One-step syntheses of aminosugars

The three-component Mannich reactions with various donor aldehydes have been studied also by Hayashi and co-workers [164], giving rise, after reduction, to several aminopolyols with high *syn*-diastereo and enantioselectivities.

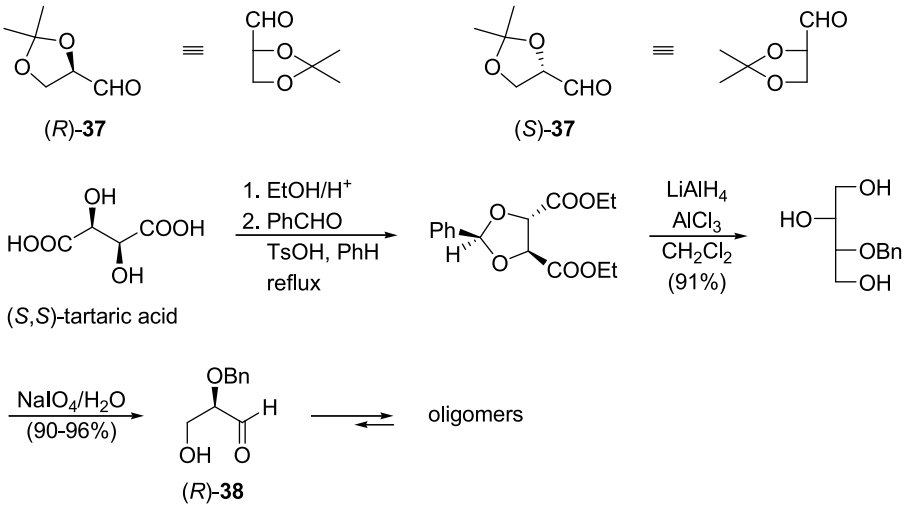
5 Chain Elongation of Aldehydes through Nucleophilic Additions

Chemical asymmetric cross-aldol condensations using enantiomerically pure Lewis acids as promoters (instead of an aldolase or α-aminoacid) have been applied to prepare monosaccharides and analogs [165,166]. If enantiomerically pure aldehydes (such as diol-protected D- or L-glyceraldehyde) are available, they can be chain-elongated by one, two, or more

carbon centers with high diastereoselectivities. The classical Kiliani–Fischer cyanohydrin synthesis [167,168,169] is a milestone in carbohydrate chemistry and has been used in numerous applications [170,171]. Nevertheless, diastereoselectivity of the nucleophile addition is often low and the harsh reaction conditions that are required to reveal the chain-elongated aldose from either their aldonic acid or directly from the cyanohydrin are serious drawbacks. Currently, there are many more flexible methods to carry out one-carbon homologations of aldehydes, including the reductive end of aldoses that will be presented below. Aldehyde allylation with allyl boronates [172,173,174,175] or with allylstannanes [176,177,178] emerge as quite useful because of their high diastereoselectivity and the diversity of modifications that can be applied to the allylic alcohols. With achiral aldehydes enantiomerically pure allylic and allenyl stannanes can be used in the asymmetric synthesis of monosaccharides and analogs [176,177,178,179].

5.1 Total Synthesis of D- and L-Glyceraldehyde and other C-3 Aldose Derivatives

The acetonide of D-glyceraldehyde (*R*-**37**: (*R*)-2,3-*O*-isopropylidene-D-glyceraldehyde) is most simply obtained from D-mannitol. D-glyceraldehyde has been derived also from D-fructose, L-glyceraldehyde from L-sorbose [180]. The acetonide of L-glyceraldehyde ((*S*)-**37**, (*S*)-2,3-*O*-isopropylidene-L-glyceraldehyde) is usually derived from ascorbic acid [181]. The aldehydes (*R*)-**37** and (*S*)-**37** are not very stable as monomers and undergo racemization on storage. Derivative (*R*)-**38** (2-*O*-benzylglyceraldehyde) has been proposed as an alternative to (*R*)-**37**. It is obtained from (*S*,*S*)-tartaric acid as shown in ● *Scheme 33* [182].

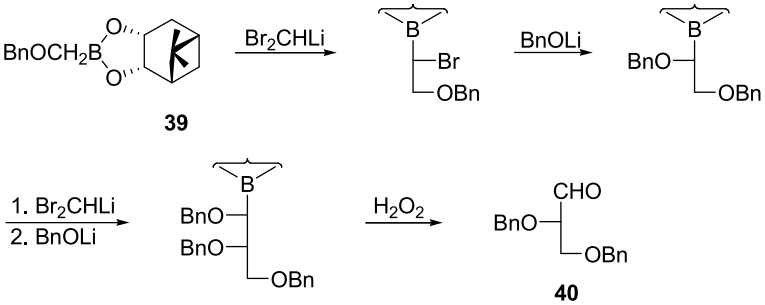


Scheme 33
Synthesis of 2-*O*-benzyl-D-glyceraldehyde

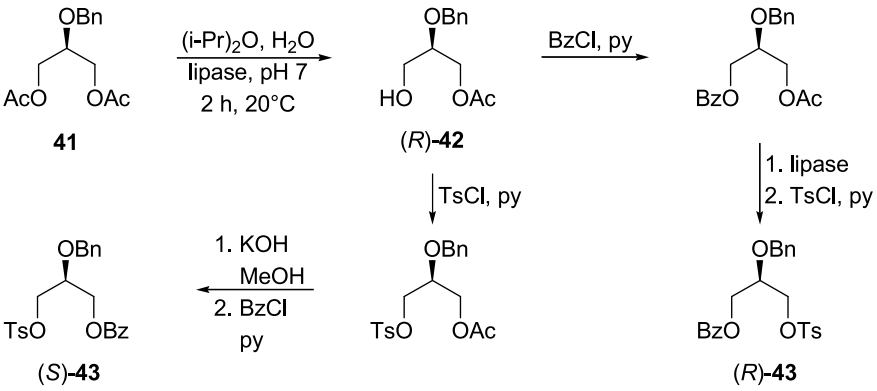
Enantiomer (*S*)-**38** can be derived from (*R*,*R*)-tartaric acid in the same way. (*R*,*R*)-Tartaric acid is obtained in large quantities from potassium hydrogen tartrate, a waste product of wineries. Racemic tartaric acid is synthesized [183] on a large scale from maleic anhydride and H_2O_2. Its resolution is carried out either by crystallization, or by enzymatic or microbiological enantiodifferentiating conversions. Thus, both (*S*,*S*)- and (*R*,*R*)-(−)-tartaric acid are supplied by the industry inexpensively [184].

Chain extension using an insertion reaction of dichloromethyllithium or dibromomethyllithium with (*S*)-pinanediol (via [(benzyloxy)methyl]boronate **39**) has been used to generate L-C_3, L-C_4, and L-C_5-aldoses [185]. In order to obtain 2,3-*O*-dibenzyl-L-glyceraldehyde **40**, the insertion reaction has to be applied twice (◉ *Scheme 34*). By repeating the process two more times, L-ribose has been prepared in this way with high enantiomeric purity [185].

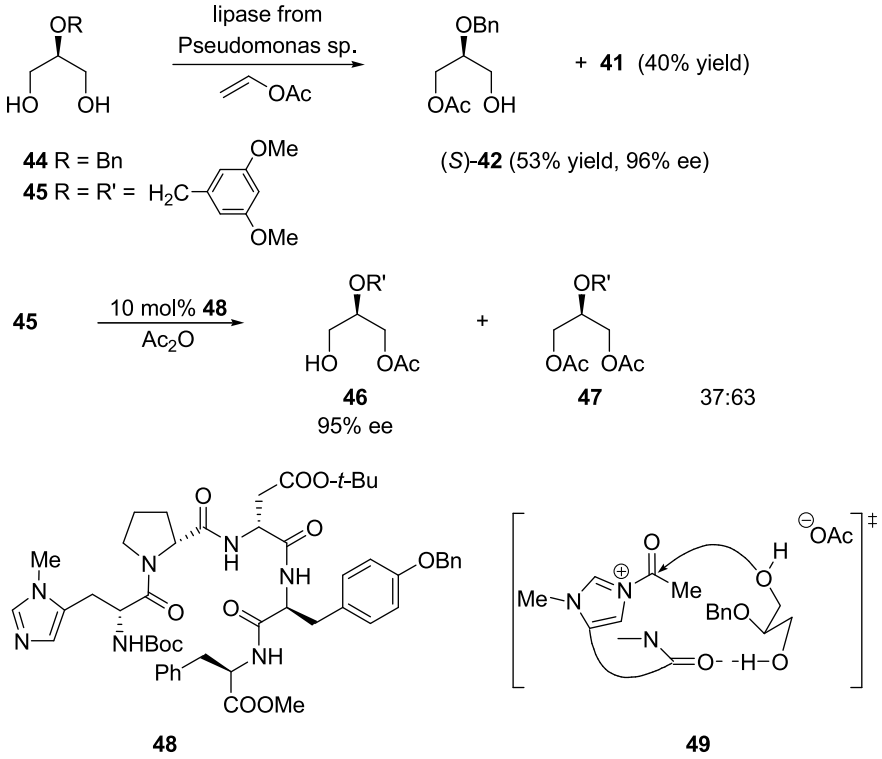
The synthesis of 3-*O*-methyl-D-glyceraldehyde starts with D-fructose [186]. The preparation of 2-*O*-methyl-D-glyceraldehyde and 2-*O*-benzyl-D-glyceraldehyde ((*R*)-**38**) starts from D-mannitol [187]. Enantiomerically pure derivatives of glycerol can be prepared on a large scale through the lipase (pig pancreas, EC 3.1.1.3)-catalyzed hydrolysis of prochiral



Scheme 34
Asymmetric chain elongation of dibromomethyllithium



Scheme 35
Desymmetrization of *meso*-diacetate by lipase-catalyzed hydrolysis synthesis of C_3-alditol derivatives



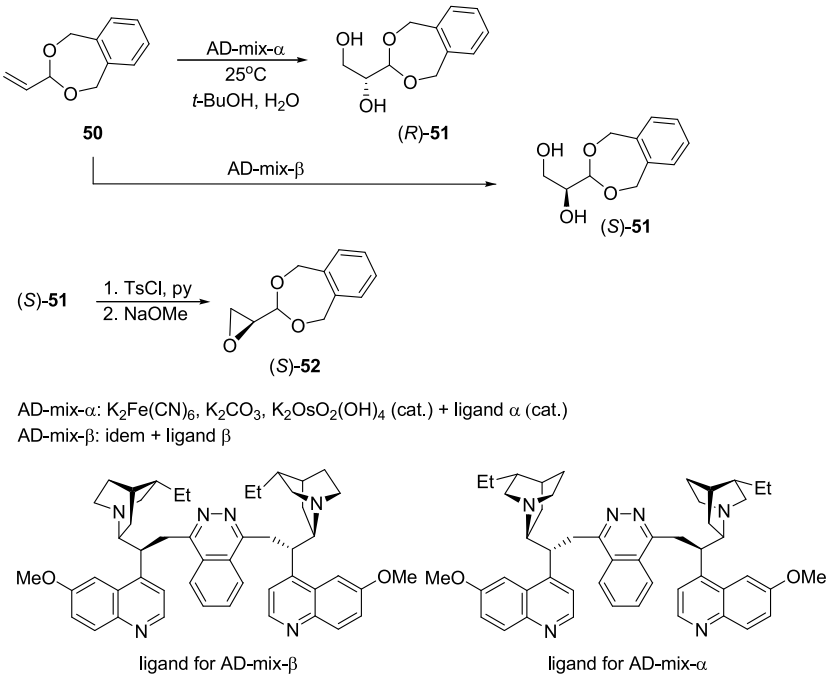
Scheme 36
Peptides as catalysts for enantioselective acetylation of alcohols

diacetate **41**. The procedure gives (*R*)-**42** (45% yield, 88% ee) which can be converted into crystalline derivative (*R*)-**43** or (*S*)-**43** (>99% ee) as shown in *Scheme 35* [188].

Instead of applying enantioselective hydrolysis of *meso* diacetates monoacetylation of *meso*-diols can generate enantiomerically enriched monoesters. The catalyst can be an esterase in vinyl acetate (e. g. **44** → (*S*)-**42**) or a short peptide derivative (e. g. **45** → **46** catalyzed by **48**) as shown in *Scheme 36*. Transition state **49** has been proposed for the asymmetric monoacetylation of diol **45** with acetic anhydride catalyzed by peptide **48** [189].

The (*R*)- and (*S*)-benzyl epoxypropyl ether have been derived from *O*-benzyl-L-serine [190]. Stable and easily-handled protected forms of L- and D-glyceraldehyde are obtained by the Sharpless asymmetric dihydroxylation of the benzene-1,2-dimethanol acetal (**50**) of acrolein (*Scheme 37*). The method produces either diol (*R*)-**51** or (*S*)-**51** with 97% ee after recrystallization from benzene. These diols can be converted into useful C-3 chiral building blocks, for instance epoxides (*R*)-**52** and (*S*)-**52**, respectively [191].

Derivatives of D- and L-glyceraldehydes such as 2-amino-2-deoxyglyceraldehyde (serinal), 3-deoxyglyceraldehyde (2-hydroxypropanal), and 2,3-dideoxy-2-aminoglyceraldehyde (2-aminopropanal) are used extensively to construct rare monosaccharides and analogs through chain-elongation applying nucleophilic addition to their carbonyl moiety. Semi-



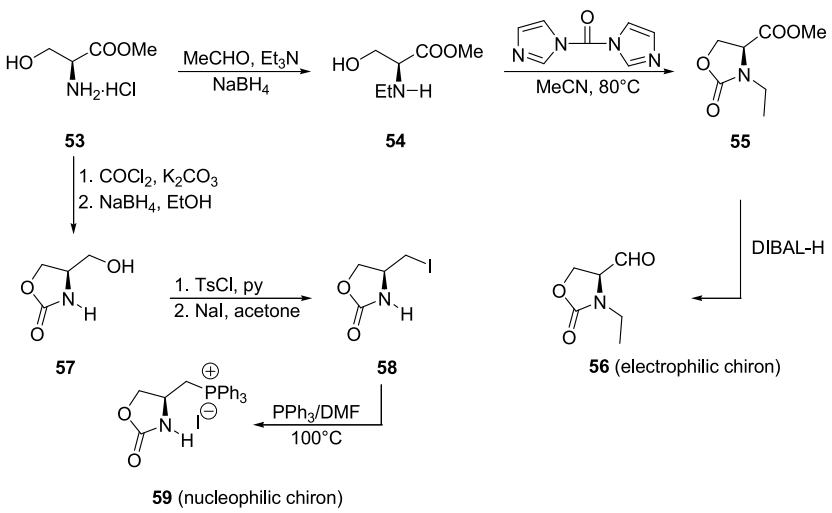
Scheme 37
Sharpless asymmetric dihydroxylation applied to the syntheses of C_3-sugar precursors

protected (*R*)- and (*S*)-2-hydroxypropanols are most simply derived from the readily available D-(−)-lactic and L-(+)-lactic acids, respectively [192]. (*S*)-2-Benzyloxypropanal can be obtained via benzylation of ethyl L-lactate, followed by reduction with $LiAlH_4$ and Swern oxidation. *N*-(*t*-Butoxycarbonyl)-L-alaninal can be obtained with high enantiomeric purity by $LiAlH_4$ reduction of the *N*-methoxy-*N*-methyl-α-(*t*-butoxycarbonylamino)carboxamide of alanine [193]. Alternatively, *N*-9-(9-phenylfluorenyl)-L-alaninal has been derived from L-alanine [194].

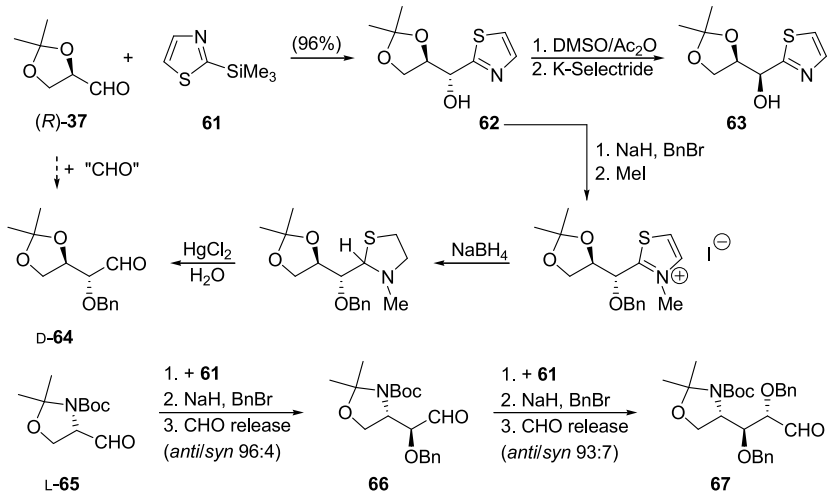
The *N*-ethyloxazolidinone **56** (◉ *Scheme 38*) is obtained from L-serine by treating (*S*)-serine methyl ester hydrochloride with Et_3N, acetaldehyde, and $NaBH_4$ to give *N*-ethylamine **54**. Oxazolidinone formation with carbonyldiimidazole leads to **55**, the reduction of which generates aldehyde **56** [195]. A nucleophilic alaninol synthon **59** has been derived from **53** by protection of the alcohol and amine moieties as a carbamate obtained by treatment with phosgene. Reduction of the ester gives the corresponding alaninol **57** which is tosylated, then displaced successively with iodide and triphenylphosphine to generate **59** (◉ *Scheme 38*) [196].

5.2 One-Carbon Homologation of Aldoses: the Thiazole-Based Method

Dondoni and co-workers [197,198,199,200,201,202,203,204,205,206] have shown that homologation of α-hydroxycarbaldehydes and α-hydroxylactones can be achieved with high



Scheme 38
Synthesis of electrophilic and nucleophilic C_3-chiron containing masked 2-amino moieties



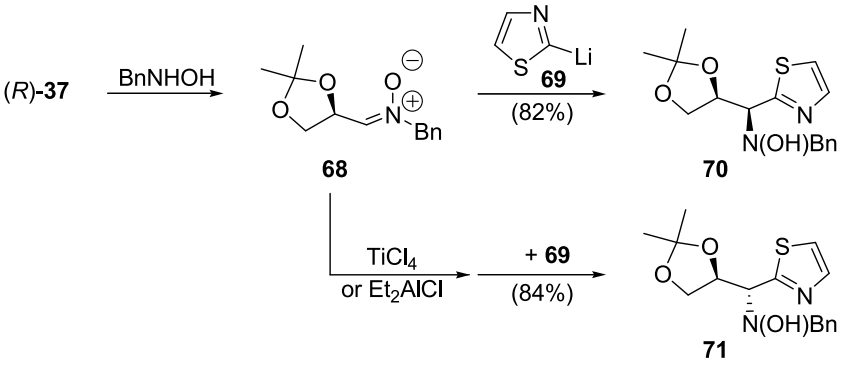
Scheme 39
Dondoni's one-carbon chain elongation

anti-selectivity by addition of 2-(trimethylsilyl)thiazole (**61**) (*Scheme 39*). For instance, D-glyceraldehyde (*R*)-**37** reacts with **61** giving **62** in 96% yields and *anti* vs. *syn* diastereoselectivity better than 95:5. Release of the carbaldehyde moiety requires protection of the alcohol as a benzyl ether, methylation of the thiazole to generate intermediate **63** that is not isolated but reduced in situ with $NaBH_4$ to give the corresponding thiazoline. Mercury(II)-

catalyzed hydrolysis liberates the semiprotected D-erythrose derivative D-**64** in 62% overall yield [207]. Methylation of the thiazole moiety can use methyl triflate instead of MeI, and copper(II) chloride can be used instead of mercury(II) chloride [208]. The iterative addition and unmasking protocols were repeated over several consecutive cycles so that the chain elongation of the triose (*R*)-**37** was brought up to a nonose derivative with all-*anti* configuration of the polyol.

For the preparation of *syn* isomers, alcohol **62** has to be oxidized into the corresponding ketone, which is reduced with K-Selectride into the *syn* isomer **64**. The α-amino aldehyde L-**65**, derived from L-serine, was converted into aminotetrose and pentose derivatives **66** and **71**, respectively. The *anti* diastereoselectivity observed for **67** of **61** to the *N*,*N*-diprotected α-amino aldehyde L-**65** can be reversed to *syn* selectivity by using a *N*-monoprotected derivative [209,210].

The reactions of *N*-benzylnitrone **68** derived from D-glyceraldehyde acetonide (*R*)-**37** with 2-lithiothiazole (**69**) gives the *syn* adduct **70** with 92% diastereoselectivity. Interestingly, the same reaction applied to **69** precomplexed with Et_2AlCl or $TiCl_4$ gives the *anti* diastereomer **71** preferentially in high yield. The method has been applied to the synthesis of all kinds of aminosugars including D-nojirimycin [204,211,212,213].

