2 kg (Tobias et al. 2015; Sackner-Bernstein et al. 2015; Hashimoto et al. 2016; Bueno et al. 2013; Clifton et al. 2014).

There are conflicting findings on the impact of LC diets on CVD risk reduction. One review suggested greater reductions in triglycerides and high density lipoprotein concentrations but less favourable effects on total and low density lipoprotein (LDL) cholesterol compared to control diets (Nordmann et al. 2006). This may relate to the higher total and saturated fat content of LC diets compared to low fat approaches.

Several reviews exploring LC diets in overweight people with T2D have found comparable reductions in weight and glycaemic control regardless of the dietary intervention used. In one review although the low carbohydrate diet led to greater improvements in glycaemic control, the

clinical relevance was questionable with a mean difference in HbA1c of 0.14% (Ajala et al. 2013).

Concerns have been raised about possible adverse effects of LC diets including inadequate micronutrient intake, lack of dietary fibre, negative effects on renal function, and increased risk of CVD. Although dietary adequacy may be compromised with lower fibre and higher amounts of red meat (Elidottir et al. 2016), there is little supporting evidence that using LC diets has detrimental effects although long-term outcome data is needed.

At present, there is no compelling evidence to recommend LC diets as first-line therapy although individuals who choose to adopt a very low or low carbohydrate diet should be supported in their decision with suggested referral to a qualified nutrition professional (Dyson 2016).

55.3.6 Formula Diets

Formula diets are liquid shakes, soups, or bars fortified with vitamins and minerals, which either partially or completely replace food in the diet for a specified period. With total diet replacement, the formula diet can provide either a low energy (800–1200 kcal/day) or a very low energy diet (less than 800 kcal/day).

55.3.6.1 Partial Meal Replacements

Partial meal replacements (MR) provide 1200–1600 kcal/day by replacing two meals per day during the weight loss phase with the remaining meal made up of healthy foods. They may help due to their pre-defined portion size and convenience.

A review comparing MR with control dietary treatments found a 2.4 kg greater reduction at 1 year (Heymsfield et al. 2003). Meal replacements were also used in the intensive multicomponent treatment and maintenance intervention in the Look AHEAD study. The intensive lifestyle group lost 8.6% of their weight at 1 year compared to 0.7% in the control group and those regularly using MR lost the most weight over this time (Wadden et al. 2009). Research in type 2 diabetes has also found MR produce greater reductions in HbA1c, fasting glucose and fasting insulin, although there have been calls for better quality research to improve confidence in the conclusions drawn (Noronha et al. 2016).

A review of evidence by the Dietitians Association of Australia in 2012 concluded "achieving a reduction in energy intake by incorporating MR, monitored by health professionals, provides greater weight loss in overweight and obese adults than general dietary advice for periods of 1–12 months" (Dietitians Association of Australia 2012). Indeed the majority of reviews on MR suggest when used as part of multicomponent programmes with health professional support they are just as effective, if not more so than other dietary treatments. There is a need for future research to incorporate longer term follow-up and explore who does best with this type of approach. Little is known about the effectiveness of MR purchased over the counter where there is no professional support, structured education, or close monitoring.

55.3.6.2 Total Diet Replacements

With a total diet replacement (TDR) all conventional foods are replaced with formula products and daily energy intake can be varied depending on the number of products advised. Traditionally, TDR provided ≤800 kcal/day and were referred to as very low energy diets (VLED). However, recent evidence has found comparable weight losses with low energy diets (LED) (800–850 kcal/day) and comparably fewer side effects (Christensen et al. 2011); therefore, focus has shifted towards using LED with intakes between 800 and 1200 kcal/day.

Interest in total diet replacements has also been sparked by the realization that conventional diets that create modest energy deficits and weight losses may lead to metabolic improvements and prevent development of disease but rarely cause remission disease once it is present. As such those with complex obesity may need to lose 15–20% weight to experience improvement or remission of comorbid disease (Scottish Intercollegiate Guidelines Network 1996). This necessitates intensive management with approaches such as TDR. Recent evidence also

suggests those losing the most weight early in treatment do better long-term running counter to the slow steady weight loss recommendation (Nackers et al. 2010; Unick et al. 2015; Wadden et al. 2011).

55.3.6.2.1 Very Low Energy Formula Diet

Very low energy diets (VLED, 600–800 kcal/day) have traditionally been the most controversial dietary treatment due to questions over long-term efficacy and historical safety concerns related to nutritional inadequacy in the early formulations that have now been resolved (Brown et al. 2015).

VLED have been shown to produce signficant short term weight losses and improvements in comorbidities although, several reviews suggest no difference in weight loss between VLED and LED over the long term (12 months) (Tsai and Wadden 2006). However, given many of these studies failed to address weight maintenance this is perhaps unsurprising. More is now known about strategies to minimize weight regain after VLED including behaviour modification, ongoing use of formula products, weight loss medication, and a longer food reintroduction phase (Johansson et al. 2014; Christensen et al. 2017).

Common side effects (diarrhoea, constipation, headaches, nausea, dizziness, poor cold tolerance, dry skin, and thinning hair) tend to be fairly mild and transient often occurring during the weight loss phase (Christensen et al. 2011; Lean et al. 2018). More serious but less common side effects include acute gout and gallstones. Clinical supervision and medical monitoring are important particularly for those with comorbid disease where medication adjustment will be needed as requirements change in response to energy restriction, metabolic changes, and rapid weight loss. The Counterweight-Plus feasibility study explored the outcome of a 12-week TDR in 91 obese participants (mean BMI 48) treated in primary care and found a mean weight loss of 12.4 kg at 12 months in those completing the study, with 33% of study participants maintaining more than 15 kg (Lean et al. 2013). This suggested such a dietary method was possible in a clinical setting given the right support.

55.3.6.2.2 VLED in Type 2 Diabetes

In 2011, a pivotal study examined the possibility of reversing beta cell failure and insulin resistance and producing T2D remission using a VLED (Lim et al. 2011). After the first week fasting glucose had normalized, hepatic insulin sensitivity improved and by week eight, beta cell function was nearly normal and pancreatic fat content had fallen (Lim et al. 2011). Excess fat (ectopic fat) in the pancreas and liver is now understood as central to T2D development and acute energy restriction key to its management (Taylor and Barnes 2018).

A number of small studies using VLED in those with T2D treated with insulin have found encouraging effects on weight loss, glycaemic control, and CVD risk although there is a need for improved study design and longer term studies (Snel et al. 2012; Paisey et al. 2002; Hammer et al. 2008; Pedersen et al. 2015).

55.3.6.2.3 Formula Low Energy Diet

Low energy diets (LED) are between 800 and 1200 kcal/day although most recent research has used formula LED diets providing 800–850 kcal/day (Brown et al. 2015).

The recent Diabetes in Remission (DiRECT) trial has shed light on the use of formula LED with a specialist weight maintenance programme in the management of early onset T2D (≤6 years) and more specifically the feasibility of inducing T2D remission (Lean et al. 2018). The study a randomized trial undertaken in 49 primary care practices, included individuals (BMI 27–45 kg/m^2) diagnosed with T2D within the previous 6 years. The intervention group followed the formula LED for 12 week, with the option to increase to 20 weeks if insufficient weight loss was achieved. A stepped food reintroduction followed with structured long-term support. The control group followed current clinical practice care of 3 monthly contacts. At 12 months, 24% of those in the intervention group had lost ≥15 kg compared to none in the control group (Lean et al. 2018). Diabetes remission, defined as HbA1c <6.5% (48 mmol/mol) after at least 2 months of all antidiabetic medication from baseline to 12 months, had occurred in nearly half of those (46%) in the

intervention group compared to 4% in the control group. Mean body weight fell by 10 kg in the intervention group and 1 kg in the control group. Although some weight regain was observed during food reintroduction and maintenance phases this was not the rapid regain reported to occur with formula TDR. This study clearly demonstrated the capacity of intensive formula low energy TDR with the additional of a long-term weight maintenance programme to produce T2D remission. The long-term follow-up of this cohort is awaited with interest and seems likely to provide further guidance on how best to optimize weight maintenance.

The NICE obesity guidance (National Institute for Clinical Excellence 2014) suggests LED can be considered in obesity management but highlighted possible nutritional inadequacy of food-based approaches. Formula low energy diets overcome this concern due to their nutritional completeness for vitamin and minerals and given the latest evidence on their efficacy it is important to consider this as an evidenced-based treatment option.

NICE recommendations on VLED state that they should not be used as a routine treatment but reserved for use in those with a clinical need for rapid weight loss (National Institute for Clinical Excellence 2014). They further recommend VLED are used as part of multicomponent programmes, require comprehensive assessment and counselling on the risks and benefits particularly the potential of weight regain.

55.3.7 Intermittent Energy Restriction

Most dietary approaches use continuous energy restriction where energy deficits are adopted daily but an alternative is to markedly restrict (60–85% lower than typical intake; or approximately 600 kcal) on only a few days and return to usual intake on the remainder. This approach has become increasingly popular and is referred to as intermittent fasting/energy restriction (IER) or colloquially as the 5:2 diet.

Findings from systematic reviews suggest IER can produce similar but not superior weight losses and metabolic improvements compared to other dietary interventions and may offer an alternative approach for some individuals (Harvie and Howell 2017; Harris et al. 2018). However, research is limited by small sample sizes and short-term duration.

Comparable metabolic improvements have been observed in total cholesterol, LDL-cholesterol, triglycerides, and/or blood pressure although in healthy overweight or obese populations greater reductions in insulin resistance have been found in those using IER (Harvie et al. 2011, 2013). No differences in body composition changes with weight loss or resting metabolism have been observed. Despite the commercial popularity of the 5:2 diet to date very few studies of a quality that could guide best practice have been published.

Although there have been some concerns this approach may trigger erratic eating patterns, eating disorders, compensatory hyperphagia on "normal" eating days or low mood, there is no supporting evidence although longer term studies are needed.

55.3.8 Fad Diets

Fad diets are those unsupported by scientific evidence, promise quick effortless weight loss, and are often accompanied by enticing marketing messages. Examples of fad diets include detox programmes, food combining, blood group diet, and the grapefruit diet.

To help patients recognize fad diets and resist their non-evidence-based solutions, the American Heart Association [www.american-heart.org] suggests being aware of the following claims:

- **Magic or miracle foods** that burn fat
- **Bizarre quantities** of only one food or type of food
- **Rigid menus**
- **Specific food combinations**
- **No warning** to those with medical conditions to seek their doctor's advice
- **No increased physical activity**

55.4 Behaviour Modification

Behavioural modification focuses on patient-centred care and incorporates motivational, behavioural, and cognitive elements while acknowledging the nurses attitudes and skills have a profound effect on outcomes. It is different from traditional advice giving where the professional is the expert and the patient a passive recipient.

55.4.1 Motivational Approaches

Motivational interviewing (MI) is "a collaborative conversation style for strengthening a person's own motivation and commitment to change" (Miller and Rollnick 2013) and involves expressing empathy, acknowledging past efforts, and helping identify patient's goals and values. Traditionally, ambivalence has been viewed as non-compliance rather than a normal part of changing that requires compassion and a problem-solving approach.

Comprehensive training is important to develop the required skills such as reflective listening, affirmations, and providing information in a helpful way. For further guidance, refer to www.motivationalinterviewing.org. Importance and confidence are key determinants of motivation. Patient's values and beliefs about change affect the importance of that change and influence motivation accordingly. If a change aligns with the individual's values, is believed important and effective, motivation will probably increase and implementation is more likely. Likewise, beliefs about one's abilities to change affect confidence that in turn can influence motivation.

55.4.2 Behavioural and Cognitive Approaches

Using cognitive behavioural approaches improves outcomes in managing obesity with a 3.1 kg greater weight loss using this approach compared to usual care (National Institute for Clinical Excellence 2014). There are a number of core strategies that form the foundation of this approach and require comprehensive training to maximize outcomes achieved.

55.4.3 Core Strategies

55.4.3.1 Self-Monitoring

Self-monitoring is a time-consuming and challenging skill but is the cornerstone of most behavioural treatments in obesity, with those regularly self-monitoring their behaviour achieving superior weight loss. Participants in the National Weight Control Registry, a database of individuals successfully maintaining greater than 10 kg weight loss, report frequent monitoring of eating habits and weight (Hill and Wing 2003).

The purpose of self-monitoring is to increase patient's awareness of their own behaviours and how they relate to weight. Monitoring can focus on eating habits, physical activity, and/or weight although in reality all of these need to be considered. This strategy can be used throughout treatment although some may become fatigued and choose to use intermittently particularly during challenging times.

Self-monitoring helps identify behaviours to address in treatment but may also independently lead to change as self-awareness enhances. Identifying the "problem" is the first step in problem solving, another important behavioural strategy. Practitioners need to accept and understand the extent of under-reporting of food intake, evident in many diaries, and not be distracted from the true purpose of self-monitoring [self-awareness and problem identification] by pursuing the quest for accurate nutrient quantification.

Paper diaries are often used to monitor food intake however phone apps, e.g. Carbs & Cals, My Fitness Pal use food photographs to guide portion size estimation and provide instant feedback and have higher rates of acceptability and satisfaction.

It is essential that self-monitoring is used sensitively given some patients may be fearful of being judged about their eating. As such it is best to reserve this strategy until trust has been

established and patients understand that the purpose of diaries is to increase awareness of their own behaviours rather than a record to be inspected and commented on by the health professional.

Self-monitoring body weight is also important with research suggesting frequent weight checks are associated with improved weight management. Although there is no agreement on the optimal frequency of weighing a number of studies suggest higher frequency, sometimes daily weighing, is more effective for weight loss and maintenance than the commonly recommended once a week checks. This higher frequency monitoring facilitates earlier identification of lapses, triggering earlier self-correction. Some patients may need guidance on how to respond to the number on the scale so the reading is treated simply as information rather than for self-criticism. In clinical practice, the frequency of weighing needs careful exploration with individuals to agree on a helpful monitoring frequency. Daily weighing is not recommended for those diagnosed with an eating disorder or in children and adolescents (Grace 2011).

55.4.3.2 Stimulus Control

The environment can have a substantial negative or positive impact on eating. This strategy involves working with patients to identify, and then develop ways of modifying, the cues or the barriers linked with overeating. A helpful time to use stimulus control is following a lapse when concrete examples of unhelpful habits can often be traced back to cue exposure. A cue can be external (situations relating to shopping, cooking, or eating) or internal (boredom, sadness, anger, hunger, cravings).

Examples of changes to external cues may include

- When shopping
  - Limiting high calorie snacks
  - Buying plenty of fruits and vegetables
- When cooking
  - Preparing only the amount needed
  - Altering portions served
  - Reducing plate size
- When eating
  - Avoiding watching TV, reading, or driving while eating
  - Prioritizing eating at the table

Eating mindlessly while preoccupied with another activity (e.g. watching TV) is an increasingly common behaviour linked with weight gain (Wansink 2011). Distracted eating reduces awareness of foods consumed and lowers satisfaction from eating. Sitting in front of the TV at other times of the day may subsequently trigger cravings and breaking this pattern by removing the stimulus and changing the location of meals may prove useful.

Eating in response to internal triggers (e.g. cravings, emotions) is common and can be challenging to manage. The first step is to make the distinction between physical hunger and food cravings. Talking through the sensations of physical hunger (gnawing in stomach, light headed, irritability, shakiness) and comparing with those associated with cravings (urges in the head or mouth, linked with emotions, often for a specific food) can be helpful.

There are then three options in managing food cravings:

- Use distraction until the food craving has passed—waiting 15–20 min and asking is this really physical hunger?
- Try to identify and address body's real needs, e.g. sleep or relaxation.
- Eat anyway—Take time, savour the taste, pick a fixed portion, and avoid feeling guilty. Recognize if this occurs too frequently; it will hinder weight loss.

55.4.3.3 Goal Setting

Planning and goal setting are essential to developing a successful action plan. It is often more meaningful to talk about the what, how, and when of change rather than SMART goals which may have limited meaning to patients. It is important not to confuse goal setting with targets such "eat less sugar" or "include breakfast" which are too vague to be helpful. Patients need to provide as much detail as possible and consider whether this is realistic.

Detailed food change plan	
What to change:	Have breakfast every day
How to change:	Set alarm 20 min earlier Leave cereal packet on table Add healthy cereal to shopping list
What might get in the way?	Press the snooze button
How might I overcome this?	Move the alarm out of reach
When will I start?	Tomorrow

55.4.3.4 Problem Solving

Problem solving is a core patient skill particularly given its value in overcoming challenging situations that can derail new behaviours. It helps patients develop a positive mindset towards overcoming difficulties rather than their avoidance. A step-by-step approach is used to identify the problem and develop various options to overcome challenges. If patients struggle to make suggestions, the practitioner can draw on other patient's experiences but asking permission before doing this may reduce resistance. The patient chooses the preferred option and a detailed plan is developed. Patients should be encouraged to think of their plan as a work in progress that can be adjusted depending on how it works in reality.

55.4.3.5 Cognitive Restructuring

Understandably, people who struggle with weight may have negative self-defeating thoughts about their size, their difficulties managing it, and the likelihood of succeeding long term. Negative thoughts tend to be automatic, distorted, unhelpful, and often accepted as true. Helping patients to identify and then challenge negative thinking requires a confident and skilled practitioner but it can be helpful for patients to consider "What evidence is there that this thought is true or false?" "What would you say to a friend who had these thoughts?" Over time, patients can learn to reframe negative thoughts in a more helpful way.

55.4.3.6 Social Support

People with higher levels of social support tend to do better in weight management compared to those with little. The forms of support can vary from family members, friends, peers, group programmes, or other social activities. Social support probably helps through its influence on motivation, self-efficacy, and self-acceptance. Helping the patients recognize the value of social support and build a network of helpful support is an important aspect of behavioural modification.

55.4.3.7 Self-Rewards

Using self-rewards or positive reinforcement after achieving a behavioural goal increases the chance of the behaviour continuing. Indeed using self-rewards increases weight loss maintenance at 12 months (Kramer et al. 1986; Brownell 1989). This can be a challenging strategy to implement as patients may struggle to identify rewards unrelated to eating or feel undeserving of a reward but perseverance is important as this strategy will support long-term behaviour change.

55.4.3.8 Relapse Prevention

Lapses are a normal part of changing and often occur in response to high-risk situations such as social events or emotional challenges. The inevitability of lapses and the need to learn management skills should be discussed at the start of treatment to ensure patients understand how to prevent lapses becoming relapse. Lapses are an opportunity for identifying high-risk situations, using problem solving to achieve different outcomes and cognitive restructuring to reframe associated negative thoughts.

55.5 Conclusions

Given the interpersonal skills of the nurse have a substantial impact on the likely outcome of obesity management, it is essential for individuals to reflect on their attitudes to obesity and invest in training to facilitate the skilled application of behaviour modification. The nurse's role may focus on raising the issue of weight sensitively and signposting to appropriate local services. When nurses are providing lifestyle treatments, comprehensive assessment is crucial to facilitate appropriate treatment choices that take account

of the complexity of obesity. A key component of the nursing role is the provision of patient education and skills development crucial to the long-term management of obesity.

Abstract

The worldwide prevalence of obesity has been described as an 'epidemic' by the World Health Organization (WHO). For the first time in human history, the prevalence of obesity and overweight now exceeds that of underweight and malnutrition and it is predicted that obesity could reverse the trend for increased life expectancy that has, to date, been realised by successive generations. The seriousness of the problem has led the Chief Executive of the UK National Health Service (NHS) to describe obesity as 'the new smoking'.

Obesity is associated with physical and mental health comorbidities including cardiovascular disease, type 2 diabetes, certain cancers, joint pathology, obstructive sleep apnoea, depression and anxiety. These comorbidities impact both on the individual patient and society as a whole through loss of economic productivity and increased healthcare costs.

Assessment of the patient with obesity requires a whole team, multi-disciplinary team (MDT) approach including, but not limited to, specialist nurses, endocrinologists, dieticians, psychologists, psychiatrists, surgeons and anaesthetists. This allows for a holistic review of the patient's physical and mental health status and an MDT treatment plan.

The treatment options for obesity include lifestyle and behavioural modification and/or pharmacotherapy and/or bariatric surgery. Of all of these treatment modalities, there is clear evidence of the superior efficacy of bariatric surgery for weight loss, long-term weight maintenance, and amelioration of obesity associated comorbidities.

Despite the significant number of obese patients that would benefit from it, in most countries bariatric surgery remains a limited treatment option. In the UK, where 25% of the adult population are obese, just 5000 bariatric operations are carried out annually which means that currently less than 1% of those who could benefit get treatment. For those patients who do undergo weight-loss surgery, the most commonly performed bariatric procedures are gastric banding, Roux-en-Y gastric bypass and sleeve gastrectomy. Specialist pre- and post-operative nursing care including long-term post-surgery follow-up are essential to good patient outcomes and overall surgical success.

Keywords

Obesity · Obesity associated comorbidities · Bariatric surgery · Gastric band · Roux-en-Y gastric bypass · Sleeve gastrectomy

Abbreviations

AUD	Alcohol use disorder
BMI	Body mass index
BOMSS	British Obesity and Metabolic Surgery Society
CPAP	Continuous Positive Airways Pressure (ventilation)
ECG	Electrocardiogram
EOSS	Edmonton Obesity Staging System
FBC	Full blood count
GORD	Gastro-oesophageal reflux disease
HADS	Hospital Anxiety and Depression Scale
KOSC	King's Obesity Staging Criteria
LFTs	Liver function tests
MDT	Multi-disciplinary team
MRI	Magnetic resonance imaging
NHS	National Health Service
NICE	National Institute for Health and Care Excellence
ODG	Oesophago-gastro-duodenoscopy
RYGB	Roux-en-Y gastric bypass
SF-36	Short Form (36) Health Survey
VLCD	Very low calorie diet
WHO	World Health Organization

Key Terms

- **Bariatric surgery**: Surgical procedures to induce weight loss.
- **EOSS**: Edmonton obesity staging system; grading of the obesity for guiding treatment decisions.
- **KOSC**: King's obesity staging criteria; tool for the assessment of the obese patient.
- **Obesity staging**: A method of grading to allow for specific treatment planning.
- **Obesity**: A body mass index of >30 kg/m^2.

- **Roux-en-Y gastric bypass, gastric banding, sleeve gastrectomy**: Mechanism of creating a physical restriction to the volume of food and liquid that the patient can consume.

Key Points

- The worldwide prevalence of obesity is increasing.
- Assessment of the obese patient includes the medical history, physical examination, diagnostic tests, and identification and management of obesity associated comorbidities.
- Bariatric surgery is the most efficacious treatment for obesity achieving weight loss, long-term weight maintenance and amelioration of obesity associated comorbidities.
- The selection of obese patients for bariatric surgery aims to identify 'the right patient for the right operation at the right time'. These decisions should be taken within a specialist multi-disciplinary team setting.
- Assessment of the obese patient, pre-operative preparation and long-term post-operative follow-up require specialist, holistic nursing care.

56.1 Assessment of the Patient with Obesity

Obesity is a chronic condition of excess adiposity associated with insulin resistance and other metabolic abnormalities that both establish and then perpetuate the condition (Heymsfield and Wadden 2017). Obesity is associated with physical and mental health comorbidities and it is these that often determine the need for both clinical intervention and consideration of bariatric surgery. The improvements in these conditions after surgery have led some to consider bariatric surgery to be a 'metabolic' as opposed to a 'weight-loss' operation (Rubino et al. 2014).

The common obesity associated comorbidities are listed in Table 56.1.

Awareness of these is essential because assessment of the patient with obesity involves identifying and managing these conditions in order to improve the health of the obese patient and to optimise these comorbidities both before and after bariatric surgery.

Obesity is defined according to body mass index (BMI) which is the weight in kilogrammes divided by the height in metres squared. A BMI of greater than 30 kgm^2 is diagnostic of obesity. The use of BMI has been endorsed by the WHO which further sub-classifies obesity into obese class 1 (BMI 30.0–34.9 kgm^2), obese class 2

Table 56.1 Common obesity associated comorbidities listed by system

Endocrine	*Cardiovascular*	*Respiratory*
Type 2 diabetes Metabolic syndrome Reduced fertility (men and women) Amenorrhoea Polycystic ovarian syndrome Hirsutism (women) Erectile dysfunction	Hypertension Dyslipidaemia Ischaemic heart disease Cerebrovascular disease Venous thromboembolism	Obstructive sleep apnoea Asthma Obesity hypoventilation syndrome
Gastro-intestinal	*Renal*	*Musculoskeletal*
Gall stones Non-alcoholic fatty liver disease Abdominal wall hernias Gastro-oesophageal reflux disease	Chronic kidney disease	Osteoarthritis Mechanical back pain
Central nervous system	*Mental health*	*Oncological*
Idiopathic intracranial hypertension	Depression Anxiety Psychosocial problems arising as a consequence of the obesity	Six times increased incidence of malignancy particularly oestrogen-mediated cancers such as breast and endometrial

Table 56.2 World Health Organization classification of weight status (WHO 1998)

Weight status	Body mass index (kgm^2)
Underweight	<18.5
Normal range	18.5–24.9
Overweight	25.0–29.9
Obese Class I	30.0–34.9
Obese Class II	35.0–39.9
Obese Class III	≥40.0

(BMI 35.0–39.9 kgm^2), and obese class 3 (BMI ≥40 kgm^2) (WHO 1998) (Table 56.2).

BMI is useful in making the diagnosis of obesity but does not assess obesity associated comorbidity and weight-related functional limitations. This is because the complications of obesity occur in individual patients at vastly different BMIs (Cummings and Cohen 2014). For example, a patient with a BMI of 30 kgm^2 might have type 2 diabetes and obstructive sleep apnoea whereas a patient with a BMI of 40 kgm^2 could be free of comorbidities. In addition, patients from certain ethnic groups, particularly those from the Indian sub-continent, are recognised as being at risk for developing the metabolic consequences of obesity at a lower BMI than that of other racial groups (Rubino et al. 2017).

The limitations of BMI in the assessment of an obese patient has led to the development of obesity clinical staging or scoring systems. These serve several purposes. Firstly, they allow the healthcare provider to organise the assessment of the patient so that all physical and mental health comorbidities as well as functional and social factors are systematically considered. In addition, these approaches allow for consistency in the re-assessment of the obese patient either after a period of time has elapsed and/or an intervention such as bariatric surgery has taken place.

Lastly, because these assessment systems take into account obesity associated comorbidities and functional limitations, they help to identify which patients are most in need of medical intervention as well as identifying patients that will experience the greatest benefit from bariatric surgery.

56.2 Clinical Assessment

56.2.1 Clinical History and Obesity Staging/Scoring Systems

The patient's history can be taken 'free-hand' or a structured obesity assessment tool can be used. The two most frequently used systems for the assessment of the obese patient are the Edmonton Obesity Staging System (EOSS) (Sharma and Kushner 2009) and the King's Obesity Staging Criteria (Aylwin and Al-Zaman 2008).

56.2.1.1 Edmonton Obesity Staging System (EOSS)

Using findings from the history, examination and commonly used diagnostic tests, the EOSS comprises a five-stage system that allows for the grading of obesity which then guides treatment decisions (Table 56.3).

Limitations of EOSS include subjectivity in the assessment of the psychological and functional impact of the obesity and variability in the cut-offs for the definition of obesity associated comorbidities such as dyslipidaemia and hypertension.

56.2.1.2 King's Obesity Staging Criteria (KOSC)

A second frequently used tool for the assessment of obese patients is the King's Obesity Staging Criteria (KOSC). KOSC consists of nine health domains, addressed in alphabetical order, that comprise the following: Airway, Body mass index, Cardiovascular disease, Diabetes, Economic complications, Functional limitations, Gonadal axis, Health status (perceived), and body Image. The extended KOSC also includes assessment of Junction (assessment of symptoms of gastro-oesophageal reflux disease), Renal function (Kidneys), Liver function and Medications.

Assessment in each domain is made through a combination of the medical history, physical examination findings, e.g. blood pressure and the results of diagnostic tests, e.g. HbA1c. Each domain is then assigned a score from zero to three. Zero indicates normal health, one 'at risk', two

Table 56.3 Edmonton Obesity Staging System (EOSS) (from van Strien et al. 1986)

Stage	Description	Management
0	Patient has no apparent obesity-related risk factors (e.g. blood pressure, serum lipids, and fasting glucose within normal range), no physical symptoms, no psychopathology, no functional limitations and/or impairment of well-being	Identification of factors contributing to increased body weight. Counselling to prevent further weight gain through lifestyle measures including healthy eating and increased physical activity
1	Patient has obesity-related subclinical risk factor(s) (e.g. borderline hypertension, impaired fasting glucose, elevated liver enzymes), mild physical symptoms (e.g. dyspnoea on moderate exertion, occasional aches and pains, fatigue), mild psychopathology, mild functional limitations, and/or mild impairment of well-being	Investigation for other (non-weight related) contributors to risk factors. More intense lifestyle interventions, including diet and exercise to prevent further weight gain. Monitoring of risk factors and health status
2	Patient has established obesity-related chronic disease(s) (e.g. hypertension, type 2 diabetes, obstructive sleep apnoea, osteoarthritis, gastro-oesophageal reflux disease, polycystic ovarian syndrome, anxiety disorder), moderate limitations in activities of daily living and/or well-being	Initiation of obesity treatments including considerations of all behavioural, pharmacological, and surgical treatment options. Close monitoring and management of comorbidities as indicated
3	Patient has established end-organ damage such as myocardial infarction, heart failure, diabetic complications, incapacitating osteoarthritis, significant psychopathology, significant functional limitation(s), and/or impairment of well-being	More intensive obesity treatment including consideration of all behavioural, pharmacological, and surgical treatment options. Aggressive management of comorbidities as indicated
4	Patient has severe (potentially end-stage) disability/ies from obesity-related chronic diseases, severe disabling psychopathology, severe functional limitation(s), and/or severe impairment of well-being	Aggressive obesity management as deemed feasible. Palliative measures including pain management, occupational therapy, and psychosocial support

'established disease', and three 'advanced disease. For example, in the 'diabetes domain', a patient without diabetes would score zero, a patient with pre-diabetes or impaired fasting glucose would score one, a patient with established diabetes would score two and a patient with advanced diabetes (e.g. the presence of diabetes-related complications) would score three. Advantages of KOSC are high reproducibility when the same patient is assessed by more than one healthcare professional (Aasheim et al. 2011) and from a practical perspective, the alphabetical format makes the structure easy to remember and ensures all important areas are covered in the assessment.

56.2.1.3 Further Assessment Beyond EOSS and KOSC

Certain important features of the assessment of the obese patient are not specifically covered by either EOSS or KOSC and these should be specifically addressed in the wider history. These include:

- Any history of very early onset paediatric obesity, hyperphagia from a young age, learning difficulties and consanguineous parentage all of which may point toward a monogenic or syndromic basis to the obesity.
- The timing of the onset of the obesity. Most obesity will come on gradually with the weight slowly increasing over many years. If the obesity is of acute onset with weight rapidly increasing over weeks or months, an underlying cause should be sought, e.g. Cushing's syndrome or a supra-sellar tumour.
- Plans for pregnancy in female patients of childbearing age as this will affect treatment decisions (see below).
- What the patient wants; it is essential to discuss the patient's ideas, concerns, and expectations with respect their obesity, treatment options, and their long-term health and weight goals.

56.2.1.4 Assessment of Psychological State, Quality of Life, and Eating Behaviours

Mental health diagnoses both past and current should be documented including the use of psychiatric medications. Certain psychiatric conditions and, in particular, untreated personality disorder are a contraindication to bariatric surgery and specialist input will be required.

Validated screening tools or questionnaires are frequently used to assess psychological state, quality of life, and eating behaviours. Patients often complete these ahead of the consultation. These screening tools reduce the possibility of subjective assessment. This is particularly important when EOSS or KOSC is used as psychological and functional status contribute to the patient's overall score. Longitudinal use of the same questionnaire also allows for consistency in long-term re-evaluation.

The questionnaires that are frequently used do not require a free text written response, but instead ask the patient to tick a box to indicate their answer or to circle a response. Patients who score highly on any particular assessment tool should be referred to the appropriate specialist for evaluation and treatment.

Quality of life encompasses physical, mental, social and emotional well-being all of which can be affected by obesity and is commonly assessed using the Short Form (36) Health Survey (SF-36) (Jenkinson et al. 1997).

Anxiety and depression are commonly found in obese patients. Whether these conditions predate the obesity and contribute to its pathogenesis or whether they occur as a consequence of the excess weight is not well defined. In clinical practice, a combination of the two scenarios often co-exists. The Hospital Anxiety and Depression Scale (HADS) is widely used to screen patients for these conditions (Zigmond and Snaith 1983). Those who score highly should be referred for further mental health evaluation.

Binge eating, the feeling of being 'addicted' to food and 'emotional eating' are common in obese patients. Useful screening tools to assess for these and other eating behaviours include the Dutch Eating Behaviour Questionnaire (van Strien et al. 1986) and the Yale Food Addiction Scale (Gearhardt et al. 2009). Patients who score highly on screening should undergo specialist assessment.

56.2.2 Physical Examination

A standard multi-systems physical examination should be performed. In particular, this should focus on the following areas:

- Measurement of body weight and height. Calibrated 'bariatric' weighing scales with a suitably high upper weight limit are required. For consistency, the same light clothing should be worn each time the measurement is performed.
- If bio-impedance weighing scales are available, then the percentage body fat can be measured. The patient must have bare feet and should empty their bladder before the measurement is performed.
- Waist and hip circumference measured with a tape measure.
- Measurement of blood pressure.
- Assessment for dysmorphic features that could suggest a monogenic or syndromic cause for the obesity.
- Assessment for signs suggestive of 'endocrine obesity', e.g. Cushing's syndrome, hypothyroidism, or acromegaly.

56.2.3 Diagnostic Tests

In all obese patients, the following investigations form a routine part of the clinical assessment:

- **Blood tests**: full blood count, renal profile (urea, creatinine, potassium, sodium), liver function tests, calcium, phosphate, vitamin D, fasting lipids, fasting glucose, HbA1c, fasting insulin, fasting C-peptide, thyroid function tests, folate, vitamin B12, ferritin, blood group and screen (in patients who will undergo bariatric surgery).
- **Electrocardiogram (ECG)**

Other tests should be performed when indicated (e.g. overnight dexamethasone suppression test in cases of suspected Cushing's syndrome).

Further investigations should be targeted to assess the impact of the obesity on the patient's health and will be guided by the clinical assessment. These additional tests, which are listed below within the domains of the extended KOSC, might include:

- **Airway**: Chest X-ray, lung function tests, sleep study
- **Cardiovascular risk**: Ambulatory blood pressure monitoring; ambulatory heart rate/rhythm monitoring; echocardiography; cardiac 'stress' testing, e.g. dobutamine stress echocardiography; coronary artery angiography
- **Diabetes**: Oral glucose tolerance test (standard or prolonged), continuous blood glucose monitoring
- **Functional limitation**: Joint and musculoskeletal imaging, e.g. plain X-rays, magnetic resonance imaging (MRI)
- **Gonadal dysfunction**: Plasma gonadotropins (luteinising hormone and follicle stimulating hormone), oestrogen, testosterone, sex hormone binding globulin
- Gastro-oesophageal **junction**: Oesophagogastro-duodenoscopy (OGD)
- **Kidney**: Urinalysis; imaging of the renal tract
- **Liver**: Liver imaging, e.g. ultrasound scan

56.3 Identification of Patients for Bariatric Surgery

The selection of obese patients for bariatric surgery aims to identify 'the right patient for the right operation at the right time'. Each of these three components will be discussed below:

56.3.1 The Right Patient

The multi-disciplinary team (MDT) should be satisfied that the patient has tried appropriate non-surgical measures but nevertheless has been unable to achieve or to maintain adequate, clinically beneficial weight loss. In most cases, prior to bariatric surgery, patients will be expected to complete a specialist weight management programme (Welbourn et al. 2016). These programmes typically teach patients about food choices and nutrition and many will also deliver psychological support. Some centres mandate that a certain level of weight loss must be achieved during the weight management programme in order for the patient to be eligible for bariatric surgery; however, such an approach is unstandardised and lacks an evidence base. Patients with a BMI of $\geq$50 kgm^2 are not usually required to participate in such a programme if direct progression to surgery is clinically indicated (National Institute for Health and Care Excellence 2014).

In the UK, eligibility for bariatric surgery is determined according to BMI criteria set out by the National Institute for Health and Care Excellence (NICE) (**National Institute for Health and Care Excellence** 2014). These are that the patient should have a BMI of $\geq$40 kgm^2 or a BMI between 35 and 40 kgm^2 in the presence of obesity associated comorbidity.

Bariatric surgery has been shown to ameliorate and in some cases to reverse type 2 diabetes (Pories et al. 1995). The shorter the duration of diabetes, the higher the likelihood of disease remission (Still et al. 2014). For this reason, a lower BMI threshold of $\geq$30 kgm^2 is set for patients with recent onset type 2 diabetes defined as a diagnosis of type 2 diabetes within the last 10 years.

Patients from certain ethnic groups, particularly those from the Indian sub-continent develop obesity associated comorbidity at a lower BMI than that of other racial groups (Rubino et al. 2017). In these patients, 2.5 kgm^2 BMI points can be subtracted from the above values.

Because of the non-linear relationship between increasing BMI and the presence of comorbidities, some authorities propose that bariatric surgery should be viewed as a 'metabolic' rather than as a 'weight-loss' operation and therefore argue against the centrality of BMI to decisions about who should and should not have surgery (Rubino et al. 2014). Currently, however, most centres will not operate on patients that do not fulfil BMI criteria.

Where a significant comorbidity has been identified, further investigations (see above) may be required either to determine fitness for surgery and/or to optimise the patient's health pre-operatively. In some cases, a specialist opinion, e.g. cardiology,

respiratory, and gastroenterology may be needed in order to further evaluate and treat a comorbidity.

The pre-operative assessment must include psychological evaluation. Screening tools such as those described above help to identify patients in need of psychological or psychiatric assessment. Contraindications to bariatric surgery include untreated personality disorder, active alcohol use disorder (AUD), substance misuse and binge eating disorder. Importantly, mental health can deteriorate after bariatric surgery with patients at risk of AUD substance misuse, depression, self-harm, and suicide (Dixon 2016). Stable pre-operative mental health is therefore essential to good post-operative outcomes.

56.3.1.1 Patient Expectations and Patient Choice

On average, a patient will lose 25–30% of their pre-operative body weight (Sjostrom 2013) but some patients will lose much less than this and some will experience significant post-operative weight regain (Odom et al. 2010). A key part of the pre-operative assessment is to ensure that the patient's goals and expectations of surgery are realistic. In particular, patients must be aware that bariatric surgery is not a panacea and that extensive eating, behavioural and lifestyle changes are required in order to fully recognise the weight loss and health benefits of the procedure. These changes include reducing portion sizes, daily exercise, adequate sleep and the development of non-food-related coping strategies in response to adverse life events. Common features of patients who regain weight after bariatric surgery include, grazing on food throughout the day, a sedentary lifestyle, poor sleep habits and a return to emotional eating in the face of difficult circumstances, e.g. job loss or bereavement. Most centres will offer pre-operative patient seminars that will prepare the patient for life after bariatric surgery.

It should be noted that many people who are eligible for bariatric surgery will choose not to have it. Common reasons cited by patients for not wanting bariatric surgery include fear of having an operation, pain, time off work (and financial repercussions), worry about post-operative life, e.g. food choices and concerns about post-operative complications. All of the patient's reasons for declining bariatric surgery should be explored. This is not so as to change their mind but to ensure that their decision is based on the correct information.

56.3.2 The Right Operation

The most commonly performed bariatric procedures are gastric banding, Roux-en-Y gastric bypass (RYGB), and sleeve gastrectomy (Fig. 56.1).

All share a common mechanism of creating a physical restriction to the volume of food and

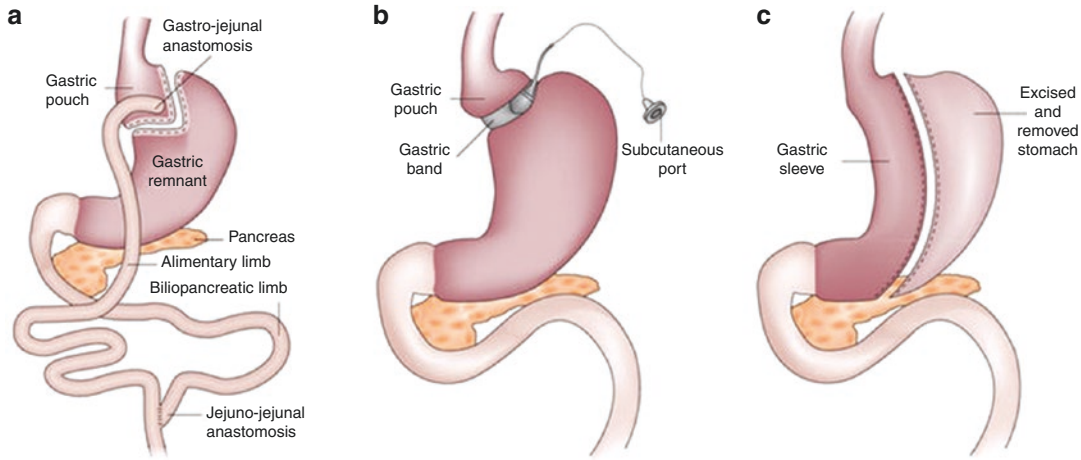

Fig. 56.1 Schemata of anatomy following Roux-en-Y gastric bypass (**a**), gastric banding (**b**), and sleeve gastrectomy (**c**). Credited to: Nat Rev Gastroenterol Hepatol. (2013) 10:575

liquid that the patient can consume. In addition, RYGB reduces the surface area of the small intestine thus producing malabsorption. RYGB and to a lesser extent sleeve gastrectomy also change the secretion of pro-satiety and pro-hunger gut hormones resulting in an enhanced sense of fullness and reduced feelings of hunger (i.e. Roux et al. 2006). This gut hormone effect is particularly strong immediately after the procedure and declines over months or years following the surgery. Therefore, in order for a patient to maximise weight loss and health improvements they must commit to eating and behavioural changes during this 'honeymoon' period.

56.3.2.1 Laparoscopic Gastric Banding

This is a restrictive procedure in which an adjustable plastic and silicon ring is fitted just below the gastro-oesophageal junction. This creates a small pouch of 15–20 mL which can only hold a small volume of food before the patient feels full. This feeling of fullness is further augmented by the slow emptying of the pouch into the rest of the stomach below. A balloon connected to an access port is attached to the plastic-silicon ring which allows the volume of the gastric pouch to be adjusted by injections in a subcutaneous port. Complications include nausea, vomiting, and post-prandial pain. In addition, the band can slip and or migrate, erode into the mucosa, leak or deflate all of which require intervention and in some cases band removal. Although patients can lose up to 15% of their body weight (Sjostrom 2013), the metabolic benefits of bariatric surgery are less commonly realised with gastric banding compared to other procedures (Pournaras et al. 2010).

56.3.2.2 Roux-en-Y Gastric Bypass (RYGB)

In Roux-en-Y gastric bypass (RYGB), the stomach is sub-divided into a small 15–30 mL gastric pouch and a lower gastric remnant. An anastomosis is formed between the gastric pouch and the jejunum. The lower gastric remnant which remains connected to the duodenum and jejunum is joined to the jejunum 75–150 cm distally to the gastro-jejunostomy. The expected weight-loss trajectory is 25–30% of starting body weight over 18–24 months (Sjostrom 2013). There may then be a 5% weight regain before a weight plateau is reached.

RYGB is associated with numerous improvements in comorbidities including remission of type 2 diabetes, reduced blood pressure, resolution of obstructive sleep apnoea and restoration of fertility. Some of these effects, particularly normalisation of blood glucose, occur almost immediately after surgery, before significant weight loss has occurred (Pories et al. 1995).

Complications of RYGB include anastomotic leak or breakdown, ulceration at the gastro-jejunal anastomosis (especially in smokers), gallstones, renal stones, post-prandial hypoglycaemia, dumping syndrome and micronutrient deficiencies. A deterioration in mental health can also occur. The potential for these physical and psychological complications mandate the need for specialist long-term follow-up.

56.3.2.3 Sleeve Gastrectomy

Worldwide, sleeve gastrectomy is now the most commonly performed bariatric procedure (Angrisani et al. 2015). This is a restrictive procedure in which the stomach is vertically divided from top to bottom. Approximately three quarters of the stomach is removed leaving behind a stomach remnant the shape of a banana along the lesser curve of the stomach that empties directly into the small intestine. In addition, the procedure may effect changes in gastric emptying and gut hormone secretion, in particular the suppression of the pro-hunger hormone ghrelin.

The comparative efficacy of sleeve gastrectomy to ameliorate comorbidities relative to RYGB is the subject of intensive debate (Andalib and Aminian 2017). A recent meta-analysis of 14 studies comprising over 5000 patients did not find a difference in comorbidity resolution between the two procedures although patients undergoing sleeve gastrectomy were found to have lost less weight at ≥5 years of follow-up (Shoar and Saber 2017).

Sleeve gastrectomy was initially developed as the first stage of a two-stage approach to the surgical

management of high-risk obese patients with a BMI >60 kgm^2 in who sleeve gastrectomy would be followed, after an interval, by laparoscopic Roux-en-Y gastric bypass (Regan et al. 2003). The efficacy and safety of the procedure however soon led to the establishment of sleeve gastrectomy as a stand-alone operation. Nevertheless, the premise of sleeve gastrectomy makes later conversion to RYGB a possibility for patients who experience poor weight loss or weight regain although issues around funding a second surgery may, in reality, prevent this.

New onset or exacerbation of pre-existing gastro-oesophageal reflux disease (GORD) have been reported after sleeve gastrectomy (Stenard and Iannelli 2015). This is thought to be at least partly due to the modified anatomy of the stomach. Most centres will advise against sleeve gastrectomy in patients with known GORD. Patients who develop *de novo* post-operative GORD or who experience symptomatic deterioration of pre-existing GORD may require conversion to RYGB.

56.3.3 Important Information for Patients Undergoing Assessment for Bariatric Surgery

During assessment for bariatric surgery, the same questions from patients commonly arise. These include the safety of the procedure, time spent in hospital, post-operative complications, and the resumption of everyday life such as working, driving and air travel.

In uncomplicated cases, patients are discharged from hospital on the same day after laparoscopic gastric banding, and can go home 24 h after RYGB or sleeve gastrectomy. Most will be able to return to work within 1–2 weeks of the operation. Once sutures have been removed (usually about 10 days after the operation) the patient can resume driving. Patients are advised to avoid air travel for 3 months after surgery because of the post-operative venous thromboembolic risk.

In a high volume centre, laparoscopic bariatric surgery has a mortality rate of <0.3% which is similar to that of laparoscopic cholecystectomy (Flum et al. 2009).

Patients should be aware that approximately one in five patients will experience a complication after bariatric surgery. These can occur in the immediate post-operative period and include the standard risks of all operations, e.g. infection, bleeding, and venous thromboembolism. More specific risks are described above by procedure type.

The patient should be aware of the risk of excess loose skin which can occur following substantial weight loss. In the UK, surgical removal of the excess skin is not routinely funded by the NHS.

56.3.4 The Right Time

Patients with type 2 diabetes are most likely to achieve diabetes remission if they have had the condition for less than 10 years. Those on insulin are more likely to be free of insulin after bariatric surgery the shorter the duration of pre-operative insulin therapy. This means that in patients with type 2 diabetes, consideration of bariatric surgery early in the disease course will maximise post-operative benefits.

Emerging evidence suggests a higher likelihood of adverse maternal and/or foetal outcomes in women undergoing pregnancy within 2 years of bariatric surgery (Johansson et al. 2015). Women of childbearing age must be advised to wait 12–18 months after surgery before trying to conceive (Mechanick et al. 2013). Those who cannot defer plans for pregnancy, e.g. those of increased age should be advised to complete their family before consideration of bariatric surgery.

In selected patients, the case for an urgent expedited operation arises. This includes patients with severe and deteriorating comorbidities and those who require urgent weight loss ahead of other treatment, e.g. organ transplant (Welbourn et al. 2016).

56.3.5 Multi-disciplinary Decision-Making

Once assessments have been completed, identification of the right patient for the right operation at the right time should be discussed and agreed

within a multi-disciplinary team (MDT) meeting (National Confidential Enquiry into Patient Outcome and Death 2012) comprising a nurse specialist, bariatric physician (usually an endocrinologist); bariatric surgeon, anaesthetist, psychologist/psychiatrist, and a dietician. It is not usual for the patient to attend the MDT meeting but their views, particularly procedure preference should be discussed.

56.4 Preparing a Patient for Bariatric Surgery

56.4.1 Assessment of Pre-operative Micronutrient Status

All bariatric procedures will affect nutritional intake and/or absorption to a greater or lesser extent. Pre-operatively, despite their excess body weight, many obese patients presenting for bariatric surgery are malnourished with micronutrient deficiencies detected during pre-assessment. These include vitamin deficiencies such as vitamin D, lack of minerals including iron and low levels of trace elements such as selenium.

Pre-operative serum micronutrient levels should be measured in order to correct deficiencies before surgery. So as to standardise practice between centres, in 2014, the British Obesity and Metabolic Surgery Society (BOMSS) issued guidelines advocating that the following micronutrients should be routinely measured and corrected as clinically indicated prior to surgery: Full blood count (FBC), ferritin, folate, vitamin B12, 25 hydroxy-vitamin D, calcium, liver function tests (LFTs), and renal function ((BOMSS) British Obesity and Metabolic Surgery Society 2014).

56.4.2 Pre-operative Diet

Prior to both RYGB and sleeve gastrectomy, patients must follow a strict, very low calorie diet (VLCD), consuming no more than 800–1000 kcal/day. The rationale for the pre-operative VLCD is to 'shrink' the liver, that is, to reduce its size through both glycogen depletion and a decrease in intra-hepatic fat stores (Colles et al. 2006). This liver 'shrinkage' makes the gastrointestinal tract more accessible to the surgeon and easier to visualise. Patients follow the VLCD with the support of a nurse specialist and bariatric dietician. If the patient has diabetes, medication down-titration will be necessary with nurse specialist support to reduce the risk of hypoglycaemia during caloric restriction. In most patients, the pre-operative diet is for the 2 weeks immediately prior to the operation date. In patients with a very high BMI (usually taken as a BMI of greater than 50 kgm^2), the MDT may advocate a 6-week pre-operative diet.

56.4.3 Smoking

Smoking increases the risk of peri-operative complications including prolonged intubation, re-intubation, pneumonia, and sepsis (Haskins et al. 2014). In addition, smoking is a specific contraindication to RYGB because of the risk of ulceration at the gastro-jejunal anastomosis. All centres will mandate that the patient stops smoking and some may require referral to a smoking cessation service. The duration of smoking cessation before surgery varies according to local guidelines but will usually be for at least 3 months. In cases where there is doubt as to whether the patient has stopped smoking, a carbon monoxide breath test can be performed although this will give a 'non-smoker' reading within 24–48 h of the last cigarette that was smoked.

56.4.4 Alcohol Consumption

The number of units of alcohol consumed per week including a history at any time of AUD must be assessed. AUD affects a minority of patients seeking bariatric surgery but if present is a contraindication to surgery by most programmes and in published guidelines (Mechanick et al. 2013). In its 2016 guidance, the American Society for Metabolic and Bariatric Surgery advocated a period of abstinence from alcohol before weight-loss surgery (Parikh et al. 2016). Almost all centres will require this of patients although the duration of pre-operative alcohol cessation varies between centres.

It is recognised that bariatric surgery and in particular RYGB can, in some patients, be associated with an increased risk of developing *de novo* post-operative AUD or AUD relapse (King et al. 2017). Of note, male sex, baseline smoking, and baseline alcohol consumption are independently related to an increased likelihood of AUD after bariatric surgery (Svensson et al. 2013).

Patients must be informed that post-operatively, particularly following RYGB, they should expect accelerated alcohol absorption, a higher maximum blood alcohol concentration and an increased time needed to eliminate alcohol (Parikh et al. 2016). These post-operative changes in alcohol pharmacokinetics will have implications for driving and for certain occupations.

56.5 Post-operative Follow-Up

56.5.1 Post-operative Micronutrient Status

After bariatric surgery, all patients must commit to the life-long need to take a complete multivitamin and mineral supplement (Mechanick et al. 2013). In women planning pregnancy, it should be ensured that the multivitamin does not contain vitamin A in order to avoid vitamin A toxicity to the foetus.

The following blood tests are routinely checked to assess for post-operative micronutrient deficiencies: renal profile, LFTs, FBC, ferritin, folate, vitamin B12, calcium, 25 hydroxy-vitamin D, fat soluble vitamins A, E, and K (by measuring prothrombin time), and trace elements (zinc, copper, selenium, magnesium) ((BOMSS) British Obesity and Metabolic Surgery Society 2014).

The frequency of monitoring is determined by the type of bariatric procedure and the circumstances of the individual patient. If micronutrient deficiencies are identified, patient compliance with their multivitamin and mineral supplement must be ascertained in addition to specialist dietetic review. Where necessary, a specific micronutrient might be required in addition to the supplement tablet.

56.5.2 The Post-operative Diet and Food Choices

For the first seven days after surgery, patients can ingest water and fluids, such as a thin soup. Patients are encouraged to take small sips and some may choose to use a straw to help with this. This slow pace of consumption reduces the likelihood of nausea and vomiting. After a week, patients progress on to pureed foods and runny foods such as yogurt for four weeks. If this is tolerated, they move on to eating soft foods such as mashed potato. After six weeks, they can gradually return to eating foods of other textures, building up to a balanced healthy diet. All must receive ongoing support to chew food, to eat slowly and to consume significantly smaller portions compared to pre-operative meal life. In addition, they are advised to stop eating as soon as they feel full. Patients who cannot follow this advice are very likely to experience abdominal pain, nausea, and vomiting.

Evidence suggests that the changes in gut hormone secretion that occur particularly after RYGB not only influence satiety but also reduce interest in high calorie, high sugar foods, an effect that is likely to be centrally mediated (Scholtz et al. 2014).

Those patients who placed an emotional value on food before surgery will require support to develop new coping strategies instead of eating. Post-operatively some patients will experience a ‘mourning’ period at the ‘loss’ of food and this will require specialist support, in particular so that the patient does not turn to other substances such as alcohol.

56.5.3 Medication Changes

Immediately after surgery, the patient’s medication needs change and this transition period requires careful nursing support. Two changes mandate attention. The first is the addition of new medications commonly comprising a vitamin and mineral supplement, a proton pump inhibitor, and ursodeoxycholic acid which alters the enterohepatic circulation of bile salts and may reduce the incidence of post-operative gallstones (Uy et al. 2008).

The second change is the dose reduction or discontinuation of medications that the patient was taking pre-operatively, in particular medications for the treatment of type 2 diabetes and hypertension. Blood glucose and blood pressure will be closely monitored as part of the immediate post-operative care (over the first few days, weeks and months) usually by a nurse specialist and decisions taken regarding optimal pharmacotherapy.

56.6 Conclusions

The worldwide prevalence of obesity is increasing. Obesity is associated with significant physical and mental health comorbidities which may be ameliorated by bariatric surgery. Deciding on who should undergo weight-loss surgery (the right patient), which operation they should have (the right operation) and when (at the right time) is complex and is based upon specialist, often nurse-led, pre-assessment followed by multidisciplinary decision-making. Nurse-led, long-term follow-up using a holistic and patient-centred model of care minimises post-operative complications and optimises long-term health and weight loss.

56.7 Key Points to Provoke Readers' Critical Thinking

Key point 1
Less than 1% of patients who would benefit from a bariatric procedure undergo surgery. What factors do you consider to be barriers to treatment?

Key point 2
Should a patient be mandated to lose a certain amount of weight through a non-surgical weight management programme before being considered eligible for bariatric surgery?

Key point 3
Should patients, who fail to lose weight after bariatric surgery, or who experience weight regain be offered further (revisional) surgery?

Key point 4
Which of these three patients do you think would derive the most benefit from bariatric surgery?

- **Patient 1**: A 73-year-old woman with a BMI of 54 kgm^2 who has severely limited mobility due to her weight and is mainly housebound.
- **Patient 2**: A 39-year-old man with a BMI of 41 kgm^2 who has had type 2 diabetes for 16 years. He has significant diabetes-related complications including end-stage chronic kidney disease and is registered partially sighted because of advanced diabetic retinopathy.
- **Patient 3**: A 24-year-old man of South Asian heritage who has a BMI of 33 kgm^2. He has poorly controlled type 2 diabetes and hypertension treated with two anti-hypertensive medications.

Box 56.1 Case Scenario
A 39-year-old woman with a BMI of 43 kgm^2 presents to the obesity clinic. The KOSC is used to assess her obesity. She smokes ten cigarettes per day. She has symptoms suggestive of obstructive sleep apnoea. She has hypertension for which she takes one anti-hypertensive medication. Type 2 diabetes had been diagnosed 7 years earlier and she had recently been commenced on a long-acting insulin in addition to metformin. She is unemployed. She scores highly on the HADS questionnaire indicating symptoms of depression and anxiety.

She is reviewed by the specialist obesity psychiatrist and is prescribed a selective serotonin reuptake inhibitor (SSRI). She is referred for a sleep study which diagnoses obstructive sleep apnoea and overnight continuous positive airways pressure (CPAP) ventilation is commenced.

She is assessed for bariatric surgery and attends a smoking cessation service. Following MDT discussion, she undergoes Roux-en-Y gastric bypass. On the first

Box 56.1 (continued)

post-operative day, her insulin is discontinued. On review with her nurse specialist one month after surgery, she is found to be normotensive and her blood pressure medication is stopped. Six months after surgery, she undergoes psychiatric review. Her mood has significantly improved and the SSRI is weaned down and then stopped. CPAP is discontinued after a repeat sleep study. One year after the operation, she has lost 27% of her total body weight. She has found a new job which she enjoys. She continues to see her nurse specialist for clinical follow-up and support with post-operative life. Fourteen months after bariatric surgery, she tells her nurse specialist, 'I am a completely different person. Before, I felt tired and unhealthy and I hated the insulin injections. I also felt sad most of the time and I never wanted to go out. It's been hard work but with your help, I have completely changed the way I eat and the way that I think about food. And I exercise every day, no excuses. Now I have energy and I feel good and I love my new job. The operation has changed my life'.

Abstract

Raised lipid levels are a significant risk factor for coronary heart disease. Lipids are a heterogeneous group of substances which include cholesterol, triglycerides, lipoproteins and apolipoproteins. The link between increased lipid levels and atherosclerosis has been known since the early 1900s. Optimum levels of total cholesterol and low density lipoprotein cholesterol (LDL) are unknown but the general consensus is 'the lower the better' with some guidelines suggesting that the goal should be an LDL of <1.8 mmol/L (<70 mg/dL).

Familial hypercholesterolaemia (FH) is an autosomal dominant genetic condition which is characterised by elevated levels of cholesterol and an increased risk of premature coronary heart disease (CHD). Patients with heterozygous familial hyperchlosterolaemia typically develop coronary disease 10 years earlier than the general population. The condition remains under diagnosed, and there is a worldwide need for early detection and treatment to be improved.

Statins are the first choice lipid-lowering therapy. However, maximum tolerated doses may not be sufficient to reduce lipid levels to target, and there are a variety of other agents that can be used in combination with statins or as an alternative for patients who are unable to tolerate statin therapy. There are also several novel lipid-lowering therapies that will potentially enable more patients to achieve desired lipid levels. Lipoprotein apheresis, which is a dialysis-like therapy, is another treatment option for those patients whose lipid levels remain elevated despite optimum medical therapy.

Key Terms

- **Tendon xanthoma**: Accumulation of cholesterol rich material found in the tendons of the hands, feet and heels
- **Xanthelasma**: Cholesterol deposits usually on or around the eyelids
- **Corneal arcus**: Cholesterol deposits in the periphery of the cornea
- **Homozygous**: Identical alleles at a gene locus
- Heterozygous—different alleles at a gene locus
- **Receptor negative**: No or minimal receptor activity
- **Receptor defective**: Reduced receptor activity
- **HEART UK**: The cholesterol charity

Key Points

- Coronary heart disease remains the leading cause of death worldwide.
- Raised lipid levels are one of the main risk factors for the development of atherosclerosis.
- Lifestyle and dietary changes are recommended for all patients.
- Familial hypercholesterolaemia is a genetic disorder of lipid metabolism caused by a mutation of the LDL receptor gene.
- Treatment for raised lipid levels includes lifestyle changes, lipid-lowering medications and for a small number of patients, lipoprotein apheresis.

57.1 Introduction

Cardiovascular disease including coronary heart disease (CHD) remains the leading cause of death worldwide (Perk et al. 2012). In the UK, nearly 70,000 deaths annually can be attributed to the CHD. Although mortality from CHD is falling in the UK, more than one in seven men and nearly one in ten women die every year from CHD (BHF British Heart Foundation 2015). Improvements in lifestyle, diet, exercise, smoking cessation, weight control and becoming more health conscious as well as the new developments in lipid-lowering medications and therapies are part of the reason behind the reduction (Ellegård et al. 2007).

Three risk factors—elevated cholesterol, smoking and hypertension or combinations of these factors are responsible for more than 75% of all cardiovascular disease worldwide (WHO). Elevated cholesterol carries the greatest attributable risk for CHD (Wilson et al. 1998).

This chapter will describe the various lipids and examine why abnormal levels cause health problems. Familial hypercholesterolaemia (FH), a genetic disorder of lipid metabolism will be described, together with the treatments available to treat raised lipid levels. The first section will concentrate on definitions, the types of lipids, epidemiology and pathology.

57.2 Lipid Disorders

57.2.1 Definition of Lipid Disorders

Lipids are basically fats however there is no unifying structure. Included in lipids are substances in which fatty acids are an essential component such as triglycerides but also other substances which have varied structures such as cholesterol. Lipids are a heterogeneous group of substances which have a low solubility in water but are more readily soluble in a mixture of chloroform and ethanol (Durrington 2007). Lipids are not in themselves bad as they are essential to life, however if levels become elevated the risk of CHD increases.

The World Health Organisation classification of hyperlipidaemia is shown in Table 57.1.

57.2.2 Types of Lipids

57.2.2.1 Cholesterol

Cholesterol is the predominant sterol in vertebrates. It is an essential component of cell membranes where it is present as free cholesterol, as is most of the cholesterol in the body. It is also the precursor for steroid hormones and vitamin D. Cholesterol esters are more of a storage form which are prevented from interacting with cell

Table 57.1 WHO classification of hyperlipidaemia

Type	Lipoproteins elevated	Lipids elevated
I	Chylomicrons	Triglycerides and cholesterol
IIa	LDL	Cholesterol
IIb	VLDL and LDL	Cholesterol and triglycerides
III	β-VLDL	Triglycerides and cholesterol
IV	VLDL	Triglycerides
V	Chylomicrons and VLDL	Triglycerides and cholesterol

Durrington and Sniderman (2000)
LDL low-density lipoprotein, *VLDL* very low-density lipoprotein

membranes. In the plasma and extracellular fluid, cholesterol is present in lipoproteins, largely as cholesterol esters. The role of cholesterol within the phospholipid layer of the cell membrane appears to be to regulate and stabilise its fluidity. This may influence important properties such as permeability (Durrington 2007).

Cholesterol is absorbed from the gut; however, this absorption is not complete and usually only about 30–60% of the amount ingested is actually absorbed. Cholesterol is both absorbed from the gut and excreted back into it as part of bile. The body synthesises at least as much cholesterol as is ingested each day. Almost all tissues in the body can synthesise cholesterol but it is the liver, gut and central nervous system which synthesise the majority in the adult. Cholesterol synthesis is immensely complex. The cholesterol molecule is constructed from acetyl-CoA obtained from β-oxidation of fatty acids or from carbohydrate breakdown. The full process contains 37 steps which is beyond the scope of this chapter (Durrington 2007). An important step in the process is when 3-hydroxy-methylglutaryl CoA is converted to mevalonic acid. The enzyme responsible for this process, HMG-CoA reductase, can be inhibited by physiological factors such as the intracellular level of cholesterol. Tissues which are supplied with cholesterol in large quantities from the liver and gut will therefore down-regulate their own cholesterol biosynthesis (Durrington and Sniderman 2000). Statins, are HMG-CoA reductase inhibitors, which will be described later in the chapter, also act on this enzyme. The average cholesterol level of adults living in England and Scotland is 5.3 mmol/L (205 mg/dL) (BHF/HEART UK 2011).

57.2.2.2 Triglycerides

Triglycerides constitute the main energy source of the body. An average lean adult male has about 15 g of triglyceride stored which represents an energy store to survive starvation for about 3 months (Durrington and Sniderman 2000). Triglyceride is stored in adipose tissue which has an important role in protecting the vital organs. Subcutaneous adipose tissue also provides a layer of thermal insulation.

Triglycerides are digested in the gut to fatty acids and monoglycerides which are then absorbed into the enterocyte and synthesised into chylomicrons to be transported to the tissues (Durrington and Sniderman 2000). The liver also has the ability to synthesise triglycerides from fatty acids in the circulation or synthesised from glucose. These triglycerides are then assembled into very low density lipoprotein particles (VLDL) and released into the circulation.

The release of fatty acids from adipose tissue is under the control of an enzyme called lipase. Once released from the glycerol to which they are bound, the fatty acids move out of the adipose cell and are transported to other tissues.

57.2.2.3 Lipoproteins

Lipoproteins are macromolecular complexes of lipids and proteins, the protein components of which are apolipoproteins or enzymes. A major function of lipoproteins is to transport lipids through the vascular and extravascular body fluids. The principle sources of lipoproteins are the liver and the gut. Chylomicrons are the largest of the lipoproteins and are produced by the gut following the absorption of the products of fat digestion. The absorption of fat is usually complete within a few hours of a meal and the chylomicron concentration fluctuates related to this. Following the ingestion of food, there is a postprandial rise in triglycerides which is due to chylomicrons. This rise may be only modest in fit, healthy people but may be marked in others (Durrington and Sniderman 2000).

Lipoprotein lipase is the enzyme that is responsible for removing the triglyceride component from chylomicrons. It hydrolyses triglyceride to monotriglycerides and fatty acids. The monoglycerides are then broken down to glycerol and fatty acids by other tissue lipases. These fatty acids and glycerol are then taken up by the cells and either respired or resynchronised back into triglycerides for storage (Durrington and Sniderman 2000).

57.2.2.4 Low Density Lipoprotein

Low density lipoprotein (LDL) is a smaller triglyceride-rich particle then very low density lipoprotein (VLDL). LDL is described as being respon-

sible for supplying cholesterol to the tissues especially during growth. There is great heterogeneity in LDL particle composition caused by the differences in the amount of cholesterol in each LDL particle (Durrington and Sniderman 2000). LDL is often described as 'bad cholesterol' as it is one of the major causes of coronary atherosclerosis.

57.2.2.5 High Density Lipoprotein

Approximately two thirds of serum cholesterol is present in LDL, a small amount is present in VLDL but the majority of the remainder is in high density lipoprotein (HDL). HDL is a small molecule compared with the other lipoproteins and so can easily cross the vascular endothelium. Its concentration in the tissue fluids is much closer to its intravascular concentration than for LDL (Durrington 2007). HDL is able to receive excess cholesterol from the tissues which is then transferred out of HDL to the liver to other lipoproteins. Low levels of HDL are associated with an increased risk of CHD. HDL is believed to have a protective role against atherosclerosis possibly due to the ability of HDL to promote the transfer of cholesterol from tissues to the liver, the so-called reverse cholesterol transport (Durrington and Sniderman 2000). HDL is therefore often referred to as 'good cholesterol'.

57.2.2.6 Apolipoprotein A

The main apolipoproteins of HDL are apolipoprotein A (Apo A) of which there are two major ones in humans—apolipoprotein AI and apolipoprotein AII. Of the two, apolipoprotein AI is the most abundant and is present in health in the plasma in concentrations which usually exceed apolipoprotein B. In the tissue fluid, apolipoprotein AI is the apolipoprotein with the greatest concentration (Durrington 2007). Apolipoprotein AI and AII are secreted from the gut and the liver.

57.2.2.7 Apolipoprotein B

Apolipoprotein B (Apo B) is central to the lipoprotein transport system. It is the most abundant protein in LDL. Apolipoprotein B is essential for the assembly and secretion of chylomicrons and VLDL and also for the removal of LDL via the LDL receptor. This is because apolipoprotein B is the part of LDL that is recognised by the LDL receptor (Durrington and Sniderman 2000). There are two types of Apo B–Apo B100, which is produced by the liver and Apo B48, which is produced by the gut in humans. This has approximately 48% of the weight of Apo B100, hence its name, and does not bind to lipoprotein receptors (Durrington 2007).

57.2.2.7.1 Apolipoprotein (a)

Apolipoprotein (a) is present in a Lipoprotein called lipoprotein (a) [Lp(a)] and was discovered by Berg in the 1960s (Berg 1963). It is a plasma lipoprotein consisting of a cholesterol-rich LDL particle with one molecule of apolipoprotein B100 and an additional protein, apolipoprotein (a), attached via a disulphide bond. Lp(a) does not appear to have a triglyceride-rich lipoprotein precursor and is thought to be secreted by the liver. The level of Lp(a) is higher in people whose ancestors originated in Africa or the Indian subcontinent then in those of European origin, suggesting an ethnic difference (Durrington 2007).

57.2.3 Why Lipids Are Important

The first discovery of the link between cholesterol and atherosclerosis was described in 1913 in a rabbit model by Anitchkow (1913). Then, in the same year, Bacmeister and Henes reported for the first time, an association between raised levels of cholesterol and atherosclerosis in humans (Bacmeister and Henes 1913). In the past 30 years, several trials have been carried out which have demonstrated the benefit of reducing levels of cholesterol and therefore the event rate for CHD. One of the first large studies was the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT). This showed that an 8% reduction in total cholesterol for a mean of 7.4 years was associated with a 19% reduction in myocardial infarction or CHD death (LRC 1984). Since 1989 there have been a series of large-scale prospective interventional trials which have established that lowering LDL reduces the risk of CHD and diminishes mortality and morbidity in both primary and secondary prevention (Packard et al. 1998; Scandinavian Simvastatin Survival Study Group 1994; Pfeffer et al. 1995).

57.2.4 Epidemiology

The link between the level of cholesterol and CHD has been confirmed in a large number of prospective epidemiological studies and has been shown to be accounted for by the LDL component of circulating cholesterol (Anderson et al. 1987; Law et al. 1994; Assmann et al. 1998). In 2008, the estimated prevalence of raised cholesterol in males in the UK was 65.6% and in the USA it was 53.3%; for females for figures were 65.7% and 56.9%, respectively (WHO 2011). The role of HDL as an independent inverse predictor of CHD has been established in numerous observational epidemiological studies. These studies suggest that the risk of CHD decreases by 2–3% for each 1 mg/dL (0.03 mmol/L) increase in HDL after correction for other CHD risk factors (Gordon et al. 1989). The exact physiological role of raised Lp(a) in not totally understood; however, it has emerged that an elevated level of more than 600 mg/L is an important independent risk factor and is predictive of adverse outcomes in atherosclerotic disease (Cremer et al. 1994; Danesh et al. 2000).

57.2.5 Pathophysiology of Coronary Heart Disease

The majority of CHD is caused by atherosclerosis. Atherosclerosis is a complex disorder which is still not fully understood. What is known is that it is caused by a progressive accumulation of lipids, complex carbohydrates, blood, blood products and calcific deposits within the intimal layer of the artery wall with infiltration and increased production of vascular smooth muscle cells. These processes result in atheroma (Pottle 2012). Atheroma tends to be distributed in focal areas of the artery in plaques which often occur around branching vessels or areas where there is arterial curvature suggesting that haemodynamic stressors may play a part in initiating the process. Atherosclerotic plaques may occur as three presentations: fatty streaks, fibrous plaques and advanced lesions. Fatty streaks are flat, lipid-rich lesions which are thought to be benign and cause little or no obstruction to the coronary artery. They are, however, the precursor to advanced atheromatous lesions. Conversion of the fatty streaks to atheroma is dependent on the proliferation of vascular smooth muscle cells into fibroblasts (Pottle 2012).

White fibrous plaques are produced which protrude into the lumen of the artery. This is followed by further proliferation of vascular smooth muscle cells which results in the formation of a tough fibrous cap. A 'lipid-rich' pool then develops underneath which are released when foam cells die. Advanced lesions are composed of fibrous tissue, lipids, blood products and fibrin. The lipid-rich core in these lesions may increase in size and become calcified (Fig. 57.1). Atherosclerotic plaques may be described as concentric, where the plaque is distributed around the circumference of the artery or eccentric where they do not involve the entire circumference of the artery. This results in an area of normal or

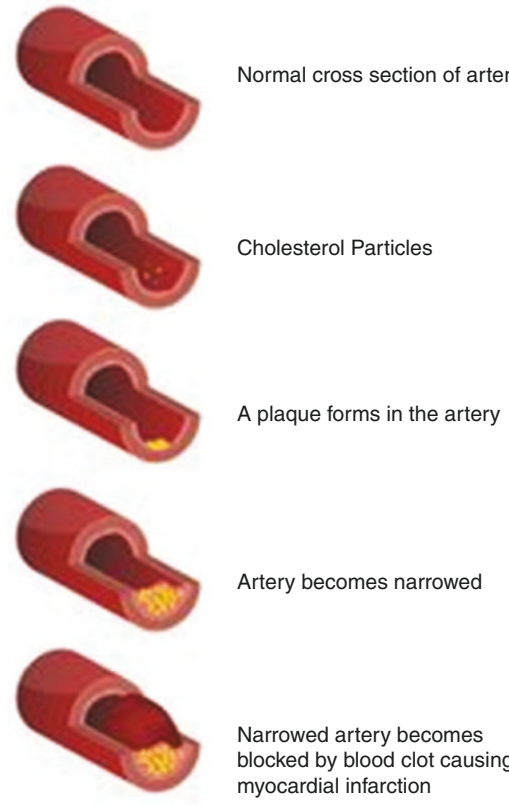

Fig. 57.1 The process of atherosclerosis development

near normal artery wall (Waller et al. 1992). The majority of fatal CHD events are thought to be caused by eccentric plaques (Waller 1989).

57.2.6 Treatment Targets

The treatment targets for lipid management are primarily based on results from clinical trials. In most trials, the LDL level has been used as the target for therapy and so this is the primary target in management of dyslipidaemia. The ESC/EAS guidelines on management of dyslipidaemia recommend modulating the intensity of the preventative intervention according to the level of the total cardiovascular risk (ESC/EAS 2011). Every 1.0 mmol/L (40 mg/dL) reduction in LDL is associated with a 22% reduction in cardiovascular mortality and morbidity (Baigent et al. 2010). The ESC/EAS recommended targets for LDL are shown in Table 57.2.

The American ACC/AHA guidelines on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults were updated in 2013 (Stone et al. 2014). These guidelines are based solely on the results of randomised controlled trials (RCT) with atherosclerotic cardiovascular disease outcomes. Observational studies and those with less than 18 months follow-up were excluded. The main difference between these guidelines and the European ones is that the American guidelines do not support the use of specific LDL targets. Clinicians are recommended to use a new Pooled Cohort Equation to estimate the 10-year atherosclerotic cardiovascular risk to accurately identify those people at high risk. Statin therapy can therefore be focused on those who are most likely to benefit (Stone et al. 2014). Recent guidance from the European Atherosclerosis Society and the European Federation of Clinical Chemistry and Laboratory Medicine (Nordestgaard et al. 2016) recommend that non-fasting blood samples should routinely be used for assessment of plasma lipid profiles.

Table 57.2 The ESC/EAS recommended targets for LDL

Level of risk	Target LDL level
Very high CVD risk (established CVD, type 2 diabetes, type 1 diabetes with target organ damage, moderate to severe CKD, SCORE level of >10%	<1.8 mmol/L (<70 mg/dL) and or >50% reduction when target level cannot be reached
High CVD risk (markedly elevated single risk factors, a SCORE level of >5 to <10%	<2.5 mmol/L (<100 mg/dL)
Moderate CVD risk (SCORE level >1 to <5)	<3.0 mmol/L (<115 mg/dL)

Adapted from ESC/EAS (2011)
CVD cardiovascular disease, *CKD* chronic kidney disease, *LDL* low-density lipoprotein, *SCORE* Systematic Coronary Risk Evaluation, *ESC* European Society of Cardiology, *EAS* European Atherosclerosis Society

57.3 Familial Hypercholesterolaemia

This section will describe familial hypercholesterolaemia, explain how it can be diagnosed and discuss the consequences of this condition.