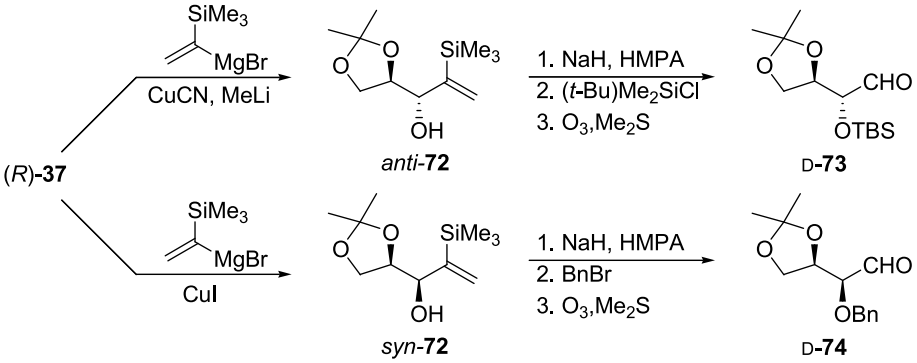


Scheme 40
Dondoni's synthesis of amino sugars

5.3 Other Methods of One-Carbon Chain Elongation of Aldoses

An alternative method (*Scheme 41*) for the homologation of D-glyceraldehyde derivative (*R*)-**37** to derivatives of D-erythrose D-**73** and D-threose D-**74** has been proposed by Kusakabe and Sato [214]. Reaction of (*R*)-**37** with appropriate 1-(trimethylsilyl)vinyl-copper reagents leads to either *anti* or *syn* stereoselective adducts *anti*-**72** *anti* (*anti*/*syn* 20:1) or *syn*-**72** *syn* (*syn*/*anti* 98:2) in 87% yield. Alcohol protection, followed by ozonolysis furnishes D-**73** and D-**74**, respectively.

The nitroaldol condensation with nitromethane (Henry's reaction), followed by Nef decomposition of the resultant nitronate under strongly acidic conditions has been used to elongate aldehydes. For instance, *N*-acetyl-D-mannosamine has been converted into *N*-acetylneu-



Scheme 41
***Anti* and *syn* diastereoselective vinylations of D-glyceraldehyde acetonide**

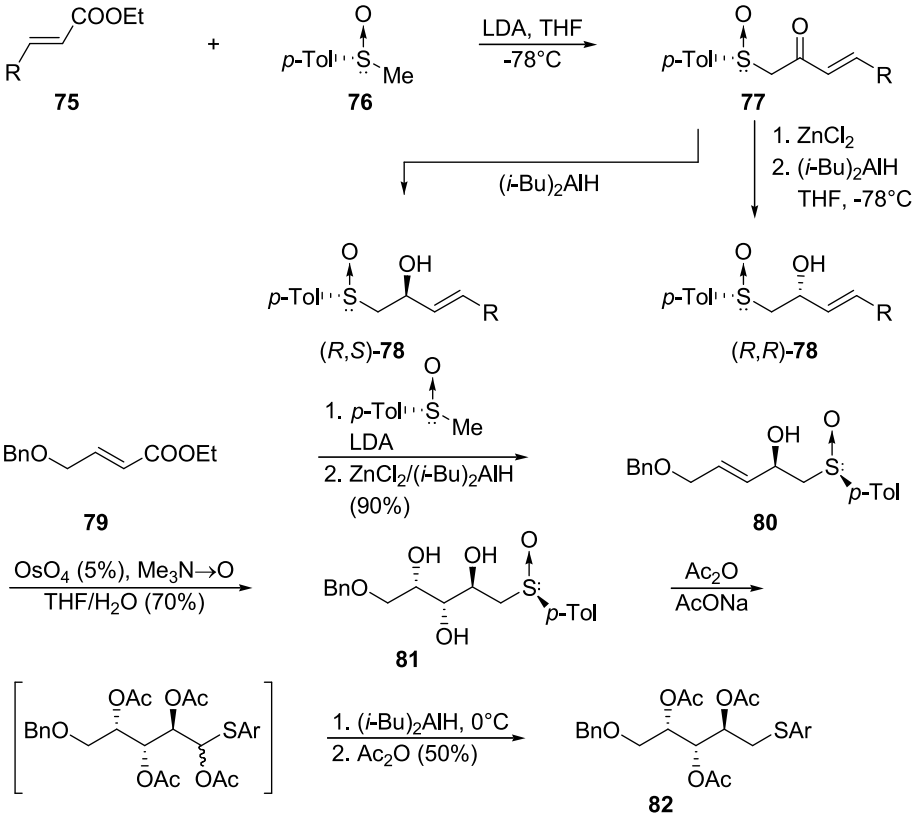
raminic acid applying this method iteratively [215]. Et_3N-catalyzed addition of CH_3NO_2 to 1,4:3,6-dianhydrofructose and subsequent Pd-C-catalyzed hydrogenation afforded 2-*C*-aminomethyl-1,4:3,6-dianhydromannitol [216]. Chikashita and co-workers [217] have reported good levels of *anti* diastereoselectivity better than 99% in an iterative *syn*-selective homologation sequence using 2-lithio-1,3-dithiane [218,219] with 2,3-*O*-cyclohexylidene-D-glyceraldehyde. Addition of MeMgI to sugar-derived aldehydes is highly diastereoselective when the aldehyde is precomplexed with $ZnCl_2$ in CH_2Cl_2/Et_2O at –78 °C. The alcohol so-obtained gives access to L-fucose, 1,5-dideoxy-1,5-imino-L-fucitol, and 5-thio-L-*fuco*pyranose [220].

The one-carbon elongation of aldoses to ketoses using iodomethyllithium adding to the corresponding aldonolactones has been used by Bessières and Morin to convert D-mannose into D-*manno*-hept-2-ulose, and L-arabinose into L-fructose [221]. The addition of Grignard reagent to lactols or aldehydes derived form D-glucose, or D-mannose, has allowed the preparation of higher-carbon sugars [222]. Syntheses of 3-deoxy-2-ulosonic acids have utilized the reactions of ketene dithio-acetals obtained via Horner–Emmons or Peterson olefination of 2-deoxy-1,5-hexono-lactones [223]. Wittig methylenation of 2,3,4-tri-*O*-benzyl-6-*O*-(4-methoxybenzyl)-D-glucopyranose gives an enitol that is converted into 7-*O*-(4-methoxybenzyl)-4,5-di-*O*-benzyl-3,6-anhydro-L-*ido*-hept-1-enitol. Further steps generate (3*S*,4*R*,5*S*)-3,4-dibenzyloxy-2-methylidene-5-vinyltetrahydrofuran. The latter allyl-vinyl ether is isomerized into a mixture of (1*R* and 1*S*,2*R*,3*S*)-1-hydroxy-2,3-dibenzyloxycyclohept-4-ene on treatment with $(i\text{-}Bu)_3Al$ in CH_2Cl_2 [224]. Wittig methylenation of 2,3-*O*-isopropylidene-D-ribofuranose and subsequent Malaprade oxidation ($NaIO_4/H_2O/CH_2Cl_2$) gives a γ,δ-unsaturated aldehyde that generates L-ribose after alkene dihydroxylation and acetonide hydrolysis [225]. L-apiose has been obtained following a similar synthetic procedure [225].

5.4 Additions of Enantiomerically Pure One-Carbon Synthon

The addition of (+)-(*R*)-methyl *p*-tolylsulfoxide (**76**) to carboxylic esters gives the corresponding β-ketosulfoxides. When applied to α,β-unsaturated esters **75**, the ketosulfoxides **77** so-obtained are reduced with high diastereoselectivity with $LiAlH_4$ or $(i\text{-}Bu)_2AlH$

(DIBAL-H) giving optically β-hydroxy sulfoxides such as (*R*,*S*)-**78** and (*R*,*R*)-**78** [226]. When applied to ester **79**, this method generates allylic alcohol **80** that undergoes highly diastereoselective osmium-catalyzed dihydroxylation giving **81**. A Pummerer rearrangement and subsequent reduction with $(i\text{-Bu})_2$AlH and acetylation furnish the L-arabinitol derivative **82** (Scheme 42) [227].

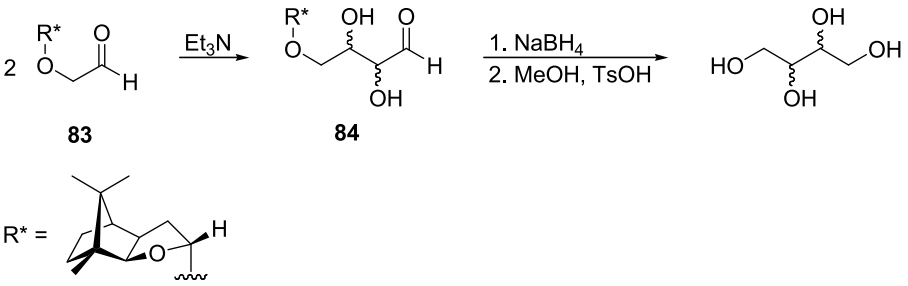


Scheme 42
Asymmetric synthesis of L-arabinitol derivatives via stereoselective dihydroxylation of an enantiomerically pure allylic alcohol

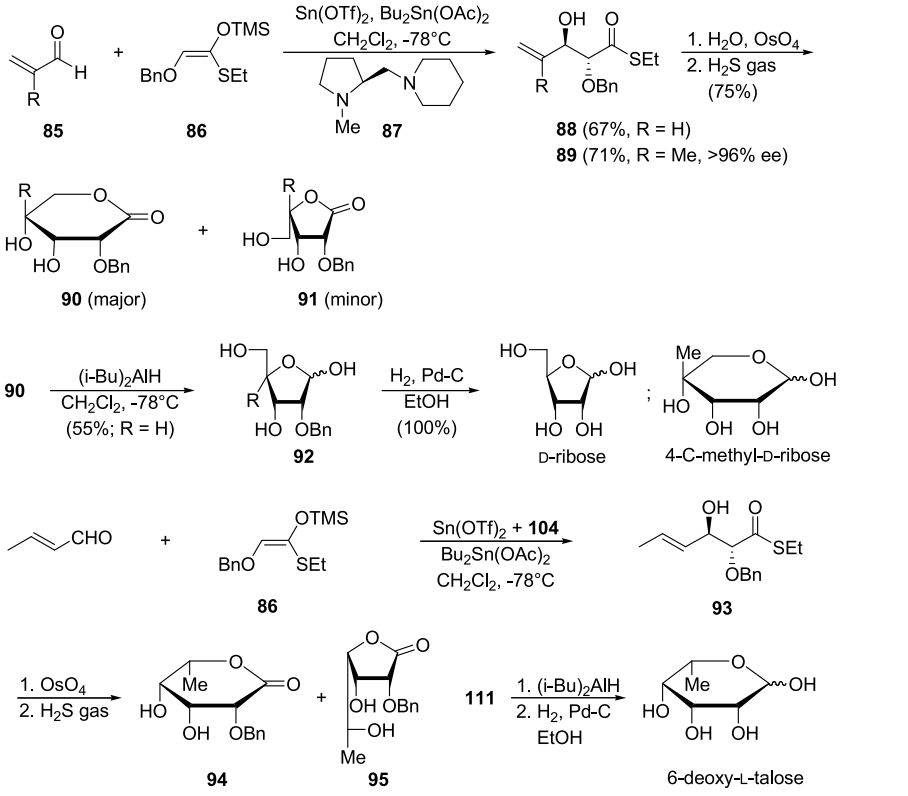
5.5 Two-Carbon Chain Elongation of Aldehydes

5.5.1 Asymmetric Aldol Reactions

Enantiomerically pure glycolaldehyde derivatives **83** undergo aldol condensations in the presence of Et_3N giving mixtures of erythrose and threose derivatives **84** (Scheme 43) for which the erythrose/threose ratio reaches 58:42 and the L/D ratio 62:38 [228,229].

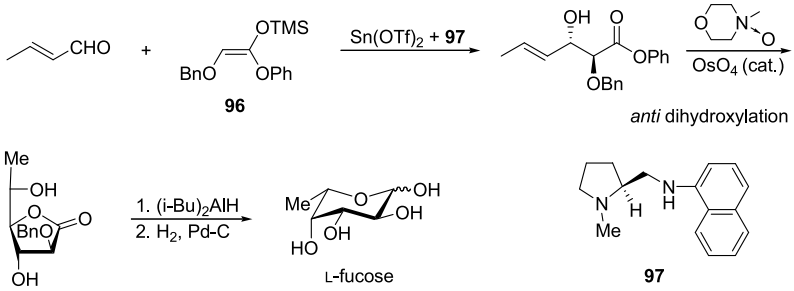


Scheme 43
Asymmetry induced by chiral auxiliary in the aldol condensation of glycoaldehyde



Scheme 44
Mukaiyama's asymmetric aldol reactions: total synthesis of D-ribose, 4-*C*-methyl-D-ribose, and 6-deoxy-L-talose

A very elegant asymmetric synthesis of D-ribose from achiral starting materials has been presented by Mukaiyama and co-workers [165]. It is based on the cross-aldolization of crotonaldehyde (**85**, R = H) and enoxysilane **86** in the presence of an enantiomerically pure diamine **87**, the chiral inducer (*Scheme 44*). High diastereoselectivity (*anti*/*syn* > 98:2) and high



Scheme 45
Kobayashi's total synthesis of L-fucose

enantioselectivity (>97% ee for *anti* aldol) are observed. The *anti*-aldol **88** is then doubly hydroxylated with moderate facial selectivity to give a 72:28 mixture of aldonolactones **90** and **91**. Reduction of the major lactone **90** provides **92**, the debenzylation of which furnishes D-ribose. The same method has been applied to prepare 4-*C*-methyl-D-ribose and 6-deoxy-L-talose starting with methacrolein (**85**, R = Me) and (*E*)-but-2-enal ((*E*)-crotonaldehyde), respectively (*Scheme 44*) [230,231].

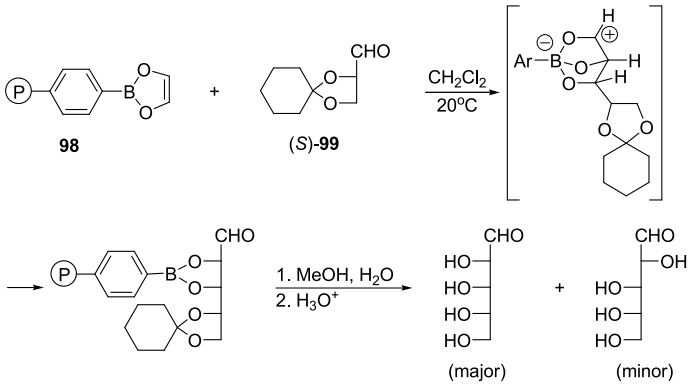
Applying an analogous method, Kobayashi and Kawasuji [166] have prepared L-fucose from (*E*)-crotonaldehyde and the benzyloxyketene acetal **96** in four steps and 49% overall yield (*Scheme 45*). The asymmetric aldol condensation is catalyzed by a complex made of $Sn(OTf)_2$ and chiral diamine **97**.

5.5.2 Nucleophilic Additions to Enantiomerically Pure Aldehydes

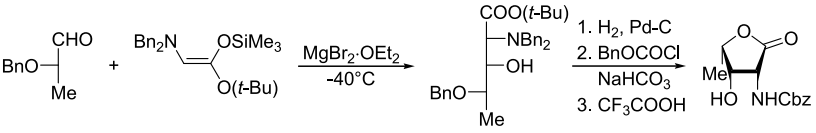
Mukaiyama and co-workers have pioneered many routes to the total syntheses of rare carbohydrates such as the 2-amino-2-deoxypentoses. In 1982 they reported that the potassium enolate derived from the magnesium salt of a (*R*)-atrolactic acid derivative adds to 2,3-*O*-isopropylidene-D-glyceraldehyde in a highly stereoselective manner giving, after alcohol protection, imine hydrolysis and amine protection, a D-arabinopentonate derivative [231]. Further elaboration leads to 2-acetamido-2-deoxy-D-arabinose. In a similar fashion, starting from (*S*)-atrolactic acid, 2-acetamido-2-deoxy-D-ribose has been prepared [232,233,234,235,236].

Several syntheses of aminodeoxypentoses have employed a similar approach in which a three-carbon starting material is condensed with a two-carbon entity [237]. A synthetic equivalent of the glycoaldehyde anion, the dioxaborole **98** (*Scheme 46*) has been used for the carbon chain elongation of aldehydes. Thus L-ribose is prepared from the addition of 2,3-*O*-cyclohexylidene-L-glyceraldehyde (*S*)-**99** to **98**. Double addition and higher addition reaction to yield polymers is alleviated by using a polymer-supported reagent [238].

Ethyl (*S*)-lactate has been the primary source of chirality in several syntheses of aminodeoxycarbohydrates. The derivative **101** of 2-amino-2-deoxy-L-lyxonic acid is the major product of condensation of 2-*O*-benzyl L-lactaldehyde with silyl ketene acetal **100**. The derived ester **101** can be converted into lactone **102** (*Scheme 47*) [239] an intermediate for the synthesis of L-daunosamine and L-vancosamine [240,241]. L-Mannose and L-altrose



Scheme 46
Synthesis of L-ribose with a polymer-supported glycoaldehyde anion equivalent



Scheme 47
Synthesis of a 2,5-dideoxy-2-aminoaldonolactone

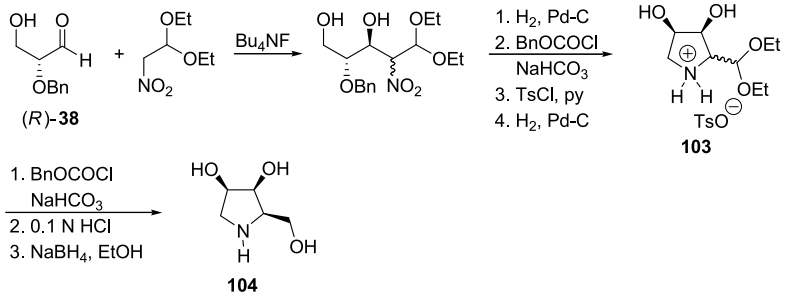
derivatives have been derived from 2,3-*O*-isopropylidene-L-glyceraldehyde via its reaction with 3-C-lithiated 5,6-dihydro-1,4-dithiine-2-yl[(4-methoxybenzyl)oxy]methane [242]. The same approach combining this organolithium reagent with (*R*)-benzyl gylcidyl ether leads to 4-deoxy-L-hexose derivatives [243].

5.5.3 Nitro-Aldol Condensations

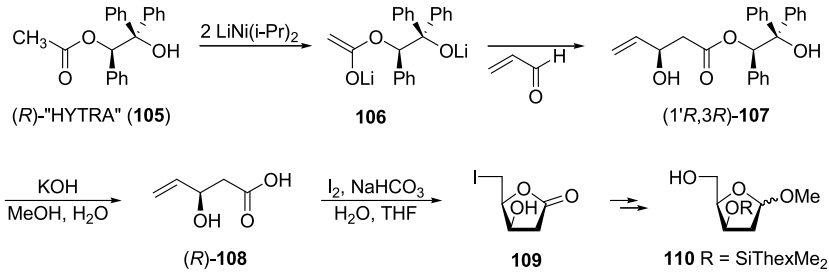
The syntheses of D- and L-2-amino-2-deoxy-arabinose and of 1,4-dideoxy-1,4-imino-D-lyxitol **104** have been achieved via the nitro-aldol condensation (Henry's reaction) of 2-*O*-benzyl-D-glyceraldehyde (*R*)-**38** and the diethyl acetal of nitroacetaldehyde (*Scheme 48*) which gives a 88:12 mixture of the *arabino* and *ribo*-adducts. Their reduction and subsequent protection of the amines so-obtained, then selective tosylation of the primary alcohol and hydrogenolysis gives **103**, which is then converted into **104** [244].