57.3.1 Definition of Familial Hypercholesterolaemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder usually resulting from a mutation in the LDL receptor gene that leads to receptor absence or malfunction (Goldstein et al. 1983). The genetic basis of this disorder was discovered by Goldstein and Brown in 1979 who demonstrated mutations in the gene encoding the LDL receptor; one allele being affected in the heterozygote and both alleles in homozygotes (Goldstein and Brown (1979). Other genetic causes of FH include familial defective apolipoprotein B100, autosomal recessive hypercholesterolaemia and FH3, caused by gain-of-function mutations in the proprotein convertase subtilisin/kexin type 9 (PCSK9) gene (Radar et al. 2003). The gene for the LDL receptor is located on chromosome 19 (Durrington 2007).

57.3.2 Background

FH is characterised by increased hepatic cholesterol production, and decreased clearance of LDL

which result in accumulation of LDL in the plasma. The mutation of the LDL receptor prevents it from participating effectively in LDL uptake. It cannot be transported to the cell surface, cannot bind properly to LDL once it gets to the cell surface, cannot be internalised and is not released from the endosome. A wide range of mutations of the LDL receptor have already been found and the number continues to increase.

57.3.3 Prevalence

It has previously been estimated that the prevalence of heterozygous FH in Northern America and Europe was 1:500 and of homozygous FH, 1:1,000,000 but more recent data indicates that the frequency of heterozygotes in Europe may be as high as 1:200 (Nordestgaard et al. 2013) and of homozygotes 1:300,000 (Sjouke et al. 2015). In societies which have arisen relatively recently from a small number of settlers or migrants, the frequency of FH may be even higher and it may be caused by a smaller number of mutations. As an example, as many as 1:80 South Africans of Dutch or French decent have FH and the majority have one of only three different LDL-receptor mutations (Durrington and Sniderman 2000). Two of the mutations can be traced back to two of the early Dutch settlers and the other to a Huguenot migrant.

57.3.4 Diagnosis

Patients with heterozygous FH often come to medical attention due to the markedly elevated incidence of cardiovascular disease, clinical symptoms developing in the third or fourth decade of life (Marais 2004). Alternatively, they may be identified through cascade testing in affected families or during routine lipid screening. Identification of the 'index' patient is important because it represents the starting point for family tracing or 'cascade testing' by which the majority of cases of FH can be detected (Hadfield et al. 2009). This is important because it enables early intervention including lifestyle measures and management of other major cardiovascular risk factors.

There are several diagnostic tools for the clinical diagnosis of FH including those from the Dutch Lipid Clinics, Simon Broome Registry and the US MEDPED Programme. There are, however, no internationally agreed criteria for the phenotypic diagnosis of FH. The Simon Broome Criteria for FH (1991) is widely used in the UK and is shown in Table 57.3.

Secondary causes of hypercholesterolaemia such as primary hypothyroidism, proteinuria, cholestasis and medications such as corticosteroids must be excluded, but it is important to note that FH may co-exist with other cardiovascular risk factors especially metabolic syndrome and diabetes.

57.3.5 Cholesterol Levels

Serum cholesterol in FH is raised from birth. Serum cholesterol rises in the first year of life to a mean of 4.1 mmol/L (160 mg/dL) and persists

Table 57.3 Simon Broome criteria for FH

Definite FH
Raised cholesterol:
In children (<16 years): Total cholesterol >6.7 mmol/L
OR LDL >4.0 mmol/L
In adults (>16 years): Total cholesterol >7.5 mmol/L
OR LDL >4.9 mmol/L
AND
Tendon xanthomata in the patient or in a first- or second-degree relative
OR
DNA-based evidence of an LDL receptor, familial defective Apo B100 or PCSK9 mutation
Possible FH
Raised cholesterol:
In children (<16 years): Total cholesterol >6.7 mmol/L
OR LDL >4.0 mmol/L
In adults (>16 years): Total cholesterol >7.5 mmol/L
OR LDL >4.9 mmol/L
AND one of the following:
Family history of premature myocardial infarction
MI at <50 years in second degree
MI at <60 years in first-degree relatives
OR
Family history of raised cholesterol
In adults (>16 years), first- or second-degree relatives: Total cholesterol >7.5 mmol/L
In children (<16 years), first-degree relatives: Total cholesterol >6.7 mmol/L

until the early teens with the mean levels being similar in boys and girls before puberty (Durrington and Sniderman 2000). The normal range for cholesterol has little variation with age during childhood which allows a diagnostic threshold for childhood FH to be defined.

Homozygous FH has historically been diagnosed on the basis of an untreated plasma LDL level of >13 mmol/L (>500 mg/dL) or a treated LDL concentration of ≥8.0 mmol/L (≥300 mg/dL) and the presence of cutaneous or tendon xanthomas before the age of 10 or the presence of untreated elevated LDL levels consistent with heterozygous FH in both parents (Cuchel et al. 2014).

LDL levels are typically four times and about two times higher in family members with homozygous FH and heterozygous FH, respectively, when compared to non-affected family members (Soutar and Naoumova 2007). The range of LDL levels may overlap significantly between heterozygous FH and homozygous FH and untreated LDL levels of <13 mmol/L (<500 mg/dL) can be found in patients with genetically confirmed homozygous FH (Bertolini et al. 2013).

57.3.6 Signs

Tendon xanthomata are localised infiltrates of lipid containing foam cells that histologically resemble atheroma and are the diagnostic hallmarks of FH. Xanthelasma of the soft connecting tissues of the eyelids and corneal arcus may also occur but are not specific for FH; however, they often occur earlier in life in those with FH than patients with more common polygenic raised cholesterol. Corneal arcus that occurs in the third of fourth decade of life may indicate FH. Xanthelasma frequently occur in women with previously normal cholesterol levels in their first pregnancy. In heterozygous FH, xanthomata rarely develop before adulthood (less than 10%) and are completely absent in a considerable proportion of patients (Assmann et al. 1999). In homozygous FH, xanthomata may be present at birth and usually develop before the age of 2 years.

The most common sites for xanthomas are the tendons overlying the knuckles, the Achilles tendons, the pre-tibial insertion of the patellar tendon and the elbows (Fig. 57.2). The skin over the xanthomas is normal in colour and the xanthomata feel hard. The cholesterol accumulation is deep within the tendons and a large amount of the swelling is fibrous.

57.3.7 Cardiovascular Consequences of FH

FH is a treatable disease but aggressive lipid lowering is required to achieve the target LDL reduction of 50%. However despite the prevalence of

Fig. 57.2 Tendon xanthomas on the knuckles and Achilles

the disease and the availability of effective options, FH remains underdiagnosed and undertreated particularly in children. Some estimates suggest that only approximately 20% of patients are diagnosed and of these only a small number receive appropriate treatment (Goldberg et al. 2011).

The median age for the development of CHD in patients with heterozygous FH in men is approximately 50 and for women it develops about 9 years later (Durrington and Sniderman 2000). In homozygous FH, the first major cardiovascular event often occurs during adolescence although in patients who are receptor negative, angina, myocardial infarction and death have been reported in early childhood (Kolansky et al. 2008). Untreated homozygous FH patients who are LDL receptor negative rarely survive beyond the second decade and although those who are LDL receptor defective have a better prognosis, they almost all develop significant CHD by the age of 30 (Cuchel et al. 2014). Homozygous FH is characterised by the development of accelerated atherosclerosis which typically affects the aortic root, compromising the coronary ostia and also the carotid, descending aorta, renal and ileo-femoral arteries (Raal and Santos 2012).

57.4 Treatment of Lipid Disorders

57.4.1 Lifestyle Changes

Approximately six in ten adults in England have a total cholesterol (TC) level above the target of 5.0 mmol/L (200 mg/dL) (Townsend et al. 2012). Lipid-lowering medication is the mainstay of cholesterol reduction; however; it is important that individuals also adhere to a healthy diet if they are to achieve desired levels of cholesterol. There are a variety of guidelines available to assist in the advice and treatment that patients should receive however patient-specific differences may necessitate an individualised approach to cardiovascular disease management.

57.4.1.1 Dietary Management of Raised Cholesterol

In many patients, lipid disorders can be successfully managed with lifestyle changes. Detailed recommendations and guidelines for weight control, physical activity levels, smoking cessation and diet have been developed by numerous national and international organisations and professional societies. Dietary modifications are the cornerstone of therapy for patients with raised lipid levels. The National Cholesterol Education Programme Guidelines recommend a decrease in the level of saturated fat intake to <7% of calories, a decrease in cholesterol intake to <200 mg/day and an increase in soluble fibre intake to 10–25 g/day and plant sterols/stanols (2 g/day) (NCEP 2002). There is a need for a diet that is not only realistic, but one that delivers impactful cholesterol lowering results such as 'the ultimate cholesterol lowering plan' (HEART UK n.d.). With good adherence to dietary changes, reductions in cholesterol levels of 5–10% can be achieved (BHF/HEART UK 2011). Patients with homozygous FH should receive dietary counselling by a registered dietician (Gidding et al. 2009).

For patients with raised triglyceride levels, emphasis must be given to raising the ratio of monounsaturated to saturated fatty acids and on increasing the energy intake from complex carbohydrates without increasing all carbohydrates as carbohydrates, saturated fat and alcohol can all contribute to elevated plasma triglyceride concentrations (Gotto et al. 2003).

A high level of HDL (>60 mg/dL/≥1.6 mmol/L) is considered to be a negative risk factor for CHD whereas an HDL level of <40 mg/dL/<1.0 mol/L increases the risk of the development of CHD (NCEP 2002). HDL levels are however, little affected by the type of dietary fatty acids. The key lifestyle changes to increase HDL are weight loss in those who are overweight, increased physical activity and smoking cessation. With smoking cessation, HDL levels increase by 6–8 mg/dL (0.15–0.20 mmol/L) on average and significant improvements can occur within as little as 30 days (Gotto et al. 2003).

Estruch et al. (2013) studied Spanish patients who were at high cardiovascular risk but who had no cardiovascular disease on enrolment. They showed that for those patients at high cardiovascular risk, a Mediterranean diet supplemented with extra-virgin olive oil or nuts, reduced the incidence of major cardiovascular events.

There are a variety of foods which can actively help in lowering cholesterol levels including, pulses, fruit and vegetables soy protein and plant sterols and stanols (Hark and Deen 2005). Oats and barley are both fat soluble fibres. Beans, peas, chickpeas and lentils have fat soluble fibres in addition to vegetable protein, folic acid and other antioxidants. They all have a very low glycaemia index resulting in lowering of blood pressure, improvement in the lipid profile and also blood sugar control (Abeysekara et al. 2012).

Apples, strawberries and grapes all have antioxidant properties. Avocados contain monounsaturated fatty acids, dietary fibre, essential nutrients and phytochemicals which can help to improve overall diet quality, nutrient intake and reduce the risk of metabolic syndrome (Fulgoni III et al. 2013). Raw carrots cause an increase in serum carotene levels which helps in reducing cholesterol levels (Robertson et al. 1979).

Soy protein has a modest LDL-C lowering effect (3–5%) (Dewell et al. 2006). Fish is low in saturated fat. Cold water fish are rich in omega-3 fatty acids which lower plasma triglyceride levels and may improve the coagulation profile as it reduces clot formation. A randomised controlled trial in Japan examined the effect of omega-3 fatty acid supplements in Japanese hypercholesterolaemia patients (18,645) with and without coronary artery disease (CAD) (Yokoyama et al. 2007). Twenty-six percent of the total number of recruits in the study had CAD, of which 21% had a prior history of myocardial infarction, 61% had angina and 18% were recruited following revascularisation. Analysis of the results for patients without CAD found that omega-3 fatty acid supplementation had no effect on the primary outcome, or any of the secondary outcomes compared with no supplementation. Fish oil supplementation is no longer recommended and the National Institute for Health and Care Excellence in the UK no longer recommends that patients include oily fish in their diet as a means of reducing preventing CHD (NICE 2014).

Plant sterols and stanols are compounds which occur naturally in plant-based foods and aid digestion. They imitate the way cholesterol works thereby reducing the amount of cholesterol absorbed by the body. Plant sterols are structurally similar to cholesterol and can be divided into phytosterols and phytostanols. They work by mimicking cholesterol and competing with it for space in fatty particles that are absorbed from the gut. The result is less cholesterol and less bile absorbed into the body. This prompts the liver to take more cholesterol from the circulation and to recycle it as cholesterol-rich bile, which serves as an aid to digestion. The daily consumption of 2 g of phytosterols can effectively lower total cholesterol and LDL by 7–10% in humans and have little effect on HDL and triglyceride levels when consumed with the main meal (Abumweis et al. 2008). Currently, there are no data available indicating that cholesterol lowering through plant sterol ingestion results in prevention of CVD. The NICE guidance (2014) states that patients should not be advised to take plant sterols and stanols to prevent CVD; however, they remain in the NCEP guidelines and they may still be recommended for patients with FH (Moruisi et al. 2006).

Red yeast rice is a source of fermented pigment used in China as a food colourant and flavour enhancer. The possible bioactive effects of red yeast rice are related to a statin-like mechanism of inhibition of HMG-CoA reductase. Different preparations have different concentrations of monacolins, the bioactive ingredients which lower total cholesterol and LDL although long-term safety of consumption of these products is not fully understood. One randomised study from China in patients with CAD showed that a particularly purified extract of red yeast rice reduced recurrent events by 45% (Lu et al. 2008).

57.4.2 Lipid-Modifying Drug Therapy

If lipid goals have not been achieved in primary prevention despite lifestyle changes, then drug therapy may be indicated to supplement the life-

style modifications. In secondary prevention, lipid-modifying drug therapy is almost always indicated.

Statins are the most widely recommended treatment for hypercholesterolaemia. Statins reduce the production of cholesterol in the liver by blocking the enzyme 3-hydroxyl-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase. Their principle effect is to lower plasma LDL although there may be modest increases in HDL and variable decreases in triglycerides dependant on the agent and dose used. A number of large-scale clinical trials have demonstrated that statins substantially reduce cardiovascular morbidity and mortality in both primary and secondary prevention (Downs et al. 1998; Scandinavian Simvastatin Survival Study Group 1994). The 4S study was the first landmark trial in which simvastatin was given to patients with moderately raised cholesterol levels who were known to have CHD. Total mortality was significantly reduced as was the rate of coronary events. In the Cholesterol Treatment Trialist's meta-analysis of individual participant data from >170,000 participants in 26 randomised trials of statins, a 10% proportional reduction in all-cause mortality and 20% proportional reduction in CVD death per 1.0 mmol/L (approx. 40 mg/dL) LDL-C reduction was reported (Baigent et al. 2010).

Statins are the first-line treatment for most people with high cholesterol. Side effects are rare but can include intestinal problems, liver damage, muscle tenderness, asymptomatic increases in liver transaminases and myopathy. Drugs in this class may also interact with other medications such as calcium channel blockers and some antibiotics due to the metabolic pathway used. This can result in significant increases in the plasma levels of statins, increasing the potential for adverse effects. Patients taking statins need to be advised to avoid grapefruit as it is metabolised through the same cytochrome P450 system. There is also some evidence that statins have a number of properties beyond LDL lowering that may contribute to their benefits. These properties are often referred to as pleotropic effects and include improvement in endothelial function, anti-inflammatory effects, antioxidant effects and plaque stabilisation (Davignon and Laaksoen 1999). Current NICE guidance in the UK recommends the use of atorvastatin 20 mg for primary prevention and atorvastatin 80 mg for secondary prevention (NICE 2014).

Statins are generally safe and well tolerated. They do, however cause a rare side effect called myositis which is defined as muscle symptoms in association with a substantially elevated serum creatine kinase concentration. The European Atherosclerosis Society has published a consensus statement on how this condition should be assessed and managed (Stroes et al. 2015).

Bile acid sequesterants or resins act by irreversibly binding the bile produced by the liver. Bile helps the digestion and absorption of fats in the intestine. The depletion in the bile acid pool leads to a greater breakdown of cholesterol to form bile salts. This then promotes up-regulation of the LDL receptors in the liver to maintain the cholesterol pool in the liver. The LDL lowering is 10–20% (Durrington and Sniderman 2000). Although this process can effectively reduce LDL, it can aggravate production of triglycerides. Bile acid sequesterants interfere with the absorption of fat soluble vitamins and supplements of these may be required. At the top dose of 24 g of cholestyramine or 4.5 g of cholestagel, a reduction in LDL-C of 18–25% has been observed. No major effect on HDL has been reported, while triglycerides may increase in some predisposed patients (ESC/EAS 2011).

Fibrates have a much weaker effect on LDL than statins and act mainly by decreasing serum triglycerides and inhibiting lipoprotein lipase activity (The FIELD Study Investigators 2005). The overall efficacy of fibrates on CVD outcomes is much less robust than of statins. Recent meta-analyses have reported that fibrate therapy reduced major CVD events by 13%, the benefits being most evident in patients with elevated triglyceride levels (>2.3 mmol/L/90 mg/dL) (Jun et al. 2010).

Cholesterol absorption inhibitors lower cholesterol by inhibiting the intestinal absorption of dietary and biliary cholesterol by blocking the passage across the intestinal wall. They favourably affect triglyceride and HDL levels in mono-

therapy and in combination with statins (Gagné et al. 2002). The IMPROVE-IT study examined the addition of ezetimibe to statin therapy in patients who had been hospitalised for an acute coronary syndrome within the previous 10 days. The study concluded that when added to statin therapy, ezetimibe resulted in incremental lowering of the LDL level and improved cardiovascular outcomes (Cannon et al. 2015). Ezetimibe is recommended to be used as monotherapy for patients in whom statin therapy is contraindicated or co-administered with a statin if the LDL is not adequately controlled after dose titration of the statin or if dose titration is limited by statin intolerance (NICE 2016).

Nicotinic acid is a B vitamin that markedly reduces VLDL and LDL and substantially increases HDL. It also is the only hypolipidaemic agents that reduces Lp(a). Its mechanism of action is not fully known but reduces VLDL secretion by the liver (Durrington and Sniderman 2000). Although successful in reducing cholesterol levels, this group of drugs are not well tolerated and the main drugs available have recently been withdrawn in the UK and Europe due to their side effect profile.

57.4.3 Novel Drug Therapies

In the last few years, a variety of novel lipid-lowering agents with different mechanisms of action have been developed which have the potential to further improve the management of hypercholesterolaemia.

57.4.3.1 Mipomersen

Mipomersen is a second-generation antisense oligonucleotide which targets the messenger ribo-nucleic acid (mRNA) of Apo B. It is administered by subcutaneous injection and acts by reducing the translation of Apo B mRNA and the synthesis by the ribosome leading to reduced secretion of VLDL (Crooke and Geary 2013). In a placebo-controlled double-blind study of patients with homozygous FH, weekly injections of mipomersen resulted in further reductions from baseline at 26 weeks in plasma levels of LDL (mean 25% reduction), Apo B (mean 27% reduction and Lp(a) (mean 31% reduction) versus placebo. A significant number of patients reported injection site reactions (76%) some of which were long-lasting. Other adverse reactions included flu-like symptoms which typically appeared 2 days after the injection (Raal et al. 2010). Mipomersen has been approved by the Food and Drug Administration in the USA for patients with homozygous FH; however, the licence for use in Europe was withdrawn due to the adverse event profile.

57.4.3.2 Lomitapide

Lomitapide is an inhibitor of the microsomal triglyceride transport protein (MTP) which is a key protein in the assembly and secretion of Apo B containing lipoproteins in the liver and intestine. An open-label trial of maximally tolerated doses in homozygous FH patients showed reduction in LDL of approximately 50% and Lp(a) of approximately 15% at 26 weeks in addition to standard care including lipoprotein apheresis. The LDL reductions were maintained over a further 12 months follow-up (Cuchel et al. 2013). The most frequently observed side effects were gastrointestinal and liver fat accumulation. The gastrointestinal effects were reduced by using a gradual dose-escalation regimen combined with adherence to a very low-fat diet (<20% of energy from fat). Lomitapide is licenced for use in homozygous FH adults in the USA and Europe although the high cost of the drug may limit its use.

57.4.3.3 PCSK9 Inhibitors

Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors reduce circulating LDL levels by preventing the degradation of LDL receptors when bound to PCSK9. Studies with monoclonal antibodies to PCSK9 have shown that the addition of these agents to moderate or high intensity statins in patients with primary hypercholesterolaemia resulted in additional LDL lowering. Most patients achieved LDL levels of less than 1.8 mmol/L (70 mg/dL) at 12 weeks. Adverse events were reported in 36%

of patients and were most commonly musculoskeletal or headaches (Robinson et al. 2014). The safety and efficacy of one of the PCSK9 inhibitors has been evaluated at 52 weeks demonstrating that added to diet alone, to low dose statin or high dose statin with or with ezetimibe there was a significant reduction in LDL levels in patients with a range of cardiovascular risks (Blom et al. 2014). PCSK9 inhibitors have been licenced since 2016 and their use is increasing for patients who fail to reach target cholesterol levels despite maximum tolerated statins or those who are statin intolerant.

57.4.3.4 Cholesterol Ester Transfer Protein Inhibitors

Cholesterol ester transfer protein (CETP) reduces circulating HDL levels by transferring cholesterol ester from HDL to larger lipoproteins such as chylomicrons, VLDL and LDL in exchange for triglyceride. It creates a smaller, cholesterol-depleted HDL, therefore remodelling the HDL which is potentially beneficial in removing excess tissue cholesterol together with a small, cholesterol-depleted LDL which is highly atherogenic (Durrington 2012). CETP activity is elevated in dyslipidaemia and early onset CAD (Bhatnagar et al. 1993). It is known that there is an inverse relationship between HDL and CVD which has led to the hypothesis that therapies that raise HDL levels may ameliorate future CVD risk. Inhibiting CETP is one potential mechanism of achieving this.

There are four CETP inhibitors which have reached late-stage clinical development. The development of one of these—torcetrapib was halted after studies showed an increase in cardiovascular events and total mortality; however, it was not felt that these affects were due to CETP inhibition (Vergeer et al. 2008). Anacetrapib given in addition to statins was seen to increase the HDL level by approximately 140% with no observable adverse effects on cardiovascular outcomes (Cannon et al. 2010). Similar studies with dalcetrapib also showed no adverse cardiovascular effects but the increase in HDL was more modest at approximately 30% (Robinson 2010). The lack of positive outcome data for CETP inhibitors has resulted in them not yet being used in routine clinical practice. Further studies on the class of drug are required together with development of novel drugs to identify their exact place in the management of raised cholesterol.

Figure 57.3 shows the development of lipid-lowering therapy over the past 60 years.

57.4.4 Lipoprotein Apheresis

Lipoprotein apheresis is a selective extracorporeal treatment, similar to renal dialysis, which removes atherogenic Apo B 100 containing lipoproteins from the circulation. It can be used to treat raised cholesterol levels in patients with FH and non-familial hypercholesterolaemia who have failed to reach target levels with maximum tolerated diet and medication.

The first successful use of plasma exchange to treat homozygous FH was described in 1975 (Thompson et al. 1975). Lipoprotein apheresis is now accepted as the treatment of choice for patients with homozygous FH and for heterozygotes with cardiovascular disease refractory to lipid-lowering drug therapy. Lipoprotein apheresis should also be considered for patients with accelerated coronary disease and significantly raised Lp(a) whose LDL cholesterol remains raised despite maximal drug therapy.

There are a several guidelines for the use of lipoprotein apheresis worldwide which all vary slightly, as do the number of patients receiving treatment. The National Lipid Association Expert Panel on Familial Hypercholesterolaemia (Ito et al. 2011) recommend the use of apheresis in patients who, after 6 months, do not have an

Fig. 57.3 Development of lipid-lowering therapy

adequate response to maximum tolerated drug therapy in the following cases:

- Functional homozygous FH patients with LDL cholesterol ≥300 mg/dL (7.7 mmol/L) (or non-HDL cholesterol ≥330 mg/dL/8.5 mmol/L).
- Functional heterozygous FH patients with LDL cholesterol ≥300 mg/dL (7.7 mmol/L) (or non-HDL cholesterol ≥330 mg/dL/8.5 mmol/L) and 0–1 risk factors.
- Functional heterozygous FH patients with LDL cholesterol ≥200 mg/dL (5.1 mmol/L) (or non-HDL cholesterol ≥230 mg/dL/5.9 mmol/L) and high-risk characteristics such as ≥2 risk factors or high lipoprotein (a) ≥50 mg/dL using an isoform insensitive assay.
- Functional heterozygotes with LDL cholesterol ≥160 mg/dL (4.1 mmol/L) (or non-HDL cholesterol ≥190 mg/dL/4.9 mmol/L) and very high-risk characteristics (established CHD, other cardiovascular disease or diabetes) (Ito et al. 2011)

In Germany, LDL apheresis is recommended for all patients with homozygous FH and LDL >500 mg/dL (12.9 mmol/L) and for patients with severe hypercholesterolaemia when maximal diet and drug therapy for more than 1 year has failed to lower the LDL sufficiently (Working Party on medical treatment of the Federal Committee 2009). Some German centres also recommend considering apheresis treatment to patients with Lp(a) >600 mg/L with progressive CHD despite optimal control of other risk factors (Heigl et al. 2009).

In the UK, the LDL Apheresis Working Group of HEART UK has recommended that LDL apheresis should be considered for:

- All patients with homozygous FH older than 7 years of age with a total cholesterol of >350 mg/dL (9.0 mmol/L) or a decrease of less than 50% on drug therapy
- Patients with heterozygous FH or a family history of premature cardiac death with significant progression of coronary disease if the LDL is more than 200 mg/dL (5.2 mmol/L) or a decrease of less than 40% on maximal drug therapy
- Patients with Lp(a) >600 mg/L with progression of CAD if the LDL is >125 mg/dL (3.2 mmol/L) despite maximal drug therapy (Thompson et al. 2008).

Despite these recommendations, lipoprotein apheresis is widely underused and the frequency varies across Europe and the rest of the world. It is estimated that 12 per million of the population receive apheresis in Germany, three per million in Sweden, two per million in France and Italy and 0.6 per million in the UK (Thompson et al. 2008). In the USA, there were approximately 250 patients being treated in 35 apheresis centres in 2006 (Nordestgaard et al. 2013).

There are several methods available for lipoprotein apheresis. Initial methods involved the separation of plasma from red blood cells prior to the removal of LDL and Lp(a). These include immunoadsorption, double filtration, dextran sulphate cellulose adsorption and heparin-induced extracorporeal LDL-cholesterol precipitation. Newer methods such as direct adsorption of lipoproteins and direct haemoperfusion remove the lipoproteins from whole blood.

Although there are technical differences between the different methods, studies have demonstrated no significant differences in reduction of lipoproteins or in clinical outcomes (Julius et al. 2008). Treatment duration varies depending on the system used but is usually between 1.5 and 4.0 h. Factors which affect treatment duration include the blood flow achieved, method of venous access used, target volume of blood/plasma to be treated and the patient's condition. Treatment requires the insertion of two large gauge vascular access catheters into the patents peripheral veins or via an arterio-venous fistula. Occasionally, insertion of a long-term central line is required if the two previous methods of vascular access fail.

Lipoprotein apheresis treatment is generally well tolerated with side effects and adverse events being reported in approximately 3–5% of treatments (Gordon et al. 1998). Overall, it is a safe and effective treatment but there is a need to

expand the availability of the therapy in many countries of the world.

57.5 Conclusions

Raised lipid levels are an important risk factor for CHD. Patients with FH have an increased risk of premature coronary disease and it is important that they receive optimum therapy to reduce the likelihood of them experiencing coronary events. There are a variety of interventions that can reduce lipid levels including lifestyle changes, medication and lipoprotein apheresis. Each patient needs to be individually assessed in order to determine the most appropriate management plan to achieve target lipid levels.

Case Study 1

Mr Smith is a 55-year-old man. He was admitted to a tertiary cardiac centre as an emergency with an acute myocardial infarction (MI). He had no previous medical history but was a smoker. He was treated with primary angioplasty and underwent insertion of 2 drug eluting stents to his left anterior descending coronary artery. Prior to discharge he was reviewed by one of the cardiac rehabilitation nurses who gave him advice on smoking cessation and on a low-fat diet.

His cholesterol level was checked during his admission and was found to be 6.7 mmol/L (260 mg/dL). As part of his secondary prevention treatment, he was started on Atorvastatin 80 mg od. Mr Smith was concerned about taking a statin as he had read reports in the press that they had side effects. He was counselled by one of the pharmacists who explained the importance of cholesterol reduction following his MI and also explained that side effects were rare but that it was important that he should inform his GP of any problems he had with any of his medication. He was also advised to have his cholesterol level rechecked in 3 months to ensure that his level had been reduced adequately.

Case Study 2

Mrs Brown is a 50-year-old lady who was diagnosed with familial hypercholesterolaemia (FH) when she was 40 years old. Her father had died from a myocardial infarction when he was 38 years old, and her paternal grandfather and uncle had also died before the age of 50. Her raised cholesterol level was found during a health check at work. and she was then sent to the regional cardiac centre for genetic testing. This had shown that she had a mutation of the LDL receptor. Mrs Brown has two children who are 25 and 27 years old who have also been tested for FH. Neither of them has been found to have the mutation. Mrs Brown's LDL level was 6.0 mmol/L (190 mg/dL) when she was diagnosed. She was prescribed Atorvastatin 80 mg od which reduced her LDL to 3.0 mmol/L (115 mg/dL). As this level remains higher than the target for someone with FH, she has recently been started on Ezetimibe 10 mg od in addition to her statin. She has also had a discussion with her lipidologist about one of the newer drugs that can be used for raised cholesterol. They have agreed that if her LDL level continues to be greater than 1.8 mmol/L (70 mg/dL) on statin and Ezetimibe combination therapy she will try a PCSK9 inhibitor. She is concerned that this new medication is given by injection and has decided that she would prefer to try other oral lipid-lowering therapy first.

Nursing process in the management of patients with lipid disorders and FH

- Identify patients with raised lipid levels
- Provide information and advice regarding diet and lifestyle changes that patients can make to help reduce lipid levels
- Identify patient knowledge deficits and areas for additional education
- Advise patients on how frequently they should have their lipid levels checked
- If patients have xanthelasma or tendon xanthomas and are not known to have FH, facilitate referral to a lipid specialist
- Discuss the need for lipid-lowering therapy with patients
- Provide advice on potential side effects of medication and the action to be taken if patients think they are experiencing side effects
- Ensure patients are aware that lipid-lowering therapy is lifelong

- Allow time for patients to express their possible concerns about lipid-lowering therapy to facilitate adherence
- Evaluate the patients response to lipid-lowering therapy and give advice on the need to increase or add additional medication as necessary
- Identify patients whose lipid levels remain above target and ensure they are referred to a lipid specialist
- Discuss the need for cascade testing with patients who are diagnosed with FH
- Advise women of child bearing age of the need to stop lipid-lowering therapy prior to planning a pregnancy
- Refer any patient known to have raised lipids who develops symptoms of chest discomfort to a cardiologist for further evaluation
- Provide information about patient support groups and websites for patients with raised lipids
- Provide emotional support to patients and their families when diagnosed with, or being investigated for FH
- Be aware of new medications being used or under investigation for use in patients with raised lipid levels

Abstract

More than three quarters of children treated for cancer survive into adulthood with this number continuing to rise. Successful transition is now recognised as an important facet of care in both paediatric and adult medicine. It encompasses "the purposeful, planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health care systems" (Blum et al. 1993). It is not simply transfer of care to another provider but should be a gradual process taking into account physical and psychological maturity as well as the availability and structure of local resources.

Childhood cancer survivors (CCS) have to cope not only with the late effects of treatment but also come to terms with their initial diagnosis, the uncertainty about relapse and the risk of second malignancies. Specialist nursing skills are required to deal with these issues, the emphasis of this being support, screening and clinical review, ensuring a swift referral process for suspected second malignancy or late effects (LE) requiring specialised care, i.e. cardiomyopathy, hypothyroidism, and premature ovarian failure.

Key Terms

- **Late effects**: Complications due to cancer treatment.
- **PanCare**: Pan-European network to improve the care of childhood cancer survivors.
- **Survivorship care plan**: Cancer treatment history and recommended follow-up plan.
- **Transition**: An active, planned, coordinated comprehensive process to enable transfer from child-centered to adult-oriented health care system.

Key Points

- The number of childhood cancer survivors is growing.
- This patient population may be at risk of premature morbidity or mortality due to their previous cancer treatments or the cancer itself and are at risk of second malignancies.
- There are a paucity of transition programmes for childhood cancer survivors to enable a successful transfer from child-orientated health care services to adult-orientated healthcare.
- Transition is specific to each individual survivor and needs to be considered from the following perspectives; developmental stage and understanding, medical, psychological, educational, and vocational.
- It requires a multidisciplinary approach.
- Patients should be empowered to be collaborative in their transition process.

58.1 Introduction

The overall 5-year survival rate following childhood cancer is now greater than 80% in developed European countries (Winter et al. 2015) and (M Van Laar 2013). For some cancers, such as acute lymphoblastic leukaemia and Hodgkin's disease, cure rates exceed 90% (Cohen 2005). Consequently, the cohort of CCS is increasing worldwide, year on year presenting a significant challenge for service provision. This not only impacts paediatric services but also adult services as these children mature into adolescence and adulthood. Although these survival rates are a positive aspect of the speciality, childhood cancer survivorship is known to be associated with adverse long-term physical and psychological LE. Whilst some will manifest in childhood, others may manifest many years, even decades following completion of treatment and into adulthood. CCS who fail to successfully transition to adult-orientated LE clinics will miss out on their risk-based LE follow-up and potentially experience late morbidity and early mortality (Klassen et al. 2014).

LE following cancer treatment in childhood is presented in Chap. 2. The most common impacts of the primary three treatments for childhood cancer (chemotherapy, radiation therapy, and surgery) are on growth, endocrine function, fertility, neuropsychology, and the cardiac system. Two thirds of childhood cancer survivors will experience at least one LE with the endocrine system commonly involved. Another third of patients will develop two or more LE which may be severe or life-threatening (Oeffinger et al. 2006). Therefore, transition services for CCS must include competent health professionals from multiple disciplines with insight and an understanding of the potential LE following childhood cancer. This prevalence of endocrine disorders amongst CCS combined with increased survival rates for this patient cohort will all add to the

demand for lifelong endocrine input for CCS (Brignarello et al. 2013). Indeed a study by Sadak et al. (2013) suggested that CCS preferred a paediatric health care professional known to them or one with knowledge of childhood cancer to remain part of the clinical team in transition.

Another element of successful transition is that early detection of LE using planned surveillance with a focus on prevention and detection may reduce psychological and health problems. Endocrinopathies are now well recognised and common amongst survivors of childhood cancer. Thus, LE follow-up requires endocrinologists and endocrine nurses to be part of their survivorship teams (Patterson et al. 2012). Furthermore, the research by Sadak et al. (2013) identifies that adult survivors of childhood cancer rated their comprehensive survivorship care as the most beneficial aspect of their wider LE care. They also suggested that preferences for transition may be multifactorial and include the role of parents in continuing to attend LE follow-up appointments (Kinahan et al. 2008), cultural sensitivities associated to race and ethnicity, and the importance of the role of nuclear families (Casillas et al. 2010).

Models of shared care survivorship have been proposed and are often developed to suit local services with consideration of available facilities, systems, and professionals. The logistics of professionals facilitating clinics across adult and paediatric hospital sites can be complex. Furthermore, paediatric settings often lack developmentally appropriate facilities for adolescents (Blum 2002). That said, the exact location of good LE follow-up may be located in either paediatric or adult out-patient settings depending on local circumstance. In some areas, specialised childhood LE clinics exist which are only able to deliver appropriate risk-based follow-up for children and young people following completion of their cancer treatment but may be unable to provide ongoing LE follow-up care once these patients move into adulthood. If this is the case, these patients may then be discharged back to their general practitioner (GP) in primary care. If this model needs to be adopted, it is essential that a summary of the patient's treatment and individualised care plan for future screening is appended to their discharge summary. This will allow the GP or primary care physician to continue to provide this screening, assessment, and management of LE.

These documents are commonly referred to as survivorship care plans (SCP). The accurate information included in these care plans together with the nature of the individual's current problems and a realistic view of the future are all essential. However, McClellan et al. (2013) identified that many young adult survivors of childhood cancer do not have an SCP. Furthermore, the provision of an SCP is seen by many health professionals as a costly and time-consuming addition to a patients care pathway (Hewitt 2007). The Institute of Medicine (2006) recommends that certain core components be universally present in SCPs, with the provision on SCPs being the second recommendation in their adult survivors report (Hewitt et al. 2005; Alfano and Rowland 2016). The core components expected to be listed in any post-treatment care plan are: details of diagnosis and treatment, potential consequences, recommendations for type and timing of follow-up, and recommendations for preventative services, e.g. psychosocial resources if locally available.

Evaluation of SCPs in adult bowel cancer survivors demonstrated that 80% of respondents were likely to engage with them if one was made available with 30% commenting on how useful it would be for continuity of care at follow-up appointments (Baravelli et al. 2009). This is echoed in work undertaken by Slater (2010) where a participant responded "showing my SCP to whichever physician I see will save a lot of messing around and repetition". Clearly this is transferable to the care for CCS due to their requirement to continue follow-up lifelong and across multi-professional teams. A standardised approach to the SCP format has demonstrated an improvement in the early detection, intervention, and management of recurrent disease and LE (Earle 2007).

Negative aspects of SCPs have also been addressed, with 17% of survivors raising concern about information regarding recurrence and family risk, although all agreed it should be retained despite the potential distress (Slater 2010). They have also described themselves as being overwhelmed at the end of active treatment, receiving

so much information they could not absorb it all (Hewitt 2007). Overall however SCP's can be viewed as a successful tool to pre-empt or address individual issues before they arise whilst at the same time offering survivors a source of control, shared knowledge, and a free flow of information and transparency about their continuing health journey (Hewitt 2007).

A scoping exercise to identify successful models of transitional care for young people (YP) with a variety of complex health needs (CHN) was undertaken in the UK in 2011 (Watson et al. 2011). This demonstrated a paucity of evidence to inform best practice about both the process of and what constitutes effective transitional care. From this work a transition programme named "Ready, Steady, Go" (RSG) was devised (National Institute of Health and Care Excellence (NICE) 2017). RSG is a suite of resources designed to deliver high-quality transition for young people (YP) across all subspecialties. The objective of RSG is to deliver high-quality transition thereby improving patient and young people's experience and ability to manage their healthcare independently in a cost-effective manner.

58.2 What Is Transition?

Transition is a phenomenon that occurs in all of our everyday lives, independent of health status and age (Mulder et al. 2016). Examples of these transitions are starting school, puberty, moving away from home to study, and gaining employment. Without doubt adolescence is a significant time in our lives for all adolescents and not just those with an underlying chronic health condition. It is a point in life where individuals strive to move from dependence and seek their own identity. The end point is cited by (Evans 1996) as being a time when "adolescents are expected to emerge into adult life with a positive sense of self-worth and an established identity, a comfortable body image, and the ability to form relationships with others of the same and opposite sexes. They should have an ability to think in abstract terms, to verbalise conceptually, and to have attained emotional and practical independence". Thus, adolescence can be described as a time of tension and uncertainty as the individual strives to establish an identity and plan for the future (Hollis and Morgan 2001). As children and young people grow and mature, their cognitive, medical, and social needs for information also change. These combined health and psychosocial needs must be responded to by the LE team in a timely and developmentally appropriate way. Myelination and maturation of the central nervous system is not normally complete until the middle of the third decade and may be incomplete or abnormal in some LE patients (see below). For this reason, risk-taking behaviour is more common (including non-adherence to therapies) and explanations or educational material should be appropriate for the developmental age of the young person. Likewise, achievement of peak bone mass is not until a similar age and so treatments to improve bone health such as growth hormone at a reduced dose on attainment of adult height remains an "active" medical issue.

Children undergoing treatment for cancer achieve a number of other transitions during their treatment journey. The first is upon completion of active treatment and entering a period of clinical surveillance which follows their immediate end of treatment where the emphasis is primarily on screening for recurrence. This follow-up is usually performed by the treating oncologist/haematologist. The second transition is to a specific LE follow-up clinic, often with new personnel although others will link from the earlier acute clinical period. The third transition is to a transition LE service either in paediatric or adult services or discharge to primary care. Where local adolescent medical specialists are available, there may even be other transitions to adult care and eventually care of the elderly!

Core specialists within LE teams usually include: Consultant paediatric oncologist, Specialist LE nurse, Consultant Endocrinologist, Psychologist, and a specific multidisciplinary team co-ordinator. Nurse specialists' benefit from an oncology background as their knowledge of cancer treatment is fundamental to ongoing assessment and patient education. In the UK, the Royal College of Nursing competencies identify the core knowledge and skills required (RCN 2011). There also need to be rapid referral pathways to fertility, orthopaedic, ophthalmology,

and other sub-specialisms to deal with specific late effects of some treatments.

It is also important to understand what transition is NOT; it is not simply a transfer process to an equivalent adult specialist from a paediatric specialist. The consequences of not undertaking transition in a structured way involving a multiprofessional team leaves the patient at significant risk of harm (Mulder et al. 2016).

Recently, PanCare, a multidisciplinary pan-European network of professionals, survivors, and their families that aims to reduce the frequency, severity, and impact of late side-effects of the treatment of children and adolescents with cancer (https://www.pancare.eu) provided a definition of transition of care of childhood cancer survivors: "Transition of childhood cancer survivors is an active, planned, coordinated, comprehensive, multidisciplinary process to enable childhood and adolescent cancer survivors to effectively and harmoniously transfer from child-centred to adult-oriented health care systems. The transition of care process should be flexible, developmentally appropriate and consider the medical, psychosocial, educational and vocational needs of survivors, their families and care-givers, and promote a healthy lifestyle and self-management" (Mulder et al. 2016). The definition highlights the importance of the guided process of transition starting early in follow-up and including the multidisciplinary team involved in the care before and after transition. PanCare is currently working on evidence-based guidelines to help implementing transition in follow-up.

58.3 Barriers to Transition

Adolescents, when asked to identify their individual barriers to transition cited their level of maturity, readiness to assume responsibility for their own future health and lack of knowledge of their health condition and its implications as factors (Granek et al. 2012). Furthermore, due to the very nature of some cancer treatments used in childhood and the toxicity they cause, memory and learning function may be affected. Thus, the ability of some CCS to have the cognitive and developmental maturation to fully understand and engage with transition is lowered. This also impacts on information giving, not only around transition but also around their previous cancer journey and potential future health risks. In the majority of cases, this continues to be facilitated through the parents/carers participation in consultations.

It is suggested widely that transition should begin at age 11+ years but should always take into account the needs of the families and patient. A study in the UK of transition process (Downing et al. 2017) demonstrated that parents tend to monopolise questioning in the consultation until around 16 year of age and that there was some benefit in allowing the young person to set an agenda for their own consultation. Actively discussing early on the need to separate young people from their parents during the consultation to allow them to discuss topics such as sexuality is a very important part of the process. The provision of a personalised record with space to record questions that occur between appointments and the provision of web-based material targeted at their specific conditions may also aid effective communication (Downing et al. 2017). It is also important to try to individualise follow-up arrangements taking into account tertiary education, jobs, and relationships as these develop. If these issues are not taken into account when scheduling appointments at a new hospital there is a 30% loss to follow-up of patients in the first year of transition with patients who cancel or do not attend appointments in the first year of the process being 14 times more likely to be completely lost to follow-up (Downing et al. 2013).

58.4 Conclusions

Childhood cancer survivorship brings with it many challenges for children, young people, the family, and those providing care. This chapter has provided a comprehensive overview of the considerations and principles required by health care professionals and multidisciplinary teams to ensure safe, evidence-based, individualised, and holistic transitional care for this patient cohort.

Case Studies

Sophie

Diagnosis	Rhabdomyosarcoma of the naso-pharynx
Age at diagnosis	6
Treatment	Chemotherapy and adjuvant radiotherapy (pituitary involved in radiation field)
Age at transition	16
Late effects/known endocrinopathies at transition	Growth hormone deficiency Primary hypothyroidism Adrenal insufficiency (delayed presentation age 15)
Medication	Growth hormone (GH) until age 12 when she achieved "final adult height" and no longer wanted to receive "daily injection" Thyroxine Hydrocortisone (Oral daily replacement and emergency IM injection)
Follow-up in TYA LE service	Annual endocrine screening bloods demonstrate a low IGF1, Sophie reluctant to restart GH therapy
Age 17	Presents to clinic with concerns re central adiposity, enlarging breasts and struggling to keep pace with her peers; re-tested for GHD using adult protocol and found to be GH deficient with a peak of just 0.10 μg/L and drifting IGF1
Age 18	Sophie presents with pain and swelling of oropharynx ? Disease recurrence Low threshold for imaging Nothing on imaging, under close review and patient knows to contact service if further problems between appointments
Ongoing issues	This case demonstrates the longitudinal nature of endocrine late effects and the danger of patients being lost to follow-up, especially given this young woman's delayed presentation of adrenal insufficiency Furthermore, it highlights an increasing and ageing population of childhood cancer survivors, emphasising the need for knowledge sharing and education regarding late effects with nurses practising in adult clinical settings

Tom

Diagnosis	Craniopharyngioma
Age at diagnosis	13 ***June 2004***
Treatment	Neuroendoscopic fenestration and drainage of cystic components ***August 2004*** Further fenestration ***July 2005*** due to ↑ in size of cystic components and surgical resection of solid component ***August 2005*** 6 weeks of radiation therapy for recurrence of disease ***February 2009***
Age at transition	16
Known endocrinopathies at transition	***Pan-hypo-pituitarism*** Growth hormone deficiency Primary hypothyroidism Adrenal insufficiency Diabetes insipidus Hypogonadism
Known late effects	Reduced visual fields Memory and learning difficulties Impaired quality of life
Potential late effects—radiation specific	Secondary malignancy Neuropsychological dysfunction Hypothalamic/pituitary dysfunction Reduced bone mineral density **Site Specific** **Skin and hair** Pigmented skin lesions, hypoplasia, fibrosis, atrophy, telangiectasia **Soft tissue** Hypoplasia, fibrosis, atrophy **Any major artery** Atheroma, stenosis

Diagnosis	Craniopharyngioma
Medication	***Full replacement therapy*** Thyroxine Hydrocortisone (Oral daily replacement and emergency IM injection) Testosterone (gel preparation swapped to long-acting depot injection) Desmopressin (DDAVP) Growth hormone
Follow-up in TYA LE service	Annual endocrine screening bloods demonstrate poor compliance with medication. Tom is a shift worker and requires support from his keyworker and consultant in managing his replacement medications around his frequently changing working hours
Age 17	Greater difficulties with short-term memory—referred to psychological services
Ongoing issues	This case demonstrates the common endocrine pathway for a complex patient, but also highlights the importance of oncology knowledge or oncology input into the multi-professional clinic

Adam

Diagnosis	Hodgkin Lymphoma
Age at diagnosis	14 ***May 2006*** Recurrence ***October 2006***
Treatment	Excision biopsy ***Nov06*** **Chemotherapy** ***Initial diagnosis*** Gonadotoxic and cardio toxic agents ***Recurrence*** Further gonadotoxic and respiratory affecting agents **Radiotherapy** At time of recurrence—whole neck 25 Gy in 14 fractions. Whole anterior and posterior neck
Age at transition	16
Known endocrinopathies at transition	Hypothyroidism
Known late effects	Nil currently
Potential late effects—radiation specific	Impaired quality of life Secondary malignancy Cardiac dysfunction Gonadal dysfunction Respiratory dysfunction—exposure to 100% O_2 therapy hazardous **Radiation—Site Specific** **Skin and hair** Pigmented skin lesions, hypoplasia, fibrosis, atrophy, telangiectasia, secondary malignancy **Soft tissue** Hypoplasia, fibrosis, atrophy **Any major artery** Atheroma, stenosis ***Thyroid (Neck)*** Thyroid dysfunction, nodules, and/or malignancy
Medication	Thyroxine
Follow-up in TYA LE service	GP and Primary care team in the transition LE clinic screen thyroid bloods annually Annual follow-up with palpation of thyroid gland assessing for any nodules Questioning re sexual function and desire to undergo sperm assessment at a time when Adam is ready to explore this further Adam aware of seeking medical advice if he feels any new "lumps or bumps"
Ongoing issues	Adam's case demonstrates the complexities of being a childhood cancer survivor with an isolated endocrinopathy, whilst being at risk of other significant treatment-related sequelae

Kate

Diagnosis	Adrenal tumour
Age at diagnosis	4.5 years
Presentation	Sudden onset of obesity Tired Unable to sit from prone Height 75% Weight 90% PH2 B1 No cliteromegaly Vague mass below liver Cushingoid appearance
Investigations and results	Midnight cortisol 647 Undetectable ACTH Raised urinary free cortisols (UFC) USS and CT scan showed right adrenal mass with no calcification 7 × 5 cm
Treatment	***Initial Surgery*** Resection attempt abandoned due to highly vascular tumour with extensive blood loss Cushing's syndrome remained Commenced ***ketoconazole***, ***metyrapone*** with ***radiotherapy*** to tumour Cortisol and UFC remained high so commenced on ***mitotane*** but remained Cushingoid Concurrent episode of meningococcal sepsis requiring intensive care ***Aminoglutethimide*** added to the regimen with biochemical response and metyrapone was withdrawn but Kate felt very unwell on ***ketoconazole, aminoglutethimide,*** and **mitotane** Thus ***aminoglutethimide*** withdrawn and biochemical remission continued with symptomatic improvement and ***ketoconazole*** at a reduced dose along with continued ***mitotane***
14 months later, age 6	Kate developed mitotane-related encephalitis with ataxia, slurred speech, and reduced conscious level so mitotane was withdrawn and her neurological symptoms resolved Whilst just on ketoconazole Kate had asystolic cardiac arrest with long QT interval so ketoconazole withdrawn and Cushing's syndrome reappeared Interventional radiology attempted embolisation of the tumour and reduced blood supply to superior 50% of the mass
22 months from presentation	Second ***surgery*** was successful and "cure" achieved
Puberty	Early puberty at age 9 with menarche at age 12 despite potential for gonadal failure 2^0 to mitotane chemotherapy
Age at transition	Gradual process involving multi-professionals from the age of 16
Issues at transition	Intensive psychological support for Kate and her mother was required to allow them to attend hospital appointments and recognise that future life without an adrenal tumour was possible Dexa scans confirmed only minor reduction in bone mineral density She experienced 1 Addisonian crisis with gastroenteritis and steroid replacement was continued Striae were treated with topical retinoids Weight reduction advice was unsuccessful until she entered a relationship and her BMI fell to 50%
Late effects and/or known endocrinopathies at transition	Adrenal insufficiency

Diagnosis	Adrenal tumour
Potential late effects	Impaired quality of life Secondary malignancy Cardiac dysfunction Gonadal dysfunction **Radiation—Site Specific** **Skin and hair** Pigmented skin lesions, hypoplasia, fibrosis, atrophy, telangiectasia, secondary malignancy **Soft tissue** Hypoplasia, fibrosis, atrophy **Any major artery** Atheroma, stenosis **Abdomen** Abdominal Adverse pregnancy outcome Gastrointestinal dysfunction, diarrhoea Gastrointestinal fibrosis, stricture Hepatic dysfunction Hepatic fibrosis, cirrhosis Splenic dysfunction Renal hypoplasia Glomerular dysfunction Proteinuria Hypertension
Medication	Replacement hydrocortisone
Follow-up in TYA LE service	She began training as a midwife and despite management with an oral contraceptive she became pregnant and delivered a healthy boy at 19 years of age
Age 30	Receives annual USS surveillance of the tumour area but remains well with no sign of second malignancy
Ongoing considerations/issues	This case illustrates the issues that may be faced by a survivor of an extremely dramatic and rare medical problem in early life with multiple life-threatening events but eventual "cure"

Abstract

Due to remarkable improvements in treatment and supportive care over the past several decades, survival rates for childhood cancer currently exceed 80%. Nevertheless, survivors exposed to cranial radiotherapy (CRT) are at particularly high risk for long-term morbidity, such as endocrine insufficiencies, metabolic complications, and cardiovascular morbidity. Research report that 40–50% of survivors will develop an endocrine disorder over their lifetime. Deficiencies of one or more anterior pituitary hormones have been described following therapeutic CRT for primary brain tumors, nasopharyngeal tumors, and following prophylactic CRT for childhood acute lymphoblastic leukemia (ALL). For at risk-survivors, new endocrinopathies can develop decades following cancer treatment, and

lifelong surveillance is mandatory. Studies have consistently shown a strong correlation between the total radiation dose and the development of pituitary deficits. Further, age at treatment and also time since treatment has strong implications on pituitary hormone deficiencies. Risk factors for low BMD include high dose methotrexate, cumulative doses of glucocorticoids, male gender, and low physical activity. Any combination of these factors may result in osteopenia, not reaching optimal peak bone mass and osteoporosis later in life. Infertility is an important potential consequence of treatment for childhood cancer and identification of survivors for whom strategies to preserve fertility are required. Women treated with radiotherapy affecting ovarian and uterine function are at high risk of acute ovarian failure, premature menopause, complications including spontaneous abortion and preterm labor. Radiotherapy to the gonads, total body irradiation, and high dose chemotherapy may result in a number of effects on the male reproductive system in survivors. Detailed information about the past cancer treatment including surgery, the type and cumulative doses of chemotherapy, and radiotherapy volumes and doses are needed to estimate health risks associated with childhood cancer. A risk-based care approach, for all childhood cancer survivors, should include a systematic plan for lifelong screening, surveillance, and prevention that incorporates risk estimates.

Keywords

Childhood cancer survivors · Cranial radiotherapy · Late complications · Hypothalamic-pituitary insufficiency · Long-term morbidity Bone mineral density · Infertility

Abbreviations

ACTH	Adrenocorticotropic hormone
ALL	Acute lymphoblastic leukemia
BIA	Bioelectrical impedance measurement
BMD	Bone mineral density
CCS	Childhood cancer survivors
CRT	Cranial radiotherapy
DEXA	Dual-energy X-ray absorptiometry
FSH	Follicle stimulating hormone
GH	Growth hormone
GHD	Growth hormone deficiency
GHRH	Growth hormone releasing hormone
Gy	Grey
H-P	Hypothalamic-pituitary
IGF-1	Insulin like growth factor
ITT	Insulin tolerance test
LH	Luteinizing hormone
PRL	Prolactin
RT	Radiotherapy
TSH	Thyrotropin stimulating hormone

Key Terms

- **Anthracyclines:** Chemotherapy known to affect the cardiac function.
- **BMD:** Bone mineral density.
- **Cranial radiotherapy**: Whole brain radiotherapy.
- **GHD:** growth hormone deficiency.
- **Hypothalamus:** Important for energy balance and food intake.
- **Metabolic complications:** Obesity, lipid abnormalities, insulin resistance.
- **Survivorship care plan**: Comprehensive treatment summary with information about potential cancer-related health risks.

Key Points

- Childhood cancer survivors exposed to cranial radiotherapy (CRT) are at particularly high risk for long-term morbidity, such as endocrine insufficiencies, metabolic complications, and cardiovascular morbidity.
- For at risk-survivors, new endocrinopathies can develop decades following cancer treatment, and lifelong surveillance is mandatory.
- Hypothalamus is more radiosensitive than the pituitary. With lower doses of CRT (<30 Gy), the primary site of radiation damage is the hypothalamus and this usually causes isolated GH deficiency (GHD).
- Survivors exposed to CRT are at particularly high metabolic risk and increased risk of cardiovascular diseases later in

life. Risk factors for these complications include obesity, physical inactivity, lipid abnormalities, and insulin resistance.

- Survivors of ALL and of tumors in the pituitary-hypothalamic area are at greatest risk for obesity. CRT can cause CNS damage, in particular hypothalamic. This may promote obesity via a number of possible mechanisms: growth hormone deficiency, leptin resistance or hypothalamic regulation of food intake, and energy expenditure.
- The survivors should be provided with a comprehensive treatment summary, a systematic survivorship care plan for lifelong screening, surveillance, and prevention.

59.1 Pathophysiology of Radiation Damage

The pathophysiology of radiation damage remains poorly understood. Direct injury to the hypothalamic-pituitary (H-P) cells, rather than reduced hypothalamic blood flow, is the major cause of progressive H-P dysfunction after fractionated cranial radiotherapy. Direct neuronal damage has been shown in studies of rat pituitary cell survival and growth hormone (GH) secretion after in vitro irradiation of pituitary cell cultures (Hochberg et al. 1983). They recorded a marked sensitivity of the somatropes to single doses of radiation. Further, differential radiosensitivity of H-P function, including dose and time dependency of anterior pituitary hormone deficiencies have been demonstrated in rats. GH and PRL were most sensitive and decreased by more than 90% after irradiation and ACTH was the most robust hormone (Robinson et al. 2001). In humans, the neurotoxicity of any radiation therapy is a function of the total radiation dose, the fraction size, and the time between the duration of the radiation schedule. Using no more than 2 Gy per fraction and no more than 5 fractions per week will minimize the damage to a healthy hypothalamic-pituitary axis. Higher doses of radiotherapy (>60 Gy) causes damage to both hypothalamus and pituitary resulting in early multiple anterior pituitary hormone deficiencies (Lam et al. 1991). Direct stimulation with exogenous GHRH, LHRH, or TRH will demonstrate impaired GH, LH/FSH, and TSH secretion from pituitary. On the other hand, verified hypothalamic dysfunction is shown by delayed responses to LHRH and TRH tests (Lam et al. 1991) and also by different GH stimulation tests. The convincing test of diagnosing GH deficiency in the early years after CRT in ALL survivors is the insulin tolerance test as it reveals dysfunction of the entire hypothalamus-pituitary axis compared to GHRH-arginine test stimulating the pituitary direct (Björk et al. 2005). The presence of hyperprolactinemia due to a reduction in hypothalamic release of the inhibitory neurotransmitter, dopamine, has been described in those intensively irradiated for brain tumors, but less frequently in those treated for leukemia with less intensive radiation schedules (Lam et al. 1991).

Given the differential radiosensitivity of H-P function with GH axis as the most sensitive, variable degrees of GHD are usually seen in isolation after lower radiation doses used in leukemia survivors (18–24 Gy). With higher radiotherapy doses used in nasopharyngeal carcinoma and skull base tumors (>60 Gy) anterior pituitary hormones are affected with an early and multiple pituitary hormone deficits. (Lam et al. 1991)

Age influences the impact of radiation on H-P function such as younger age increases vulnerability to radiation damage. Younger children treated with prophylactic cranial radiotherapy for childhood ALL are more sensitive to radiation-induced GHD than older children (Link et al. 2004). In patients treated with high radiation dose (>40 Gy) for tumors of head and neck, it was shown that children younger than 15 years of age had higher risk of GHD a short time after treatment compared to older patients. However, the patients older than 15 years showed increased risk of ACTH and LH deficiency (Samaan et al. 1982).

59.2 Hypopituitarism After Radiotherapy

The most commonly diagnosed chronic conditions after cranial radiotherapy (CRT) involves the endocrine system and in particular the hypothalamic-pituitary axis (Brignardello et al.

2013; Chemaitilly et al. 2015). Deficiencies of one or more anterior pituitary hormones have been described following therapeutic CRT for primary brain tumors, nasopharyngeal tumors, and following prophylactic CRT for childhood acute lymphoblastic leukemia (ALL). Studies have consistently shown a strong positive correlation between the total radiation dose and the development of pituitary deficits (Sklar and Constine 1995). Further, age at treatment and also time since treatment has strong implications on pituitary hormone deficiencies (Link et al. 2004). It has become apparent that the pituitary hormone deficiencies can develop after many years after radiotherapy and studies have suggested that the damage might be at the level of hypothalamus (Littley et al. 1988). There is a difference in the incidence of anterior pituitary hormone deficiencies, with secretion of growth hormone (GH) being the most frequently affected followed by gonadotropin, adrenocorticotropic hormone (ACTH), and thyroid stimulating hormone (TSH). Prolactin (PRL) insufficiency is probably an early occurring insufficiency (Fig. 59.1). The most important predictive factors to deficient hormone axes are dose of CRT, age at CRT, and time since CRT. Hypopituitarism is an important diagnosis to make correctly and endocrine nurses and endocrinologists should be involved at an early stage of patient management. It has been shown that untreated pituitary deficiency is associated with poor health.

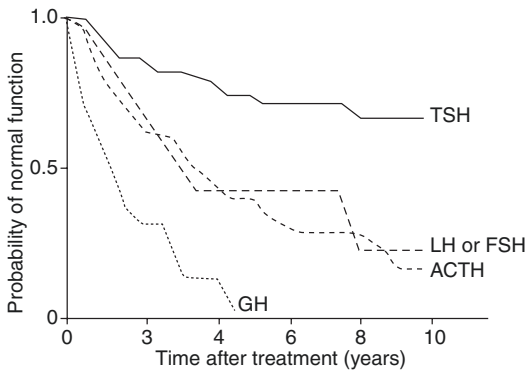

Fig. 59.1 Probability of a normal hypothalamic-pituitary axis after cranial radiotherapy (Littley MD, Shalet SM, Beardwell CG, Ahmed SR, Applegate G, Sutton ML. Hypopituitarism following external radiotherapy for pituitary tumors in adults. Q J Med 1988;262:145–160)

59.2.1 Growth Hormone Deficiency

GH deficiency (GHD) is usually the first and often the only established endocrine sequel of CRT (Littley et al. 1988). CRT in children frequently causes abnormal hypothalamic-pituitary function later in life (Link et al. 2004) and growth deficits have been reported consistently after doses of >24 Gy cranial radiotherapy (Link et al. 2004; Sklar and Constine 1995). However, GHD has also been shown during childhood in ALL patients after low doses of <20 Gy (Brennan et al. 1998), but these data are less consistent.

Based on the background to hypothalamic-pituitary disease, different GH tests must be carefully considered (Björk et al. 2005). There are clear cut-off levels for GH when a GHD is diagnosed, i.e., for the insulin tolerance test (ITT) the level is GH < 3 μg/L (or 9 mU/L) and for the growth hormone releasing hormone (GHRH)-arginine test which is BMI dependent, we used the same cut-off levels (Björk et al. 2005). Thus, Björk et al. (2005) recorded that the ITT clearly reflected the presence of early radiation-induced GHD, but this was not always the case with the GHRH-arginine test, which more confirmed the diagnosis later in life. The GHRH-arginine test is more a stimulation test directly on the pituitary, reflecting the pituitary GH secretion. However, when the GH response to GHRH-arginine was low we considered the patient to be clearly GHD (Björk et al. 2005). Thus, it would appear that primarily the hypothalamus and then later direct pituitary damage from CRT was the cause of GH deficiency among the former ALL patients.

Brennan et al. (1998) investigated GH secretion after CRT in 32 adults, 6.8–28.6 (median 17.8 years) years since CRT. Nine of the patients were severely GHD (peak GH response <9 mU/L to both provocative agents arginine and ITT) and a further 12 patients were GH insufficient (peak GH response <20 mU/L to both tests with at least one peak GH response >9 mU/L). They had all received between 18 and 24 Gy. A group of 44 childhood ALL with a median of 25 years (19–32) of whom all were treated with CRT median 24 Gy (range 18–24 Gy) were investigated. They were treated with CRT at a median age of 5 years

(range 1–18) and 17 years had passed since ALL treatment and CRT (Link et al. 2004). According to the ITT and/or the GHRH-arginine test 91% were considered GHD. All patients with a peak GH 3.9 μg or more on the GHRH-arginine test performed an ITT.

Among 310 childhood cancer survivors, the most frequent hormone deficiency was gonadal, primary hypothyroidism, and GHD (Brignardello et al. 2013). GHD was evaluated using standard GH tests. GHD was found among 16.13%, where the most frequent background diagnosis was brain tumors, followed by hematological malignancies.

In a recent paper from Chemaitilly et al. (2015) on a mixed population of adults with childhood cancer, with 72% leukemia diagnosis, about 46.5% were diagnosed with GHD. However, GHD was defined only as a measurement of morning serum IGF-I < −2.0 *z*-score. This is probably a strong underestimation as serum IGF-I is not considered sufficient to set the diagnosis of GHD (Growth hormone research society).

59.2.2 Gonadotropin Secretion

Gonadotropin deficiency in childhood cancer survivors is most frequent after a radiation dose to the hypothalamus-pituitary axis of >40 Gy (Pasqualini et al. 1987) and can be presented with a spectrum from subclinical to severe impairment. It is the second most common anterior pituitary hormone deficiency after CRT. Clinically significant gonadotropin deficiency after CRT is often apparent after long-term follow-up with an incidence of 20–50% (Constine et al. 1993). However, a remarkable increase in incidence is reported following a more intensive radiation schedules with an onset as early as 12 months after radiotherapy (Samaan et al. 1982). Gonadotropin deficiency in CCS can be subtle and detected only by GnRH testing, as well as severe with diminished circulating sex hormone levels. In a mixed population of CCS, LH and FSH deficiency was recognized in 11% of the total cohort of survivors 27 years after cancer diagnosis. After CRT doses more than 40 Gy, the prevalence of LH and FSH deficiency was 23% and 8% after CRT doses of less than 40 Gy (Chemaitilly et al. 2015). Male sex, CRT dose >22 Gy and BMI > 30 kg/m were associated with higher odds of LH and FSH deficiency (Chemaitilly et al. 2015). In another study, only including men, of 199 childhood cancer survivors showed that 13 survivors had central hypogonadism 14 years after cancer diagnosis (Brignardello et al. 2013). The risk of hypogonadism was higher in survivors treated with CRT. Radiation doses of <50 Gy may cause premature activation of the H-P gonadal axis resulting in precocious puberty (Brauner and Rappaport 1985). ALL survivors treated with a moderate dose of CRT of 18–24 Gy have an increased risk of precocious puberty, but almost exclusively in girls (Leiper et al. 1987). GHD is almost always present in irradiated children which makes the outcome of precocious puberty worse as the pubertal growth spurt will be further attenuated. In addition, the window of opportunity to treat the child with GH is reduced in the GHD child who is already pubertal. The mechanism of early puberty after radiotherapy is related to damage at the level of hypothalamus with increased frequency and amplitude of GnRH pulsatile secretion by the hypothalamus. Other results have also been reported; a large study of 949 female ALL survivors found craniospinal radiotherapy to be associated with an increased risk of late-onset menarche (Chow et al. 2009). Thus, both early and delayed puberty can be seen.

59.2.3 ACTH Deficiency

The hypothalamic-pituitary-adrenal (HPA) axis appears to be relatively resistant to radiotherapy in patients treated for childhood cancer. Clinically apparent ACTH deficiency is uncommon after cranial radiotherapy. After a total radiation dose of <50 Gy to the H-P axis around 3% of childhood brain tumor survivors present with ACTH deficiency short time after (3–10 years) after diagnosis (Constine et al. 1993). After radiation doses of >50 Gy, the frequency of ACTH deficiency is significantly increased in

survivors with head and neck tumors with rates of 27–35% up to 15 years after treatment (Lam et al. 1991). In a study including 310 childhood cancer survivors, the authors found 4 survivors with central hypoadrenalism. Among the 310 survivors, 74 were treated with cranial radiotherapy in childhood (Brignardello et al. 2013). Chemaitilly et al. (2015) investigated a mixed population of CCS, 27 years after CRT, and found that 4% of the survivors was ACTH deficient. In a group of ALL survivors, treated with a moderate dose of CRT (18–24 Gy), Follin et al. (2014) report ACTH insufficiency. Thirty-eight percent ALL survivors had a subnormal cortisol response to an insulin tolerance test (ITT) (257–478 nmol/L) while there was no significant difference in basal cortisol levels between ALL survivors and healthy matched control subjects. ALL women, but not ALL men had significantly lower ACTH levels compared to gender matched controls. However, only a few survivors needed regular hydrocortisone replacement. GHD might mask the presence of a hidden central adrenal insufficiency. If GH therapy is introduced, there will be an increase in the conversion of hormonally active cortisol to inactive cortisone and a decrease in cortisol levels can be apparent. An increased awareness of the risk for adrenal insufficiency is of importance and in particular when the survivors start GH therapy.

59.2.4 TSH Deficiency

The H-P-thyroid axis appears to be the most robust hormone to radiation damage. The incidence of TSH deficiency has been reported to be as low as 3–5% in childhood brain tumors (Livesey et al. 1990), but also more frequent recorded among CCS treated with an intensive radiotherapy schedule with doses >50 Gy (Pai et al. 2001). In ALL survivors treated <30 Gy, there are conflicting results in early studies, with no risk or an increased risk (Lando et al. 2001) of central hypothyroidism after CRT. After a follow-up of an average of 6 years after ALL treatment, one out of the 33 children was found to have a papillary carcinoma of the thyroid. Thyroid function was normal in all patients, with the exception of one case which showed high basal levels TSH levels, but normal response to TRH. This hormonal alteration was later normalized. In a study with 8 years of follow-up of survivors of childhood ALL treated with prophylactic CRT no adverse effect on hypothalamic-pituitary-thyroid function was recorded (Lando et al. 2001).

Hypothalamic-pituitary-thyroid dysregulation after CRT, identified by a TRH-stimulation test or TSH surge, has been recognized in as many as 15% of former ALL patients 10 years after CRT (Chow et al. 2009). In a study from Follin et al. (2013) with a median of 20 years of follow-up, no significant difference in basal TSH and only slight disparity of free T_4 levels (higher), which indicates no known clinical significance, was shown. However, a slightly lower TSH response to a TRH test, shown in 13 ALL patients, might be an early indication of TSH dysfunction. This is in contrast to Darzy and Shalet (2005) who 11.5 years after cancer treatment (with mixed diagnosis), found increased TRH-stimulated TSH levels in cranially irradiated patients with GHD as compared to matched controls. Disparity in results may be due to differences in radiation dose, type of cancer, age at cancer diagnosis, and particularly in follow-up time. Further, GHD plays a role in the regulation of thyroid hormone metabolism, with both a central effect, with an increase in somatostatin inhibition of TSH secretion, and a peripheral effect with an increased conversion of free T_4 to free T3.

Among 310 CCS, the most frequent hormone deficiency was gonadal, primary hypothyroidism, and GHD, after a median time of 16 years since diagnosis (Brignardello et al. 2013). They documented at least one endocrine disease among 50% of CCS. Primary hypothyroidism was diagnosed among 18%, whereas seven patients had central hypothyroidism. A study from the USA investigated a mixed population of adults with childhood cancer with a mean of 27 years after treatment and 7.5% were considered TSH deficient (Chemaitilly et al. 2015).

59.2.5 Abnormalities of Prolactin Secretion

Hyperprolactinemia after treatment with CRT for childhood cancer has been reported in studies investigating children treated with a dose >40 Gy after a short follow-up (Constine et al. 1993; Livesey et al. 1990). The hyperprolactinemia is due to the reduction in the neurotransmitter, dopamine, which has an inhibitory effect on prolactin secretion. Hyperprolactinemia after radiotherapy has no significant biological impact on the vast majority of the patients. In rare cases, high levels of prolactin can cause impaired gonadotropin secretion and pubertal delay in children (Littley et al. 1988) On the other hand, hypoprolactinemia has also been recorded in ALL survivors after CRT, but after long-term follow-up (Follin et al. 2013). It has been suggested that severe prolactin (PRL) deficiency occurs late after all other anterior pituitary insufficiencies in the evolution of hypopituitarism and that very low levels of PRL is related to the severity of hypopituitarism (Mukherjee et al. 2006). Littley et al. (1988) showed that after CRT to adults basal PRL showed an early rise, followed by a gradual decline after a few years. CRT seems to cause a primarily diminished inhibition of PRL secretion resulting in increased basal PRL levels, followed by a slowly developing lactotroph dysfunction. In contrast, in rats exposed to non-fractionated CRT, GH and PRL were shown to be most sensitive of all pituitary hormones, with a dramatic decrease with time and dose after irradiation (Robinson et al. 2001). It has been shown that PRL deficiency, thus very low PRL levels, was independently associated with reduced levels of serum IGF-I in severely GHD adults and that PRL deficiency can act as a surrogate marker for the severity of GHD (Mukherjee et al. 2006). Follin et al. (2013) recorded significantly lower basal PRL levels and PRL area under the curve (AUC) after GHRH-arginine stimulation test in 44 ALL survivors compared to matched controls of both gender. Seven ALL women reported pregnancies during follow-up and six out of seven women reported failure to lactate. Thus, it was reported that ALL patients treated with CRT are not only GH deficient but also PRL insufficient 20 years (8–27) after diagnosis (Follin et al. 2013).

59.3 Metabolic Disorders

Long-term survivors of childhood cancer are at increased risk of cardiovascular disease. In a study from the UK, the authors analyzed a cohort of 4082 survivors and found a fivefold excess of deaths from cardiovascular causes (Hawkins et al. 1994). Survivors of childhood cancer exposed to CRT are at particularly high metabolic risk and increased risk of cardiovascular diseases later in life. Risk factors for these complications include obesity, physical inactivity, lipid abnormalities, and insulin resistance. Further, survivors of childhood ALL and brain tumors with hypothalamic damage are at increased risk for obesity (Lustig et al. 2003). Childhood cancer survivors, treated with CRT have an increased risk of GH deficiency and they can also experience an anthracycline-induced left ventricular dysfunction which are risk factors for developing metabolic complications. Further, the metabolic hormones insulin and leptin, with receptors in the hypothalamus have shown resistance (Link et al. 2004) among the GH-deficient ALL survivors (Link et al. 2004; Brennan et al. 1998), suggesting a radiation-induced hypothalamic dysfunction. Janiszewski et al. (2007) report that ALL survivors treated with CRT have increased abdominal and liver fat, insulin resistance, and dyslipidemia, and these parameters are associated with lower IGF-1 levels. A Swedish study of ALL survivors treated with CRT found a strong correlation between stimulated peak of growth hormone secretion during insulin tolerance test and several cardiovascular risk factors (Link et al. 2004). Survivors of childhood brain tumors have been reported to have an increased blood pressure, waist-hip ratio, LDL cholesterol, and lower HDL cholesterol, and some of these cardiovascular risk factors were most abnormal in those with GHD (Heikens et al. 2000). GH therapy has been beneficial in reducing the prevalence of metabolic syndrome in the ALL survivors (Follin et al. 2010) (Fig. 59.2). The

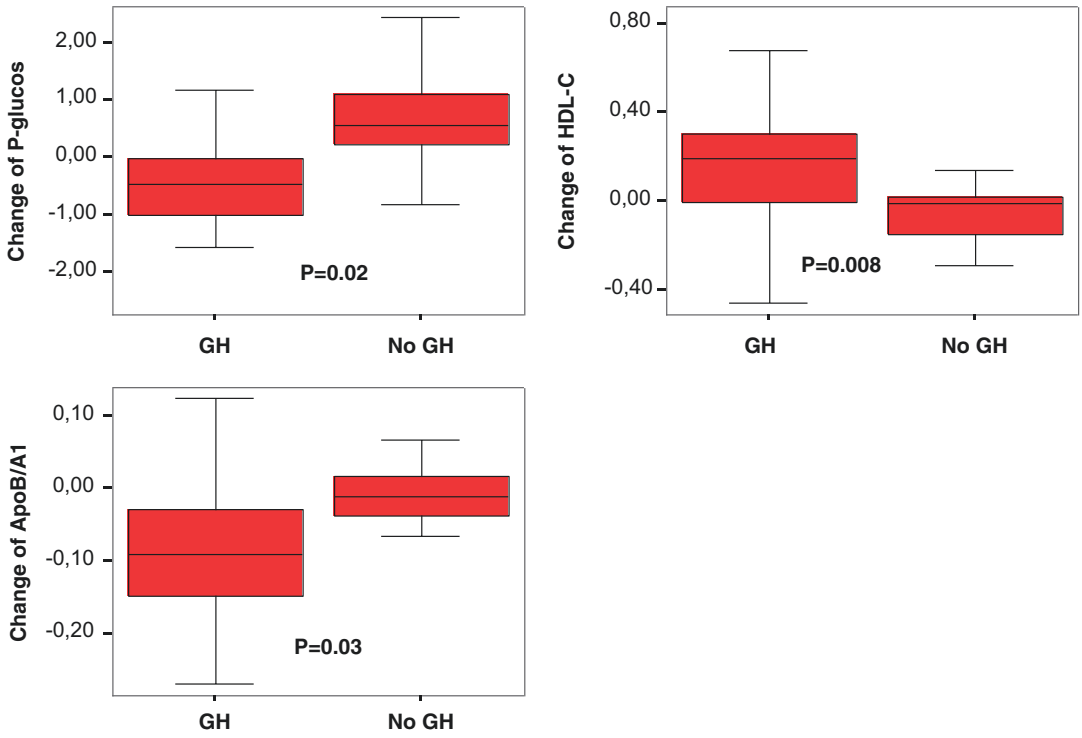

Fig. 59.2 Differences in change of cardiovascular risk factors between GH-treated and non-GH-treated ALL survivors (Follin c J Clin Endocrinol Metab. 2010 Aug;95(8):3726-35. doi: 10.1210/jc.2010-0117. Epub 2010 May 19)

survivors need to be offered multidisciplinary interventions with lifestyle changes and also lipid-lowering medication when necessary.