5.5.4 Nucleophilic Additions of Enantiomerically Pure Enolates

Braun's enantiomerically pure acetate **105** ((*R*)-"HYTRA") [245] can be converted to the lithium enolate **106**. Subsequent addition to acrolein predominantly gives (1′*R*,3*R*)-**107** (diastereoselectivity: 92:8). Alkaline hydrolysis of (1′*R*,3*R*)-**107** provides (*R*)-**108** with 83% ee (*Scheme 49*). On treatment of (*R*)-**108** with (*S*)-1-phenylethylamine and recrystallization,



Scheme 48
Synthesis of 1,4-dideoxy-1,4-imino-D-lyxitol



Scheme 49
Diastereoselective addition aldol reaction with (*R*)-"HYTRA"

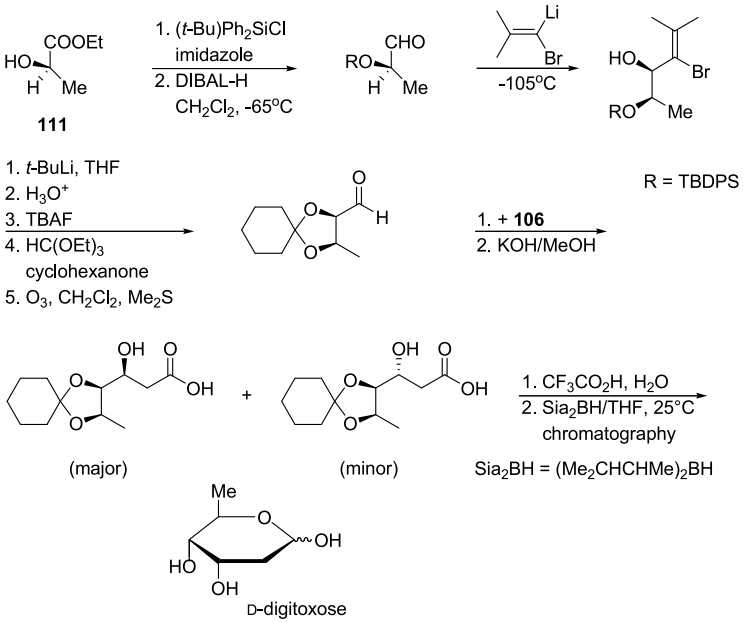
(*R*)-**108** is isolated in 42% overall yield and >99% ee. This compound has been converted into **109** by iodolactonization. It is a precursor of all kinds of 2-deoxyfuranosides [246].

D-Digitoxose, a component of cardiac glycosides found in *Digitalis purpurea* and other higher plants, can be prepared following a similar method starting from ethyl (*R*)-lactate (**111**) and (*R*)-HYTRA (*Scheme 50*) [247].

The chiral titanated bislactim ether **112** undergoes 1,2-addition to α,β-unsaturated aldehydes. With methacrolein it gives adduct **113**, the epoxidation of which and subsequent hydrolysis forms the branched-chain amino-acid derivative **114** (*Scheme 51*) [248].

The phenylalanine-derived oxazolidinone **115** undergoes a diastereoselective aldol reaction with crotonaldehyde to give the *syn* product **116**. Formation of the Weinreb amide, followed by silylation of the crude secondary alcohol provides **117**. The chiral auxiliary is recovered at this stage. Product **117** is a potential precursor of all kinds of monosaccharides and analogs, including of 1-deoxynojirimycin (*Scheme 52*) [249].

The C_{33}–C_{37}-unit of (+)-calyculin A (a marine natural product) is an amide derived from 5-*O*-methyl-4-deoxy-4-dimethylamino-D-ribonic acid that has been prepared by Evans and co-workers [250]. *N*-Protection of sarcosine as benzyl carbamate affords acid **118** which is activated and used to *N*-acylate the (*S*)-phenylalanine-derived oxazolidinone. This gives **119** that is methoxymethylated diastereoselectively (98:2) to give **120**. Reductive removal of the chiral auxiliary, followed by Swern oxidation forms aldehyde **121** with little racemization if



Scheme 50

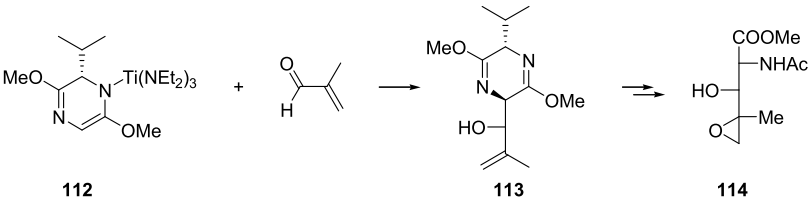
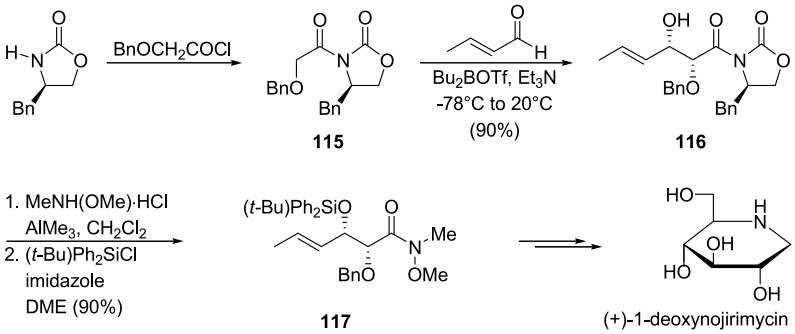
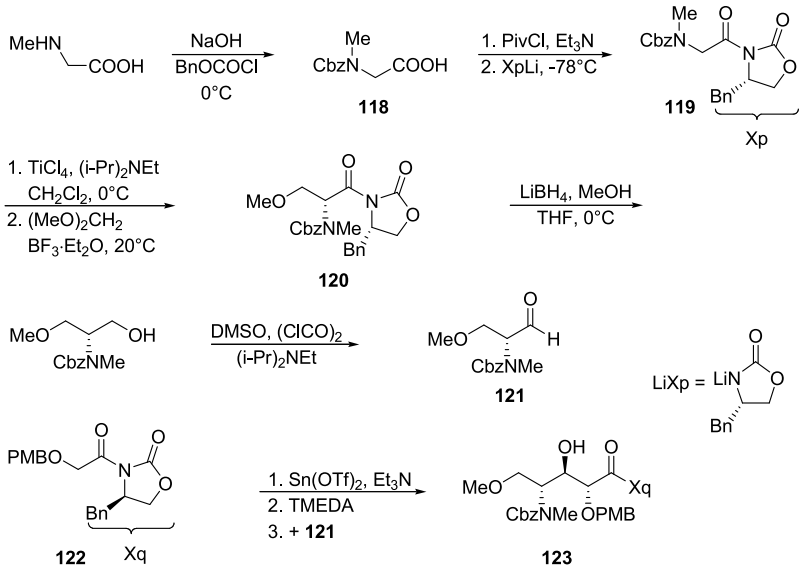


Scheme 51
Use of an enantiomerically pure bislactim ether



Scheme 52
Use of an Evans' homochiral enolate



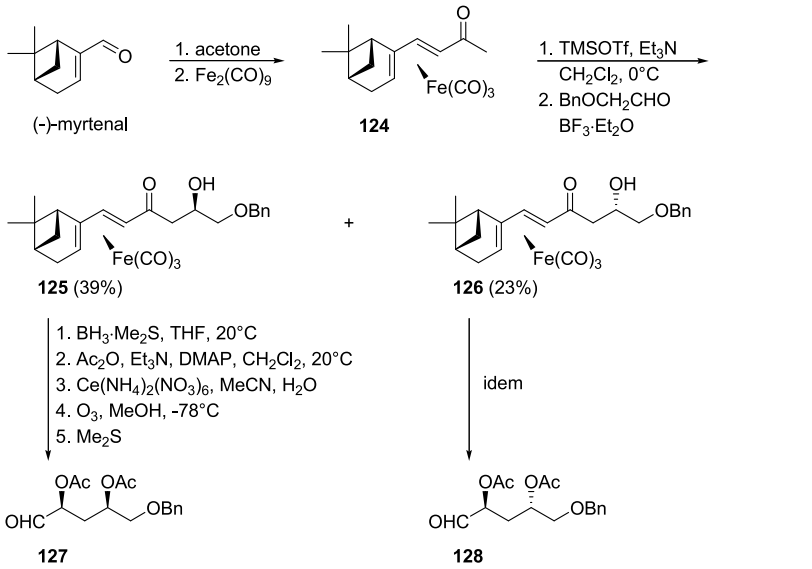
Scheme 53
Synthesis of a 4-deoxy-4-dimethylamino-D-ribonic acid derivative

the Hünig base (*i*-Pr$_2$NEt) (i-Pr = isopropyl) is used instead of the usual Et$_3$N. Enolization of imide **122**, followed by addition of tetramethylethylenediamine and then of aldehyde **121** gives rise to the *anti*-aldol **123** (60%) accompanied by 24% of other diastereomers (*Scheme 53*). Compound **123** has been used for amide formation with primary amines.

An enantioselective synthesis of 3-deoxypentoses from (−)-myrtenal has been proposed by Franck-Neumann and co-workers (*Scheme 54*) [251]. It features the Mukaiyama cross-aldolization of benzyloxyacetaldehyde and the tricarbonyliron complex **124** derived from the condensation of (−)-myrtenal with acetone. The diastereomeric aldols **125** and**126** are separated and converted (*Scheme 54*) into 3-deoxypentoses **127** and **128** [251].

Enders and Jegelka [252,253] have used 1,3-dioxan-5-one **25** to construct enantiomerically pure C$_5$- to C$_9$-deoxycarbohydrates. For example, reaction of **25** with SAMP [(*S*)-(−)-amino-2-(methoxymethyl)pyrrolidine] gives hydrazone **129** which is deprotonated and alkylated with methyl iodide to yield **130**. The monoalkylated hydrazone is then alkylated in the same manner with chloromethyl benzyl ether to form **131**. Cleavage of the hydrazone with ozone furnishes the protected ulose **132** (>98% de, >98% ee) which is deprotected to (−)-5-deoxy-L-*threo*-3-pentulose **133**. Reduction of **132** with L-Selectride and subsequent deprotection provides 5-deoxy-D-arabinitol (>95% de, >95% ee) (*Scheme 55*).

Seeberger and co-workers [254] have reacted ester **134** with acetaldehyde using a lithium salt of 2,2,4,4-tetramethylpiridine (LTMP; lithium 2,2,6,6-tetramethylpiperidide) as the base. This gives a 4:1 mixture of diastereomers, the major of which was treated with PhI(C(O)CF$_3$)$_2$ and then with aqueous CF$_3$COOH to generate L-aceric acid methyl ester **135** (*Scheme 56*).



Scheme 54

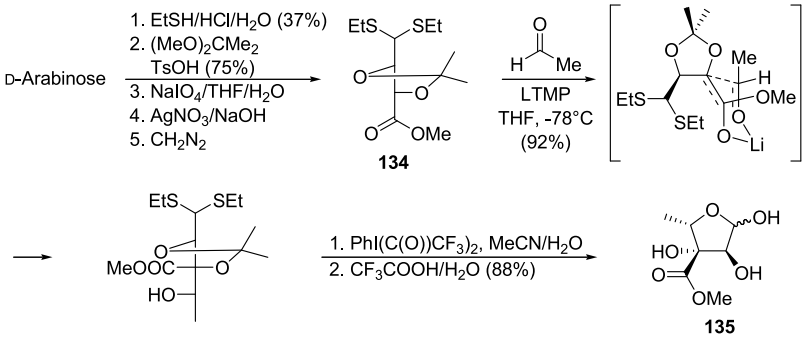
Enders' synthesis of 5-deoxy-D-arabinitol

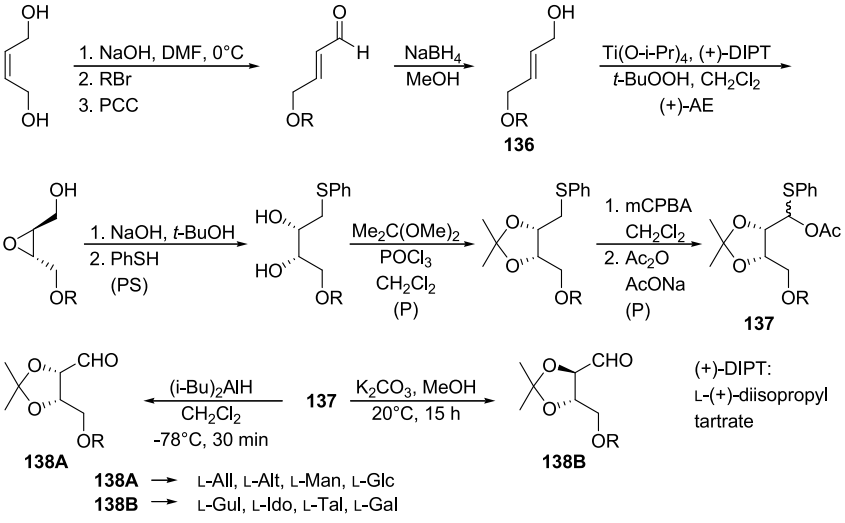


Scheme 56
Synthesis of aceric acid methyl ester

5.5.5 Aldehyde Olefination and Asymmetric Epoxidation

Wittig olefination of D- or L-glyceraldehyde acetonide with $Ph_3P{=}CHCHO$ gives, after reduction of the enal with diisobutylaluminum hydride, (*E*)-allylic alcohols that undergo Katsuki–Sharpless enantioselective epoxidation [255,256,257]. The method has been applied to prepare D-arabinitol (=D-lyxitol) and ribitol (a *meso* alditol) and D-arabinitol (or xylitol, another *meso* alditol) [258].

The Katsuki–Sharpless asymmetric epoxidation of (*E*)-allylic alcohols is the key-step in the total synthesis of all tetroses and hexoses developed by Sharpless and Masamune [259,260] and that are summarized in *Scheme 57* for the L-series. The epoxide obtained by oxidation of



Scheme 57
Sharpless and Masamune's syntheses of tetroses and hexoses

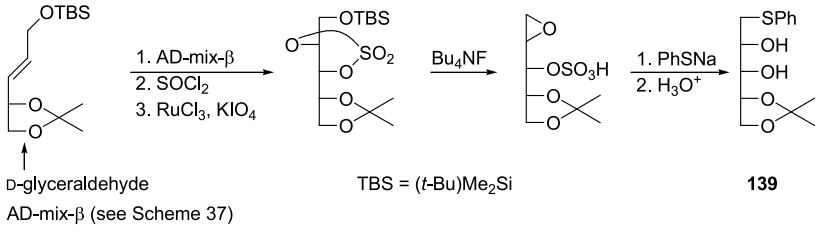
the allylic alcohol **136** undergoes a Payne rearrangement in the presence of NaOH, giving terminal epoxides that open regioselectively by PhSNa to give the corresponding phenylsulfide. After protection of the diol as acetonide, the sulfides are oxidized with metachloroperbenzoic acid into the corresponding sulfoxides that undergo Pummerer rearrangement on treatment with Ac_2O and AcONa liberating, after hydrolysis, the corresponding tetrose derivative **137**. Thus, (*Z*)-but-2-ene-1,4-diol can be converted into four L-tetroses (*Scheme 57*). Tetrose **138A** and **138B** can be reacted with $Ph_3PCHCHO$ giving (*E*)-hex-2-en-1-ol derivatives that undergo the same sequence of reactions as above (PS, P, P). This has permitted the synthesis of the eight L-hexoses. Starting with epoxidation of **136** with (−)-AE instead of (+)-AE, all D-tetrose and D-hexoses are obtained in the same way.

The methodology of Wittig–Horner–Emmons olefination to convert an aldehyde into the corresponding two-carbon chain elongated allylic alcohol and its subsequent asymmetric epoxidation has been used to prepare (+)-galactonojirimycin, (+)-nojirimycin, 1-deoxygalactonojirimycin, and 1-deoxynojirimycin, the method involves the regioselective opening of the epoxides with the azide anion [257,261,262,263,264,265,266,267].

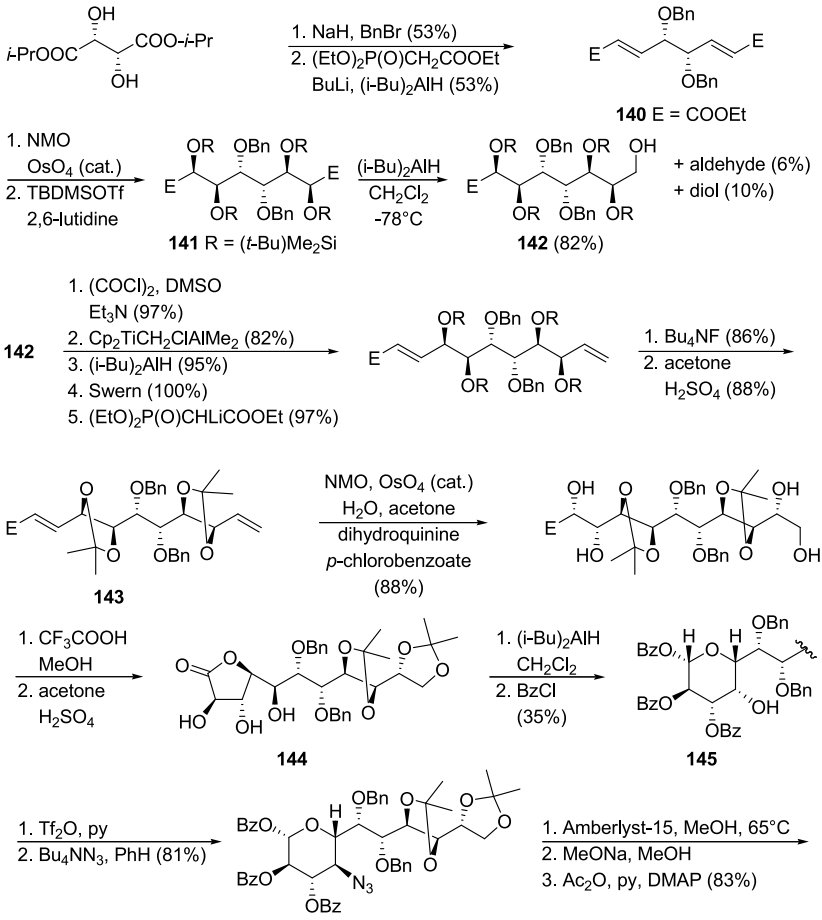
5.5.6 Aldehyde Olefination and Dihydroxylation

An example of the synthesis of a C_5-monosaccharide derivative (**139**) applying Sharpless asymmetric dihydroxylation is shown in *Scheme 58* [268,269,270,271].

Ikemoto and Schreiber [272,273] have prepared (−)-hikizimycin starting from L-(+)-tartaric acid for the hikosamine portion, and from D-glucose for the kanosamine part (for an alternative synthesis see [274]). The synthesis of a suitably protected form of hikosamine follows a two-directional chain strategy with terminus differentiation (*Scheme 59*) [273]. L-(+)-Diisopropyl tartrate, which will provide the C(6) and C(7) stereocenters of the undecose, is benzylated. In the same pot reduction with DIBAL-H and Wittig–Horner–Emmons double-chain elongation provides **140**. Double dihydroxylation of **140** follows Kishi's rule [275], giving a tetrol with high diastereoselectivity that is protected as silyl tetraether **141**. Desymmetrization of the diethyl octadioate **141** is possible with DIBAL-H in CH_2Cl_2 which generates alcohol **142** as the main product. This can be attributed to an entropy effect: once DIBAL-H, a dimeric reagent, has reacted with one of the two carboxylic moieties, a highly polar intermediate (aluminum alcoholate) is formed which blocks a large number of solvent molecules (CH_2Cl_2, "Napalm effect") and thus increases dramatically the mass of the system



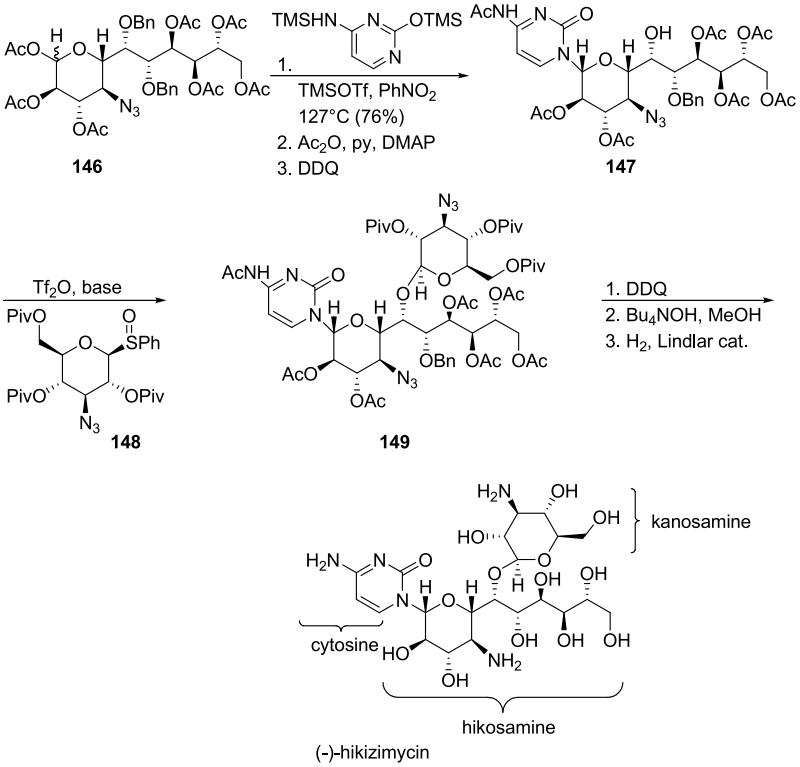
Scheme 58
Sharpless asymmetric dihydroxylation of an allylic silyl ether; configuration inversion via regioselective intramolecular displacement of cyclic sulfate



Scheme 59

Schreiber's synthesis of (−)-hikizimycin featuring a two-directional chain elongation strategy involving aldehyde olefination and face-selective dihydroxylations. **(see also on the following page)**

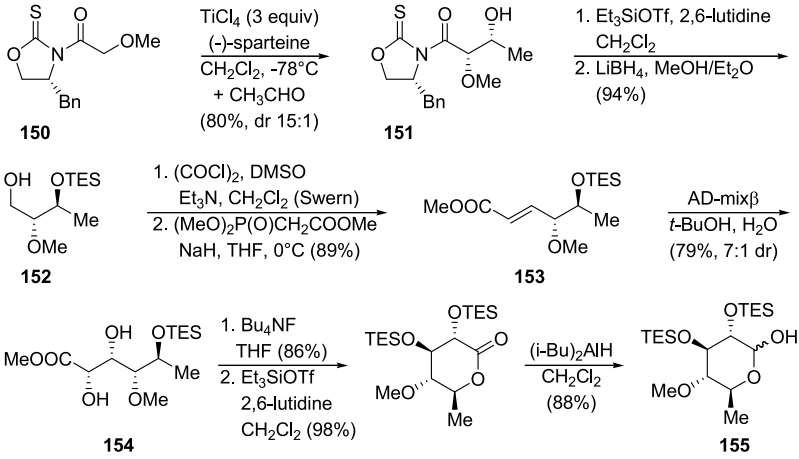
compared with the starting material. The reaction of the second carboxylic moiety is thus retarded because of a more negative entropy of condensation. (The larger the mass of the two reactants, the more negative is the entropy variation of their condensation, translational entropy. If the rate constant ratio of the two successive reductions were $k_1/k_2 = 2$, a maximum yield of 49% would have been obtained for **142**). Swern oxidation of **142**, followed by Tebbe vinylation, ester group reduction into a primary alcohol, then Swern oxidation into the corresponding aldehyde and Wittig–Horner–Emmons olefination generates a diene. Its four silyl ethers are exchanged for two acetonides giving **143**. Double hydroxylation in the presence of dihydroquinine *p*-chlorobenzoate leads to a tetrol with a good diastereoselectivity which gives γ-lactone **144** under acidic conditions. γ-Lactone**144** is then reduced into the corresponding furanose and converted into pyranoside **145**, with an unprotected 4-hydroxy group (steric hindrance). The latter is esterified as a triflate and then displaced with an azide anion.



Scheme 59 (continued)

This operation introduces the nitrogen moiety with the required configuration. Acetonide methanolysis followed by methanolysis of the benzoates and acetylation generates pyranoside **146** which undergoes Vorbrüggen's glycosidation with bis(trimethylsilyl)cytosine giving an intermediate that is acetylated and oxidized with dichlorodicyanobenzoquinone (DDQ). This leads to a site selective debenzylation of the 6-benzyloxy moiety giving **147**. Glycosidation of **147** with **148** under Kahne's conditions [276] gives **149**. Deprotection and hydrogenation of **149** furnishes (−)-hikizimycin.

Phenylalanine-derived oxazolidinone has been used in *Scheme 52* as a chiral auxiliary for asymmetric cross-aldolization (Evans-aldol reactions [277,278,279,280,281,282,283,284,285]). The 6-deoxy-L-glucose derivative **155** has been prepared by Crimmins and Long [286] starting with the condensation of acetaldehyde with the chlorotitanium enolate of *O*-methyl glycolyloxazolidinethione **150**. A 5:1 mixture is obtained from which pure **151** is isolated by a single crystallization. After alcohol silylation and subsequent reductive removal of the amide, alcohol **152** is obtained. Swern oxidation of **152** and subsequent Horner–Wadsworth–Emmons olefination provides ene-ester **153**. Sharpless asymmetric dihydroxylation provides diol **154** which was then converted into **155** (*Scheme 60*) (see also [287]).

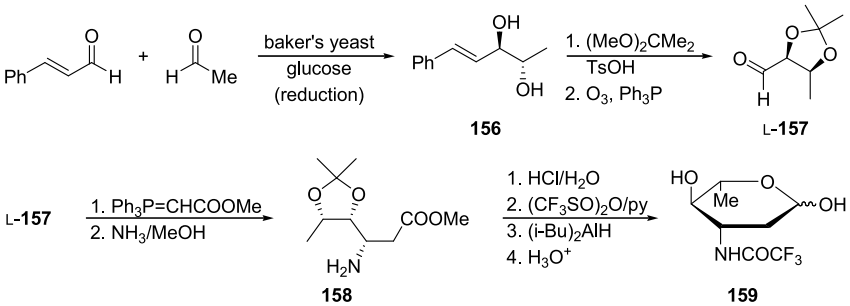


Scheme 60
Crimmins' synthesis of 6-deoxy-4-*O*-methyl-D-glucose

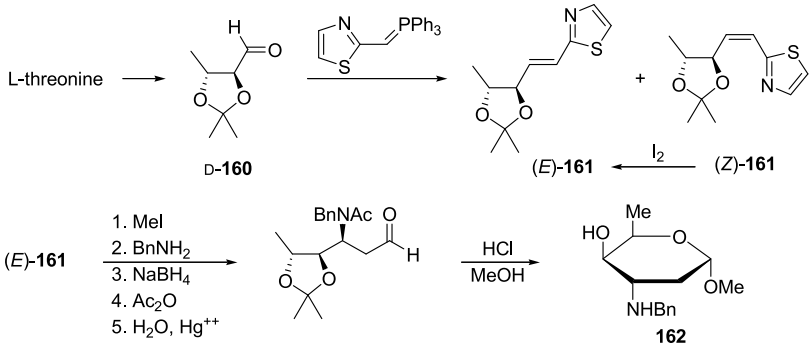
5.5.7 Aldehyde Olefination and Conjugate Addition

The first asymmetric total synthesis of acosamine and daunosamine starting from a nonsugar precursor was reported by Fuganti and co-workers [288,289,290,291]. They found that baker's yeast catalyzes the asymmetric pinacolic cross-coupling of cinnamaldehyde and ethenal giving *anti*-diol **156**. This diol is protected as an acetonide and submitted to ozonolysis giving L-**157**. Olefination of L-**157** with $Ph_3P{=}CHCOOMe$, followed by treatment with ammonia, provides **158** that is then converted into *N*-trifluoroacetylacosamine **158** (*Scheme 61*).

Methyl 3-*epi*-D-daunosaminide **162** has been derived from D-**160** via a Wittig-type olefination using (2-thiazolylmethylene)triphenylphosphorane (*Scheme 62*). A 1:1 mixture of (*E*)- and (*Z*)-alkenes is obtained which is isomerized in the presence of iodine into a 9:1 mixture of (*E*)-**161** and (*Z*)-**161**. Methylation of the thiazole moiety increases the electrophilicity of the alkene which then adds nucleophiles such as benzylamine. The adduct is treated with



Scheme 61
Fuganti's synthesis of *N*-trifluoroacetyl-L-acosamine



Scheme 62
Dondoni's synthesis of methyl *N*-benzyl-3-*epi*-D-daunosaminide

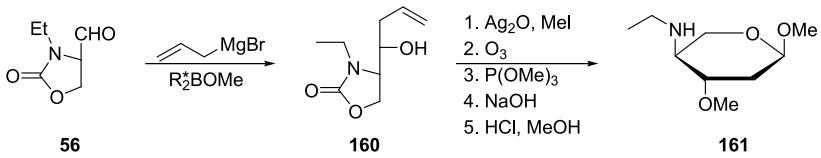
$NaBH_4$ to give a thiazolidine. Acetylation and mercury-mediated hydrolysis of the thiazolidine ring and subsequent acidic treatment in methanol yields the *N*-benzyl 3-*epi*-D-daunosaminide **162** [292].

5.5.8 Allylation and Subsequent Ozonolysis

The biologically important 2-deoxypentoses can be prepared readily by two-carbon chain elongation of 2,3-*O*-isopropylidene-D-glyceraldehyde following Roush's allylation method that relies on the highly diastereoselective additions of enantiomerically pure allylboronates derived from (*R*,*R*)- and (*S*,*S*)-tartaric acid. Similarly, the 2,6-dideoxyhexose derivatives have also been obtained by a similar route [293,294,295].

Addition of allylmagnesium bromide to serinal derivative **56** is *syn* selective in the presence of (−)-β-methoxydiisopinocampheylborane giving the *erythro* derivative **160** (*Scheme 62*). Methylation of the alcoholic moiety of **160**, followed by ozonolysis with reductive work-up, hydrolysis of the carbamate and acidic treatment forms the methyl glycoside **161** of the E-ring moiety of calicheamicin. A similar approach has been proposed by Roush starting from L-serinal derivative L-**65** [296] (*Scheme 63*).

The reaction of diallylzinc with 4-deoxy-2,3-*O*-isopropylidene-L-threose is *anti* stereoselective. After diol deprotection and ozonolysis 2-deoxy-L-fucose is obtained [297,298]. Similarly, allylation of (3*S*,4*S*)-3,4-isopropylidenedioxybutan-2-one leads to L-mycarose

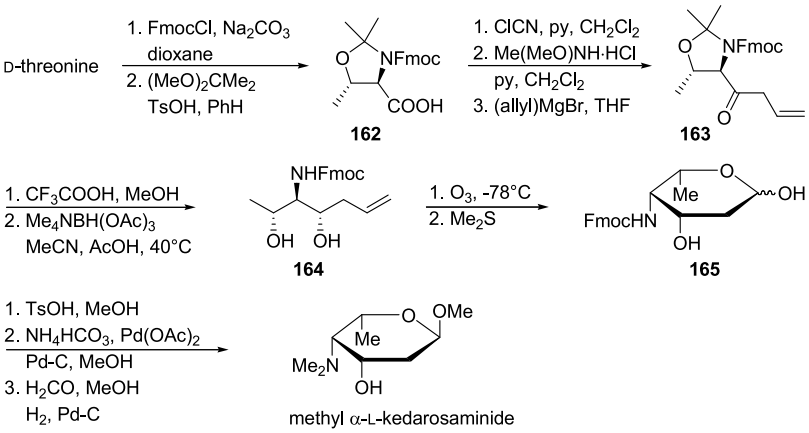


Scheme 63
Asymmetric allylation catalyzed by (−)-β-methoxydiisopinocamphenylborane

(2,6-dideoxy-3-*C*-methyl-L-ribohexopyranse). Using allylmagnesium bromide, L-boivinone and 2,3-dideoxy-L-*arabiono*-hexopyranose are prepared [299].

Two-carbon chain elongation of protected D-glyceraldehyde (*R*)-**37** and (*R*)-**99** can be realized via (*E*)-γ-alkoxyallylboronate additions, followed by alkene ozonolysis, furnishing D-arabinose derivatives [300].

The first noncarbohydrate-based asymmetric synthesis of kedarosamine uses the *N*,*O*-protected D-threonine **162**. It is converted into the corresponding Weinreb amide via the acyl chloride. Coupling with the allyl Grignard reagent provides **163**. The nonchelation controlled reduction of ketone **163** with $NaBH_4$ is *syn*-selective, whereas 1,2-chelation controlled reduction with $Zn(BH_4)_2$ is *anti*-selective. Deacetalization of **163** first, followed by reduction with the Evans' reagent, gives the *anti*-alcohol **164**. This product is then cleaved by ozonolysis, and subsequent ring closure to the corresponding pyranoses **165** occurs spontaneously. Fischer's glycosidation of **165** with methanol, followed by amine deprotection and methylation yields methyl α-L-kedarosaminide (◉ *Scheme 64*) [301].



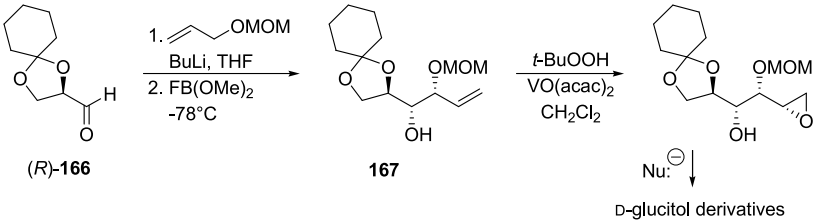
◘ Scheme 64
Kihlberg's synthesis of methyl α-L-kedarosaminide

5.6 Three-Carbon Chain Elongation

5.6.1 Allylmetal Additions

Roush's three-carbon-chain elongation method applied to 2,3-*O*-cyclohexylidene-D-glyceraldehyde (*R*)-**166** is an efficient approach to D-glucitol derivatives which relies on the *syn* selective epoxidation of homoallylic alcohol **167** (◉ *Scheme 65*) [300,302].

Addition of allyl bromide to *N*-benzyl-*N*-carbobenzoxy-*O*-*tert*-butyldimethyl-D-serinal in the presence of $SnCl_2$ and NaI gives preferentially the *anti*-adduct which was converted into enantiomerically pure 1,3-dideoxynojirimycin [303].



Scheme 65
Roush's conversion of D-glyceraldehyde into D-glucitol derivatives

5.6.2 Wittig–Horner–Emmons Olefination

Wittig–Horner–Emmons olefination of serinal derivative L-**65** with carbonylphosphorane **168** generates enone **169** which can be converted to (−)-nojirimycin via *anti*-dihydroxylation and reduction with $NaBH_4$ (*Scheme 66*), whereas reduction with Red-Al [Red-Al = $(MeOCH_2CH_2O)_2AlH_2Na$] leads to (−)-mannonojirimycin [304]. A similar analogue has been applied to generate galactostatine [305] and sialic acid analogues [306].

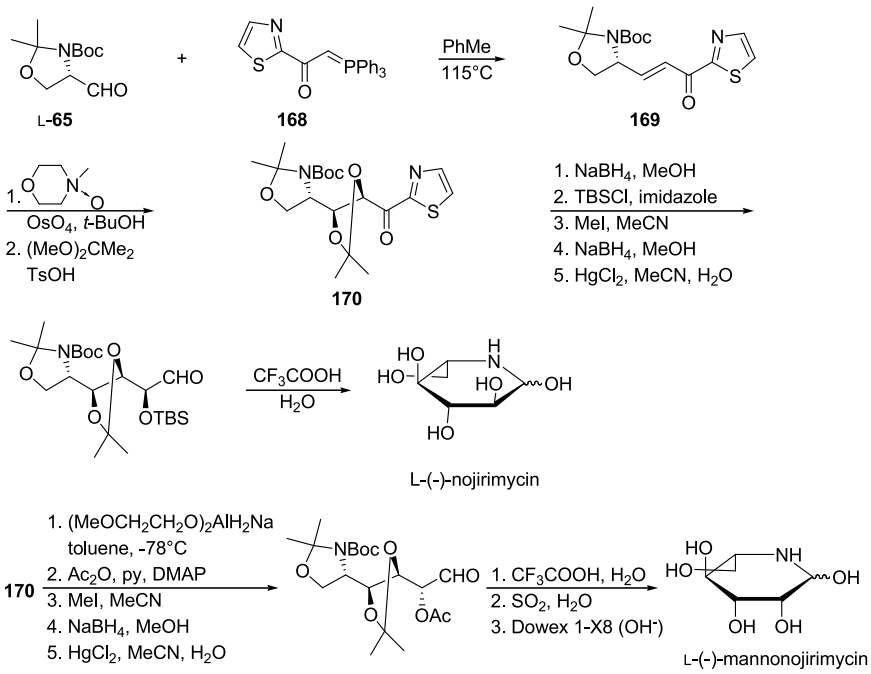
5.6.3 Aldol Reaction

Total syntheses of 3-deoxy-D-*ribo* and 3-deoxy-D-*arabino*-hexose have been realized via the cross-aldolization of 2,3-*O*-isopropylidene-D-glyceraldehyde (*R*)-**37** and 1,1-dimethoxyacetone (*Scheme 67*). The key step of the synthesis is the diastereoselective reduction of one of the aldols **171** via boron chelates. Treatment of **171** with triisobutylborane, and then with $NaBH_4$ gives *syn*-1,3- (**173**) and *anti*-1,3-diol **174** in a ratio 95:5. Acidic hydrolysis of **173** provides 3-deoxy-D-*ribo*-hexose. If aldol **171** is treated first with an equimolar amount of aluminum triisopropoxide, diol **174** is obtained in 62% yield (together with 15% of **173**). Compound **174** is converted then into 3-deoxy-D-*arabino*-hexose [307].

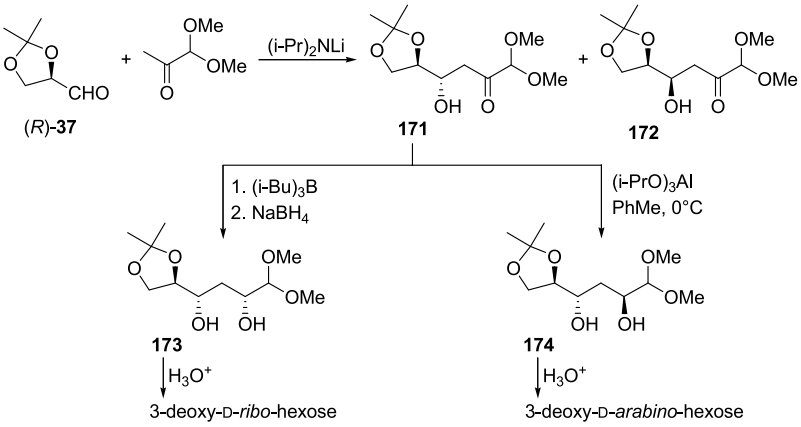
In a systematic study of the aldol reaction of methyl ketones Evans and co-workers [308,309] found that asymmetric induction in lithium enolates to α-alkoxy aldehydes is superior to that obtained from the corresponding enoxyboranes and enoxysilanes. The level of asymmetric induction in the lithium enolate additions is relatively insensitive to both the nature of the α-oxygen protective group and the steric hindrance of the enolate nucleophile. These additions are, however, sensitive to the nature of the β-alkyl substituent. For *anti*-α,β-dialkoxy-aldehydes, their reactions with methyl ketone enolates give mostly 3,4-*anti* products with consistently superior diastereoselectivity relative to the *syn*-α,β-dialkoxy-aldehydes. With α,β-isopropylidenedioxy-aldehydes the diastereoselectivity is the same regardless of the *syn*- vs. *anti*-α,β relative configuration. A Cornforth transition-state model (*Fig. 3*) is proposed to account for these observations in which the β-substituent dictates the position in space occupied by the α-oxygen protecting group (P1), which in turn governs aldehyde π-facial selectivity due to its proximity to the approaching enolate.

5.6.4 Other Methods of Three-Carbon Chain Elongation of Aldoses and Derivatives

Sames and Polt [310] have converted L-serine into *N*-methylfucosamine (*Scheme 68*). The method relies on the diastereoselective propenyllithium addition to the aldehyde derived from



Scheme 66
Dondoni's synthesis of azasugars



Scheme 67
Conversion of D-glyceraldehyde into 3-deoxy-D-hexoses

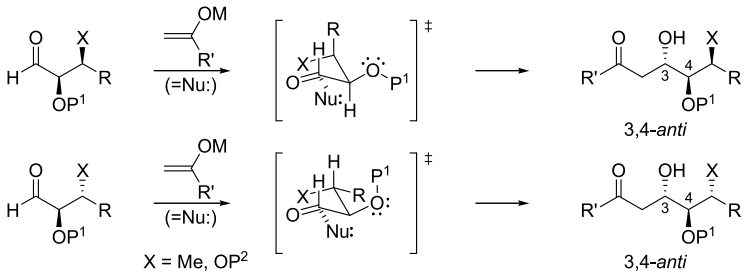


Figure 3
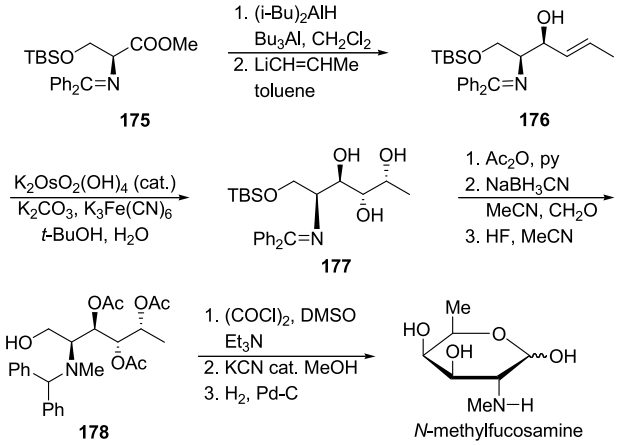
Preferred diastereoselectivities in aldol reaction



Scheme 68
Polt and Sames' synthesis of methylfucosamine

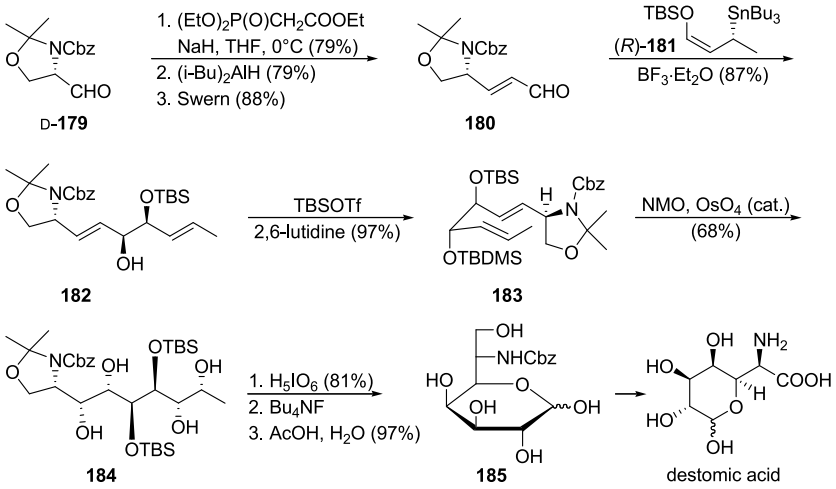
protected L-serine derivative **175** giving allylic alcohol **176**. Catalytic osmylation of **176** gives a 6:1 mixture of *anti*,*syn* **177** and *syn*,*syn*-aminotriols. Protection of the triol **177** as triacetate, reductive methylation, and desilylation provides **178**. Successive Swern oxidation, methanolysis, and benzhydryl group hydrogenolysis leads to *N*-methylfucosamine [311] (for other examples of three-carbon homologations: [312,313,314,315]).