Survivors of childhood cancer treated with bone marrow transplantation are at particularly high risk of metabolic abnormalities such as greater prevalence of diabetes and increased risk of hypertension (Baker et al. 2007). There was a greater risk for diabetes in those who had undergone total body irradiation in their treatment regimen suggesting an increased insulin resistance.

59.3.1 Obesity

Childhood cancer survivors are at increased risk if obesity and the evidence for the increased prevalence is complex given the variations of the different cancer diseases, treatments and outcomes, and small sample sizes. In clinical routine practice, obesity is most defined using BMI (body mass index). However, in research more direct measures of body fat may be more preferable. Frequently used methods of body composition are dual-energy X-ray absorptiometry (DEXA) and bioelectrical impedance measurements (BIA). These methods subdivide body composition into two compartments: fat mass and fat-free mass. Survivors of ALL and of tumors in the pituitary-hypothalamic area are at greatest risk for obesity (more details in Chap. 13). The obesity is a major cause for concern as the survivors also have an increased risk of cardiovascular, metabolic, pituitary, and psychosocial sequelae. Cranial radiotherapy can cause CNS damage (in particular hypothalamic) (Lustig et al. 2003). This may promote obesity via a number of possible mechanisms: growth hormone deficiency, leptin resistance or hypothalamic regulation of food intake, and energy expenditure. Growth hormone deficiency has been shown to be associated with obesity (Carroll et al. 1998) and CCS treated with CRT are known to be GHD. In addition, a

study of 1765 adult survivors of ALL has shown that those who received CRT had an increased risk of obesity, and this risk was greatest for girls treated under the age of 4 years (Oeffinger et al. 2003). This may be related to the effect of CRT on GH secretion and also producing earlier onset of puberty and reduced final height. CNS-directed therapy contributes to the obesity in CCS, but it is not the only determinant of obesity. ALL survivors who did not receive CRT and only treated with chemotherapy are at increased risk of weight gain (Reilly et al. 2000). However, ALL survivors have also received attention reporting evidence for disturbances of energy balance including obesity (Oeffinger et al. 2003). Reduced physical activity has been suggested as one major cause of obesity in ALL survivors. The reasons for reduced physical activity could be motor impairments, musculoskeletal pathology, impairments of exercise capacity. Further, total energy expenditure studies have reported abnormalities in energy balance in ALL survivors (Warner et al. 1998). Identify survivors at particularly high risk of obesity is important as they can be prioritized for interventions such as prevention with healthy lifestyle and physical activity, including treatment of obesity or metabolic risk reduction. Thus, young age at diagnosis and gender (female) are associated with increased risk of obesity. In a large cohort of children with brain tumors, the authors identified risk factors for the development of obesity. These risk factors included, younger age at diagnosis, radiation dose range of 51–72 Gy to the hypothalamus, the presence of endocrinopathy, and location of the tumor at hypothalamus, in particular craniopharyngioma (Lustig et al. 2003). The main consequences of obesity after childhood cancer are presence of cardiovascular risk factors, increased risk of diabetes, increased risk of fatty liver, low health-related quality of life, and lower self-esteem.

59.4 Bone Health

Patients treated for childhood cancer have been exposed to multiple influences that may adversely affect bone health. These include the disease itself, radiotherapy, chemotherapy, poor nutrition, and low physical activity. Some treatments have direct deleterious effects on bone, and some have more indirect effects mediated through endocrine abnormalities. The earlier treatment protocols that included CRT in ALL survivors may result in GHD and low bone mineral density (BMD) in lumbar spine and femoral neck (Follin et al. 2011; Nussey et al. 1991). The risk for fractures, which is the most important outcome in clinical practice, after long-term follow-up is unknown. Another relevant outcome measure is BMD, but this is only a surrogate marker for fracture risk. BMD may be difficult to analyze in CCS who have impaired growth and reduced final height, which may have an impact on bone size. The reported risk factors for low BMD include high dose methotrexate, cumulative doses of glucocorticoids, male gender, and low physical activity. Any combination of these factors may result in osteopenia, not reaching optimal peak bone mass and osteoporosis later in life.

59.4.1 Radiation Damage and Bone Health

Spinal radiotherapy can cause direct damage to vertebrae, and sometimes it takes months or years to become a problem for the survivors. Spinal RT is excluded in most modern treatment protocols, but still craniospinal irradiation is used for certain tumors such as medulloblastomas.

CRT may cause decreased longitudinal bone growth and bone mass, suggesting an effect of pituitary insufficiency and in particular GHD. GH plays a key role in the longitudinal bone growth and the attainment of peak bone mass. A number of cross-sectional studies on BMD after childhood ALL confirm that CRT is a risk factor for low BMD, especially in the lumbar spine (Follin et al. 2011; Gilsanz et al. 1990). A few studies have linked GH status after CRT to BMD and report that survivors with untreated GHD had low BMD in the lumbar spine and femoral neck compared to survivors treated with GH (Follin et al.

2011; Nussey et al. 1991). Further, it has been shown that both GH and IGF-I stimulate osteoblasts resulting in bone formation, but also bone resorption (Ohlsson et al. 1998). Survivors of childhood brain tumors who received CRT and were followed for median 15 years showed that whole body and lumbar spine BMD were lower compared to survivors without CRT (Odame et al. 2006). The negative effect of GHD on BMD can be prevented by treating the survivors with GH, including continuing the treatment into adulthood when peak bone mass is attained (Follin et al. 2011; Nussey et al. 1991). Another effect of insufficient pituitary hormone secretion may be TSH and LH/FSH deficiency which may play a role in some survivors. Thyroid hormone is a major regulator of normal skeletal development and growth before puberty. Untreated primary hypothyroidism, which may occur after neck irradiation as in Hodgkin's lymphoma, may cause bone loss (Sklar et al. 2001). Further, sex steroids are required to achieve a normal growth during puberty and estrogen is necessary to maintain bone health in both genders. In men, testosterone is converted to estrogen which aids normal bone mineral accretion and survivors who are deficient in estrogen or testosterone may develop osteoporosis. Testicular radiotherapy, as in the treatment protocol for ALL with testicular relapse, is related to a high risk of Leydig cell dysfunction with a need of androgen substitution among these survivors. In women, abdominal, pelvic, or spinal irradiation may cause primary ovarian failure and estrogen deficiency.

59.5 Fertility

Infertility in childhood cancer survivors is a potential complication dependent on the treatment during childhood, but also the underlying disease. Gonadal injury is a well-established consequence of cytotoxic chemotherapy and radiotherapy. However, predicting the likelihood of gonadal dysfunction in the individual survivor may be a difficult task. In general, females seem less sensitive to the adverse effects of chemotherapy compared to males. Measuring the gonadotropins and testosterone in pre-pubertal male survivors will not be informative. On the other hand, assessment of growth and puberty is of importance and the presence of secondary sexual characteristics will give information on testosterone production. In females, the normal ovarian function based on the resumption of regular menses after therapy and normal hormone levels does not exclude damage to the ovaries. However, the absence of regular menses does not mean that the survivors will be infertile (Wallace et al. 2005). Women treated with radiotherapy affecting ovarian and uterine function are at high risk of acute ovarian failure, premature menopause, complications including spontaneous abortion and preterm labor. These data are important for family planning and obstetrical management.

59.5.1 Male Fertility

Radiotherapy to the gonads, total body irradiation and high dose chemotherapy, may result in a number of effects on the male reproductive system in long-term survivors. These include direct damage to the gonads and also indirect damage to hypothalamus-pituitary axis. Damage on germ, Sertoli or Leydig cells may result in reduced gonadal function. Impaired germ cells will interfere with spermatogenesis and damage on the supporting Sertoli cells will indirectly affect germ cells and hence spermatogenesis. Recovery of spermatogenesis and sperm production may occur several years after treatment. Effects on Leydig cells may result in failure to produce testosterone, important for initiation of spermatogenesis and the development of secondary sexual characteristics (Meistrich et al. 1992). Male survivors who become azoospermic by cancer treatment have increased FSH and lower inhibin B, including a decrease in testis weight or sperm count, than those who are non-azoospermic. However, survivors treated pre-pubertally may develop secondary sexual characteristics normally despite the fact that

there may be effects on the spermatogenesis. The effect of radiotherapy depends on the dose, target organ, and number of fractions. Radiotherapy of <20 Gy may damage the seminiferous epithelium, affecting spermatogonia leading to oligozoospermia (Wallace and Thomson 2003). Higher doses of >20 Gy may affect the Leydig cells which results in reduced serum testosterone levels and high serum gonadotropins. This is supported by research in survivors of Hodgkin's lymphoma reporting reduced testicular volume including increased FSH levels in these survivors, suggesting damage to the seminiferous epithelium (Pont and Albrecht 1997). Direct radiotherapy to the testis may cause damage to germ cells resulting in permanent azoospermia (Wallace and Thomson 2003). After treatment with fractionated radiotherapy gonadal recovery has been reported in less than 20% of the survivors (Socie et al. 2003).

Chemotherapy has a negative effect on the fertility and the most gonadotoxic agents are procarbazine and alkylating agents such as cyclophosphamide. The damage depends on the dose and the frequency of the administration. Survivors of Hodgkin's lymphoma and Ewing's sarcoma receiving cumulative doses of cisplatin >400 mg/m^2 have an increased risk of impaired spermatogenic function (Pont and Albrecht 1997). ALL survivors and brain tumor survivors treated with surgery only are at low risk of infertility, which means <20%. Brain tumor survivors treated with CRT > 24 Gy and neuroblastoma survivors are at medium risk and of high risk treatment (>80%), which includes total body irradiation or treatment with alkylating agents, are Hodgkin's lymphoma and Ewing's sarcoma.

59.5.2 Female Fertility

A successful pregnancy requires a fully functional hypothalamic-pituitary-ovarian axis, including a uterus capable of growing with the developing fetus to the birth. Childhood cancer treatment may result in fertility defects such as hypothalamic-pituitary insufficiency leading to arrested puberty and primary amenorrhea. If damage occurs after puberty, the survivor will have an increased risk of secondary amenorrhea. Damage direct to the ovaries will result in reduction of the primordial follicles, leading to infertility or premature menopause. The biological ovarian age in childhood cancer survivors is approximately 10 years ahead of their chronological age. Any occurrence of ovarian failure before age 40 is classified as premature menopause and a substantial proportion of the survivors experience premature menopause (Larsen et al. 2003). The negative effects on cancer treatment on female fertility may be mediated through the hypothalamic-pituitary axis, the ovary or the uterus. Radiotherapy is well-known to act on all three of these systems, but direct effects of chemotherapy on the hypothalamic-pituitary axis and the uterus have not been reported. Brain tumor and ALL survivors treated with cranial radiotherapy >24 Gy have an increased risk of delayed puberty or secondary amenorrhea in girls. However, lower doses are associated with early puberty or precocious puberty (Critchley et al. 2002). Livesey et al. (1990) showed that girls who had been treated with craniospinal irradiation developed high gonadotropins suggesting an ovarian dysfunction. Radiotherapy may affect the volume, vascularization, and endometrial thickness of the uterine characteristics, and the degree depends of the radiation dose and the site of the irradiation. The pre-pubertal uterus is more sensitive to irradiation as the development of the uterus is not completed before the onset of puberty. Pelvic irradiation of 20–30 Gy results in impaired uterine development including reduced volume and vascularization (Critchley et al. 2002). Lower doses of radiotherapy, e.g., total body irradiation, also cause reduced uterine volume, impaired blood flow, and absent endometrium and are associated with adverse pregnancy outcome in female survivors. Evidence shows that children of CCS are not at higher risk of congenital abnormalities compared to children of parents without a history of childhood cancer (Edgar and Wallace 2007).

Nevertheless, it has been reported that childhood cancer survivors worry about their fertility and the health of their offspring and that female survivors worry more than the male survivors (Zebrack et al. 2004). Thus, proper scientific information to the survivors is mandatory and can possibly reduce fertility-related anxieties. In addition, some survivors have concerns about their ability to be a good parent, but the survivors also report that their cancer experience as making them better parents.

59.6 Follow-up and Nursing Perspectives

Because of the steady increase in long-term survival rates after childhood cancer, health care professionals caring for CCS should be aware of the unique health risks resulting from the cancer experience. The survivors need to receive appropriate health surveillance and interventions to reduce morbidity and mortality. Further, offering understanding and support with a holistic approach, rather than merely focusing on living with complications, may be a way in which to strengthen the survivors' healthiness. Work, together with the survivors, towards independence for them. Key elements of independence are individual autonomy, be actively involved in decision-making and access to physical and social environment. Offer support in the survivors decision-making by asking "what do you want to do" instead of telling the survivors what they should do. Many CCS experience their daily lives as a struggle and as a complicated issue to cope with. It has been reported that an understanding of the survivors' situation, as well as support for managing daily life is fundamental for the survivors. They also report a lack of understanding and support from the community, and this was connected with a fear for the future. The follow-up of late complications has been shown to be crucial for increasing the survivors' understanding of complications after surviving cancer and they experienced increased self-confidence (Pålsson et al. 2017).

CRT and total body irradiation may cause pituitary insufficiency, primary hypothyroidism, or gonadal insufficiency. Although GHD is the most common deficiency after CRT, it is not always easy to diagnose. A careful follow-up with a combination of growth monitoring through childhood and puberty, regular monitoring of IGF-1 levels and proper stimulation tests for GH are required in these survivors. Long-term monitoring of pituitary hormones including attention to symptoms of pituitary insufficiency is also required in survivors who have been treated with CRT. The health care professionals should be aware of that impaired hormone secretion may occur many years after treatment and hormone substitution can be necessary. In survivors of Hodgkin's lymphoma who have received neck irradiation long-term follow-up of free T4 and TSH is mandatory as they have an increased risk of hypothyroidism.

Survivors of childhood cancer exposed to CRT are at high metabolic risk and increased risk of cardiovascular diseases later in life. Risk factors for these complications include obesity, physical inactivity, lipid abnormalities, and insulin resistance. Reduced physical activity is one major cause of obesity in survivors. It is important to identify survivors at high risk of obesity as they should be prioritized for multidisciplinary interventions such as prevention with healthy lifestyle and physical activity, including treatment of obesity or metabolic risk reduction. The risk for osteopenia or osteoporosis also makes the recommendations of physical activity to the survivors of utmost importance. Weight-bearing activities, such as walking, running, tennis playing, or dancing, causes new bone tissue form and this makes the bones stronger. Monitoring the female survivors at regular intervals after the completion of treatment is of importance. Fertility-related concerns are a major source of distress in many young female survivors and proper information about the facts that the risk of congenital abnormalities are not increased compared to the general population (Fig. 59.3).

- Provide the survivors with a comprehensive treatment summary, a survivorship care plan, which provides information about potential cancer-related health risks.
- Evaluate all aspects of the survivors health status to be able to offer an appropriate plan for lifelong screening, surveillance, and prevention.
- Offer support to strengthen the survivors' healthiness by not focusing on living with complications.
- Plan together with the survivors to work towards an independent life and to be able to manage daily life.
- Ensure long-term monitoring of pituitary hormones including attention to symptoms of pituitary insufficiency.
- Coordinate a careful follow up with a combination of growth monitoring through childhood and puberty, regular monitoring of IGF-1 levels, proper stimulation tests for GH.
- Be aware of that impaired hormone secretion may occur many years after treatment.
- Identify the survivors risk for metabolic complications such as obesity, physical inactivity, lipid abnormalities and insulin resistance.
- Facilitate multidisciplinary interventions such as prevention with healthy lifestyle and physical activity, including treatment of obesity or metabolic risk reduction.
- Act as a key worker and facilitate the contact with the oncologist, endocrinologist, dietician, physiotherapist, psychologist and primary care. Ensure continuity and safety.

Fig. 59.3 Nursing process in the care of childhood cancer survivors

59.7 Conclusions

Detailed information about the past cancer treatment are needed to estimate health risks associated with childhood cancer. Ideally, the childhood cancer survivors will be provided with a comprehensive treatment summary, a survivorship care plan, which provides information about potential cancer-related health risks and health surveillance recommendations, including a systematic plan for lifelong screening, surveillance, and prevention.

CCS exposed to CRT are at particularly high risk for long-term morbidity, such as endocrine insufficiencies, metabolic complications, and cardiovascular morbidity. New endocrinopathies can develop decades following cancer treatment, and lifelong surveillance is mandatory. There is evidence for a strong correlation between the total radiation dose and the development of pituitary deficits. Further, age at treatment and also time since treatment have strong implications on pituitary hormone deficiencies. There is evidence that the hypothalamus is more radiosensitive than the pituitary. Survivors of ALL and of tumors in the pituitary-hypothalamic area are at greatest risk for obesity. The obesity may be promoted via a number of possible mechanisms: growth hormone deficiency, leptin resistance or hypothalamic regulation of food intake, and energy expenditure. Young age at diagnosis and gender (female) are associated with increased risk of obesity. The main consequences of obesity after childhood cancer are presence of cardiovascular risk factors, increased risk of diabetes, increased

risk of fatty liver, low health-related quality of life, and lower self-esteem.

Risk factors for low BMD include high dose methotrexate, cumulative doses of glucocorticoids, male gender, and low physical activity. Any combination of these factors may result in osteopenia, not reaching optimal peak bone mass and osteoporosis later in life. CRT may cause decreased longitudinal bone growth and bone mass, suggesting an effect of pituitary insufficiency and in particular GHD. GH plays a key role in the longitudinal bone growth and the attainment of peak bone mass.

Infertility is an important potential consequence of treatment for childhood cancer and identification of survivors for whom strategies to preserve fertility are required. Women treated with radiotherapy affecting ovarian and uterine function are at high risk of acute ovarian failure, premature menopause, complications including spontaneous abortion and preterm labor. These data are important for family planning and obstetrical management. Radiotherapy to the gonads, total body irradiation, and high dose chemotherapy may result in a number of effects on the male reproductive system in survivors. These include direct damage to the gonads and also indirect damage to hypothalamus-pituitary axis. Recovery of spermatogenesis and sperm production may occur several years after treatment.

Abstract

Childhood cancer is a life-threatening disease and has a major impact on patient and family. Diagnosis is followed by intense treatment putting patients at high risk for late adverse outcomes, including neurocognitive deficits and psychosocial problems, such as psychological distress, post-traumatic stress disorder (PTSD), fatigue, low educational achievement, and unemployment. Psychosocial health in childhood cancer survivors is often interrelated; psychological distress expressed as low mood, depression, and anxiety are associated with insufficient sleep, poor sleep quality and fatigue, as well as with lack of employment and low income. Survivors of central nervous system (CNS) tumors and those who received cranial radiation are at particular high risk for any of these problems, but also women and

children who were diagnosed at a younger age. Preventive measures during cancer treatment are important. But also continued support and if necessary treatment during the whole cancer trajectory and into long-term follow-up of adult is necessary to reduce problems and improve quality of survivorship.

Keywords
Radiation therapy · Neuropsychological testing · Neurotoxicity · Depression Anxiety · Fatigue · Follow-up care

Abbreviations

ADHA	Attention deficit/hyperactivity disorder
ALL	Acute lymphoblastic leukemia
CCSS	Childhood Cancer Survivor Study
CNS	Central nervous system
CRP	Cognitive Remediation Program
CSF	Cerebrospinal fluid
DNA	Deoxyribonucleic acid
ENT	Ear, nose, throat
MRI	Magnetic resonance imaging
PTSD	Post-traumatic stress disorder
PTSS	Post-traumatic stress symptoms

Key Terms

- **Neurocognitive dysfunction:** changes in cognitive function after a brain insult, particularly in the presence of physical evidence of structural brain changes.
- **Neuroprotective agents**: agents designed to protect the brain from the toxic effects of chemical and imaging treatments.
- **Neuropsychological deficits**: achievement of scores below that of a normative reference standard on psychological testing.

Key Points

- Neurocognitive dysfunction are very common in childhood cancer survivors and highest in CNS tumor survivors.
- Effective interventions to decrease or prevent neurocognitive dysfunctions are under investigation.
- Survivors of childhood cancer are at high risk for psychological distress, post-traumatic stress symptoms, and fatigue.
- Survivors of CNS tumors are at particularly high risk of low educational achievement and unemployment.
- Psychosocial support during treatment and in long-term follow-up should help mitigating these problems.

60.1 Introduction

Cancer in childhood is a very severe and often life-threatening disease, and today it remains the second most common cause of death in children in developed countries. The diagnosis of cancer is usually followed by intense treatment including chemotherapy and/or radiotherapy. Depending on the cancer type, children might have to attend treatment for several years, which has a major impact on their life including family, friends, and school. However, long-term survival of children with cancer has increased over recent decades due to important advances in diagnostics and treatment as well as managing acute and long-term side effects. Accordingly, attention has turned to the quality of survivorship for the increasing population of childhood cancer survivors. Cancer and treatment leave children at a high risk for late adverse outcomes (late effects), such as cardiovascular, pulmonary or endocrine problems, second cancer, but also neurocognitive and psychosocial problems. In this chapter, we are going to summarize long-term neurocognitive and psychosocial consequences of cancer in childhood.

60.2 Neurocognitive Dysfunction

Neuropsychological deficits are unfortunately common, especially within the subgroup of central nervous system (CNS) tumors. Up to 40% of survivors, or even more in survivors of CNS tumors, demonstrate neurocognitive dysfunction (Zeltzer et al. 2009). They often demonstrate some form of deficit either on presenting history/school perfor-

mance or on formal psychological testing, varying from mild learning difficulties to severe impairment (Janzen et al. 2015). One study has shown that around 25% of childhood cancer survivors qualified for special education in school (Ullrich and Embry 2012). Newer findings have estimated that around 40–50% of acute lymphoblastic leukemia survivors and around 70–80% of CNS tumor survivors will require special education services at some point through their school career (Ullrich and Embry 2012). The neurocognitive difficulties persist over time or even increase over time and become more obvious once independent employment should be initiated and established. In adulthood, pediatric CNS tumor survivors report the poorest health-related quality of life among childhood cancer survivors, secondary to neuropsychological and other treatment-related late effects (Zeltzer et al. 2009). Because neuropsychological deficits significantly impact the quality of life, psychosocial functioning, educational attainment, and employment status of childhood cancer survivors, there is urgent need to identify and minimize these deficits in order to optimize functional outcome.

Neuropsychological outcomes for individual childhood cancer survivors are highly variable and depend on multiple, interrelated disease- and treatment-related variables, including age at diagnosis, characteristics of the tumor or metastasis (location within the CNS), required surgical interventions and adjuvant therapy, especially any CNS directed therapy like cranial irradiation or intrathecal chemotherapy. Neuropsychological effects are moderated by the child's individual characteristics gender, pre-morbid functioning and genetics as well as environmental factors. The last two mentioned are still not fully understood and under further investigation. Further, as the mechanisms of treatment-related neurotoxicity have been partially understood, the potential for risk-adapted treatments, neuroprotective agents, and strategies for neuronal repair have emerged, which could substantially reduce morbidity.

Different study groups worldwide have developed guidelines for the identification and intervention of neurocognitive dysfunction in childhood cancer survivors (Nathan et al. 2007). Questionnaires for childhood cancer survivors have been developed to assess neurocognitive functioning (Phillips et al. 2015). Childhood Cancer Survivor Study (CCSS) Neurocognitive questionnaire, a large number of childhood cancer survivors in the aftercare setting have been assessed.

Given the importance of the topic in many of the newer treatment protocols especially for CNS tumors minimizing neurotoxicity is one of the main aims. Tools and investigations for neurocognitive dysfunction measurements are implemented either throughout treatment or after completion of treatment and being in aftercare (Noll et al. 2013).

There is considerable heterogeneity in individual neuropsychological outcomes for childhood cancer survivors given the variety of tumor types and treatments as well as associated time and individual factors. So no single neuropsychological phenotype exits, but many different types varying from no deficits over mild learning or attention deficits to severe limitations in intelligence and adaptive functioning which restrict independent living (Janzen et al. 2015). Overall attention problems are particularly prevalent in the group of leukemia and CNS tumor survivors (Zeltzer et al. 2009).

In the early beginning of neuropsychological testing, general measures of intelligence were tested to predict academic performance. Today, multiple core functions are measured including attention, processing speed, working memory, psychomotor skills and new learning, underlying the ability to learn efficiently and retain information. As the testing is time consuming and requires a patient in good condition the timing of the testing is important. Initial testing—meaning at time of diagnosis—is impossible as the patient is too sick and will require immediate medical attention. So in general the first baseline testing happens quite some time after the initial diagnosis and is already biased by the underlying disease as well as the initiated treatment. Childhood cancer survivors will require multiple testing through their medical journey matching time points of therapeutic interventions as well as academic development, e.g., starting high school, college, or university.

Overall neuropsychological effects appear to be cumulative regardless of the treatment used. Executive functioning impairment has been reported in up to 14% of adult childhood cancer survivors (Zeltzer et al. 2009). Age at diagnosis is a significant predictor of outcome given that brain

structure is injured in the maturation phase. The younger the child at diagnosis is the greater the risk of severe neuropsychological impairment.

60.2.1 Tumor Characteristics

Childhood cancer with CNS location either as primary CNS tumors or metastasis like in leukemias/lymphomas or solid tumors will have a direct impact on the neuropsychological outcome as brain structure is damaged or destroyed. There is an extensive body of literature on neurocognitive dysfunction for survivors of ALL as well as CNS tumors. Special risk factors for children with ALL are cranial radiation therapy, intravenous and intrathecal methotrexate, corticosteroids, and female gender. Main risk factors in CNS tumor patients are cranial radiation therapy, tumor invasion of normal brain, trauma from surgical resection, hydrocephalus, and seizures (Butler and Mulhern 2005). Hydrocephalus as result of a blocked cerebrospinal fluid flow has shown to be a strong predictor of long-term neuropsychological deficits especially the longer the hydrocephalus has been present, e.g., in low grade gliomas of the posterior fossa. Other tumor entities with an increased risk of neurocognitive impairment are acute myelogenous leukemia, non-Hodgkin lymphoma, or tumors of the head and neck undergoing radiation therapy (Nathan et al. 2007).

60.2.2 Treatments

Surgery: Any surgical intervention to the brain is adding an additional risk factor for neuropsychological sequelae. The brain becomes more vulnerable as the blood–brain barrier is damaged.

Postsurgical complications like infection or cerebellar mutism syndrome are adding a further damage. Cerebellar mutism syndrome is a postsurgical complication in around 2.5% of all posterior fossa surgeries. The syndrome is characterized by diminished or absent speech, dysarthria, and linguistic difficulties. It is often accompanied by ataxia, muscular hypotonia, and emotional lability (Janzen et al. 2015). The underlying pathomechanism is not fully understood, and so far no specific treatment has been established. Children who develop this syndrome show significantly lower performance on measures of processing speed, attention, working memory, executive processes, and academic performance which persists over time.

Radiation: Over the past decades, radiation therapy has been identified as the most significant risk factor for long-term neuropsychological deficits. Higher dose (≥3500 cGy) and volume of radiation therapy associated with poorer outcomes, particularly in young children. Due to these facts radiation therapy has been postponed—whenever possible given the underlying disease—until the age of 3 or 4 years or even older. Doses as well as volume were decreased due to newer radiation techniques, but even children with an underlying leukemia receiving cranial low dose radiation of 1200 or 1800 cGy showed neuropsychological deficits. Proton therapy with maximal radiation dose to the tumor and minimal to no dose to the surrounding tissue is now used in children for many tumors whenever a proton facility is available, but so far no long-term data on neuropsychological outcomes exits.

Lots of data has been collected on intellectual decline following whole brain radiation therapy. Losses of 25–30 full-scale IQ points are not uncommon, and the majority of children treated with cranial radiation prior to 7 years of age require special education (Janzen et al. 2015).

Radiation therapy disrupts the protracted process of myelination within the brain, which normally begins prenatally and continues through childhood and adolescence. The resulting white-matter damage is directly related to the nature and severity of neuropsychological impairment.

Chemotherapy: Given the function of the blood–brain barrier, the brain should be protected against most of the chemotherapeutic agents because not many of them can penetrate into the cerebrospinal fluid (CSF) or the brain tissue. But the blood–brain barrier is damaged in primary CNS tumors. A large body of literature exits on the neuropsychological effects of methotrexate from ALL treatment. However, the effect should not be seen in isolation, but in combination with other chemotherapeutic drugs or irradiation.

Glucocorticoid steroids (e.g., prednisone and dexamethasone) are widely used in the treatment of leukemias and lymphomas but also as a potent antiemetic. They are directly associated with acute neurobehavioral difficulties in children and long-term

memory difficulties. Platinum-based chemotherapy is associated with a high risk of hearing loss, vinca alkaloids are associated with peripheral neuropathy resulting in reduced fine motor skills. High dose cytarabine is associated with acute neurotoxicity typically demonstrating in cerebellar dysfunction.

Stem cell transplantation: Given that conditioning treatments for stem cell transplantation are often using similar chemotherapeutic drugs but in higher dosing as well as total body irradiation neurocognitive impairment can be worsened, but has to be seen in combination with the previous treatment as well as the underlying disease. In some clinical studies for brain tumors in young children, high dose chemotherapy and autologous stem cell transplantation are used instead of cranial irradiation, and the neurocognitive outcome seems to be better, but long-term outcome data still have to confirm these preliminary findings.

60.2.3 Mechanism of Neurocognitive Damage

Chemotherapy and radiotherapy are causing mainly white-matter damage especially cortical and subcortical. This results in demyelination and glial cell destruction. This damage can be visualized by specific magnetic resonance imaging sequences (Nathan et al. 2007). Multiple animal models have been established to study the damage mode and to test possible interventions.

Another pathomechanism for radiation damage may be explained by disruption of the microvascular system supplying blood to the brain. This results in calcification of fiber tracts and restriction of blood supply to certain parts of the brain (Nathan et al. 2007).

60.2.4 Moderators: Individual, Genetic and Environmental Variables

The neuropsychological outcome is also influenced by individual factors. Age at the time of diagnosis is a well-established predictor; younger age at diagnosis is correlated with a poorer neuropsychological outcome.

Gender is another individual risk factor. Girls seem to have greater treatment-related neuropsychological impairment than boys, the reason is not quite clear yet.

The neurocognitive outcome is also influenced by the pre-morbid level of functioning. This level is difficult to record as normally formal testing at diagnosis is impossible due to the poor health condition of the child. Indirect assessment of the level is only possible through information of the previous academic performance, but this is dependent on the age of the child at diagnosis as well as the potential diagnostic delay.

Preexisting neurological or developmental conditions such as neurofibromatosis type 1 are an additional risk factor for neurocognitive deficits. Such conditions need to be identified prior to initiation of therapy as in this case treatment modifications (e.g., no radiation therapy) have to be put in place.

Identification of genetic risk factors mainly genetic polymorphisms is in its early stage, but will potentially play a significant role within the next years. In the current focus are enzymes like glutathione S-transferase or enzymes in the folate metabolism pathway that are involved in chemotherapy metabolism and clearance (Nathan et al. 2007).

Genetic polymorphism testing for ototoxicity due to platinum-based chemotherapy or peripheral neurotoxicity due to vinca alkaloid toxicity will hopefully be implemented within the next decade and could dictate individual chemotherapeutic drug dosing.

Family functioning around and after diagnosis can also influence the severity of neurocognitive outcomes as with more support and resources more modified interventions can be put in place. Stress and family conflict can have a negative impact on neurocognitive outcomes (Ullrich and Embry 2012).

Socioeconomic status of the family has been shown to be an important environmental factor. Lower socioeconomic status was associated with greater neurocognitive decline in survivors of ALL and can also impact the outcome in CNS tumor survivors (Ullrich and Embry 2012).

60.2.5 Interventions

Comprehensive neuropsychological evaluations over time are strongly recommended for all child-

hood cancer survivors and are nowadays implemented in many treatment protocols. The treatment centers need to provide the resources in form of qualified personell as well as space and testing tools. Enough time needs to be allocated for discussing the test results with the patient and the caregiver and with professionals involved in possible interventions, e.g., teachers. Especially for this task, counselor-liaison professionals can help with educational planning, advocacy, and coordination of school reentry as they will attend meetings in the clinic as well as in the community (Butler et al. 2008b).

Support in the classroom can help in many areas, e.g., problems with fine motor skills such as handwriting or the use of a computer, problems with slow processing speed such as needing additional time to complete the task or attention problems asking for extra tutoring assistance. Unfortunately as there is clearly a lack of resources and support, parents have to be strong advocates for their children to fulfill their educational and social needs and enhance the knowledge about neuropsychological late effects. Continued career counseling beyond definitive employment is required.

Comorbidities from the disease and treatment like seizures, visual or hearing impairment, and endocrinopathies should be identified and treated as they are co-factors for a worse neurocognitive outcome. Close collaboration with colleagues from neuropediatrics, ophthalmology, endocrinology, and ENT is essential.

Many interventions at different time points (early/during active treatment vs. late/aftercare period) have been developed and tested over the last years. Cognitive Remediation Program (CRP) combines attention training, special education strategies and aspects of cognitive-behavioral therapy. It is a time intense program with moderate intervention-related benefits so far (Butler et al. 2008a).

As attention deficits are prevalent, medication which is used in children with attention deficit/hyperactivity disorder (ADHD) has been tested as stimulants in childhood cancer survivors. So far methylphenidate (Ritalin) has shown some improvement in attention/concentration and neurocognitive side effects, but overall there are quite a few limitations (Butler et al. 2008b). Stimulant medication is only short acting, but improvement after discontinuation of the medication cannot be expected. Secondarily, stimulant medication should not add severe long-term side effects, but long-term safety data on stimulant medication is incomplete so far.

Another promising pharmacological intervention has been run with modafenil in CNS tumor patients from the Children's Oncology Group following completion of multimodal treatment. The medication has been tested over a 6 weeks period and will compare side effects, cognitive function, and fatigue with this alternative stimulant (Noll et al. 2013).

But in summary as pharmacological interventions in this heavily pre-treated group could add potentially severe side effects due to changes in the metabolism pathway (pharmacokinetics), non-medication and feasible home-based interventions have been developed. A computerized cognitive training called Cogmed system was found to be feasible and acceptable to be implemented within the areas of attention deficit and working memory issues. With regular training, improvements in visual working memory can be maintained (Hardy et al. 2013). Again the Children's Oncology Group has run a pilot study in CNS tumor patients receiving cranial radiation using a home-based, computerized cognitive training program.

Results from different regular exercise intervention studies have also shown a positive effect on neurocognitive deficits similar to results on people with dementia. The underlying idea is to promote cell recovery by stimulation of the proliferation and/or differentiation of endogenous stem cells or progenitors. Limitation of a regular exercise intervention is often the severe physical handicaps of the childhood cancer survivors, especially following treatment for a CNS or bone tumor.

Another intervention taking place either during or early after treatment is a specialized rehabilitation in a clinical setting. Children and their parents (depending on the age of the child) are benefiting from a variety of different rehabilitation services, e.g., physiotherapy, occupational therapy, dietician, teacher, psychologist, sports, arts as well as counseling sessions about coping strategies within peer groups. Germany, for example, has quite a few of these specialized rehabilitation clinics and many childhood cancer patients and their parents benefit from such a 4-week intervention.

60.2.6 Future Directions

Whereas currently all interventions are based on already existing deficits, preventative measurements should take place in the near future. Neuropsychological testing needs to be standardized with regard to the tool for different age groups as well as the evaluation points. Assessment should be done computerized as often as possible. Especially in CNS tumor patients, neurocognitive sequelae are part of the neurosurgical planning. Maximum extent of tumor resection should go hand in hand with preserved neurological function. Specific MRI sequences as well as intraoperative monitoring can help facilitating this goal. Endoscopic biopsies have become more and more standard compared to an open biopsy to minimize damage to the normal brain structure.

With the newer and widely available techniques, tumors can be better characterized on a molecular level and treatment can be individualized and risk adapted, so potentially no CNS irradiation therapy is needed or can be delayed as much as possible. As an example in ALL, intrathecal chemotherapy has replaced cranial irradiation for almost all risk groups. The newest radiation technique should be used whenever possible including proton beam therapy. Combination of neurotoxic chemotherapy and radiation therapy should be avoided if tumor biology permits this.

Neuroprotective agents are also under investigation with the idea to prevent neurotoxicity from healthy brain tissue by enhancing DNA repair and reducing cell death and neuroinflammation. Ideally, such an agent would be given prior to any irradiation or chemotherapy. Under discussion as neuroprotective agents are some vitamins or even erythropoietin which needs to be tested first in an animal model.

60.3 Psychosocial Issues

The diagnosis of childhood cancer has a major impact on the child, the family, and the social environment. Intense treatment often prevents patients from participating in ordinary daily life such as attending school and playing with friends. Later on, medical late effects can affect survivors' life and impact their emotional experience and their social life. We will therefore address four areas in which childhood cancer was shown to have a major impact on survivors' life:

- Psychological distress, such as depression, or anxiety
- Post-traumatic stress symptoms (PTSS) and post-traumatic stress disorder (PTSD)
- Fatigue
- Social problems, education and employment

Although we address these four topics separately, it is important to keep in mind that psychosocial health in childhood cancer survivors is often interrelated: psychological distress expressed as low mood, depression, and anxiety was found to be associated with insufficient sleep, poor sleep quality, and fatigue (Walter et al. 2015; Mulrooney et al. 2008), as well as with lack of employment and low income (Gurney et al. 2009).

60.3.1 Psychological Distress

60.3.1.1 Description of the Problem

Psychological distress can be described as emotional suffering covering symptoms such as depression, anxiety, somatization, and impaired emotional well-being. Psychological distress may start during or early after treatment. Diagnosis of cancer is a highly stressful event; patients and their family may experience anxiety about the diagnosis, treatment, and expected outcomes, and once treatment is completed fear of cancer recurrence and/or late effects may continue. Depressive symptoms might occur because of pain, physical changes, late effects, or problems occurring with family, friends, in school or later on in employment.

60.3.1.2 Who Is at Risk

In general, most childhood cancer survivors fare well and most do not suffer from significant psychological distress (Lund et al. 2011; Michel

et al. 2010). However, several studies found a considerable number of survivors reporting psychological distress. In a Swiss study of adult survivors of childhood cancer, around 25% of survivors reported psychological distress compared to 10% expected in the general population (Michel et al. 2010). Particularly, survivors who had been diagnosed with a CNS tumor were found to be at increased risk for psychological distress (Lown et al. 2015; Lund et al. 2011; Michel et al. 2010). Similarly, treatment with cranial radiation was found to be associated with poor emotional health in adult survivors (Zeltzer et al. 2008) and with higher likelihood for depression and anxiety in school-aged survivors of childhood cancer (Lund et al. 2011). In addition, more survivors of ALL reported low psychological well-being, anxiety, and depression (Lown et al. 2015; Lund et al. 2011).

Similar to the general population, female survivors of childhood cancer were at higher risk for psychological distress (Lund et al. 2011, Michel et al. 2010). Additionally, survivors who reported other psychological problems were unemployed, had low income, or an immigration background were more likely to suffer from psychological distress (Gurney et al. 2009; Michel et al. 2010).

60.3.1.3 Development Over Time

So far, longitudinal studies are rare in the field of psychological distress after childhood cancer. One study in survivors of childhood ALL found a higher proportion of children at risk for anxiety and depression compared to the expected proportion in the general population in the time between 1 month and 3 years after completion of chemotherapy treatment (Kunin-Batson et al. 2016). However, the prevalence for clinically relevant anxiety and depression was not increased. While the risk for anxiety decreased within the first year after treatment, and increased again after 3 years, the prevalence of elevated depression was fairly consistent over time. Because children with increased scores in anxiety or depression are at higher risk for later distress, early detection, and effective interventions are important and necessary (Kunin-Batson et al. 2016).

60.3.2 Post-traumatic Stress Symptoms (PTSS) and Post-traumatic Stress Disorder (PTSD)

60.3.2.1 Description of the Problem

PTSS and PTSD are another important problem occurring after childhood cancer. PTSD is characterized by avoidance of situations associated with the trauma (e.g., going back to the hospital for follow-up appointments), intrusive thoughts or re-experience of symptoms (e.g., nightmares or a sense of reliving cancer-related events), and heightened arousal (e.g., insomnia or hypervigilance). For childhood cancer survivors lifetime prevalence of post-traumatic stress disorder ranged from 20 to 35% (Bruce 2006). The lifetime prevalence in parents of childhood cancer survivors was even higher ranging from 27 to 54%.

60.3.2.2 Who Is at Risk

Similar to other forms of psychological distress, female survivors were found to be at higher risk for PTSD (Bruce 2006). No associations with objective diagnosis or treatment factors were found; however, subjective perceptions of these, as well as current perceptions of cancer or life threat were risk factors for PTSD and PTSS (Bruce 2006). Additionally reduced social support, impaired family functioning and number of other stressful life events increased the risk for PTSD and PTSS (Bruce 2006). Generally, recent research indicates that stressful life events only constitute one part of the necessary prerequisites for the development of PTSD; a genetic vulnerability appears to be the other major player.

60.3.3 Fatigue

60.3.3.1 Description of the Problem

Sleep and the quality of sleep play a fundamental role in psychological health. Fatigue can be defined as an overwhelming feeling of tiredness coming along with lack of energy and a feeling of exhaustion, which is associated with impaired

physical and/or cognitive functioning. Cancer-related fatigue is a persistent, subjective sense of tiredness related to cancer or the treatment of cancer that interferes with the usual functioning. Although cancer-related fatigue and fatigue as late effects have been recognized as important problems in survivors of cancer in adulthood, the relevance has not yet been widely studied in survivors of childhood cancer.

Sleep problems are prevalent in cancer patients and include difficulties to fall asleep or staying asleep, poor sleep quality, and short sleep duration. In children with cancer, excessive daytime sleepiness is the most common symptom of sleep disorders and may lead to the manifestation of other sleep problems or anxiety or depression (Walter et al. 2015). Sleep problems during treatment have the potential to become chronic. They might continue and result in sleep problems and fatigue in adult survivors of childhood cancer (Walter et al. 2015); 15–30 years after diagnosis and treatment up to 19% of survivors suffer from fatigue (Mulrooney et al. 2008).

60.3.3.2 Who Is at Risk

Again, women were found to be more likely to suffer from fatigue, as were survivors who had been treated with radiotherapy (Mulrooney et al. 2008). Also survivors of ALL, CNS tumors, Hodgkin's lymphoma, soft tissue sarcoma, and bone tumors showed increased levels of fatigue (Mulrooney et al. 2008). Survivors who suffered from medical late effects such as lung fibrosis, congestive heart failure, who were depressed and those who were not married were also more likely to suffer from fatigue (Mulrooney et al. 2008). In turn, insufficient sleep or poor sleep quality was shown to impact mood and increase depression and anxiety (Walter et al. 2015).

60.3.4 Education and Employment

60.3.4.1 Description of the Problems

Many childhood cancer patients are confronted with the diagnosis during an important time of their education. Being away from school for repeated and sometimes longer periods of time may affect educational achievements later in life. Educational achievement but also cancer, treatment, and late effects might impact other social outcomes of survivors such as employment.

While finding employment appropriate to education and personal interest is an important goal for many, research has indicated that it might be even more important for survivors. Many survivors seek a career in health care in order to help others by using their own experiences (Brown et al. 2016). Others found that the self-image and sense of competence of survivors is often closely tied to their career and daily work experiences (de Boer et al. 2006). However, for many childhood cancer survivors it may be difficult obtaining a job if they suffer from late effects which limit their daily functioning.

Psychosocial late effects thus include lower educational attainment and higher use of special education programs compared to their siblings or the general population. Survivors are also less likely to reach high skilled, professional positions, or to work fulltime. They are at risk of receiving lower income and are also more likely to be unemployed (de Boer et al. 2006; Gurney et al. 2009; Lown et al. 2015).

60.3.4.2 Who Is at Risk

Most studies did not show lower educational outcomes for survivors of most cancer types. However, survivors of CNS tumors achieved significantly lower educational levels than other childhood cancer survivors and their siblings and peers (Lund et al. 2011). Many of these survivors were in need of special education programs (Gurney et al. 2009). They had a high risk to not graduate from college, remain unemployed, and have a lower income (Armstrong et al. 2009; de Boer et al. 2006). However, not all survivors of non-CNS tumors may easily and directly achieve a similar level of education and employment as their peers. Especially survivors of leukemia, non-Hodgkin's lymphoma, and neuroblastoma were found to be at greater risk for having educational problems (Gurney et al. 2009). However,

the use of special education programs mitigated the increased risk for not completing high school in most survivors (Gurney et al. 2009).

Cranial radiation therapy was most consistently found to be associated with poor psychosocial outcomes such as problems with education and employment; the risk was increased for being unemployed, repeating a school grade, not entering college, the attendance of special education programs and antisocial behavior, which may influence the course of education and employment as well (Gurney et al. 2009; Lund et al. 2011). Other risk factors related to the treatment include hematopoietic cell transplant (de Boer et al. 2006; Lown et al. 2015) and intrathecal therapy, which both were associated with poorer educational achievement and the attendance to special education programs (Gurney et al. 2009, Lund et al. 2011).

Female survivors were found to be less likely to achieve higher educational outcomes and being at higher risk for unemployment (de Boer et al. 2006; Lund et al. 2011). Younger age at diagnosis was found to be associated with lower intelligence, poorer educational achievement, and higher risk of unemployment; again this effect was especially pronounced in CNS tumor survivors (Gurney et al. 2009, Lund et al. 2011). Survivors with pre-morbid learning difficulties, emotional difficulties, low income or education, younger age at diagnosis (de Boer et al. 2006, Lown et al. 2015), and chronic medical conditions (Gurney et al. 2009) were at higher risk for low education and poor employment status.

Survivors suffering from more somatic health problems, including late effects due to cancer and its treatment, were found to be at risk for failing a grade, achieve lower educational levels, more likely to be unemployed, and report a lower income (Lund et al. 2011). Interestingly, the effects were smaller in Europe compared to the effects found in the United States and Canada (Lund et al. 2011). Also the risk for survivors of becoming unemployed was higher in the United States compared to Europe. Explanations may be higher job rejection rates for cancer survivors in the United States and Canada, and generally less discrimination regarding cancer and better access to medical care in Europe (de Boer et al. 2006, Lund et al. 2011).

Psychological distress such as depression and anxiety, as well as physical performance limitations were found to be associated with lack of employment and low income as well as other difficulties with expected adult social roles (Gurney et al. 2009).

60.4 Conclusions

Childhood cancer survivors are faced with a high risk of late effects, not only medical conditions but, as we have shown, also neurocognitive and psychosocial problems are common. To detect and treat these late adverse outcomes early regular follow-up is important. Follow-up care for childhood cancer survivors adapted to their age and including transition to adult care is still not established comprehensively. However, standards for follow-up care childhood cancer have been developed, including the recently published standards for psychosocial follow-up (Lown et al. 2015). In addition, guidelines are currently being developed within the International Guidelines Harmonization Group (www.ighg.org). These guidelines will provide specific recommendations on who needs what kind of screening and follow-up care, and in which frequency. These standards and guidelines will help to provide adequate care for patients and survivors in all phases of their cancer trajectory, starting at diagnosis and leading long into adulthood. In the future, neurocognitive and psychosocial problems in survivors should thus be reduced and quality of survivorship further improved.

Abstract

Hyponatraemia is common in the hospital settings. This is one of the endocrine emergencies where poor diagnosis, treatment and management can have profound outcomes for this group of patients. The mortality rate of this group of patients consistently show poorer outcomes compared to other disorders. The Endocrine Society and European Society of Endocrinology recently published comprehensive and complex recommendations to guide clinicians and healthcare professions to adopt more cohesive strategies to deal with the challenging nature of this medical emergency. Implementation of these recommendations will require a systematic approach and team-effort to ensure these guidelines are translated in day-to-day use. Endocrine nurses, who often work closely with endocrine colleagues, need to understand the implication of these guidelines in their roles and duties. The first step requires an understanding of the diagnosis and treatment process to treat this condition then to follow up the support within the team to ensure the clinical management plan is executed in line with clinical guidelines. The cycle of audit plays an important role to ensure the guidelines are robust so that further changes may bring about better outcomes for patients with hyponatraemia.

Keywords

Hyponatraemia · Adult · Children · Clinical guidelines · Severity · Symptoms · Outcomes

Abbreviations

ACE	Angiotensin-converting enzyme
ADH	Anti-diuretic hormone
ARBs	Angiotensin-II receptor blockers
AVP	Arginine vasopressin
AVPR2	Arginine vasopressin receptor 2
CNS	Central nervous system
CT	Computer tomography
CXR	Chest X ray
ECF	Extracellular fluid
GCS	Glasgow Coma Score
GFR	Glomerular filtration rate
ICF	Intracellular fluid
K	Potassium
MAOi	Monoamine oxidase inhibitors
MRI	Magnetic resonance imaging
Na^+	Sodium
NaCl	Sodium chloride
NSAIDs	Non-steroidal anti-inflammatory drugs
ODS	Osmotic demyelinating syndrome
SIAD	Syndrome of inappropriate anti-diuretic hormone
SSRIs	Serotonin-selective reuptake inhibitors

Key Terms

- **Hyponatraemia:** Low sodium in serum. The interpretation is based on biochemical severity, duration of hyponatraemia and symptoms. Assessing volume status is an important step in differentiating the diagnosis of hyponatraemia.
- **Tonicity:** Tonicity is a property of a solution which is equal to the sum of the concentrations of solutes that have the capacity to exert an osmotic force across a semi-permeable membrane.
- **Osmolality:** This is a measure of the number of particles present in a solution and is independent of the size or weight of the particles.
- **Volume status:** Usually refers to extracellular volume which indicates the solute status.
- **Clinical guidelines:** Set of recommendations on diagnostic approach and treatment to guide clinical treat certain condition.

Key Points

- Hyponatraemia is a common electrolyte imbalance in the clinical setting and has shown frequent poor outcomes and consequences.

- Hyponatraemia is an independent predictor of mortality for patients in the hospital setting.
- Focus should be placed on initial assessment, history taking and accurately performed investigations which lead to an accurate diagnosis before a specific treatment algorithm is initiated.
- Clinical guidelines for hyponatraemia provide a better structure and management for this high risk group.
- Endocrine nurses in adult or paediatric settings play a key role through direct patient care, working with other nursing colleagues, adopting an educational role to raise awareness and risk of hyponatraemia, and to conduct clinical audit so that better process can be implemented in the management of patients with hyponatraemia.

61.1 Introduction

Hyponatraemia is defined as a low sodium in blood. It is a very common medical condition which occurs up to 30% of hospital admission (Upadhyay et al. 2009). Hyponatraemia is associated with increased mortality, morbidity and length of hospital stay in patients presenting with a spectrum of conditions (Spasovski et al. 2014; Verbalis et al. 2013; Tzoulis et al. 2014a). It is usually caused by disturbance in ADH secretion leading to serum electrolyte imbalance. It is a common incidental finding on routine blood tests often presenting asymptomatically.

Clinical guidelines (Spasovski et al. 2014; Verbalis et al. 2013) are often complex and difficult for non-specialists to understand. Therefore the application by inexperienced practitioners in the clinical setting may be problematic. This chapter aims to simplify and bring together the key points from these clinical guidelines and to bring some focus for endocrine nurses to apply in their day-to-day roles and responsibilities.

This chapter is going to focus on:

- Outline and definition of hyponatraemia
- Causes and diagnosis
- Investigation and treatments according to clinical guidelines
- Role of the endocrine nurse in inpatient and outpatient settings

61.2 Definition of Hyponatraemia

The European Society of Endocrinology (Spasovski et al. 2014) and the Endocrine Society (Verbalis et al. 2013) clinical guidelines on diagnosis and treatment of hyponatraemia defined it as a serum sodium (Na^+) of less than 135 mmol/L. However, it is important to exclude spurious hyponatremia due to high lipid levels which may produce apparent hyponatraemia in some assays.

Classification of hyponatraemia is based on three factors:

61.2.1 Based on Biochemical Severity

(a) Mild hyponatraemia when the serum sodium concentration is 130–135 mmol/L.
(b) Moderate hyponatraemia when the serum sodium concentration is 125–129 mmol/L.
(c) Severe hyponatraemia when the serum sodium concentration is less than 125 mmol/L.

61.2.2 Based on Duration of Hyponatraemia

(a) Acute—duration of less than 48 h
(b) Chronic—duration of 48 h or more

61.2.3 Based on Symptoms (Box 61.1)

Box 61.1 Classification of Hyponatraemia Based on Symptoms

Moderately severe	Nausea without vomiting Confusion Headache Muscle cramp Feeling weak Gait disturbance, ataxia and falls Concentration and cognitive deficits Unspecific symptoms
Severe	Vomiting Drowsiness Coma Cardiopulmonary dysfunction Raised intracranial pressure symptoms Deep somnolence of Glasgow Coma Scale ≤8 Seizures
Moderately severe to severe symptoms may suggest a degree of brain oedema. This list is not exhaustive, all symptoms that can be signs of cerebral oedema should be considered as severe or moderate symptoms that can be caused by hyponatraemia	

61.3 Adult Hyponatraemia

61.3.1 Symptoms of Hyponatraemia

In a recent study, looking at 147 patients with severe hyponatraemia (Krummel et al. 2016), hyponatraemia symptoms were collated and the results are shown in Table 61.1. The majority of patients in the lowest serum sodium group had symptoms with the highest in severe neurological symptoms such as seizures, coma and confusion. Krummel et al. (2016) were unable to find association between the severity of neurological symptoms and the timing of hyponatraemia as the prior serum values were not available. However, they found that severe neurological symptoms were more likely to develop within 24 h in the very acute hyponatraemia patients, which is 24 h earlier than in the clinical guidelines (Spasovski et al. 2014; Verbalis et al. 2013).

61.3.2 Causes of Hyponatraemia

Common causes of hyponatraemia are dilution effects, dehydration or drug induced. This can be multifactorial due to:

- Syndrome of inappropriate secretion of anti-diuretic hormone (SIADH)
- Heart failure
- Liver failure
- Kidney disease
- Gastrointestinal sodium loss in severe diarrhoea and vomiting
- Adrenal insufficiency
- High water low solute intake—primary polydipsia
- Cerebral salt wasting
- Medication induced
- Hypothyroidism

Table 61.1 presents the frequency of symptoms in patients presenting with hyponatraemia (Krummel et al. 2016).

Arginine vasopressin (AVP), also called vasopressin or ADH (anti-diuretic hormone), is a peptide and neurohypophysial (posterior pituitary) hormone found in most mammals. Its two primary functions are to retain water in the body and to constrict blood vessels.

In the kidney, it retains water by increasing the water permeability of the kidney's collecting duct and distal convoluted tubules in inducing translocation of aquaporin water channels located in the plasma membrane of collecting duct cells to increase water absorption.

At high levels, it also increases peripheral vascular resistance by constricting blood vessels leading to an increase in arterial blood pressure. Most of vasopressin is stored in the posterior pituitary to be released into the bloodstream, and it has a very short half-life of 5–10 min (Baylis 2002).

Inappropriate elevation of arginine vasopressin (AVP) plays a key role in most states of hyponatraemia. Its secretion is stimulated by a rise in serum osmolality through the activation of osmoreceptors in hypothalamus and baroreceptors pressure changes in the carotid sinus, aortic arch, cardiac atria and pulmonary venous system.

Table 61.1 Hyponatraemia and associated symptoms

	All patients *N* = 147	Na < 110 mmol/L *N* = 20	Na 110–115 mmol/L *N* = 41	Na 116–120 mmol/L *N* = 86
With symptoms (%)	83 (56.5%)	19 (95%)	23 (56.1%)	41 (47.7%)
Severe neurological symptoms Seizures (%) Coma (%)	13 (8.8%) 9 (6.1%) 4 (15.0%)	7 (35%) 4 (20%) 3 (15%)	2 (4.9%) 1 (2.4%) 1 (2.4%)	4 (4.7%) 4 (4.7%) 0 (0%)
Confusion (%)	42 (28.6%)	10 (50%)	11 (26.8%)	21 (24.4%)
Nausea/vomiting (%)	17 (11.6%)	3 (15%)	6 (14.6%)	8 (9.3%)
Gait disturbance/fall (%)	20 (13.6%)	4 (20%)	7 (17.1%)	9 (10.5%)
Other symptoms (%)	7 (4.8%)	2 (10%)	2 (4.9%)	3 (3.5%)

Adapted from Krummel et al. (2016)

Failure to suppress AVP secretion in response to a low serum sodium and osmolality will result in water retention and hyponatraemia if one has sufficient hypotonic fluid intake.

61.3.2.1 Syndrome of Inappropriate Diuretic Hormone Secretion (SIADH)

SIADH is defined as:

- Clinically euvolaemic
- Serum osmolality <270 mOsm/kg
- Inappropriately concentrated urine >100 mOsm/kg, usually >300 mOsm/kg
- Increased urine Na^+ (> 20 mmol/L)
- Normal adrenal and thyroid function

In normal physiology, when the serum concentration increases, it drives thirst and leads to drinking behaviour. Once the body fluids reach a certain concentration, it suppresses vasopressin secretion allowing aquaresis to prevent over hydration. In SIADH, although the total water is increased, it is not clinically observed as the water is distributed within intracellular and extracellular tissues. General anaesthesia, nausea, pain, stress and a variety of non-specific drugs can be a potent stimulus for vasopressin secretion and can cause SIADH. However, there are four patterns of SIADH:

(a) Type I
This is caused by excessive and erratic vasopressin secretion that are independent of changes in serum osmolality.

(b) Type II
This is caused by an osmoregulatory defect where water excretion continues despite a lowered plasma osmolality.

(c) Type III
Normal and appropriate osmoregulation of the hormone, but when there is a decrease in serum osmotic pressure there is a constant non-suppressible vasopressin secretion cause by neurohypophysial damage, loss of inhibitory osmoregulatory neurons or persistent non-osmotic stimulation.

(d) Type IV
Normal osmoregulated vasopressin secretion but patients still fulfil SIADH criteria. The defect may lie within the kidney.

SIADH can be caused by other conditions small cell lung cancer, gastrointestinal tract malignancy, drugs such as desmopressin, carbamazepine, pulmonary conditions such as pneumonia, tuberculosis, intracranial pathology such as brain tumours, meningitis and other conditions such as HIV and multiple sclerosis (Hannon and Thompson 2010).

61.3.2.2 Heart Failure

Heart failure can cause hyponatraemia in several ways:

(a) Atrial pressure is increased but the complex atrial-renal reflexes that modulate renal sodium and water excretion are blunted.

(b) High-pressure baroreceptors in the left ventricle, carotid body, aortic arch and juxtaglomerular apparatus are less stretched, leading

to increase adrenergic activity, renin secretion and non-osmotic AVP release.

(c) Heart failure patients often has severe renal vasoconstriction with a decrease GFR and alteration in peritubular Starling forces leading to enhanced tubular sodium and water reabsorption.

61.3.2.3 Liver Disease

(a) Advanced liver cirrhosis can lead to portal hypertension which in turn causes arterial vasodilation and a decrease in stretch receptors in carotids and aortic arch. This eventually leads to decrease in adrenergic activity, renin secretion and non-osmotic AVP release as described in Sect. 61.3.2.2.

61.3.2.4 Kidney Diseases

(a) Severe renal vasoconstriction with a reduction in GFR in chronic kidney diseases leads to enhanced sodium and water reabsorption.

(b) Nephrogenic syndrome of inappropriate antidiuresis secondary to a mutation in the arginine vasopressin receptor AVPR2 in renal tubules presented with hyponatraemia has recently been reported (Powlson et al. 2016). This is caused by the inability of these mutated AVPR2 to achieve appropriate antidiuresis.

61.3.2.5 Gastrointestinal Sodium Loss in Severe Diarrhoea and Vomiting

(a) In diarrhoea and vomiting, the body loses sodium through the gastrointestinal tract.

(b) If a patient ingests low sodium such as water, tea or toast, this will dilute the serum further leading to hyponatraemia.

61.3.2.6 Adrenal Insufficiency

(a) Low aldosterone in primary insufficiency causes renal sodium loss and leads to hyponatraemia.

(b) In secondary adrenal insufficiency, reduction or an absence of ACTH leads to low cortisol and this persistent low cortisol leads to a rise in vasopressin, in part due to a loss of blood pressure.

61.3.2.7 High Water Low Solute Intake: Primary Polydipsia

(a) Excess water intake overtakes what the kidney can eliminate and leads to 'wash out' in the renal tubules. Patients with profound hyponatraemia due to primary polydipsia were found to have high prevalence of psychiatric, addictive and affective disorders (Sailer et al. 2017).

61.3.2.8 Cerebral Salt Wasting

(a) The term above is referred to the syndrome of sodium loss from renal observed following head injury, subarachnoid haemorrhage, neurosurgery or intracranial disorders. The hyponatraemia is caused by the initial intravascular volume loss trigger a baroreceptor pressure changes and leads to AVP secretion. Currently, it is thought to be extremely rare.

61.3.2.9 Hypothyroidism

(a) Hyponatraemia caused by hypothyroidism is extremely rare and this may be referred to myxoedema in severe hypothyroidism in which the cardiac output may be compromised leading to disturbances in AVP release. In a recent study, among 576 inpatient admissions with euvolaemic hyponatraemia, no cases of hyponatraemia were diagnosed (Cuesta et al. 2016), and this was supported by findings of an earlier larger analysis (Croal et al. 1997). In a large national survey (Holland-Bill et al. 2015) of first-time acute admission over a 5-year period, only 12.9% patients presented with hypothyroidism. However, the severity hypothyroidism was not explored in this study.

61.3.2.10 Medication-Induced

Drug-induced hyponatraemia is well recognised as also reflected in clinical guidelines (Spasovski et al. 2014; Verbalis et al. 2013) and is summarised in Table 61.2.

Table 61.2 Medications which can induce hyponatraemia

Diuretics	– Thiazides (can cause even after chronic use), e.g. bendroflumethiazide – Thiazide-like, e.g. indapamide – Potassium-sparing, e.g. spironolactone, amiloride – Loop diuretics (usually only a contributory factor), e.g. furosemide
Antihypertensive drugs	– ACE inhibitors, e.g. ramipril, lisinopril – ARBs, e.g. losartan, candesartan
Antidepressants	– Tricyclic, e.g. amitriptyline, dosulepin – SSRI, e.g. citalopram, paroxetine – MAOi, e.g. venlafaxine
Anti-epileptic drugs	– Carbamazepine – Oxcarbazepine – Sodium valproate
Anti-psychotic drugs	– Phenothiazines, e.g. chlorpromazine, prochlorperazine – Butyrophenones, e.g. haloperidol
Anti-cancer drugs	– Platinum agents, e.g. cisplatin, carboplatin – Alkylating agents, e.g. cyclophosphamide, melphalan, ifosfamide
Miscellaneous	– Desmopressin, oxytocin – NSAIDs – Amiodarone – Sulfonylurea—glipizide, glibenclamide
Proton pump inhibitors	– Omeprazole, Pantoprazole

ACE inhibitors angiotensin-converting enzyme inhibitor, *ARBs* angiotensin-II receptor blockers, *SSRIs* serotonin-selective reuptake inhibitors, *MAOi* monoamine oxidase inhibitors, *NSAIDs* non-steroidal anti-inflammatory drugs

61.3.3 Hyponatraemia Caused by Plasma Tonicity

Basal serum osmolality varies between individuals in the range 280–295 mOsm/kg. However, abnormally high concentration of lipids or proteins in plasma can interfere with the accurate measurement of sodium which leads to the term pseudo-hyponatraemia. These interfering factors can include unmeasured solutes such as mannitol, urea, maltose, alcohol, intravenous immunoglobulins or radiographic contrast agents, rendering the diagnosis of hyponatraemia extremely challenging in some clinical settings.

61.3.4 Mortality Rate and Volume Status of Hyponatraemia

In a study (Tzoulis et al. 2014a) looking at the mortality rate in a general hospital for 139 hospitalised patients with a serum sodium ≤128 mmol/L, patients with hyponatraemia had an inpatient mortality rate of 17.3% and were more than three times more likely to die during their hospital stay compared with controls. In a larger survey (Holland-Bill et al. 2015) involving first-time admissions in Denmark, the prevalence of admission with hyponatraemia was 15% (41,803 patients). Thirty-day mortality was 3.6% in normonatraemic patient, whereas patients with various degrees of hyponatraemia ranges had mortality rates between 7.3 and 10.4%. The mortality risk was increased across all clinical subgroups and remained increased by 30–40% over 1 year. These data are similar to another observational (Kuramatsu et al. 2014) study involving 464 patients conducted in a single US hospital over a 5-year period where the prevalence of hyponatremia on hospital admission was 15.6%. The inpatient mortality rate was 2.5-fold increase compared with non-hyponatraemia patients.

In an attempt to understand the mortality rate among SIADH, hypovolaemic and hypervolaemic hyponatraemia patients (Cuesta et al. 2017), 1323 admissions within these 3 groups were studied. Hyponatraemia groups had a higher mortality rate of 9.1% compared to a normal control group of 3.8%. In addition, hyponatraemic patients with SIADH had a lower mortality than patients with hypovolaemic and hypervolaemic hyponatraemia. The study also concluded that hypervolaemic hyponatraemia patient has the highest risk ratio of 4.9. Both hypovalaemic and hypervolaemic hyponatraemia patients had higher mean and SD scores in Charlson

Comorbidity Index which predicts 1 year mortality for a patient who may have a range of comorbid conditions. The study also reflects that mortality is likely linked to the severity of the underlying disease processes leading to the development of hyponatraemia.

61.3.5 Management of Acute and Chronic Hyponatraemia

The management of acute and chronic hyponatraemia is essayed in the European Society of Endocrinology clinical guidelines (Spasovski et al. 2014) and the Endocrine Society clinical guidelines (Verbalis et al. 2013). In acute hyponatraemia where brain cell swells too quickly, the brain's ability to adapt is impaired and this results in brain oedema with the risk of brain herniation. Conversely, in chronic hyponatraemia where the hyponatraemia develops over several days, brain cells have more time to extrude organic solutes allowing intracellular and extracellular osmolality to equalise without a large increase in cell water. Therefore, rapid overcorrection of chronic hyponatraemia can lead to neurological sequelae caused by the osmotic demyelination syndrome, previously known as pontine or extrapontine myelinolysis (Corona et al. 2014). The osmotic demyelination syndrome is the breakdown of myelin sheath which insulates individual neurons. Clinically, it can manifest with hypotonia, tremors and involuntary muscle spasm.

61.3.6 Diagnosis of Hyponatraemia

A group of experienced UK clinicians recommended (Grant et al. 2015) that a thorough clinical examination to access the patient's hydration status and some basic blood and urine tests are essential in elucidating the cause of hyponatraemia and guide its clinical management. They also recommended five key steps before commencing on treatment:

(a) Making the right diagnosis
This begins with a good clinical history and examination.

(b) Baseline investigations
It is important to consider the possible causes listed in Sect. 61.3.2. It has been reported that under-investigation is a common occurrence in clinical practice (Tzoulis et al. 2014b). Table 61.3 showed the gaps of investigation for hyponatraemia in three separate studies. Each of them shows the shortfalls addressed by clinical guidelines (Spasovski et al. 2014; Verbalis et al. 2013).

(c) Consider the context
Knowing certain conditions that may inform the diagnosis

(d) Assess hydration status
Clinical assessment to define if patient is hypovolaemic, hypervolaemic or euvolaemic has impact of the diagnosis and management of hyponatraemia (Table 61.4). However, in practice this is both challenging and inconsistent even with experienced clinicians as it has low sensitivity and specificity (Hoorn and Zietse 2017). A recent study found the clinical assessment of volume status was documented in 62/100 (62%) cases (Tzoulis et al. 2014b). Grant et al. (2015) suggested that if unsure of a patient's volume status one could infuse 0.9% normal saline 1 L over 12 h as a trial with a strict monitoring of serum sodium 6 hourly; hypovolaemic patients will respond well, whereas SIADH patient will usually not improve.

Table 61.3 Investigation and assessment of patients with hyponatraemia during admission

Investigation	Tzoulis et al. (2014b) (%)	Krummel et al. (2016) (%)	Cuesta et al. (2016) (%)
Volume status	62		
Serum osmolality	39	34	
Urine osmolality	33		86
Urine sodium	29		86
Paired osmolality—sodium	23		
Serum TSH	61	48.9	91
Serum cortisol	31	17.6	84
Full work-up	18		
Expert input	16		

(e) Acute severe hyponatraemia
This is a medical emergency and should be treated immediately without delay for the diagnosis of the cause of hyponatraemia.

61.3.7 Investigations of Hyponatraemia

Following the diagnosis of hyponatraemia, there are some important blood biochemistry screening and urine screening tests. Glucose, lipids, cortisol, thyroid function, liver function, serum osmolality, urine osmolality, urine sodium and potassium. This information can help to differentiate the underlying causes of hyponatraemia. It is essential to take into account all causes of hyponatraemia including the possible interference including volume status on examination (Hannon and Thompson 2010; Cuesta et al. 2017) as listed in Table 61.4 below.

Key Assessments and Tests for Hyponatraemia

- History taking: symptoms, underlying condition, common precipitants
- Examination: establishing the fluid status
- Screening panels: glucose, lipids, cortisol, thyroid function, liver function, plasma osmolality, urine osmolality, urine sodium and potassium
- Other investigations as indicated: CXR, Synacthen test (also called ACTH, cosyntropin or tetracosactide test), CT head

Further Tests That May Be Needed

- Check plasma ACTH if suspected of adrenal insufficiency
- May (rarely) require Glucagon test or Insulin Stress Test to diagnosis secondary adrenal insufficiency or hypopituitarism (Cuesta et al. 2016).
- Water deprivation or prolonged water deprivation if has mild hyponatraemia or suspect of primary polydipsia.
- Water load test has been described for patient with intermittent hyponatraemia with nephrogenic syndrome of inappropriate antidiuresis (Powlson et al. 2016).
- In the case of suspected osmotic demyelination syndrome, MRI of the brain may reveal the condition (Corona et al. 2014).

Table 61.4 Differential diagnosis by volume status

Hypovolaemic (hyponatraemia with decreased ECF volume)		Euvolaemic (hyponatraemia with normal ECF volume)		Hypervolaemic (hyponatraemia with increased ECF volume)	
Reduced skin turgor, dry membranes, tachycardia, low BP or postural hypotension		Underlying illness		Oedema, raised JVP, ascites, pulmonary oedema, underlying illness	
Urinary Na >20 mmol/L	Urinary Na <20 mmol/L	Urinary Na >20 mmol/L	Urinary Na <20 mmol/L	Urinary Na >20 mmol/L	Urinary Na <20 mmol/L
Renal losses – Osmotic diuresis – Diuretic therapy – Addison's disease – Salt-losing nephropathy – Cerebral salt wasting – Ketonuria	Extra-renal losses – Diarrhoea – Vomiting – Burns – Fistulae – Pancreatitis – Mucosal loss – Sodium depletion post-diuretics	– SIADH – Secondary adrenal insufficiency – Addison's disease (with secondary ADH response)—hypothyroidism – Diuretic therapy – Drugs	ECF loss with inappropriate fluid replacement	– Acute or chronic renal failure – Diuretic therapy for heart failure	– Nephrotic syndrome – Cirrhosis – Cardiac failure

Adapted from Hannon and Thompson (2010)

61.3.8 Treatment of Hyponatraemia in Adult Patients

Acute and severe symptoms at presentation, particularly when significant neurological symptoms listed are present, constitutes a medical emergency and treatment should be instigated immediately.

61.3.8.1 General Rules of Treatment for Hyponatraemia

The following general rules apply in the treatment of hyponatraemia (Spasovski et al. 2014; Verbalis et al. 2013; Grant et al. 2015).

Box 61.2 General Rules of Treatment for Hyponatraemia

Management is determined by:

- Severity of symptoms—GCS scores ≤8 is classified as severe.
- Acute or chronic: acute hyponatraemia <48 h; chronic hyponatraemia >48 h
- If unsure of status, follow severe hyponatraemia algorithm.
- Intravascular volume: Decide if patient is hypovolaemic, euvolaemic or hypervolaemic.

In all patients

- Determine the rates of correction.
- Stop any offending medications and recheck serum sodium.
- Treat underlying cause.
- Review volume status, see Table 61.2 and check urinary sodium.
  If patient is hypovolaemic, start 0.9% normal saline.
  If patient is hypervolaemic, treat underlying causes.
- If patient is euvolaemic, determine if hypotonic hyponatraemia by checking serum and urine osmolality.
  - If serum osmolality >275 mOsm/kg, consider causes of hypertonic hyponatraemia such as hyperglycaemia or mannitol infusion/hypertonic radiocontrast.
  - If urinary osmolality <100 mOsm/kg, consider primary polydipsia and other causes.
  - If serum osmolality <275 mOsm/kg, urine osmolality >100 mOsm/kg, urinary sodium >20 mmol/L likely caused SIADH; please see section of SIADH below.
  - If plasma osmolality <275 mOsm/kg, urine osmolality >100 mOsm/kg, urinary sodium <20 mmol/L, reconsider the volume status as this may reflect intravascular volume depletion.
- First-line treatment Free water fluid restriction (no water consumption and IV fluids unless hypovolaemic with acute hyponatraemia, then start with 0.9% saline).
- Specialist review.
- Transfer to high dependency unit.
- Check serum sodium 6 hourly and adjust trend.
- Safe limited no more than 10 mmol/L in first 24 h then 8 mmol/L in the subsequent 24 h (18 mmol/L in 48 h) aiming to achieve serum sodium of 130 mmol/L.

Exclude other possible aetiologies for a definitive diagnosis.

SIAD and Treatment

- First-line treatment free water fluid restriction.
- Second-line treatment with tolvaptan 7.5–15 mg as a single dose.
- Tolvaptan binds and blocks the V2 receptor to correct hyponatraemia in SIADH.
- Before tolvaptan is initiated to treat SIADH, it is essential that patients are allowed to drink in response to thirst. Check serum sodium 6 hourly to exclude rapid correction.
- Demeclocycline is used to treat hyponatraemia associated with SIAD secondary to malignant disease. It causes nephrogenic diabetes insipidus in 60% of patients and causes nephrotoxicity in patients with liver cirrhosis. The onset of action is unpredictable and normally takes 2–5 days. It is started at 150 mg thrice daily assessed in 3 days and increased if needed.

61.3.8.2 Management of Patients with Severe Symptomatic Hyponatraemia

Box 61.3 presents details on the management of hyponatraemia based on European and US/Canada guidelines (Spasovski et al. 2014; Tzoulis et al. 2014a).

Box 61.3 Management of Patients with Severe Symptomatic Hyponatraemia

If patient presents with CNS disturbance, confusion, headache, drowsiness, coma/altered GCS, seizure or encephalopathy, start the following treatment immediately.

- Secure airway
- Obtain intravenous access
- Draw baseline Na
- Instigate a close monitoring environment when starting hypertonic infusion

UK and EU guidelines for all acute or chronic severe symptomatic hyponatraemia:

- Within first hour, begin administration of 150 mL hypertonic 3% saline infusion intravenously over 20 min then check serum sodium.
- Repeat after 20 min if no clinical improvement while waiting for serum sodium.
- Repeat twice on the above regimen if no clinical improvement or until 5 mmol/L increase in serum sodium.
- Follow up management after 5 mmol/L rise in serum sodium and improvement in symptoms:
  Stop hypertonic saline infusion.
  Keep intravenous line open minimum volume 0.9% normal saline.
  Start diagnosis-specific treatment.
  Limit increase of serum sodium to 10 mmol/L first 24 h then no more than 8 mmol/L in subsequent 24 h thereafter until serum sodium reaches 130 mmol/L.
  Recheck serum sodium at 6 h, 12 h and daily until stable under stable treatment.
- Follow up management after 5 mmol/L rise in serum sodium and **NO** improvement in symptoms:
  Continue hypertonic 3% saline infusion or equivalent aim for additional 1 mmol/L increase in serum sodium.
  When symptoms improved, serum sodium concentration increases to 10 mmol/L in total or reaches 130 mmol/L (whichever is first), stop hypertonic 3% saline infusion.
  Explore other causes of symptoms.

Check serum sodium concentration every 4 h as long as an intravenous infusion hypertonic 3% saline or equivalent is continued.

UK and EU guidelines for over correction of hyponatraemia:

- Intervene for re-lowering the serum sodium concentration if it increases >10 mmol/L during the first 24 h or > 8 mmol/L in any 24 h thereafter.
- Discontinue ongoing active treatment.
- Consult an expert to discuss if it is appropriate to start an infusion of 10 mL/kg body weight of electrolyte-free water (e.g. glucose solutions) over 1 h under strict monitoring of urine output and fluid balance.
- Consult an expert to discuss if it is appropriate to add intravenous desmopressin 2 μg with the understanding that this should not be repeated more frequently than every 8 h.

US, Canada and Australia guideline for acute symptomatic hyponatraemia

- For severe symptoms:
- 100 mL of hypertonic 3% saline infused over 10 min, repeat three times as needed.
- For mild to moderate symptoms with a low risk of herniation:
- Hypertonic 3% saline infused at 0.5–2 mL/kg/h.
- The rate of correction need not be restricted in patients with true acute hyponatraemia nor in reducing the over correction. Follow the chronic hyponatraemia regimen if not certain if the hyponatraemia is acute or chronic.