5.7 Four-Carbon Chain Elongation

5.7.1 (But-2-en-1-yl) Metal Addition

The addition of crotylstannane derivatives to aldehydes are highly diastereoselective in the presence of $MgBr_2 \cdot OEt_2$ as the promoter [316,317,318].

The octitol derivative **184** has been prepared via BF_3 etherate-promoted addition of (*R*)-γ-OTBS allylic stannane (*R*)-**181** to enal **180** derived from L-serine (*Scheme 69*) [319]. This leads to a single *syn*-adduct **182** which is converted to the silyl ether **183**. This compound



Scheme 69
Marshall's allylation applied to the synthesis of destomic acid

adopts probably the Saito conformation which makes the double *cis*-dihydroxylation doubly diastereoselective with the formation of tetrol **184** as a major product. Selective oxidative cleavage of tetrol **184** affords a lactol. Desilylation followed by acetonide hydrolysis generates **185**, a precursor of destomic acid (see also: [320,321]).

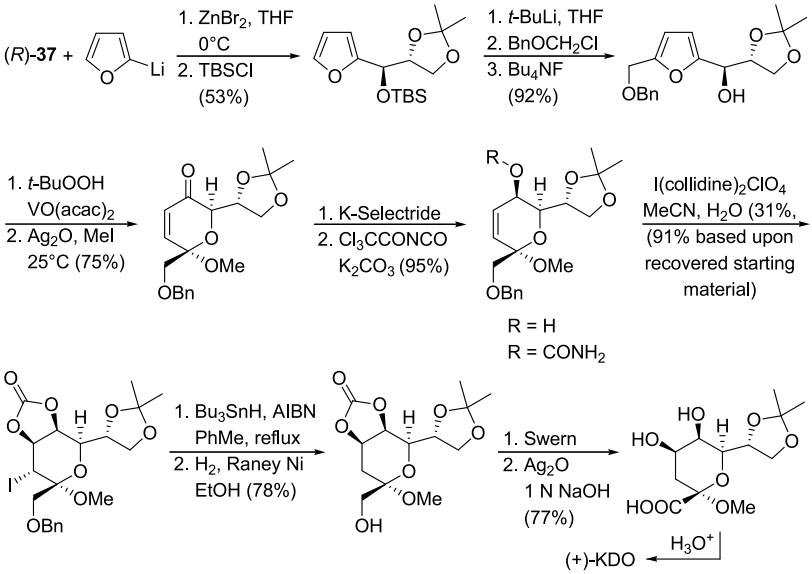
5.7.2 Nucleophilic Addition of α-Furyl Derivatives

A synthesis of (+)-KDO (*Scheme 70*) has been reported by Martin and Zinke [322] which relies on the highly stereoselective addition of 2-furyllithium to 2,3-*O*-isopropylidene-D-glyceraldehyde (*R*)-**37** [323].

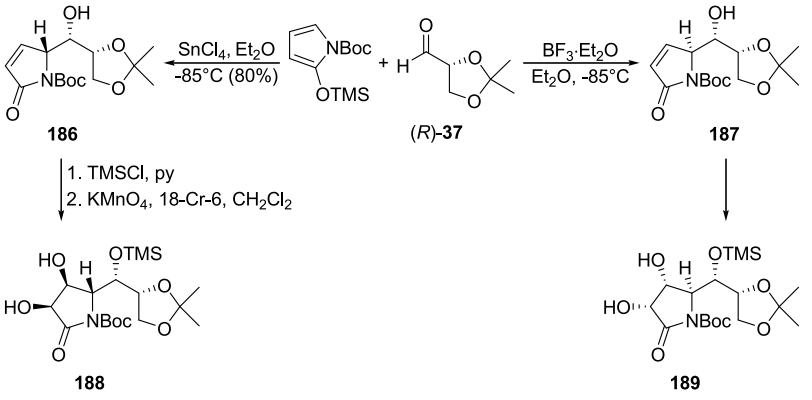
Condensation of 2,3-*O*-isopropylidene-D-glyceraldehyde-*N*-benzylimine with 2-(trimethylsilyloxy)furan in the presence of a Lewis acid generates a mixture of butenolides that has been converted into a D-*ribo*-*N*,*N*-diprotected derivative in 68% yield and then into enantiomerically pure 1,5-dideoxy-1,5-imino-D-*glycero*-D-*allo*-heptitol [324].

5.7.3 Hydroxyalkylation of Pyrrole Derivatives

The Lewis acid-promoted condensation of *N*-(*t*-butyloxycarbonyl)-2-(*t*-butyldimethylsiloxy) pyrrole with 2,3-*O*-isopropylidene-D-glyceraldehyde ((*R*)-**37**) generates pyrrolidones with high diastereoselectivity. For instance, with 1.5 equivalent of $SnCl_4$ in ether, the reaction gives crystalline D-*arabino*-configurated α,β-unsaturated γ-lactam **186** as the sole product, whereas, in the presence of one equivalent of BF_3 etherate, reversal stereochemistry is observed, resulting in predominant formation of crystalline D-*ribo*-epimer **187**, along with less than 20% of **186**. Almost quantitative epimerization **186** → **187** occurs on treatment with Et_3N in CH_2Cl_2in the presence of 4-dimethylaminopyridine (*Scheme 71*). Dihydroxylations of the



Scheme 70
Martin's asymmetric synthesis of (+)-KDO

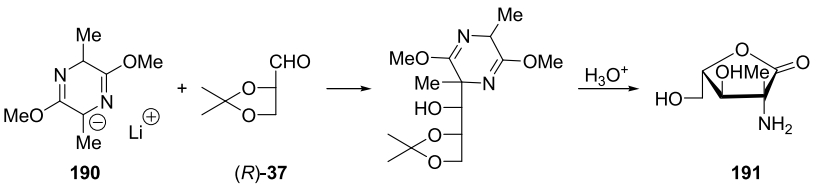


Scheme 71
Aminodeoxyaldonolactams through hydroxyalkylation of a pyrrole derivative

trimethylsilyl ethers of **186** and **187** generate the 4-amino-4-deoxy-heptono-1,4-lactam derivatives **188** and **189**, respectively [325,326]. Lactam hydrolysis of **188** with LiOH, followed by Malaprade diol cleavage with $NaIO_4$ and further oxidation and deprotection allows preparing 4-*epi*-polyoxamic acid [327]. Lactam **186** and its enantiomer derived from (*S*)-**37** have been converted into all four stereomers of *cis*-1,2-dihydroxypyrrolizidine [328]. Compounds **186** and **187** have been used also to prepare the *trans*-2,3-*cis*-3,4-dihydroxyprolines [329,330].

5.8 Synthesis of Branched-Chain Monosaccharides from C_3-Aldoses

Most of the methods presented for the de novo synthesis of "linear" monosaccharides can be used to prepare branched-chain sugars and analogs and some examples are given below. The branched-chain aminolactone **191** has been prepared by two-carbon chain elongation via addition of **190** to 2,3-*O*-isopropylidene-L-glyceraldehyde (*R*)-**37** (Scheme 72) [331].



Scheme 72
Synthesis of a branched-chain amino aldonolactone

Aldol reaction of (*S*)-2-benzyloxypropanal with the lithium enolate of methyl 2-methoxypropanoate gives a 7:2:1 mixture of β-hydroxyesters. The major product has been converted into L-cladinose, a saccharide moiety of erythromycin A [332]. The isomeric methyl 3,6-dideoxy-3-*C*-methylhexofuranosides have been derived from (*S*)-2-benzyloxypropanal via homoaldol reactions in three steps.

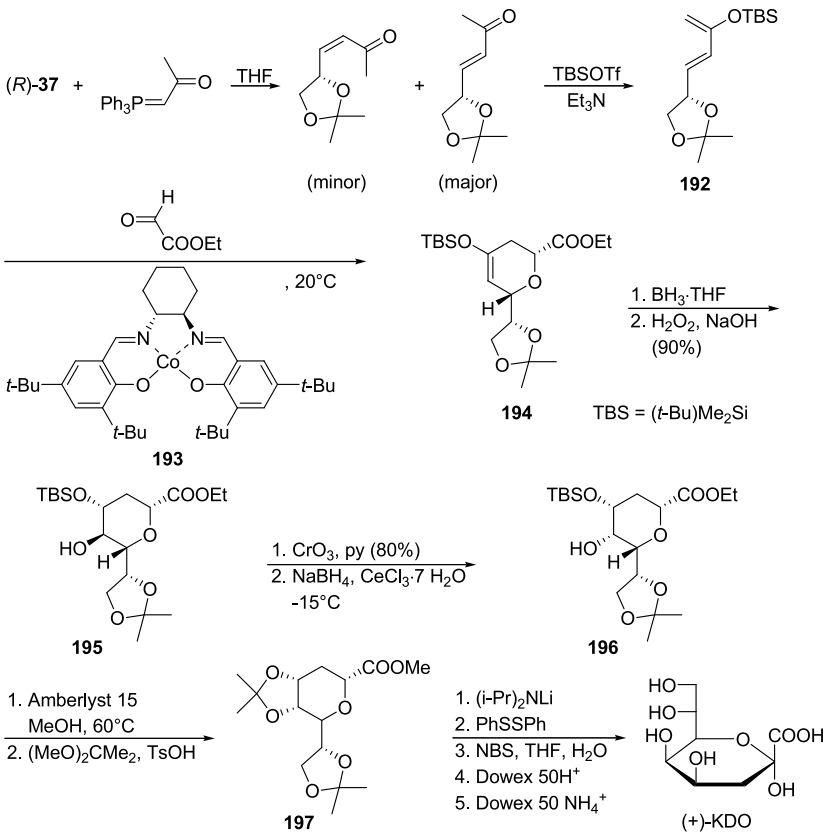
L-Arcanose and L-olimycose have been prepared in enantiomerically pure forms and with high stereoselectivity by Lewis-acid promoted addition of (*S*)-2-benzyloxypropanal to 1-trimethylsilyl-2,3-butadiene. Depending on the nature of the Lewis acid either the *syn* (with $TiCl_4$) or the *anti* adduct (with $BF_3 \cdot Et_2O$) can be obtained. Epoxidation with lateral control by the allylic alcohol moieties and standard reactions lead to the unprotected monosaccharides [334]. Total syntheses of 2,3-dideoxy-3-*C*-methyl-D-*manno*-heptose and of 2,3-dideoxy-2,3-di-*C*-methyl-D-*glycero*-D-*galacto*-heptose have been realized by addition of 2-(trimethylsiloxy)furan to 2,3-*O*-isopropylidene-D-glyceraldehyde ((*R*)-**37**) [335].

6 Hetero-Diels–Alder Additions

6.1 Achiral Aldehydes as Dienophiles

The cycloadditions of achiral oxy-substituted dienes with aldehydes in the presence of enantiomerically pure (+)-Eu(hfc)$_3$ [hfc = 3-(heptafluoropropylhydroxymethylene)-(+)-camphorate] shows only modest enantioselectivities. Similarly, modest diastereoselectivities are observed for the reactions of chiral oxy-substituted dienes with aldehydes in the presence of achiral Eu(fod)$_3$ (fod = 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedienoate). However, the combination of chiral dienes with chiral (+)-Eu(hfc)$_3$ catalyst shows interesting interactivities, resulting in some instances in diastereoselectivities of 97:3. This has permitted a total synthesis of L-glucose [336,337,338].

By applying a similar approach, Wu and co-workers [339] have observed a highly double-stereoselective hetero-Diels–Alder addition between diene **192** and ethyl glyoxylate catalyzed



Scheme 73
Wu's synthesis of (+)-KDO

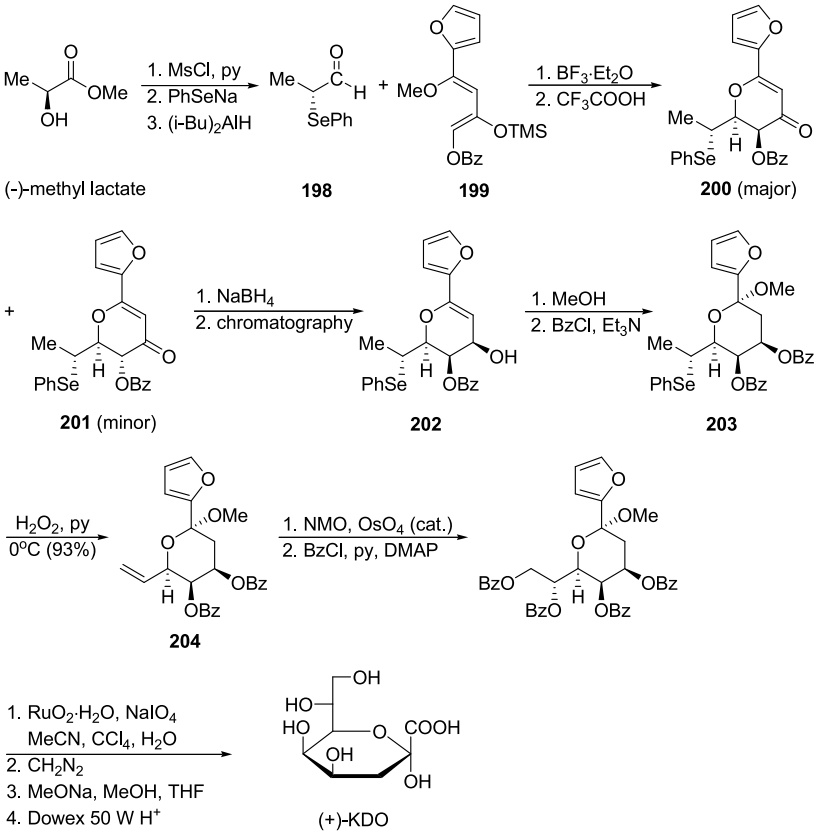
by the (salen)Co^{II} complex **193** (*Scheme 73*). The major adduct **194** is hydroborated to give alcohol **195** that is inverted via oxidation and subsequent reduction to **196**. Acid methanolysis followed by diol protection furnishes **197**. Quenching of the lithium enolate of **197** with phenyl disulfide and subsequent oxidation with *N*-bromosuccinimide forms, after deprotection, (+)-KDO (3-deoxy-D-*manno*-oct-2-ulosonic acid) [340].

The reaction of 5-nitrofuran-2-carbaldehyde and 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosides of (*E*,*E*)-4-ethoxy-2-[(tertbutyl)dimethylsilyloxy]butadien-1-yl can be highly diastereoselective depending on the nature of the lanthanide Lewis acid used to promote the cycloaddition ($Yb(fod)_3$, $La(fod)_3$). The adducts so-obtained are readily converted into β-D-glucopyranosyl (1→4)-linked glycals [341]. 1-(*Z*)-Alkoxy-4-(*E*)-methoxybutadiene derivatives add to ethyl glyoxylate and diethyl oxomalonate under thermal and hyperbaric conditions. They provide dihydropyranic products with high stereoselectivities. These hetero-Diels–Alder adducts can be converted into racemic allose, mannose, and gulose derivatives [342] (for other hetero-Diels–Alder adducts of this aldehyde, see [343,344,345,346,347]).

6.2 Chiral Aldehydes as Dienophiles: Synthesis of Long-Chain Sugars

The first total synthesis of (+)-KDO was presented by Danishefsky and co-workers (*Scheme 74*) [348]. The hetero-Diels–Alder addition of α-selenoaldehyde **198** to the α-furyl-substituted diene **199** gives an adduct mixture which on treatment with CF_3COOH delivers a 5:1 mixture of *cis*/*trans* dihydropyrones **200** and **201**. Reduction of pure **200** generates **202** which adds methanol like a glycal; after benzoylation **203** is obtained. Oxidative elimination of the phenylseleno group gives alkene **204** which is dihydroxylated to a diol, the benzoylation of which affords a tetrabenzoate, the oxidation of it with RuO_4, followed by esterification with diazomethane, generates methyl KDO α-methyl glycoside. Deprotection leads to (+)-KDO.

The octosyl acids are isolated from *Streptomyces cacaoi*; they are part of a broader group of polyoxin antifungal nucleosides [349]. Danishefsky and co-workers [350] have reported a total synthesis of octosyl acid A featuring the hetero-Diels–Alder addition of (*E*)-1-methoxy-3-(trimethylsilyloxy)butadiene to a protected D-ribose-derived aldehyde.



Scheme 74
Danishefsky's total synthesis of (+)-KDO

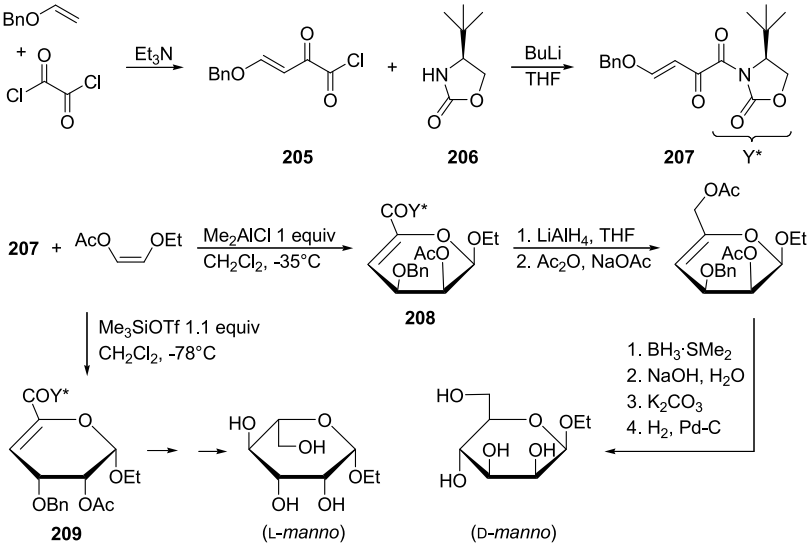
An elegant total synthesis of a semi-protected form of lincosamine has been realized by Marshall and Beaudoin [319]. Destomic acid (6-amino-6-deoxy-L-*glycero*-D-*galacto*-heptonic acid) has been derived in a similar way from a L-serinal derivative via hetero-Diels–Alder addition to 1-ethoxy-3-[(trimethylsilyl)oxy]-4-benzyloxy-1,3-butadiene. A similar method has been applied also to prepare a semi-protected form of anhydrogalantinic acid, a component of the antibiotic galantin I [351].

6.3 Hetero-Diels–Alder Addition of 1-Oxa-1,3-Dienes

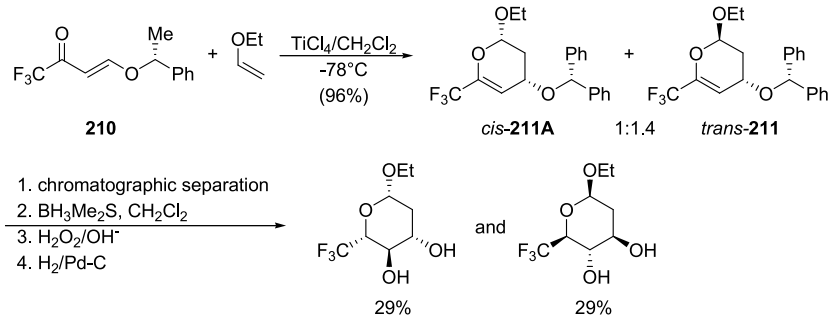
The [4+2]-cycloaddition of α,β-unsaturated aldehydes and ketones (1-oxa-1,3-dienes) to enol ethers (Diels–Alder addition with inverse electron demand) has been an attractive route for the synthesis of 3,4-dihydro-2H-pyrans [352,353,354,355,356,357,358] which can be converted into deoxy- and dideoxypyranosides [359,360,361,362,363,364,365,366,367].

The enantiopure 1-oxa-1,3-diene **207** is prepared by acylation of benzyl vinyl ether with oxalyl chloride; this generates acyl chloride **205** which acylates the lithium salt of 2-oxazolidinone **206**. In the presence of Me_2AlCl, diene **207** adds to (*Z*)-1-acetoxy-2-ethoxyethene giving mostly adduct **208**, whereas, when using Me_3SiOTf as a promoter of the hetero-Diels–Alder addition, diastereomer **209** is the major adduct (*Scheme 75*). Adducts **208** and **209** have been converted into ethyl β-D-mannopyranoside and ethyl-β-L-mannopyranoside, respectively [368,369]. L-Olivose has been prepared via a similar approach [370].

The Diels–Alder additions of enantiomerically pure oxadienes to (*Z*)-2-ethoxyvinyl acetate are highly diastereoselective and have been used to prepare derivatives of 4-deoxy-D-*lyxo*-hexose [357]. Larsen and co-workers [371] have prepared 2,6-dideoxy-6,6,6-trifluoro-*arabino*-



Scheme 75
Tietze's synthesis of L-hexoses



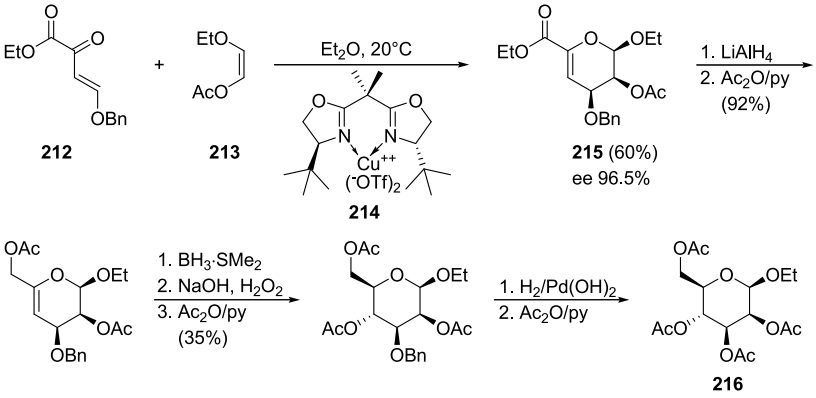
Scheme 76
Synthesis of 2,6-dideoxy-6,6,6-trifluoro-*arabino*-hexoses

hexoses via a $TiCl_4$-catalyzed hetero-Diels–Alder addition of (*E*)-1,1,1-trifluoro-4-[(1*R*)-1-phenylethoxy]but-3-en-2-one (**210**) to ethyl vinyl ether giving a mixture of adducts *cis*-**211** and *trans*-**211** (Scheme 76).

Alternatively monosaccharides have been prepared via cycloaddition of chiral enol ethers to oxadienes [372,373,374].

Independently, the groups of Evans [375,376,377] and Jørgensen [378] have shown that β,γ-unsaturated α-keto esters react with ethyl vinyl ether in the presence of enantiomerically pure bisoxazoline copper(II) complexes as catalysts leading to enantiomerically enriched dihydropyrans. For instance **212** and **213** in ether at 20 °C and in the presence of complex **214** add to give the *endo* adduct **215** in 60% yield and with 96.5% ee. The latter is then converted into ethyl β-D-*manno*-pyranoside tetraacetate **216** (Scheme 77) [379].

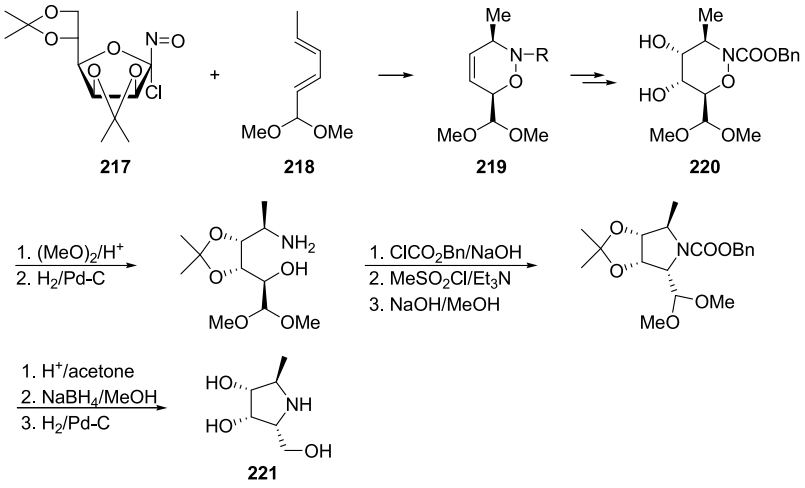
The first catalytic, highly enantioselective hetero-Diels–Alder reactions of thiabutadienes with an acyloxazolidinone dienophile using homochiral copper and nickel triflate and perchlorate bis(oxazoline) and bis(imine)complex catalysts to generate dihydrothiopyrans have been reported by Saito et al. [380].



Scheme 77
Jørgensen's asymmetric synthesis of an ethyl β-D-mannopyranoside derivative

6.4 Nitroso Dienophiles: Synthesis of Azasugars

Homochiral nitroso dienophiles can add to conjugated dienes in the hetero-Diels–Alder mode, sometimes with good diastereoselectivity [381,382,383,384]. For instance, the chloronitroso dienophile **217** derived from D-mannose [385] adds to diene **218** in MeOH/HC(OMe)$_3$ to give adduct **219** which has been converted into the 1,5,6-trideoxy-1,5-iminoalditols [383,386,387, 388] and into the potent α-L-fucosidase and α-galactosidase inhibitor **221** (Scheme 78) [389].

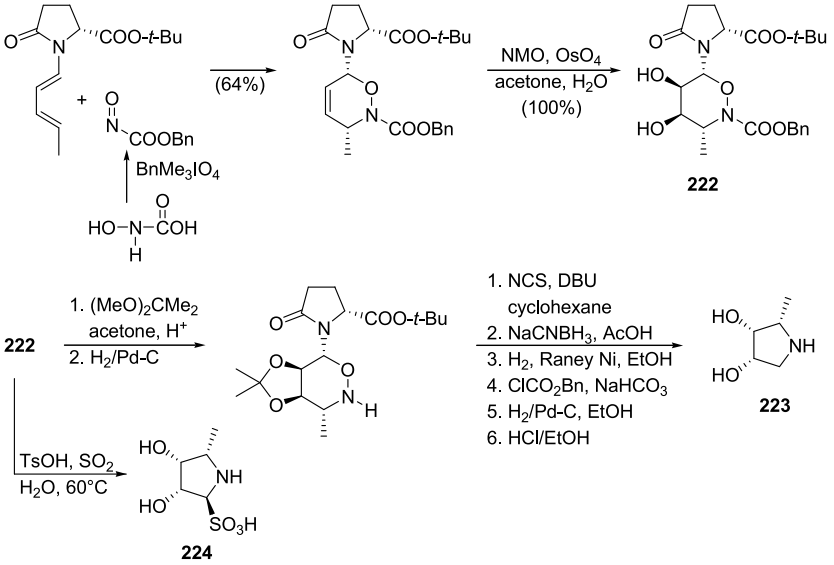


Scheme 78
Defoin's synthesis of 2,5-imino-2,5,6-trideoxy-D-altritol

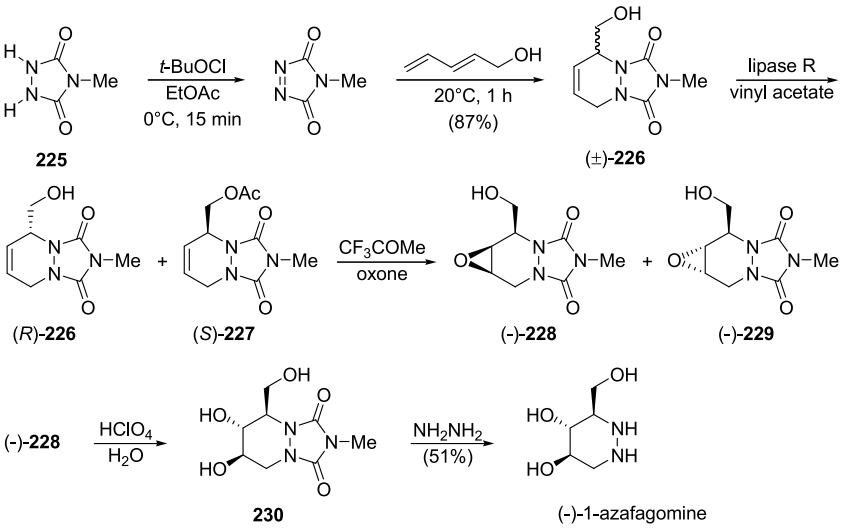
Good diastereoselectivity has been observed for the hetero-Diels–Alder addition of homochiral 1,3-dienes with achiral acyl-nitroso dienophiles. An example is shown in Scheme 79 for the total synthesis of 4-amino-4,5-dideoxy-L-lyxose derivatives **223** and **224** (potent inhibitors α-L-fucosidase), respectively [390] (see also [391,392,393]).

6.5 *N*-Methyltriazoline-3,5-Dione as the Dienophile: Synthesis of 1-Azafagomine

Methyl urazol **225** is oxidized into *N*-methyl triazoline-3,5-dione with *tert*-butyl hypochlorite. Without isolation it reacts with (*E*)-penta-2,4-diene-1-ol giving adduct (±)-**226** as a racemic mixture. On treatment of (±)-**226** with a lipase (R/Novozym 435) in vinyl acetate 38% of ester (*S*)-**227** (86% ee) and 29% of alcohol (*R*)-**226** (59% ee) is isolated. Epoxidation of (*S*)-**227** provides 13% of (−)-**228** and 68% of (−)-**229**. The latter epoxide is hydrolyzed under acidic conditions to provide **230** that reacts with hydrazine to give enantiomerically pure (−)-1-azafagomine (Scheme 80) [394]. This compound has a slow binding inhibitor of almond β-glucosidase (K_i = 0.33 μM). A similar sequence of reactions converts (*R*)-**226** into (+)-1-azafagomine. The latter is not an inhibitor of β-glucosidases [395].



Scheme 79
Defoin's synthesis of 4-amino-4,5-dideoxy-L-lyxose derivatives



Scheme 80
Bols' synthesis of 1-azafagomine

7 Cycloadditions of Furans

7.1 Diels–Alder Additions

Just and his group have pioneered the use of 7-oxabicyclo[2.2.1]hept-2-enes as starting materials in the synthesis of carbohydrates and analogs [396,397,398,399,400]. These bicyclic systems have the advantage to undergo highly face selective reactions. They are obtained simply by Diels–Alder addition of furan to alkene dienophiles [401,402,403,404,405,407].

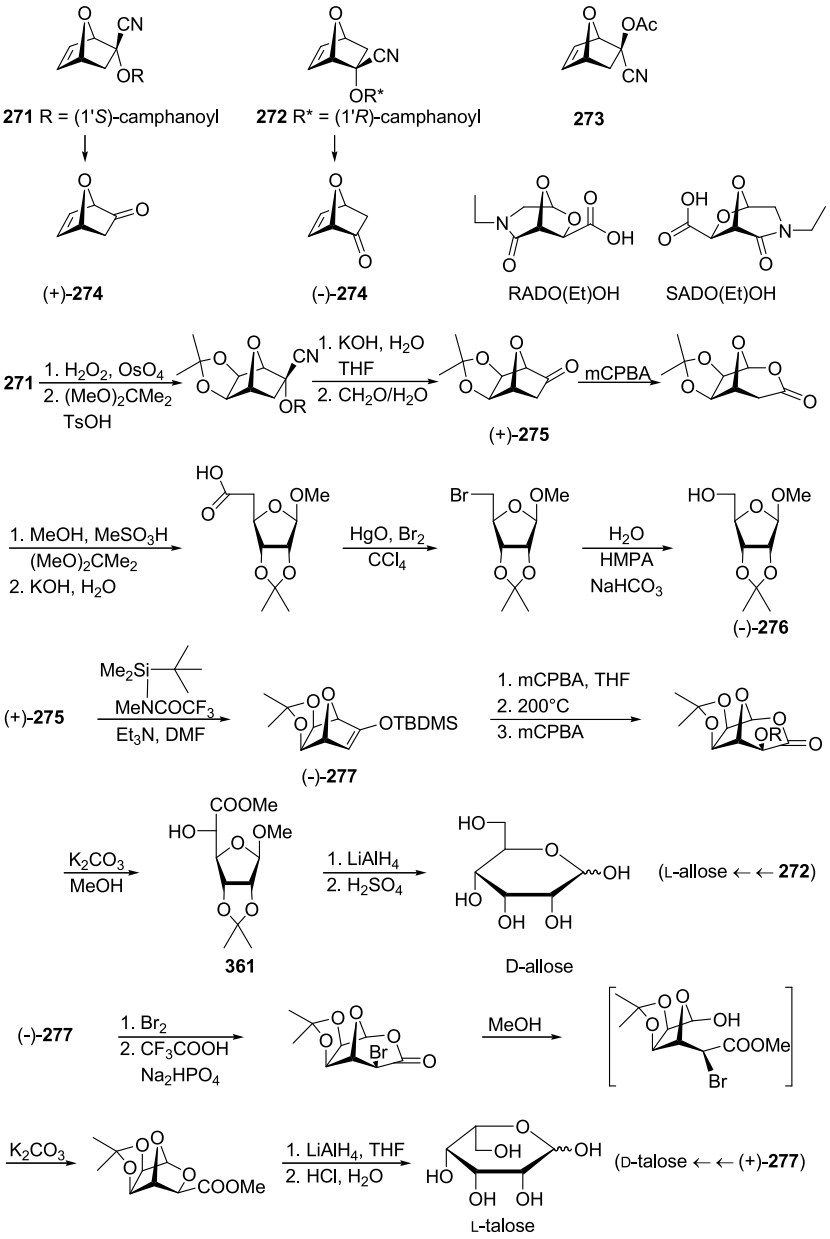
7.2 The "Naked Sugars of the First Generation"

The 1-cyanovinyl (1′*S*)-camphanate (derived from (1*S*)-camphanic acid and pyruvonitrile) adds to furan in the presence of ZnI_2 as the catalyst. After 7 days at room temperature a mixture of four possible diastereomeric Diels–Alder adducts is formed (95%) from which pure adduct **271** can be isolated by crystallization. Unreacted furan is recovered and the diastereomer mixture left from the crystallization is heated to give furan and 1-cyanovinyl (1′*S*)-camphanate that can be recycled to prepare more of the diastereomerically pure adduct **271** (the reversibility of the furan Diels–Alder addition is exploited here). Starting from (1*R*)-camphanic acid which is also commercially available, pure adduct **272** can be prepared in large quantities as readily [408]. Camphanic acid auxiliaries can be replaced by the chiral auxiliaries RADO(Et)OH or SADO(Et)OH derived from (*R*,*R*)-tartaric acid and (*S*,*S*)-tartaric acid [409,410]. Using 1-cyanovinyl acetate as the dienophile, a mixture of racemic adducts is obtained which is hydrolyzed into a mixture of cyanohydrines that can be resolved by complex formation with brucine. Reaction of the diastereomerically pure complex with Ac_2O provides the enantiomerically pure 7-oxanorbornene derivatives **273** [411] (for other enantiomerically enriched 7-oxabicyclo[2.2.1]heptane derivatives [412]).

Enantiomerically pure 7-oxanorbornenyl derivatives **271**, **272**, **273**, and their products of saponification (recovery of the chiral auxiliary in the aqueous phase), ketones (+)-**274** and (−)-**274**, are coined "naked sugars of the first generation" because they are chirons (= enantiomerically pure synthetic intermediates) like those derived from natural hexoses. They are enantiomerically pure like natural sugars, but with three unsubstituted (naked) carbon centers, the substitution of which follows highly stereoselective methods giving polysubstituted 7-oxabicyclo[2.2.1]heptane-2-ones that can be oxidized into the corresponding uronolactones as illustrated in *Scheme 81* for the total synthesis of the riboside derivative (−)-**276**, D-allose and L-talose [413].

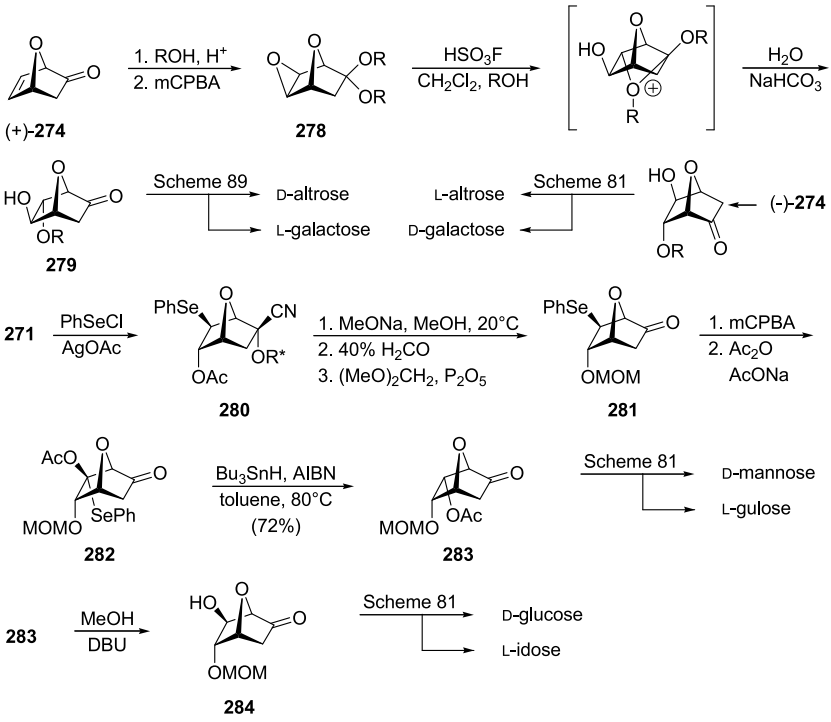
Acetals of (+)-**274** are epoxidized into **278** (*Scheme 82*). Acid promoted ring opening of the epoxides of **278** with participation of the *endo* OR group finally leads to the *trans*-5,6-dioxy-substituted 7-oxabicyclo[2.2.1]heptan-2-ones **279** [414,415,416]. The reaction sequences of *Scheme 81* applied to **279**, and to its enantiomer obtained from (−)-**277**, generate D- and L-altrose or L- and D-galactose, respectively.

Electrophilic addition of PhSeCl to alkene **271** is highly stereo- and regioselective (steric effects) and provides adduct **280** if carried out in the presence of an acetate nucleophile. Methanolysis, treatment with formaline and protection of the *endo* alcohol gives ketone **281**. Low-temperature oxidation of the selenide **281** generates a selenoxide which does not elimi-



Scheme 81

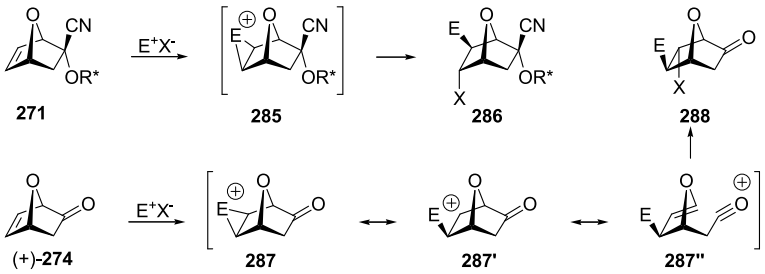
"Naked sugars of the first generation": asymmetric total synthesis of carbohydrates with early recovery of the chiral auxiliary



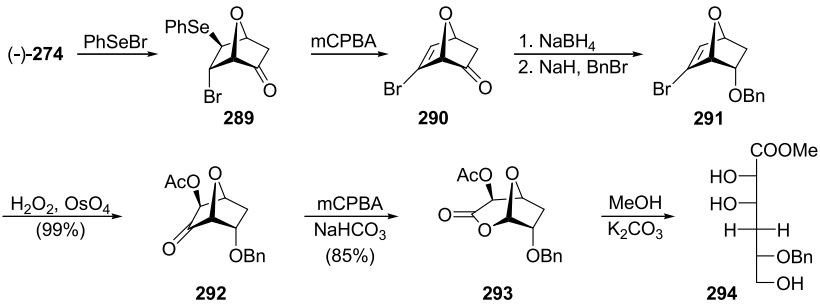
Scheme 82
Asymmetric synthesis of hexoses starting from furan

nate readily but has the time to undergo a seleno-Pummerer rearrangement in the presence of acetic anhydride and sodium acetate, leading to **282**. Reductive elimination of the seleno moiety with tin hydride forms **283** bearing two *endo* hydroxy groups protected in an orthogonal fashion (*Scheme 82*) [417]. Applying reactions of *Scheme 81* to **283** and to its enantiomer generate hexoses with a *manno* or *gulo* configuration. Methanolysis of **283** occurs with complete epimerization at C(6) (retro-aldol, aldolization) giving **284**, a precursor of D-glucose and L-idose derivatives (*Scheme 82*).