US, Canada and Australia guideline for chronic symptomatic hyponatraemia in order to avoid ODS

- Determine high risk factors of putting patients of developing osmotic demyelinating syndrome:
- Serum sodium concentration of ≤105 mmol/L, hypokalaemia, alcoholism, malnutrition, and advanced liver disease.
- Determine if patient is in high risk group if has serum sodium concentration of ≤120 mmol/L over 48 h.
- Minimise correction of serum sodium by 4–8 mmol/L/day with a lower goal of 4–6 mmol/L/day if risk of ODS is high.
- High risk of ODS: 8 mmol/L in any 24 h period.
- Normal risk of ODS: 10–12 mmol/L in any 24 h period, 18 mmol/L in any 48 h period.

61.3.9 Challenges with Hyponatraemia Management in Clinical Settings

There are challenges in implementing the hyponatraemia clinical guidelines in real-world settings. Table 61.3 summarised the three prospective and retrospective studies looking at hyponatraemia patients' biochemical markers and assessment during their admissions.

From the Table, there are clear clinical shortfalls in the investigations and management of patients with hyponatraemia. Both studies by Krummel et al. (2016) and Tzoulis et al. (2014b) were retrospective studies, but Cuesta et al. (2016) was a prospective study involving a specific IT software to alert principle investigator when serum sodium decreased fall into the hyponatraemia inclusion criteria. Despite the extra effort by Cuesta et al. (2016), 17% of the criteria required for the study were not obtained despite requests. These frustrations and concerns were shared recently (Gleeson et al. 2016) that knowledge on how to manage diabetes insipidus in health is limited to endocrine outpatient settings, whereas inpatient care will expose these patients to a range of medical staff with no

expertise in this area. They highlighted that in a recent audit of 17 admissions for 8 patients with diabetes insipidus, 88% of these patients had 39 missed/delayed dose of desmopressin and concomitant administration of hydrocortisone was missed in 35.7% admission. Urinary sodium, one of the most important biochemical tests in investigation of hyponatraemia, was measured in less than one-third of cases (Tzoulis et al. 2014b). The data has also shown 63.1% of patients being discharged with persistent hyponatraemia. The complex hyponatraemia management hurdle is not going to be solved by an endocrine team. There is also the challenge of implementing fluids restriction regimen for these ward-based patients in concordance with clinical guidelines.

The Endocrine Society clinical guidelines make the following recommendation for fluid restriction:

- Restrict all fluid intake.
- Aim for a fluid restriction that is 500 mL/day below the 24 h urine volume.
- Do not restrict sodium or protein intake unless indicated.

They also make the following recommendation that could predict the likely failure of fluid restriction:

- High urine osmolality of over 500 mOsm/kg H_2O.
- Sum of the urine sodium and potassium concentration exceed the serum sodium concentration.
- 24 h urine volume of less than 1500 mL/day.
- Increase in serum sodium concentration of less than 2 mmol/L/day in 24–48 h on a fluid restriction of ≤1 L/day.

However, more data is needed to understand if these recommendations are transferable into clinical settings. More importantly, how these guidelines and recommendations are going to be executed, what processes need to put in place to ensure the guidelines are followed and how is it going to affect patient outcomes.

61.3.10 Identifying the Gaps for Endocrine Nurses to Develop in the Management of Adult Hyponatraemia

Clinical guidelines have made recommendations to improve clinical practice. In order to translate clinical guidelines into clinical setting, there should be a system in place in hospital to identify patients with hyponatraemia so that the right treatment plan can be instigated. Table 61.3 has shown when a group of patients with hyponatraemia are identified in clinical setting by an admission pathway (Cuesta et al. 2016) and seen by someone who has experience in hyponatraemia within 48 h of development of hyponatraemia, there is a higher rate of investigations and assessments conducted compared to the other two groups (Krummel et al. 2016; Tzoulis et al. 2014b) where hyponatraemia data was collected retrospectively.

Most of the endocrine services are outpatient based but still need to provide inpatient support for patients presented with endocrine issues, as in Table 61.5 patients with hyponatraemia are admitted in various inpatient areas (Tzoulis et al. 2014a). From the evidence presented in this chapter, there are several conclusions and recommendations that can be drawn from these data:

- The endocrine nurse can provide help and support to endocrine colleagues to make an accurate diagnosis and improve management of hyponatraemia through:
  <u>Immediate response during acute hyponatraemia phase:</u>
  (a) Collect relevant screening panels for glucose, lipids, cortisol, thyroid function, liver function, plasma osmolality, urine osmolality, urine sodium and potassium.
  (b) Liaise with the lab for urgent results turnaround.
  (c) Ensure observations including GSC scores are taken when the patient presents in the outpatient endocrine unit.
  (d) Admit patient as an emergency and refer the patient to an endocrine specialist for further investigation and management.

(e) Liaise with the ward staff to ensure clinical management plan is followed including a strict fluid restriction management.
(f) Work closely with inpatient colleagues to monitor patient progress.
(g) Ward-based teaching to educate ward-based staff the implications of hyponatraemia, how it is treated and outcomes of these patients.
(h) Support the patient and carer through patient education on hyponatraemia and support their clinical management plan before and after patient's discharge from hospital.

Post-acute phase:

(a) Carry out further endocrine test such as Synacthen test, water load test, water deprivation test, prolonged water deprivation or other diagnostic procedures such as Glucagon or Insulin Stress Test to check if patient has secondary adrenal insufficiency.
(b) If the patient is diagnosed with adrenal insufficiency, patient, carer and family member will require sick-day rule training on teaching patient, carers and family to manage adrenal insufficiency on day-to-day basis, as well as during sick-day management. More information on sick-day rules is covered in adrenal section in Part V and in adrenal crisis section of this chapter.
(c) If the patient requires a Synacthen test, water load test, water deprivation test or prolonged water deprivation test to further investigate the cause of hyponatraemia, this must be explained verbally and in writing to the patients. These clinical tests have clinical procedures to follow; however, this will not be addressed in this chapter as there are several versions of this procedure available online (Barts Endocrine Protocols 2009; Endocrinology handbook endocrine unit Imperial 2016).

Inpatient and outpatient support for patients with hyponatraemia

In a retrospective audit (Behan et al. 2015) looking at the frequency and impact of abnormal serum sodium among cranial diabetes insipidus patients with normal and abnormal thirst in an inpatient and outpatient setting, 77% of the neurosurgical inpatient admissions and 60% of the non-neurosurgical admission as well as 40% outpatient patients had hyponatraemia. This data shows that more efforts are needed to educate healthcare professionals in hospital settings, both in inpatient and outpatient, to be more aware of the risks exposed by patients with hyponatraemia. Endocrine nurses have educator role to address the risk of hyponatraemia in hospital setting, just like the diabetes nurse has education role in improving the care of diabetes patients in hospital. However, in practice, endocrine nurses have to cover for so many diseases within endocrine system in their patient care, getting the opportunity to address this shortfall requires imagination and careful thought. Cuesta et al. (2016) had shown if endocrine team can utilise an IT system to identify patients with hyponatraemia in hospital settings, it led to better screening and allowed an earlier interventions on these patients. There are several roles for endocrine nurses in neurosurgical and non-neurosurgical hospital setting:

(a) Support the patient who has surgery-induced hyponatraemia; this will include follow-up appointments for blood tests for electrolytes and assessment, liaise with primary care or General Practitioners to provide the necessary continuity of treatment and care.
(b) Patient and carers need to be aware of signs of hyponatraemia such as excessive drinking, polyuria and symptoms such as headache, feeling unwell or changes in neurological status. Patient and carers need to understand this requires emergency attentions and seek medical help immediately.
(c) Patients with abnormal thirst and cranial diabetes insipidus-treated desmopressin are also more likely to develop hypernatraemia when attending outpatient clinics

(Behan et al. 2015). Endocrine nurse clinic needs to be aware of these risks where patients can present with hypernatraemia and lethargy, irritability, ataxic, tremor, hyperreflexia, seizures and reduced GCS. Treatment must be instigated immediately with support from endocrine or emergency team.

Strategic role in safeguarding hyponatraemia patients in hospital through audits

This role includes conducting audits to look at the risks involved in patients with hyponatraemia, similar to various studies involving audits and retrospective methods looking at hyponatraemic patients' outcomes. However, in order to avoid replication, endocrine nurses can focus on areas such as policies, processes and procedures to see how to improve and build on this, to other endocrine emergencies such as adrenal crisis, thyroid storm or thyrotoxicosis and pituitary apoplexy. As health is dynamic, implementation of the audit findings need to be re-evaluated and re-audited as necessary and interventions as well as outcomes need to be captured and shared through publication so that endocrine communities can improve the outcomes for this rare endocrine condition.

All these service improvement initiatives require service investment, which means investing in more endocrine doctors and nurses. Clinical audit is a useful way to identify shortfalls in service and make a case for extra resources. This commitment must be part of the long-term organisational strategy to improve patients' outcomes and part of the continuous service improvement plan.

61.4 Hyponatraemia in Children

61.4.1 Symptoms of Hyponatraemia

Most children with mild to moderate hyponatraemia are asymptomatic, particularly when slow in onset. However, a child with hyponatraemia can present with nausea, vomiting, crying, headache, lethargy/irritability, hyporeflexia, an altered level consciousness and, in very severe cases, seizures and cardiopulmonary arrest. However, the early signs and symptoms of acute hyponatraemia are often non-specific. Healthcare professionals may attribute this to effects of surgery, anaesthetics, opioid medications or the underlying disease. Hyponatraemia with severe symptoms, or acute hyponatraemic encephalopathy, is a medical emergency and a child must be seen and managed immediately.

61.4.2 Causes of Hyponatraemia

Common causes of hyponatraemia in children are dilution effect, dehydration or drug induced. This can be multifactorial due to:

Iatrogenic:	Intravenous fluid administration such as hypotonic solutions
	Excessive water intake
	Diluted formula feeds
	Drug-induced
SIADH	Syndrome of inappropriate antidiuresis
GI loss	Gastrointestinal sodium loss in severe diarrhoea and vomiting
Extra-renal losses	Skin (sweating or burns)
Renal losses	Cerebral salt wasting, absence of aldosterone or lack of effect (e.g. 21-hydroxylase deficiency)
Other	Heart failure, liver failure, adrenal insufficiency, diabetic ketoacidosis

Table 61.5 Patient distribution for hyponatraemia was found in these specialties

Medical Specialty (77%)	Geriatrics 16.5% Oncology 8.6% Neurology 5% Haematology 2.2%	Hepatology 14.4% Cardiology 5.8% Gastroenterology 2.9% Infectious disease 0.7%	General medicine 13.7% Nephrology 5% Respiratory 2.2%
Surgical Specialty (19.4%)	Orthopaedics 5.8% Urology 2.9% Obstetrics 0.7%	General surgery 4.3% Vascular surgery 2.2%	Hepatobiliary 2.9% Plastic surgery 0.7%
ICU 2.2%	Accident and emergency 1.4%		

Adapted from Tzoulis et al. (2014a)

It has now been recognised that administering hypotonic solutions put children at a greater risk of developing life-threatening hyponatraemia than other types of fluid and should always be prescribed with caution (Medicines and Healthcare products Regulatory Agency 2012; Foster et al. 2014). Several national agencies have put up safety bulletin alerts (Foster et al. 2014; NPSA 2009; Koczmara et al. 2010), but this unnecessary death is still occurring. With hypotonic solution administration, the brain cells are unable to compensate for the rapid decrease in serum osmolality. The brain's ability to adapt is impaired and this results in brain oedema with the risk of brain herniation. Children exhibit symptoms more quickly than adults in response to abnormal sodium levels as there is less room for brain cells to swell.

Impaired free water excretion and high antidiuretic hormone levels caused by infections such as meningitis, encephalitis, sepsis, pneumonia, surgery, pain, nausea and vomiting are contributory factors to hyponatraemia. In children taking desmopressin for nocturnal enuresis, excess fluid intake can also lead to hyponatraemia.

61.4.3 Assessment for Hyponatraemia

Assessment of a child involves the points raised in the adult section of this chapter. This also includes full physical and biochemical assessment. Assessment of a child's hydration status is mandatory, as well as serum sodium, potassium, chloride, urea, glucose and osmolality, plus urinary sodium and osmolality.

61.4.4 Management of Hyponatraemia

There is no clinical guidelines for hyponatraemia specifically for a paediatric setting. However, the general principle from the clinical guidelines can be adapted. There are several important rules and precaution steps to be taken (NPSA 2009):

(a) Never routinely give any hypotonic solutions such as 0.18% sodium chloride (NaCl) with 4% glucose from stock level and general use to treat children. They must be removed and replaced with suitable alternative intravenous infusions. There should be restricted availability of these intravenous infusions to critical care and specialist areas such as renal, liver and cardiac units.
(b) Use 0.9% NaCl or 5% glucose as maintenance fluid.
(c) Prescribed fluids must be given the same considerations as other medicines with reference to dose, indications, contraindications, monitoring and most importantly volume.
(d) Whichever fluid is used, monitor serum sodium concentration regularly to avoid hypo- or hypernatraemia.
(e) Give enteral feeds where possible as fluid replacement, and the volume given should be included in fluid intake calculation.
(f) Put in place local clinical guidelines for the management of paediatric hyponatraemia including the fluid management protocol.
(g) Ensure guidelines are complied with by ensuring adequate training and supervision for all staff involved in the prescribing, administering and monitoring of intravenous infusions for children.
(h) Encourage hospital-acquired hyponatraemia incidents reporting via local reporting systems.

61.4.5 Symptomatic Hyponatraemia with Seizures and/or Neurological Deterioration

(a) Follow local emergency procedure to secure airway, breathing and circulation by involving the local emergency or resuscitation team. Hyponatraemia often responds poorly to standard anticonvulsants and do not delay sodium correction. Notify the intensive care unit and arrange for transfer as soon possible.

The golden rule is do not over treat hyponatraemia.

(b) Follow the local policy of NaCl replacement for hyponatraemia. Measure serum sodium at set intervals once correction has commenced.
(c) Investigate the cause of hyponatraemia and treat accordingly.

61.4.6 Hyponatraemia with No Symptoms

The management is influenced by a child's hydration status which can be influenced by underlying causes such as gastroenteritis, diarrhoea and vomiting. It is important to avoid over-rapid correction and allow plasma sodium concentration to rise no more than 8 mmol/L/day, aiming for correction to 135 mmol/L. This can be achieved by fluid restriction to increase the rise of serum sodium. If a child has moderate dehydration and serum sodium 130–135 mmol/L, try nasogastric rehydration. If a child has severe dehydration, give 0.9% NaCl until the child can take enteral feeds and measure electrolyte 4 hourly until stable. If hyponatraemia is caused by hyperglycaemia, correction of blood glucose should correct hyponatraemia. If hyponatraemia persists despite glucose correction, 0.9% NaCl should be used to correct hyponatraemia.

61.4.7 The Role of the Endocrine Nurse in Paediatric Hyponatraemia

The role of the endocrine nurse in paediatric setting for hyponatraemia is similar to the one listed in the adult section of this chapter. However, it has been recommended that clinical guidelines need to be put in place to ensure the safety of a child is maintained in hospital setting (NPSA 2009). This includes working closely with ward staff to ensure hypotonic solution is only made available to clinical areas such as intensive care, renal, liver and cardiac units. Endocrine specialist nurse in paediatric setting can also raise the awareness on the risk of hyponatraemia in paediatric setting by working closely with ward staff by providing them with training and support. Clinical audit is an effective way to assessment if the paediatric hyponatraemia clinical guideline is followed and well implemented.

61.5 Conclusions

The management of the patient with hyponatraemia is often a team approach, and the endocrine nurse must safeguard the well-being of the patient, by working closely with their endocrine colleagues. In paediatric setting, hyponatraemia can be minimised and in some cases avoided. Healthcare professionals need to be aware of this risk when caring for a child who can present with hyponatraemia due to surgical or medical interventions.

Most evidence suggests that over-enthusiastic treatment of hyponatraemia is considerably more dangerous than treatment that is slow or relatively ineffective in the case of mild or moderate hyponatremia. However, a collective team approach coupled with awareness of clinical guidelines and executing a clear clinical management plan will undoubtedly lead to more desirable patient outcomes.

Abstract

Adrenal crisis (AC) is a potentially life-threatening event in patients with adrenal insufficiency (AI). Patients with AI are at risk of developing AC if glucocorticoid replacement is reduced or stopped, or if the dose is not increased during periods of intercurrent illness or major emotional and physical stress. Infections and gastroenteritis are the main precipitating factors for AC which must be treated immediately with parenteral hydrocortisone administration. Mortality is twofold in patients with AI and 1 in 12 patients have at least one hospital admission per year due to AC. Most hospital admissions and deaths from AC can be prevented with prompt management. Education and support for self-management for patients and their families is of paramount importance to achieve optimal adherence with "sick day rules" and to prevent AC. Every patient should be provided with an emergency steroid card, a hydrocortisone injection pack and regular training on self-administration. Patients and families should be encouraged to access information and resources available via the patient advocacy groups. Moreover, raising awareness and training of healthcare professionals in the acute service and developing appropriate care pathways such as ambulance "red flag" protocols ensures that patients are treated immediately when presenting with AC. This chapter presents a comprehensive overview of the causes, clinical presentation, treatment, and prevention of AC. Specific sections in the chapter focus on the care and unique needs of the child presenting with AC and their families. A great emphasis is given on patient education with a focus on the key role of the endocrine nurse as an advanced practitioner in this aspect of patient care. This chapter follows on from Chap. 37 in the adrenal section and we strongly recommend the reader refers to it for a comprehensive overview of the diagnosis and management of adrenal insufficiency.

Keywords

Adrenal insufficiency · Adrenal crisis · Hydrocortisone · Glucocorticoids · Patient education · Steroid card · MedicAlert Hypoglycaemia

Abbreviations

AC	Adrenal crisis
AI	Adrenal insufficiency
GC	Glucocorticoid
HDC	Hydrocortisone
HRT	Hormone replacement therapy
IM	Intramuscular
IV	Intravenous
PAI	Primary adrenal insufficiency
SAI	Secondary adrenal insufficiency
SC	Subcutaneous

Key Terms

- **Adrenocorticotropic hormone (ACTH):** Is the hormone responsible for stimulating cortisol production from the adrenal glands, which is essential for life.
- **Adrenal insufficiency (AI):** Refers to the failure or impairment of the adrenal glands which can be primary adrenal insufficiency (PAI) most commonly autoimmune or Addison's disease, or secondary adrenal insufficiency (SAI) due to hypothalamic-pituitary diseases, resulting in cortisol deficiency.
- **ACTH stimulation test:** Is a diagnostic test to assess the adrenal steroid production after the administration of the synthetic ACTH analogue Tetracosactide
- **Adrenal crisis:** is life-threatening emergency caused by inadequate production of the adrenal hormone cortisol in situations of stress.

Key Points

- Adrenal crisis (AC) is a life-threatening event for patients with adrenal insufficiency (AI) and must be treated immediately with parenteral hydrocortisone to avoid hospitalisation and preventable death.

- Gastroenteritis with vomiting/diarrhoea and other infections are the main triggers for AC but other stressful events and illness can precipitate AC.
- The patient and their families should receive adequate education to follow "sick day rules" and to adjust medication appropriately during intercurrent illness and major stress.
- Education and treatment plans should be tailored to each patient's and family's individual needs.
- The endocrine nurse, through advanced practice skills and clinical expertise, plays a key role in the care and education of patients with AI and their families.

62.1 Introduction

Adrenal crisis (AC) or otherwise known as Addisonian crisis is a life-threatening emergency for people with adrenal insufficiency (AI). As we saw in Chap. 37, AI results from failure or impairment of the adrenal glands which can be primary (PAI), most commonly autoimmune or Addison's disease, or secondary (SAI) due to hypothalamic-pituitary disorders; it requires lifelong glucocorticoid (GC) replacement therapy and mineralocorticoid replacement for patients with PAI.

Patients with AI are at risk of developing AC if GCs are reduced or stopped, or if the dose is not increased during periods of intercurrent illness or other major psychological and physical stress such as surgical procedures or trauma to mimic the normal increase in physiological cortisol response to such situations (Johannsson et al. 2014). This is also referred to as "sick day rules" (Bornstein et al. 2016). Failure to do so can lead to an AC which presents with profoundly impaired well-being, nausea and vomiting, hypotension, hypovolaemic shock, and can be fatal without immediate administration of parenteral hydrocortisone (Allolio 2015). Risk of AC is also high in patients with long-term corticosteroids who may stop treatment abruptly or are unable to take tablets, e.g. vomiting/diarrhoea or surgical procedures (Schuetz et al. 2015; Broersen et al. 2015). The narrative in Box 62.1 illustrates the negative impact an AC can have on a patient's life. It also emphasises the crucial role the endocrine nurse plays in supporting and providing patients and their families with the right information at the right time to prepare them for prevention and management of an AC.

Box 62.1 A Patient Story Emphasising the Importance of the Role of the Endocrine Nurse

I was diagnosed with a large pituitary tumour in 2012. I had surgery shortly after diagnosis and straight after started levothyroxine, hydrocortisone, and HRT. I also saw a nurse the same day who gave me lots of information on hydrocortisone. She gave me leaflets too but I didn't quite get to read them. …I was devastated about my brain tumour [pituitary macroadenoma] diagnosis and that I have to take medication for the rest of my life so it didn't seem that important what she was saying.

Eight months later, I had norovirus with really bad vomiting and diarrhoea. I felt extremely weak and was losing consciousness, my husband called an ambulance. I don't remember much but a flashback from the nurse's voice came back to me saying "if you have vomiting, it can be life threatening…". As I was passing out, I saw my life flashing past. I was terrified that I was dying and that I will leave my children motherless without even having the chance to say "goodbye!". I woke up in hospital. Luckily for me the paramedic knew what an adrenal crisis was and gave me the hydrocortisone injection immediately. I did not die but will never get over the trauma from that experience.

When I was in hospital (different to where I had my surgery), the endocrine nurse came to see me. She gave me information on how I can manage an adrenal crisis and gave me an injection kit. This time of course I did take notice of what she was saying!... She saw me again in

(continued)

Box 62.1 (continued)

[outpatient's] clinic, it turns out I was taking too much hydrocortisone and too late in the day, that's why I was putting on so much weight and not sleeping well. She was very patient, explained everything in detail and simple language and showed me and my husband how to give the injection. I see her now every six months, my life has been transformed, and she started me on growth hormone too. I had another [adrenal] crisis from food poisoning when I was on holiday 6 months ago, but my husband gave me the [hydrocortisone] injection immediately, I felt better straight away and did not have to go to the hospital. I was fine after 2 days and we enjoyed our holiday. I am now always prepared and carry my injection kit with me all the time.

I wanted to share my story so all patients in my position DEMAND to see an endocrine specialist nurse! But most importantly to get information at the right time. It was pointless telling me how to take my medication at the time when I was devastated from such a dreadful diagnosis. It turns out the pituitary tumour is nothing compared to what comes next. I would not have the quality of life I have now without her [the endocrine nurse's] support and hope she will be at the hospital for many years to come. Thank you so much for all your help!...

Quote taken from anonymised patient responses from a Pituitary Nurse-led Clinic service evaluation project (from Llahana et al. 2018, unpublished data)

62.2 Clinical Presentation of Crisis in Adults

The most frequent precipitating factors for AC are gastrointestinal infections, vomiting, diarrhoea and fever for more than 50% of patients, but also other stressful events such as surgery, dental procedures, major pain, emotional distress, pregnancy, extreme temperatures and physical exertion (Hahner et al. 2010, 2015a; White and Arlt 2010; White and Wass 2015; Smans et al. 2016; Rushworth and Torpy 2014). Table 62.1 lists the most common triggering factors for AC as reported by patients in six studies.

AC is the first presentation of AI for up to 50% of patients with Addison's disease. Patients developing an AC have major impairment of general health and present with the following clinical signs and symptoms requiring immediate parenteral hydrocortisone administration (Bornstein et al. 2016; Allolio 2015; Bancos et al. 2015; Arlt and Society for Endocrinology Clinical Committee 2016).

- Fatigue, profound lack of energy, and general weakness
- History of weight loss
- Generalised skin hyper-pigmentation in patients with PAI
- Nausea and/or vomiting
- Abdominal pain, tenderness, and guarding
- Fever >38 °C
- Hypotension (systolic blood pressure < 100 mmHg), postural dizziness and hypotension (≥20 mmHg drop in blood pressure from supine to standing position)
- Hyponatraemia (≤132 nmol/L), hyperkalaemia (in PAI), hypoglycaemia (more common in children)
- Confusion, somnolence, delirium, and impaired cognition
- At a later stage, symptoms accelerate to hypovolaemic shock, pre-renal failure (increased serum creatinine due to hypovolaemia), loss of consciousness, and coma leading to cardiovascular failure and death

Improvement in clinical signs and symptoms should be expected within 24 h (Allolio 2015). This improvement of clinical conditions after parenteral administration of hydrocortisone is important as it differentiates an adrenal crisis from other severe medical conditions which require relevant treatment. Development of an AC usually takes several hours; however some

patients, especially children, can deteriorate very rapidly even within 1 h (Allolio 2015). This makes it difficult for patients to take preventative measures and be fit to self-administer hydrocortisone injection.

Allolio also graded the severity of AC from 1 to 4 as follows depending on the setting required for treatment and outcome (Allolio 2015):

- Grade 1: Outpatient care only [this may also be home setting or general practice and includes administration of parenteral hydrocortisone 100 mg by the patient, family member, or healthcare professional]
- Grade 2: In hospital care [includes hospital admission on a general ward due to signs and symptoms of an adrenal crisis]
- Grade 3: Admission to intensive care unit resulting from AC
- Grade 4: Death from adrenal crisis (with or without parenteral glucocorticoid administration)

62.2.1 Presentation of Adrenal Crisis in Children

The possibility of AI should be considered as a provisional diagnosis in any severely unwell neonate or child presenting to an emergency department (Miller et al. 2008; Brook and Dattani 2012). For Emergency Department staff, a neonate or child presenting in a severe state of systemic collapse with hypoglycaemia, hypotension, and fluid and electrolyte disturbance should trigger a provisional diagnostic path to rule out the possibility of life-threatening AC. Both hypoglycaemia and AI are inter-related conditions as cortisol is a counter-regulatory hormone important for systemic support, balancing blood sugar via hepatic gluconeogenesis and maintaining blood pressure and electrolyte levels (Kwok et al. 2005). Depending on the significance of the presentation, resuscitative procedures may be required before critical blood samples can be adequately obtained. Once the neonate or child is stabilised, further evaluation will be required to ascertain the cause of the event, with a comprehensive history and consultation by an endocrinologist if hormone deficiencies are detected or suspected (Brook and Dattani 2012; Linder et al. 1990).

An AC can be a result of a seriously unwell neonate or child as a new presentation or a child with a known diagnosis where an AC can be precipitated by a significant illness, trauma, or stress if left untreated can be fatal (Miller et al. 2008; Brook and Dattani 2012; Webb and Krone 2015). Precipitating factors for AC which need parenteral hydrocortisone administration are similar to the adult patients but nonadherence to medication can affect children more severely leading to:

- Cortisol insufficiency/hypoglycaemia
- Postural hypotension/pallor
- Impaired growth and weight
- Lethargy and tiredness
- Lack of energy and exercise tolerance

The management of an acute adrenal crisis involves an immediate triage and history of the presenting issues and symptoms whilst emergency management procedures are instigated. An infant or child presenting in a state of systemic collapse may exhibit any of the following (Miller et al. 2008; Brook and Dattani 2012; Webb and Krone 2015):

Presentation

- Drowsy and difficult to rouse
- Pale and mottled in appearance
- A neonate with persistent jaundice or a bronzed appearance of the skin
- A male infant with signs of mild–moderate pigmented genitalia, umbilicus, nipples, and crease lines

Observations

- Hypothermic, tachycardic, laboured and rapid breathing, hypotensive, delayed capillary return, hypoglycaemia

History

Neonate/infant: poor and difficult feeding, excessively sleepy and lethargic, not waking for feeds, vomiting, poor urine output, significant weight loss >10%.

Child: lethargy, muscle weakness with a lack of energy, poor appetite, failure to thrive with evident growth failure and poor weight gain. Presentation may follow a period of prolonged fasting and or inadequate oral intake exacerbated by an inter-current illness. There is often a history of slow and prolonged recovery from illness.

62.3 Prevalence and Mortality of Adrenal Crisis

The prevalence of primary AI is 93–140 patients/million population and secondary AI is 150–280/per million (Arlt and Allolio 2003) with an estimated population between 110,000 and 213,000 patients with AI in the European Union (Allolio 2015). The standard mortality rate (SMR) for patients with AI is more than twofold compared to the average population (Bergthorsdottir et al. 2006; Tomlinson et al. 2001). AC is a factor that increases the mortality rate in patients with AI. Erichsen et al. (2009) found that SMR was significantly elevated in patients diagnosed before the age of 40 years; this was more pronounced in males with SMR 2.03 (CI 1.19–2.86) and younger patients were at higher risk of sudden death from

AC. Four patients died from AC during a 2-year prospective study of 364 patients with AI (767.5 patient years) leading to a mortality rate from AC of 0.5/100 patient years (Hahner et al. 2015a). Similar findings were reported by another study from Australia which looked at hospital admissions for patients with AI and found that four patients ($N = 467$) had died with a principal diagnosis of AC (Rushworth and Torpy 2014). Hospitalisations and deaths from AC are potentially preventable and if treated promptly can save patients' lives. The late Professor Bruno Allolio estimated that, at the current mortality rate for AC, between 5526 and 10,647 patients with AI, in an average population of 507 million people in the European Union, will die from a potentially preventable AC (Allolio 2015).

Studies from Europe show an incidence of AC between 5 and 10 AC per 100 patient years (Hahner et al. 2010, 2015a; White and Arlt 2010; Smans et al. 2016). An earlier study from Japan showed a much higher incidence and 29% of patients ($N = 137$) had experienced at least one AC episode (Omori et al. 2003). The incidence of AC is somewhat higher in patients with PAI who have combined GC and mineralocorticoid deficiency compared to those with SAI (Hahner et al. 2010; Smans et al. 2016). Comorbidities, such as diabetes, asthma, premature ovarian failure, and coeliac disease, are added risk factors for AC for more than 50% of patients with PAI (White and Arlt 2010; White and Wass 2015), and diabetes insipidus and growth hormone deficiency for approx. 70% of patients with SAI (White and Wass 2015).

The prevalence of hospitalisation due to AC is also very high for this patient population, even though most hospital admissions could be prevented with prompt parenteral administration of hydrocortisone (Allolio 2015; Wass and Arlt 2012). An international study found that 38% of participants ($N = 977$) had been hospitalised at least once during the past 12 months and of these hospital admissions, 17% were due to an AC, i.e. 1 in 6 patients with a hospital admission (Forss et al. 2012). One in 12 patients report at least one hospital admission per year related to an AC (Hahner et al. 2015a; White and Arlt 2010), and 10.6% of patients with PAI, and 7.4% with SAI who reported AC had this on four or more occasions (Hahner et al. 2010). This suggests that there is a subgroup of patients at high risk and we need to identify and support them with relevant individualised treatment planning and education. In addition to health burden and risk to patient's lives, AC has significant cost implications for the health service despite the low prevalence of AI. In 2015, 2052 AC-related hospital admissions were recorded in National Health Service (NHS) hospitals in England (HSCIS 2015), which incurs a minimum cost to the NHS of £3.2 million/year (€3.6 million or $4.2) based on a daily inpatient rate of £1565 (DoH 2015).

62.4 Prevention of Adrenal Crisis and GC Adjustment in Increased Stress

Patients with AI need to increase the dose of their GC replacement to mirror the physiological increase in serum cortisol levels during major stress and illness. In the cases where oral tablet intake is not possible, immediate parenteral hydrocortisone administration is crucial to prevent life-threatening AC. This is normally referred to as "sick day rules". Professors John Wass and Wiebke Arlt, leading experts in AI, emphasise that "*prevention of adrenal crisis is better than cure*" (Wass and Arlt 2012). Endocrine nurses should be leading on this aspect of care for patients with AI and ensure that all patients and their families are provided with the necessary information and resources to minimise the risk of hospitalisations and to eliminate preventable deaths from AC. They should also strive for strategic involvement in improving care services for patients with AI, including the development of nurse-led services and clinics in specialist centres and coordination of seamless care pathways for acute services and primary care. Close collaboration with patient advocacy groups is also essential (see next section).

62.4.1 GC Replacement During Intercurrent Illness and "Sick Day Rules"

A number of cross-sectional studies found that 26–38% of patients with AI did not adjust the GRT dose during stressful events or intercurrent

Table 62.2 Glucocorticoid dose adjustment in stressful events and intercurrent illness (adapted from Allolio (2015) and Bornstein et al. (2016))

Increased stress situations or events	**Hydrocortisone (HDC) dose adjustment**
Strenuous physical activity (e.g. marathon running, hiking, moving house, gardening)	Take 5–10 mg HDC 30–60 min before activity
Long-haul flights (e.g. trans-Atlantic)	Take 5–10 mg HDC 30–60 min before flight take off
Major emotional/mental stress (major end of year exams, job interview, death of close relative/family member)	Add 10–20 mg HDC to standards replacement dose
Long days (e.g. Saturday night out, wedding parties, working late)	Take an additional 5–10 mg HDC before going out or late evening
Shift working	Adjust HDC to take during the awake times
Ramadan fasting	Switch to long acting GC, take dose before dawn
Intercurrent illness/procedures	**Able to take GC orally**
Illness with or without fever (unable to work or go by with daily routine)	Double (fever >38 °C) or triple (fever >39 °C) dose of HDC until recovery, **take at least three times daily**, return to standard dose within 1–2 days by tapering down
Minor painful procedures (e.g. skin mole removal, tattooing, body piercing)	Take 10 mg HDC 60 min before procedure, if infection develops, additional HDC needed as per above
Major dental work with local anaesthetic (e.g. root canal, implant)	Take an extra 20 mg HDC 60 min before procedure, double dose for 24 h
Minor dental procedure (filling, scale and polish, hygienist)	Take 10 mg HDC 60 min before procedure, take an extra dose later in the day if pain or discomfort
If taking dual-release hydrocortisone (Plenadren®) or prednisolone once daily	
Febrile intercurrent illness	Increase dose to twice or thrice daily with 6–10-h intervals between tablets
For short stressful events (as above)	Take a single dose of HDC of 5–10 mg or 20 mg for more severe stress 30–60 mg prior to event
More severe intercurrent illness	**Requires parenteral hydrocortisone**
Gastroenteritis with vomiting and/or diarrhoea, trauma (unable to take tablets)	Immediate hydrocortisone 100 mg IM or SC administration, to be repeated after 6–12 h; seek medical help if symptoms don't improve
Severe infection (e.g. pneumonia)	As above

NOTE: This table provides general guidance but each patient's needs should be assessed individually.

illness (Llahana 2013; Flemming and Kristensen 1999; van Eck et al. 2016; Peacey et al. 1993). All patients and their families should receive detailed patient education in face-to-face consultations to advise them on "sick day rules" based on their individual needs for GC replacement. It is advised that patients should add 5–10 mg of hydrocortisone to their normal dose about 30–60 min before any events of excessive/major physical, emotional, or mental stress (Allolio 2015), such as exams, job interviews, extreme physical exercise, and bereavement (Table 62.2). However, it is important to remember that the degree to which patients are affected by similar stressful situations varies from patient to patient (please read the case scenarios in Box 62.2).

Box 62.2 Case Scenario of GC Dose Adjustment in Stressful Events

Two students take end of year exams. The first student who has Addison's disease tells you he experiences severe perspiration, hot flushes, tachycardia, dizziness, and anxiety when entering the classroom and finds it impossible to focus. The second student has hypopituitarism following surgery for non-functioning pituitary adenoma; he feels slightly anxious, but he is still able to focus on his exam and performs well. None of them were previously advised on what to do in stressful events such as an exam. They are both on a daily dose of hydrocortisone 10 + 5 + 5 mg. What do you advise them?

The endocrine nurse should take a detailed history of events that affect the patient's well-being or that may have triggered AC episodes in the past and should educate them on recognising and managing these situations through appropriate adjustment of GC therapy. In the case scenarios in Box 62.2, the first patient should be advised to take an extra 10 mg of hydrocortisone before the exam, but the second patient does not necessarily need to increase the dose, assuming he adheres to his daily dose of hydrocortisone. The dose of GC also needs to be adjusted accordingly with concomitant use of certain drugs such as mitotane or foods (please see table in Chap. 37 for food and drug interactions with GC).

For intercurrent illness such as infections, injuries, flu, and fever, the dose of GC should be doubled or tripled (Table 62.2). It should be maintained for the duration of illness and reduced back to the standard dose within 1–2 days after recovery (Bornstein et al. 2016; Allolio 2015). It is also important to advise patients to take hydrocortisone in three divided doses daily with 5–7 h between tablets; some patients with SAI for example may only take hydrocortisone once or twice daily for their maintenance dose.

For patients who take long acting GC, such as prednisolone or dual-release hydrocortisone (Plenadren®), the total daily dose should be increased by administering the maintenance dose twice or thrice daily with 6–10-h intervals, i.e. increase in the number of administrations, not increase in the morning dose (EMA 2018; Nilsson et al. 2017). For short periods of increased stress, e.g. extreme sports, a single dose of immediate-release hydrocortisone of 5–10 mg should be taken prior to the stressful event.

For more severe illness, vomiting, diarrhoea, and when the patient is unable to take tablets orally in situations such as elective procedures or surgery, hydrocortisone must be administered immediately intramuscularly (IM) or intravenously (IV) at 50–100 mg followed by 100 mg every 6 h. For patients who are not comfortable with self-administering IM injections, subcutaneous (SC) administration of hydrocortisone is a good alternative, with only an 11 min delay in reaching desired cortisol levels compared to the IM injection, (Hahner et al. 2013). In the absence

Table 62.3 Glucocorticoid replacement during surgical and other invasive procedures (adapted from Allolio (2015), Bornstein et al. (2016), Husebye et al. (2014), and Wass et al. (2017))

Surgical or other procedures	Pre-operative needs for hydrocortisone (HDC)	Post-operative needs for hydrocortisone (HDC)
Long major surgery with long recovery time (e.g. open-heart surgery, major bowel surgery, transplant surgery)	100 mg hydrocortisone IM or IV just before anaesthesia	100 mg IM or IV every 6 h or continuous IV infusion 200 mg/24 h or until able to eat and drink normally *(discharged from ITU)* If well, then double oral dose for 48+ h, then taper the return to normal dose
Major surgery with rapid recovery (caesarean section, laparoscopic surgery)	100 mg hydrocortisone IM or IV just before anaesthesia	100 mg IM or IV or continuous infusion 200 mg/24 h for 24–48 h for 24–48 h *(or until able to eat and drink normally)* If well, then double oral dose for 24–48 h, then return to normal dose
Labour and vaginal birth	100 mg hydrocortisone IM or IV at onset of active labour, immediately followed by continuous IV infusion 200 mg/24 h or 100 mg IM or IV 6 hourly until delivery	Double oral dose for 24–48 h after delivery If well, then return to normal dose
Minor surgery (e.g. cataracts, laparoscopic surgery with local anaesthetic, IVF egg collection surgery)	100 mg hydrocortisone IM just before anaesthesia	Double oral dose for 24 h, then return to normal dose

(continued)

Table 62.3 (continued)

Surgical or other procedures	Pre-operative needs for hydrocortisone (HDC)	Post-operative needs for hydrocortisone (HDC)
Major dental surgery (e.g. tooth extraction, orthodontic surgery)	100 mg hydrocortisone IM just before anaesthesia	Double oral dose for 24 h, then return to normal dose
Invasive bowel procedures requiring laxatives (e.g. colonoscopy)	Hospital admission overnight with IV fluids and 100 mg hydrocortisone IM during preparation period (bowel cleaning), 100 mg hydrocortisone IM before start of procedure	Double oral dose for 24 h, then return to normal dose
Other invasive procedures (e.g. endoscopy)	100 mg hydrocortisone IM just before start of procedure	Double oral dose for 24 h, then return to normal dose

Download Pdf guidelines from the UK Addison's Disease Self Help Group (https://www.addisons.org.uk/files/file/4-adshg-surgical-guidelines/)

of diarrhoea, rectal suppositories of prednisolone 100 mg are also easy to administer if parenteral hydrocortisone is not possible (Bornstein et al. 2016; Quinkler and Hahner 2012) although these are not available in every country. Table 62.3 presents details on need for GC replacement during elective surgical or nil by mouth procedures and other investigations (adapted from Bornstein et al. (2016), Allolio (2015), Arlt and Allolio (2003), Husebye et al. (2014), and Wass et al. (2017)).

The two-step process for "sick day rules" can simplify patient education regarding symptom awareness and the correct adjustment of GC replacement dose and it is easier for healthcare professionals and patients to understand and follow (Bornstein et al. 2016; Arlt and Society for Endocrinology Clinical Committee 2016) (Box 62.3).

Box 62.3 The Simple Two-Step Process of "Sick Day Rules" for GC Replacement

Sick Day Rule 1: the need to double or triple daily oral GC dose during intercurrent illness often accompanied by fever that requires bed rest and/or antibiotics**.**

Sick Day Rule 2: the need to administer hydrocortisone per IV, IM, or SC injection during prolonged vomiting or diarrhoea, during preparation for colonoscopy or in case of acute trauma or surgery.

62.4.2 Tools and Resources Important in the Prevention of AC

Additional measures are important to ensure patients and their families are prepared to manage and prevent AC. Patients should have sufficient supply of GC tablets to account for dose increase during intercurrent illness and should be advised to always carry medication with them, especially when travelling. It is our responsibility to provide all patients with AI with a Steroid Emergency Card, such as should they require urgent care or be rendered unconscious, the attending paramedical staff or the triaging team in the Emergency Department knows that the emergency hydrocortisone administration is a life-saving treatment which must not be delayed (Grossman 2010). This can be strengthened by the patient wearing a MedicAlert bracelet, necklace, or anklet (Bornstein et al. 2016; Allolio 2015; Bancos et al. 2015; Husebye et al. 2014; Grossman 2010) indicating their need for hydrocortisone injection for AC (a patient attending our clinic has tattooed this below his neckline).

The development and rollout of the highly standardised European Steroid Emergency Card (Quinkler et al. 2015) has made a significant contribution to raising awareness of the risk associated with AC risks and provides precise instructions for healthcare professionals in the acute service on the treatment of AC. The credit-card-sized card (Fig. 62.1) is endorsed by the European Society of Endocrinology (https://www.ese-hormones.org/). It has so far been

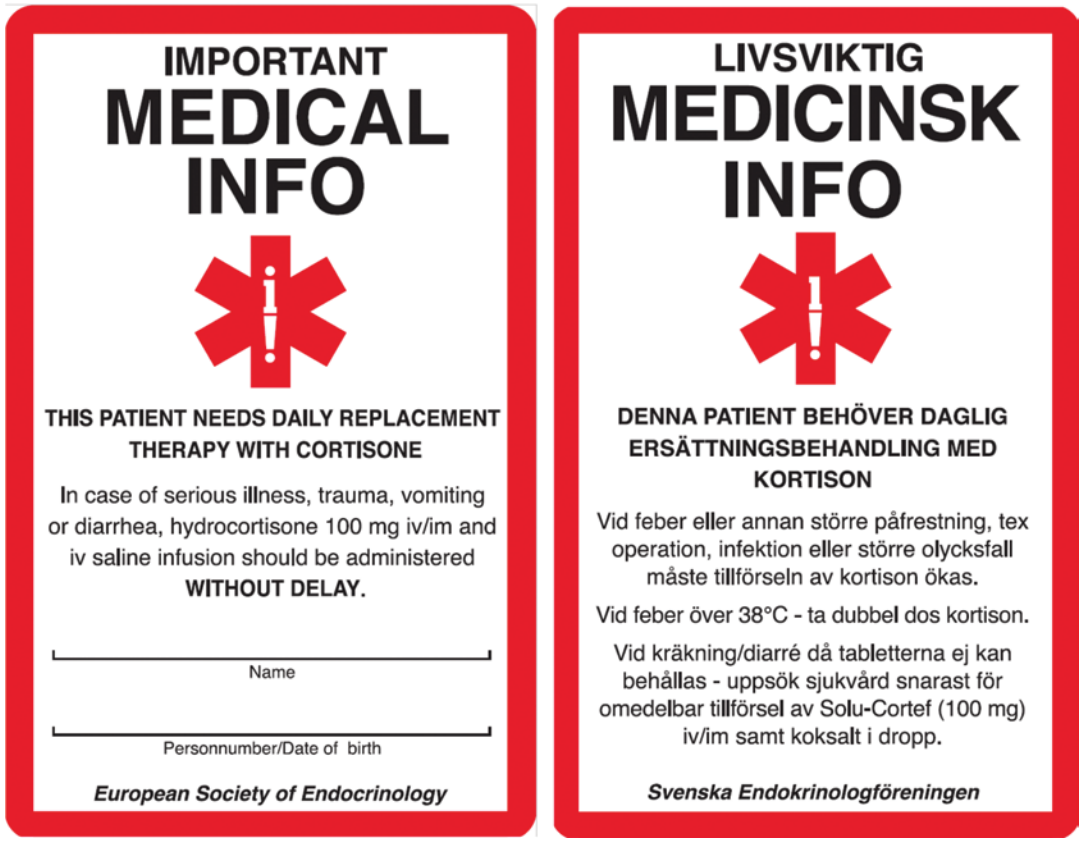

Fig. 62.1 The standardised European Emergency Steroid Card. Translated in 25 languages (two-sided English and Swedish here) and available to download from AdrenalNet (https://adrenals.eu/emergency-card/), used with permission

translated in 25 languages (double-sided card with English as the international side) and more than 110,000 cards have been distributed across Europe by AdrenalNet, a non-profit organisation aiming to promote knowledge and improve quality of care in AI (https://adrenals.eu/).

All patients should be provided with a specially designed "hydrocortisone emergency pack" (Grossman 2010) which should include the following: the hydrocortisone 100 mg injection for IM or SC administration, 2 syringes, 2 needles, at least 10 extra hydrocortisone tablets, 2 rectal suppositories of prednisolone 100 mg (where available), the emergency steroid card (Fig. 62.1) or a medical letter with the patient details (name, address, diagnosis, and treatment), brief guidelines for the treatment of AC (e.g. the credit card concertina wallet with printed guidelines developed by the Addison's Disease Self Help Group, Fig. 62.2). The case study in Box 62.4 emphasises the value of these resources for patients with AI.

Fig. 62.2 Guidelines for treatment of AC in a credit card concertina wallet. Used with permission from Addison's Disease Self Help Group (translated in 10 languages and available to download from https://www.addisons.org.uk/files/file/71-adshg-adrenal-crisis-guidelines/)

Box 62.4 A Case Study Elucidating the Importance of the Preventative Measures for AC

I am 51 years old and have had Addison's since 1995. We travel to Lanzarote regularly; it is our second home. We are very familiar with the surroundings and climate; I always take adequate supplies of all my medications, a medical letter for travelling, plus a couple of emergency injection kits. In the last 10 years we have been visiting, we have never had to make use of any of the medical facilities—until now.

We had a nice relaxing afternoon in the sun. My first mistake of the day was to remove my medical emblem from my neck—I didn't want it to affect my suntan.

As we were driving back, life took a sudden turn when we were involved in a road traffic accident… a car did not give way and crashed into the passenger side where I was sitting. I was immediately aware of pain in my arm and shoulder and a large gash on my chest. Fortunately, my husband suffered minimal injuries. The accident involved the police attending, the fire brigade cutting me out of the car and an ambulance, with none of the crew able to speak English.

We didn't have an emergency injection in the car with us, but we did have a large supply of hydrocortisone tablets. …I was not allowed to have anything orally, and then I vomited. I was taken to a private hospital and when we got there the situation was quickly brought under control by English-speaking doctors. They quickly gave me IV fluids and steroids whilst they sorted out my injuries. I was very well cared for.

So here are my lessons learned, that I now have to remember to put into practice:

When you travel, take a copy of the ADSHG adrenal crisis guidelines, stating you have Addison's, in the language of the country you are visiting.

Don't ever remove your medical jewellery—you wear it for a reason, even if you are sun bathing.

Take your emergency injection kit with you everywhere you go.

Always take more medication on your holiday than you will ever think you will need—and don't keep it all in one place.

Make sure your insurance covers all your pre-existing conditions.

NOTE: Patient case study published in the Addison's Disease Self Help Group (ADSHG) newsletter, used with permission from ADSHG (https://www.addisons.org.uk).

A third of patients experienced AC away from home and relied on emergency-care clinicians for the management of AC (White and Arlt 2010). Interestingly, 62–68% of patients with AI held an up-to-date emergency injection kit (White and Arlt 2010; Hahner et al. 2015b) but only 12% managed to self-administer the injection when they experienced an AC (White and Arlt 2010) and only 19% were trained to self-inject (Hahner et al. 2015b). Two other studies found that only 60% of patients carry an emergency medical-alert card even though they were all provided with a card and verbal/written information at their consultation (Flemming and Kristensen 1999; van Eck et al. 2016).

At every consultation, the endocrine nurse should emphasise the need for patients to wear a MedicAlert and to always carry a steroid emergency card and the emergency injection pack, particularly when travelling to places with limited access to medical services. Patients should also be encouraged to inform friends, family, or work colleagues of their risk of AC and how to use the emergency pack. Endocrinology clinics should make these resources available for their patients, and it should be the responsibility of the endocrine nurse to check that patients have an up-to-date emergency injection.

The use of digital health technology, online resources, and electronic patient records provide the patient and healthcare professional with timely access to information where and when needed. Information leaflets and online videos on administering the hydrocortisone injection available from websites of the patient advocacy groups can be exceptionally useful and membership in these organisations should be encouraged for all patients. The AdrenalNet (https://adrenals.eu/) has developed a free smartphone multilingual app which offers essential information on all aspects of management of AI and AC and has the possibil-

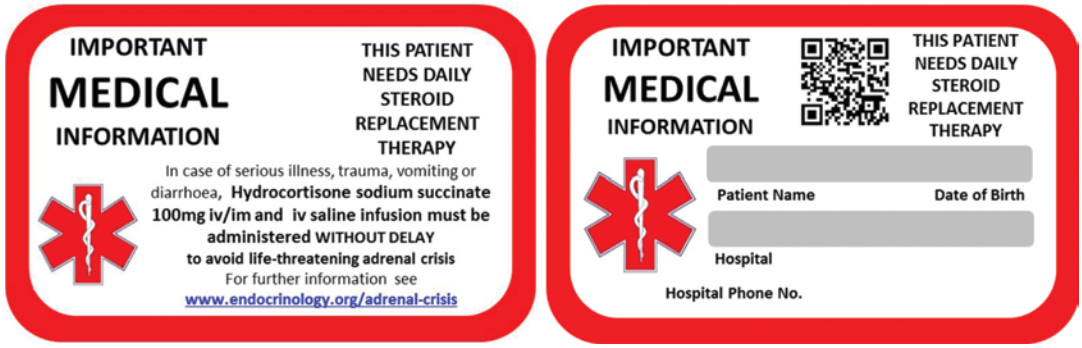

Fig. 62.3 Using the QR code of the Emergency Steroid Card to access guidance on treatment for AC. Card translated in 14 languages and available to download from the Society for Endocrinology, UK (https://www.endocrinology.org/adrenal-crisis)

ity to link up with the patient's hospital records where hospital system allows. In our hospital (London, UK), we have incorporated "alert messages" in the patients' electronic records advising of the risk and treatment for AC. Similarly, the new Emergency Steroid Card from the Society for Endocrinology in the UK includes a QR code (Fig. 62.3) which links to the website with the emergency guidance for treatment of AC. Patients with access to a smart phone can be encouraged to add this card as a wallpaper on their phone.

62.5 Treatment of AC in Adult Patients with AI

Patients with known or suspected AI presenting with AC must be treated immediately as failure to do so can be life-threatening (Box 62.5).

Box 62.5 Urgent Treatment for Adrenal Crisis Can Save Patients' Lives

TREAT FIRST, DIAGNOSE LATER!
Patients with suspected adrenal crisis should be treated immediately with intramuscular or intravenous hydrocortisone and prompt rehydration with isotonic saline of 1000 mL within the first hour. Diagnostic measures should never delay treatment.

Treatment of AC includes the following steps (Bornstein et al. 2016; Allolio 2015; Bancos et al. 2015; Arlt and Society for Endocrinology Clinical Committee 2016; Arlt and Allolio 2003; Husebye et al. 2014).

- **Immediate bolus IV or IM injection of hydrocortisone 100 mg** (hydrocortisone sodium succinate or hydrocortisone sodium phosphate) followed by continuous IV infusion of 200 mg hydrocortisone for 24 h (alternatively 50 mg every 6 h IM or IV bolus), reduced to hydrocortisone 100 mg/day the following day. Hydrocortisone acetate must not be used to treat AC due to its slow release, microcrystalline formulation (Wass et al. 2017).
- **Rehydration to correct hypovolaemia with rapid intravenous of 1000 mL isotonic saline** infusion (or 5% glucose in isotonic saline) within the first hour and, 500 mL in the second hour, followed by continuous fluid administration (usually 4–6 L in 24 h). Fluid overload should be monitored in case of renal impairment and elderly patients. Continuous cardiac monitoring, regular assessment of patients' electrolytes, and vital signs to monitor clinical recovery.
- **Relevant treatment of the precipitating factor of AC**, e.g. infection, trauma, other hormone deficiencies in SAI. Treatment for AC should result in clinical recovery within 24 h. If improvement does not occur, alternative causes for the profound impairment of health need to be considered again. Depending on the severity of the intercurrent illness, admission to the intensive care or high-dependency unit may be necessary (Allolio 2015; Husebye et al. 2014).

- **When the patient is clinically stable** and able to return to oral GC intake, "sick day rules" should be followed until full recovery and the GC dose should be tapered down to usual maintenance dose within 24–72 h.
- **Urgent endocrinology review** is necessary, especially for patients with a new diagnosis of AI. A nursing review is also crucial to review and advise the patient and their families on "sick day rules" and assess the need for further education and outpatient input.

62.5.1 Prevention and Treatment of AC in Children with AI

Children can develop AC quicker and more severely than adults with hypoglycaemia, very common presenting symptom of AC in children, and which can lead to severe brain damage. To prevent AC, "sick day rules" must be followed immediately after the onset of symptoms occur and GC dose should be increased for any significant illness (Speiser et al. 2010). Table 62.4 presents the

Table 62.4 A practical guide to plan, predict and manage illness events in children to prevent an AC

Patients with adrenal insufficiency (AI) are at risk of an adrenal crisis when unwell: e.g. significant illness or injury or procedures requiring anaesthesia. In these situations increased "**stress**" **doses** of hydrocortisone (HDC) are required. This condition can be life threatening if treatment is withheld

Managed care plans are critical in ensuring parents and patients understand the importance of compliance with their medication and to follow "sick day rules" when illness occurs

Minor illness:	**Moderate illness:**
Stress HDC doses are not required for incidental/minor illnesses, such as cough, sniffles, runny nose or regular school exams • Monitor and encourage fluids and oral intake • Observe and monitor for any symptoms indicating a more significant illness (possible respiratory, middle ear, urinary tract infections or abdominal upset) • Seek medical advice • *Refer to emergency letter* **Immunisations:** monitor for symptoms/fevers • Oral stress dose for 24 h **Vomiting of medications:** if within 1 h: • Repeat the dose and observe for further episodes • Refer to emergency letter	Not their usual self, labile demeanor, cranky, irritable, off their food, fever above 38 °C Inter-current illness—upper respiratory, flu-like symptoms, headache with or without fever Mild episode of diarrhoea and/or vomiting (D&V) • Oral stress HC doses with a sweet drink for 24 h or until well again • Encourage oral fluids and a light diet • Glucose/electrolyte solution for D&V • Monitor for deterioration • Give IM HDC if deterioration and go to the Emergency department *Follow instructions in your emergency letter* *If in doubt, seek medical advice* **Medical and dental Procedures**: prolonged fasting, anaesthesia and surgery require stress HDC dosing • Procedure plan required

Major illness/crisis (critical) immediate medical attention required

Symptoms:

- Persistent diarrhoea and/or vomiting, significant injury (fracture, head injury)
- Significant systemic illness requiring admission to hospital
- Lethargy, drowsiness, dizziness and confusion and reduced conscious level
- Pale and mottled appearance, poor capillary return

Interim Management:

- Urgent injection of intramuscular HDC injection required
- *Parents should administer IMI HDC immediately and take child to hospital*
- *Carers/teachers should call an ambulance and state child with AI needs cortisone injection urgently*
- *All parents/carers should be trained in IM injection of HDC administration*

Critical observations:

- Hypoglycaemia and hypotension, tachycardia, dyspnea, hypothermia with circulatory collapse with poor capillary return, deterioration to coma, shock and impending death

Triage assessment: immediate—without delay—noting medical alert—adrenal Insufficiency

- Instigate emergency management noted in emergency letter
  - IM HDC stat: prevent an adrenal crisis—first PRIORITY
- IM Glucagon: hypoglycaemia <2.6 nmol/L, buccal glucose gel if needed
- IV access and fluid resuscitation as per standard hospital protocols (intra-osseous if need) and ongoing IV/oral stress HDC is needed until well again
- Oxygen, ECG monitor, thermal blanket, BGL, electrolytes and hormone profile are needed

Clinical Practice Guideline developed by Irene Mitchelhill, Endocrine Clinical Nurse Consultant, Sydney Children's Hospital Randwick NSW Australia. Document available via: http://www.schn.health.nsw.gov.au/policies/pdf/2014-9017.pdf

clinical guidance developed by the paediatric nurse consultant and her team to support parents and healthcare professionals with identifying and applying "sick day rules" to various situations which can precipitate AC in a child with AI.

Hydrocortisone should be used in the treatment of AC in children for its GC and mineralocorticoid action and rapid bioavailability. The calculation of a "stress dose" of hydrocortisone for children is determined between 3 and 10 times the normal physiological secretion of cortisone of 6–9 mg/m^2/day up to 15 mg/m^2/day (Migeon and Lanes 2009). Tripling the upper limit in this range is often used as a starting point for such calculating sick day doses. The actual dose given for sick day events is determined on the severity of the stressful event and is prescribed between 50 and 100 mg/m^2 (Bornstein et al. 2016).

A child with a suspected AC must be treated immediately with parenteral hydrocortisone (IM as priority pending IV access) and diagnostic measures must not delay administration. As a general guide, the following steps should be followed (Bornstein et al. 2016; Lecahwg 2002) although it is advisable to refer to hospital emergency management guidelines if available.

Step 1: Give Hydrocortisone IM/IV as a stat dose using a suggested aged-based dosing guide of: 25 mg <3 years, 50 mg 3–12 years, 100 mg >12 years of age (Bornstein et al. 2016).

NB: Such doses should be repeated if there is an inadequate response.

If IV access is difficult, this is given as an IM injection as a priority for systemic support which can aid IV access.

IM Glucagon follows hydrocortisone for any hypoglycaemia.

Step 2: Start immediate rehydration with isotonic saline infusion according to protocols for age: 10–20 mL/kg 0.9% saline, with ongoing maintenance plus deficit for dehydration given as 0.9% saline and 5% glucose and adjusted according to electrolytes and blood glucose (SCHN 2017; RCHM 2016).

Step 3: Correct hypoglycaemia which is often evident with AC in children. If blood glucose (BG) level <3.5 mmol/L, give 2 mL/kg IV of 10% glucose and recheck BG in 30 min. IM Glucagon should be given if IV access is delayed. (SCHN 2017; RCHM 2016).

Step 4: Start continuous IV infusion of hydrocortisone after bolus injection at 45 mg/m^2, or in divided doses 6 hourly using the following age-related dosage guide: ≤3 years—20–30 mg per 24 h, 3–12 years—50–60 mg per 24 h; >12 years—100 mg per 24 h (Webb and Krone 2015).

Omeprazole should be considered to prevent gastritis if stress hydrocortisone treatment is prolonged.

Step 5: Treat the precipitating factor (infection or trauma) and manage fevers for comfort.

Step 6: Contact an endocrinologist for urgent review of the child and further management of hydrocortisone dosing.

Step 7: Patient education about "sick day rules" by the endocrine nurse.

Step 8: Stress cover is required for any significant procedures requiring anaesthesia or surgery. Children should have an emergency management plan with medical alerts on both hospital and ambulance systems.

Education and regular review of knowledge is critical for a positive outcome for the child and normal growth and development. Parents of children with known adrenal insufficiency are required to understand the need for additional "stress doses" of glucocorticoids during any significant intercurrent illness, injury, or procedures surgery requiring anaesthesia.

An education review regarding emergency management plans should occur on a regular basis with emergency letters updated yearly. All families should be supplied with a hydrocortisone injection kit for emergencies and trained in its use. Many parents find it difficult to make the "judgement call" regarding the severity of their child's illness and often delay giving an injection of hydrocortisone. A Canadian study of 136 children with AI conducted between 1973 and 2007 found that the use of GC stress doses and administration of hydrocortisone injection increased significantly after 1997 ($p < 0.05$) with improvement in patient education and access to the emergency hydrocortisone injection kit at home (Leblicq et al. 2011).

Nursing management of the critically ill neonate, infant, or child commences with the initial presentation at triage and emergency rescue procedures, the subsequent diagnosis and continues through the treatment and recovery phase until the infant/child is back to full health and lifelong. The most critical component of this process is in providing support for the parents, who will be in a state of shock and disbelief, with their child presenting with a life-threatening condition. Providing clear and simple explanations for the parent initially will help them understand the emergency management procedures and what has led to the cause of the presentation.

Preventing delays at the triage desk in an emergency department is essential (Hahner et al. 2015b). It is important for all parents and adolescents to practice the preparation and administration of an injection on a regular basis to be able to administer the injection before going to the emergency department. Endocrine on-call services are provided by most tertiary healthcare facilities, which can provide important advice and guidance for any concerns.

62.5.2 Management of AC in the Acute Setting

Many ACs occur by the slow reaction time of clinicians involved in the acute care of patients presenting with an AC as they do not understand the urgency of treatment for acute AC or fail to heed the request of well-informed patients for urgent administration of hydrocortisone injection. (Wass and Arlt 2012).

Severe delays in the administration of the emergency hydrocortisone injection have been reported with 15% of patients having to wait between 6 and 12 h (Ibrahim et al. 2015); this led to lengthy hospitalisations for 41% of patients in another study (Hahner et al. 2015b). About one in five patients encountered clinicians who had ignored presentation of their medical-alert identification when presenting with an AC (Hahner et al. 2015b). Many patients felt averse to seeking medical help in an AC due to such delays (Ibrahim et al. 2015).

The use of hydrocortisone injection and training for paramedical staff on management of AC and the establishment of a "flagging" system for paramedics to have warning when attending the patient with AI has been successfully adopted by most ambulance services across Great Britain (Box 62.6). This service was initiated in the South of England and led by an endocrinology clinical nurse specialist (CNS) (Cox 2006). Patients feel safer when they ring the ambulance service, and paramedics are more prepared and competent at managing an AC successfully without delays (Quinkler and Hahner 2012).

Box 62.6 Good Clinical Practice Example: Development of a Care Pathway for Management of AC by Ambulance Service

Sue Cox, a Clinical Nurse Specialist from Torbay in the South of England, UK, initiated and led the development of a training programme and treatment pathway on the management of AC for the local ambulance crew in 2005. A few weeks later, Kevin, one of the paramedics who attended the training, was able to respond promptly to an emergency call to a 63-year-old man at his home who had collapsed and was not breathing following an AC. Hydrocortisone 100 mg was administered immediately and the patient regained consciousness on the journey to hospital. Response time was 20–30 min and the patient made a complete recovery and was discharged from hospital 2 days later.

Since then, endocrinology specialists led by Professor John Wass in collaboration with the national patient advocacy groups, the Addison's Disease Self Help Group (https://

www.addisons.org.uk) and the Pituitary Foundation (https://www.pituitary.org.uk), and the Joint Royal Colleges Ambulance Liaison Committee, have developed a national pathway and guidance on the treatment of AC which is adopted by most ambulance services in the UK. This results in improved awareness among paramedical staff regarding the treatment of AC and can avoid unnecessary hospital admissions and eliminate preventable deaths.

The "**Get Red Flagged**" campaign by the Pituitary Foundation has also been a significant development in the UK as it empowers patients with AI to register with their local ambulance, so they can be "flagged" for priority attendance by a vehicle carrying emergency hydrocortisone.

NOTE: The case study, used with permission from the Addison's Disease Self Help Group, was published in their newsletter, ***issue 83, March 2006.***

The endocrine nurse has a crucial role in ensuring that patients and their families know how to contact acute services and, where available, to register with the ambulance service. Involvement or leading on training and teaching sessions for acute care healthcare professionals should also form an important component of the endocrine nurses' role. Until the time comes when all paramedical staff and acute care healthcare professionals are fully trained on treatment protocols for AC, it is important that we prepare our patients to act based on the principle of:

> "*The well-informed patient (or his/her relative) guides the poorly informed health-care professional!*" (Allolio 2015: R121).

62.6 Patient Education for the Prevention and Management of Adrenal Crisis

Patient education is of paramount importance in the prevention and management of AC and the endocrine nurse is a key player in this aspect.

All patients with AI, their families, partners, and/or friends should be involved in the education process to support patients' self-management and prevention of AC. This helps to act adequately in critical situations in a self-care setting and to communicate with healthcare professionals who are not familiar with AC. Patient education should cover the following aspects:

- Daily maintenance of GC replacement to avoid over- or under-replacement
- "Sick day rules" and adjustment of GC replacement during intercurrent illness
- Prevention and management of AC and training on self-administration for hydrocortisone injection

Nursing-led education programmes for patients with AI have been documented since the early 1960s (Shea et al. 1965) and recent evidence suggests that patient education interventions improve satisfaction and knowledge with GC replacement and prevention of AC. Group education programmes for patients with AI are now standard practice in many centres across the world and have shown improvement in the patients' satisfaction, confidence, and knowledge of adjusting GC replacement during "sick days" and self-administration of hydrocortisone injection to prevent AC (Repping-Wuts et al. 2013; Saeed et al. 2011; van der Meij et al. 2016). Patient education however does not translate to improved adherence to GC replacement (Llahana 2013; van Eck et al. 2016) or reduction in the prevalence of AC and hospital admissions (Hahner et al. 2010; 2015a; van der Meij et al. 2016), even though

patients attended highly experienced units in AI with skilled staff and good patient education standards.

Omori et al. found that duration from diagnosis of AI longer than 4 years was the largest single contributor to the relative risk factor for AC as patients' ability to recognise and prevent AC had declined over the years. Although they could not elucidate on reasons for this, they postulated that patients had forgotten their "sick day rules" and suggested that patient education is provided in every consultation (Omori et al. 2003). In another study of 338 patients with AI, less than 42% could recall information on GC dose adjustment and use of emergency steroid card, following face-to-face teaching during clinic consultations (Harsch et al. 2010). It is therefore recommended that patient education is provided at every consultation and at least annually (Bornstein et al. 2016; Allolio 2015).

62.6.1 Pitfalls in the Patient Education Process and Future Directions

The goal for patient education is to achieve long-lasting changes in health behaviour and for this a robust research methodology is needed to develop and deliver structured educational programmes (Llahana and Thomas 2016). Patient education programmes in AI have so far lacked theoretical underpinning and a research methodology which can explain the likely influences of the programme on behaviour change; details of the interventions are not fully reported, and more importantly outcome measures are not clearly articulated.

To this end, a standardised structured education programme in AI was developed and established in Germany in 2014 (Box 62.7); preliminary data from 212 patients show significant improvement in self-management and prevention of AC post intervention (Eff et al. 2016).

Box 62.7 The Structured Group Education Programme for Patients with AI in Germany

The Adrenal Section of the German Society for Endocrinology initiated in 2014 a structured patient group education programme in AI which has now been adopted by 77 endocrinology centres across Germany; endocrinology nurses have played a crucial role in the development of this programme and are at the core of its delivery. An 8-h training session every year is required to attain certification to deliver this programme, ensuring thus standardisation of the programme and transferability across the centres; 186 nurses and physicians completed the certification training at the time of writing this chapter.

After successful participation of the teaching course, the centres are qualified for the use of the teaching programme. Standardised training materials (and the teaching program) are available to all qualified teaching teams via an internet-based platform. The programme consists of multiple elements, topics, and learning points to tailor the teaching individually to the needs of the patients attending. The teaching is delivered in 2 sessions of 90–120 min each and takes place in small groups of 3–5 patients with accompanying relatives or spouses. The patients learn general information on adrenal insufficiency, signs and symptoms of hypocortisolism, the steroid adjustment in special situations and critical situations, and learn self-administration of parenteral hydrocortisone.

Good practice example provided by and used with permission from Marcus Quinkler, Professor of Endocrinology, Berlin, Germany.

Despite advantages of group educational programmes, one should not assume that this approach is suitable for all patients. Geographical dispersion, time/date restrictions when educational programmes are delivered, literacy levels, and patients' comfort levels of learning and interacting within a group may often influence low uptake and attendance rates in these programmes (Repping-Wuts et al. 2013; Martinez-Momblan et al. 2016). Group educational programmes generally adopt a "one fits all" approach which lacks the ability to individualise the intervention to each patient's needs. "Real-time" access to information and continuous reinforcement of existing knowledge is important and support should continue beyond the duration of a formal educational programme.

Specific individualised education and a person-based plan (Yardley et al. 2015) of "sick day rules" should be provided to patients with AI and this can only be achieved with one-to-one consultations. This however can be time consuming and, with current financial pressures in the health service, resources may not always allow detailed cover of all aspects of patient education. With recent advances in digital technology, we need to be creative and eHealth educational programmes may present many opportunities to provide patients with "real-time" structured and individualised education to complement face-to-face care away from the traditional hospital setting (Llahana and Thomas 2016; Yardley et al. 2015).

Moreover, education programmes should not only aim to improve patient's knowledge and self-management but should also adopt psychosocial approaches to address patient motivations, beliefs, and perceptions of their condition and treatment. Evidence shows a clear association between patient beliefs, concerns, and attitudes regarding their GC treatment, nonadherence, and increase in the incidence of AC (Allolio 2015; Smans et al. 2016; Chapman et al. 2016; Rushworth et al. 2015; Tiemensma et al. 2014). A pragmatic approach should be provided for patients to understand the necessity for the adjustment of GC replacement during sick days and that this but could potentially save their lives.

Education should not be directed only to patients and their families, but should include healthcare professionals such as general practitioners, paramedical staff, and emergency services clinicians. A wider awareness is needed to inform the public, school teachers, employers, and most importantly to influence the political agenda in addressing the seriousness of the AC and to eliminate preventable hospitalisations and deaths from AC. The current "emergency pack" is very complex for an already compromised patient to be able to self-administer when having an AC, and hence patients must rely on family, friends, and acute medical services. As Allolio stated, only the availability of a hydrocortisone autoinjector will bypass the current barriers of self-administration and as industry are reluctant to develop such a device, public funding is needed (Allolio 2015). More robust evidence is needed, and endocrine nurses are strategically placed to collect research and clinical data regarding patients' and families' needs to support the need for this change in the management of AC. This requires them to practise at an advanced level with clinical expertise, expert coaching, consultation skills, and research competence (Hamric et al. 2013) (please read Chaps. 67–69 for more details).

62.7 The Importance of Collaboration with Patient Advocacy Groups

The value of resources and importance of collaboration with patient support groups in AI has already been highlighted throughout this chapter; below we describe the resources available via the Addison's Disease Self Help Group (ADSHG) to illustrate this further. Endocrine nurses should encourage membership as it can be helpful in allowing patients with AI to associate with others with the same conditions and similar experiences. This can encourage a more active and independent role in self-management.

62.7.1 The Addison's Disease Self Help Group (ADSHG), UK

ADSHG is supported by an independent panel of endocrinologists with an interest in adrenal medicine, known as the Addison's Clinical Advisory Panel. They have authored a series of valuable medical guidelines on the management of Addison's disease and adrenal crisis, which the charity makes available to the public on its website, free of charge. ADSHG literature, available as open access publications on its website, may be copied by medical practitioners for use as an educational resource with their patients, or by individuals for personal use.

The growth of social media over the past decade has profoundly changed the dynamic of voluntary groups and peer support for medical conditions. In addition to print literature, ADSHG today offers its community of interest a series of open access educational videos, also published on You Tube, illustrating intramuscular injection method for prevention of adrenal crisis. The charity makes print copies of its literature available, at cost, through its online Shop, along with practical documentation to support emergency medical treatment or elective surgery, such as the hospital folder. Subscribers to the charity also benefit from access to a confidential (closed) discussion forum where they can share day-to-day experiences with others. There is also a privately published newsletter for members available to the charity's registered subscribers, who numbered nearly 2000 in the summer of 2018. ADSHG members arrange local social meetings around the UK, and the charity's annual medical lecture and AGM usually takes place in London in early summer.

Peer learning and support is increasingly recognised as a useful tool to facilitate effective self-management by patients with long-term conditions. Hearing from others that self-injection was easier than they had thought and hurt less than they feared will often provide more reassurance to the newly diagnosed patient than anything a clinician could say. Peer learning can literally help to save lives. In the 2 years since it was launched online, ADSHG's Personal stories video about self-injection has been viewed more than 8600 times.

Personal stories conveyed via ADSHG's web discussion forum, about how people who are steroid dependent adjust their medication for infectious illness, can often offer practical guidance to those newly diagnosed more speedily and concretely than the same "sick day rules" instruction could be relayed from their GP or endocrine team.

62.8 Conclusions

This chapter provided a comprehensive overview of the causes, prevalence, and clinical presentation of adrenal crisis in adults and children with adrenal insufficiency. It is a life-threatening condition, and although easily treatable, many patients still experience devastating hospital admissions and fatalities which are preventable with immediate treatment with parenteral hydrocortisone. Patient education and supportive infrastructure and care services are the key to improving the prevalence of AC. The endocrine nurse is a key member in the multidisciplinary team to support patients and their families with day-to-day self-management and prevention of AC. Endocrine nurses however should also strive for strategic involvement in the care services and driving the political agenda to emphasise the need for improvement and change to minimise the preventable hospitalisations and to eliminate the devastating deaths from AC. Involvement in research is necessary as the endocrine nurse is best placed to identify and address research questions that can provide the evidence needed to change practice.

Abstract

This chapter outlines the presentation, assessment, and management of patients presenting with acute thyroid-related illness including thyroid storm and myxoedema coma. Thyroid storm is a clinical diagnosis describing severe thyrotoxicosis, often with multi-organ dysfunction. Patients need intensive care, and treatment to reduce the metabolic effects of thyrotoxicosis and lower circulating thyroid hormones. Thyrotoxicosis is the term for the clinical syndrome that results from exposure to excessive levels of circulating thyroid hormones. Hyperthyroidism is used to describe thyrotoxicosis resulting from overproduction of thyroid hormones by thyroid cells and there are several possible aetiologies. Thyrotoxicosis also occurs in the absence of hyperthyroidism, for example, when stored hormones are released in a destructive thyroiditis. The common causes of hyperthyroidism (Graves' disease, toxic nodular goitre, Hashimoto's thyroiditis, and others) are comprehensively covered in Chapter 28. Myxoedema coma is a rare presentation of severe hypothyroidism. It is most commonly seen in the elderly. Management is supportive and includes thyroid hormone replacement; there is often hypothermia and cardiac dysfunction. Mortality in myxoedema coma remains high.

T3	Tri-iodothyronine, liothyronine
T4	Thyroxine, levothyroxine
TSH	Thyroid stimulating hormone

Key Terms

- **Hyperthyroid:** Conditions that cause increased secretion of thyroid hormones from the thyroid gland that leads to thyrotoxicosis.
- **Thyrotoxicosis:** Clinical syndrome results from exposure to excessive levels of circulating thyroid hormones.
- **Thyroid (thyrotoxic) storm:** A clinical diagnosis describing severe thyrotoxicosis, often with multi-organ dysfunction.
- **Myxoedema coma:** An emergency hypothyroid condition presented with hypothermia, reduced conscious level, bradycardia, bradycapnoea, hypoxaemia, hyponatraemia, hypercapnia, hypercalcaemia, hypoglycaemia, and elevated creatine kinase.

Key Points

- Thyroid storm is a rare endocrine emergency and occurs in patients with untreated or undertreated thyrotoxicosis. The most common aetiology is Graves' disease. (Refer to thyroid chapter for explanation of Graves' disease).
- The diagnosis is a clinical one.
- Clinical symptoms are caused by elevated circulating levels of free thyroid hormones, causing severe features of thyrotoxicosis and multi-organ dysfunction.
- Prompt recognition and urgent management are required to improve outcome. Patients should be managed in the HDU or ITU.
- Myxoedema coma is a rare endocrine emergency. The condition most commonly occurs in the elderly and is associated with high mortality.
- Management involves supportive care and replacement of thyroid hormone deficiency.