Under conditions of kinetic control, the cyano-esters (e. g. **271**) add soft electrophiles E^+X^- to generate the corresponding adducts **286** with high *exo* face selectivity and high regioselectivity. In these cases, the bridged ion intermediates **285** are attacked preferentially by the nucleophile X^- at C(5), the center that is the least sterically hindered and also the one which can support the highest partial positive charge [field effect of the electron-withdrawing CN and ester substituents at C(2)]. With the 7-oxabicyclo[2.2.1]hept-5-en-2-one ((+)-**274**, derived from **271**) electrophiles E^+X^- add with opposite regioselectivity and give the corresponding adducts **288**. The nucleophile's (X^-) preference for carbon center C(6) is attributed to the electron-releasing effect of the carbonyl function in positively charged intermediates **287** ↔ **287′** ↔ **287″** due to favorable n(CO) ↔ σ C(1,2) ↔ pC(6)$^+$ hyperconjugative interaction (frangomeric effect of the carbonyl n electron pairs) [418,419,420,421,422,423]. The



Scheme 83
The highly stereo- and regioselective electrophilic additions of the "naked sugars"



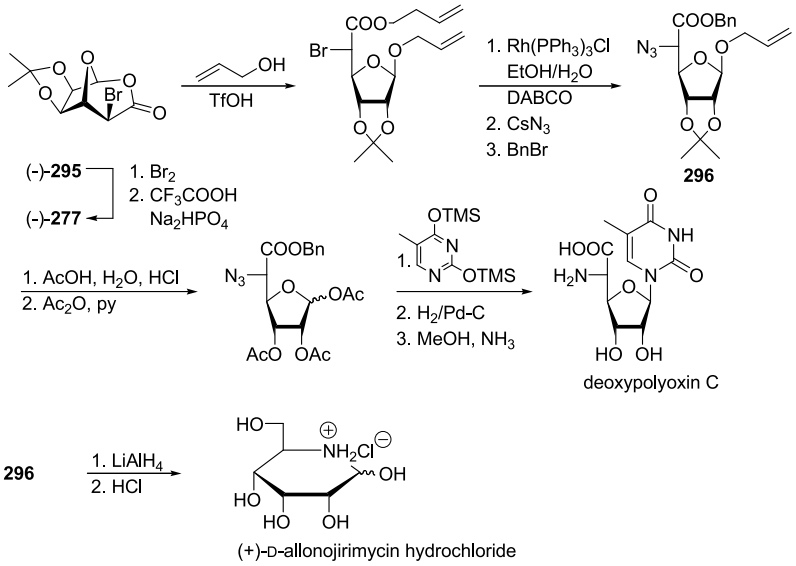
Scheme 84
Total synthesis of a 4-deoxypyranoside and derivatives

principle described here (Scheme 83) has been applied to convert the "naked sugars" into 2-, 3-, and 4-deoxyhexoses and derivatives in highly stereoselective manners [424,425,426], an example is summarized in Scheme 84.

Addition of PhSeBr to enone (−)-**274** gives adduct **289** which undergoes oxidative elimination of the phenylseleno group, to give bromoenone **290**. Ketone reduction and protection of the *endo* alcohol furnishes **291**, the double hydroxylation of its chloralkene unit generates **292** after acetylation. Baeyer–Villiger oxidation yields uronolactone **293** which has been converted into 3-deoxy-α-D-*arabino*-hexopyranoside and into methyl 4-deoxyhexonate **294** [426].

The "naked sugars of the first generation" (**271**, **272**, **273**, (+)-**274**, (−)-**274**) are useful chirons to prepare all kinds of rare sugar derivatives [427,428,429,430], as shown below, and of analogs such as *C*-linked disaccharides [431,432,433,434,435,436,437,438,439,440]. They have been converted into conduritols, cyclitols, and carbahexose derivatives [416,441]. The bicyclic ketones can also be converted into their enoxysilanes and then cleaved by ozonolysis. Depending on the work-up conditions 2,5-anhydrohexaldaric acid or 2,5-anhydrohexonic acid derivatives can be prepared readily, in both their enantiomerically pure forms [442,443,444, 445].

Light-induced aziridination of the benzyl acetal of (+)-**274** with $BocN_3$ (Boc = (*t*-Bu)OCO) gives an aziridine that converted into methyl 3-amino-3-deoxy-α-D-altropyranoside [446], and into 3-amino-3-deoxy-L-idose [447].

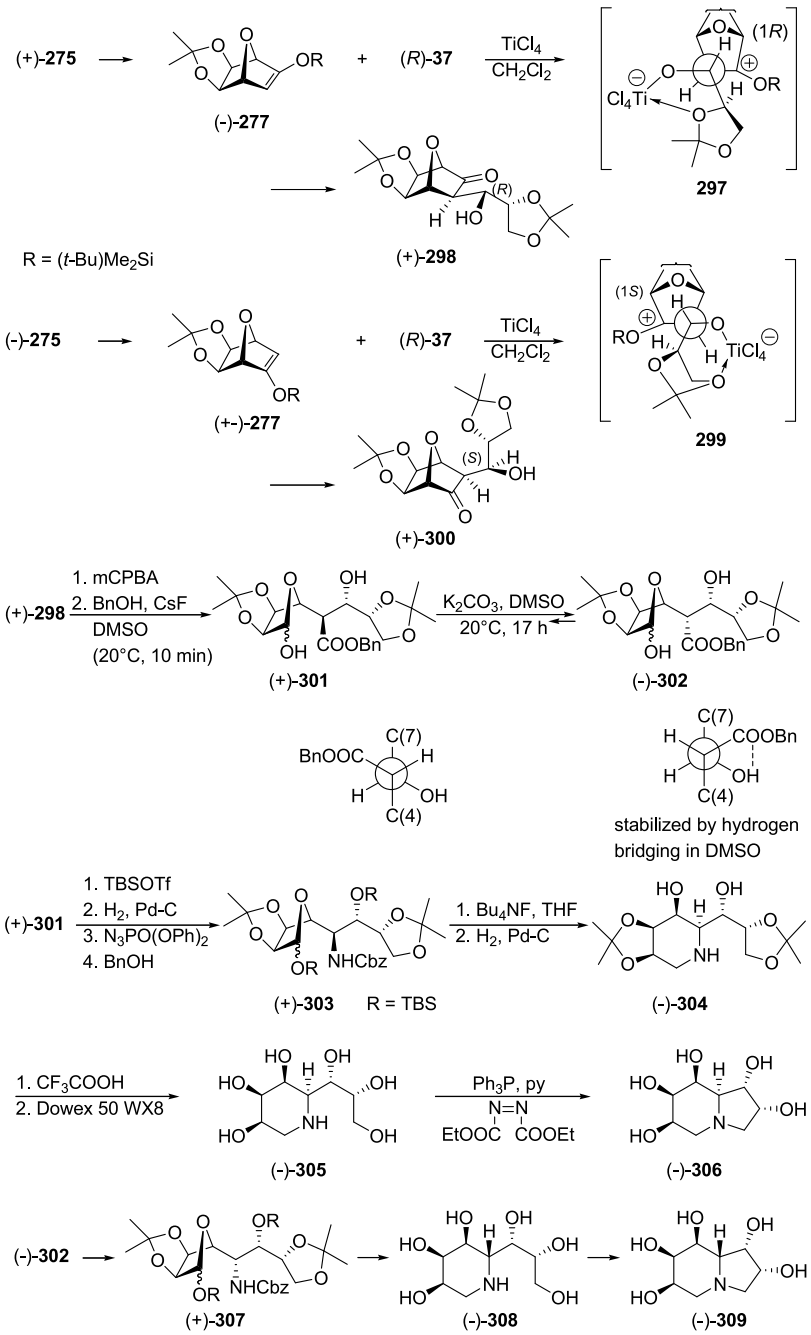


Scheme 85
Total synthesis of deoxypolyoxin C and of (+)-D-allonojirimycin

The "naked sugar" methodology has also provided deoxypolyoxin C (*Scheme 85*). The α-bromouronolactone (−)-**295** gives an allyl uronic ester on treatment with allyl alcohol and triflic acid. Selective hydrolysis of the allyl ester, followed by displacement of the bromide with the azide anion with retention of configuration generates an intermediate cesium carboxylate that reacts with benzyl bromide to give **296**. Conversion of **296** into a triacetate, followed by Vorbrüggen's glycosidation, reduction, and deprotection yields deoxypolyoxin C [448]. Intermediate **296** has been converted in two steps into (+)-D-allonojirimycin (*Scheme 85*) [449]. L-Daunosamine [427] and 2,3-dideoxy-D-*arabino*-hexose have also been derived from the "naked sugars" **271** and (+)-**274**, respectively [450,451].

7.3 Long-Chain Carbohydrates and Analogs

Mukaiyama cross-aldolizations of 2,3-*O*-isopropylidene-D-glyceraldehyde (*R*)-**37** with bicyclic ketones (+)-**275** and (−)-**275** are highly diastereoselective and lead to aldols (+)-**298** and (+)-**300**, respectively. For steric reasons only the *exo* face of the enoxysilanes (−)-**277** and (+)-**277** (see *Scheme 86*) can be attacked by the complexes [(*R*)-**37**] · $TiCl_4$. Depending on the configuration of the enoxysilanes, the (*R*)-**37** complex involving the 2-O or that involving the 3-O coordination with $TiCl_4$ reacts (transition states **297** vs. **299**, *Scheme 86*) to minimize steric repulsions. Baeyer–Villiger oxidation of aldol (+)-**301** generates the corresponding uronolactone that reacts with benzyl alcohol in DMSO and in the presence of cesium fluoride (base catalyst) to give the benzyl uronate (+)-**301** after 10 minutes at room temperature. On staying at this temperature in the presence of CsF, or of another base such



Scheme 86

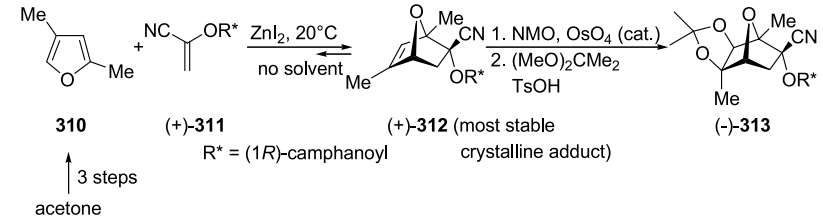
Cross-aldol reactions with "naked sugars": synthesis of long-chain carbohydrates, indolizidines, and analogs

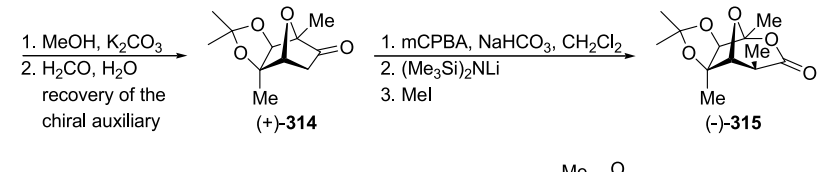
as K_2CO_3, (+)-**302** is epimerized into the more stable uronic ester (−)-**302**. Silylation of (+)-**301**, followed by hydrogenolysis of the benzyl ester and subsequent Curtius rearrangement (one-pot operation), provides the partially protected 5-amino-5-deoxy-D-*erythro*-D-*talo*-octofuranosides (+)-**303**. Desilylation of (+)-**303** and subsequent hydrogenolysis liberates the amine that engenders an imine with the aldose which is hydrogenated under the hydrogenolysis conditions, to give (−)-1,5-dideoxy-1,5-imino-2,3:7,8-di-*O*-isopropylidene-D-*erythro*-D-*talo*-octitol (−)-**304**. Acidic hydrolysis gives the unprotected 1,5-dideoxy-1,5-imino-octitol (−)-**305** which can be converted into the unprotected pentahydroxyindolizidine (−)-**306** in one step under Mitsunobu conditions. The same methods applied to benzyl uronate (−)-**302** leads to (+)-**307** that can be converted into (−)-1,5-dideoxy-1,5-imino-D-*erythro*-L-*allo*-octitol (−)-**308** and pentahydroxyindolizidine (−)-**309**. Following similar routes, aldol (+)-**300** has been converted into stereomeric 1,5-dideoxy-1,5-imino-alditols and pentahydroxyindolizidines. With the possibility to substitute the 7-oxabicyclo[2.2.1]heptan-2-one at C(5) and C(6) with two protected hydroxy groups in all possible configurations (see ❯ *Scheme 81*) or with other groups, the reaction sequence of ❯ *Scheme 86* makes possible the preparation of a large number of octose derivatives. This demonstrates the high efficiency and versatility of the "naked sugar" methodology for the de novo synthesis of unusual and complicated monosaccharides [452,453].

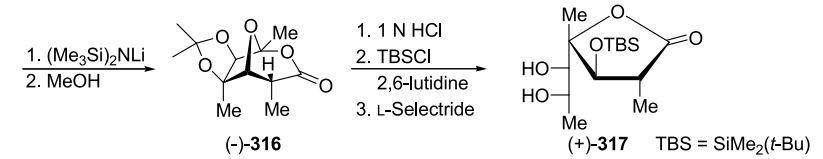
7.4 "Naked Sugars of the Second Generation": Synthesis of Doubly Branched-Chain Sugars

Doubly branched heptono-1,4-lactones as well as polypropionate fragments have been obtained from 2,4-dimethylfuran (**310**) via its Diels–Alder addition to 1-cyanovinyl-(1′*R*)-camphanate (+)-**311** [454]. Without solvent, the ZnI_2-catalyzed and reversible cycloaddition leads to a major crystalline diastereomeric adduct (+)-**312**. Double hydroxylation of the alkene moiety of (+)-**312**, followed by diol protection as an acetonide provides (−)-**313**. Methanolysis followed by treatment with formaline liberates ketone (+)-**314**. Baeyer–Villiger oxidation and subsequent α-methylation generates the *exo*-α-methyluronolactone (−)-**315**. Quenching of the lithium enolate of (−)-**315** with MeOH at –50 °C gives the *endo*-α-methyluronolactone (−)-**316**. Acidic hydrolysis of (−)-**316** and subsequent silylation and reduction forms (+)-**317** as the major heptono-1,4-lactone (❯ *Scheme 87*). Similarly, enantiomers of this doubly branched sugar can be prepared starting from adduct (−)-**318** obtained by addition of 2,4-dimethylfuran (**310**) to 1-cyanovinyl (1′*S*)-camphanate [(−)-**311**)]. After conversion of (−)-**318** into dimethyl acetal **319**, regio- and *exo*-face selective hydroboration and further transformations generate the doubly branched uronic acid (−)-**321** [455].

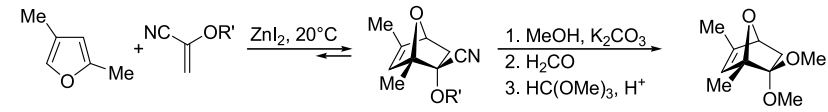
The method of thermodynamic diastereoselection (through diastereoselective crystallization of equilibrating adducts, see ❯ *Scheme 87*) has been applied to furan derivatives bearing chiral auxiliaries that can be recovered readily. For instance, the acetal of (2*S*,3*S*)-butane-2,3-diol and furfural is equilibrated in molten maleic anhydride with one major crystalline product [456]. In a similar way (1,*S*)-camphanate of furfuryl alcohol undergoes Diels–Alder addition in molten maleic anhydride giving one major crystalline adduct (+)-**322** [457] that has been converted into doubly branched carba-hexopyranoses and derivatives [458], and into the new 2,6-dideoxy-2,6-iminoheptitol **324** (❯ *Scheme 88*) [459].

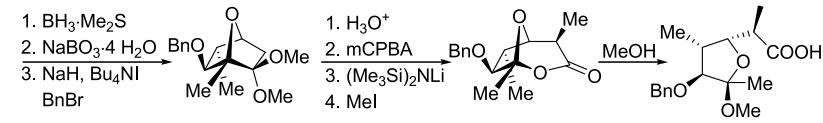






a





b

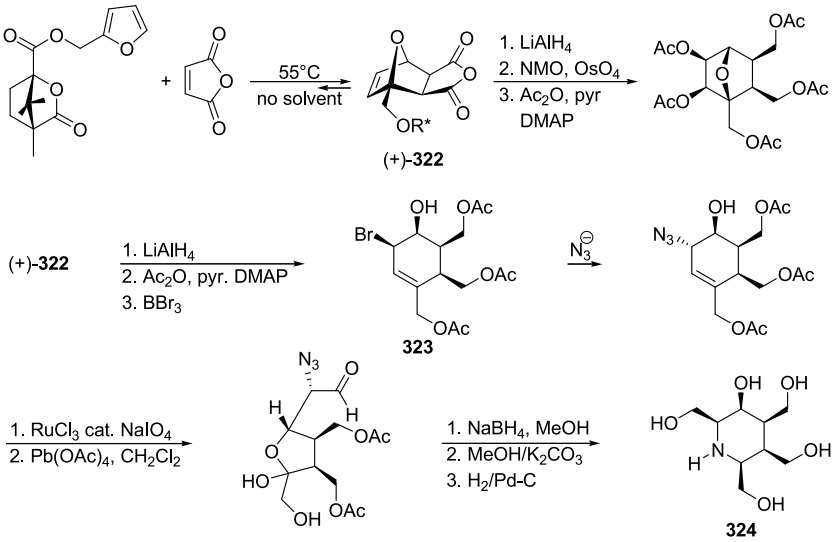
Scheme 87
Applications of the "naked sugars of the second generation" to the synthesis of branched-chain sugar derivatives

7.5 [4+3]-Cycloadditions of Furan

Apart from [4+2]-cycloadditions, furans undergo [4+3]-cycloadditions and dipolar [2+3]-cycloadditions. The reaction of nitrones to furan has been applied to prepare (+)-Norijimycin [460], aminopolyols [461,462,463] (+)- and (−)-1-deoxynojirimycin, (+)- and (−)-1-deoxy-idononojirimycin [464].

7.5.1 Synthesis of Semi-Protected 2,6-Anhydroheptitols

The [4+3]-cycloaddition of furan to the 1,3-dibromo-2-oxyallyl cation generates, after dehalogenation with the zinc/copper couple, 8-oxabicyclo[3.2.1]oct-6-en-3-one (**325**). It



Scheme 88
Synthesis of a doubly branched iminoalditol

was converted into the semi-protected methyl 3,6-anhydro-2-deoxy-L-allo-heptonate **326** (*Scheme 89*) [465].

Hoffmann and co-workers [466,467] have developed general procedures that convert **325** into a number of 2,6-anhydroheptitols as enantiomerically pure isomers (*Scheme 90*). The treatment of **325** with (+)-bis[(*R*)-1-phenylethyl]amine, nBuLi, and Et_3SiCl/Et_3N (in situ quench) in THF gives the corresponding silyl enol ether that is oxidized with *meta*-chloroperbenzoic acid (mCPBA) in THF/H_2O into (−)-**327**. The β-hydroxyketone so-obtained is silylated and enolized on its turn with lithium diisopropylamide (LDA) in the presence of Et_3SiCl/Et_3N. The intermediate enol ether is then oxidized on its turn with mCPBA. After treatment with $CF_3COOH/THF/H_2O$ (−)-**328** is isolated in 62% overall yield. The reduction of (−)-**328** with $NaBH(OAc)_3$ gives *endo* alcohol **329**, whereas reduction with $NaBH_4$ and $MgBr_2$ in MeOH affords the exo alcohol **331**. Oxidative cleavage of the endocyclic alkene moieties of **329** and **331**, and subsequent reduction with $NaBH_4$ and acetalization with benzaldehyde dimethyl acetal provides alditols **330** and **332**, respectively. Selective monobenzoylation of **331**, followed by inversion of alcohol at C-2 provides **333** that is then converted into the 2,6-anhydroheptitol derivative **334** (*Scheme 90*).