63.1 Thyroid Emergency: Thyroid Storm and Myxoedema Coma

There are two types of endocrine emergencies related to thyroid conditions: (1) thyroid storm which is a clinical diagnosis describing severe thyrotoxicosis and (2) myxoedema coma describing severe hypothyroidism. It is most commonly seen in the elderly.

63.2 Thyroid Storm

This potentially life-threatening condition can be an initial presentation of an undiagnosed patient or an acute exacerbation of thyrotoxicosis. It is characterised by marked hyper-metabolism and an exaggerated adrenergic response. As well as being an initial presentation, thyroid storm may be precipitated by specific thyroid treatments (surgery or radioiodine) in a patient with inadequately controlled thyrotoxicosis, or in a patient with thyrotoxicosis following parturition or during a severe illness (including uncontrolled diabetes, severe infection, or myocardial infarction (Bahn et al. 2011)). Hyperpyrexia is the striking feature but tachycardia, atrial fibrillation (AF), heart failure, agitation, confusion, vomiting, diarrhoea, coma,

Table 63.1 Systemic effects of thyrotoxicosis

System	Effects
General	Weight reduction, nervousness, irritability, heat intolerance, fatigue, poor sleep
Skin	Warm, moist palms, hyperhidrosis, urticaria, itching, exacerbation of eczema
Eye	Periorbital oedema, lid lag and retraction, chemosis, exophthalmos, opthalmoplegia, redness, loss of vision
CNS	Irritability, worsening of psychiatric conditions, stupor, coma
CVS	Tachycardia, cardiomegaly, heart failure, rhythm disturbance
Respiratory	Dyspnoea
Bone	Reduced bone mineral density
Fertility/reproduction	Gynaecomastia, infertility, light or absent menstrual periods
Metabolic	Hyperglycaemia, hypercalcaemia
Gastrointestinal	Diarrhoea/hyperdefecation
Neuromuscular	Tremor, myopathy, paralysis

and shock can variably occur. Patients are best managed in an intensive care/therapy environment (ITU). Treatment is aimed at reducing thyroid hormone secretion, supportive therapy, and treatment of the precipitating underlying cause.

63.2.1 Clinical Presentation of Thyroid Storm

The clinical features of thyrotoxicosis depend on the severity and duration of the condition, age of the patient, extra-thyroidal manifestations, and the specific cause of the thyrotoxicosis. Thyroid hormone excess affects all organ systems and the symptoms and signs of thyrotoxicosis are similar regardless of aetiology. Widespread effects occur due to the stimulation of metabolic processes and sensitisation of the sympathetic nervous system (Table 63.1). In the elderly, the symptoms may be less marked than in younger patients. Graves' disease has additional features, in particular thyroid eye disease and diffuse goitre with bruit, indicative of increased vascularity.

Both Graves' disease and toxic nodular goitre are commonly associated with enlargement of the thyroid gland. Toxic adenoma and multinodular goitre commonly result in an asymmetric thyroid gland. The goitre of Graves' disease is typically visible, diffusely enlarged, smooth, and in more severe presentations associated with a bruit or thrill.

Thyroid storm is a rare but important presentation of untreated or undertreated thyrotoxicosis. Also known as thyroid crisis this is a life-threatening condition, with features of thyrotoxicosis and acute multisystem involvement with dysfunction.

63.2.2 Diagnosis of Thyroid (Thyrotoxic) Storm

The diagnosis is a clinical one and should be considered in the patient with fever, abnormal mental state, rapid sinus tachycardia, or atrial fibrillation, who also has signs of thyrotoxicosis (Burch and Wartofsky 1993). Thyrotoxic storm is an acute life-threatening metabolic emergency. If the diagnosis is suspected, anti-thyroid medical treatment should be started without delay (e.g. when suspected even if not biochemically confirmed). Maintenance of the circulation with tissue oxygenation is a key requirement, often with a combination of fluids for volume expansion and beta-blockade to reduce the associated autonomic overdrive .

63.2.3 Priorities in the Assessment and Management of Severe Thyrotoxicosis

63.2.3.1 Assessment: Is This Thyrotoxic Storm?

- The diagnosis of thyrotoxic storm is a clinical one and is based on the identification of actual or impending decompensation of organ function due to thyrotoxicosis (Table 63.2).
- The diagnosis is difficult as thyroid storm represents the end of a spectrum of severity and

due to inter-patient differences in the tipping point between compensated organ stress and decompensated organ failure.

- Although no universally accepted criteria currently exist, the Burch-Wartofsky Point Scale (BWPS; see Table 63.2) can be used to assess disease severity and guide the extent of treatment and monitoring.

63.2.3.2 Assessment: What Has Triggered the Thyrotoxic Storm?

- Thyrotoxic storm may occur in the course of the natural history of an underlying thyrotoxic process, particularly Graves' disease. It is more often related to decompensation caused by an intercurrent precipitant. This is most frequently an infective illness, but may also be surgery (particularly thyroid surgery or occasionally non-thyroid surgery), other critical illness, and childbirth (Carroll and Matfin 2010).
- Other iatrogenic causes include radioactive iodine therapy in patients with insufficiently controlled hyperthyroidism, abrupt cessation of anti-thyroid medications (or non-adherence to these), administration of iodine-containing pharmaceuticals (e.g. amiodarone) or contrast agents (e.g. for CT imaging), induction of anaesthesia, or neck stimulation in Graves' disease with large goitre (Migneco et al. 2005).

63.2.3.3 Immediate Management

Thyroid storm is an acutely life-threatening condition and must be managed in a level 2 or 3 (resuscitation area/HDU/ITU) setting. Often patients present to the Emergency Department and the condition requires prompt recognition, stabilisation, and initiation of management prior to transfer to an inpatient HDU or ITU (Akamizu et al. 2012). Figure 63.1 outlines an algorithm for the management of thyroid storm (Fig. 63.1). The immediate management priorities (golden hour) are:

- Rapid assessment of airway, breathing, circulation, and conscious level. Establish continuous monitoring of blood pressure, heart rate, and ECG.

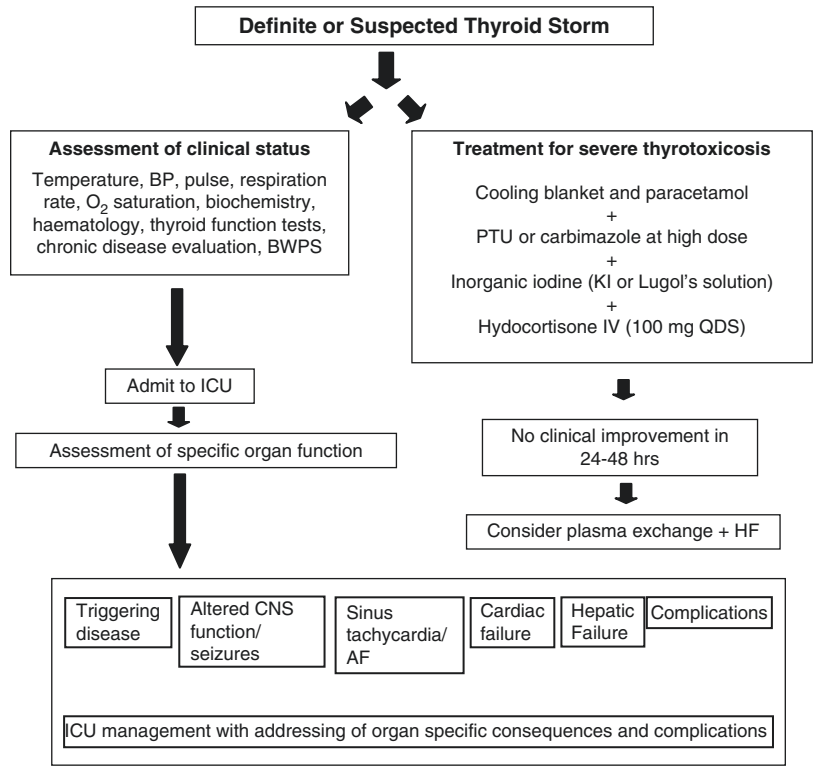

Fig. 63.1 Algorithm for the management of suspected thyroid storm. *BP* blood pressure, *APACHE* acute physiology and chronic health evaluation, *CNS* central nervous system, *ICU* intensive care/ therapy unit, *HF* haemofiltration, *KI* potassium iodide, *AF* atrial fibrillation

- Airway management by competent staff if the airway is compromised or the Glasgow Coma Scale score is less than 8/15.
- Supplemental oxygen if needed to maintain arterial oxygen saturation >95%.
- Haemodynamic stabilisation. Hypotension may be due to high output cardiac failure or a compromising tachyarrhythmia (usually supraventricular). Direct current cardioversion is usually unsuccessful for AF in a severely hyperthyroid patient. Unless there is clinical suspicion of underlying cardiomyopathy, rate-related failure may be managed with a short-acting beta-blocker (e.g. IV esmolol) with prompt withdrawal if clinical state worsens. Patients with thyrotoxic storm and heart failure must be managed in a level 3 environment with continuous BP and CVP monitoring.
- Assessment for common precipitants of thyrotoxic storm: sepsis, diabetic ketoacidosis, or myocardial infarction (see above). If identified, appropriate management initiated. When no precipitating factor is apparent, broad-spectrum antibiotics are warranted until intercurrent infection has been excluded. Cooling measures should be employed to correct fever, initially with paracetamol 1000 mg PO/IV.
- Administer a non-cardioselective beta-blocker, e.g. propranolol 40–80 mg PO. If rapid onset of action needed or if oral route unavailable due to reduced conscious level, intravenous esmolol 50–100 μg/kg/min may be used. Consider an arterial line for continuous blood pressure monitoring if IV beta-blockers initiated.
- Administer a thionamide to prevent further thyroid hormone production, e.g. propylthiouracil 500–1000 mg loading dose PO (followed by 250 mg 4-hourly). Carbimazole may also be used (20–30 mg every 4–6 h PO). There are no intravenous preparations but they may be given via nasogastric tube or rectally if there are concerns about absorption.
- Transfer to HDU/ITU for continuing management.

63.2.3.4 Further Management

- The ongoing management of thyroid storm is directed at reducing further production of thyroid hormone, blocking its release, inhibiting conversion of T4 to active T3, and limiting the adrenergic effects of high thyroid hormone activity. Thionamide treatment should be continued. Propylthiouracil at a dose of 250 mg every 4–6 h has been the preferred agent due to its potential additional benefit in reducing conversion of T4 to active T3. Concerns regarding an association between propylthiouracil and hepatitis should be taken into account and in patients with known liver disease or if liver function tests become abnormal, carbimazole 60–80 mg daily is an alternative. "Cold" iodine (i.e. non-radioactive iodine) can be administered in the form of 3–5 drops of Lugol's solution (5% elemental iodine, 10% potassium iodide in distilled water) or a saturated solution of potassium iodide (SSKI), diluted in water three times daily, making use of the Wolff-Chaikoff effect in which high doses of iodine result in blockade of the incorporation of iodine into thyroglobulin. Effectiveness of iodine solutions is time-limited to approximately 10 days, after which the thyroid escapes this effect by downregulating iodine transporters.
- A beta-blocker should be administered to negate the catecholaminergic effects of thyrotoxicosis. Oral propranolol is most frequently used due to its additional capacity to block peripheral T4 to T3 conversion. The dose is titrated according to cardiovascular variables. In thyrotoxic storm, 60–120 mg 6-hourly PO may be required. Glucocorticoids also reduce peripheral conversion of T4 to T3: hydrocortisone 100 mg 6-hourly IV is a suitable dose.
- In extreme, treatment refractory thyrotoxicosis, plasmapheresis has been used to clear circulating thyroid hormones to allow a window for emergency thyroidectomy to be performed safely.

63.2.4 Outcome of Thyroid Storm

Thyroid storm is a medical emergency with a high mortality rate. Until recently, there has been little published material on the management and outcome of thyroid storm. A taskforce from the Japan Thyroid Association and Japan Endocrine Society have reported data from nationwide surveys, contributing significantly to our knowledge base (Isozaki et al. 2016). This information has helped inform guidance on the assessment and management of the patient with thyroid storm. A recent study (2016) including 356 cases reported an overall mortality rate of 10.7%. In this group of patients, methimazole was the most commonly used anti-thyroid drug, and it has been suggested that there is little difference in outcome and survival, between methimazole and PTU. Most of the patients in this report had multi-modal therapy with ATDs, cold iodine, and corticosteroids, reflecting the severe nature of the presentations. One-hundred percent of thyroid storm patients required admission to ICU and approximately 50% were intubated with positive pressure ventilation. The median length of stay for this group of patients was 10 days. Angell et al. recently highlighted alterations in CNS function (altered mentation) as a risk factor in addition to the BWPS for poor outcome and need for intensive support (Angell et al. 2015). Therapeutic plasma exchange to remove excessive circulating free thyroid hormones has been reported in a small number of patients. This technique appears safe and effective but has a transient effect and other modalities of treatment should continue (Muller et al. 2011).

Early recognition with clinical suspicion, prompt structured management, and intensive support are each an essential requirement for the management of the adult with thyroid storm.

63.2.5 Severe Hypothyroidism/ Myxoedema Coma

At the extreme end of the hypothyroid spectrum is the rare endocrine emergency of myxoedema coma. This condition is thought to have a

prevalence of less than 1 per million per year and is mostly a disease of the elderly. The physical signs of hypothermia closely resemble those of myxoedema coma; however, if there is other evidence of hypothyroidism thyroid hormone and hydrocortisone (as there may be co-existing autoimmune adrenal insufficiency) should be given. Even with treatment, the mortality from myxoedema coma is high (Pangtey et al. 2017).

63.2.5.1 Assessment: Is This Myxoedema Coma?

- Myxoedema coma is a clinical diagnosis and requires an index of suspicion. Known thyroid disease and hypothermia with altered consciousness should prompt consideration of the diagnosis.
- Hypothermia and reduced conscious level are the cardinal features (although most patients are not actually comatose, i.e. Glasgow Coma Scale <8).
- Bradycardia, bradypnoea, and hypoxaemia are common.
- Hyponatraemia, hypercapnia, hypercalcaemia, hypoglycaemia and elevated creatinine kinase are often present.

63.2.5.2 Assessment: What Has Caused the Myxoedema Coma?

- Myxoedema coma is most commonly precipitated by an event causing an increased metabolic demand which exceeds the adaptive mechanisms compensating for chronic hypothyroidism, such as infection or trauma.
- Other triggers include cold weather, long-lie in a cold environment, sedative agents, general anaesthesia, acute coronary syndrome, and CVA.
- Hashimoto's thyroiditis, amiodarone, and lithium use has each resulted in presentation of myxoedema coma.

63.2.5.3 Immediate Management

- ABCDE assessment
  - Airway—may be compromised by oedema of the upper respiratory tract structures. Airway adjuncts or intubation may be required, especially if airway not considered safe.
  - Breathing—ventilatory failure is usual and should be confirmed with arterial blood gas analysis. Assisted ventilation is often necessary for the first 24–48 h.
  - Circulation—careful fluid resuscitation, recognising the likely impairment of cardiac contractility, can be employed. Glucocorticoids should be administered (50–100 mg 6-hourly IV). The possibility of undiagnosed autoimmune adrenal insufficiency as a comorbidity should be considered.
- Correct hypoglycaemia using intravenous glucose.
- If possible avoid using a warming blanket. Instead gently and slowly, increase temperature naturally if hypothermic.
- Identify the precipitant and initiate treatment.
  - Infection may be occult and sepsis is unlikely to be accompanied by an elevated temperature. If in doubt, take blood for culture and administer broad-spectrum antibiotics.
  - The ECG will be abnormal and usually shows bradycardia, small voltage QRS complexes, and flattened or inverted T-waves. Varying degrees of heart block may be present. Measure the QTc interval which may be prolonged bringing a risk of polymorphic ventricular tachycardia (torsades des pointes). Assess for evidence of myocardial ischaemia or infarction.
  - Cerebellar signs may be the result of severe hypothyroidism but assess for evidence of an acute stroke.
  - Assess for evidence of an upper gastrointestinal bleed.
  - Obtain a collateral history—there will most commonly be a history of hypothyroidism, thyroid surgery, or radioiodine ablation.
  - Review the drug history for new medications which may have precipitated the acute presentation.

Alert the critical care team and transfer to an appropriate ITU or HDU bed when resuscitation effective.

63.2.5.4 Further Management

Thyroid Hormone Replacement

- Restoration of thyroid hormone activity is essential. There is no high-grade evidence to suggest how this is best achieved. Replacement may be enteral or parenteral; with T4, T3, or both. In the UK IV liothyronine (T3) is available and commonly used.
- Restoring normal target tissue thyroid hormone activity as soon as possible to reverse life-threatening disturbance of body systems must be weighed against the possibility of inducing fatal tachyarrhythmia with rapid correction. The enteral route should lead to a less abrupt increase in circulating thyroid hormone levels and allows for the use of T4 (levothyroxine) which, by virtue of requiring peripheral conversion to T3 for maximal activity, a smoother tissue response. However, absorption may be impaired by oedema, slow transit, or ileus. The intravenous route limits one to using T3 since intravenous preparations of T4 are not commonly available. The associated rapid increase in thyroid hormone receptor activity may induce adverse cardiac events.
- The choice of treatment should be made on a patient-specific basis. The options are:
  - NG T4 alone:
  - NG T4 plus T3
  - IV T3: typically 20 μg/24 h

– T3 and T4 replacement should be carefully titrated against free thyroid hormone levels which may be measured daily. Over-replacement risks tachyarrhythmia in what is likely to be at least temporarily a myopathic heart. Commonly T3 is commenced at escalating doses with subsequent introduction of T4 provided there is no precipitation of myocardial ischaemia or tachyarrhythmia.

63.2.5.5 Supportive Care

- Hypothermia should not be treated with external rewarming since this will induce peripheral vasodilatation negating the compensatory diversion of blood flow to the vital organs.
- Glucocorticoids should be continued until co-existing adrenal insufficiency has been excluded by a short synacthen (co-syntropin) test.
- Ongoing supportive management of organ failure (e.g. mechanical ventilation or vasopressors) while awaiting response to thyroid hormone replacement is a key determinant of outcome. The time to recovery may be variable depending on the duration of severe hypothyroidism.
- Patients should be managed in the ICU, and many will need organ support including inotropic treatment.

63.2.6 Outcome of Patients Presenting with Myxoedema Coma

Myxoedema coma typically occurs in the elderly, often with co-existing chronic health issues. Until recently, there was a paucity of outcome data. A nationwide inpatient database study from Japan recently reported the mortality in myxoedema coma to be ~30% (Ono et al. 2017). Cardiovascular disease was the most common comorbidity and many patients presented during winter months. Older age and need for inotropic support were risk factors for mortality. Although rare, myxoedema coma is associated with significant morbidity and mortality (Murthy et al. 2015; Mathew et al. 2011).

63.3 The Role of Endocrine Nurse in Thyroid Emergency

The majority of patients experiencing a severe thyroid emergency will be admitted to an accident and emergency department. Therefore, an outpatient-based endocrine nurse will rarely be involved in this scenario. However for an endocrine nurse who is involved in thyroid clinics, seeing thyroid patients for blood tests or providing education and supportive care for patients, family, and carers with thyroid conditions, raising awareness on the risk and consequences of thyrotoxicosis, thyroid storm, or myxoedema coma should be part of the patient education for thyroid conditions.

This patient education awareness is important and is as important as the education of adrenal insufficiency patients with steroids replacement therapy, in order to prevent the risk of adrenal crisis or the over treatment with steroids.

An assessment tool for severe thyroid storm (Table 63.2) can be used to determine if a patient is at risk or has developed thyroid storm when assessed in a thyroid clinic. This tool requires the assessor to have the relevant clinical skills in order to make the diagnosis. If the risk of thyroid storm is suspected or identified, an endocrine nurse will need to escalate this emergency to colleagues to seek help and support.

Myxoedema coma is a critical situation. The role of the endocrine nurse is to support ward base colleagues in the management of this group of rare patients and the patients next of kin by utilising their endocrine expertise.

Thyroid storm and myxoedema coma each has complex multi-professional treatment algorithms. Clinical guidelines may be drafted in order to maximise the management of these rare and high-risk patients. The endocrine nurse has an essential role to ensure patient management is followed, patient outcomes measured and support is given to patient, family, and carers. The nurse should follow the guidelines appropriate for their individual clinical setting. Following recovery from severe thyroid-related illness, close follow-up care, and often thyroidectomy for Graves' disease is best managed by the multidisciplinary endocrine team.

63.4 Conclusions

Emergency thyroid presentations including thyroid storm and myxoedema coma are rare but serious consequences of thyroid disease. The mortality and morbidity from these conditions is significant. Endocrine nurse specialists involved in thyroid management must be aware of these complications and recognise presentations at the severe end of the thyroid disease spectrum. Co-ordination of care for the patient with severe thyroid disease is best provided by an experienced endocrine nurse specialist as part of a comprehensive multi-disciplinary team.

Abstract

Pituitary apoplexy is a rare medical emergency in patients with pituitary tumours. Patients may present at emergency departments or at different medical services and this can lead to diagnostic difficulties and delays. Pituitary apoplexy is caused by a rapid increase in the size of the intrasellar contents leading to increase in the intrasellar pressure. This increased pressure may lead to loss of blood supply to the pituitary gland causing infarction, tumour cell death, bleeding, and tumour swelling. Patient can present with sudden

onset of headache, vomiting, visual impairment, and decreased consciousness.

Assessment of suspected pituitary apoplexy includes a mixture of clinical, endocrine, and radiological assessments. Clinical management includes immediate steroid therapy followed by the decision to manage conservatively or surgically. The long-term follow-up includes endocrine and visual assessment and imaging surveillance. The endocrine specialist nurse has an important role in acute management of the patient with apoplexy including performing endocrine testing, steroid replacement therapy education and long term monitoring and outcome measurement.

Key Terms

- **Apoplexy:** clinical syndrome caused by haemorrhage and/or infarction of the pituitary gland.
- **Decompressive surgery:** pituitary surgery to relieve new or deteriorating visual deficit or neurological deterioration.

Key Points

- Pituitary apoplexy is a rare endocrine emergency and occurs in patients with existing pituitary tumours.
- Clinical symptoms are caused by rapid increase in size of the intrasellar contents, leading to increase in the intrasellar pressure.
- Clinical guidelines provide evidence based and expert consensus data for more effective management of this clinical emergency.
- The endocrine nurse has a vital role to play in the management of this group of patients in both the acute and chronic phases of treatment.

64.1 Introduction

Pituitary apoplexy is a rare medical emergency. The incidence of pituitary apoplexy is between 2 and 7% when defined on the basis of clinical signs with surgical or histopathological evidence. It occurs in a small number of patients with a pituitary tumour, most often a non-functioning macroadenoma. In over 80% of patients, pituitary apoplexy is the first presentation of an underlying pituitary tumour (Rajasekaran et al. 2011).

Apoplexy usually occurs in patients with pre-existing pituitary adenomas and evolves within hours or days. Diagnosing pituitary apoplexy can be difficult and delayed due to clinical unawareness of the presence of a pre-existing pituitary tumour. Patients may present as an emergency to emergency units or to different specialties. This can lead to diagnostic difficulties and delays with significant morbidity and possible mortality.

There are uncertainties about the management of pituitary apoplexy. It is not clear whether immediate neurosurgical intervention is essential to improve outcomes, or if a more conservative approach provides similar outcomes. UK National guidelines have therefore been developed and published with wide consultation of stakeholders in 2011 (Rajasekaran et al. 2011; Baldeweg et al. 2016).

64.2 Definition of Pituitary Apoplexy

Classical pituitary apoplexy refers to a clinical syndrome caused by haemorrhage and/or infarction of the pituitary gland. Patients can present with

- Sudden onset of headache
- Vomiting
- Visual impairment and
- Decreased consciousness

64.3 Pathophysiology of the Clinical Manifestations

The clinical manifestations of pituitary apoplexy are due to a rapid increase in the size of the intrasellar contents, leading to increase in the intrasellar pressure. This sudden increase in size of a pituitary adenoma may compress the following:

- Normal pituitary gland
- Optic nerves
- Nerves that control eye movements

The compression may also lead to a loss of blood supply (pituitary infarct), which can cause tumour cell death, bleeding, and sudden tumour swelling (Rajasekaran et al. 2011).

The earliest most common symptom of pituitary apoplexy is sudden severe headache which may be accompanied by nausea and vomiting. Lateral compression can affect the contents of the cavernous sinus leading to ocular palsies in nearly 70% of the patients (Rajasekaran et al. 2011).

The third (oculomotor) nerve is the most common cranial nerve affected. Decreased visual acuity and visual field defects, specifically bitemporal hemianopia are seen in nearly 75% of the patients and are caused by optic chiasmal compression. Extravasation of blood or necrotic tissue into the subarachnoid space can cause meningism resulting in fever, photophobia, and altered consciousness level.

64.4 Precipitating Factors

Precipitating factors have been identified in nearly half of cases of pituitary apoplexy. The commonest precipitating factor was hypertension. Major surgery, especially coronary artery bypass grafting, can also precipitate apoplexy (Rajasekaran et al. 2011; Baldeweg et al. 2016).

For the specialist nurse, it is especially important to know that dynamic testing of the pituitary gland, using gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and insulin tolerance test (ITT) have all been reported to trigger pituitary apoplexy. In the reported cases of pituitary apoplexy after pituitary tests apoplexy occurred within 2 h in 83% and within 88 h in all patients (Rajasekaran et al. 2011).

Patients known to have a pituitary tumour must therefore be observed for signs and symptoms of pituitary apoplexy when performing pituitary stimulation tests, commencing anticoagulation therapy, or undertaking coronary artery bypass or other major surgery.

64.5 Assessments

64.5.1 Clinical Assessments

A diagnosis of pituitary apoplexy should be considered in all patients presenting with acute severe headache with or without neuro-ophthalmic signs. Figure 64.1 presents the algorithm for the emergency management of pituitary apoplexy in adult patients published by the Society for Endocrinology in the UK (Baldeweg et al. 2016).

Pituitary apoplexy most frequently occurs in a patient with an undiagnosed pituitary tumour. Initial assessment of the patients presenting with

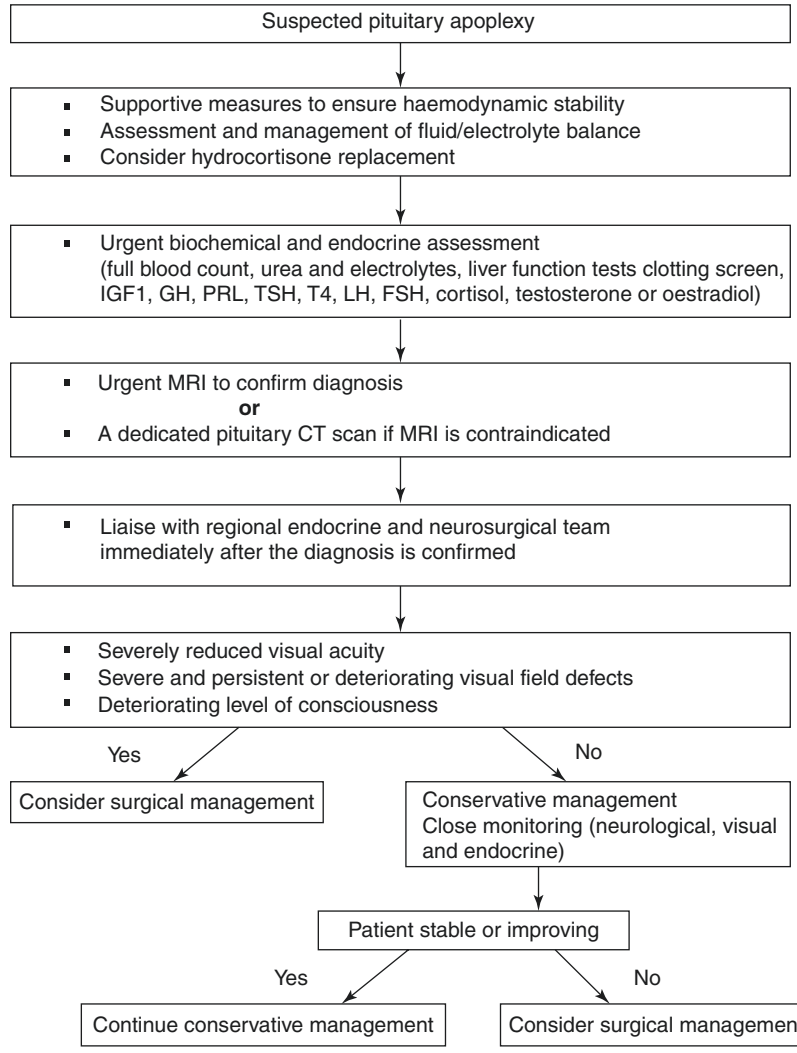

Fig. 64.1 Algorithm for the management of pituitary apoplexy. Baldeweg SE, et al. Society for Endocrinology Endocrine Emergency Guidance: Emergency management of pituitary apoplexy in adult patients. Endocr Connect. 2016;5 (5):G12-g5. Open access no copyright permission required: Free via Creative Commons: CC

symptoms consistent with pituitary apoplexy should include a detailed history followed by a thorough physical examination including cranial nerves and visual fields to confrontation. The clinical symptoms mimic other common neurological emergencies such as subarachnoid haemorrhage, bacterial meningitis, or stroke. Clinical presentation can be either acute or subacute, with slow development of symptoms and signs and this is largely determined by the extent of haemorrhage, oedema, and necrosis. Formal visual fields assessment must be undertaken when the patient is clinically stable, preferably within 24 h of the suspected diagnosis (Rajasekaran et al. 2011; Baldeweg et al. 2016; Randeva et al. 1999).

In haemodynamically unstable patients, intravenous hydrocortisone should be administered after taking blood samples for baseline endocrine function tests (Rajasekaran et al. 2011).

Patients who have been diagnosed with a pituitary tumour should be given clear information regarding the signs and symptoms of pituitary apoplexy and the precipitating factors.

64.5.2 Endocrine Assessments

Nearly 80% of patients will have deficiency of one or more anterior pituitary hormones at presentation. Clinically, the most crucial deficit is that of adrenocorticotroph hormone (ACTH) and

has been reported in up to 70% of the patients. Thyrotropin and gonadotropin deficiencies are observed in 50 and 75% of the patients, respectively. Hyponatremia has been reported in up to 40% of the patients due either to the syndrome of inappropriate antidiuretic hormone secretion or hypocortisolism (Randeva et al. 1999; Sibal et al. 2004; Ayuk et al. 2004).

Patients with suspected pituitary apoplexy should have urgent blood samples taken for electrolytes, renal function, liver function, clotting screen, full blood count, and random cortisol, prolactin, free thyroxine (FT4), thyroid-stimulating hormone (TSH), insulin-like growth factor 1 (IGF-1), growth hormone, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone in men and oestradiol in women.

64.5.3 Radiological Assessments

Computerized tomography (CT) is the most commonly used imaging modality in an acute clinical setting if a patient presents with severer headache and/or ophthalmoplegia or altered consciousness level. CT scan is diagnostic in approx. 25% of cases but this rises to 80% for those with extrasellar mass (Baldeweg et al. 2016).

Urgent MRI scan must be done in all patients with suspected pituitary apoplexy to confirm the diagnosis. Magnetic resonance imaging (MRI) is the radiological investigation of choice for a suspected diagnosis of pituitary apoplexy. A dedicated pituitary CT scan is indicated if the MRI scan is either contraindicated or not possible. The results of the MRI or CT scan should be clearly explained to the patient as soon as possible after the investigation.

64.6 Clinical Managements of Pituitary Apoplexy

64.6.1 Steroid Therapy in Pituitary Apoplexy

Acute secondary adrenal insufficiency is the major source of mortality associated with pituitary apoplexy. It is seen in approximately two-thirds of patients with pituitary tumour apoplexy. Before the results of confirmatory tests are available, prompt intramuscular or intravenous corticosteroid replacement should be started in patients who are haemodynamically unstable, or for patients who have other symptoms or signs suggestive of hypoadrenalism. Patients with pituitary apoplexy frequently present with nausea and vomiting; hence, oral corticosteroids are not recommended in the acute setting.

Hydrocortisone 100–200 mg as an intravenous bolus is recommended followed either by 2–4 mg per hour by continuous intravenous infusion or 50–100 mg six hourly by intramuscular injection. Once the patient has recovered from the acute episode, the hydrocortisone dose should be quickly tapered to a standard maintenance dose of 20–30 mg per day, orally usually in three divided doses. The immediate medical management of patients with pituitary apoplexy should include careful assessment of fluid and electrolyte balance, replacement of corticosteroids, and supportive measures to ensure haemodynamic stability (Baldeweg et al. 2016).

Indications for empirical steroid therapy in patients with pituitary apoplexy are haemodynamic instability, altered consciousness level, reduced visual acuity, and severe visual field defects. Patients who do not fulfil the criteria for urgent empirical steroid therapy should be considered for treatment with steroids, if their 09.00 serum cortisol is less than 550 nmol/L.(19 ng/dL) ACTH reserve should be reassessed 2–3 months after the episode of acute pituitary tumour apoplexy has resolved (Rajasekaran et al. 2011).

64.6.2 Surgery or Conservative Management

Patients with pituitary apoplexy should first be stabilized medically with steroid replacement as required. The decision to manage conservatively or with surgical intervention should be made carefully by a multidisciplinary team, including experts in neurosurgery, endocrinology, and ophthalmology (Rajasekaran et al. 2011). Semi-elective trans-

sphenoidal surgery should be considered for patients who are clinically stable, but show no improvement or deterioration in the neuro-ophthalmic signs. Such an approach would enable the surgery to be performed by the pituitary surgeon, rather than by the on call neurosurgical team. If no pituitary surgeon is available, consideration should be given to transfer to the nearest available neurosurgical unit. The rationale behind the clinical decisions should be fully explained to the patient and when possible their informed consent should be obtained. The presence of a new or deteriorating visual deficit or neurological deterioration should prompt further urgent imaging with a view to decompressive surgery (Rajasekaran et al. 2011; Baldeweg et al. 2016).

Renal functions and electrolytes should be checked daily. Further endocrine specialist evaluation to assess possible under or over secretion of pituitary hormones should be undertaken in stable patients.

Once a diagnosis has been confirmed and the patient is medically stabilized, it is recommended that all patients be transferred to a speciality neurosurgical/pituitary facility/unit (neurosurgical high dependency unit (HDU). Liaison and consultation with specialist neurosurgical/endocrine teams at the receiving location is strongly recommended. This team must also have access to specialist endocrine and ophthalmological expertise (Baldeweg et al. 2016).

64.6.2.1 Immediate Post-Operative Care

The post-operative management of patients following surgery for pituitary apoplexy is similar to that of elective pituitary surgery for pituitary tumour. However, as most patients with pituitary apoplexy may not have had a full endocrine work-up prior to the operation, it is essential to monitor them more closely perioperatively.

It is important to watch out for transient diabetes insipidus. This is noted post-operatively in up to 16% of the patients with pituitary apoplexy during their hospital stay (Arafah et al. 1990). Plasma and urine osmolality should be checked immediately if diabetes insipidus is suspected. Other potential post-operative complications include cortisol deficiency, visual loss, cerebrospinal fluid leakage, and meningitis. These should be proactively considered.

Patients should be reviewed hourly to assess the fluid balance and as appropriate serum urea, serum creatinine, and serum electrolytes.

64.6.2.2 Post-Operative Endocrine Assessment

Evaluation of steroid reserve and thyroid functions should be undertaken carefully during the post-operative period. The 09.00 serum cortisol is initially used to assess the steroid status. Cortisol values should be interpreted with caution in women, who have stopped oestrogen replacement therapy less than 6 weeks before surgery because of the confounding effect of raised cortisol binding globulin levels (Rajasekaran et al. 2011; Randeva et al. 1999).

Thyroid function (FT4 and TSH) should be tested on day 3 or day 4 after surgery. Thyroid function can be normal in the immediate post-operative period, and hence it is important to test again at 4–8 weeks post-operatively. Sick euthyroid syndrome can sometimes complicate the biochemical picture and affect the interpretation of thyroid function test results (Rajasekaran et al. 2011; Randeva et al. 1999).

If pre-operative steroid reserve adequate or unknown:

Check 9 am serum cortisol on day 2 and day 3 post-operatively in patients with no evidence of cortisol deficiency before operation. If the patient is already taking hydrocortisone replacement, omit the evening dose for the previous day before checking.

If pre-operative steroid reserve deficient:

In patients with proven cortisol deficiency before surgery, continue hydrocortisone and consider changing over to maintenance dosage when

stable. These patients will need further assessment at 4–8 weeks to determine whether they will need long-term steroids.

64.6.3 Visual Assessment

Visual acuity, eye movements, and visual fields should be examined at the bedside preferably within 48 h, and this should be followed by formal visual field assessment. Patients who develop unexpected visual loss or significant deterioration in the visual fields should have an urgent MRI scan and a review by the neurosurgical team (Rajasekaran et al. 2011).

64.7 Long-Term Follow-up and Outcomes

64.7.1 Endocrine Outcomes

All patients with pituitary apoplexy should have an endocrine review at 4–8 weeks following the event. They should undergo full biochemical assessment of pituitary function.

Studies have shown partial or complete recovery of pituitary function in up to 50% of patients (Arafah et al. 1990). Nearly 80% of the patients will need some form of hormone replacement after apoplexy (Randeva et al. 1999; Ayuk et al. 2004).

Growth hormone deficiency is the most commonly observed deficit after apoplexy and is present in almost all patients. The data suggest that long-term hormone replacement therapy following pituitary apoplexy is corticosteroids in 60–80%, thyroid hormone in 50–60%, desmopressin in 10–25% of patients, and testosterone in 60–80% of men (Baldeweg et al. 2016; Randeva et al. 1999; Ayuk et al. 2004).

Patients treated for apoplexy should have an annual biochemical assessment of pituitary function which should include FT4, TSH, LH, FSH, testosterone in men, oestradiol in women, prolactin, IGF-1, and dynamic tests of cortisol and growth hormone secretion if clinically appropriate (Rajasekaran et al. 2011).

64.7.2 Visual Outcomes

Visual acuity, visual field defects, and ophthalmoplegia have been reported to improve in the majority of the patients after surgical decompression. Such improvement can be observed early in the immediate post-operative period and often continues for several weeks after surgery. Patients should undergo formal assessment of their visual acuity, eye movements, and visual fields about 6–8 weeks after diagnosis of pituitary apoplexy (Rajasekaran et al. 2011).

64.7.3 Long-Term Monitoring and Surveillance

Recurrent apoplexy and tumour regrowth has been documented both in surgically and conservatively managed group of patients. Therefore, all patients who have been treated for apoplexy need long-term follow-up imaging to detect recurrent growth. Additional long-term management depends on the nature of the underlying pituitary tumour (Rajasekaran et al. 2011; Arafah et al. 1990).

Both conservatively and surgically treated patients need close radiological follow-up and if residual tumour or recurrence is detected, additional modalities such as radiotherapy or redo-surgery should be considered:

(a) MRI scan is recommended at 3–6 months after apoplexy and thereafter an annual MRI scan should be considered for the next 5 years, then two yearly.
(b) All patients require at least an annual clinical review preferably in a joint endocrine/neurosurgical clinic. It is recommended that all patients be discussed within the pituitary multidisciplinary team.

(c) There should be recognition of the psychological aspects of pituitary disease and support from endocrine specialist nurse and patient support organizations like The Pituitary Foundation should be provided where appropriate (www.pituitary.org.uk).

64.8 The Role of the Endocrine Specialist Nurse in the Management of Patients with Pituitary Apoplexy

The role of the endocrine specialist nurse in the management of the patient with pituitary apoplexy spans from the moment of diagnosis to the lifelong long-term management including education, psychological support, dynamic endocrine testing, and multidisciplinary team discussions as well as nurse-led clinic consultations.

In the acute settings, endocrine nurses who perform endocrine testing need to be aware of the risk involved in endocrine testing. In some endocrine centres, the task of performing endocrine testing is separated from the role of endocrine specialist nurse hence awareness of the risk involved needs to be communicated to all health care professionals involved in dynamic testing. If a patient presents acutely with signs or symptoms of pituitary apoplexy in the endocrine nurse led clinics, an endocrine nurse will need to have some knowledge or skills to recognize this emergency situation. A working group of endocrine specialist nurses supported by The Society for Endocrinology (UK) published a framework of competencies for endocrine specialist nurses, which provides guidance in the nursing management of different endocrine conditions. It also supports role development and performance at different levels of competence and expertise (Kieffer et al. 2015). In the "dynamic function testing" competency of the framework, an expert endocrine nurse will need to have the skills and knowledge as well as the ability to integrate clinical guideline of pituitary apoplexy into clinical setting to ensure the safety of their patients is upheld (Kieffer et al. 2015).

Whilst there is no specific competency framework for pituitary apoplexy, the competencies on "dynamic function testing", steroid replacement therapy", and "hypopituitarism" can be directly related to management of patients with pituitary apoplexy.

Especially, the "hypopituitarism" competency includes a number of skills and roles for endocrine specialist nurses which are very useful and relevant for patients with pituitary apoplexy (Kieffer et al. 2015):

- To display a comprehensive knowledge of the disease process and evaluate biochemical results and scans
- To demonstrate advanced communication skills to share complex information with patients regarding the risks/benefits of surgical vs medical treatment options
- To analyse dynamic testing results and prescribe when appropriate, recognizing when medical input is needed
- To interpret monitoring results, advising on treatment changes or adjustment
- To actively take part in MDTs discussing complex patients and their management
- To identify patients at increased risk and develops robust strategies to achieve safety and concordance with prescribed replacements
- To liaise with relevant patient support groups, sharing expertise and collaborating with the wider community
- To support junior staff

64.9 Conclusions

Pituitary apoplexy is a medical emergency requiring close multidisciplinary working between the acute medical team, the endocrinologists, ophthalmologists, and neurosurgeons.

There is currently uncertainty whether conservative or surgical treatment is most appropriate and treatment decisions must be individualized for each patient.

The main acute endocrine issue is steroid replacement and it here as well as in the long-term management of these patients that the endocrine specialist nurse plays an important role to optimize the outcome for each patient.

Abstract

Neuroendocrine tumours (NETs) are a heterogenous group of cancers that can cause characteristic hormonal syndromes, such as carcinoid syndrome. The incidence and prevalence of NETs is increasing and though many are slow growing, others are aggressive high grade cancers.

Surgery is the only possible curative approach, but since the majority of NETS present only once they have metastasised, treatment is more often directed at control of disease, management of symptoms, and improvement in the quality of life.

Commonly used treatments include palliative resections and drug therapy with somatostatin analogues (SSAs), as well as targeted therapies such as everolimus. SSAs have been shown to improve the symptoms of carcinoid syndrome and stabilise tumour growth in many patients. Liver-directed therapies are also commonly used, e.g. ablation or hepatic artery embolisation, to improve symptoms control in patients with worsening syndromes. More recently, peptide receptor radionuclide therapy (PRRT) has been shown to be effective in treating patients with somatostatin receptor positive disease. However, there is lack of evidence as to the best approach to managing many patients, and overall response rates to treatment are often low.

Caring for individual with NETs is therefore complex and challenging. Effective care and support requires the cooperation of a multidisciplinary team covering a broad range of specialities with the patient actively involved in decision-making. Patients may live with advanced disease for many years. They face a roller-coaster ride of multiple treatments, often with different teams, ongoing symptoms, and the psychological and social burden of living with a life-limiting illness. As gastrointestinal symptoms are commonplace, the use of gastroenterologists interested in NETs and the involvement of a specialist NET dietitian are essential in managing patients' symptoms.

Specialist nurses are well-placed within the MDT to take on a key worker role, supporting patients through a complex illness trajectory, providing a consistent single point of contact.

Key aspects of the role include liaising with the MDT, support with treatment decision-making, holistic assessment of need, management of symptoms, and ongoing informational and psychological support.

Keywords

Key Terms

- **Cell differentiation:** differentiated cancers are mature cells look like cells in the tissue it arose from. Differentiated cancers tend to be decidedly less aggressive than undifferentiated cancers composed of immature cells.
- **Tumour grading:** assessment of markers of tumor aggression or rapid growth
- **Staging:** assessment of extent of tumour metastasis.
- **Survival analysis:** survival depends on many factors including primary site, grade, and stage at diagnosis.
- **Palliative surgery:** a treatment in the presence of metastatic disease to help control patients' symptoms and potentially improve prognosis and quality of life.

Learning Objectives

On completion of the chapter, the learner should be able to:

1. Describe the aetiology and epidemiology of neuroendocrine tumours (NETs).
2. Identify common presentations NETs and how they are diagnosed.
3. Understand the range of treatment options for NETs, including somatostatin analogues, liver-directed therapies, and peptide receptor radionuclide therapy (PRRT).
4. Identify management strategies for NET patients' quality of life concerns.
5. Understand the role of the specialist nurse and dietitian in supporting individuals and their families with NETs.

What does it mean to you ...

What does it mean to you…
… the Nurse Practitioner who shrugged her shoulders when I begged her for help?
… the consultant who prescribed me anti-depressants?
... the consultant who advised me to drink mint tea, eat yogurt and stay away from vegetables?
What does it mean to you, the technician who laughed as he did my scan, again, ... 'that'll do' he said. But was it clear enough?
What does it mean to you...
… the locum GP, the newly posted GP, the nearly-ready-to-retire GP, when faced with a tearful female who is complaining, yet again, of having a sore stomach?
'... she's been told it's mild gastritis and acid reflux for God's sake! What more can I do?!'

What does it mean to you, the person responsible for booking the Octreotide scan? As I sat and waited for three weeks before I asked ... 'what's going on?'
What does it mean to you, the person who told them I was away on the honeymoon I'd had to cancel, because the consultant advised strongly against the long-haul flight?
What does it mean to you, the person who failed to pass on my correct mobile number?
What does it mean to you?
It means nothing.
You sleep at night.
You aren't in pain.
You aren't worrying.
You aren't surrounded by loved ones desperate for some news on the situation.
You aren't worried about your future.
What does it mean to me?
It means 55 months have passed.
It means I face an uncertain future.
It means my cancer has probably spread.
It means my tumour (the one they've found so far) is now almost 2cm.
It means my hopes are fading fast.
It means I may never see my daughter graduate, walk down the aisle or have my first grandchild.
It means I probably won't get to do that PhD I want to.
It means I may never see Sri Lanka (my honeymoon destination) I may never make my anniversaries (I got married less than 4 weeks ago).
Will I see my 50th birthday?
Will I ever be pain free?
Or will my remaining time be filled with injections, scans, tests and appointments?
So, next time you see a patient, next time someone sits in front of you, begging for help, next time you fill in that referral form, pass on medical information, complete a scan ...
…next time, remember it may not mean much to you, but it is my life and to me, this is everything.
It is all I have!

65.1 Neuroendocrine Cells and Their Function

Neuroendocrine tumours (NETs) are a heterogenous group of cancers that arise from neuroendocrine cells. They account for around 0.5% of gastrointestinal and bronchopulmonary malignancies (Yao et al. 2008). They are most commonly found in the gastrointestinal system and lungs but can also originate in other areas, including the pancreas, ovaries, thyroid, and adrenal glands. See Box 65.1 for examples of NETS.

Box 65.1 Examples of Different Types of NETs

Gastrointestinal NETs: **gastric, duodenal, pancreatic, small intestine, appendiceal (including goblet cell), colon, rectal, ovarian**
Lung NETs
Pancreatic NETs **(non-functioning)**
Pancreatic NETs **(functioning): gastrinoma, VIPoma, insulinoma, somatostatinoma, glucagonoma**
Phaeochromocytoma and paraganglioma
Merkel cell carcinoma
Medullary thyroid cancer

Neuroendocrine cells are found in many sites throughout the body. They are specialised cells that can synthesise, store, and release hormones into the blood, integrating the nervous and endocrine systems. They are found in endocrine tissue throughout the body, e.g. endocrine glands such as the adrenal, pancreas, and thyroid glands, as well as in cells of the diffuse endocrine system, for example, within the mucosa of the lungs and the gastrointestinal tract.

When tumours arise from this tissue because of the neuroendocrine cells' ability to secrete metabolically active substances, they can cause distinct clinical syndromes. Examples of hormones the NETs release are shown in Table 65.1.

Table 65.1 Examples of hormones released by neuroendocrine tumours

Hormone	Function	Associated tumours
Serotonin	Regulating gastrointestinal activity	Range of neuroendocrine tumours
Somatostatin	Inhibits the release of growth hormone and suppresses the release of gastrointestinal hormones	Somatostatinoma
Gastrin	Regulates stomach acid production	Gastrinoma
Insulin	Regulates blood sugar levels	Insulinoma

65.2 Incidence and Risk Factors

65.2.1 Incidence and Prevalence

The overall incidence of NETs is hard to confirm, due to wide variation across different studies (Ramage et al. 2012). However, NETs are relatively uncommon cancers, with incident rates in studies varying from around 1.0/100,000 to over 5/100,000 in a recent Canadian study (Hallet et al. 2015). This represents around 1% of digestive cancer incidence; however, due to their overall good prognosis, prevalence rates are relatively high. Indeed, gastrointestinal NETs were the second most prevalent digestive tumour type in the USA after colorectal cancers (Yao et al. 2008).

Several studies show that the incidence of NETs is increasing over time. UK rates have increased fourfold from the 1970s to 2006 with similar increases in the USA (Lawrence et al. 2011) though smaller increases have been recorded in Europe (Lepage et al. 2013). This increase has also been at a greater rate than other cancers. A number of factors may account for this increase, including improved detection due to changes in imaging and endoscopic screening procedures. Similarly, over time there have been a number of changes in the recording and coding of NETs, e.g. adding in a number of poorly differentiated NETs, and also including benign and malignant tumours which could account for some of this increase (Huguet et al. 2015). However, it is unlikely that this fully explains the overall increase in incidence.

65.2.2 Risk Factors for Neuroendocrine Tumours

NETs can develop at any age, but most cases occur in people 60 years of age and older.

It is generally unclear why a particular individual may develop a NET; however, there are a number of known risk factors. A family history of cancer can increase the risk of developing NETs, and diabetes has also been implicated as a risk factor for gastric NETs (Hassan et al. 2008). Chronic atrophic gastritis is also closely linked to the development of type 1 gastric NETs (Fave et al. 2016).

65.2.2.1 NETs in Children and Young Adults

NETs are relatively rare within the paediatric and young adult population, with an incidence of 2.8 NETs per million under the age of 30 years. The incidence rate for the paediatric population alone is even lower, with a rate of less than 0.1 NETs per million under the age of 10 years, and 1 per million for ages between 10 and 14 years (Navalkele et al. 2011). The Surveillance, Epidemiology and End Results (SEER) database in the USA was analysed by Yao and colleagues showing that bronchial NETs, medullary carcinoma of the thyroid, and appendiceal NETs make up over 50% of NETs in those under 30 years of age (Yao et al. 2008). A number of those will be related to hereditary syndromes such as MEN1, MEN2, and VHL [See Sect. 65.2.3 below and Chap. 66].

65.2.3 Genetics

NETs may occur as part of familial endocrine cancer syndromes such as multiple endocrine neoplasia 1 and 2 (MEN 1, MEN2) (see Chap. 66), as well as neurofibromatosis type 1 (NF1)

and Von Hippel-Lindau disease (VHL). However, the majority of NETs occur as non-familial/sporadic isolated tumours. At diagnosis, a detailed family history and clinical examination is essential as part of the workup to check for a likely genetic diagnosis. If appropriate, genetic testing can be offered and carried out. The incidence of MEN 1 is higher in certain tumours such as gastrinoma, around 25%, and approximately 5% in insulinoma, but it is extremely rare in small intestinal NETs (Ramage et al. 2012).

65.3 Classification of NETs

NETs have previously lacked a uniform classification and grading system, but the World Health Organisation (WHO) have a new and generally agreed system. Broadly speaking they are classified according to site of origin, graded into well-differentiated and poorly differentiated tumours and staged through the anatomical spread of the disease. These will all guide the treatment decision-making process and helps to establish likely prognosis.

65.3.1 Site of Origin

NETs are now classified by their site of origin and their grade. Table 65.2 shows the classification of gastroenteropancreatic NETS (GEP-NETs) by site.

65.3.2 Grading

Grading of NETs refers to the inherent biological aggressiveness of the tumour. Differentiation and proliferation indexes are combined to provide information that should guide health care professionals as to how the disease may behave. Ki-67 is

Table 65.2 Classification of gastroenteropancreatic NETS (GEP-NETs) by site

Primary site	Description	Metastatic behaviour
Gastric Nets	Type I. Most common type of gastric NET (70–80%). Develop in association with atrophic gastritis and associated high gastrin and gastric acid levels Type II-Rare-only accounting for 5% of gastric NETs. Can occur in the context of MEN 1, and gastrinoma Type III-Around 20% of gastric NETs. Not associated with high gastrin or gastric acid output	Often small and numerous. Generally favourable prognosis. Rarely metastasise Often small and multiple. Up to 30% may metastasise Normally singular and >2 cm in size. Often invasive and metastatic
Duodenal Nets	Rare-only around 2% of NETs. Generally not associated with functional syndrome, however can be related to ZES	Around 50% have spread to local lymph nodes, though <10% have distant metastases. Overall 5-year survival >80%
Small intestinal NETs	Account for at least 25% of NETs. 20–30% have carcinoid syndrome (see Table 65.6)	Majority are well differentiated, slow growing in nature, though more than half have metastasised at diagnosis
Rectal NETs	Often present incidentally on colonoscopy or sigmoidoscopy. May have rectal bleeding, change in bowel habit	Less than 10% have metastasised at diagnosis with excellent overall survival. For those with distant metastases, prognosis is poor
Appendiceal NETs	Account for majority of appendiceal tumours. Generally found incidentally on post-operative histology	Prognosis excellent for majority, approaching 100% for localised disease
Pancreatic NETs (panNETs)	Arise from pancreatic islet cells. Can be non-functioning (majority of panNETs) or have specific function dependent on secretory hormone (See Table 65.6) Mainly sporadic but can be associated with MEN1, Von Hippel-Lindau syndrome and neurofibromatosis 1	Non-functional panNETs; Overall 5-year survival around 40%. Survival of functioning panNETs is dependent on specific tumour type

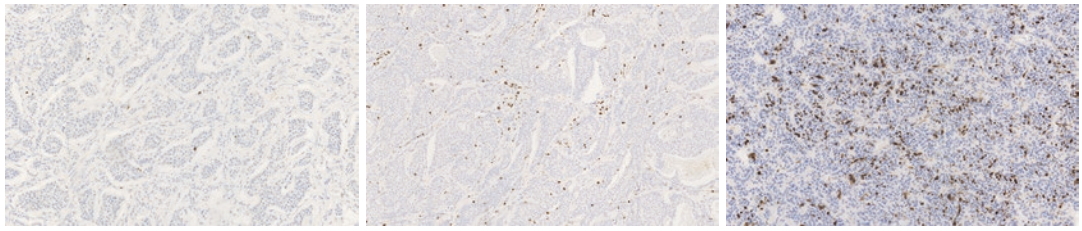

Fig. 65.1 Grading GEP NET with Ki-67 staining. Increased immunostaining highlighted as grade increases

a marker which measures the growth fraction of a given cell population and generally a higher Ki-67 suggests more cells are actively dividing and therefore the tumour may behave more aggressively (see Fig. 65.1). The World Health Organisation (WHO) proposed the following grading criteria for GI and pancreatic NETs in 2010 (Table 65.3) (Rindi et al. 2010) and bronchial (Lung) NETs in 2015 (Table 65.4) (Travis et al. 2015).

A 2017 update in pancreatic NETs has separated out high grade tumours into well-differentiated and poorly differentiated variants. This is based on evidence that some tumours with a high Ki-67 index, but with well-differentiated morphology, have a better overall prognosis and different behaviour than those which are poorly differentiated carcinomas (Basturk et al. 2015).

65.3.3 Staging

The tumour node metastases (TNM) staging system is used for the staging of NETs by both the European Neuroendocrine Tumor Society (ENETS) and the American Joint Committee on Cancer, though no universal agreed system yet exists for NETs (Luo et al. 2016). The TNM system varies for each primary site but predominantly uses:

- The size and location of the primary (original) tumour
- Lymph node involvement (whether or not the cancer has spread to the nearby lymph nodes)
- Presence or absence of distant metastasis (whether or not the cancer has spread to distant areas of the body)

Table 65.3 ENETS/WHO classification of neuroendocrine tumours in the gastrointestinal (GI) tract

Differentiation	Grade	Mitotic count	Ki-67 index %
Well differentiated	NET Grade 1 (Low)	<2 per 10 HPF	<3%
Well differentiated	NET Grade 2 (Intermediate)	2–20 per 10 10HPF	3 to 20%
Poorly differentiated	NEC Grade 3 (High)	>20 per 10 HPF	>20%

Abbreviation: *NEC* Neuroendocrine carcinoma, *HPF* high-power fields, *ENETS* European Neuroendocrine Tumor Society, *WHO* World Health Organisation

Table 65.4 2015 WHO criteria for diagnosis of pulmonary neuroendocrine neoplasms

Grade	Criteria: morphology, mitotic count/10 HPF and necrosis
Typical carcinoid	Carcinoid morphology, <2 per 10 HPF with no necrosis
Atypical carcinoid	Carcinoid morphology with 2–10 per 10 HPF **or** necrosis
Large cell NEC	Neuroendocrine morphology, >10 per 10 HPF **with** necrosis-often extensive
Small cell NEC	Small size, >10 per 10HPF (median 80 per 10 HPF) **with** frequent necrosis

Abbreviations: *HPF* high-power fields, *NEC* Neuroendocrine carcinoma, *WHO* World Health Organisation

65.3.4 Metastatic Spread

Around half of patients present with metastatic disease though this varies dramatically in relation to the primary site. For example, over 60% of small intestinal NETs are likely to have metastasised, compared to 15% from the lung and only 5% of patients with an appendiceal primary

(Ramage et al. 2012). Also, poorly differentiated NETs are more likely to have metastasised at diagnosis compared to well-differentiated NETs. The most common sites of metastases are the liver and small intestine mesentery, with other common sites including other intraperitoneal sites, bone and the lung (Riihimäki et al. 2016). However, they may also metastasise to unusual sites such as the orbit, breast, and heart.

65.4 Survival

Data from several studies shows that the median 5-year survival of all patients with NETs may be as much as 60% though this drops to less than 50% over 10 years (Hallet et al. 2015). Survival depends on many factors including primary site, grade, and stage at diagnosis. Therefore, overall median survival rates for NETs as a broad group are not particularly helpful. For example, appendiceal NETs have survival rates in excess of 90%, whereas pancreatic NETs have a poorer prognosis with survival rates more typically 40–49% (Lepage et al. 2010).

Having metastatic disease at diagnosis is a poor prognostic factor, with a 10-year overall survival (OS) of 17.5% in a recent Canadian study (Hallet et al. 2015). Table 65.5 compares median survival for a range of primary tumour sites plus stage at diagnosis.

Poorly differentiated neuroendocrine carcinomas (NECs) are highly aggressive tumours, similar to small cell lung cancers and prognosis is comparable with 5-year survival rates generally in single figures.

Table 65.5 Median survival in months by primary tumour site

Site	Localised	Regional	Distant
Appendix	>360	>360	27
Caecum	135	107	41
Rectum	290	90	22
Duodenum	107	101	57
Gastric	154	71	13
Lung	227	154	16
Pancreas	136	77	24
Small bowel	111	105	56

65.5 Diagnosis

65.5.1 Introduction

Since NETs are a heterogenous group of tumours, they have a wide variety of clinical presentations. Symptoms will vary depending on where the NETs are located, how fast they are growing, and also if they have metastasised. Many patients with GEP-NETs present with typically vague or non-specific bowel symptoms. This, combined with their rarity, can lead to delays in diagnosis for many years. Studies have shown that it can take on average 5–7 years from initial symptoms to a diagnosis of a NET (Modlin et al. 2008). This may include multiple GP visits, inconclusive investigations, and often a diagnosis of other gastrointestinal complaints such as irritable bowel syndrome (IBS) or gastritis. The impact of this is that many NET patients begin their cancer pathway with heightened feelings of anxiety and frustration.

Even when a NET is suspected, patients often face a complex process of investigations, including a number of imaging techniques, a multitude of blood tests, and also referral to specialist centres as some tests are not available locally. This can lead to further delays and increased anxiety before treatment is commenced. Specialist nurses can play a key role within the MDT in ensuring that tests are correctly organised, carried out in a timely fashion, and that the different specialities work effectively together to reduce delays. Patients need to be kept accurately informed throughout about each investigation, why they are necessary and their likely timing. Managing anxiety, frustrations over waiting, and natural concerns about findings is a key part of good nursing support at this time.

65.5.2 Presenting Signs and Symptoms

65.5.2.1 Functioning Tumours

Many GEP-NETs have the potential to release biologically active substances into the circulation (Kaltsas et al. 2004). Those that cause clinical

Table 65.6 Functional NETs and their common symptoms

Tumour	Symptoms
Carcinoid tumour	Dry flushing, diarrhoea and abdominal cramping, asthma like wheeze, carcinoid heart disease (fibrosis of the heart valves, predominantly right sided)
Insulinoma	Confusion, sweating, dizziness, weakness, unconsciousness, symptoms relieved with eating
Gastrinoma	Zollinger-Ellison syndrome of severe peptic ulceration and diarrhoea, or diarrhoea alone
Glucagonoma	Necrolytic migratory erythema, weight loss, diabetes mellitus, stomatitis, diarrhoea
VIPoma	Verner-Morrison syndrome of profuse watery diarrhoea with marked hypokalaemia
Somatostatinoma	Cholelithiasis, weight loss, diarrhoea and steatorrhoea, diabetes mellitus

Table adapted from Ramage et al. (2012)

syndromes are termed "functioning" tumours. These include about 20% of small intestinal NETs where people experience the "carcinoid syndrome", and about 40% of pancreatic NETs which cause specific syndromes based on the peptide that they secrete (Ramage et al. 2012; Ramage and Davies 2003) [see Table 65.6 below].

65.5.2.2 Non-functioning Tumours

With non-functioning tumours, symptoms are caused by the mass effect of the primary tumour and related metastatic disease GEP-NETs often present with features such as pain, nausea and vomiting, weight loss, and fatigue. Pain and nausea may be due to local tumour invasion, bowel obstruction, or mesenteric ischaemia. (See Sect. 65.6.1.2.1 in Sect. 65.6). Weight loss may be related to diarrhoea and malabsorption of food, and general malaise in more advanced tumours. Fatigue may be due to the disease process and to exacerbating factors such as pain and anaemia.

Patients with lung NETs may present with cough, wheeze, shortness of breath, chest pain, or haemoptysis.

NETs may also be found incidentally: for example, the majority of appendiceal NETs are found either on surgery for appendicitis or colonic surgery, and around 20% of bronchial NETs are found incidentally on radiography (Ramage et al. 2012).

N.B. Patients with functioning tumours may of course also have symptoms from the mass effect of their tumour.

65.5.3 Investigations

65.5.3.1 Medical History

Presenting signs and symptoms and past medical history are important to capture accurately. This can give a clue to the possible type of NET, the length of time a person may have had symptoms, and whether or not there is a possibility of a genetic or familial element.

65.5.3.2 Laboratory Tests

A range of laboratory tests are used to help diagnose and also to assess treatment effectiveness and prognosis.

65.5.3.2.1 Routine Laboratory Tests

These will include full blood count, renal and liver function tests, and often thyroid function tests as well. Other common blood tests include serum calcium, parathyroid hormone, prolactin levels, and IGF-1 levels in pancreatic NETs to rule out MEN 1 syndrome (see Chap. 66). Some centres may test for a range of common tumour markers, e.g. CEA, CA125, CA19-9 for a differential diagnosis.

65.5.3.2.2 Specialised Laboratory Tests

As many NETs secrete a variety of bioactive products, some less common laboratory tests are an important part of the diagnostic process. These include

- Chromogranin A (and B) (CgA and CgB): This is the most sensitive biomarker in a range of NETs. It can be measured in serum or plasma. High levels are suggestive of a poor prognosis. Limitations are that it is raised by protein pump inhibitors and histamine 2

receptor antagonists, as well as in chronic gastritis and renal failure.

- Fasting gut peptides: These are used to help identify a number of NETs, including functioning pancreatic NETs. Peptides that are checked are somatostatin, gastrin, glucagon, vasoactive intestinal peptide (VIP), and pancreatic polypeptide. In gastric NETs, these laboratory tests can be difficult to interpret as gastrin and CgA are raised in many common conditions where gastric acid is reduced or absent, including atrophic gastritis.

  N.B. Chromogranin and fasting gut peptides can generally not be carried out in the community. They require to being spun and frozen shortly after they are taken and can only be processed in some specialist labs.
- 5-hydroxyindoleacetic acid (5HIAA): Raised levels are found in many small intestinal NETs as well as NETs of the stomach and respiratory system. It is the main breakdown metabolite of serotonin. It is normally measured in a 24-h urine collection though some centres now use a single urine specimen or plasma sample. 5HIAA levels can be altered by a range of drugs and serotonin-rich foods, e.g. pineapple, banana, avocado, walnuts amongst others. Many centres require patients to exclude these foods from their diet for 48 h before and during the 24 h collection to exclude false-positive results (Pape et al. 2012).
- NT-proBNP: This is a useful screen for carcinoid heart disease. Many centres would also carry out an echocardiogram. Monitoring can typically be on an annual basis, or if symptoms of carcinoid heart disease develop (Hart et al. 2017).

65.5.3.2.3 Insulinoma

For suspected insulinoma, glucose, insulin, and C-peptide levels will be measured, as well as proinsulin if available. A 48–72 h fast with serial blood glucose analysis is the gold standard diagnostic tool. However, in around 5% of patients hypoglycaemia may only be revealed postprandially (Okabayashi et al. 2013).

65.5.3.3 Imaging

Imaging of both the primary tumour and any potential metastatic disease is an essential part of the diagnostic phase. It can determine if surgical resection is possible, whether treatment for metastatic disease is appropriate, and what is likely to be the most effective treatment modality. Imaging will also be used extensively during follow-up to assess the effectiveness of any treatment as well as ongoing surveillance after potentially curative treatment.

There are a range of imaging techniques available to diagnose and stage NETs; some are available in most, if not all centres, other techniques are more specialised and only available in a few regional centres.

65.5.3.3.1 Computed Tomography (CT)/ Magnetic Resonance Imaging(MRI)

Standard CTs and MRI are well-established tools to diagnose a number of different types of NETs. They are also an excellent tool for ongoing follow-up and assessment of treatment response. However, CTs can lack sensitivity for detecting primary small intestinal NETs (Ramage et al. 2012). MRIs are sensitive in detecting bone and liver metastases and are good for surveillance due to the absence of radiation.

65.5.3.3.2 Somatostatin Scintigraphy

As NETs generally express high levels of somatostatin receptors (SSTRs), the standard nuclear medicine technique for investigating NETs has been SSTR scintigraphy with *Octreoscans* (Pape et al. 2012). Octreotide, which is a synthetic analogue of somatostatin, is radiolabelled with ^{111}indium. This attaches to tumour cells with SSTRs, and this is picked up on a gamma scanner. It is standard practice to combine this with SPECT/CT. However, in recent years ^{68}Ga Dotatate positron emission tomography (PET) imaging has become the gold standard, having greater sensitivity and specificity than *Octreoscans*. Studies confirm that this technique may have a major impact on treatment decision-making, in particular identifying additional patients who might benefit from peptide receptor radionuclide therapy (PRRT) (Deppen et al. 2016), [see Fig. 65.2 below].

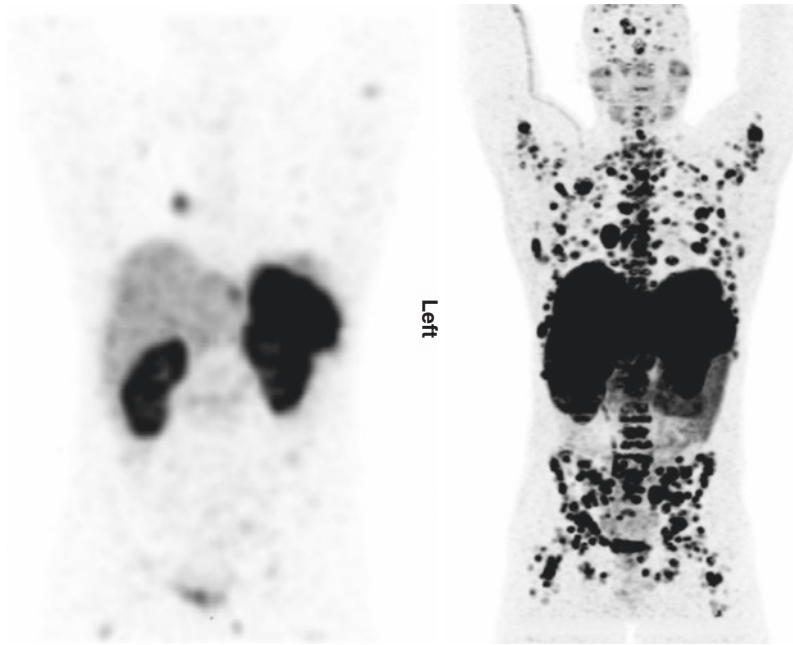

Fig. 65.2 ^{111}In-Octreotide vs ^{68}Ga Dotatate in a patient with known metastatic NET. (Written consent and permission has been obtained from the patient to use these images). Images highlight strikingly different uptake on a patient with both ^{111}In-Octreotide and 68 Ga Dotatate PET scans. The Octreoscan did not demonstrate sufficient avidity to consider use of Somatostatin analogue or Peptide Receptor Radionuclide Therapy. ^{68}Ga Dotatate PET showed high level of avidity and also greater disease burden than expected. The patient proceeded to have ^{177}Lu PRRT therapy on the basis of the ^{68}Ga Dotatate PET result

65.5.3.3.3 FDG-PET

FDG-PET lacks sensitivity with most well-differentiated NETs. However, it can be useful in staging primary bronchial and poorly differentiated aggressive NETs. Higher proliferation or Ki-67 indexing may indicate the use of PET-FDG.

65.5.3.4 Endoscopy

Gastric NETs may require endoscopy, combined with biopsy. Endoscopic ultrasound is also useful in detecting gastric, pancreatic, and duodenal NETs. Pulmonary NETs often require bronchoscopy.

65.5.3.5 Histopathology

Pathology is essential to effectively classify and diagnose NETs. NETs have a very distinctive appearance which can be identified through immunohistochemical staining. Tissue can be obtained through biopsy, via endoscopy, or during surgery. [See Sect. 65.3.2 under Sect. 65.3].

65.6 Treatment of NETs

A range of surgical and medical interventions are used in the management of NET patients. The choice of treatment depends on a number of factors including:

- The location and type of the primary tumour
- The extent of disease spread
- The patient's condition and comorbidities
- Patient preference
- Availability of treatments

The key to optimal management is early detection and diagnosis.

65.6.1 Surgery

65.6.1.1 Potentially Curative Surgery

Surgery offers the possibility of cure for patients diagnosed with small volume/resectable disease. Common examples in NETs include:

- Appendiceal NET: Appendicectomy, with right hemicolectomy for some higher risk tumours
- Bronchial NET: Wedge resection, segment, or lobe resection
- Duodenum: may vary from simple endoscopic resection for small tumours to pancreaticoduodenectomy (Whipple's procedure)
- Ileum: Small bowel resection. May include part of mesentery.
- Pancreas: distal resection of single lesion in tail of pancreas to Whipple's procedure for pancreatic head tumour

Even after successful resection many patients still need to be followed up long term as disease may reoccur many years after the initial surgery (Knigge et al. 2017).

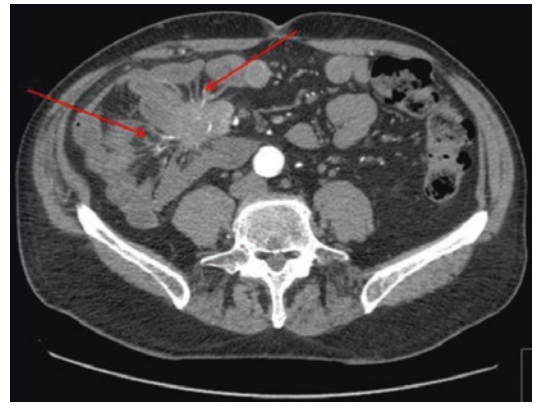

Fig. 65.3 Desmoplastic Reaction and fibrosis of Small bowel mesentery. (Written consent and permission has been obtained from the patient to use these images). Desmoplastic Reaction: CT scan showing desmoplastic reaction from mesenteric metastatic lymph node mass. This patient presented with symptoms of abdominal pain, poor appetite, weight loss and erratic bowel habit. Diagnosed with a small intestinal NET with mesenteric and liver metastases. They were commenced on a somatostatin analogue which initially improved their symptoms. However, over 18 months their symptoms and quality of life worsened, with increased pain and erratic bowel habit. They underwent a small bowel and mesenteric resection for palliation of symptoms with excellent symptomatic benefit

65.6.1.2 Palliative Surgery: Primary Tumour

Surgery is also used as a treatment in the presence of metastatic disease to help control patients' symptoms and potentially improve prognosis and quality of life. Due to the heterogeneity of NETs, the surgery type can range from small resections to extensive surgery. The rationale is that removing the primary tumour may either improve disease survival and/or the quality of life for the patients. It may also prevent the patient presenting later with small bowel resection, [see Sect. 65.6.1.2.1 below].

65.6.1.2.1 Small Intestinal Resections

The area around the primary tumour and mesenteric metastases can become fibrotic and cause a diffuse desmoplastic reaction. This may cause the small bowel to narrow and kink and can lead to bowel obstruction. The fibrosis and tumour mass can also narrow the surrounding mesenteric blood vessels and lead to bowel ischaemia (see Fig. 65.3). Patients in these situations have recurrent bowel obstruction with severe pain and may be unable to tolerate oral diet and need permanent parental nutrition [see Sect. 65.7.3]. This has a huge impact on their quality of life, and they have a poor overall prognosis (Moris et al. 2018).

Radical mesenteric and small intestinal resection may need to be considered to prevent these symptoms, stop them worsening, or to manage them if already present.

However, the mesenteric disease may be inoperable as the blood supply to the bowel would be lost during resection. Resectability of the tumour at an early stage is discussed as part of an MDT meeting, and the involvement of the surrounding blood vessels and lymph nodes will determine if surgery is possible (Capurso et al. 2012).

65.6.1.2.2 Pancreatic Surgery

Resecting a primary pancreatic mass in the presence of metastatic disease may also be consid-

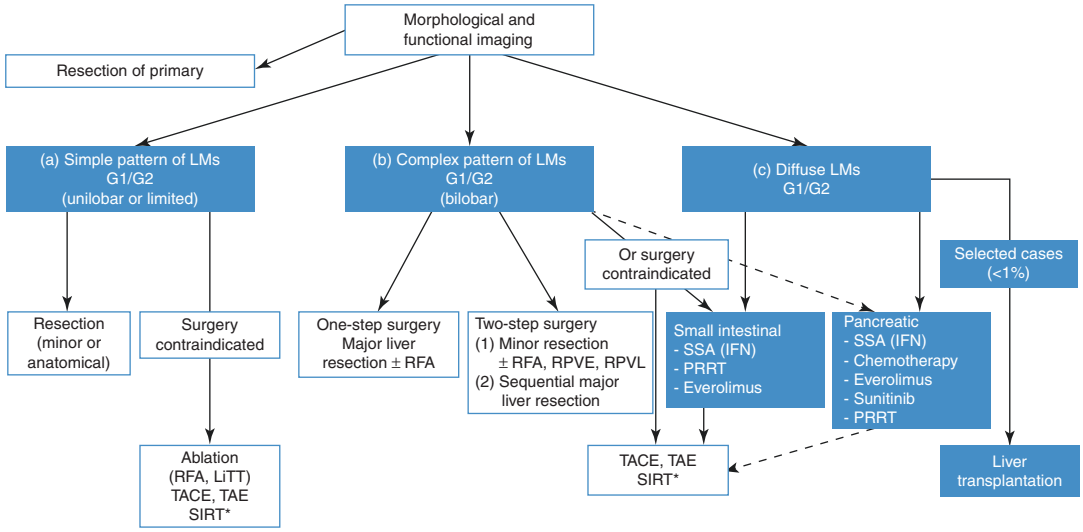

Fig. 65.4 ENETs algorithm for supporting decision making in managing metastatic liver disease. Pavel et al 2016. ENETS Consensus Guidelines Update for the Management of Distant Metastatic Disease of Intestinal, Pancreatic, Bronchial Neuroendocrine Neoplasms (NEN) and NEN of Unknown Primary Site, p 173 (Open access article)

ered. It can reduce the tumour burden and improve symptoms for the patient. However, if the tumour is located in the head of pancreas a Whipple's procedure is needed. This may not be recommended in the presence of known metastatic disease due to the complication risk related to this surgery and ongoing risks related to abscess development after local liver-directed treatments (Partelli et al. 2017).

65.6.2 Liver-Directed Treatments

NETs commonly spread to the liver, often causing significant symptoms, including pain and hormonal syndromes. For those patients with functional tumours, treating the metastases can reduce the release of hormones and the associated symptoms can improve, i.e. for carcinoid syndrome patients this can mean a reduction in flushing frequency and intensity, frequency of diarrhoea, and can reduce the risk of damage to the heart valves. This approach may also improve overall survival in some cases and also benefit quality of life (Frilling et al. 2014).

There are many liver-directed therapies used for this patient group. This includes liver resections, debulking procedures, embolisation (with or without chemotherapy), radio frequency ablation (RFA), intra-arterial peptide receptor radio-targeted therapy (PRRT), and selective internal radiation therapy (SIRT) (Pavel et al. 2016).

There is no standard plan to treat liver metastases and a lack of comparative study data to support a particular approach. Therefore, each case needs to be considered individually by a specialist MDT. The size, number, and position of tumours, the overall disease burden as well as the patient's health status and preference all need considered (De Baere et al. 2015). Figure 65.4 shows an ENETS algorithm for supporting decision-making in managing metastatic liver disease (Pavel et al. 2016).

65.6.2.1 Palliative Hepatic Surgery

Hepatic surgery may be used to improve the symptoms related to uncontrolled hormone production e.g. refractory carcinoid syndrome, Verner-Morrison syndrome (VIPomas), and insu-

linomas (Pavel et al. 2016). Palliative resections for patient that are non-functional are considered if the volume of disease is causing symptoms for the patient. Surgical teams within the NET MDT are becoming more aggressive in their approach to treating these patients to try and improve patient outcomes, with two- or three-step operations occurring more often.

65.6.2.2 Radiofrequency Ablation (RFA)

RFA has been used for many years, sometimes in combination with liver resection to achieve complete responses. Ablation therapies are less invasive than surgery and patients do not need an extended hospital inpatient stay. RFA can reduce the secretion of hormones from tumours and therefore reduce symptoms, such as diarrhoea and flushing from carcinoid syndrome (Eriksson et al. 2008). Tumours need to be generally <5 cm for this treatment to be effective (Elias et al. 2005).

65.6.2.3 Hepatic Embolisation Therapies

Embolisation of the hepatic artery can result in ischaemia and necrosis of tumours within the liver. It also reduces secretions of peptides from metastatic NETs. Selective hepatic transarterial embolisation (TAE), transarterial chemoembolisation (TACE), or radioembolisation (RE) with yttrium-90 microspheres has been shown to produce objective disease responses and control symptoms in a number of patients with NET (Kennedy et al. 2015). Normal liver tissue is spared as it also receives its blood supply from the portal vein.

65.6.2.4 Liver Transplantation

Liver transplantation is generally not recommended as a treatment for advanced NETs. In highly selected patients (i.e. young patients with functional syndromes demonstrating resistance to medical therapy), this may be a treatment option if it can be confirmed that there is no extra-hepatic disease (Neychev and Kebebew 2017). Each country has individual criteria regarding transplantation.

65.6.3 Drug Therapies

There are a number of different systemic therapies available to treat NETs, including somatostatin analogues, targeted therapies such as everolimus and sunitinib, and cytotoxic chemotherapy. A number of clinical trials have shown their use in controlling disease and managing symptoms; however, there is a lack of direct comparison through clinical trials and a lack of clarity as to the order in which treatments should be used. Guidelines therefore tend to suggest a range of available options and issues to consider when choosing a particular therapy, see Fig. 65.5.

65.6.3.1 Somatostatin Analogues (SSAs)

Somatostatin is a peptide that inhibits the release of hormones/peptides including serotonin, insulin, glucagon, and VIP. Somatostatin receptors (SSTRs) are present in the majority of NETs, but far less in poorly differentiated NECs (Sharma et al. 2016). SSAs are a synthetic version of somatostatin and have been produced in short (octreotide) and long-acting formulations (Lanreotide Autogel and Sandostatin LAR).

These drugs target and block the SSTRs and have been used for many years to control the functional syndromes of both carcinoid tumours and functional pancreatic islet tumours, such as insulinomas and gastrinoma. They reduce the release of the peptides hyper secreted by NET tumours and around 75% of patients will get effective benefit from their use (Khan et al. 2011).

Studies have also confirmed the anti-tumour effect of these agents and therefore they are now also used to treat non-functional NETs, which are SSTR positive. The optimal dosages for anti-tumour effect have not been studied; however, in the two main randomised controlled trials (RCTs) Sandostatin LAR 30 mg and Lanreotide Autogel 120 mg every 28 days were studied and found to be effective in prolonging disease stability and progression-free survival (Rinke et al. 2009; Caplin et al. 2014).

Lanreotide Autogel and Sandostatin LAR are typically administered every 4 weeks. In instances where patients continue to have uncontrolled symptoms the period between

Drug	Functionality	Grading	Primary site	SSTR status	Special considerations
Octreotide	+/–	G1	midgut	+	low tumor burden
Lanreotide	+/–	G1/G2 (–10%)	midgut, pancreas	+	low and high (>25%) liver tumor burden
IFN-alpha 2b	+/–	G1/G2	midgut		if SSTR negative
STZ/5-FU	+/–	G1/G2	pancreas		progressive in short-term* or high tumor burden or symptomatic
TEM/CAP	+/–	G2	pancreas		progressive in short-term* or high tumor burden or symptomatic; if STZ is contraindicated or not available
Everolimus	+/–	G1/G2	lung		atypical carcinoid and/or SSTR negative
			pancreas		insulinoma or contraindication for CTX
			midgut		if SSTR negative
Sunitinib	+/–	G1/G2	pancreas		contraindication for CTX
PRRT	+/–	G1/G2	midgut	+ (required)	extended disease; extrahepatic disease, e.g. bone metastasis
Cisplatin§/ etoposide	+/–	G3	any		all poorly differentiated NEC

CAP = Capecitabine; TEM = temozolomide. *≤6–12 months. § Cisplatin can be replaced by carboplatin.

Fig. 65.5 Therapeutic options and conditons for preferential use as a first-line therapy for advancd NEN. Pavel et al 2016. ENETS Consensus Guidelines Update for the Management of Distant Metastatic Disease of Intestinal, Pancreatic, Bronchial Neuroendocrine Neoplasms (NEN) and NEN of Unknown Primary Site, p174 (Open access article)

injections may be reduced or the dose increased over those mentioned above (see Sec. 65.7.2.1).

SSAs are generally well tolerated. Gut-related side-effects are quite common at the start of treatment; however, these often settle over the first few months of treatment. For management of side-effects, see Table 65.7.

65.6.3.2 Interferon

Interferon is licenced for use in Europe for patients with the "carcinoid syndrome". This treatment is often used alongside SSAs to help control refractory carcinoid syndrome and a more recent study has shown anti-proliferative effects although it is not currently licenced for this use (Yao et al. 2015; Oberg 2000). It has been found to have both symptomatic and biochemical benefit, but its mode of action remains unclear. It can be administered as a standard therapy Interferon alpha 2b or in a pegylated form Peginterferon alpha 2b.

Close monitoring is needed due to the side-effect profile including early/transient flu-like symptoms, and ongoing mood disturbances, suicidal thoughts, headache, fatigue, sleep disturbances, and haematological toxicity. It must also be stopped for a period of time before planned surgery and other treatments to allow time for the blood levels to recover.

65.6.3.3 Systemic Anti-Cancer Treatments (SACTs)

65.6.3.3.1 Targeted Agents

Targeted agents such as everolimus and sunitinib are approved for use in NETs. Everolimus is a rapamycin inhibitor which is licenced for use in progressive panNETs, G1/G2 non-functional gastrointestinal NETs, and Bronchial NETs (Yao et al. 2011, 2016). The dose and regimen for NET patients is 10 mgs once a day. Frequent side-effects are stomatitis, skin rash, diarrhoea, and myelotoxicity (Yao et al. 2011).

Table 65.7 Management of common side-effects of somatostatin analogue injections

Organ affected	Symptoms	Management
Gastrointestinal	Nausea, abdominal pain, steatorrhoea, malabsorption of fat from diet, flatulence (due to transient pancreatic exocrine insufficiency (PEI))	Anti-emetics, antispasmodics, pancreatic enzyme replacement therapy can be considered for ongoing symptoms of PEI. Measurement of fat-soluble vitamins
Altered blood sugar regulation	Potential signs of high or low blood sugars	Increased monitoring for diabetics. Otherwise occasional HbA1c is sufficient monitoring
Gallstone development	Often asymptomatic	Ultrasound of gall bladder. Prophylactic cholecystectomy if other planned surgery

Everolimus can also increase the glucose levels in patients and has a potential role in treating insulinoma (Kulke et al. 2009).

Sunitinib is a tyrosine kinase inhibitor and is licenced for use in progressive well-differentiated panNETs (Raymond et al. 2011) at a dose of 37.5 mgs once a day. Side-effects include neutropenia, hypertension, diarrhoea, and fatigue.

Both targeted agents require patients to take tablets on a daily basis. They will require regular monitoring to review and control toxicities to help with compliance and to try to ensure a good quality of life throughout treatment.

Despite the demonstration of improved progression-free survival in patients with advanced NETs, the overall tumour response rates with targeted agents have been poor, typically in single figures (Neychev and Kebebew 2017). A comprehensive review of the patient's history including the comorbidities such as diabetes or lung diseases is imperative when deciding the treatment of choice, or whether to offer the option of best supportive care, managing symptoms as they arise.

65.6.3.3.2 Cytotoxic Chemotherapy

For patients with bulky, rapidly progressive disease, or those with poorly differentiated NETs, treatment with cytotoxic chemotherapy may be considered. It is usually only considered in patients with progressive or bulky pancreatic NETs, G3 tumours, or in progressive G2 disease (Garcia-Carbonero et al. 2016).

For G1/G2 tumours streptozocin (STZ)-based chemotherapy regimens have been found to be effective for patients with progressive disease, and the additional of doxorubicin has increased the effectiveness of STZ regimens; however, due to the cumulative cardiotoxicity of doxorubicin it usage is limited (Garcia-Carbonero et al. 2016). Temozolomide-based regimens have also shown promise in the setting of pancreatic NETs (Koumarianou et al. 2015), possibly paired with capecitabine.

In high grade neuroendocrine carcinomas (NECs), platinum-based chemotherapy regimens are the mainstay for treatment in advanced and metastatic disease as long as the patient's performance status allows. Regimens with oxaliplatin and irinotecan may be used second-line although these regimens have not been fully evaluated. More research is needed regarding treatment for patients with metastatic NECs as there are limited treatment options and their overall survival is typically less than 12 months (Garcia-Carbonero et al. 2016).

65.6.4 Peptide Receptor Radionuclide Therapy (PRRT)

The expression of SSTRs in many well-differentiated NET tumours is used to identify tumours throughout the body, i.e. ^{68}Ga Dotatate PET scans and ^{111}In-octreotide scans and is also targeted by SSAs. This ability to target the receptors of the tumours is exploited further by the use of radiolabelled somatostatin analogues. With retrospective data from a number of studies suggesting response rates of over 25% (Kwekkeboom et al. 2008), this has become an established treatment for inoperable, loco-regional, and metastatic GEP-NETs in many countries. A recent randomised controlled trial comparing ^{177}Lu-octreotide to high-dose octroetide in progressive, well-differentiated, midgut NETs supports this, with an objective response of 18% for ^{177}Lu-octreotide compared to 3% in the octreotide arm (Strosberg et al. 2017). (See Fig. 65.6 for example of disease response).

The two main radionuclides used are Lutetium 177 (^{177}Lu) and Yttrium 90 (^{90}Y) with evidence suggesting lower renal toxicity with ^{177}Lu compared to ^{90}Y (Baum et al. 2015). Amino-acid infusions are

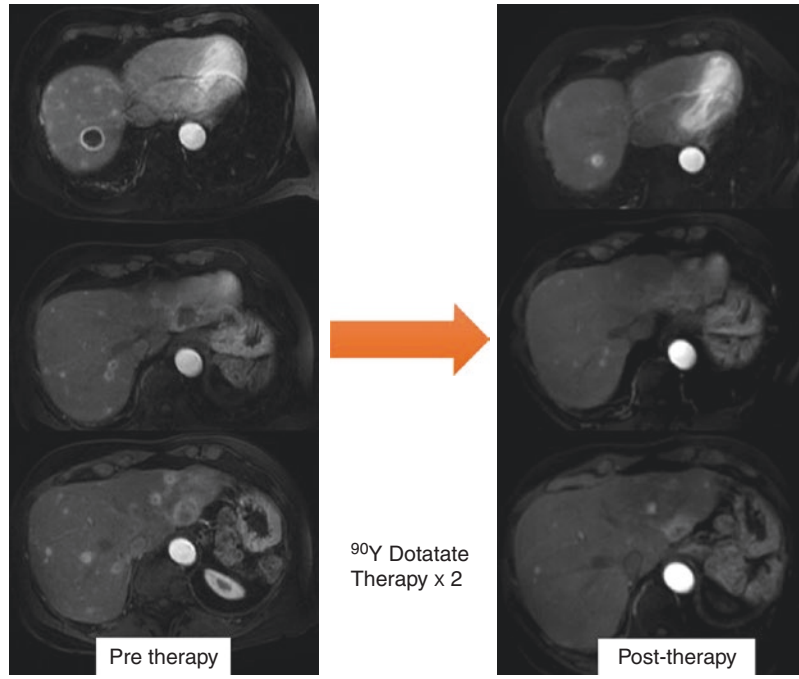

Fig. 65.6 Response to ^{90}Y Dotatate therapy. (Written consent and permission has been obtained from the patient to use these images). CT Liver, pre and post ^{90}Y-Dotatate Therapy, showing clear reduction in the size of liver metastases

given to reduce renal toxicity. Common side-effects include nausea and vomiting, alongside the amino-acid infusion, neutropenia, and thrombocytopenia. These treatments are radioactive and as such have stringent radiation protection measures that are followed. Typically patients are treated in lead-lined rooms to reduce the exposure to the hospital staff and other patients, and they need to be self-caring due to the radiation protection measures. Contraindications also include moderate-to-severe renal impairment, impaired haematological, hepatic or cardiac function, and pregnancy or breast feeding. After each cycle of treatment patients can be monitored by telephone clinics alongside fortnightly bloods to help assess their recovery.

This treatment is not currently used first-line and requires specialist knowledge so should be carried out within a NET centre to ensure selection and monitoring of patients as appropriate.

65.6.5 Treatment Decision-Making and NETs

It is clear from above that there are a wide range of active therapies available to treat patients with NET. However, there are several areas of uncertainty regarding the most effective way to utilise these. These include:

- Limited evidence on the correct sequencing of treatments, i.e. what should be first-, second-, or third-line therapy.
- Many treatments lack robust phase 3 data, and they are used based on small-scale retrospective studies and on best expert opinion. The choice of treatment may therefore vary from centre to centre as well as from region to region.
- Access to specialist therapies and imaging techniques is variable, for example, both PRRT and ^{68}Ga-Dotatate PET scans are only available in some countries and even within individual countries access may only be in a few specialist centres.

Other issues that make decision-making challenging include knowing when to change therapy and how to determine progressive disease. Should progression be defined as:

- Worsening symptoms?
- Radiological progression? or
- Biochemical progression?

NETs may be extremely slow growing and radiological imaging may not capture progression effectively. Patients may have stable disease on imaging but have worsening symptoms and changes in tumour markers. Other patients may

have slowly growing disease but remain clinically very well. Therefore, treatment decisions need to be based on an accurate assessment of all three and the clinical judgement of a specialist team.

For a number of patients with low volume/low grade disease, who are symptomatically well, an appropriate approach may be to offer active surveillance rather than a treatment which may have a number of side-effects and possibly reduce quality of life. This approach can feel intuitively wrong for someone who has just been diagnosed with cancer.

Accurately assessing the patient and family concerns, long-term goals, and hopes are essential when we lack certainty on the value of different therapeutic options. Giving people time to consider the merit of each and supporting them with the uncertainty that this brings is key to effective patient-centred decision-making.

A recent survey in the UK highlighted that NET patients are far less likely to receive written information about their type of cancer, the tests they undergo, or the treatment that they receive (Quality Health 2015). Therefore, it is essential that patients are directed to specialist NET teams and specialist information resource and are given the chance to discuss options with an expert team to help them consider all options.

65.7 Nursing Support of Patients with NETs

Caring for individual with neuroendocrine tumours is complex and challenging. There are a wide range of diagnoses which encompass neuroendocrine tumours, including different tumour types, grades, and stages. These range from small indolent tumours to widespread, aggressive cancers, with the whole range in-between. The lack of clear evidence on how to best manage many of these can make for high levels of uncertainty for patient and their families as well as health care professionals who care for them. The complex range of symptoms that many patients have requires a wide range of knowledge and skill and input from many different disciplines and specialities (see Box 65.2).

This section explores the nurse's role through focus on three common concerns that are raised by many patients living with NETs

Box 65.2 Specialist Nurses and the MDT

The care of this complex condition requires the cooperation of a multidisciplinary team covering a broad range of specialties with the patient actively involved in decision-making. Patients may live with advanced disease for many years. They face a roller-coaster ride of multiple treatments, often with different teams, ongoing symptoms, and the psychological and social burden of living with a life-limiting illness.

Specialist **nurses** are well-placed within the MDT to take on a **key worker role**, supporting patients through a **complex illness trajectory**, providing a consistent single point of contact.

The key worker role includes:

1. Liaising with the MDT to ensure the patient's treatment trajectory is effectively managed.
2. Support with treatment decision-making
3. Holistic assessment of need
4. Ongoing informational and psychological support
5. Management of symptoms

Patient Quote

"Knowing that I could always call [the nurse] at any time was a godsend. They understood my case, they were often there at my appointments or at the end of a phone and I'm not sure how I would have managed without their support. I always felt that they were fighting in my corner".

(Written consent and permission has been obtained from the patient to use this quote)

1. Health-related quality of life
2. Gastrointestinal symptoms
3. Management of nutritional issues

65.7.1 Health-Related Quality of Life and NETs

There is limited research information about the impact of neuroendocrine tumours on health-related quality of life (HRQoL). NETs are rela-

tively rare and the heterogeneity of NETs makes it difficult to draw clear conclusions about the impact on specific groups of NET patients (Yao et al. 2008). Several studies have measured HRQoL in patients with NETs and show that overall HRQoL is reduced compared to the general populations in those countries (Beaumont et al. 2012). What is also known is that hormonal related symptoms, such as diarrhoea and flushing, can greatly affect HRQoL (Vinik et al. 2016). Other tumour-related symptoms including fatigue and pain also impact on HRQoL and mental health issues such as anxiety, sadness at illness, and depression are not uncommon (Singh et al. 2016). A recent global survey of HRQoL in NET patients noted that nearly three quarters of patients stated their disease had a moderate to significant impact on their lives. Over 90% had made lifestyle changes and over half had significant stress and anxiety levels and worried about their future (Singh et al. 2016).

As many NET patients have metastatic disease, and may also have limited treatment options, HRQoL becomes the key focus of care for health care professional and patients (Pearman et al. 2016). Many NET treatments are focused primarily on reducing symptoms in an attempt to improve HRQoL, for example, somatostatin analogues or liver-directed therapies in patients with carcinoid syndrome. A few studies have examined the impact of treatment on HRQoL, suggesting that some treatments, including surgery and PRRT, can have beneficial effects on HRQoL in patients with GEP-NETs (Martini et al. 2016). However, others are less conclusive (Vinik et al. 2016), and the balance between benefits and side-effects of a range of treatments in NETs needs further exploration.

65.7.1.1 Patient Support

Specialist nurses are often well-placed to support patients by giving time for patients to talk about the impact of their illness on their quality of life, assessing their concerns and implementing strategies to respond to these. A focus on holistic health needs assessment and patient-reported concerns/outcomes (PROMs) is useful and a number of tools exist to support this (National Cancer Action Team 2011). Holistic needs assessment can uncover unexpected concerns, focus on what is most important to the patient and guide support strategies and referrals to other agencies and health care professionals.

Some concerns that patients raise may be resolved directly in consultations, through for example giving tailored information or prescribing medication. Other concerns may require input from other agencies such as psychological services, social work, or specialist palliative care teams.

Case Study 1

(Written consent and permission has been obtained from the patient to use this case study)

Psychological Assessment and Management

Joanne is a 32-year-old lady who presented with a 2-year history of intermittent chest infections. Investigations, including lung biopsy, led to the diagnosis of a *typical bronchial NET* and plans were in place for this to be excised. A preoperative FDG-PET scan showed an indeterminate liver lesion, and a further *Octreoscan* suggested possible liver metastases. Her surgery was cancelled and she was referred to the NET specialist team at her closest Centre of Excellence.

During our first meeting, she was pacing back and forward in the clinic room, tearful and clearly highly distressed. Her partner was sitting in a chair crying. Efforts were made to try to explain the diagnosis to her and the plan to biopsy her liver: meanwhile, we would commence her on a somatostatin analogue—our view was that starting a treatment might help focus her anxiety.

Further assessment by the specialist nurse that day highlighted a history of anxiety disorder since her late teens. She'd lost over 10 kg in weight since the results of her scan, 10 days earlier, she was unable to sleep, and felt sick all the time. She remained distressed throughout the visit, even after treatment was started, and she had a panic attack.

A decision was made to contact the out of hours psychological medicine team for advice. They reviewed Joanne in clinic and arranged for her GP to prescribe some mild sedatives to assist with sleep and she was commenced on anti-depressants. She was also enrolled on a depression management

programme for cancer patients available in the specialist centre.

Sadly the biopsy confirmed metastatic NET and over the next 18 months Joanne underwent a number of different treatments. Throughout this time she required intensive input from the psychological medicine team, who provided invaluable support throughout this period. Though she now has stable disease she has a daily struggle with anxiety and depression and continues to use both the specialist nurse and psychological medicine team for ongoing support.

Learning Point

This case highlights the benefit of a systematic approach to assessment and management of anxiety and depression in patients with cancer.

Questions

How could psychological assessment and support be improved within your own clinical setting?

What role could nurses play in this?

Others may be resolved by the patient taking responsibility for further action (National Cancer Action Team 2011), for example by attending a support group (see Box 65.3) or speaking to relatives about their feelings. It is well known that social support can play a key role in how patients cope with illness and this is supported in studies in NETs (Haugland et al. 2016).

Box 65.3 Patient Support Groups (NET Natter Groups UK)

In the UK, there is a large network of NET ***Natter*** groups, set up by the NET Patient Foundation charity. These groups allow patients to share experiences, deal with emotionsn and feel less isolated. They range from informal meetings of a small number of patients and family members affected by NETs to more formal meetings with specialist speakers. As they are NET specific, they can also help those with rare cancers feel less isolated and normalise their situation.

Patient/Carer Quotes

"It's been amazing meeting other patients with NETs, being able to talk about John's illness and realise we're not alone in this". "The specialist talks and information are great, but most of all it's getting together with other people with a NET, sharing tips on dealing with symptoms… having a laugh or even crying together".

For more information, see: https://www.netpatientfoundation.org/ and **Box 65.4**.

(Written consent and permission has been obtained from the patient to use these quotes)

Box 65.4 Patient Advocacy Groups: The NET Patient Foundation

The *NET Patient Foundation* was founded in 2006 by Cathy Bouvier the NET specialist nurse at the Royal Free Hospital in London. There was a small support group there called *Living with Carcinoid*, that was set up by the now Chairman, Peter Gwilliam and his wife. Cathy knew that something had to be done to address the huge unmet need she was sensing throughout the UK from the many calls she was receiving, the misinformation, and the isolation. Together with two patients, Andy and Cathy, they were able to launch a wider charity, and with Peter's permission the *NET Patient Foundation* was formed

The aim was to provide better information to all NET patients with all types of NET. The website was started, thanks to a generous donation from Paul Hunter, a well-known snooker player, who had been diagnosed with a NET and subsequently lost his battle at the age of 28. Cathy left her post at the Royal Free Hospital to carry on the work for patients in the community. It was a huge leap of faith, but one that she has never regretted 12 years on.

Cathy Bouvier highlights the five pillars of activity below:

- Support—we have two specialist nurses, a medical advisory board, two psychologists and our NET Natter programme, providing community support all over the UK, alongside supportive tools for our patients including wallet cards for easy access to the toilet and carcinoid crisis emergency prevention.
- Education—patient materials are a passion of ours. We provide "new patient pack" to 90+ hospitals in the UK. We also provide factsheets for all NET types and have "easy to read" ENETS guidelines incorporated into every factsheet.
- Advocacy—we strive to be an evidence-based advocacy group, collecting real-life data from the NET community to drive change in both commissioning for NET treatments and clinical practice. We developed our own Patient Experience Survey gathering nearly 1000 responses in England alone, we produced the first report challenging the Cancer Plan in England and the second report supporting the NET Scottish community is due out on NCD 2017. We also employ a dedicated NET Cancer Analyst who is working hard to get relevant data for us to support our NET services.
- Research—we have our clinical fund supporting pilot projects in the UK, in collaboration with UKINETs. Grants are released once a year. We also run in-house projects and projects related to diet, nutrition, quality of life, and unmet needs.
- Awareness—this incorporates and overarches all our five pillars of activity and all our work.

The future is about gathering data, pushing for qualitative research to be integrated into clinical studies, focusing on the real needs of our patient population, helping patients live better with their disease, and empowering patients and all who are involved in NET patient care to be educated and knowledgeable. We can only do this by working closely with our colleagues. Our services work alongside and complement acute services provided by health care teams. We sit on executive boards of the European NET Nurse Group, our national medical society, and the global NET group INCA. True holistic care requires all affected by neuroendocrine cancer to be supported from diagnosis through treatment and beyond, by a committed group of health care professionals and allied health care professionals, for which I believe, medical advocacy organisations, should be recognised as.

Catherine Bouvier
NET Patient Foundation
netpatientfoundation.org

65.7.1.1.1 Patient Advocacy

The NET Patient Foundation is one of a number of charities that support and advocate on behalf of NET patients. The International Neuroendocrine Cancer Alliance (INCA) has its mission to be the global advocate for NET patients, working to raise awareness of NETs, supporting research, disseminating information, and sharing best practice.

65.7.2 Gastrointestinal Symptoms in NETs

Gastrointestinal (GI) symptoms are a major cause of morbidity for many patients with NETs, impacting on their life in many ways, causing isolation and embarrassment as well as contributing to other symptoms such as fatigue and weight loss. Many patients have been treated for a range of GI symptoms prior to diagnosis, e.g. IBS, indigestion, gallstones, and gastric ulcer, with several studies confirming abdominal pain as the most common presenting symptom (Ter-Minassian et al. 2013).

Typically, patients with gastroenteropancreatic NETS will have multiple GI symptoms, for example, abdominal pain, bowel cramps, greasy/oily stools, excessive flatulence, diarrhoea, urgency, lack of appetite, early satiety, and weight

Table 65.8 Common causes of abdominal symptoms in gastroenteropancreatic NETs

Functional hormonal symptoms (Carcinoid, Verner-Morrison, Zollinger-Ellison)	Diarrhoea, abdominal cramps, weight loss
Mass effect of tumour	Abdominal pain, obstruction, poor appetite, overflow diarrhoea, weight loss, nausea
Treatments	Chemotherapy-diarrhoea, somatostatin analogues, abdominal cramping, nausea, and vomiting
Mesenteric fibrosis and mesenteric angina	Cramping abdominal pain, obstruction, erratic bowel habit-diarrhoea/constipation, early satiety, weight loss

loss. Being able to appropriately assess these symptoms, consider causes, and then treat them effectively can substantially improve quality of life. The causes of symptoms are often multifactorial (see Table 65.8 below) and to manage these effectively, systematic and detailed history taking is essential. The use of a gastroenterology team and dietetic service experienced and interested in NETs can be invaluable. Four of the most common and troublesome causes of GI symptoms and their management are described below.

Case Study 2

(Written consent and permission has been obtained from the patient to use this case study)

The Importance of Specialist NET Centre Care

Eight years ago Arnold presented with a 4-year history of lower abdominal pain, weight loss, and increasing diarrhoea. Previous endoscopic investigations had been negative and he had initially been diagnosed as having irritable bowel syndrome. However, as his weight loss increased further investigations were arranged. A CT CAP confirmed a 4 cm mesenteric mass, multiple mesenteric lymph nodes, and bilateral multiple liver metastases. A biopsy confirmed a grade 1 well-differentiated NET, with a Ki-67 of 1%. His baseline urine 5HIAA was normal and his chromogranin A was 8 × upper limit of normal. He was seen by his local surgical team, who deemed his abdominal disease inoperable and he came under the care of a local oncologist who commenced him on 4-weekly depot octreotide injections.

Arnold's disease remained stable for 4 years though he had ongoing abdominal discomfort, bloating, occasional nausea and vomiting, gradual weight loss, and fatigue. He used MST 20 mg twice a day for pain, with oramorph for breakthrough and "*thought the symptoms were a normal part of my illness*".

In 2015, he was referred to a specialist NET centre, due to progressive liver metastases. He had worsening diarrhoea and his urine 5HIAA was 5 × upper limit of normal. A ^{68}Ga-dotatate PET scan confirmed uptake, both in his abdominal and liver disease. He was therefore treated with 4 cycles of ^{177}Lu-peptide receptor radionuclide therapy. He tolerated this well, with only mild nausea and his liver metastases reduced in size slightly. His diarrhoea also improved significantly.

Over the next 6 months, regular telephone review with his specialist nurse revealed that his abdominal pain was worsening significantly, despite input from a specialist dietitian, adaptation of diet, and use of further analgesia. The hepatobiliary surgeons arranged a CT scan; confirming worsening mesenteric desmoplasia and swollen small bowel loops. The specialist MDT felt that resection of the mesenteric mass was feasible and Arnold underwent ileal and mesenteric disease resection in late 2016. His abdominal pain immediately resolved and he had improved appetite. However, he had worsening diarrhoea post-operatively, up to nine times daily, which despite codeine and loperamide did not resolve. He commenced *Creon* for possible pancreatic insufficiency due to his octreotide injections. This made a small improvement only. He

was reviewed by the gastroenterology team, a SeHCAT scan was carried out and it confirmed severe bile acid malabsorption. He commenced colesevelam with excellent results. He now opens his bowels twice daily and is currently pain free. His most recent scans show stable liver metastases.

Learning Points

Early review by specialist centres is essential to enable access to treatments possibly not considered in local hospitals. This has the ability to improve the overall outlook and quality of life for patients with metastatic NETs.

Assessment of disease progression also needs to include symptoms and quality of life not just whether disease is stable.

Table 65.9 Management of refractory carcinoid syndrome induced diarrhoea

Dose escalation of somatostatin analogue injections	Initially try injections every 3 weeks. Can consider 2 weekly Can also use short-acting octreotide as breakthroughTypically 100–200 μg three times daily (Toumpanakis and Caplin 2013) Options of IV octreotide or a syringe driver can also be considered as a palliative measure; however, these are likely only to benefit for a limited period of time
Telotristat etiprate	Tryptophan hydroxylase inhibitor, shown to reduce frequency of carcinoid induced diarrhoea in around one third of patients (Riechelmann et al. 2017)
Loco-regional therapies to reduce disease burden in liver	Radiofrequency ablation, hepatic embolisation, surgical debulking [see **Sect. 65.6.2**]
Systemic therapies	Peptide receptor radionuclide therapy, everolimus, interferon

65.7.2.1 Carcinoid Syndrome-Related Diarrhoea

This is typically found in patients with metastatic small intestinal NETs, but also some bronchial NETs. Diarrhoea is often frequent, watery, and may often not respond fully to loperamide or codeine-based treatments. It can also be accompanied with abdominal pain and cramps. Treatment is classically with long-acting somatostatin analogues, which provides excellent initial response in over 75% of patients (Toumpanakis and Caplin 2013). However, over time the effect tends to wear off and in this situation a number of options need to be considered to manage this. There is a lack of strong evidence advocating one particular approach; however, small-scale studies and years of treatment experience support a number of worthwhile strategies (Riechelmann et al. 2017) highlighted in Table 65.9 below.

65.7.2.2 Small Intestinal Bacterial Overgrowth

Small intestinal bacterial overgrowth [SIBO] is common in patients who have undergone upper GI surgery, for example, many patients with small intestinal and pancreatic NETs. It causes malabsorption and a whole range of vague gut symptoms including bloating, flatulence, abdominal distension, abdominal pain, and diarrhoea. H_2 carbohydrate breath tests are the preferred methods for evaluating SIBO though no gold standard approach exists (Andreyev et al. 2016). Treatment involves the use of antibiotics, reviewing symptom benefit and the management of any nutritional deficiencies that may have occurred. Repeat courses of antibiotics may be required as the underlying causes cannot always be addressed (Andreyev et al. 2016).

65.7.2.3 Bile Acid Malabsorption

Patients with small intestinal NETs who've had ileal resections are at high risk of bile acid malabsorption [BAM]. Other risks include cholecystectomy and treatment with chemotherapy. Diagnosis is through a SeHCAT scan and treatment is with bile acid sequestrants such as colesevelam (Andreyev et al. 2016). Dietary fat reduction can be considered but this could exacerbate weight loss and requires expert dietetic input. Anti-diarrhoea medication can also be trialled.

65.7.2.4 Exocrine Pancreatic Insufficiency

Exocrine pancreatic insufficiency [EPI] is a common problem for many NET patients, due to a

combination of pancreatic disease, upper GI/hepatobiliary surgery, and the use of somatostatin analogues. Diagnosis is through a non-liquid stool sample for faecal elastase; however, many centres empirically trial pancreatic enzyme replacement therapy PERT, without confirmed faecal elastase results (See Box 65.5 Malabsorption Issues and NETs).

Box 65.5 Malabsorption Issues and NETs

Fat has been suggested as a trigger of carcinoid syndrome; however, fat triggering a loose stool bowel movement may be more related to malabsorption and exocrine pancreatic insufficiency (EPI), or bile acid malabsorption (BAM) rather than tumour function. EPI is more likely to occur if the patient is prescribed somatostatin analogues due to their effect on pancreatic function. The treatment is pancreatic enzyme replacement therapy (PERT) with: Creon®/Nutrizym®, /Pancrease HL®/Pancrex®.

Some patients benefit from taking an anti-acid drug 30 min before taking the enzymes, as a gastric pH of 4.5 or under will reduce activity of the enzymes.

- ***Suggested starting dose:***
  - One × ~25,000 units of lipase capsule with all snacks/drinks
  - Two × ~25,000 units of lipase capsule with all main meals.
- The dose can then be titrated upwards. Sometimes ~75,000 units of lipase per main meal is enough, but some people may need more than this.

BAM is more likely to occur if the gall bladder or the terminal ileum has been removed, or is diseased. The treatment for this is a low fat diet or a bile acid sequestrant.

EPI and vitamin deficiency

If EPI is not treated with sufficient PERT, fat-soluble vitamins are at highest risk of not being absorbed properly. Patients can develop night blindness from insufficient vitamin A, bone weakness from insufficient vitamin D, poor skin and immunity from insufficient vitamin E, and bruising and bleeding from insufficient vitamin K.

Where somatostatin analogues are the likely cause of EPI, low vitamin B12 levels have also been observed. A study of 54 patients mostly with serotonin-producing tumours and on somatostatin analogues found only one fifth of patients had steatorrhoea (meaning EPI was most severe in a fifth), but malabsorption was still chronic enough to result in deficiencies: 6% were deficient in vitamin A, 28% were deficient in vitamin D, 15% were deficient in vitamin E, 63% were deficient in vitamin K1, and 58% were deficient in erythrocyte vitamin E (Fiebrich et al. 2010).

It is therefore important to monitor these vitamins if EPI is diagnosed, or the patient is at risk of developing EPI through prescription of somatostatin analogues.

65.7.2.5 Nursing Care of Patients with GI Symptoms

For most patients, the GI symptoms are ongoing in nature and management strategies aim to improve quality of life where possible. Nurses have a key role in assessing patients' symptoms and guiding referral to appropriate teams such as gastroenterology and dietetics. They also need to support patients with symptom management and guiding patients in adjusting to living with complex symptoms and enabling patients to maintain privacy and dignity. This may include advice on fluid intake, dietary changes, medication, hygiene, incontinence aids, wallet cards to assist access to toilet facilities, and also psychological support.

65.7.3 Dietary Management of Neuroendocrine Tumours

Patients with neuroendocrine tumours (NETs) often have problems digesting foods, even if their

NET is not within the digestive system. For example, surgery, drug therapies, and the tumour hormone/peptide secretions can affect gut function, with weight loss, malabsorption, and nutrient deficiencies very common as a result. Even if there are no digestive issues, diet sometimes needs to be adjusted because of blood glucose levels, surgery, or obstruction. Not all patients have problems with their weight, but use of a malnutrition screening tool together with thorough anthropometrical measurements is recommended. A tool alone may not highlight any loss of muscle and muscle function and therefore early cachexia, especially in the overweight/obese.

Because NETs also behave differently and have unique treatments compared to many other cancers, NET patients do require access to specialist dietetic input, and any hospital specialising in NETs should include a NET Specialist Dietitian within their multidisciplinary team.

This section focuses on a few areas of dietary management which are unique to NET cancers.

65.7.3.1 Serotonin-Producing Tumours (Carcinoid Syndrome)

Serotonin-producing NETs were once known as "carcinoid" tumours, and although the name has been changed to specify the site of the tumour and tumour functionality, "carcinoid syndrome" still remains a physical diagnosis, and one which requires dietetic input.

65.7.3.1.1 Niacin

When the body makes large amounts of serotonin, the amino-acid tryptophan stores are used up. When tryptophan stores are too low, it cannot be converted into enough niacin. Mild niacin deficiency may lead to fatigue, sore mouth, depression, and indigestion/vomiting. If severe, this can develop into pellagra. The three main symptoms of this are:

- Dementia
- Diarrhoea
- Dermatitis

Two studies that have investigated niacin deficiency show that between 28 and 45% of patients with carcinoid tumours and carcinoid syndrome were found to be niacin insufficient or deficient (Shah et al. 2005; Bouma et al. 2016). Bouma et al. recommend that the urinary niacin metabolite N1-methylnicotinamide is checked at diagnosis and niacin is supplemented appropriately. Though the EU nutrient reference value (NRV) for niacin is 16 mg/day [a number of centres recommend patients should take a daily niacin (B3) containing tablet such as Vitamin B Strong compound], the 2016 study found that a much higher mean dose of 144 mg was required to prevent and treat niacin deficiency in the majority of serotonin-producing NET patients (Bouma et al. 2016).

65.7.3.1.2 Carcinoid Syndrome Triggers

As well as stress and anxiety, anecdotal data has shown that for some patients certain foods and drinks can "trigger" carcinoid syndrome. The types of foods/drinks that cause this reaction are individual in nature. Assessment by a specialist NET dietitian is crucial here as many patients are often told to eliminate these and other foods without knowing if they trigger symptoms or not, and as a result diets may get too restrictive, and worsen quality of life.

Possible triggers include:

- Large meals
- Spices
- Alcohol
- Meals moderate to high in amines may also trigger symptoms in some people: these include aged cheese, alcohol, smoked/salted fish and meat, yeast, fermented-tofu, miso, sauerkraut, large doses of caffeine, chocolate, peanuts, brazil nuts, coconut, avocado, banana, raspberries, most soya products, broad beans.

The foods above have been known to trigger symptoms, but it is important to let patients know that they are not harmful. The most reliable method of identifying possible "trigger foods" is with a food and symptom diary. The diary is completed by the patient over a 1–2-week period including food intake, medications, and then the symptoms experienced afterwards.

A dietitian can also play a role in investigating what type of loose stools are occurring. Hormone/peptide-related diarrhoea will continue without eating and is likely to be more watery. Malabsorption such as steatorrhoea is more likely to occur within a few hours of eating, but can occur over night if not prevented—see [**Box 65.5** Malabsorption issues in NETs].

65.7.3.2 Small Bowel Obstruction

Where small bowel primary tumour and mesenteric metastases cause a diffuse desmoplastic reaction the risk of bowel obstruction will start to increase [see Sect. 65.6.1]. Diet should be tailored to the patient and their individual obstruction risk. The diet that is recommended should depend on the risk of obstruction (has it happened before, the size of the lumen) and where obstruction is likely to occur (how digested the food should be in that part of the intestine). All patients at risk of a small bowel obstruction require detailed assessment and advice from a dietitian.

Traditionally, a "low fibre diet" was given to all patients at risk of bowel obstructions, but this approach lacks clear evidence. However, having a lot of very high fibre foods all in one go can cause an obstruction in many people, whereas too little fibre can cause constipation. Often the foods that have caused obstruction have not had any fibre in them at all and can be tough meat or fish bones. Therefore, the consistency of food may matter the most and a "staged" diet approach may be the correct approach. This would include using food consistency varying from soft solids to liquids, with small amounts of fibre (no bits) equally spaced out throughout a day. This is an area that urgently requires research.

When a patient cannot tolerate any food or liquid orally, parenteral nutrition may be the only option. These patients face very challenging symptoms, overall have a poor prognosis (Moris et al. 2018), and require intensive input from NET specialists, dietitians, and palliative care teams.

65.7.3.3 Pancreatic NETs

Pancreatic NETs (panNETs) classify a heterogenous group of tumours including both non-functioning tumours and functioning tumours such as

- Glucagonomas
- Insulinomas
- Gastrinomas

Tumours that are non-functioning can require less dietetic input than functioning tumours; however, most patients will require help if they have had surgery to the pancreas, or have EPI. Most patients with a tumour to the head of the pancreas will require PERT, whereas patients with a tumour in the body or tail of pancreas should be closely monitored for signs of EPI. Please see **Box 65.5 Malabsorption Issues in NETs** for dosing.

65.7.3.3.1 Blood Glucose

PanNETs as a group of tumours can increase or lower blood sugar levels. Functioning insulinomas and glucagonomas directly produce hormones to raise or lower glucose levels. Management of these tumours alone is challenging, but it has been known that these two tumours can co-exist too, making regular glucose monitoring even more important. All patients with a functioning insulinoma will require dietetic input at some point.

Surgery to remove part of or the entire pancreas can lead to diabetes and some treatments such as somatostatin analogues can also affect blood glucose levels. Patients with EPI will need PERT to help break down starches and prevent hypoglycaemia. See **Box 65.5 Malabsorption Issues in NETs**.

65.8 Conclusions

NETs are a diverse group of malignancies that cause characteristic hormonal syndromes, such as carcinoid syndrome. Though a number of NETs are cured by surgery, the majority present only once they have metastasised, so treatment is more often directed at control of disease, management of symptoms, and improvement in quality of life.

There are a wide range of treatments, which can improve the symptoms of carcinoid syndrome and stabilise tumour growth in many patients. However, there is lack of evidence as to the best approach to managing many patients, and overall response rates to treatment are often low.

Caring for individual with neuroendocrine tumours is therefore complex and challenging. Patients may live with advanced disease for many years and often face a roller-coaster ride of multiple treatments, ongoing symptoms, and the psychological and social burden of living with a life-limiting illness. As gastrointestinal symptoms are commonplace, the use of gastroenterologists interested in NETs and the involvement of a specialist NET dietitian are essential in managing patients' symptoms.

Specialist nurses are well-placed within the MDT to take on a key worker role, supporting patients through a complex illness trajectory, providing a consistent single point of contact.

Abstract

Multiple endocrine neoplasia is a rare inherited condition characterised by the development of multiple tumours of the endocrine system. It is inherited in an autosomal dominant way, and there are now four distinct recognised forms. Tumours that occur in MEN patients often occur earlier in life than in sporadic cases and may also often be multiple in nature.

MEN 1 is characterised by parathyroid, pancreatic, and pituitary tumours. Parathyroid and pituitary tumours are almost universally benign, whereas pancreatic tumours can be malignant.

Management of MEN 1 therefore involves close monitoring of tumour growth, and symptoms through regular screening and then treatment of specific tumours if required. For parathyroid tumours, surgery is the definitive treatment to resolve problems of hypercalcaemia. How early this should be carried out is still debated. Pancreatic NETs are the major

cause of morbidity and mortality in MEN 1 though many remain small and asymptomatic. Again there is uncertainty as to when to intervene surgically, with a need to weigh up the risk of tumour spread versus the long-term complications of major pancreatic surgery.

International guidelines have been produced to assist with management decisions and further research is required to clarify best treatment options.

MEN 2 and 3 are caused by a genetic defect in the *RET* proto-oncogene. It is characterised by medullary thyroid cancer (MTC) and phaeochromocytoma with primary parathyroid hyperplasia also common in MEN 2. Individuals with MEN 3 rarely get parathyroid hyperplasia but do get several other additional features, including mucosal neuromas, ganglioneuromatoses of the GI tract, and a Marfanoid habitus.

Early screening and total thyroidectomy early in life is the definitive approach to prevent metastatic MTC. Hyperparathyroidism is often mild in MEN 2 and treatment is similar to sporadic cases. Management of phaeochromocytomas is typically adrenal surgery. Due to the multiple nature of tumours, bilateral adrenalectomy and lifelong steroid replacement may be required. Due to the rarity and complex nature of these conditions, individuals and their families should preferably be managed within specialist multi-disciplinary teams.

Specialist nurses are well placed to support patients navigate their way through complex pathways, improve communication within the MDT, support with ongoing symptoms, aid with treatment decision-making and offer emotional and psychological support for individuals facing lifelong uncertainty.

Keywords

Multiple endocrine neoplasia · MEN 1, MEN 2 · Pancreatic neuroendocrine tumours Genetic screening medullary thyroid cancer Phaeochromocytoma · Primary hyperparathyroidism

Abbreviations

FMTC	Familial medullary thyroid cancer
GEPNETS	Gastroenteropancreatic neuroendocrine tumours
HD	Hirschsprung disease
IGF-1	Insulin growth factor-1
NET	Neuroendocrine tumours
MTC	Medullary thyroid cancer
PTH	Parathyroid hormone

Key Terms

- **Sporadic tumors:** non inherited tumours
- **Non-functioning panNETs:** non metatasising tumours
- **Proband:** person with a disease who is the point of origin for genetic testing

Learning Objectives

On completion of the chapter, the learner should be able to:

- Describe the aetiology and epidemiology of MEN disorders
- Identify common presentations of MEN disorders and how they are diagnosed
- Understand the multiple treatment options for common tumours found in MEN disorders, including parathyroid adenomas, pancreatic NETs, phaeochromocytoma, and medullary thyroid cancer
- Identify ethical issues relating to genetics and screening for the range of MEN disorders
- Understand the role of a specialist nurse in supporting individuals and their families with MEN 1 disorders

66.1 Introduction

Multiple Endocrine Neoplasia (MEN) is a rare inherited condition characterised by the development of tumours involving at least two endocrine glands in a single individual (Thakker 2014).

Table 66.1 MEN subtypes, associated tumours, and genetic mutation

MEN subtype	Associated tumours and disorders	Known genetic mutation
MEN 1: Werner's syndrome	Parathyroid, pancreatic islet, and anterior pituitary tumours; plus range of other endocrine and non-endocrine tumours	Menin mutations
MEN 2: Sipple's syndrome (previously MEN 2A) Also rare subtype known as MTC only MEN 2	Medullary thyroid carcinoma (MTC) in association with phaeochromocytoma and parathyroid tumours	Tyrosine kinase receptor mutations encoded RET proto-oncogene
MEN 3: (previously MEN 2B)	MTC and phaeochromocytoma, Marfanoid habitus, mucosal neuroma, medullated corneal fibres, and intestinal autonomic ganglion dysfunction—leading to megacolon	*RET* mutations
MEN 4	Parathyroid and anterior pituitary tutors in possible association with tumours of the adrenals, kidneys, and reproductive organs	Cyclin-dependent kinase inhibitor (*CDNK18*) mutations

Four major forms are now recognised, each with tumour development in specific endocrine glands, and each with its own different genetic abnormality (Table 66.1). All forms of MEN may be inherited as an autosomal dominant syndrome, though around 10% occur sporadically, de novo.

This chapter will focus initially on MEN 1 and then on MEN 2A and 2B (now known as MEN 2 and 3) in the final section.

66.2 MEN 1

66.2.1 Aetiology and Epidemiology

MEN 1 is a rare disorder, affecting around 1/30,000 with an equal distribution across the sexes (Marini et al. 2009). The pathology was first described in the early 1900s, but it was not till 1954 that the familial nature of the syndrome was described by Dr. Wermer in 1954. The MEN 1 gene was discovered in 1997.

It affects all age groups, with a reported range from 5 to over 80 years of age, with a 98% biochemical penetrance and 80% clinical penetrance by the fifth decade. Diagnosis before the age of 10 is rare (Marini et al. 2009). Inheritance is autosomal dominant, with a 50% chance for a parent to transmit the disease to their children. The MEN 1 gene is located on Chromosome 11q13 and codes for a protein called menin. This has a role in genome stability, and regulating transcription, cell division, and proliferation (Thakker et al. 2012).

Table 66.2 Prevalence of endocrine tumours in MEN 1 patients

Tumour localisation	Prevalence
Parathyroid adenoma	95%
Gastroenteropancreatic (GEP) tumours. Vast majority are gastrinoma, insulinoma, and non-functioning pancreatic tumours. More rarely, ViPoma, glucagonoma, and somatostatinoma	~40%
Anterior pituitary tumours (majority are prolactinoma, but also somatotropinomas, corticotropinomas, and non-functioning adenomas)	~30%
Adrenal gland tumours	~20% (but many small adenomas as well)
Other neuroendocrine tumours, e.g. bronchial, thymic, gastric NETs	~10%

Adapted from: Marini, F. *et al.* (2009)

MEN 1 mutations can be identified in between 70 and 95% of MEN 1 patients (Marini et al. 2009).

66.2.2 Diagnosis

Diagnosis of MEN 1 can be defined by 1 of 3 criteria:

1. Clinical: a patient with 2 or more MEN 1-associated tumours
2. Familial: a patient with 1 MEN 1-associated tumour and a first-degree relative with an established diagnosis of MEN 1

3. Genetic: an individual who has an identified germline MEN 1 mutation but who is currently asymptomatic and does not have any biochemical or radiological evidence of tumour development (Thakker et al. 2012; Thakker 2010)

66.2.3 Clinical Presentation

MEN 1 is associated with a wide range of endocrine tumours (Table 66.2), but patients typically present with:

- tumours of the parathyroid gland presenting as hyperparathyroidism (95% of cases)
- pancreatic neuroendocrine tumours (~40%)
- anterior pituitary tumours (~30%)

Other endocrine and non-endocrine tumours also occur, such as carcinoids, lipomas, meningiomas, and facial angiofibromas (Table 66.2) (Marini et al. 2009).

66.2.3.1 Primary Hyperparathyroidism

By far the most common presentation, around 90% of patients, is with primary hyperparathyroidism (Thakker 2010). The hypercalcaemia caused by primary hyperparathyroidism may present as kidney stones, vague hypercalcaemic symptoms, e.g. polyuria, polydipsia, constipation, malaise, or may be asymptomatic and picked up on screening (Table 66.3). Severe hypercalcaemia is rare. It differs from the more common sporadic form of the disease in a number of ways, e.g. presenting earlier in life and more commonly with multiple gland disease (Eller-Vainicher et al. 2009) (see Table 66.4 for more detail).

Table 66.3 Common clinical signs and symptoms of hypercalcaemia

Gastrointestinal tract	Constipation, anorexia, nausea and vomiting, constipation
CNS	Lethargy, depression, decreased alertness
Kidneys	Excessive urination, dehydration, hypercalciuria, increased risk for kidney stones
Skeletal changes	Increased bone resorption, fractures
Cardiovascular system	Hypertension, shortened QT interval

Table 66.4 Comparison of clinical features of sporadic and MEN-associated tumours

Sporadic Tumours	MEN 1-associated tumours
Sporadic parathyroid adenomas Onset usually sixth decade Generally single tumour Female/male prevalence 2:1 Usually cured by surgery No hypocalcaemia or hypoparathyroidism after surgery	MEN 1 parathyroid adenomas Onset usually third decade Often multiple tumours and all parathyroid glands affected No sex prevalence Common recurrences after subtotal parathyroidectomy Permanent hypoparathyroidism after total parathyroidectomy
Sporadic insulinomas Usually during or after fourth decade. Usually single lesion	MEN 1 insulinomas Typically third decade, can be single or multiple
Sporadic gastrinomas Onset during or after fifth decade. More commonly in pancreas	MEN 1 gastrinomas Multiple, small. Onset usually before fifth decade 90% in duodenum
Sporadic pituitary adenomas Rarely macroadenomas. Good response to medical therapy	MEN 1 pituitary adenomas Frequently macroadenomas, often secrete multiple hormones
Sporadic carcinoids Often midgut or hindgut. Often associated with carcinoid syndrome, secrete serotonin	MEN 1 carcinoids Higher prevalence in bronchi, thymus, and pancreas. Normally non-secreting

Adapted from: Marini, F. *et al.* (2009)

66.2.3.2 Pituitary Adenomas

Series reports vary but between 15 and 40% of patients with MEN 1 will have pituitary adenomas, most commonly prolactinomas, but somatotroph, corticotroph, gonadotroph, and non-functioning tumours can also occur (Brandi et al. 2001). Compared to pituitary tumours in non-MEN 1 patients they may present more typically as larger and more aggressive tumours with hypersecretion more difficult to normalise. However, treatment remains similar to those with sporadic adenomas (Arnold 2017).

66.2.3.3 Gastroenteropancreatic Neuroendocrine Tumours [GEPNETS]

Parathyroid tumours and pituitary adenomas are typically benign causing their effect either through the overproduction of hormones or the local mass effect (Marini et al. 2009). However, other tumours, such as GEP NETs, thymic and bronchial carcinoids, are associated with a risk of malignancy (Thakker et al. 2012) and have become the main tumour-related cause of death in patients with MEN 1. Up to 70% of patients who are symptomatically affected by MEN1 may die early from MEN 1-related cancer, with a French case series showing around half of patients dying by around 50 years of age (Goudet et al. 2010). The vast majority of GEP NETs are gastrinomas, insulinomas, and non-functioning NETs.

66.2.3.3.1 Gastrinomas

Between 30 and 70% of patients with MEN 1will have GEP NETs, with the most common clinical presentation being Zollinger-Ellison syndrome (ZES), caused by gastrinomas, which can lead to severe peptic ulcer disease. Typical symptoms include dyspepsia, epigastric pain, vomiting, chronic diarrhoea, and weight loss (Marini et al. 2009). In contrast to sporadically occurring gastrinomas, those in patients with MEN 1 are often multifocal, small, and occur overwhelmingly in the duodenum (Table 66.4), making cure by surgery difficult (see Sect. 66.2.4).

66.2.3.3.2 Insulinomas

Insulinomas are often small, may be multiple, and typically present before the age of 40. Around 20% of MEN 1 patients will have insulinoma and 50% of patients with multiple insulinomas will have MEN 1. Though predominantly benign in behaviour, their multiple nature can lead to the need for more extensive pancreatic surgery, with corresponding morbidity.

66.2.3.3.3 Non-functioning Pancreatic Nets (panNETs)

Non-functioning panNETs are amongst the most common GEPNET tumours in patients with MEN 1, occurring in up to 50% of MEN 1 patients. They are not associated with a clinical syndrome, which can make them more difficult to diagnose early. Due to their malignant potential and the ability to metastasise to the liver, they are a major cause of morbidity and mortality in MEN 1 patients (Thomas-Marques et al. 2006). Most clinicians would therefore suggest early radiological screening for these tumours (Thakker et al. 2012) though the clinical significance of small non-functioning tumours (<2 cm) has yet to be established.

66.2.3.3.4 Other Neuroendocrine Tumours

These occur in more than 3% of patients with MEN 1 and may occur in the lung, GI tract, or thymus (Thakker et al. 2012). Though thymic carcinoids are not common in patients with MEN 1, for example, occurring in only 2.6% in a French retrospective series (Goudet et al. 2009), they are typically aggressive with a poor overall prognosis. Heavy smoking may be a risk factor and they appear mainly in men. Screening with chest radiography may be prudent and prophylactic thymectomy is recommended by several groups in patients undergoing parathyroidectomy (Thakker et al. 2012).

Bronchial carcinoids, on the other hand, tend to be less aggressive and may not impact significantly on overall survival of MEN 1 patents (Thakker et al. 2012).

Gastric NETs are typically small and multiple and may be detected incidentally during gastric endoscopy. They may be found in over 70% of patients with MEN1 and typically behave in a benign manner.

66.2.3.3.5 Other Tumours

There are a range of other tumours which also occur with increased frequency in MEN 1, including adrenal tumours, meningiomas, and cutaneous tumours. Cutaneous tumours include lipomas, facial angiofibromas, and collagenomas. Their frequency varies in different case series but lipomas may occur in over one third of MEN 1 cases and facial angiofibromas and collagenomas may be even more common.

Management of lipomas is conservative but they can be removed for cosmetic reasons. Facial angiofibromas and collagenomas may aid in early diagnosis of MEN 1 during screening. They do not normally require treatment.

66.2.4 Treatment of Specific Tumours Associated with MEN 1

Treatment modalities for MEN 1-related tumours are similar to those used for similar tumours in non-MEN 1 patients. However, the treatment can be more challenging and outcomes are often poorer, partly due to the early occurrence of tumours in MEN 1 as well as the presence of multiple tumours, making full surgical resection harder. Full details of treatment will not be explored in this chapter as they are covered throughout the rest of the book.

66.2.4.1 Parathyroid Tumours

Surgical excision is the definitive treatment in hyperparathyroidism, but there is no consensus on how early this should be performed in the course of the disease (Thakker et al. 2012). Surgical intervention is indicated in symptomatic hypercalcaemia, nephrolithiasis (renal calculi), and evidence of reduced bone density (Arnold 2017). Since hypercalcaemia may also exacerbate hypergastrinaemia, parathyroidectomy may reduce gastrin levels in MEN1 patients with ZES. In asymptomatic patients, most centres follow a regime of continuing active surveillance (Arnold 2017).

Once surgery is indicated, open bilateral neck exploration is recommended since all four glands are usually affected with hyperplasia or adenomas (Thakker et al. 2012). Subtotal parathyroidectomy (3½ gland removal) is recommended to reduce the risk of persistent disease and to leave some functioning parathyroid tissue. Prophylactic thymectomy may also be performed as there is often parathyroid tissue found within the thymus. It can also reduce, but not completely remove the future risk of thymic carcinoid (Goudet et al. 2009).

Recurrent hypercalcaemia can occur after subtotal surgery in around half of MEN 1 patients (Schreinemakers et al. 2011). If all four glands are clearly affected, then total parathyroidectomy may be carried out, sometimes with a small parathyroid autograft, often in the forearm muscles. This is less likely to lead to persistent hyperparathyroidism but more likely to cause hypoparathyroidism (Arnold 2017). The autograft can avoid the need for vitamin D replacement, and if recurrent hyperparathyroidism is observed then it can be removed under local anaesthetic, though this can be difficult if the tissue becomes embedded in the skin. An alternative approach is to treat the often mild hypercalcaemia with cinacalcet.

Persistent hypocalcaemia is treated with oral calcitriol or one alfa-calcidiol (1,25-dihydroxyvitamin D) although management of hypoparathyroidism can be challenging even with vitamin D and calcium replacement. Many patients experience ongoing chronic symptoms such as muscle aches, fatigue, and low mood. Many clinicians would therefore suggest that total parathyroidectomy should be reserved for symptomatic hypercalcaemic patients, with close surveillance for all others. It is possible that recombinant PTH will provide a more effective, albeit expensive, form of replacement.

66.2.4.2 Pancreatic NETs

66.2.4.2.1 Gastrinomas

Gastrinomas cause a high rate of morbidity and mortality in MEN 1 patients, due to the marked gastric acid production and recurrent peptic ulceration. Management with proton pump inhibitors, often in high dose, is a standard first approach to inhibit gastric secretion and relieve peptic ulcer symptoms. Some patients may also require additional treatment with H2 antagonists such as ranitidine which reduce production of gastric acid (Thakker et al. 2012).

The role of surgery is controversial. Due to multiple tumours within the duodenum and the high prevalence of lymph node spread, gastrinoma surgery is rarely curative with only a small percentage of individuals disease free long-term after surgery (Thakker et al. 2012). However, larger gastrinomas are at higher risk of metastasising, which is difficult to treat successfully, though overall survival at 15 years has been reported at around 50% (McKenna and Edil 2014). Some authors therefore recommend surgery for tumours over a certain size, e.g. 2 cm (Thakker et al. 2012) though again there is a lack of consensus as to the long-term benefit of such an approach. Major surgery such as Whipple pancreaticoduodectomy may achieve an effective cure rate (Imamura et al. 2011) though the long-term quality of life implications are extensive, including diabetes mellitus, weight loss, and malabsorption syndromes.

Considering the lack of definitive evidence an individualised approach is required when deciding

on how best to manage this situation, considering patients' wishes, comorbidities, age, and life-expectancy. A detailed and open discussion with patients is essential to highlight the risks and potential benefits of surgery, exploring any possible reduction in risk of metastatic disease versus the morbidity and mortality associated with surgery.

For low grade metastatic disease somatostatin analogues can be used and in higher grade disease chemotherapy is also an option. Liver metastases can also be treated with specific directed therapies such as ablation, debulking, and embolisation. Peptide Receptor Radionuclide Therapy (PRRT) can also be considered in patients with ^{111}In-octreotide or ^{68}Ga-dotatate PET scan positivity (Falconi et al. 2016).

66.2.4.2.2 Insulinomas

Medical treatment of insulinoma in MEN 1 patients consists of diazoxide, corticosteroids, and somatostatin analogues (see Chap. 65). It is not often successful long term and surgery is generally the most successful primary treatment. If possible, pancreatic surgery should be minimised, e.g. enucleation of a single lesion or partial pancreatectomy. However, in MEN 1 simple enucleation may well not be curative and in patients with multiple tumours total pancreatectomy may be necessary (Okabayashi et al. 2013). In metastatic disease, PRRT can have excellent results for octreotide avid disease, with remissions of several years reported in case series (van Schaik et al. 2011). Other options include hepatic embolisation and chemotherapy (Okabayashi et al. 2013).

Case Study 1

(Written consent and permission has been obtained from the patient to use this case study)

Management of Functional NETs in MEN 1

Jane is a 23-year-old student with MEN 1. She was screened from an early age, her father had sadly died from MEN 1, and was used to regular blood and imaging tests. She has a known pituitary micro adenoma and an MRI aged 11 showed several pancreatic lesions in the tail of her pancreas. As these started to enlarge, she had a distal pancreatectomy aged 13 and was clinically well for 3 years.

Aged 16 she developed multiple duodenal gastrinomas, with Zollinger-Ellison syndrome. Despite PPIs, her gastric symptoms worsened and she had a pancreas sparing duodenectomy which confirmed Grade 2 well-differentiated NET, which was strongly gastrin positive.

Jane made a good recovery from surgery and her gastrin level normalised. However, 8 months later she was waking at night hungry and sweating and this was relieved by eating. A 72 h fast confirmed an insulinoma and she was commenced on diazoxide to control blood sugars. This was poorly tolerated, with nausea, headaches, and hirsutism particularly distressing for this young woman. An MRI scan confirmed several cystic lesions in the pancreas and a specialist nuclear medicine scan confirmed that a central lesion was the likely insulin-secreting lesion. After extensive information and counselling support from the surgeons and specialist nurse she agreed to have a completion pancreatectomy aged 19. The pathology confirmed 7 NETs, the largest of which stained for insulin.

Jane has recovered well from the surgery; however, at a regular follow-up visit she was in tears and described how traumatic she'd found the whole experience. She was having recurrent nightmares, every night, about the experience which was impacting heavily on her life.

After further assessment of her concerns, her specialist nurse felt that Jane needed high level psychological input. Despite not having a cancer diagnosis, she was able to arrange for Jane to meet with the specialist teenage young adult cancer psychologist. Through a period of focused counselling this has helped reduce her anxiety significantly and her nightmares have now stopped. She will continue on lifelong surveillance and is aware that she has a risk of metastatic NET in the future.

Learning Points

The impact of lifelong surveillance and treatment should not be underestimated in teenage/young adult population.

Skilled psychological assessment and support can be key to successful management of patients with MEN 1.

Questions to Consider

Would Holistic Needs Assessment assist in picking up complex psychosocial needs and concerns?

How could you integrate these into your everyday role?

66.2.4.2.3 Non-functioning Neuroendocrine Tumours

Management of asymptomatic non-functioning panNETs is controversial. Surgery can be successful in excising the majority of tumours. However, surgical complications including diabetes, steatorrhoea, and other chronic gut symptoms may be experienced by patients. The natural history of these small tumours is not known, and early surgery has the potential to reduce an individual's quality of life when they may have remained well and at low risk of metastatic spread for many years (Falconi et al. 2016). This has to be balanced against the risk of metastatic disease being difficult to treat.

There is no consensus on the size of tumours at which to suggest surgery, with recommendations ranging from as low as 1 cm, to over 2 cm whilst approaches to surveillance also vary (Thakker et al. 2012).

Metastatic pancreatic NETs have been shown to respond to both tyrosine kinase inhibitors (Raymond et al. 2011) and the mTOR inhibitor everolimus (Yao et al. 2011). Chemotherapy, and other liver directed therapies may also be considered. Median survival for metastatic disease is around 24 months (Yao et al. 2008).

66.2.4.3 Pituitary Tumours

Clinical features and treatments are the same as in non-MEN 1 patients, (see Part III). However, medical treatment may be overall less successful than in non-MEN 1 patients, leading to more frequent use of surgery (Thakker et al. 2012).

66.2.5 Genetic Testing

Since discovery of the MEN 1 gene, it has been possible to test the DNA of individuals for detection of pathogenic gene variants even before clinical signs occur. However, there are limited data to show whether this early detection leads to interventions which in turn reduces morbidity or mortality (Arnold 2017).

There are a number of potential benefits of DNA testing including:

- Confirming the clinical diagnosis of MEN 1 syndrome in a proband
- Determining if specific testing can be offered to relatives of a proband
- Determining whether or not asymptomatic relatives of a proband carry the mutant gene (Thakker et al. 2012)

Individuals who have a negative genetic test can be spared invasive and time-consuming screening and will have the reassurance that they cannot transmit the disease to their offspring. For those who test positive a screening programme can be discussed with them. Their individual concerns and risk need openly talked through with an expert team and a screening regime can be tailored around the available evidence, their wishes, and the views of the clinical team.

Based upon the possible benefits of screening an international group of MEN 1 experts suggested offering DNA analysis to

- Any index patient with clinical MEN 1 (two or more tumours of MEN1 type)
- All first-degree relatives of known MEN 1 mutation carriers
- Individuals with suspicious or atypical MEN 1 (e.g. multiple parathyroid tumours, multiple panNETs) (Thakker et al. 2012)

Parents may give consent for genetic testing in children but the child's best interests should be the

main influence on determining when genetic testing should be carried out (The British Society for Human Genetics 2010). Genetic testing is regarded as appropriate, where it will determine the potential need for screening or treatment. However, if there is no immediate benefit for the child then the recommendation would be to delay until a child is old enough to choose for themselves. Advice is that parents should be supported to make decisions in open discussion with the clinical genetics team (The British Society for Human Genetics 2010).

66.2.5.1 Approaches to Screening

Asymptomatic individuals with MEN 1, known MEN 1 pathogenic mutation carriers and those in whom risk has not been eliminated through negative DNA analysis, should be followed up with an ongoing programme of screening surveillance. The inclusion of annual clinical and biochemical screening is well established, with the aim to get earlier diagnosis and treatment to reduce morbidity and mortality.

This would involve looking for:

1. Signs and symptoms of MEN-1-associated tumours
2. Biochemical measurement of serum calcium, PTH, prolactin, and IGF-1 to screen for hyperparathyroidism and pituitary adenomas.

The addition of further radiological and biochemical screening tests may vary across centres and the evidence to support the value of one particular approach is limited. However, published guidelines do exist which support a more aggressive and early approach to screening in those individuals deemed at risk, with extensive biochemical and radiological screening (see Table 66.5). This approach is based on the possible early manifestation of MEN 1 tumours, including non-functioning panNETs which are known to play a major part in early MEN 1 morbidity and mortality (Newey et al. 2009).

66.2.5.2 Childhood Genetic Screening

In adults viewed as being capable and provided with potential risks and benefits then they are making an informed decision. For children and young people, there are three main concerns: that genetic knowledge may introduce possible psychological or social harms, that minors are

Table 66.5 Suggested screening regime for individuals at high risk of developing MEN 1

Tumour	Age to start	Annual biochemical test	Imaging regime (time interval)	Nursing issues
Parathyroid	8	Calcium, PTH	None	Close support required if children needle phobic
Pancreatic NET				
Gastrinoma	20	Gastrin	None	Some young patients may find MRI/CT distressing Discuss risk/benefits closely with family. May need to reduce frequency of imaging dependent on blood results and family preference
Insulinoma	5	Fasting glucose, insulin	None	
Other pNET	<10	Chromogranin-A, Fasting gut peptides	MRI, CT, or endoscopic ultrasound annually	
Anterior pituitary	5	Prolactin, IGF-1	MRI every 3 years	Can be combined as part of annual imaging above
Adrenal	<10	None, unless signs and symptoms of functioning tumour or identified tumour on imaging	MRI or CT (annually with pancreatic imaging)	Can be combined as part of pancreatic imaging above
Thymic and Bronchial carcinoid	15	None	CT or MRI (every 1–2 years)	None

Adapted from Thaker et al. (2012)

not autonomous individuals, and that they may not be capable of fully assessing the potential risks and benefits of this knowledge (McConkie-Rosell and Spiridigliozzi 2004). Some children may struggle both with imaging approaches such as MRI, which can be stressful and traumatic, as well as blood sampling. Parents may also experience anxiety and guilt at the possibility of having passed on the condition to their child, whilst others may be reluctant to subject their asymptomatic child to investigation. Some families may decide not to have their children undergo clinical biochemical and radiological surveillance until seen to be autonomous enough to make an informed decision.

When children are not competent to give informed consent, the main consideration should be the welfare of the child. Building close links with patients and families is essential. To support families in deciding whether to take-up clinical surveillance, it is important to present them with the risks and benefits of evidence-based pre-symptomatic surveillance. It is not uncommon for paediatric endocrine centres to have an evidenced-based screening table to promote equity and uniformity in the surveillance of families (see Table 66.5). The use of specialist paediatric teams and experienced counselling support can help build trust and manage the uncertainty of decision-making (see Box 66.1).

Box 66.1 Information Sharing and Support with Children and Young People

Information sharing with a child or young person about genetic testing is important, and they should not be excluded from the discussion under the false belief that this will protect them. The developmental level of the child needs to be taken into account when deciding when and how to share this information. This is where support from other affected families can be of great help through the sharing of experiences.

Supportive interventions such as web-based discussion forums and patient-run support groups can play a hugely important role for families of affected children. They are particularly good at serving as an ongoing means of addressing information and supportive needs; from families who are going through similar experiences.

66.3 MEN 2 and 3

Multiple Endocrine Neoplasia type 2 (MEN 2) is a rare autosomal dominant disorder. Its prevalence is estimated at around 1/30,000 (Lips and Ball 2017a) with two main subtypes: MEN 2A, accounting for 75% of cases and MEN 2B 25%. These have recently been renamed as MEN 2 and MEN 3 respectively.

66.3.1 Clinical Presentation

MEN 2 is characterised by medullary thyroid cancer (MTC), phaechromocytoma, and primary parathyroid hyperplasia. There are four variants which are highlighted in Table 66.6. In MEN 3, parathyroid hyperplasia is extremely rare, but there are several other additional features—mucosal neuromas, ganglioneuromatoses of the GI tract, and a Marfanoid habitus (El-Kholy 2005) (see Table 66.6).

Classical MEN 2 is the most common subtype, virtually all patients develop MTC and smaller numbers develop phaeochromocytomas or hyperparathyroidism depending on the specific *RET* mutations (Frank-Raue et al. 2010).

66.3.1.1 Medullary Thyroid Cancer

75% of medullary thyroid cancers are sporadic, with 25% relating to MEN 2 and 3 and Familial Medullary Thyroid Cancer (FMTC) (Perros et al. 2014). It only accounts for around 5% of thyroid cancers but treatment of this condition is challenging, with early diagnosis being of vital importance. In MEN 2 and 3, nearly all patients develop MTC (Wells Jr et al. 2015). In MEN 2-associated MTC the peak incidence of index

Table 66.6 Clinical manifestation of MEN 2 and 3

MEN type 2	MEN type 3
Classical MEN 2; Medullary thyroid cancer (100%), phaechromocytoma (50%), hyperparathyroid hyperplasia (20–30%)	Medullary thyroid cancer
MEN 2 with cutaneous lichen amyloidosis (CLA)	Phaeochromocytoma
MEN 2 with Hirschsprung disease (HD)	Other: Mucosal neuroma Intestinal ganglioneuromas Marfanoid habitus[a]
Familial Medullary Thyroid cancer (FMTC)—MTC but no other manifestations of MEN 2A or 2B	

[a]Marfanoid habitus: a group of symptoms including long limbs, a crowded oral maxilla, sometimes with a high arched palate, **arachnodactyly**, and hyperlaxity

(new) cases is between 20 and 30 years of age. It is usually multifocal and presents as a thyroid nodule, cervical lymphadenopathy, or symptoms of an increase in serum calcitonin, e.g. diarrhoea and flushing (Wells Jr et al. 2015). Spread to adjacent cervical lymph nodes is common and can make cure difficult. Most tumours fortunately do not display aggressive behaviour and can run an indolent course for many decades: 10-year survival in observational studies has been shown to be up to 75% (Modigliani et al. 1998).

MTC tends to be more aggressive in MEN 3, often with an early age of presentation, i.e. before the age of 5 and a poorer prognosis (Lee and Norton 2000). De novo mutations account for around half of cases. Poor prognostic factors include nodal disease, large primary tumour, and metastatic disease (Lips and Ball 2017a). More aggressive tumours can spread to bone, lung, and/or liver.

In asymptomatic patients, found through screening in a known MEN 2 family, MTC is often diagnosed in its pre-cancerous state, known as C-cell hyperplasia (CCH). Serum calcitonin levels will usually correlate with tumour size and are nearly always high in patients who have palpable tumours. There is also a higher likelihood of residual disease if it is discovered clinically rather than through screening (Lips and Ball 2017b).

66.3.1.2 Phaeochromocytoma

Phaeochromocytomas occur in about 50% of MEN 2 patients, with frequency depending on the specific *RET* mutation. They occur earlier than in sporadic forms, with an average age of presentation in the third to fourth decades and are frequently bilateral, which is extremely rare in the sporadic form (Webb et al. 1980). It is unusual for them to precede MTC as the initial presentation of MEN 2, and they are normally identified through ongoing surveillance screening. Diagnosis is the same as sporadic cases with biochemical testing and imaging studies. They are almost invariably benign in behaviour.

66.3.1.3 Primary Hyperparathyroidism

Hyperparathyroidism is not associated with MEN 3 or FMTC. In MEN 2, it is almost always multiglandular and occurs in up to 20–30% of MEN 2A patients (El-Kholy 2005). It is normally mild and asymptomatic and has a low recurrence rate post-surgery after subtotal parathyroidectomy (O'Riordain et al. 1993).

66.3.1.4 MEN 2 with Cutaneous Lichen Amyloidosis (CLA)

CLA is a rare disorder that can occur sporadically, but also in a hereditary pattern associated with MEN 2. The CLA associated with MEN 2 occurs almost exclusively with *RET* codon 634 mutations. It can occur at a young age and is characterised by skin lesions, particularly in the scapular region, with symptoms of intense itching that worsen due to stress but can respond to sun exposure. Typical treatments include moisturising creams, local steroid cream, antihistamines, and phototherapy though benefits are normally partial (Wells Jr et al. 2015).

66.3.1.5 MEN 2 with Hirschsprung Disease (HD)

Hirschsprung disease occurs in less than 10% of MEN 2 cases (Wells Jr et al. 2015) and is normally present at birth. It is the result of failure of nerve cell development in the large bowel and affects the colon causing problems with passing stool.

Symptoms include constipation, swollen belly, vomiting, and diarrhoea. Treatment is by surgery to bypass the affected part of the bowel (Amiel and Lyonnet 2001).

66.3.1.6 MEN 3

In MEN 3, the MTC often presents in infancy and is highly aggressive, metastasising to regional lymph or distant sites (Wells Jr et al. 2015). Around 50% also develop phaeochromocytomas.

MEN 3 patients have unique physical appearance: Marfanoid habitus, ophthalmologic abnormalities (thickened and inverted eyelids, inability to make tears, ptosis), and intestinal ganglioneuroma. Most have abdominal symptoms, with bloating, constipation, and diarrhoea and can develop intestinal obstruction requiring surgery (Cohen et al. 2002).

Most MEN 3 cases present as new (de novo) *RET* mutations, with only around 25% occurring in known families with MEN 3 (Kloos et al. 2009).

66.3.2 Diagnosis

Diagnosis of MEN 2 and 3 is through the presence of the clinical features of the disease, a relevant family history and genetic testing. If no *RET* germline mutation or inheritance pattern can be identified, then at least two of MTC, phaeochromocytoma and primary parathyroidism are needed to clinically diagnose MEN 2 and a majority of features of MEN 3 are needed to make a clinical diagnosis of that disorder (Kloos et al. 2009).

Familial MTC is a subset of MEN 2, in which individuals only develop MTC, without any other manifestations of MEN 2 or 3. In small families, there is a risk of misclassifying FMTC and failing to appreciate the risk of phaeochromocytoma. Proposed criteria for confirmed FMTC therefore are:

- Kindred more than 10 carriers or with multiple carriers or affected members older than 50
- Adequate medical review to exclude phaeochromocytoma and hyperparathyroidism, particularly in older subjects (Wells Jr et al. 2015)

66.3.3 Genetics and Screening

The genetic defect in MEN 2 involves the *RET* proto-oncogene, discovered in 1985 by Takahashi (Wells Jr et al. 2015). The *RET* gene is on chromosome 10 (10q:11-2) and mutations result in a gain in function. Since its discovery over 100 different types of mutation have been discovered in patients with MEN 2, but the vast majority are associated with codon 634. Mutations involving different codons on the gene lead to different manifestations of MEN 2 (Lee and Norton 2000). Most cases of MEN 3 are attributable to a mutation at codon 918.

Genetic testing should be carried out in all patients with clinical MEN 2 and 3 in order to identify the specific RET mutation and establish appropriate family screening. In known MEN 2 families, it is usual to sequence the known area of mutation only. In new families, as the cost of sequencing continues to decrease, the entire gene is normally sequenced. All individuals should be offered genetic counselling as part of this process (Wells Jr et al. 2015).

If no germline mutation is found, then only a small risk of hereditary MTC remains as virtually all MEN 2 and 3 patients will have a *RET* mutation (Wells Jr et al. 2015). Once a *RET* mutation is discovered in an index case, genetic testing should also be performed in first- and second-degree family members.

66.3.3.1 Sporadic MTC DNA Analysis

RET mutation screening should also be offered to patients with apparently sporadic MEN 2-related tumours if age younger than 35, multicentric tumours or two different organs affected. Some clinicians would support all patients with sporadic MTC having RET mutation screening (Kloos et al. 2009). Unsuspected familial cases are identified in up to 7% of cases despite apparent negative family history (Wells Jr et al. 2015).

66.3.3.2 Ethical Issues Around Genetic Screening

In clinical genetics, there is a potential tension between confidentiality and disclosure because

of the shared nature of genetics information (Lucassen and Hall 2012). In most situations, individual with a diagnosis of MEN 2 or 3 will be willing to share that information with appropriate members of their family who may ultimately be at risk and no dilemma therefore exists. Doctors and nurses can support patients to identify and tell at-risk family members, but this is best carried out with trained genetic counsellors, who will be able to talk through fully the risk that the family members may have. The seriousness of the disease and management strategies, including prevention, screening, and treatments should all be included in these discussions. Consent can be given orally or in writing and should be clearly recorded in the individual's health records by the health professional (Lucassen and Hall 2012).

However, Rosenthal and Diekema (2011) highlight that uptake of screening is significantly less than 100% (Rosenthal and Diekema 2011). Barriers to screening may include education level, literacy, culture, and social/family relationships as well as access to genetics counselling services. Ethical dilemmas arise when individuals refuse to inform family members and in particular refusal to disclose to children the risks that they face. In this situation, the affected individual's right to autonomy and confidentiality conflicts with the risk of harm to others. In such situations, health professionals need to balance their duty of care to their patient with the duty to help or protect someone from serious harm. In such a situation, professionals should seek advice from legal and ethical experts within their organisation to support their decision-making.

66.3.3.3 Screening Programmes

Screening for MEN 2 and 3 associated tumours is essential in all individuals with germline *RET* mutations and should begin immediately on diagnosis and continue annually with appropriate biochemical and clinical testing as highlighted in Tables 66.7 and 66.8 below. The age to commence screening varies depending upon the specific *RET* mutation. In MEN 3 (Codon 918), thyroidectomy should be carried out within the first year of life. In other high-risk categories screening for MTC with neck examination, U/S and serum calcitonin should begin aged 3 and thyroidectomy is recommended by age 5, depending on the specific mutation (Wells Jr et al. 2015). In lower risk patients, annual screening is ongoing and thyroidectomy will be recommended if serum calcitonin starts to rise.

Annual screening for phaeochromocytoma and hyperparathyroidism should begin by age 11 in the high-risk categories and otherwise by age 16. Note that those with MEN 3 do not need screening for hyperparathyroidism (Lips and Ball 2017b).

66.3.4 Treatment

66.3.4.1 MTC: Preventative Surgery

The key to successful management of MTC in MEN 2 and 3 is through early and preventative

Table 66.7 Screening for phaeochromocytoma and hyperparathyroidism in MEN 2 and 3 patients

		Phaeochromocytoma: Annual screening	Hyperparathyroidism: Annual screening
Risk	*RET* codon mutation	TEST: Plasma and/or urinary metanephrines If positive then adrenal imaging	TEST: Serum calcium If elevated, then PTH
Highest (MEN 3)	918	11 years	Not applicable
High	634,883	11 years	11 years
Moderate	533, 609, 611, 618, 620, 630, 666, 768, 790, 804, 891, 912	16 years	16 years

Adapted from Lips and Ball (2017b), data originally published by Wells Jr et al. (2015)

Table 66.8 Screening and timing of thyroidectomy for MTC

Risk	*RET* codon mutation	Recommended age to begin annual screening for MTC—annual physical examination, neck U/S, and serum calcitonin	Recommended timing of thyroidectomy
Highest	918 (MEN 3)	Not applicable	In the first months to year of life
High	634,883	3 years	At or before the age of 5 years
Moderate	533, 609, 611, 618, 620, 630, 666, 768, 790, 804, 891, 912	5 years	Childhood or young adulthood

Adapted from Lips and Ball (2017b), data originally published by Wells Jr et al. (2015)

surgical intervention with total thyroidectomy (Kloos et al. 2009). It is possible to remove the thyroid before signs of cancer or at least whilst still confined to the thyroid gland. Though the term prophylactic thyroidectomy suggests there being no cancer present, in most cases C-cell hyperplasia (CCH) or MTC is already present when the surgical specimen is sent to pathology. Around 90% of young patients with *RET* mutations have no evidence of recurrence 7 years post-surgery (Perros et al. 2014).

The optimal timing of surgery is based on the specific *RET* DNA mutation as the behaviour of the disease correlates with particular genotypes (different codon mutations). However, there is clear variation in behaviour amongst different families with the same genetic mutation and also within individual families. Surgery should preferably be before the age of 6 months in MEN 3 but within the first year and before the age of 5 for the most common 634 mutated MEN 2 (Perros et al. 2014).

It is essential to assess for the presence of phaeochromocytoma before proceeding with surgery by measuring plasma metanephrines, urinary metanephrines, or both. If a phaeochromocytoma is found, it should be removed first to reduce the risk of surgical morbidity and mortality.

Baseline calcitonin also provides useful information in determining the risk of and extent of lymph node metastases.

Surgery should be total thyroidectomy with dissection of adjacent nodal tissue and modified neck and/or mediastinal dissections if positive nodes are found. In very young children, it can be hard to identify the parathyroid glands, which increases the risk of hypoparathyroidism post-surgery and if no positive nodes are noted during the operation then central neck dissection can be reasonably avoided (Wells Jr et al. 2015). Such surgery should obviously only be carried out by a specialist endocrine or paediatric surgeon (Perros et al. 2014).

Post-surgery patients should be screened regularly with calcitonin levels to assess for possible relapse (Perros et al. 2014). Long-term management is essentially the same as for sporadic MTC and can be found in Chap. 29.

66.3.4.2 Treatment of Phaeochromocytoma

For patients with bilateral phaeochromocytoma, bilateral adrenalectomy is the required treatment, with subsequent glucocorticoid and mineralocorticoid replacement. It can also be considered in patients with unilateral phaeochromocytoma but with a family history of aggressive bilateral adrenal disease. Otherwise, unilateral adrenalectomy is the treatment of choice in patients with unilateral disease. Though there is a high risk of requiring further surgery in the future, many patients will not require this, and relapse may not occur for many years (Lips and Ball 2017a). Subtotal (cortical sparing) adrenalectomy prevents the need for corticosteroid supplementation. However, this does increase the risk of relapse over the patient's lifetime.

66.3.4.3 Treatment of Primary Hyperparathyroidism

Once biochemically confirmed the approach is the same as for sporadic primary hyperparathyroidism. However, it should be noted that it is often mild or asymptomatic in patients with MEN 2. In asymptomatic patients, surgery can be deferred with ongoing surveillance of calcium, creatinine, and bone density. If any of these deteriorates, then surgery should be considered (Bilezikian et al. 2014). In a recent review and retrospective study (Scholten et al. 2010), subtotal parathyroidectomy or minimally invasive parathyroidectomy have been shown to be effective, thus reducing the requirement for total parathyroidectomy and the risk of hypoparathyroidism. If required, forearm grafting of parathyroid tissue can reduce the risk of long-term hypoparathyroidism.

Hypoparathyroidism is often diagnosed at time of thyroidectomy for MTC and enlarged glands are removed at that time. For patients who've had previous thyroidectomy, localisation studies with sestamibi scanning, ultrasound, or CT should be carried out pre-surgery. Enlarged parathyroid glands should be removed. PTH monitoring may be carried out intraoperatively and further exploration until PTH normalises.

66.4 Nursing Support and Quality of Life Issues in MEN

Being diagnosed with a genetic disorder affects not only the physical health of an individual, but also has psychological and social impacts on the individual and their families. As nurses working with these individuals/families, we need to be prepared and understand the implications of the diagnosis and learn to anticipate a wide range of reactions to such a diagnosis (New York-Mid-Atlantic Consortium for Genetic and Newborn Screening Services 2009).

A diagnosis has the potential to help or harm a patient; therefore, responses may include guilt, fear, and anger but also relief due to getting an explanation for ongoing health issues. Diagnosis can also provide access to support services and ongoing treatment and surveillance options.

Individuals face a potential lifetime of investigation and treatments, but without the possibility of a cure. They may have concerns over difficult treatment decisions with high levels of uncertainty both as to the best approach to managing the disease and the likely outcomes of treatment. There is also the challenge of living with the risk of a shortened life-expectancy.

MEN Case Study 2: Management of Metastatic Disease in MEN 1

(Written consent and permission has been obtained from the patient to use this case study)

Ian is a 42-year-old male with MEN 1, his mother also having had MEN 1. He started annual screening aged 21. By age 30 he'd had a distal pancreatectomy for a non-functioning pancreatic NET and a subtotal parathyroidectomy for hyperparathyroidism. He was clinically well.

At 33 years of age, two liver metastases were found on MRI. These were completely resected and confirmed metastatic non-functioning pancreatic NET. Two years later, an MRI showed progressive liver metastases, throughout both lobes of his liver. As surgery was now not an option, he commenced streptozocin and capecitabine chemotherapy. At this point, he met the NET specialist nurse who then supported him throughout his future treatments. After 6 cycles of chemotherapy, a scan confirmed stable disease.

Eighteen months after stopping chemotherapy, Ian had further progression of liver metastases. A trial of everolimus was not well tolerated, with diarrhoea, mucositis, and poorly controlled blood sugars, and it was stopped after only 3 cycles. A post-treatment scan sadly confirmed further progression. He was then treated with Selective Internal Radiation Therapy (SIRT) and had extensive reduction of the known liver metastases.

Over a 3-year period, the metastases slowly enlarged again. A ^{68}Ga Dotatate scan showed good uptake in his liver metastases. He was therefore treated with 4 cycles of

^{177}Lutetium PRRT over an 8-month period. He found being isolated for treatment extremely stressful and needed intensive support from his specialist team to enable him to safely complete all of the therapy. A post-treatment CT and MRI showed excellent disease response, with a greater than 50% reduction in the liver metastases. 18 months on his disease remains stable.

Ian is currently well but clearly faces an uncertain future. His main physical symptoms relate to his pancreatic surgery. He is an insulin controlled diabetic and has a number of gut-related issues including frequency and steatorrhoea. Through regular nursing support and focused holistic assessments Ian has also opened up about his anxiety and low mood, his inability to plan for the future. He also has feelings of guilt related to his eldest child who is MEN 1 positive. He has been referred to a specialist MEN counsellor to help manage these issues. He has not yet had genetic screening of his second and third children, aged 11 and 9.

Questions to Consider

Ian is currently well but clearly has non-curative disease. At what point would you consider introducing specialist palliative care services for this man?

How would you support him to make appropriate decisions about whether or not to screen his younger children?

For children with an inherited endocrine tumour condition, the severity of reaction to this diagnosis is often dependent on the individual's perception of how it impacts their life. Important variables to consider in relation to the psychological impact on a child include: pain, cognitive difficulties, visibility and appearance factors, and the interference or impact any of these might have on daily life (Edwards and Titman 2010). Children and young people affected by an inherited endocrine tumour condition will undergo regular clinical surveillance and hospital visits that are a reminder of their illness state; and since these conditions are inherited the child will often have experience of a parent's tumour diagnosis and treatment.

For adults, regular hospital visits for surveillance or treatment may impact on their employment and career. Health or life insurance may be impacted upon, all potentially impacting on their financial security. In a recent survey in the UK (Winter and Grey 2016), over half of respondents with an MEN inherited condition felt that it had a negative impact on their long-term mental/emotional well-being, their employment/career and family life. A recent survey of over 200 MEN 1 patients in the USA also found that MEN 1 patients reported worse health-related quality of life scores compared with the general population. Persistent hypercalcaemia after surgery was associated with higher levels of anxiety, depression, fatigue, and decreased social functioning; travelling greater than 50 miles to appointments and having more than 20 appointments per year were associated with lower health-related QoL (Goswami et al. 2017).

Diagnosis can affect relationships and family dynamics, having implications for a decision to have children, or causing parental guilt when finding out that their offspring have inherited the disorder. Individuals with MEN planning to have children should be offered access to specialist genetic counsellors. Options include natural conception, with or without prenatal testing, *in vitro* fertilisation (IVF), either using donor sperm/eggs or with preimplantation genetic diagnosis (PGD), and adoption (Winter et al. 2016). Prenatal testing is via chorionic villus sampling or amniocentesis. Preimplantation genetic diagnosis involves testing newly fertilised embryos in a laboratory for the MEN 2 or 3 gene mutation that the parent is known to carry. Embryos which do not have the affected gene can be transplanted back into the womb. This process has been approved for MEN 1 and MEN 2 or 3 within the UK by the Human fertilisation and Embryology Authority (HFEA 2017).

Family members without the condition can experience guilt that they are not affected and parents may focus more time and attention on siblings who are affected (New York-Mid-Atlantic Consortium for Genetic and Newborn Screening Services 2009).

Nurses are often well placed to provide in-depth information and support for patients and their families in these situations. They are often the first point of contact, helping with coordination of scanning or biochemical investigations for adults or their children, discussing the meaning of results and the nature of treatments. Enabling individuals to access specialist supports is essential, for example, genetic counsellors, psychologists, and social workers as well as support groups, either local or national. All individuals should be offered genetic counselling and detailed information about the condition. Several countries also have charities that offer information and support for individuals and families with MEN, e.g. AMEND in the UK.

Box 66.2 Association for Multiple Endocrine Neoplasia Disorders (AMEND)

AMEND was established by patients, for patients, in 2002 when there were no patient information resources or support services for families with multiple endocrine neoplasia disorders. Living with a rare disease can feel isolating for the patient, and therefore meeting others with the condition can be an enormously positive experience. In addition, the provision of patient-appropriate information on the disorders empowers patients to seek the best medical care and treatments.

AMEND offers free membership, a free counselling service, free patient events, and free information resources for families affected by MEN disorders, sporadic medullary thyroid cancer (MTC), SDH syndromes, and Adrenocortical Cancer (ACC). We develop information resources for children through to adults with the help of our expert Medical Advisory Team, and a specialist Consultant Psychotherapist provides our counselling service. In order to connect patients for mutual support and reduce isolation, we run and moderate several private social media groups, and have a nationwide network of trained regional volunteers who organise local, informal events.

AMEND works closely with researchers and leaders in the field, including as a European Patient Advocacy Group (EPAG) in the European Reference Networks for Rare Adult Cancers (EURACAN) and Rare Endocrine Disorders (ENDO-ERN), and on the NHS England Specialist Endocrinology Clinical Reference Group. We offer research grants when funds allow, and offers to connect patients with researchers and research projects where appropriate.

Patients often find it difficult to talk or to contact the specialists caring for them or their family, especially if they feel that their query may be seen as trivial. AMEND is an easily accessible network of expert patients backed up with an expert Medical Advisory Team. As shown in the case study below, empowering patients with the correct information in an easily digestible format can result in not just the relief of patients' anxieties, but also in improvements in MDT communication and care.

Case Study

A mother with MEN1 who has a 24-year-old son, also with MEN1, contacted AMEND in 2018. She was seeking clarification as to why a surgeon might suggest surgery, including a possible Whipple's procedure, for her son's 1.2 cm pancreatic islet cell tumour. We spoke with and listened to the mother at length to fully understand her situation, then shared her question anonymously with AMEND's expert Medical Advisory Team. Their advice—that surgery for a 1.2 cm pancreatic tumour would be unusual and not in line with current guidelines—was shared with the mother. This gave both her and her son the confidence to return to their medical team and successfully challenge the suggestion. The process highlighted a breakdown in communication within the medical team that was then successfully resolved.

> *"Thank you very much….I talked with James last night….and he's less anxious. ….we will go to the next consultation better informed and more confident about what to ask".*

This level of support is best provided in a specialist centre and multi-disciplinary team (MDT) used to seeing a wide range of patients and their families. With MEN patients it is essential to have an endocrinologist with expertise in MEN to coordinate this care but the MDT should be able to access endocrine, hepato-biliary, pituitary, and cardiothoracic surgeons; oncologists; radiologists including those with expertise in nuclear medicine, histopathologists, geneticists, and specialist nurses.

66.5 Conclusions

Multiple endocrine neoplasia is a rare inherited conditions characterised by the development of multiple tumours of the endocrine system. Tumours often occur earlier in life than in sporadic cases and may also often be multiple in nature.

MEN 1 is characterised by parathyroid, pancreatic, and pituitary tumours. Parathyroid and pituitary tumours are almost universally benign, whereas pancreatic tumours can be malignant. Management involves close monitoring of tumour growth, and symptoms through regular screening and then treatment of specific tumours if required. Pancreatic NETs are the major cause of morbidity and mortality in MEN 1 though many remain small and asymptomatic. There is uncertainty as to when to intervene surgically, with a need to weigh up the risk of tumour spread versus the long-term complications of major pancreatic surgery. International guidelines have been produced to assist with management decisions and further research is required to clarify best treatment options.

MEN 2 and 3 are caused by a genetic defect in the *RET* proto-oncogene, characterised by medullary thyroid cancer (MTC) and phaeochromocytoma with primary parathyroid hyperplasia also common in MEN 2. Early screening and total thyroidectomy early in life is the definitive approach to prevent metastatic MTC.

Due to the rarity and complex nature of these conditions, individuals and their families should preferably be managed within specialist multidisciplinary teams. Specialist nurses are well placed to support patients navigate their way through complex pathways, improve communication within the MDT, support with ongoing symptoms, aid with treatment decision-making, and offer emotional and psychological support for individuals facing lifelong uncertainty.

Acknowledgments With special thanks to Jo Grey, CEO of Multiple Endocrine Neoplasia Disorders (AMEND)—www.amend.org.uk for her contribution to this chapter with a case study and information on the Patient Advocacy Group.

Abstract

Advanced practice roles emerged from a combination of economic factors, staffing needs, political action, and supportive legislation. Fuelled by similar issues, there is a global movement for the development and implementation of advanced practice roles in primary care (general practice) and specialty roles, including endocrinology. Predicted shortages of physicians, particularly for practice in rural and underserved populations, along with spiralling health care costs have made more attractive the philosophy of integrating independent advanced practitioners into an organization and health care system.

To this end, a global definition is needed that clarifies the concept of 'advanced' practice and forms a basis for operationalization of these roles. Scope of practice regulations, and credentialing requirements for practice, are dependent on this conceptualization. Specialty practice can be further delineation with a description of competencies.

The increasing complexity of illness and knowledge explosion have resulted in more specialization and driven the need for higher education in nursing. This is also a global trend.

Utilization of nurses as physician substitutes and different country and organizational specific practice models have resulted in role confusion and poor standardization. Using a unifying concept can help to alleviate this confusion for patients and other health care practitioners. More standardization allows for comparative research to further support the efficacy and quantify improvement in patient outcomes achievable by advanced practice nurses.

In this chapter, these issues are explored with recommendations for the application in endocrine nursing.

Keywords

Advanced practice nursing · Advanced nursing practice · Nurse practitioner · Nurse consultant · Clinical nurse specialist · Global Definition · Endocrinology · Endocrine nurse Competence framework

Abbreviations

APN	Advanced practice nurse
CNS	Clinical nurse specialist
NC	Nurse Consultant
NHS	National Health System (Trust)
NP	Nurse practitioner
RN	Registered nurse
WHO	World Health Organization

Key Terms

- **Sustainable development goals:** Health and wellness related goals for the world set by the UN General Assembly
- **Advanced practice nurses:** A title to articulate professional role identity, clinical competencies and expertise
- **Role conceptualization:** Theories and models that provide a framework for role development

Key Points

- Advanced practice nurses are in demand globally, driven by factors such as cost containment, physician shortages, and underserved populations.
- Role titles and role descriptions within and between countries differ, creating confusion for patients, physicians, other health care providers and regulatory bodies.
- There is significant overlap in clinical competencies for all advanced practice roles, but practice specialties, environment, and culture differ.
- The International Council of Nurses identifies Nurse Practitioner/Advanced Nursing Practices, defining these roles as meeting specific criteria.
- A US Consensus Model recognized APNs to include certified: Clinical Nurse Specialists, Nurse Practitioners, Nurse Midwifes, and Nurse Anaesthetists.
- The APN should include the following agreed competencies, independent of area of practice: Direct clinical practice; Education and coaching; Consultation; Research and evidence-based practice; Leadership and management; and Collaboration and innovation.
- An endocrine specialist APN is defined by general criteria and achievement of specific clinical competencies, but the role should encompass all APN agreed competencies.

67.1 Introduction

The demand for skilled advanced practice nurses is no evident in half the world's nations. Political and economic goals as well as United Nations (UN) sustainable development goals have all contributed to growth or APNs internationally (UN General Assembly, 2015). In rural, isolated and underserved regions, nurses have practised independently or with remote support for many centuries. Midwives represent the oldest independent nursing role. In times of health threats or physician shortages, nurses have often filled the gaps. Although many countries have enacted legislation allowing autonomous APN practice, full and unrestricted practice remains elusive in some countries and in over half of US states.

Lack of clarity in a global concept of APN and its definition continues to inhibit role development, international mobility, and credentialing. This leads to role confusion for nurses, patients, physicians, administrators, and other health care professionals. Without clarity in the definition and conceptualization of advanced practice, targeted political action, role development; role-related research and the determination of scope of practice are challenged.

Patient acuity is rising, new diseases have emerged and many populations are ageing. This demands more nursing skill and knowledge. Although a Master's degree and/or a postgraduate certification may be required for practice, this is not a global standard.

Understanding the historical background and current direction of advanced practice globally is vital to sustaining and developing AP roles. Advanced practice nurses have been shown to provide high-quality patient care, improve outcomes and patient satisfaction. Despite health care leadership and governmental commissioned reports supporting the need for APNs to practice to the full extent of their education and training, this is not a reality in many regions, countries, or clinical settings.

This chapter explores components and competencies indicative of advanced practice and specific roles recognized as AP roles in numerous countries. These aspects of APN are discussed with reference to AP roles in endocrinology.

67.2 Global Definition of Advanced Practice Nursing

Advanced practice nursing (APN) is rapidly expanding globally. Over 70 countries currently have or are paving the way to implement APN care models (ICN 2015). It is estimated that 70% of the hospitals in the world have embraced some form of nursing advanced practice (Parker and Hill 2017).

A conceptual model for APN should answer some of the following questions (Arslanian-Engoren, 2018):

- What is the scope and purpose of APN and how does it differ from those of other providers offering similar services?
- Can an overarching conceptualisation of advanced nursing be articulated?
- How can one distinguish among basic, expert and advanced levels of nursing practice?
- What are the characteristics of APN and in what setting does this practice occur?
- What knowledge and skills are required and what support do APNs need to develop?
- Which patients benefit from APN care and what type of pressing health problems are APNs a solution in terms of improving outcomes, quality of care, and cost effectiveness?

Fig. 67.1 Key questions relating to a conceptual APN model

In 2015, the UN General Assembly announced 17 sustainable development goals (SDG), pledging world commitment to achieving these by 2030. The third SDG is pertinent to nurses 'ensure healthy lives and promote well-being for all at all ages' (United Nations General Assembly 2015). Subsequent briefs from the International Council of Nurses (ICN) to, and supported by, the World Health Organization (WHO), emphasized nurses as linchpins, essential to achieving these goals (White 2016; Squires et al. 2018). Research demonstrates that quality of care and patient outcomes are improved when nurses are provided with adequate educational preparation, resources, policy, and organizational support in care delivery (Squires et al. 2016). The Committee on the Robert Wood Johnson Foundation Initiative on the Future of Nursing at the Institute of Medicine in the USA and the Triple Impact report by the All-Party Parliamentary Group on Global Health in the UK, both endorsed nurses practicing to the full extent of their training as a means to achieve better regional and global health care outcomes (IOM 2010; APGGH 2016). Advanced practice nursing is seen as a driving force for innovation and for developing new models of care delivery, and as integral to achieving health care reform (Bryant-Lukosius 2014).

Despite conceptual support and rapid expansion of advanced practice roles, global consensus of the definition of advanced practice is lacking. However, some common features emerge on analyses. Most countries require a higher academic level, such as a Master's degree or graduate level of education. Although clinical competencies are outlined, this may include the management of chronic conditions, generalist or specialist roles. Not all countries include a function in illness diagnosis and treatment in their definitions of APN and only one reviewed was found to mention autonomous practice (Fig. 67.1). Some outline roles that are considered APN and others do not (Table 67.1).

Terminology used to describe APN roles also varies and adds to the confusion regarding role definitions (Bryant-Lukosius and Dicenso 2004). All practice roles and titles are significantly influenced by political, regulatory, organizational, and site/country-specific factors. The ICN International NP/APN network was established as a global professional voice to promote standardization in the definition of APN practice, but fails to outline roles considered as advanced practice (Sheer and Wong 2008).

67.3 Conceptualization of Advanced Practice Nursing

Conceptual models are generally used to guide research and theory development. When thinking of advanced practice nurses (APN), conceptual models may help APNs to articulate professional role identity and competencies, providing a basis for further development of knowledge and clinical expertise (Arslanian-Engoren 2018).

Table 67.1 Definitions of advanced practice

Organization/country	Definition of APN
International Council of Nurses (2008)	A registered nurse who has acquired the expert knowledge base, complex decision-making skills, and clinical competencies for expanded practice, the characteristics of which are shaped by the context and/or country in which he or she is credentialed to practice
Canadian Nurses Association (2008)	Advanced level of clinical nursing practice that maximizes the use of graduate educational preparation and expertise in meeting the health needs of individuals
American Nurses Association https://www.nursingworld.org/practice-policy/scope-of-practice/	• Registered Nurses (RN) • Treat and diagnose illnesses • Advise the public on health issues • Manage chronic disease, and engage in continuous education to remain ahead of any technological, methodological, or other developments in the field • Hold at least a Master's degree
Royal College of Nursing (UK) (2010)	• Autonomous practice • Critical thinking and assessment • High levels of accurate decision-making and problem solving • Values-based care • Improves practice • High degree of knowledge, skill, and experience applied in the nurse–patient/client relationships • Achieves optimal outcomes through critical thinking • Prepared at Master's level • May work in a specialist or generalist capacity

A conceptual model is designed to answer such questions as:

- What activities are performed by APNs that are considered 'advanced'? How do these differ from a traditional practice nurse?
- What education is required for nursing practice to be considered 'advanced'?
- To what extent do APNs become a physician replacement? To be considered 'advanced practice', is it necessary to incorporate activities traditionally done by physicians and does this make them 'mini doctors' or 'maxi nurses'?
- What does the term 'clinical expertise' mean? Does this refer to a narrower or a broader scope of practice? i.e. Would APNs with subspecialty clinical expertise such as pituitary conditions, but no clinical experience in general endocrinology, still be considered APNs in endocrinology?
- Is autonomy of practice an essential component of APN practice?

Conceptual clarity of APN (what it is and what it is not) is important not only for patient safety, and role regulation but also for effective intra- and inter-professional collaboration. Historical documents have recorded some nurses practising at what would now be considered advanced practice levels at a minimum in the nineteenth century but without clear formalized structure, education, and regulation. Advanced practice nursing was theoretically conceptualized in the 1980s (Hamric and Spross 1983), and many nurse authors have developed models that aimed to support and provide clarity to the advanced practice.

Despite progress made to date, challenges remain. One of the main challenges is the lack of a well-defined and consistent vocabulary to conceptualize APN. For example, in the USA and Australia the term *advanced practice nursing* is used. In Canada (CAN 2008), the UK and Europe, the preferred term is *advanced nursing practice*. This lack of consensus is apparent even within the auspices of the International Council of Nurses, which has adopted the term *advanced practice nursing* (ICN 2008), yet the title of the ICN-endorsed textbook is 'Advanced Nursing Practice' (Schober 2016). Similarly, the ICN refers only to Nurse Practitioners (NP) and Clinical Nurse Specialists (CNS) (Bryant-Lukosius and Martin-Misener 2016), and does not mention other role titles. This lack of a consistent and coherent terminology creates confusion. A global concept of advanced practice is

further hampered by diverse cultures and practice environments. This lack of clarity in definition ultimately impacts scope of practice, practice regulation, and role implementation (Hamric and Tracy 2018).

67.4 Global History of the Development of Advanced Practice Roles

Over time advanced practice nursing and the scope of practice in advanced roles have been influenced and shaped by social, political, economic, legislative, environmental, and technological issues. Demand for nurses to take on more medical roles is apparent in times of physician shortage (Lusk et al. 2018). This has driven 'expanded' practice roles, particularly during military activity. Nurses are recorded as administering anaesthesia during the American civil war (1861–1865) with a nursing manual of the time giving specific instructions regarding the use of chloroform and hypodermic syringes (Lusk et al. 2018). Beginning in 1889, nurse anaesthetists were formally trained at Mayo clinic in the USA. Although isolated institutions and physicians supported the development of nurse administered anaesthesia, there was a concomitant push back and legal action from several medical associations claiming nurses were 'practicing medicine without a licence'. Although challenges were rebuked by appellate courts, a decision in Kentucky US legalized nurse anaesthesia but as 'subordinate' to a physician (Lusk et al. 2018). This has had long standing ramifications for advanced practice across the USA with respect to independent practice in state practice act legislation.

From the growing complexity of nursing, specialty roles have emerged and along with these, the need for more specialized knowledge. The role of clinical nurse specialist (CNS) emerged in psychiatry during Quaker reform movement in mid-nineteenth century in England (Lusk et al. 2018). Other specialties adopted a CNS role which remained the dominant APN role. In the USA in 1980s, the role slowly transitioned from direct clinical care to administrative roles. The introduction of cost-cutting measures, coded billing, and capitated payments resulted in many CNS roles being cut from hospital budgets. The CNS role was not reinstated until federal legislation allowed payment for their services in the late 1990s (Lusk et al. 2018). However in the UK, with the support of the National Health System (NHS) and the recognition of potential cost savings, 87% of hospitals reported employing CNSs, and 37% APNs (Sibbald et al. 2006). Midwifery, though a long standing, traditionally autonomous role, was challenged by medicalization during the late nineteenth century, and evolved with formal training in the UK after 1872 and in the USA at the beginning of the twentieth century.

The role of nurse practitioner (NP) emerged in 1965 with a certificate programme developed by Loretta Ford and Henry Silver MD in Colorado USA, for the purpose of providing improved access to paediatric well child care (Lusk et al. 2018; Keeling 2015). This heralded the beginning of NP training. Eventually, education at Master's and Doctoral levels along with specialty credentialing was recommended or required for NP credentialing. Almost simultaneously, the NHS (UK) instituted payment to physicians for meeting chronic care and illness prevention targets. Primary care or general practice facilities employing APNs were more able to meet these targets (Sibbald et al. 2006). The trend to employ ANPs was further enhanced in 2004 with payment to practices that attain quality care goals.

In the UK, Australia, New Zealand, Canada, and the USA, nurses have been not only been seen as an economic advantage, but also willing to provide cost-effective care for economically disadvantaged populations and in remote rural areas (CIE 2013; Halcomb et al. 2014; Duffield et al. 2009; Lusk et al. 2018). These practice environments often required more medical and nursing knowledge and skills and autonomous practice. Nursing practice autonomy, such as previously exercised prescribing authority, appears to have been limited in the early nineteenth century by medical practice acts and legislative changes. Despite limitations on independent pre-

scribing and drug dispensation, rural nurses in the USA continued operating autonomously in rural remote and underserved areas using 'standing or verbal orders' authorized remotely by a physician (Keeling 2015). In 1955, the American Nurses Association issued a narrow definition of extended nursing practice. This was intended to clarify practice yet actually curtailed the use of advanced skills and limited nursing autonomy for treatment decisions (Keeling 2015).

The advent of the first NP certificate programme by Loretta Ford and Dr. Henry Silver essentially paved the way to restore autonomy and ANP via advanced practice certification (Keeling 2015). NPs were sanctioned to practice in primary care in New South Wales, Australia in 2000 in response to efforts to contain health care costs and provide broader access to care (MacLellan et al. 2015). As in the USA, each state regulated nursing practice. However, federal regulation in Australia in 2010 with the passage of the *Health Legislation Amendment* (Midwives and Nurse Practitioner) Act 2010 (Health Legislation Amendment 2010; MacLellan et al. 2015), created a single, national, practice act for NPs. This act also allowed direct reimbursement for services for qualified, endorsed ANPs and, thereby, independent practice. In the UK, advanced practice roles emerged from general (primary care) practices with the introduction in 1997 of the role of the nurse consultant supported by several governmental practice development projects (Duffield et al. 2009). Role confusion continues to limit practice in the UK. Likewise, nurse practice regulation continues to be restricted in autonomy and require the oversite of a physician in some states in the USA (Maier 2015; Lusk et al. 2018).

The demand for skilled personnel in the context of physician shortages, changing patterns, and higher acuity of illness and ageing populations have continued to fuel demand for nurses with more knowledge and skills. Nursing specialization is an evolution based on the growing complexity of care. Insightful leadership, political action, and legislative support have resulted in higher educational requirements and credentialing standards for advanced practitioners and has given rise to rapidly expanding roles (Hamric and Tracy 2018). In endocrinology, knowledge and skill development has been supported by the development of a competency framework developed in the UK to guide nurses through a career progression from novice to expert (Kieffer et al. 2015; Casey et al. 2013). However, these have not been supported by empirical work or an evidence-based approach.

APN development in endocrinology is anticipated to follow the same pattern of expansion, driven by similar demands as previously described. On the contrary, a large body of empirical evidence at national and European level is found from clinical nurse specialists working in diabetes supporting their role has followed a distinct APN development (Llahana et al. 2001; Llahana et al. 2004; Llahana 2005; Davis et al. 2008; Vrijhoef et al. 2009). Diabetes was reported to affect 8.7% of the global population in 2014 and is projected to be the seventh leading cause of death by 2030 (Global Report on Diabetes 2016). Low- and middle-income countries are disproportionately affected. A global epidemic of hypo- and hyperthyroidism is reported (Taylor et al. 2018). A US-based analysis in 2014 reported a shortfall of approximately 1500 adult and 100 paediatric full time equivalent endocrinologists, with a projected need for a 5.5% increase in trainee intake per year to meet estimated future demands (Vigersky et al. 2014). Regardless, endocrine diseases, such as diabetes and thyroid disease, threaten to overwhelm resources. APNs such as nurse practitioners, nurse diabetes specialists with a high level of education and specialized expertise, are well positioned to provide collaborative care to these populations and those with other endocrine diseases. Advanced education or Master's degree is required for credentialing as an ANP or NP in a number of countries (Duffield et al. 2009). Tertiary education programmes in endocrine nursing at a Master's degree level are currently being offered in the UK and the USA (Evans Kreider and Iris Padilla 2018).

67.5 Competencies for Advanced Practice Nursing

67.5.1 Definition of APN

The most extensive work on developing and clarifying the APN role has been undertaken by Hamric and Hanson over the 6 editions of their 'Advanced Practice Nursing' textbook. Their conceptual definition of APN is adopted in this textbook:

'Advanced practice nursing is the patient-focused application of an expanded range of competencies to improve health outcomes for patients and populations in a specialized clinical area of the larger discipline of nursing' (p. 65) (Hamric and Tracy 2018). Barron et al. (2005) identified three primary criteria which must be met before a nurse can be considered an advanced practice nurse. These include: Graduate education at Master's or Doctoral level, professional certification for practice at an advanced level within a nursing speciality, and practice focused on patients and their families with direct clinical practice as a central focus.

One of the earliest conceptual models to apply across all APN roles was introduced by McCaffrey-Boyle et al. (1996) and refined further in the later editions of the textbook (Spross 2014). Key components of the model (Fig. 67.2) include the primary criteria required by a nurse to perform an APN role, the central competency which is direct clinical practice and seven additional core competencies which are dependent on clinical practice. The model also takes into account the environmental and contextual factors which must support and be managed for APN roles to flourish and be supported (Spross 2014).

67.5.2 Direct Clinical Practice

The role of the APN was established to provide expert clinical care and improve the quality of patient care and nursing practice.

APNs function in many specialties, settings, patient or client populations. Despite variability in role description and implementation, Tracy (2018) suggests that the following six characteristics should be common across all APN roles:

1. Use of holistic perspective
2. Formation of therapeutic partnerships with patients/clients
3. Expert clinical performance in their area of practice
4. Use of reflective practice
5. Use of evidence as a guide to practice
6. Use of diverse approaches to health and illness management.

As an expert practitioner, the APN provides nursing care at an advanced level in his or her area of practice and demonstrates excellent clinical judgement (Tracy 2018). Moreover, the APN is able to develop clinical protocols for the care of patients and have the ability to manage those patients throughout the course of their condition/illness.

The several stages of role development (refer to Chap. 67), the acquisition of more advanced skills than those of general nurses, and the length of clinical experience enables the APN to move away from rules towards a more intuitive approach in interventions by integrating theory into practice (Benner 1984).

APNs, as expert practitioners, assess the patients' condition with a high level of discriminative judgement. They determine priorities of care and design a plan of care with advanced knowledge and skills. Furthermore, they implement comprehensive and individualized care and evaluate the quality of the care provided. This continuity of care assists patients/caregivers and complements their capacity to achieve or maintain optimum health and functioning. In the context of endocrine practice, this equates to maximizing the individuals capacity for self-management of endocrine disorders and assist the patient to maximize quality of life.

The clinical expertise of the APN should not only improve the level of care received by those patients with whom they interact, but also overall quality of nursing care. The APN functions as a role model for other nursing staff and provides guidance in professional career by modelling expert care for patients using a theoretical basis

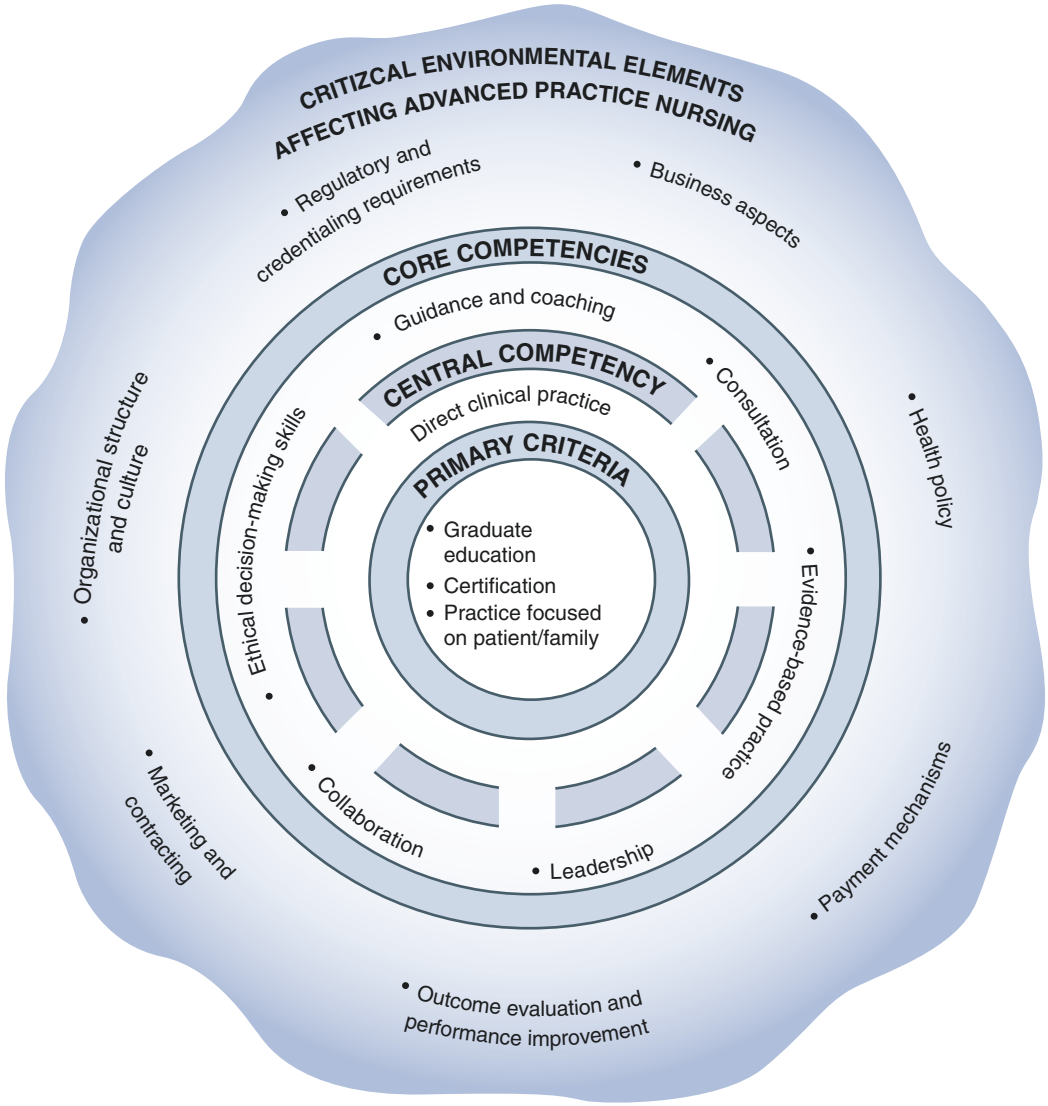

Fig. 67.2 Hamric's model of advanced practice nursing. Used with permission from Spross JA (2014) Conceptualisations of Advanced Practice Nursing. In: Hamric, A. B., Hanson, C. M., Tracy, M. F. & O'Grady, E.T. (Eds). *Advanced practice nursing: An integrative approach*, 5th Edition. Elsevier Health Sciences, pages: 27–65. [Fig. 2-4, page 44]

for care. However, in order to act as a role model, the APN needs to be accepted by other members of the health care team as an advanced practitioner. Therefore, effective and sustained impact on clinical practice requires APNs to prove their competence and skills as expert practitioners.

If APNs lack such skills or are unable to efficiently translate knowledge into the clinical practice setting, nursing staff may not value the APN's suggestions and may consider the APN as an intruder/threat (Llahana 2005). Moreover, 'hands-on' practice of patient care increases the visibility of APNs and direct contact with patients/clients and other health professionals enables the APN to advocate for both patients and staff.

In direct care delivery, APNs participate in quality assurance activities and establishing standards of care. They use evidence-based prac-

tice, generate research questions applicable to clinical practice, and identify translational opportunities to implement research findings (Llahana 2005; Tracy 2018).

67.5.3 Education and Coaching

Educational responsibilities are a key part of the APN role. The practice of remaining up-to-date on relevant, new, and emerging information and sharing information in a clear and timely manner is characteristic of effective APN teaching interventions (McCaffrey-Boyle 1996).

'Patient-focused instruction' is the mainstay of the APN education role and is the characteristic which most differentiates the APN role from staff development educators and academics. The APN has expert knowledge and skills and holds a strategic position for critical patient and family education. Open discussion of patient problems, individualized assessment, and shared decision-making are the hallmarks of conjoint patient-specific care planning (and staff learning). Teaching may be structured or impromptu one-to-one or in a group setting either face-to-face or via mobile health communication (telenursing, web-enabled, SMS, etc.) (Spross et al. 2000).

Development of new educational tools and programmes is another example of the APN educational involvement. The APN's clinical experience yields data on patient and family health and informational needs. The APN is in an ideal position to identify needs, select and implement the most appropriate teaching method for each patient or situation (McCaffrey-Boyle 1996). Proficiency in the utilization of learning theory in APN multifaceted education roles is paramount for both professional and non-professional learners (Llahana 2005).

Part of the APN's role as an educator is to teach and inform not only patients and their families/carers, but also their colleagues, staff, and/or students. Integrating counselling and effective communication into routine one-to-one exchanges is an efficient way to integrate professional development into practice—in particular when discussing challenges and problems.

APNs act as role models for other health professionals by demonstrating the practical integration of theory and evidence-based practice, maintaining a focus on continuous process improvement of clinical care, and integrating new knowledge into practice. The APN has a professional responsibility to be an educator and mentor for graduate nursing students, sharing their knowledge, and modelling advanced practice nursing for the next generation of APNs (Llahana 2005; Spross and Babine 2013).

67.5.4 Consultation

Consultation refers to providing assistance and fostering the consultee's ability to master a given situation. It requires several essential elements: Availability, willingness, insight, clinical expertise, communication skills, and a non-judgemental attitude (McCaffrey-Boyle 1996; Llahana 2005; Vosit-Steller and Morse 2014). It is important to note that these are functions of all advanced practice and is independent of the role of the APN role of nurse consultant.

The degree of importance placed on the consultative component of the APN practice is largely determined by the needs of the staff and patients with whom the APN is working, the expertise of the staff, plus the philosophy, goals, and priorities of nursing administration (Barron and White 2005). Effective consultation on a complex patient problem requires sensitivity. Emphasis is given to the patient's feelings and on how he or she may be assisted to accept the respective health condition and adapt to a new way of living (McCaffrey-Boyle 1996).

The APN is expected to be a content expert assisting in a wide range of approaches and solutions to clinical/health system problems, either internal or external to the practice setting. Moreover, the APN is a resource who provides pertinent information and alternatives, enabling nurses and other health professionals to make decisions that are responsive to dynamic clinical situations (Vosit-Steller and Morse 2014).

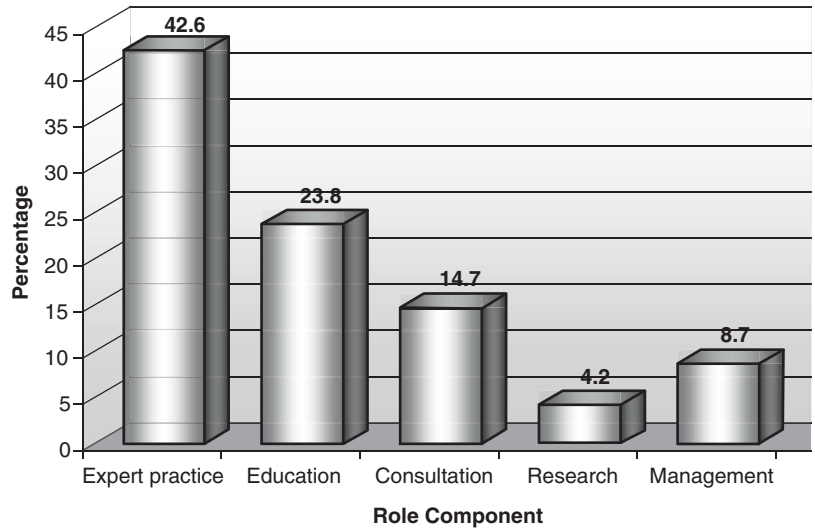

Fig. 67.3 Percentage of total working time allotted to each role component in a national study of clinical nurse specialists in diabetes in the UK (Llahana 2005)

The emphasis placed on the fluctuation of the consultative role over time, but nursing consultation remains an essential and valued activity for most APNs. It is worthwhile to distinguish between formal and informal consultation (Barron and White 2005). The latter often occurs spontaneously and may involve brief questions regarding patient care, a setting or an organizational issue. Informal consultation often occurs when the APN is available and present in a patient care unit. Such rapid consultations are just as likely to be initiated in a corridor or stairwell. Informal consultations occur regularly but as Pearson (2018) emphasizes, APNs need to be cautious and capable of determining when a problem is complex and a quick answer is not appropriate. In these types of scenarios, APNs should direct the consultation towards a more formal and planned approach. Documentation of consultations and decision-making process is also crucial.

67.5.5 Research and Evidence-Based Practice

Although research is an equally important APN competency, there is evidence suggesting that the least amount of APN time is dedicated to research, audit, and evidence-based practice (Scott 1999; Melnyk et al. 2014). A nationwide study involving 334 clinical nurse specialists (CNSs) in diabetes, revealed that only 4.2% of time was spent on research-related activities (Llahana 2005) (Fig. 67.3). The research competency facilitates the APN improving quality of nursing care via scholarly inquiry and translational application of research findings to clinical practice. Research is essential for building and extending the knowledge base for nursing practice. It guides and facilitates clinical decision-making and provides greater understanding of the impact of nursing interventions on patient outcomes (Llahana 2005; Gray 2018).

Frequently, research involvement is collaborative and interdisciplinary in the form of an audit or service evaluation. As a member of a research team, an APN is in a unique position to contribute to the generation of clinically based knowledge, to create a link between practical application and theoretical design, and to support continuous quality improvement. An APN is the clinical expert who understands clinical issues and has access to patients. In contrast, a nurse researcher is the research expert, well understands research methodology, and has access to the tools and resources that are essential for conducting research (Sparacino 2000).

A perceived barrier that may preclude APNs from active participation in research activities is the assumption that research is only worthwhile if one is a principal investigator. This is an overly narrow

view and neglects the fact that research encompasses a continuum of activities that includes scholarly inquiry, conducting prospective or retrospective research as well as utilizing research findings. This may involve (1) interpretation and use of research, (2) evaluation of practice, and (3) participation in collaborative research (Sparacino 2005; Llahana 2005) (see Research Chap. 69).

67.5.6 Leadership and Management

Leadership includes the APN's responsibility for clinical innovation and change, as well as formal and informal impact/influence on patient care and health system (Sparacino 2005). Clinical leadership, management knowledge, skills, and processes enhance APNs' effectiveness as leaders, regardless of position within the organizational hierarchy. The APN has significant formal and informal influence and must strike a balance between visionary and practical. Moreover, the APN may serve as a link between a variety of resources and nursing staff and asserts clinical and professional leadership in the practice setting, health care system, in health care policy and delivery decisions, or in the administration of direct care programmes (Sparacino 2000).

Clinical and leadership competencies articulate with the other APN competencies to support the overall purpose and goals of an organization relating to the provision of patient care. To external observers, many health care organizations/systems may resemble a maze with lack of coordination and bureaucratic hurdles. For this reason, the APN plays an important role by working with staff, patients, and families to help them comprehend the complexities and navigate the health care system. The APN can also serve as an advocate during times of organizational change (Llahana 2005; Carter and Reed 2018).

67.5.7 Collaboration and Innovation

In their practice, APNs collaborate with nurses, physicians, other health care providers, as well as patients and their families. Therefore, they must have skills and abilities that foster effective interdisciplinary collaboration and teamwork. Collaboration is a key component for team building, developing synergism, and finding/implementing integrative solutions. It contributes to overall high-quality and cost-efficient patient care. According to Sparacino (2000), collaboration is an essential competency of an APN, and it is the product of clinical competence, effective communication, mutual trust, valuing complementary knowledge/skills, collegiality, and a favourable organizational structure. It is a transversal competency, meaning that the APN collaborates and coordinates activities when performing other role components.

One outcome of APN-coordinated collaboration is empowering nurses and recognizing nurses as critical members of the health care team. APNs build collaborative relationships with patients and families. This provides an interface between patients, families, physicians, and other health care professionals to promote effective and efficient health care (Carter et al. 2018).

Innovation is perhaps the most challenging role to describe, perform, and/or understand, and it is not a distinct competency. Rather, innovation results from the performance of the other role competencies. It has been posited that the ultimate goal of the APN is to be a successful change agent. Lancaster (1982) defined change agent as one who:

'…generates ideas, introduces the innovation, develops a climate for planned change by overcoming resistance and marshalling forces for acceptance, and implements and evaluates the change' (p. 20).

The role of the APN as a change agent aims to improve patient care and nursing practice and promote effective communication and collaboration with other health care personnel. Change is a never ending process, which, as Hanson and Malone (2000) state, '…must be woven into the fabric of everyday life and work' (pp. 284–285). Change can be both challenging and invigorating, but at the same time, can be difficult and painful. Understanding and using theories of change and implementation frameworks can help

the APN develop strategies and skills to introduce innovation in their work environment and be successful agents of change.

67.5.8 Independent Nurse Prescribing

Prescriptive authority was the focus of APN political action in the USA in the late 1980s. Oregon and Washington State were the first to attain prescriptive autonomy (Lusk et al. 2018). Many states were subsequently granted prescriptive authority to nurses under the supervision of a licenced physician. In 2017, all 50 states and the District of Columbia had legalized prescriptive authority for APNs but the scope of independent prescribing is limited in some states and dependent on a physician licence in others. Currently, 18 US states allow ANPs independent prescriptive privileges. All states require formal graduate level coursework and registration as an APN before granting initial privileges and most require continuing education credits for recertification (AANP 2018; APRN Consensus Statement 2008). The American Association of Nurse Practitioners (AANP 2015) position statement declared unrestricted nurse prescribing, as essential to ANP role performance.

However, prescription of controlled substances in the USA was under the auspices of the Comprehensive Drug Abuse Prevention and Control Act of 1970 and regulated by the Drug Enforcement Agency (DEA). Prescription of controlled 'scheduled' substances required the issuance of a registration number. This was only issued to licenced physicians and dentists until the 1990s. Nurses were first issued registration under the licence of a physician with whom they had a working relationship. Independent DEA registration numbers were granted to NPs according to state-specific prescriptive scope of practice in 1993 (Department of Justice 1993).

In the UK, non-medical prescribing was first recommended by the Cumberlege Report in 1986 to facilitate care provided by community nurses. The subsequent Crown Report supported independent, formulary based, nurse prescribing but legislative support and implementation did not occur until 1992 (Cope et al. 2016). Nurses were mandated to prescribe within a supervised framework termed 'dependent' and later 'supplementary' prescribing. The formulary was extended in 2005 to any licenced medicine, which included specified controlled substances and was expanded to allow independent prescribing limited to the practitioners area of clinical expertise.

'Non-medical' prescribers must be a registrant in their profession and meet a set of criteria prior to being granted privileges. Prerequisite requirement is a minimum three years post-registration clinical experience with 1 year in the clinical area or specialty in which they wish to prescribe. Completion of a programme of at least 26 weeks of didactic training plus 12 days of supervised clinical experience is required to achieve qualification (Cope et al. 2016). Courses are offered at a number of tertiary education facilities at bachelor's and Master's degree levels or as independent courses. The content may include:

- Assessment, consultation skills, and history taking
- Legal and professional issues relating to non-medical prescribing
- Decision-making and evidence-based prescribing
- Psychological and ethical issues applied to prescribing
- Pharmacology and drug actions
- Leadership, accountability, and clinical governance
- Development of clinical management plans as a supplementary prescriber (from Middlesex University London).

Nurse prescribing has been demonstrated to be safe, to improve patient outcomes, and is appreciated by patients. The practice has also been introduced in Australia, New Zealand, Canada, Sweden, Finland, Ireland, Netherlands, and Spain according to country-specific limitations (Cope et al. 2016).

67.6 Operational Definitions of Advanced Practice Nursing

There are four APN roles: Clinical nurse specialist (CNS), nurse practitioner (NP), nurse midwife, and certified registered nurse anaesthetist. However, depending on health system and culture, titles may vary (i.e. nurse consultant (NC), clinical nurse consultant). For the field of endocrinology, roles are primarily CNS, NP, and NC.

67.6.1 The Clinical Nurse Specialist (CNS)

In the 1950s, the CNS role developed in the USA to provide an expert practitioner service at the bedside of the patient. Today, the role of the CNS has expanded beyond the hospital setting, with a client-based focus. The National Association of Clinical Nurse Specialists (USA) defines the CNS role as practicing in three spheres of influence: the patient/client sphere (e.g. advocacy), the nurse/nursing practice sphere (e.g. teams), and the organization/system sphere (e.g. implementing evidence-based practice) (NACNS 2004). Specialization in nursing implies a deeper level of knowledge, skills, and qualifications within a particular field of nursing care than one typically acquires during general training (Llahana 2005). Since the early 1980s, the American Nurses Association (1984) defined specialization as a narrow focus on a part of the whole field of nursing, which requires the application of a broad range of theories to selected nursing phenomena. This secures depth of understanding as a basis for advances in nursing. The reduction in the range of knowledge expected of CNSs results in the development of the depth of knowledge and skills that can be applied directly in the clinical setting to enhance patient care (Llahana 2005). Therefore, as Wade and Moyer (1989) categorically stated, CNSs know more and more about less and less.

From its inception, the CNS role has been firmly grounded in clinical practice but includes other components such as expert coaching and guidance, consultation, research, clinical and professional leadership, collaboration, and ethical decision-making (Hamric and Spross 1989; Sparacino 2005; Llahana 2005; Tracy and Sendelbach 2018). The CNS role is multifaceted and complex. CNS practice is often flexible and responsive to the needs of patients and/or institutions.

67.6.2 The Nurse Practitioner

The nurse practitioner (NP) is a role that was developed in 1960s in the USA. NPs have grown in number nationally and have spread internationally. While rooted in the discipline of nursing, the NP principally functions in a physician replacement model. In contrast to the CNS role that focuses on three distinct spheres, the NP is rigorously trained in the '3-Ps' pathophysiology, pharmacology, and physical examination. This training enables nurse practitioners to assess, diagnose, and treat patients (National Council of State Boards of Nursing. https://www.ncsbn.org/index.htm—accessed 07.07.2018). Notably, autonomy and prescriptive authority vary across nations, states/territories, and localities. In some situations, NPs may practice independently while in other areas, additional restrictions may exist related to the level of autonomy for assessing, diagnosing, and treating based on regulatory scope of practice.

A Master's degree is frequently required for entry to practice as an NP and in some countries a clinical doctorate is either required or strongly recommended. Post master's graduate certificate with a focus on paediatric, family, geriatric, psychiatric care, or women's health is required for certification to practice in many states in the USA.

67.6.3 The Nurse Consultant

The Nurse Consultant (NC) role exists primarily in the UK and Australia. Initial NC posts were introduced in the UK in 1999 to advance nursing practice, research, and education, as well as to provide

professional leadership and quality care to improve patient outcomes (Department of Health 1999). The NC role is based on four components: (1) clinical practice, (2) education and training, (3) leadership, and (4) research and service development (Mitchell et al. 2010; Llahana 2010). Currently, there are more than 500 NCs across the UK working in different specialities. NCs are typically the most senior APNs in the UK and at the top rank of the profession both in status and in salary. At least half of the NC's work is dedicated to direct clinical care, while education, leadership, research, and strategic involvement in service and policy development comprises the remaining time. NCs have a national and international profile and influence in their area of specialty. A Master's level of education is required but more organizations expect NCs to have or undertake a Doctoral degree.

A study by Mitchell et al. (2010) found that NCs contribute service-wide to the implementation of public health policy, service delivery, and policy development, achieving expected competencies and improving health outcomes. They identified four consistent themes in relation to the NC role: (1) entrepreneurial activity and innovation; (2) clinical autonomy and role dynamism; (3) influential national and international research conduct; (4) consultancy and education across discipline boundaries. These included descriptions of higher order skills that surpass usual requirements for the APN practice and the role differs from that of the Nurse Practitioner (NP) or CNS in several aspects (Table 67.2) (Mitchell et al. 2010, Maylor 2005). Figure 67.4 provides an example from the CN role of one of the authors of this chapter. The framework of the NC in endocrinology role with core components and sources of expectations for the role is delineated in Fig. 67.5.

In Australia, the role of Clinical Nurse Consultants (CNC) was introduced in 1986. This APN role closely resembles that of the Clinical Nurse Specialists in the UK and the USA and differs from the Nurse Practitioner role (Fernandez et al. 2017; Baldwin et al. 2013). The multiple titles can lead to role confusion—especially at an international level. For clarity, it seems most appropriate to refer to these roles under the broader APN umbrella.

Table 67.2 Perceived differences between the CN and CNS roles [adapted from Mitchell et al. (2010) and Maylor (2005)]

Consultant nurse (CN)	Clinical nurse specialist (CNS)
Role dynamism	Role description
Makes decisions where there is no precedent	Makes decisions based on protocols and policies
Clinical practice at 50% of working time; broader patient group focus	Majority of working time spent in clinical practice; manages individual patient caseload
Works alongside senior medical	Often answers to senior medical staff
Advanced research adviser	Resource for current research-based practice
Conducts and coordinates research to generate knowledge	Uses research to inform practice
Authority and strategic influence	Might have vision but not authority to influence strategy and bring about change
Clinical and strategic planning	Acts as a specialist consultant and advisor—often not hands on
Has power vested in role	Seeks vicarious power through others to support own perspective

67.7 An APN Competency Framework for Endocrine Nurses

The goal of a competency framework is to provide standardization, consistent high level of care. Competencies that distinguish the APN are shared by all APN roles whereas clinical competencies are specific to the specialty and some to the organization or practice setting. (Kieffer et al. 2015) (Table 67.3).

Detailed competency frameworks provide a guide for new nurses entering the field regarding role expectations and a path for career development to achieve expert practice. The framework provides a structure on which to build an objective career ladder at an organizational level. Such a framework can serve to demonstrate competency to patients and collaborators or other stakeholders.

The reader is referred to recommended readings, Kieffer et al. (2015) for a detailed descrip-

Following appointment as a CNS in Endocrinology in 2004 and in collaboration with the Clinical Lead, the management team, the Chief Nurse and relevant stakeholders, we identified that the contextual background of the endocrine services at UCLH fully supported the necessity of the CN role to develop and provide the following:

- A more patient centred approach to enhance the quality and level of care.
- Expert, innovative and evidence-based endocrine nursing care.
- An educational strategy and a new pathway for clinical nursing within endocrinology
- A national and international profile of endocrine nursing as pivotal and equal member within the multidisciplinary team.

Being involved in writing the job description for this post and discussing it with key stakeholders enabled me to determine how the components of the CN role fitted in endocrinology care at local but also national/international level.

As seen in Fig. 67.5. The CN has five essential domains (core components) to their role; only 50% of working time is clinical practice based which allows for protected time for research and service development away from the pressures of the clinical practice. Changing roles in the same organisations came with the challenge of ensuring the CN role was "visible". During the first 3 months in the CN post I met with a large number of colleagues and key stakeholders from different areas and disciplines within the Trust. I talked about my role and asked for their input on how I could make this role successful. I have incorporated their views and suggestions into my role structure and objectives.

If I can share a few words of advice from my personal experience for endocrine nurses pursuing an APN career progression, these would be:

- Ensure you are up to the challenge of the role and the increased responsibilities. Also, that you are prepared, and you have the relevant competence and qualifications required by the role; in many counties a Master's degree is an entry criterion and Independent Nurse Prescribing is also required for example in the UK and Netherlands.
- Ensure you write a strong proposal to justify the need for an APN CN in your Organisation. What more can an APN offer compared to your current role? Unless you can prove that this role will show a significant and cost-effective improvement in patient care, it may not be approved.
- It will be impossible to achieve this on your own, independently of how competent you are. I was very fortunate to work with a supportive team and in an organisation, who valued the input of nursing in patient care and supported career progression. If you believe this is not the case for you, perhaps it is time to move to a different organisation.
- Talk to other APNs and find out what their role entails and how they made it a success? I spent about 12 months gathering information and talking to people before finalising the job description and proposal for the CN role.
- Finally, remember that in many organisations the APN posts, once advertised, will be open to anyone to apply. Be prepared for a rigorous interviewing process involved in selecting the right candidate. Have you thought about what you will do if, after all your hard work, you do not get the job?
- Persevere and do not give up! You will face a lot of hurdles, especially in today's financial climate, but if you really believe you have what it takes, the APN role whether this is NP, CNS or CN, role will be a reality.

Fig. 67.4 A case study of a Nurse Consultant in Endocrinology role development in the UK

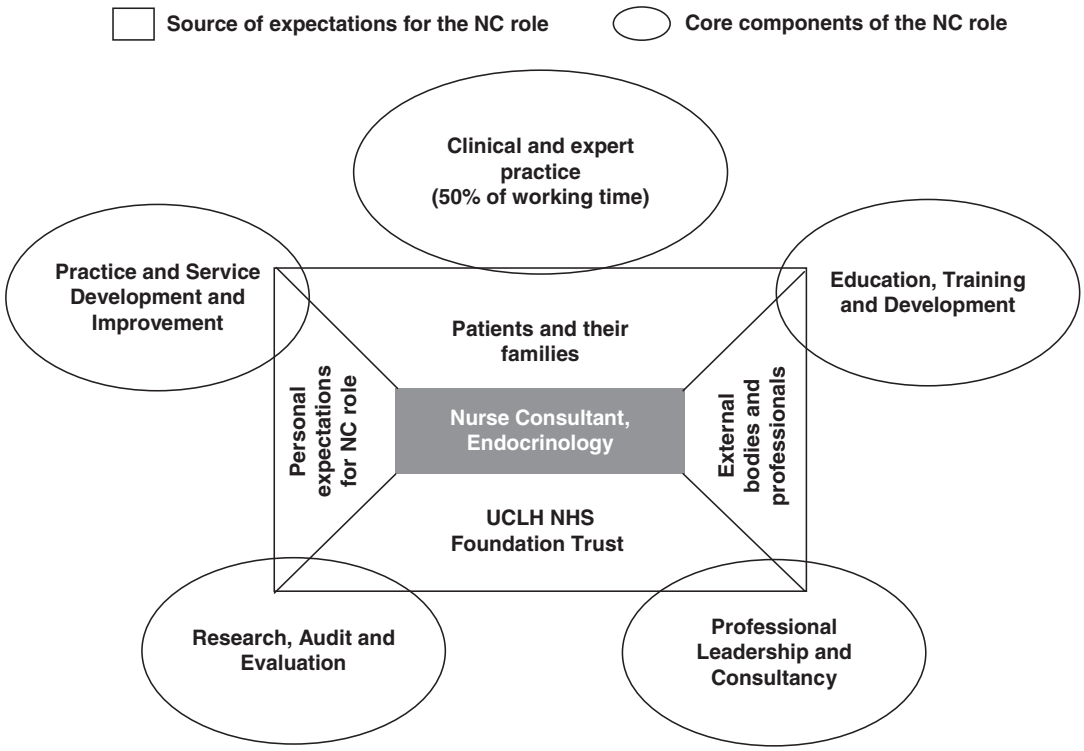

Fig. 67.5 Nurse Consultant Framework: core components and sources of expectations for the role (developed by S. Llahana)

tion of a number of specific endocrine clinical competencies. An APN in endocrinology is expected to be an autonomous expert.

67.8 Implementation of an APN Role

The implementation of APN roles into health care organizations and systems has been challenging and has generally followed an ad hoc, unregulated course in most countries. One approach that has been demonstrated to be effective for introducing APN roles in diverse health systems from Europe to Latin America is the participatory, evidence-based, patient-focused process for guiding the development, implementation, and evaluation of advanced practice nursing (P.E.P.P.A.) framework. Formal policies and guidelines are important for supporting effective APN role implementation (Bryant-Lukosius and Dicenso 2004; Boyko et al. 2016; Oldenburger et al. 2017). Indeed, legislation for title protection, education at accredited educational institutions, clear professional competencies and licensure regulations are crucial to the success of the APN role. Thus, reaching consensus on role definition and a guiding conceptual framework is highly relevant.

67.9 Nurse-Led Clinics

In some settings, nurse-led clinics have been established to fill a service gap, but may also be a novel care model to provide service for management of chronic conditions. Nurses are required to have advanced specialty knowledge and usually work autonomously (Khair and Chaplin 2017). Nurse-led clinics improve access to care, foster inter-professional collaborative relationships, foster nurse leadership development, and improve patient outcomes.

Table 67.3 General and specialty APN competency framework

Competency dimensions	
Research	Care management
Clinical and professional	Evidence-based practice
Leadership	Professional autonomy
Mentoring and coaching	Health promotion
Collaboration and inter-professional relationships	Communication
Ethical and legal practice	Cultural competencies
Education and teaching	Advocacy
Quality management and safety	Change management
Consulting	Expert clinical judgement
	Consulting
Specialist competencies	
Competency 1: Acromegaly	Competency 7: Hypogonadism
Competency 2: Benign adrenal tumours	Competency 8: Hypopituitarism
Competency 3: Cushing's syndrome	Competency 9: Osteoporosis
Competency 4: Endocrine dynamic function testing	Competency 10: Polycystic ovary syndrome
Competency 5: Growth hormone deficiency	Competency 11: Steroid replacement therapy disorders of the pituitary and adrenal glands
Competency 6: Hypo- and hyperparathyroidism	Competency 12: Thyroid disease

In this environment, nurses make detailed physiological and psychologic assessments with subsequent care planning. They perform diagnostic tests, deliver treatments, monitoring of the patient's condition, prescribe and manage medications. Teaching is a large component of all ANP roles in this, as in all types of practice. Patients are usually directly referred to the nurse-led clinic for care (Khair and Chaplin 2017).

Conditions such as diabetes, atrial fibrillation, and bronchiectasis have been successfully managed using this practice model (Jacob 2017; Lawton et al. 2018). A recent study of patients with diabetes and heart disease found significant improvement in HA1c and cardiovascular endpoints that were sustained at a 2-year follow-up in patients managed at a nurse-led diabetes clinic (Wallymahmed et al. 2011). In a systematic review of 15 nurse-led clinics involving a total of >3000 patients, positive outcomes were demonstrated, patient satisfaction was increased but cost-effectiveness was equivocal (Randall et al. 2017).

Nurse-led clinics are found in the UK, Australia, and the USA. In the USA, NPs are licenced independent practitioners in 21 states plus the District of Columbia. Thereby, an NP with an entrepreneurial spirit can establish a sole practice, usually in general practice or primary care. Care delivered by NPs in this setting has been shown to achieve comparable outcomes to similar physician practices (Swan et al. 2015).

67.10 Conclusions

Economic and physician workforce shortages have historically driven a need for APNs. Restructuring of reimbursement models based on quality and illness prevention benchmarks continue to drive the demand for APN models of care. Endocrinology is not immune to these changes, and demand for APNs is likely to increase. However, standardizing the concept of advanced practice is needed, particularly in the context of endocrinology. Raising the profile of endocrine nurses through political activities, advocacy, research, and publications will be needed to improve role awareness. To develop the potential of APNs in endocrinology, achievement of expert levels of care, regardless of the setting, is essential.

Demonstration of the efficacy of care provided by APNs with comparative and outcome focused research is paramount. Working within organizations, through political action via participation in regional, national, and international networks, strengthens collaboration and provides a unified voice. It is vital that AP nurses, particularly in endocrinology, demonstrate and achieve the full potential of their practice capacity.

Abstract

The advanced practice nurse (APN) has a multifaceted role which includes many competencies and core components. As we saw in the previous chapter, APNs work independently and are highly skilled senior nurses.

S. Llahana (✉)
School of Health Sciences, City, University of London, London, UK
e-mail: Sofia.Llahana@city.ac.uk

S. Llahana et al. (eds.), *Advanced Practice in Endocrinology Nursing*,
https://doi.org/10.1007/978-3-319-99817-6_68

Their role however does not exist in isolation and it is important to understand factors that influence the role performance and development of the APN. This chapter will provide a general overview of the factors that influence role performance and development and will discuss the contextual and organisational factors salient to the APN role. The process of role development and strategies to facilitate this process will also be discussed based on a theoretical framework of developmental phases experienced by APNs throughout their career. The literature regarding the APN role is very broad and covers a wide area of various concepts, not all related to role performance. For these reasons, a theoretical framework derived from role theory and from the author's previous empirical work has been adopted to guide the discussion in this chapter. There is very limited literature on the role of endocrine nurses practising at an advanced level and this is either observational work or expert opinion statements such as the competence frameworks. Therefore, this chapter provides a comprehensive overview of the APN concepts in relation to role performance and development aiming to stimulate critical thinking and to generate research questions for empirical work related to advanced practice in endocrinology nursing.

Keywords

Advanced practice nursing · Role performance · Role development · Positive and negative developmental phases · Personal characteristics · Contextual factors · Clinical nurse specialist · Nurse practitioner

Abbreviations

APN	Advanced practice nursing
CNS	Clinical nurse specialist
NP	Nurse practitioner
CN	Consultant nurse
UK	United Kingdom
DSN	Diabetes specialist nurse

Key Terms

- **Advanced Practice Nurse:** a title to articulate professional role identity, clinical competencies and expertise.
- **Role Theory:** represents a collection of concepts and a variety of hypothetical formulations that predict how individuals perform in a given role, or under what circumstances certain types of behaviour can be expected.
- **Role development:** how role expectations are conveyed, and roles are learned in order to perform competently certain tasks or activities.
- **Role performance:** represents the result of the development process of an individual into a role. Role performance also indicates the behaviour of a person given a set of role expectations.
- **Role description:** a set of clear tasks and expectation performed by an individual in a specific role or job (otherwise known as job description).
- **Role stress:** is experienced by an individual when the social structure creates very difficult, conflicting, or impossible demands for them to meet within their set role description.

Key Points

- The APN role is influenced by expectations that APNs themselves and significant others hold for this role.
- Incompatible role expectations lead to role stress and role strain.
- Role theory provides a useful theoretical framework to explain and guide the multifaceted APN role development and performance.
- APNs experience positive and negative developmental phases during their career and this can be influenced by personal and/or contextual factors.
- Prolonged exposure to negative phases and role stress should be avoided, although short exposure to role stress can act as a motivating factor for role development and change.

68.1 Introduction

Role performance and development of the advanced practice nurse (APN) does not exist in isolation, but it is influenced either positively or negatively by many factors and expectations. The utilisation of a theoretical (conceptual) framework in understanding the role of the APN is of vast importance. According to Brink and Wood (1994), a theoretical framework is simply an explanation, based on the available literature, of how and why different concepts are expected to relate to each other.

Llahana (2005) devised a theoretical framework underpinning the role performance and development of the APN based on concepts from the field of role theory and following empirical testing in a national study involving 653 APNs working in diabetes in the UK. According to Conway (1988a):

> '…role theory represents a collection of concepts and a variety of hypothetical formulations that predict how actors will perform in a given role, or under what circumstances certain types of behaviour can be expected' (p. 63).

The exploration of the term *role* in relation to nurses' activities has constituted a significant part of the nursing literature since 1970s, although the empirical exploration of this role has focused only on partial aspects of it (Georgopoulos and Christman 1970; Robichaud and Hamric 1986; Tarsitano et al. 1986; Hamric and Spross 1989; Aikin et al. 1993; Nuccio et al. 1993; McGee and Castledine 1999; Sparacino 2005).

Role theory concepts can be related to health professions and in particular to nursing (Hardy and Conway 1988). Hence, it can be a useful theoretical framework in understanding the factors and aspects that influence the APN role development and performance. Biddle was one of the earliest role theorists who conceptualised *role* and determined that '…the role concept centres upon behaviours that are characteristic of persons in a context' (p. 56) (Biddle 1979).

This chapter explores the role behaviour of APNs in their occupational context. Role theory, as defined by Biddle (1979), is concerned with the study of human behaviours and the factors that influence those behaviours.

The APN role is influenced by expectations that APNs themselves and significant others hold for this role.[1] Incompatible role expectations lead to role stress and role strain. Moreover, this role is determined by the APN socialisation into role; that is, the process in which APNs acquire the knowledge and skills to perform their role.

68.2 The Theoretical Framework for the APN Role Development and Performance

Based on the above assertions derived from the role theory field, Llahana (2005) developed a theoretical framework to understand and guide the role performance and development of APNs. It is suggested that the following concepts are significant in understanding the APN role:

Personal Factors (personal characteristics, attributes, and skills of the APN in relation to their role performance), Context (the organisational context in which the APN role performance takes place), Role Performance, Role Socialisation (development of role), Role Expectations, Role Stress, and Role Strain resulting from incompatibility of role expectations. Figure 68.1 depicts the construction of these concepts into a theoretical framework based on available literature and empirical evidence (Llahana 2005).

The concepts within this theoretical framework that derive from role theory disciplines and are applicable to the APN role as follows:

- Behaviours are patterned and characteristic of persons within contexts (Biddle 1979). Individuals and their behaviours are dominated and shaped by their social environment, but,

[1]The term APN in the chapter includes Clinical Nurse Specialist (CNS), Nurse Practitioner (NP) and Nurse Consultant (NC).

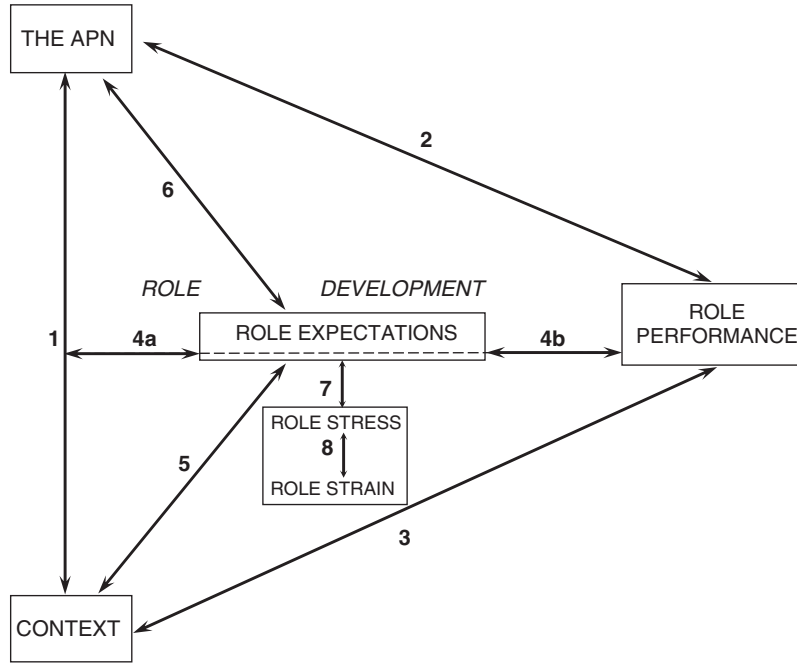

Fig. 68.1 Theoretical framework underpinning the role performance and development of the advanced practice nurse (from Llahana (2005); copyrights remain with the author)

under favourable conditions, they can change and mould social environment. [*Arrow 1*]

- Characteristics possessed by individuals such as attitude, appropriate experience, and specific training, result in effective and convincing role enactment (Sarbin and Allen 1968). The individuals' values, attitudes, motives, and beliefs influence their role performance within the social and organisational environment. Similarly, effective performance increases satisfaction and motivation to enact a particular role (Katz and Kahn 1978). [*Arrow 2*]
- The occupant's role performance is influenced by the context and the individuals who perform in this context. On the other hand, adequate role performance can shape the context in which role takes place in response to expectations for this role (Katz and Kahn 1978; Biddle 1979). [*Arrow 3*]
- The concept of socialisation relates to role development and explains how role expectations are conveyed and roles are learned (Biddle 1979). It is a continuous non-ending process by which individuals acquire the knowledge and skills to perform their roles adequately within society. The occupants' socialisation is influenced by a third-party standpoint (context) which indicates what role behaviour is expected from the occupant (Bandura 1977). [*Arrow, 1; Arrow, 4a-b*]
- Role expectations affect role performance, operate as imperatives pertaining to individuals' conduct and cognition while they enact their roles, and integrate individuals with the social structure. Occupants of interdependent positions hold role expectations for each other, and their expectations are determined to a considerable extent by the broader organisational context (Katz and Kahn 1978; Conway 1988b). [*Arrow 4b; Arrow 5; Arrow 6*]
- A condition of role stress is identified when role expectations held by the social structure (context) are incompatible with those of its role occupants and affect both parts. The occurrence of role stress results in impaired role performance (Hardy and Hardy 1988). [*Arrow 5; Arrow 6; Arrow 7; Arrow 4b*]
- The role occupant responds to the occurrence of role stress with role strain, which is the difficulty felt in meeting role requirements (Hardy and Hardy 1988). [*Arrow 8*]

The next six sections of this chapter present a detailed exploration of the concepts that compose the theoretical framework (Llahana 2005) and

their significance in relevance to the APN role performance and development.

68.3 Personal Characteristics

68.3.1 Educational Qualifications and Experience

According to Biddle (1979), roles are performed by persons, and the concept of role is confined to the behaviours of human beings. Therefore, the occupant's individual characteristics and personality shape to some extent their role performance. APNs differ in intelligence, temperament, and in the learning that they have acquired. Those differences can be reflected in their particular total behavioural repertoire. In addition, continuous and appropriate training will enhance the status of their roles, and as Biddle (1979) stated, '…not only will they [roles] be differentiated more clearly from other roles, but also their practitioners will come to be positionally designated and differentiated from others' (p. 70).

It has been recognised that initial professional education is not enough to correspond to today's complex, expanded, and advanced practice nursing activities. Meeting the needs of patients and their families demands that APNs adopt multifaceted roles which require further professional education and training (Llahana 2005). However, according to the International Council of Nurses (2008) specific practice requirements are rare, and a wide diversity in APN qualifications exists not only between different countries but also within countries. While in the USA as early as the 1980s, a master's degree level or its equivalent was recommended for APN practice (American Nurses Association 1984), in the UK the entry requirements are still vague and vary from practice to practice.

Great emphasis has been placed in recent years, especially in North America, on the doctoral preparation of APNs and the continuation of their involvement in clinical practice. A study of 20 doctorally prepared APNs demonstrated that their active involvement in clinical practice had a great impact on patient outcomes, promoting cost-effective practice and the use of clinical research (Sterling and McNally 1999).

Graduate programmes for APN preparation, although they may be divided into specific specialities, should address the common key components of theory content, clinical practice, and research. They should prepare the APN '…to think critically and abstractly, to assess care situations at an advanced level, and to use and integrate research into clinical practice' (Sparacino 2005: 419). During the postgraduate educational programmes, APNs learn to practise the integration of expert clinical judgement, management, education, and consultation skills within their role (Sparacino 2005). The graduate education provides the APN with the academic preparation and sets the scientific foundations of role components. Development of expert skills in all aspects of the role must come with experience in the practice setting following graduation.

The longer the experience in a role, the more adequately the role is performed. According to Benner (1984), clinical expertise is highly influenced by experience with similar patient populations. Expert nurses, such as APNs, with an enormous background of experience, have an intuitive grasp of each situation. They no longer rely on analytic principles (rules, guidelines, maxims) to connect their understanding of the situation to an appropriate action. Expert nurses utilise analytic problem-solving methods only when faced with a new situation or when the initial grasp of the problem proves to be incorrect. The nurse who has not seen a range of deviations from normal, although having the theoretical knowledge of the condition, has difficulties in recognising them and in teaching the patient what to expect (Llahana 2005).

68.3.2 Personal Attributes

The recommended education for a nurse to enter advanced practice is at master's level, but it can be argued that qualities of the individual are as important as qualifications in becoming an expert practitioner. Patterson and Haddad (1992) referred to attributes and characteristics which identify an advanced practitioner. These include: risk taking (trying out new ideas), vision (utilising and evaluating nursing research to guide

patient care), flexibility, articulateness (articulating and disseminating nursing knowledge by formal and informal methods), inquiring mind (participating in nursing research) self-confidence, and leadership skills (demonstrating the use of theory-based practice to other nurses).

In a study by Hamric and Taylor (1989), CNS reported that their personal attributes and skills played a significant part in the successful development and implementation of their role. These included clinical competence, self-confidence, sense of humour, motivation, flexibility, interpersonal skills, and 'a stubborn streak that would not allow failure' (p. 69). Moreover, Davis (1994) asserted that APNs should be able to practise independently and to function autonomously in order to achieve an integrated implementation of their role.

68.3.3 Skills and Competencies

Competence in practice is based on set standards, using the identified criteria of professional competency. Therefore, an agreed set of competencies needs to be developed that relates qualifications and individuals' ability to perform tasks at a given level. Confusion exists about the concept of competence, as it involves not only behaviour which can be measured, but also attributes such as attitudes, values, judgmental abilities, and personal dispositions, which present great difficulties in their evaluation. A capable practitioner, therefore, is someone who is able to draw on a broad repertoire of skills and knowledge, in different ways and in different contexts, and to perform in a way that is recognised as competent (Lillyman 1998).

Masterson and Mitchell (2003) presented three types of competence models:

- Personal competence models
- Educational competence models
- Performance outcome models

Each model has different purpose but can be used in combination to enhance the APN role performance. The personal competence models focus on individuals' personal qualities, skills, motives, and aspirations that are thought to have a direct impact on role performance. Educational competence models focus on what it is that an individual needs to know and be able to do by the end of the learning period. Finally, performance outcome models focus on the standards and criteria that the individual undertaking a particular role is expected to achieve.

The list of competencies suggested as necessary for APNs is very broad and described in detail in Chap. 67. Competence frameworks have also been developed to guide the role of the endocrine nurses caring for children and adults with endocrine disorders (Kieffer et al. 2015; Casey et al. 2013).

Other characteristics of APNs that lead to success are perseverance in their efforts to effect change by acknowledging the fact that immediate change should not be expected. They should also be able to tolerate any ambiguities or constraints of the system. Critical thinking and analysis, clinical judgement, decision-making ability, problem-solving skills, and communication and collaboration skills are also essential for advanced nursing practice (Davies and Hughes 1995). Furthermore, the ability to institute and effect change in order to improve patient care, particularly through utilising research findings, is a key component of the APN (Llahana 2005). Negotiation skill is probably the most essential dimension of organisational issues reflecting the APN's ability to facilitate and effect change. Change does not only occur at a slow pace, but can also be expensive, something which is not always attractive to management. Therefore, it is essential that APNs can provide evidence for the benefits of this change and be skilled in negotiating for its implementation (Llahana 2005).

Individuals' personal beliefs and motivation for roles are also believed to be related to the adequacy of their role performance. The same role can be perceived and experienced differently by different people, depending on how they perceive and what they expect from their role. Highly motivated individual workers produce collectively a high output for the organisation (Conway 1988b).

68.4 Context for Role Performance

Context is defined as '…any condition or state of affairs that affects behaviour' (Biddle 1979: 52). The organisational context determines to a considerable extent the role expectations held by its members, and, consequently, the role performance of APNs. In terms of expectations, in a particular setting, the role behaviour of role occupants is influenced by the expectations of others for the role. APNs work in a multidisciplinary team and with many other teams in hospital and community settings. Their role performance is, therefore, influenced by the expectations of other members of the team (Llahana 2005). An APN performs different roles in different contextual settings. For instance, when she provides education, she acts as an educator; when undertaking research, she acts as a researcher; in her personal life she might be a wife and mother.

Benner's (1984) model suggests that a practitioner can perform at an expert level in a clinical situation, given innate ability and adequate educational preparation, only when he or she (1) is highly experienced; (2) is motivated to perform well; and (3) has the available resources facilitating that situation. Should these conditions be different, the same nurse will perform at various levels of competence. More specifically, APNs, whether experienced or new to the position, have unclear ideas when entering the role and several factors discussed below affect their role development and performance.

68.4.1 Role Description

The role (job) description of APNs influences their role performance. According to Sparacino and Cooper (1990), a well-written, concise, clear and easily understood role description has the potential to increase staff and colleagues' understanding of the APN role. A generic role description should address the basic components of the role and be consistent with the philosophy of the department of nursing regarding patients' needs, institutional goals, and nursing practice. In addition, it should be specific to a defined area of specialisation and state what services APNs provide in that setting. However, although a generic job description is essential in providing guidance for role implementation, it should also allow APNs to be flexible in their role performance. Priorities should be set based on the APN attributes and the institutional and patients' immediate needs (Llahana 2005).

A clearly documented role description which is distributed to the nursing staff, administration and others facilitates the best use of the APN services (they know what type of assistance to seek from APNs and when to ask for it) and justifies the cost of their services. Vague and inexplicit role description results in incongruity in role expectations imposed on the APN from different sources within the organisation, and role conflict and ambiguity.

68.4.2 Relationships with Generalist Nurses and Other Health Professionals

Inter/intra-professional relationships also influence the role performance of the APN. Factors such as staff resistance to change, apathy, and nurses unaccustomed to consulting other nurses have been reported as barriers to the APN role implementation (Hamric and Taylor 1989). Other factors acting as barriers have been reported, such as conflicts with physicians, team members, and other health professionals. Support has been considered as one of the basic facilitators of the APN role.

The types of relationship that APN develop with general staff nurses influence their role performance either to a positive or negative extent. The fact that APNs are often in charge of evaluating patient care through clinical research and quality assurance studies sets them up as judges of the care provided. Staff nurses then may view them as a threat rather than a help, and act as an obstacle to the APN role implementation (Bousfield 1997). Therefore, a better understanding of the APN role enhances cooperation between staff nurses and APNs.

It has also been contended that APNs can deskill other nurses if they do not apply their skills and knowledge appropriately. This may create a situation in which APNs make all deci-

sions regarding a specialised and complex area of patient care. On the other hand, general nurses may be tempted to abdicate their responsibility and leave everything to APNs, and subsequently not expand their knowledge and practice (Wade and Moyer 1989; Richmond 2004).

68.4.3 Support from the Medical Profession

Gaining support from medical staff is important if the role of the APN is to survive. Traditionally, medicine has had a monopoly over other professions within the health care field. Physicians have often yearned for nurses to be their assistants and may have been upset with the autonomous route that specialist and advanced practice nursing has been taking. On the other hand, APNs are not always clear about their roles and may allow the system to misuse their abilities and skills (Castledine 1995). They are then in danger of being called or treated as medical assistants. When physicians are helped to realise that the APN role is firmly rooted in nursing and they do not wish to be seen as a new generation within the medical profession, their support will be secured. In this way, the contribution of the APN will benefit the quality of care delivered to the patient population (Bousfield 1997).

68.4.4 Administrative Support

Administrative support is essential to the adequate role performance of the APN. The APN who has administrative support can accomplish more in a shorter period of time than the one who lacks this support. This support takes many forms, such as seeking the input of APNs in administrative decision-making and in future plans, recognising their accomplishments, providing guidance, allowing autonomy and flexibility in role development and performance, and giving APNs authority in the practice setting (Hamric and Taylor 1989).

68.4.5 Peer Support and Presence of Role Models

The presence of peer support and role models is considered vital in the facilitation of the APN role performance. The opportunity to share ideas, having someone with whom to compare and contrast various methods of practice, as well as collaboration in research and writing can increase the effectiveness in creating and implementing new ideas. The distinct nature of the role makes it difficult for the APN to find someone other than another CNS to understand the problems and concerns fully and offer support, advice, and practical solutions (Hamric and Taylor 1989). Having a mentor in the institutional setting, 'someone to help you learn hospital policies and the informal power source in the system' (McFadden and Miller 1994: 31), has been cited as an essential facilitator of the APN role performance. Support by team colleagues, clinical supervision, and clinical support were some of the basic facilitators to role development identified by CNSs in the study by Newton and Waters (2001). Other supportive factors mentioned by these respondents were management support, developmental opportunities and sabbaticals, and good balance between work and home.

68.4.6 Available Time and Material Resources

Bousfield (1997) reported that CNSs often lacked structure and direction on how to manage time and justify their role activities. Moreover, the varying expectations placed upon CNSs by the organisation, medical staff, and themselves were frequently incompatible with their available time and, therefore, inhibited their role performance. Attempts to perform all the required activities at the same time often result in none of them being thoroughly and/or adequately accomplished. Therefore, it is important that realistic expectations and time-frames are agreed to assist in the accomplishment of goals and objectives.

Patient caseload was described by APNs as a 'constant stream of referrals' in a study by Newton and Waters (2001) and was made worse

by other factors such as staff shortages, poor communication with other health professionals, insecurity arising from organisational changes, lack of management support, and understanding of role. Opportunities for continuing education and services provided by professional organisations, such as position statements and standards development, can be useful.

68.4.7 Professional Autonomy and Accountability

Professional autonomy is essential in the development of the APN role and the improvement of patient care. Autonomy refers to '…the capability of existing independently, the freedom to design a total plan of care, and the opportunity to interact on an interdependent level with other professionals' (O'Rourke 1989: 130). In order for CNSs to be autonomous, accountable, and responsible, not only do they need to be skilful and competent, but they also need the authority to act or refuse to undertake any activities in each individual case (Llahana 2005).

68.5 Role Expectations

Roles never exist in isolation. The role occupants and those around them have notions about what behavioural patterns should be. Katz and Kahn (1978) viewed role expectations being determined to a considerable extent by the broader organisational context. The role expectation of a nurse is shaped by the technology of the organisation, its organisational structure, its formal policies, and its rewards and punishments. Role expectations act as evaluative standards applied to a position.

The standards of care expected from the APN are those of the competent nurse undertaking those roles. Protocols and competence frameworks can provide documentary evidence of the agreement between employer and APN (expectations of the two groups) and define roles and responsibilities. The Competence Framework for Adult Endocrinology Nurses provides an agreed framework of the areas of practice and career progression from novice to expert (Kieffer et al. 2015).

68.5.1 Role Stress and Role Strain

According to Hardy and Hardy (1988), 'when a social structure creates very difficult, conflicting, or impossible demands for occupants of positions within it, the general condition can be identified as one of role stress' (p. 159). Role stress is mainly external to the occupant and can result from interpersonal or intrapersonal sources, the location of the role in the social structure, the inadequate resources of role occupants, and the social context.

Role stress may generate role strain, which is defined as the difficulty felt in meeting one's role obligations. Role stress differs from role strain in that it refers to conditions generated from impossible, contradictory, incompatible, or excessive role expectations, while role strain refers to the incumbent's reaction to those conditions (Hardy and Hardy 1988). Therefore, role stress is a prerequisite for role strain, and they hold a linear relationship: the greater the number of stressors individuals are exposed to, the greater the role strain they experience.

Prolonged role strain places considerable burden on the person. As Hardy and Hardy (1988) suggested, if uncorrected, it may have various psychological and physiological consequences on the role occupant, such as anxiety, tension, irritation, resentment, and depression.

In health professions, including the APNs, role strain not only leads to reduced quality of care, but may even jeopardise lives. Moreover, health care workers may be drained of both energy and commitment to professional values and patient care.

It is important that role strain should not be tolerated for too long and occupants should undertake actions to deal with it. They may restructure expectations for their role, develop strategies to cope with the difficulties in overcoming role strain, or decrease the level of involvement by keeping role distance, although the latter may have detrimental effect to role performance (Llahana 2005).

Hardy and Hardy (1988) identify seven classes in the typology of role stress and define each of them as follows:

1. 'Role ambiguity—vagueness, lack of clarity of role expectations
2. Role conflict—role expectations are incompatible
3. Role incongruity—self-identity and subjective values are grossly incompatible with role expectations (role transition and poor self-role fit)
4. Role overload—too much expected in time available
5. Role underload—role expectations are minimal and underutilise abilities of role occupant
6. Role overqualification—role occupant's motivation, skills, and knowledge far exceed those required
7. Role underqualification (role incompetence)—role occupant lacks the necessary resources (commitment, skill, knowledge)' (p. 162).

From the above definitions, it can be seen that all types of role stress are directly associated with role expectations, although they originate from various sources. When role expectations are congruent with the occupants' perceptions and preferences, role stress is minimal or absent. The literature reveals that the most prevalent types of role stress regarding the role of the APN are those of role conflict, role ambiguity, and role overload (Llahana 2005).

68.5.1.1 Role Conflict

Role conflict, which Biddle (1986) defined as '… the concurrent appearance of two or more incompatible expectations for the behaviour of a person' (p. 82), is often present within the APN role. This is especially apparent due to the multifaceted role and many competencies APNs are expected to perform. For example, members of the multidisciplinary team and the clinical manager may expect the APN in endocrinology to organise educational sessions for patients with adrenal insufficiency and to run daily nurse-led clinics and, at the same time the chief nurse expects her to undertake research activities and projects as part of her job description. Being unable to conform to both expectations simultaneously, the APN is caught in a role conflict.

68.5.1.2 Role Ambiguity

Role ambiguity is one of the biggest challenges for APNs as it occurs when there is a lack of clarity of role expectations. When little information is available on expected performance or the normative expectations for the role are vague, ill defined, or unclear, the APN as the role occupant may experience role strain (Hardy and Hardy 1988).

Loudermilk (1990) identified the following sources of role ambiguity for APNs: inadequate development to the role, conflicting role expectations of administrators and staff, inconsistent job descriptions, poorly defined job qualifications, multiple accountability, inconsistent position within the bureaucratic framework, and unclear criteria for evaluation.

Role ambiguity, like role conflict, although detrimental to the incumbent's role performance when prolonged, provides the opportunity for creativity within the role and in role making. There has been great progress in the past two decades regarding clarification, structure, and continuous definition of the role of the APN (Bryant-Lukosius and Martin-Misener 2016; Hamric and Tracy 2018; ICN 2018) (please refer to Chap. 67 for more detail).

68.5.1.3 Role Overload

Role overload occurs when role expectations of equal importance are excessive relative to the time available. Although able to perform each of the role obligations competently, the role occupant is unable to complete all of them within given time limits. The occupant experiences role strain due to difficulties in deciding which expectations to comply with and which to hold off (Hardy and Hardy 1988). Evidence exists that the increased workload of APNs results in inadequate performance of all the activities and sub-roles that are expected of them. The sub-roles that are more frequently affected are those of education and research (Johns 1997; Crowley 2000; Llahana et al. 2001).

68.6 Role Development

68.6.1 Facilitators and Barriers to Role Development

According to Biddle (1979), most role theorists use the concept of *socialisation* to explain the appearance and development of roles. This is how role expectations are conveyed and roles are learned, for example how the role development takes place throughout an APN's career progression. Such roles require persons to incorporate new knowledge, alter their behaviour, and change their definition of self within the social context. Several factors already discussed can influence role development in a positive or negative way. Tables 68.1 and 68.2 present the ten most frequently reported barriers and facilitators to role development as identified by diabetes specialist nurses in a UK national study (Llahana 2005).

68.6.2 APN Role Development Process

The role development of the APN (referring mainly to the CNS role) has been discussed in a number of articles since the 1970s. A model of clinical skill acquisition broadly discussed in nursing in the past three decades has been that of Benner (1984), who described five levels of evolving expertise: novice, advanced beginner, competent, proficient, and expert. This model has been adopted by the UK competence framework for adult endocrinology nurses as a guidance on career progression through different stages of competence (Kieffer et al. 2015).

Besides the skill acquisition process, another approach to understanding CNS role development has focused on the CNS's experiences and feelings engendered as competence and confidence in practice are developed. Hamric

Table 68.1 Factors facilitating role development and the frequency of their citation by respondents ($N = 334$) (from Llahana 2005)

No.	Facilitating factors to role development of the DSN	Number of responses	
		Frequency	Percent
1	Peer support and networking with other DSNs	90	*26.9*
2	Supportive and encouraging health care team	38	*11.4*
3	Personal characteristics and attributes	35	*10.5*
4	Support for role by management/administration	31	*9.3*
5	Length of experience in the DSN post	30	*9.0*
6	Support and recognition of DSN role by medical staff	23	*6.9*
7	Flexibility and autonomy in role performance	23	*6.9*
8	Education/training related to diabetes care	15	*4.5*
9	Regular updates and ongoing education	13	*3.9*
10	Having a mentor/role model	12	*3.6*

Key: *DSN* diabetes specialist nurse

Table 68.2 Barriers to role development and the frequency of their citation by respondents ($N = 334$) (from Llahana 2005)

No.	Barriers to role development of the DSN	No. of responses	
		Frequency	Percent
1	Time pressures due to staff shortages and heavy workload	77	*23.1*
2	Lack of or constraints on resources/financial restrictions	73	*21.9*
3	Lack of support by management/administration	59	*17.7*
4	Lack of understanding of DSN role by management/health staff	38	*11.4*
5	Lack of role models and/or working alone with no peer support	14	*4.2*
6	Restraints on DSN role deriving from medical staff	14	*4.2*
7	Negative attitudes of other health professionals	13	*3.9*
8	Personal characteristics	12	*3.6*
9	Politics within the institution and organisational structure	12	*3.6*
10	Funding or time constraints for further formal education	10	*3.0*

Table 68.3 Development phases based on role experiences [adapted from Hamric and Taylor (1989), Llahana (2005), and Llahana and Hamric (2011)]

Developmental phase	Description and characteristics of each developmental phase
Orientation phase	Enthusiasm, optimism, eager to prove self to setting Anxious about ability to meet self- and institutional expectations Expects to make change
Transition phase	Self-confidence, assurance, competence, and advanced level of practice Anxiety relate to new work setting rather than role knowledge base Enthusiasm, excitement, and eagerness in bringing about improvement in new area of practice when moving within the same speciality
Frustration phase	Discouragement and questioning as a result of unrealistic expectations (either self or employer); difficult and slow-paced change; resistance encountered Feelings of inadequacy in response to the overwhelming problems encountered, pressure to prove worth
Implementation phase	Returning optimism and enthusiasm as positive feedback received and expectations realigned Reorganisation of role activities is modified in response to feedback Implementing and balancing new sub-roles Regaining sense of perspective May focus on specific project(s)
Integration phase	Self-confident and assured in role Rated self at advanced level of practice Activities reflect wide recognition, influence in area of speciality Continuously feels challenged; takes on new projects; expands practice Either moderately or very satisfied with present position Congruence between personal and organisational goals and expectations
Frozen phase	Self-confident, assured in role Rated self at intermediate or advanced practice level Experiencing anger/frustration reflecting experience Conflict between self-goals and those of organisation/supervisor Report sense of being unable to move forward due to forces outside of self
Reorganisation phase	Reported earlier experiences that represent integration Organisation experiencing major changes Pressure to change role in ways that are incongruent with own concept of CNS role and/or self-goals
Complacent phase	Experiences self in role as settled and comfortable Variable job satisfaction Questionable impact on organisation

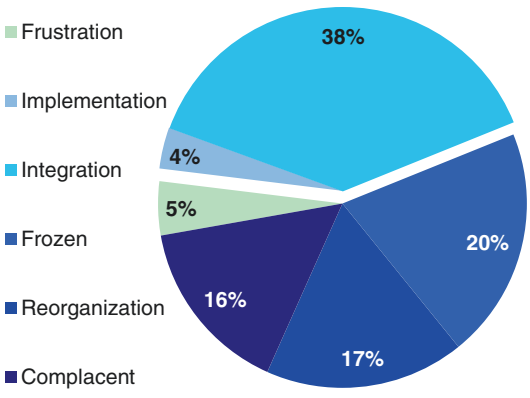

Fig. 68.2 The role developmental phase which respondents were experiencing at the time of the study ($N = 334$) (Llahana 2005; copyrights remain with the author)

and Taylor's (1989) CNS role development framework includes seven phases: Orientation, Frustration, Implementation, Integration, Frozen, Reorganisation, and Complacent. Further refinement of this model was undertaken in a national study involving 334 diabetes specialist nurses; an additional phase of transition emerged for experienced nurses moving to a different setting (Llahana 2005; Llahana and Hamric 2011). A description of the phases is presented in Table 68.3 and discussed below. Figure 68.2 presents the phase that respondents were experiencing at the time of the study.

68.6.2.1 Orientation and Transition Phases

According to Hamric and Taylor (1989), the orientation phase presents the first natural developmental step in learning a new role. It reflects the time required by APNs to become familiar with the role and the employing organisation. Llahana and Hamric (2011) in a national study of diabetes specialist nurses (DSNs) found that this phase was characterised as transition phase by respondents holding either a second, third, or fourth DSN post. This was a typical phase for experienced respondents moving into a new APN post or changing work setting within the same post.

A structured orientation plan should be organised for newly employed CNSs whether they are neophytes or experienced. It should be appropriately designed to inform the CNS not only about the role itself, but also about the organisational structure, philosophy, and policies (Hamric and Taylor 1989; Brykczynski 2009).

Bamford and Gibson (2000) identified four areas which can prepare CNSs for their role:

> 'a pre-existing educational pathway, a training post for the future CNS [APN] role, a team member to act as a role model, and a tailor-made orientation programme' (p. 286).

The first year of the CNS practice is crucial in establishing their credibility and laying the foundation for future development. Many neophyte CNSs have often the feeling that they should be 'everywhere at once' and 'all things to all people' (Llahana 2005). However, as Cameron (1994) points out, giving in to this urge could render the APN a physical wreck at best and a dabbler at worst. Therefore, it is particularly crucial to provide the neophyte CNS with help in setting limits and realistic self-expectations, in understanding how to cope with problem situations, and in maintaining a sense of perspective. The novice CNS who is taught how to work within an organisation and learns whom to consult for advice and guidance can then begin to develop a network for advancement and learning (Beecroft 2001).

During orientation phase, novice CNSs should devote the major portion of their time to direct-care activities to substantiate their role as expert practitioners. This will provide them with the competence and confidence to combine gradually other components within their practice (Llahana 2005). There is a general agreement that the CNS should attend graduate education before entering the role. The purpose of this education, as Hamric and Taylor (1989) state, should aim to prepare graduate students for the realities of the CNS role and for the possible slowness of movement through developmental phases, especially in the first year.

68.6.2.2 Positive Phases: Implementation and Integration

Implementation and integration phases have been characterised by Hamric and Taylor (1989) as positive resolution of the CNS role development. Most participants in the Llahana and Hamric (2011) study attributed the occurrence of positive phases to the opportunity to undertake new projects and introduce improvement in their area of practice. This was also attributed to further academic education and research involvement by many respondents.

During the integration phase, as the CNS has gained positive feedback and recognition relating to the effectiveness of the role, more time can be devoted to areas of scholarly interest (Llahana 2005). It is important for the CNS in this phase to have a plan to guide continued role expansion and refinement over time. Long-term projects and objectives should be organised and implemented. Hamric and Taylor (1989) suggest that the integrated CNS should be involved widely in research, writing, and other outside professional activities and act as preceptor for graduate students. Seeking appointment to key committees and taking part in the strategic decision-making process are also important in broadening the organisational impact of the CNS. Peer support was also seen as a significant facilitator of role development. The main factors, however, as contributing to the experience of implementation and integration phases came from work setting and included support, recognition, and positive feedback from management, health professionals and patients/carers (Hamric and Taylor 1989; Llahana and Hamric 2011).

68.6.2.3 Negative Phases: Frustration, Frozen, Reorganisation, and Complacent

Unlike implementation and integration, these phases share a negative and non-productive character in relation to role development (Brykczynski 2009). The prevailing factor was identified as incongruence of role expectations between respondents and other parties within their work setting, i.e. management, supervisors, health professionals, and patients/carers (Llahana and Hamric 2011).

A certain degree of role stress is inevitable in organisations and, in the short term, can often be a motivating factor for moving into positive phases. However, if uncorrected over a long-term period, role stress may be detrimental not only for CNSs but also for individuals with whom they work (Llahana 2005). The CNS, therefore, should engage in periodic self-assessment to recognise early signs of characteristics associated with these phases and take proactive steps to deal with the negative feelings (Brykczynski 2009). This is even more important during frustration phase, as CNSs have not reached an advanced level of practice and have not yet developed 'self-defence' role strategies. Neophyte CNSs are particularly vulnerable to negative role experiences and need trusted and helpful mentors/managers. Initiation of honest discussion is an important strategy in clarifying problematic role issues before they become serious (Hamric and Taylor 1989; Brykczynski 2009).

Novice CNSs can focus on short-term objectives that can be successfully implemented and provide evidence that staff and patients can benefit from their role. The resulting positive feedback and sense of achievement will increase their self-confidence and comfort within the role. Moreover, the development of good working relationships with team members and other health professionals, as well as establishment of self within the system, is essential in obtaining support and recognition.

Discussion and exchange of opinions with other CNSs who had similar experiences is helpful in relieving tension, as is having a confidant (Hamric and Taylor 1989; Brykczynski 2009). Monthly sessions for sharing concerns and planning future role objectives with a group of peers and supervisors/administrators facilitate movement through the negative phases.

Role ambiguity and lack of understanding of the role by other parties is also a contributing factor for negative phases (Llahana and Hamric 2011). This can result in lack of support, isolation, and controversial dynamics within the working environment. Bamford and Gibson (2000) reported that although CNSs can describe the key components of their role, some cannot clearly explain their role to others. It is, therefore, apparent that role clarification should be a priority, if not the most important objective, in the process of role development of a CNS. If others do not understand the benefits of the role, they will not support and accept CNSs; rather they may try to marginalise their contributions or even eliminate the role (Bigbee and Amidi-Nouri 2000; Llahana 2005).

A strategy by which CNSs can achieve this objective is the dissemination of their role description to all health professionals with whom they work. This should be well-written and concise but long enough to state exactly who CNSs are and what they provide in that particular setting. Furthermore, graduate educational programmes need to prepare CNSs to have a clear understanding of their role and to have the ability to describe it to others (Hamric and Hanson 2003).

68.7 Role Performance

Role performance refers to the differentiated behaviour or action of an occupant relevant to a specific position within a context (Hardy and Hardy 1988). Role performance represents the result of the development process (socialisation) of an individual into a role. Role performance also indicates the behaviour of a person given a set of role expectations. As already discussed, role performance is influenced by expectations, personal characteristics, and contextual factors.

The performance in a particular role is also influenced by individual behavioural tendencies, which are primarily determined by their personal attributes. These attributes include personality characteristics, intelligence, ability, knowledge level, communication skills, interpersonal skills, motivation, and prior experiences. Individuals who lack these attributes relevant to the role will not perform it successfully, although their motivation to do so is very strong (Hardy and Hardy 1988).

The structure of the social setting (context) within which a role occurs influences the occupant's performance in the particular role. Contextual factors can be individual, interpersonal, and organisational. Understanding the nature of systems in health care organisations can help health professionals to cope more adequately with problems that may arise as they attempt to perform their role (Conway 1988b). The role of the CNS is multifaceted and consists of several role components, competencies, and activities. These are discussed in detail in Chap. 67.

Finally, role expectations and role prescriptions in nursing and health professions cannot be specified in detail, because these roles are dynamic and often require unpredictable activities or behaviours. As Benner (1984) explains, although making organisational rules explicit facilitates the co-ordination and implementation of procedures with some degree of quality control, a nurse must not, for instance, follow the written nursing care plan to the letter. If changes in the patient or environment condition occur, the care plan will need to be modified accordingly. This is especially crucial for the APN as they deal with highly complex patient cases and organisational situations (Llahana 2005). Therefore, an APN must acquire the skill of situational assessment and adjustment. Moreover, APNs need to adjust the performance of a specific role to the individuality of each person. To illustrate this within endocrinology nursing, let us consider education which is a common and vital competency for the endocrine APN. Although the performed role component is education, the APN uses different approaches when educating patients, carers, or health professionals, or even when educating patients with the same condition, as each of them differs in their cognitive and physical abilities.

68.8 Conclusions

This chapter discussed the process of role development and factors that influence role performance for APNs. Personal characteristics, contextual factors, and role developmental phases contribute to the success of the APN role. Positive developmental phases maximise the potential of the CNS role performance. On the other hand, although negative experiences during role development can often be unavoidable, it is evident that CNSs should not allow themselves, nor should management tolerate them, remaining and practising in these negative phases. CNSs and their employing institutions must give attention to facilitating positive developmental phases and removing barriers to CNS role implementation throughout the course of a CNS's employment. Further research needs to focus on the relationship between the developmental phases and CNS role performance. It should also examine the effectiveness of facilitators and strategies to enhancing role development and impede negative developmental phases. Open discussion should be initiated in order to find ways of overcoming the barriers which inhibit the successful role implementation.

Abstract

This chapter introduces evidence-based practice and research, explaining the nurse's role in accessing and appraising evidence for endocrinology nursing practice. The contribution of different types of research studies to the evidence base is discussed. The chapter considers how best evidence can be implemented in practice, with reference to quality improvement methods. Nurses are in a good position to identify gaps in the available evidence and identify new research questions. Clinical academic roles provide the opportunity for nurses to take forward their research ideas and combine clinical nursing with research. Clinical research is essential for finding new treatments and improving patient care and so clinical research nurses make a vital contribution, focusing on the care of research participants within clinical research studies. All research must be conducted in accordance with international standards for research ethics and local processes for ethical scrutiny. This chapter's sections on evidence-based practice, clinical academic roles and clinical research nursing all include application to endocrinology nursing.

Keywords

Research · Evidence-based practice · Nursing
Clinical research nurse · Endocrinology
Quality improvement · Clinical academic role

Key Terms

- **Evidence:** available facts (expert opinion, literature) used to assess or validate a belief, proposition or action.
- **Evidence based practice:** the use of the best available evidence used in clinical decision-making and practice to achieve the best outcomes.
- **Research design:** describes the type of study and methodology used to answer a (clinical) question.
- **Quality assurance:** assessment of a practice against an established standard.
- **Research:** development of new knowledge.

Key Points

- Nurses need to be able to access and appraise evidence so that they can implement best evidence in practice and continually improve patient care.
- Quality improvement methods can be used to facilitate implementation of best evidence in practice.
- Nurses are in a good position to identify gaps in the available evidence and identify important new research questions.
- Nurses who are in a clinical academic role combine clinical nursing with research; these roles benefit patients, the individual nurse, the organisation and the profession.
- Clinical research nurses focus on the care of research participants within clinical research and act as an advocate to ensure patient understanding and protection.

69.1 Introduction

All nurses need to be able to access, appraise and implement best evidence for practice to ensure that patients receive best available care and that there are continuing improvements in care quality. However, there are areas of nursing practice where there is no conclusive evidence to underpin care. These gaps can inspire you to conduct research of your own, thus creating as well as using evidence. Nurses who aspire to combine clinical nursing with research can follow a clinical academic career pathway and eventually become research leaders in their field. Clinical research is essential for finding new treatments and improving patient care. Clinical research nurses often work within large, multisite research projects and thus make a vital contribution to extending the evidence base for healthcare.

This chapter first introduces evidence-based practice and research, considering how to access and implement evidence in practice. Clinical academic roles are then considered, with explanations about the benefits and the pathways available. The role of the clinical research nurse is then explained,

with reference to the skills required and competency frameworks. Finally the chapter considers the important area of ethics within research conduct. There are examples from endocrinology research and nursing practice throughout the chapter.

69.2 Introducing Evidence-Based Practice and Research

Nurses must deliver and promote care that is based on the best available evidence and so they need the ability to access and evaluate the available evidence, and to effectively implement best evidence in practice. One of the most well-known definitions of evidence-based practice came from Dr. David Sackett, the founder of the National Health Service (NHS) Research and Development Centre for Evidence Based Medicine in Oxford, England:

> '*the conscientious and judicious use of current best evidence in conjunction with clinical expertise and patient values to guide health care decisions*' (Sackett et al. 2000: 71–72)

This definition highlights that accessing best evidence is not enough; practitioners must also understand each individual patient's perspective and what matters to them, in combination with using their clinical expertise to make professional judgements. As well as applying best evidence in the care of individual patients, best evidence needs to be used when developing care guidelines, designing new services and improving care.

69.2.1 Types of Evidence

Evidence can be defined as 'the available body of facts or information indicating whether a belief or proposition is true or valid' (Oxford Living Dictionaries 2017). Evidence is produced in various ways through research, clinical audit and service evaluation/improvement. Although they all provide evidence, their purpose and method differs (see Box 69.1). All include the collection of data in a rigorous manner, which could be through measurements, questionnaires, observation or analysing documents such as healthcare records.

Box 69.1 The Purpose of Research, Audit and Service Evaluation (Adapted from Health Research Authority 2017)

Research: Attempts to derive generalisable new knowledge by addressing clearly defined questions with systematic and rigorous methods

Clinical Non-Financial Audit: Designed and conducted to produce information to inform delivery of best care

Service evaluation: Designed and conducted solely to define or judge current care: 'What standard does this service achieve?' Measures current service without reference to a standard

(Source: www.hra.nhs.uk)

Up-to-date textbooks produced by experts in the field are a helpful resource for you to access best evidence but there are many other resources available too: see Box 69.2 for examples. Endocrinology websites include information for the public and professionals and can be a useful medium to share evidence. In the United Kingdom (UK), the National Institute for Health and Care Excellence (NICE) guidelines and standards and the Cochrane library systematic

Box 69.2 Sources for Best Evidence for Endocrinology: Some Examples

- The Pituitary Foundation website: http://www.pituitary.org.uk/
- The British Thyroid Society website: http://www.btf-thyroid.org/
- American Thyroid Association website: http://www.thyroid.org/
- The British National Formulary: https://www.bnf.org
- Endocrine Society : http://press.endocrine.org/journal/endo

- The National Institute for Health and Care Excellence (NICE) evidence-based guidelines and quality standards (see www.nice.org.uk)
- The NICE evidence search website: http://www.evidence.nhs.uk/
- The Cochrane Library: online resource that provides systematic reviews of research on different topics. http://www.cochranelibrary.com/
- Expert practitioners, e.g. pharmacists can advise on side effects of medication and drug interactions
- Journal papers identified through a literature search using keywords

reviews are regularly updated and will help you to access the most current available evidence. The NICE website has an intuitive search engine and is highly recommended. You can also conduct your own literature search for research articles, by using databases and then appraising the evidence you find in journal articles.

69.2.2 Types of Research Evidence

Table 69.1 presents examples of research designs, which have been used to investigate different research questions, and contribute to the evidence base for people with endocrinology disorders.

The quality of evidence is often presented as a hierarchy in a pyramid, with meta-analyses and systematic reviews of high-quality individual RCTs at the top, followed by individual high-quality RCTs, and then other types of individual studies (non-randomised trials, surveys, qualitative studies) further down, case reports and expert opinion presented at the bottom of the pyramid. As meta-analyses and systematic reviews are considered the highest level of evidence, these make a valuable contribution to evidence-based guidelines. Systematic reviews follow a precise methodology to ensure the review is rigorous enough to provide high-quality evidence. In Table 69.1, Attridge et al.'s (2014) study is an example of a systematic review. They identified 33 RCTs of sufficient quality for inclusion, of which 28 provided data that could be entered into a meta-analysis, leading to much more powerful evidence set than that provided by an individual study alone.

An RCT uses an experimental approach to determine the effectiveness of an intervention (e.g. a medicine or a method of giving patient information). Key features of an RCT are randomisation and having a control group. As an example, in Martínez-Momblán et al.'s (2016) study (see Table 69.1), patients were randomised, which means that each person taking part had an equal chance of being in the intervention group and receiving the educational programme, or being in the control group, who did not receive this intervention. The effects of the intervention (the educational programme) were studied through pre- and post-intervention questionnaires, which included measurements of health-related quality of life, clinical parameters, level of pain and physical activity, patterns of rest, and use of health resources. RCTs are set up to control as far as possible any other factors that might affect the results, so the sample included in an RCT must meet specific inclusion and exclusion criteria. Exclusion of individuals in order to achieve control has however led to certain groups of people being under-researched, which has ethical implications as well as affecting generalisability. For example, people with learning disabilities have often been excluded from drug trials, and people who have diabetes have often been excluded from trials of wound care products.

In nursing, the notion that systematic reviews and RCTs should always be at the top of the hierarchy of evidence has attracted some criticism, as nursing practice requires multiple ways of knowing (Barker 2013). There are also many nursing topics for which there is no conclusive evidence, based on systematic reviews of RCTs. Petticrew and Roberts (2003) argue instead for a matrix of evidence rather than a hierarchy, with types of research design rated according to the research question of interest. For example, if, as in Strong et al.'s (2014) study (see Table 69.1), the research question pertains to what knowledge practice nurses have about diabetes, then a survey is an appropriate study design as it will answer the question of interest. In contrast, an RCT would

Table 69.1 Examples of endocrinology studies using different research designs

Research design	Author and title	Summary of study design
Systematic review	Attridge et al. (2014) Culturally appropriate health education for people in ethnic minority groups with type 2 diabetes mellitus	The objective was to assess the effectiveness of culturally appropriate health education for people in ethnic minority groups with type 2 diabetes mellitus. They selected randomised controlled trials (RCTs) of culturally appropriate health education for people over 16 years of age with type 2 diabetes mellitus from named ethnic minority groups residing in upper-middle-income or high-income countries. The review included 33 trials involving 7453 participants. 28 trials provided suitable data for entry into meta-analysis
Randomised controlled trial	Martínez-Momblán et al. (2016) A specific nursing educational program in patients with Cushing's syndrome	The study aim was to assess the effectiveness of an educational nursing programme in patients with Cushing's syndrome, on health-related quality of life, clinical parameters, level of pain and physical activity, patterns of rest, and use of health resources. In a randomised controlled trial, 61 patients were divided into 2 groups: an 'intervention' group where educational sessions were performed over 9 months and a 'control' group, without these sessions. Specific questionnaires were used at the beginning and end of the study, with results statistically compared
Controlled trial without randomisation	Follin et al. (2010) Cardiovascular Risk, Cardiac Function, Physical Activity, and Quality of Life with and without Long-Term Growth Hormone Therapy in Adult Survivors of Childhood Acute Lymphoblastic Leukemia	The study aim was to evaluate growth hormone (GH) therapy on cardiovascular risk, cardiac function, physical activity, and quality of life in Acute Lymphoblastic Leukaemia (ALL) patients, treated with cranial radiotherapy and chemotherapy. The study was a non-randomised prospective study with two groups of GH-deficient ALL patients and matched population controls. One ALL group received GH for 5 years and the other ALL group did not. The outcome measures were: prevalence of CV risk factors and metabolic syndrome, cardiac function, quality of life and physical activity
Non-experimental study: survey	Strong et al. (2014)	The study surveyed practice nurses to ascertain whether they are adequately equipped with knowledge, skills and resources, to provide nutrition education to people with type 2 diabetes. A self-administered questionnaire was used
Qualitative study	Gurel et al. (2014) Patient perspectives on the impact of acromegaly: results from individual and group interviews.	The study aimed to understand the impact of acromegaly on disease-related concerns and treatment choices from the patient perspective. In Phase I, 10 patients participated over the course of 5 days in a moderated online discussion board. In Phase II, a separate nine-patient cohort participated in face-to-face interviews

not be an appropriate study design to answer this research question. If your research question concerns people's experience of living with an endocrine disorder or exploration of acceptability of its treatment, then a qualitative research approach is more appropriate, as it enables the gathering of in-depth data about people's experiences or feelings. In Table 69.1, Gurel et al.'s (2014) study is an example of a qualitative study that used online discussions and individual interviews to study experiences from people's perspectives of living with acromegaly.

The application of the results of a systematic review must take into account the individual and the context of care. For example, from a critical appraisal of an extensive set of high-quality RCTs, the authors of a systematic review may conclude there is good evidence for a particular patient education device for diabetes self-management. However, for any individual patient, the use of the device in practice could be affected by another health condition (e.g. visual impairment or rheumatoid arthritis), their cognitive ability (e.g. they could have dementia or a learning disability), their literacy level or their social situation. Critics of evidence-based practice argue that generalised evidence-based guidelines detract from a person-centred approach (Barker 2013) although Sackett et al.'s (2000) definition of EBP does

include the patient's values and preferences as part of the decision-making process.

A collaborative group that supports EBP and has a strong nursing focus with a broad approach is the Joanna Briggs Institute (JBI) (see http://joannabriggs.org/). The JBI was established in Australia but has now been adopted as a global enterprise. The Cochrane library (http://www.thecochranelibrary.com) aims to provide high-quality, independent evidence to inform healthcare decision-making. The library contains databases of systematic reviews on an increasing number of topics. There is a useful section entitled 'Endocrine and metabolic' with current subtopics that include: Diabetes, High cholesterol, Neuroendocrine cancer, Nutritional deficiencies; Obesity and overweight; Other endocrine disorders and Parathyroid disorders. Attridge et al.'s (2014) study (see Table 69.1) is an example of a systematic review, accessed via the Cochrane library. Most of the systematic reviews in the 'Endocrine and metabolic' section are, like Attridge et al.'s review, diabetes related, rather than other endocrine disorders; this could indicate there are gaps in endocrinology research. There are also relatively few reviews in the Cochrane library that are focused on nursing practice and this indicates potential gaps in the nursing-related research evidence base.

69.3 Process for Implementing Evidence-Based Practice

Box 69.3 summarises the process for implementing evidence-based practice, which starts with accessing and appraising the available evidence. The key to a good literature search is to formulate the search topic into an answerable question. The most frequently used framework is PICO (population or patient problem, intervention, comparison or context, and outcome). Use of a framework like PICO is helpful to develop a good, focused research question, but it can also assist in compiling the search terms to use for identifying available evidence (Norris 2010). The 'comparison' component is optional as there may not be a comparison intervention available. Instead, the context or setting might be more relevant for some topics. As an example of using PICO, your research topic area might be to investigate ways of increasing adherence with medication for a pituitary disorder in young adults. Your research question formulated using PICO might be:

- For young people with hypopituitarism on growth hormone replacement (P), are daily reminder text messages (I) more effective than usual care (C) for achieving adherence with medication?

Box 69.3 Implementing Evidence-Based Practice

- Formulate a question to focus the evidence gathering, using the PICO format (patient/population, intervention, comparison/context, outcome)
- Identify keywords and plan how they will be combined (and/or) and any other search parameters such as publication date range, terms to exclude
- Identify the search-engines and databases to use, for example, CINAHL (Cumulative Index to Nursing and Allied Health Literature), MEDLINE, PsycINFO, BNI (British Nurse Index) and SCOPUS
- Review the database search results and select articles by rejecting irrelevant articles first on title and then, from those remaining, by reviewing the abstracts for relevance, and then finally, by reviewing the remaining articles in full.
- Critically appraise the selected research studies to make a judgement about their quality. There are many useful appraisal guidelines available; see the UK Critical Appraisal Skills Programme (CASP) at http://www.casp-uk.net, which includes checklists for appraising different types of research;
- Apply the evidence you have identified to the context of care delivery, drawing on clinical expertise and with consideration of patient values and preferences.

You can then identify your keywords from this PICO formed question. Keep records of the results of your searches and the process you followed so that you can justify your selection of papers. If you identify few relevant research studies and a critical appraisal of these reveal that the study designs are weak and the results are inconclusive, you have then identified that further research is necessary. Identifying gaps in the evidence may inspire you to conduct your own research; see later section 'Independent nursing research: pursuing a clinical academic career'.

Once you identify the evidence relating to your question, your goal is to implement evidence in practice. However, what may appear to be small changes to implement evidence-based practice can be more complex than they first appear and involve many different disciplines and changes to whole systems. Quality improvement methodology can be used to implement best evidence, through mapping current processes and then planning, trying out, evaluating and refining evidence-based changes on a small scale in repeated Plan-Do-Study-Act cycles (Langley et al. 2009). Let us consider our earlier example, of using daily text messages with young people with growth hormone deficiency to improve medication adherence. If you found high-quality evidence about this intervention from your literature review and wanted to implement this in practice with your patients, Plan-Do-Study-Act cycles could work in the following way:

1. **Plan**: You would need to first collect some baseline data about medication adherence with your service user group. You would need to conduct detailed planning and should involve colleagues and service users to co-design how you will approach the improvement. For example: who will send the text message and at what time? If it is a clinical nurse specialist, do they provide 7-day cover and is there a cost implication? You would need to plan who you will pilot the text messaging with and for how long, and what data you need to collect and how, so you can measure the improvement. You might start with just one service user, for 1 week perhaps.
2. **Do:** At this stage you will try out the text messaging as planned, while collecting the data.
3. **Study**: You will measure the effects of the text messaging by comparing the data before the improvement with the data collected at the 'Do' stage. You can use for example self-reported adherence questionnaires, biochemical markers, i.e. insulin-like growth factor 1, prescription use and stock check for their growth hormone use and patient feedback on new intervention.
4. **Act**: You next act on the results, reviewing these with your colleagues and service user group.

After this first PDSA cycle you will move into a second PDSA cycle, with planning based on the first cycle. You might next try out the text messaging with a few more service users and for a longer timeframe. You might identify other data you need to collect and review as part of the cycle. You would continue with small scale projects using PDSA cycles to continually improve how the intervention is working in practice with your service user group, before widespread rolling out of the evidence-based improvement.

69.4 Conducting Your Own Research

Some nurses working in endocrinology may be interested in creating evidence as well as using existing evidence. To conduct your own research you need to have a sound understanding about research methods, data collection methods and data analysis. One way to acquire and utilise these skills AND continue to work as a clinical nurse is through the development of a clinical academic role.

In the next section we will explain what a clinical academic is, the key benefits, describe national and local initiatives that support the development of a clinical academic, explore how you can develop your role as a clinical academic and finally we provide an example of a case study of an endocrinology clinical academic.

69.4.1 Independent Nursing Research: Pursuing a Clinical Academic Career

69.4.1.1 What Is a Clinical Academic?

A clinical academic is a registered health professional who works concurrently in a healthcare clinical setting as well as an academic (usually a university) setting (Carrick-Sen et al. (2016). The role is relatively new within the UK; however, Australia and the United States of America (USA) have established senior clinical academic roles for the last two decades. Within the UK, medicine introduced the role of the medical Academic Clinical Fellow (ACF) in 2005 (UK Clinical Research Collaboration and Modernising Medical Careers 2005). The role in medicine is now well established and valued. The research-focused clinical academic role within the UK has been developed to support and create roles within nursing, midwifery and allied health professions.

69.4.1.2 What Are the Benefits?

The benefits of a clinical academic are plentiful. Beneficiaries include patients, the individual health professional, the organisation and the profession. High quality of care is associated with continual service improvement (Care Quality Commission [CQC] 2016). Patients involved in research report increased monitoring, treatment options, care contacts and improved clinical outcomes. In the pursue of being a clinical academic, the individual gains extensive knowledge, skills and confidence relating to research methodology, advanced critical thinking and decision-making, reporting outcomes and findings and are likely to feel valued and appropriately challenged and utilised. Benefits to the organisation include increased provision of evidence-based care, increased reputation, efficiency and clinical outcomes, potentially reduced complaints and increased staff morale as well as attracting and retaining high-quality staff. The profession benefits from increased evidence-based care and treatment options and the creation of valued and appropriately developed and utilised healthcare professionals.

69.4.1.3 Initiatives That Support the Development of a Clinical Academic

In 2000, a UK-wide group was set up under the Association of UK University Hospitals (AUKUH) Director of Nursing sub-group (AUKUH 2018). The AUKUH focus on the important integration and development of service, research and education within the healthcare provider setting. The group, founded and chaired by Professor Debbie Carrick-Sen, works in close partnership with other key UK organisations, which include: the National Institute for Healthcare Research (NIHR), Health Education England (HEE), NHS Improvement, NHS England, the Royal College of Nursing (RCN) and the Royal College of Midwives (RCM). The group have been successful in achieving a number of high-quality outputs including a national career framework, identified required competences and example job descriptions, to name but a few. It has also successfully influenced this agenda including the aspiration of national clinical academic roles within HEE national mandate as well as being the focus of a number of important national strategies and initiatives. The latest output launched in October 2016 is an online healthcare provider organisation guide to support the transformation of care through research-focused clinical academic roles (Carrick-Sen et al. 2016). The guide has been endorsed by national key partners and early evaluation suggests it is extremely helpful to individuals and organisations aspiring to develop clinical academic roles. The individual and organisation case studies are reported to be particularly helpful and insightful.

Although it is possible to develop as a clinical academic without organisational support, it is highly recommended that you gain organisation/line management support. Doing so, will assist you to make the most of available opportunities in a timely way and ensure that the research you focus on is aligned to local and national service priorities.

There are a number of recognised training steps in the development of a clinical academic (Fig. 69.1). These include a number of new

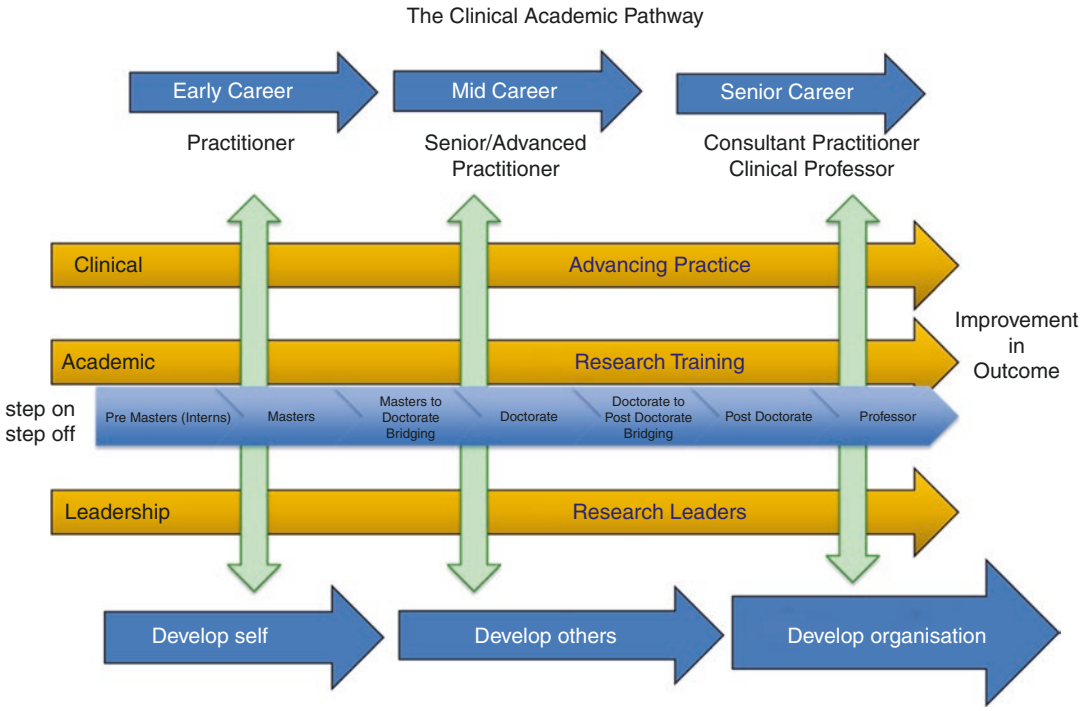

Fig. 69.1 Training steps in the development of clinical academics (developed by D. Carrick-Sen)

opportunities called 'bridging programmes'. These new bridging opportunities bridge between formal recognised qualifications and are excellent opportunities to enable you to stay on and continue to progress to a senior clinical academic. The aspiration is to develop clinical academic leaders who not only create high-quality research but also encourage and inspire others to commence and stay on the clinical academic career pathway.

Figure 69.1 represents the clinical academic pathway model that was developed by AUKUH and, in partnership with DH/NHS England, has developed and defined an embedded clinical and training pathway. This model is cross cutting and highlights early, mid and senior career. Within the career trajectory, the healthcare professional continues to develop in clinical practice, leadership and scholarship, developing self, through others and at organisation level with the purpose of improved outcome, impact, capacity and environment. Although these are important first steps, a number of challenges remain.

69.4.1.4 Developing Your Role as a Clinical Academic

It is complex to develop into a clinical academic; however, persistence and determination are key required attributes. It takes 10 years to develop and sustain a major organisational culture shift and it is important that we continue to pursue this goal globally. In times to come, it is hoped that clinical academic roles will be the norm and accepted as a valid and attractive career option. Meanwhile, there are a number of models that may work for you; one of the most common models is the 50/50 split. This is where you are likely to be currently 100% funded and employed by a healthcare provider organisation and you apply for funding to undertake research activity (+/− a formal qualification) for 50% of your time. If successful, the research funding provides finance to backfill 50% of your role and you therefore commence as a clinical academic spending some of your time doing clinical work and some of your time doing research activity. One of the current challenges is what you do at the end of that funding. Our sugges-

tion would be to apply for bridging funding, which is likely to be less hours than your formal training research funding (see Fig. 69.1) and use this time to publish and prepare for the next stage.

Working within a good multidisciplinary research team is critical to success. Another very important aspect is to identify mentors who understand your role and professional perspective, and who have the required time and commitment you need from a successful mentoring relationship. It is likely that you will need to identify and approach your mentor/s. You can have more than one and it is often beneficial if they are outside your own organisation as they can often articulate a more objective viewpoint. Mentors are often successful people who have successfully negotiated the role you are aspiring to. Box 69.4 provides an example of an endocrinology clinical academic.

Box 69.4 A Case Study of an Endocrinology Clinical Academic

Lisa Shepherd is an endocrinology clinical nurse specialist at Heart of England NHS Foundation Trust in England. Lisa's prime goal is to improve and further understand how we can help patients with primary adrenal insufficiency and to reduce the risk of developing an adrenal crisis. She has successfully completed her Masters qualification and published the findings. She was successful in attaining a place on the West Midlands HEE funded Masters to Doctorate bridging programme. During this time, she worked with an academic mentor and created a solid effective research multidisciplinary team to work with her and guide her. During the 18-month bridging programme she published two further papers to enhance her publication profile and submitted five funding applications for small amounts to undertake pilot projects that helped and increased understanding of knowledge and evidence gaps. She was successful in attaining three of these and these then further increased her research profile. She also enhanced her current national and international profile, to further build her role esteem factors. The pilot project and publications were all aligned to her research topic and therefore further building her personal storyline and creditability within the field. The publications included her supervisors and academic mentor demonstrating effective and supportive supervision. Lisa has recently submitted a high-quality NIHR clinical academic doctorate funding application to undertake a large study focused on behaviour change and technology. She is clearly dedicated, able and determined to pursue a clinical academic role and I am sure will be one of our endocrinology research leaders of the future.

69.5 Clinical Research Nursing in Endocrinology

It is important to first differentiate between a nurse conducting nurse-led research and a clinical research nurse. Nursing research is a systematic, objective process of analysing phenomena of importance to nursing. Clinical research nursing is nursing practice with a specialty focus on the care of research participants. This section will explain the role of the nurse in clinical trials, rather than other types of research.

Clinical research nursing roles may be varied. Clinical research nurses (CRNs) support study implementation within the context of a care delivery setting in primary or secondary care. Research Nurse Coordinators (RNC) are nurses primarily responsible for study coordination and data management, with a central focus on managing subject recruitment and enrolment, consistency of study implementation, data management and integrity, and compliance with regulatory requirements and reporting.

Although there are many definitions of clinical trials, they are generally considered to be

biomedical or health-related research studies in human beings that follow a pre-defined protocol. They are conducted in four phases (see Box 69.5). Interventional studies are those in which the research subjects are assigned by the investigator to a treatment or other intervention, and their outcomes are measured. Observational studies are those in which individuals are observed and their outcomes are measured by the investigators.

Box 69.5 The Four Phases of Clinical Trials

- Phase I tests a new drug or treatment in a small group of healthy volunteers.
- Phase II expands the study to a larger group of volunteers and patients.
- Phase III studies are conducted with an even larger group of patients and are often randomised to confirm therapeutic effect.
- Phase IV consists of formal post-marketing surveillance studies, which may include other population groups and surveillance for interaction with other drugs.

Competency frameworks have been developed in order for CRNs to benchmark their practice and maintain high standards of care. One example is a competency framework which has been adopted by the UK's National Institute of Health Research (NIHR) and is used extensively by CRNs working in varied clinical settings (Gelling 2011). The framework promotes patient safety and the achievement of quality data, by bringing together the knowledge and skills of the CRN. The framework is designed to be comprehensive, giving an overview of the current expectations of the work of a CRN and at various levels of seniority. It consequently also provides clear structure for career development. One of the strengths of a competency framework is that it is adaptable to meet local requirements within all research settings.

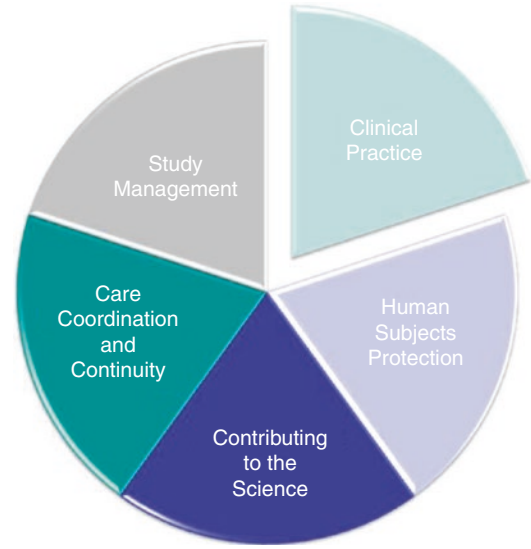

Fig. 69.2 Clinical research nursing domain dimensions (CRN 2010 Domain of Practice Committee 2009: Figure 2, p.4)

In 2009 the National Institutes of Health (NIH) CRN task force started a 4 year strategic plan to lead an international effort in order to define the specialty practice of clinical research nursing (CRN 2010 Domain of Practice Committee 2009). The domain of practice for the CRN specialty encompasses five dimensions (see Fig. 69.2), each of which houses a cluster of activities which together describe the specialty practice.

Let us now examine in more detail each of the domains.

Study management: Managing clinical research support activities: assuring patient safety, addressing clinical needs, assuring protocol integrity, accurate data collection and compliance with Good Clinical Practice guidelines (GCP).

Care Coordination and Continuity: Facilitating the education of the interdisciplinary teams, coordinating study visits, providing nursing leadership within the interdisciplinary teams and effectively communicating the impact of study procedures on the participants.

Contributing to the science: Participating as a research team member in the development of

new ideas for studies, serving as an expert in specialty areas, participating in the query and analysis of research data, mentoring junior staff, students and new investigators as members of the research team.

Human subject's protection: Facilitating the initial and ongoing informed consent process, acting as the research and development liaison, coordinating research activities to minimise patient risk and managing potential ethical and financial conflicts of interest.

Clinical practice: Providing direct nursing care to research participants, teaching using advanced practice skills and monitoring the patient, recording research data in accordance with GCP.

Professional development and career progression is essential for all CRNs and revalidation requirements expect CRNs to show engagement with evidence based continuing professional development. The 'Competency framework for research nurses' (Gelling 2011) illustrates the skills and behaviours, and knowledge and understanding, for identified clinical research nurse competencies, across the career pathway.

69.5.1 Paediatric Clinical Research Nurses and Clinical Research

Children differ from adults and have distinct healthcare needs related to anatomic, physiologic, developmental, psychological, cognitive and behavioural characteristics. A challenge for paediatric nurses is to develop and integrate best research evidence to improve the quality of care for children, adolescents and their families. Utilising findings from research with adults is not always appropriate or optimal to develop best practices for paediatric care. Paediatric clinical research nurses and nurse scientists endeavour to incorporate best practices that integrate the developmental level and health needs of the child and in the context of family-centred care.

Advocacy is an important role of the paediatric nurse working with children research participants. Although a parent or guardian must provide consent for their child to participate in a research study, children should have a voice in the decision to participate. Typically, children from age 7 years are capable of understanding basic information if it is presented at the appropriate developmental level. Nurses should be aware of the legal age of consent under the applicable law of the jurisdiction in which the research will be conducted as well as who is authorised under applicable state or local law to consent on behalf of a child to participate in research (i.e. parent, guardian, legal authorised representative). The priority of human subject's research is protection from undue harm and burden from the research and to support participants (children and their parent/guardian) to make informed decisions about participation in a research study. Children are considered a vulnerable population and special regulatory requirements provide additional protection for the inclusion of children in clinical research. The paediatric nurse must be vigilant to identify possible ethical concerns that may arise in the research process. Also, the paediatric research nurse has a key role to address and monitor safety issues and implement pain prevention or reduction strategies (e.g. blood drawing volumes, exposure to imaging studies involving radiation exposure, use of anaesthesia and procedure-related pain reduction strategies (Refer to Chap. 5)).

Translational research is also needed to develop intervention strategies to improve paediatric nursing practice (i.e. standards of paediatric nursing practice, competencies), which will promote the health of children and adolescents (Christian 2018). In 2014 the American Academy of Nursing endorsed the 'Health Care Quality and Outcomes Guidelines for Nursing of Children, Adolescents, and Families' as a framework for nurse-directed services and intervention development and testing, as well as a model for paediatric nurse education programmes. In addition, a priority to create practice-based child health nursing research networks (PBRN) which are described as 'a network of practice sites that have formed a collaboration with the express purpose to identify, investigate, and disseminate findings associated

with health problems and clinical management and treatment' is promoted in academia as well as in clinical and research settings (Betz 2013). There are child health and nursing based PBRN registered with the Agency for Healthcare Research and Quality (AHRQ) (United States of America (USA)), and this model can be expanded to facilitate the development of evidence-based paediatric nursing practice (https://pbrn.ahrq.gov/about).

69.5.2 Challenges for Clinical Research Nurses and the Benefits

Many challenges face the CRN; however, career defining skills and knowledge are gained, bringing numerous rewards and benefits. Let us review some of these challenges first.

69.5.2.1 Challenges for CRNs

Complex studies: Some challenging studies will certainly require creative thinking and problem solving.

Cross networking: Working with different multidisciplinary teams who all have their own way of doing things requires patience and flexibility.

Time management: Research nurses juggle many different aspects of work and it can be challenging to manage your time efficiently and effectively.

Skills and knowledge gained as a CRN:

Organisational: You will develop your organisational skills and adopt a flexible and adaptable approach.

In-depth knowledge: You will gain a comprehensive understanding of the specialty in which you are working and extensive knowledge of the research process and research-related legislation.

Management: This includes many different aspects of the research study, preparing trial protocols and other trial related documentation, submitting study proposals for regulatory approval and coordinating the initiation, management and completion of the research.

Attention to detail: You will develop a meticulous approach and a high level of integrity for randomisation and for collecting and recording data.

Leaders of research: Research nurses may also act as teachers, mentors and advisers to other health professionals. Some research nurses go on to develop their own research studies and undertake doctoral study.

69.5.2.2 Rewards and Benefits for CRNs

The role is varied and interesting—every day is different from the one before. CRNs take part in a study from start to finish; they hear and learn about a completely new study, enrol patients and are there to see the results that will make a difference to the patient and their families in the future. CRNs are at the frontline of improving patient care, building and maintaining personal effective relationships with patients on a long-term basis; a lot of time is spent with patients one-on-one adding value to interpersonal relationships. CRNs can develop a career pathway, accessing training and supervision within research nursing, to suit their developmental needs. As well as maintaining and building on your existing skills, you will learn many new skills that are transferable too.

Box 69.6 provides an example of endocrinology research phase 11, 111, 1V trials; all these trials include CRN involvement.

Box 69.6 Example of Endocrinology Research Trials

Phase 11 example (Halse et al. 2014)

This study's objective was to identify a dose of MK-5442 that produces osteoanabolic effects without excessive hypercalcemia. The design was a randomised, double-blind, placebo-controlled, parallel-group trial of private or institutional practice. The trial participants were 383 postmenopausal women with osteoporosis who were administered daily oral MK-5442 (2.5, 5, 7.5, 10 or 15 mg) or placebo.

Phase 111 example (Kulke et al. 2016)

This study evaluated telotristat ethyl, a tryptophan hydroxylase inhibitor, to reduce bowel movement frequency in patients with carcinoid syndrome. Patients ($N = 135$) experiencing four or more bowel movements per day, despite stable-dose somatostatin analogue therapy, received (1:1:1) placebo, telotristat ethyl 250 mg, or telotristat ethyl 500 mg three times per day orally during a 12-week double-blind treatment period.

Phase 1V example (Beck-Peccoz et al. 2015)

The PATRO Adults study is a large, multi-centre, longitudinal surveillance study of the diabetogenic potential and overall long-term safety of Omnitrope® for adults with growth hormone deficiency in real-life clinical practice. By January 2015, 855 patients had been recruited to the study; data is collected at each routine visit for treatment with Omnitrope®.

69.5.3 Clinical Research Nurse Role: A Summary

Clinical research is vital for finding new treatments and improving patient care. The CRN requires a thorough understanding of the research process and terminology, and of the specialty under investigation. The CRN acts as an advocate for patients, ensuring they are protected and supported throughout the research study. The CRN requires a wide range of skills, including management and organisation, teaching and mentoring, communication and technology. Working with other researchers and the multidisciplinary team is crucial for successful research.

The role of the CRN is diverse, rewarding and challenging. Managerial tasks and communication with participants, colleagues and study funders must be undertaken alongside the more familiar tasks of patient care and data collection. Assertiveness, determination and commitment are required to maintain high standards of clinical research, patient care and job satisfaction. The competency frameworks bring together the knowledge and skills of the CRN and are designed to be comprehensive, giving an overview of the current expectations of the work of the CRN and at various levels of seniority, and consequently providing a clear structure for career development.

69.6 Ethics in Research Conduct

The principles for conducting research ethically, in particular, that there should be voluntary consent, were established following the adoption of the World Medical Association's Declaration of Helsinki in 1964. This was the first international standard for biomedical research and led to the setting up of processes for research ethics scrutiny. Frameworks for research ethics, and therefore research ethics application documents, are based on the well-established bioethical principles: respect for autonomy, non-maleficence, beneficence and justice (Beauchamp and Childress 2013). Table 69.2 presents these principles with examples applied to research.

Each country has its own systems for research ethics scrutiny, so a nurse involved in research should be familiar with these processes. Although healthcare is devolved in the UK, there is now a UK-wide governance framework (Department of Health (England), the Department of Health (Northern Ireland), the Scottish Government Health and Social Care Directorates and the Department for Health and Social Services (Wales) 2017) The Health Research Authority (HRA) is a national body responsible for governance of research in the National Health Service (NHS). The organisation defines research and provides a decision tool to assist project leads in deciding whether their project is research, from an NHS research ethics perspective or whether it is audit, surveillance, public health or service evaluation, which the HRA states may include service improvement or quality improvement (HRA 2017). If the project does not meet the identified criteria for research, from a governance perspective (randomisation, use of treatment/care

Table 69.2 Bioethical principles (summarised from Beauchamp and Childress 2013)

Ethical principle	Explanation related to research
Respect for autonomy	The right of individuals to make decisions about taking part in research for themselves without coercion or any pressure from others. This principle underpins the necessity for informed consent in research conduct
Non-maleficence	The duty to avoid harm to others. Researchers must identify any potential harm and explain what steps will be taken to prevent, reduce or mitigate potential harm. Any potential harm must be justifiable, balanced against potential benefits of the research
Beneficence	The duty of researchers to conduct studies that are worthwhile and, where possible, to do good. Researchers must therefore justify the need for the research and demonstrate that the study's design is of a high quality, to maximise potential benefits
Justice	Upholding the rights of research participants and ensuring fairness. This principle requires inclusivity, for example, not excluding participants (e.g. those who cannot speak English) without good justification

different from usual standard, intention to derive generalisable new knowledge), then it will not require an NHS research ethics committee review although other local governance processes may be needed within the NHS (HRA 2017). The HRA website includes useful resources about all aspects of preparing a research ethics application, including informed consent, templates for consent forms and patient information sheets and processes to follow when including adults who cannot consent for themselves.

There can be blurring between research and quality improvement and so what ethical processes are necessary is not always clear-cut. The World Health Organisation (2013) recommended independent ethical oversight wherever more than minimum risk is identified, pointing out that no matter how the activity is labelled, whether research or quality improvement, what is important is that people are not subjected to risk, as risks can generally be anticipated and strategies planned to deal with them. Flaming et al. (2009) reported that the Alberta Research Ethics Community Consensus Initiative (ARECCI) network has developed ethics guidelines for quality improvement projects with six considerations; see http://www.aihealthsolutions.ca/arecci/guidelines/ for an online tool with points to consider for each question to assist with screening of level of risk based on responses. Flaming et al. (2009) suggested that anyone conducting quality improvement should use the guidelines from the start of planning their project.

69.7 Conclusions

In this chapter, we introduced evidence-based practice and research, explaining how to access and appraise evidence for endocrinology nursing practice. We discussed the nature of research evidence and the contribution of different types of research studies to the evidence base for practice. We considered how best evidence can be implemented in practice, with an example of applying quality improvement methods in practice. Nurses are in an ideal position to identify gaps in the available evidence and propose new research questions. Clinical academic roles provide the opportunity for nurses to address gaps in the evidence base and combine clinical nursing with research. We explained the benefits of clinical academic roles and the career and training pathways available for nurses. Clinical research is vital for finding new treatments and improving patient care. The role of the clinical research nurse is diverse, rewarding and challenging, and requires assertiveness, determination and commitment to maintain high standards of clinical research and patient care. All research must be conducted in accordance with international standards for research ethics and follow local processes for ethical scrutiny.