Enantiomerically pure 3-oxo-8-oxabicyclo[3.2.1]oct-2-yl derivatives have been obtained by [4+3]-addition of furan with chiral 1,2-dioxyallyl cation engendered in situ by acid-catalyzed heterolysis of enantiomerically pure mixed acetals derived from 1,1-dimethoxyacetone and enantiomerically pure secondary benzyl alcohols [467]. For instance, mixed acetal **335** is enolized into the silyl enol ether **336**. In the presence of a catalytic amount of trimethyl silyl triflate, **336** generates a cationic intermediate that adds to furan at –95 °C giving adduct (−)-**337**. The latter can be enolized regioselectively and oxidized with mCPBA giving, after esterification, pivalate **338**. Reduction with $NaBH_4$ and subsequent alkene cleavage generates

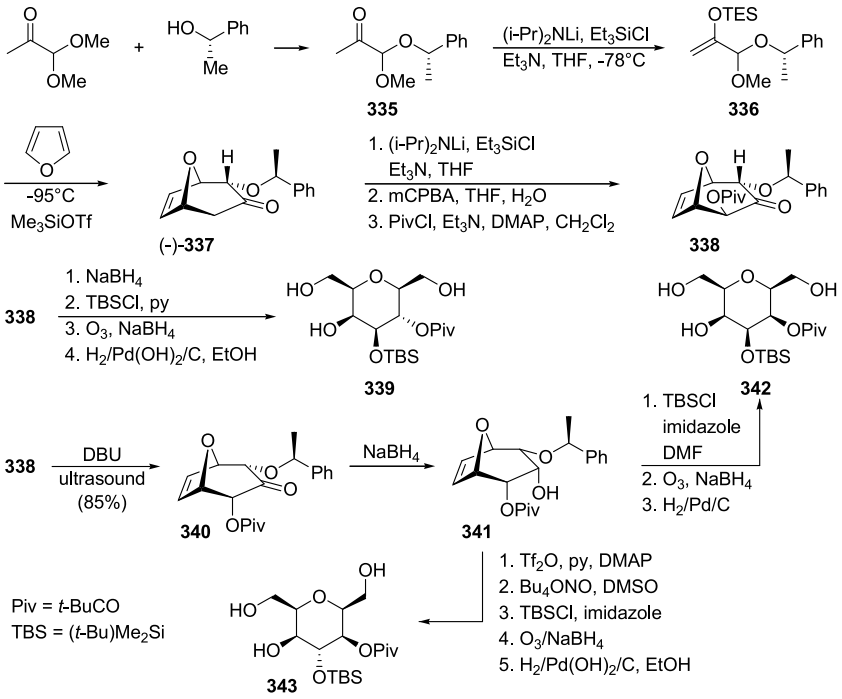
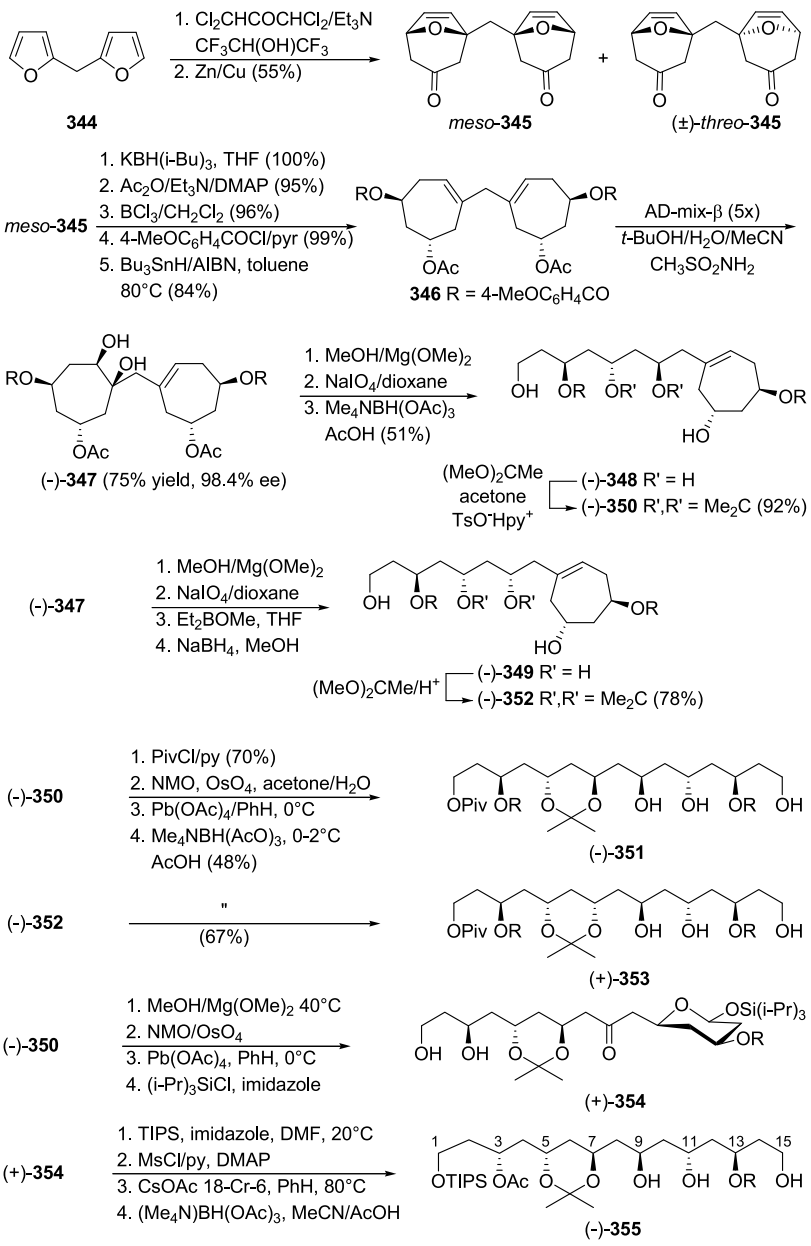


Scheme 91
Hoffmann's asymmetric [4+3]-cycloaddition of furan: total synthesis of 2,6-anhydroheptitols

339. Treatment of pivalate **338** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and ultrasound gives the 2-epimer **340**. Its reduction with $NaBH_4$ gives **341**. Subsequent alkene cleavage generates **342**. Inversion of the alcohol moiety C-3 of **342**, followed by alkene cleavage furnishes the 2,8-anhydroheptitol **343** (*Scheme 91*) [466,467].

7.6 Synthesis of Long-Chain Polyketides and Analogues

Polyketides include 1,3-polyols that can be seen as long-chain polydeoxyalditols. A noniterative and asymmetric synthesis of all possible stereoisomeric pentadecane-1,3,5,7,9,11,13,15-octols [468], of 3,5,7,9,11,13,15-heptahydroxypentadecanals [469] and corresponding 1,7-dioxaspiro[5.5]undecanes [470] has been developed applying the double [4+3]-cycloaddition of 1,1,3-trichloro-2-oxyallyl cation to 2,2′-methylenedifuran (**344**). Treatment of **344** with 2.6 equivalents of 1,1,3,3-tetrachloroacetone and Et_3N in $CF_3CH(OH)CF_3$ gives a mixture of hexachlorinated adducts that are not isolated but directly reduced with Zn/Cu in MeOH saturated with NH_4Cl. This produces a 45:55 mixture (55% based on **344**) of *meso*-**345** and (±)-*threo*-**345** that is separated by crystallization from furan first and then from H_2O. The expensive $CF_3CH(OH)CF_3$ solvent can be exchanged for toluene and the [4+3]-cycloaddition

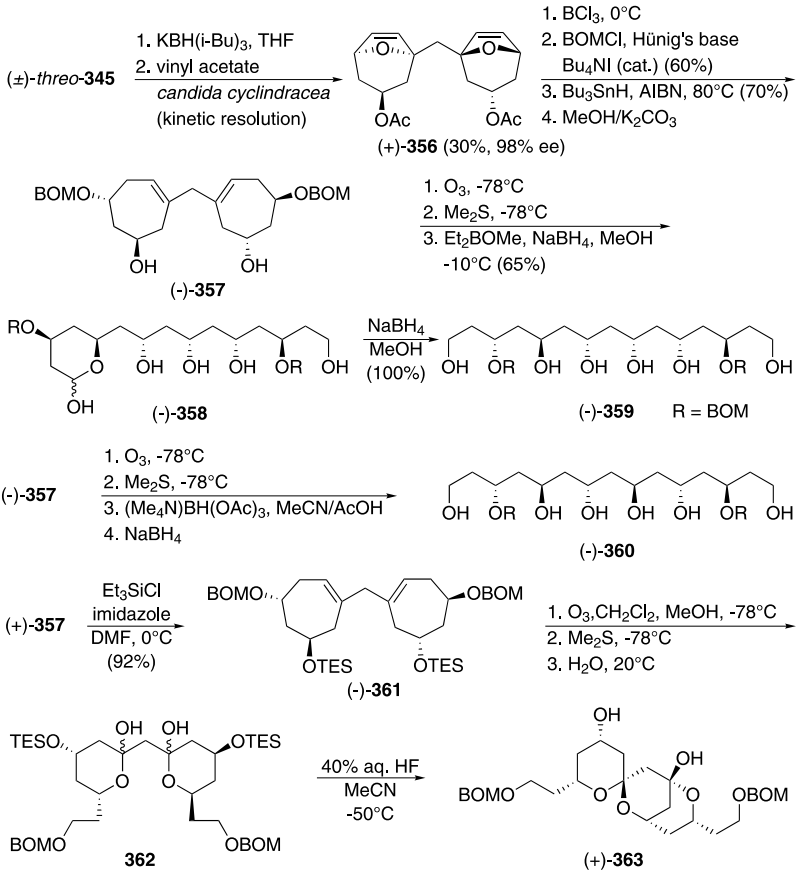


Scheme 92
Noniterative synthesis of long-chain 1,3-polyols

uses 1,3-dibromo-1,3-dichloroacetone with Et_2Zn. Under these conditions the same mixture of *meso*-**345** and *threo*-**345** is obtained in 40% yield [471].

Acetylation of diol *meso*-**345**, subsequent S_N2' opening with BCl_3, and esterification with *p*-methoxybenzoyl chloride/pyridine gives a dichloride that is dechlorinated into **346**.

Desymmetrization of **346** is realized by means of the Sharpless asymmetric dihydroxylation giving diol (−)-**347** as the major product (98.4% ee). After selective deacetylation of (−)-**347** with MeOH/$Mg(OMe)_2$, Malaprade oxidative cleavage of the vicinol diol, Evans' reduction [472] ($Me_4NBH(OAc)_3$) of the intermediate oxo-aldehyde delivers (−)-**348** in 75% overall yield, whereas Et_2BOMe and $NaBH_4$ (Narasaka's reduction [307,473]) furnishes (+)-**349**. Selective esterification of the primary alcohol moiety of (−)-**350** (acetonide of (−)-**348**) as the pivalate and subsequent oxidative cleavage of the cycloheptene ring and Evans' aldol reduction provides the semi-protected pentadecaneoctol derivative (−)-**351**. Similarly, stereoisomer (+)-**353** was derived from (−)-**352**. Two further stereoisomeric polyols



Scheme 93
Expeditious asymmetric synthesis of 3,5,7,9,11,13,15-heptahydroxypentadecanals and derivatives

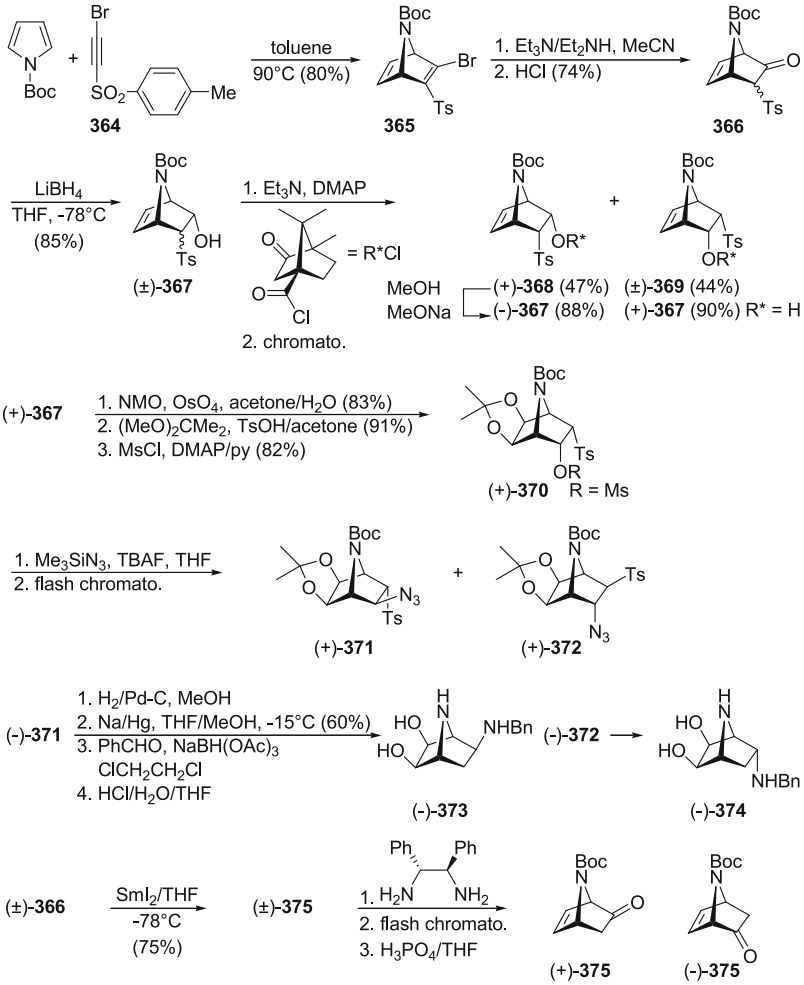
can be obtained by applying Narasaka's rather than Evans' reductive conditions. Starting with AD-mix-α, the enantiomers of these eight polyols are obtained with the same ease. Selective methanolysis of the acyclic *p*-methoxybenzoate (−)-**350** gives a diol that was then converted into (+)-**354**. Selective monosilylation of diol (+)-**354**, subsequent mesylation of the secondary alcohol and displacement with CsOAc generates, after Evans' reduction, the stereoisomeric semi-protected polyol (−)-**355**, or its 9-epimer under Narasaka's reduction conditions. Thus, combining the two enantiomeric Sharpless dihydroxylations to desymmetrize **346**, the Evans' and Narasaka's reduction techniques and the inversion of alcohol at C-3 (as shown for (+)-**354** → (−)-**355**) all possible stereoisomers of pentadecane-1,3,5,6,7,9,13,15-octols can be made quickly (*Scheme 92*). The method has been used to prepare the polyol subunit of the polyene macrolide antibiotic RK-397 [474]. It has been used also to prepare enantiomerically enriched (98%) 1-aminopentadecane-3,5,7,9,11,13,15-heptols and 1,15-diaminopentadecane-3,5,7,9,11,13-hexols and derivatives [475].

Racemic (±)-*threo*-**345** has been converted into diacetate (+)-**356** via enzymatic kinetic resolution of the corresponding racemic diol [476]. Ring opening of (+)-**356** with BCl_3, quenching of the bisborate as BOM ($PhCH_2OCH_2$bisacetal, reductive dechlorination and methanolysis of the diacetate provides diol (−)-**357**. Ozonolysis of diene (−)-**357** and subsequent Narasaka's reduction using a controlled amount of $NaBH_4$ allows the isolation of hemiacetal (−)-**358**. With an excess of $NaBH_4$, the semi-protected octol (−)-**359** is obtained. Applying Evans' conditions for reduction of the bis(β-hydroxyketone) resulting from the ozonolyis of diene (−)-**357** (−)-**360** is obtained (*Scheme 93*) [469]. With the silyl diether (−)-**361**, ozonolysis provides a mixture of hemiacetals **362** that was isomerized into spiroketal (+)-**363** (*Scheme 93*) [470].

8 Diels–Alder Addition of Pyrroles: "Naked Aza-Sugars"

Cycloaddition of 2-bromoethynyl *p*-tolyl sulfone (**364**) to *N*-Boc pyrrole gives 7-azanorbornadiene derivative **365** [477]. Treatment of **365** with Et_2NH and Et_3N, followed by hydrolysis with 10% aqueous HCl affords ketone **366** as a 1:1.2 mixture of *endo* vs. *exo* stereoisomers. Reduction of **366** with $LiBH_4$ provides exclusively the *endo*-alcohols (±)-**367** that were resolved by flash chromatography of their diastereomeric (1*S*,4*R*)-camphanates (+)-**368** and (−)-**369**. Methanolysis of these esters delivers (−)-**367** and (+)-**367**, respectively [478]. *Exo* selective dihydroxylation of alkene (+)-**367** and subsequent diol protection as an acetonide and *endo* alcohol mesylation provides (+)-**370** which was reacted with Me_3SiN_3 and Bu_4NF in THF. At 25° C a 5:1 mixture of (+)-**371** and (+)-**372** was obtained. These compounds are separated by flash column chromatography. Starting from (−)-**367** the enantiomers (−)-**371** and (−)-**372** are obtained [479]. Hydrogenation of (−)-**371**, desulfonylation with Na/Hg, reductive amination of benzaldehyde, and acidic removal of the Boc group provides (−)-**373**, an inhibitor of β-glycosidase from almonds (*Scheme 94*). Applying the same reaction sequence to (−)-**372** gives (−)-**374**. Desulfonylation of (±)-**366** with SmI_2 generates racemic *N*-Boc-7-azanorbornenone that can be resolved into (+)-**375** and (−)-**375** applying Alexakis optical resolution [480].

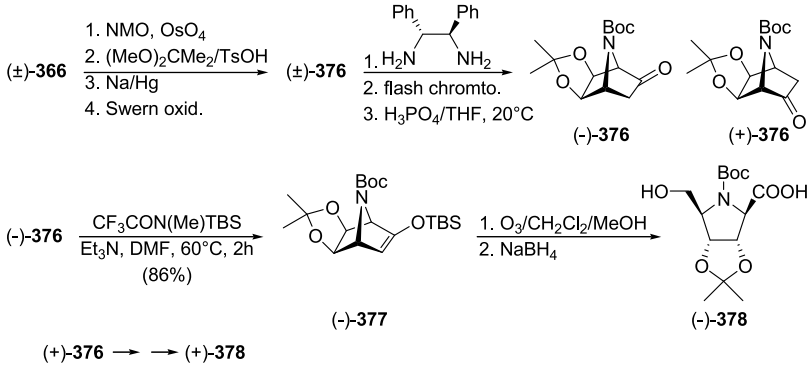
Similarly, ketone (±)-**376** obtained by dihydroxylation of **366**, followed by diol protection as acetonide, desulfonylation with Na/Hg, and Swern oxidation has been resolved by the Alex-



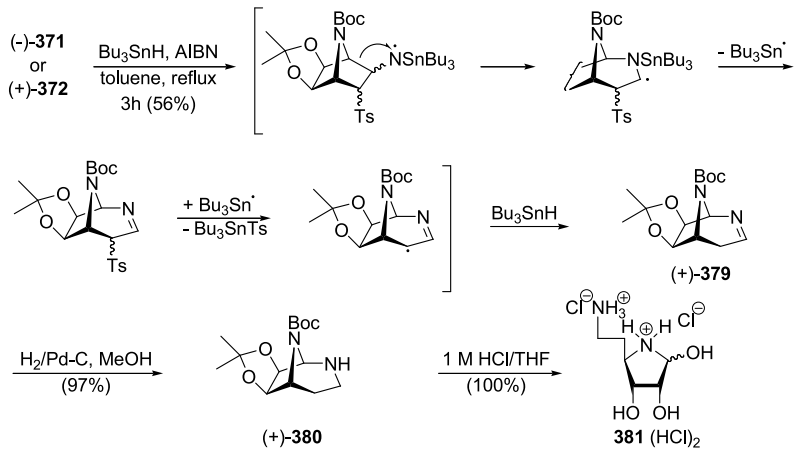
Scheme 94
Synthesis of enantiomerically pure 5-amino-7-aza-norbornane-2,3-diols and of the *N*-Boc-7-azanorbornenones ("Aza-naked sugars")

akis method [481] giving ketones (−)-**376** and (+)-**376**. The silyl enol ether (−)-**377** derived from (−)-**376** is ozonolyzed into the L-proline derivative (−)-**378** after reductive work-up with $NaBH_4$. Enantiomer (+)-**378** is obtained with the same ease from (+)-**376** (*Scheme 95*). These 2,5-dideoxy-2,5-imino-allonic acid derivatives have been used in the synthesis of tripeptides containing them [482].

Desulfonylation of (−)-**371** and (+)-**372** with Bu_3SnH and azoisobutyronitrile (AIBN) gives the 2,8-diazabicyclo[3,2,1]oct-2-ene derivative (+)-**379** as a major product. The proposed mechanism for this transformation is outlined in *Scheme 96*. Catalytic hydrogenation of (+)-**379** affords (+)-**380**. Upon treatment with aqueous HCl in THF, quantitative formation of **381** · HCl is observed. Starting from (+)-**371** and (−)-**372**, the enantiomer of **381** · $(HCl)_2$



Scheme 95
Synthesis of 2,5-dideoxy-2,5-imino-D- and L-allonic acid derivatives



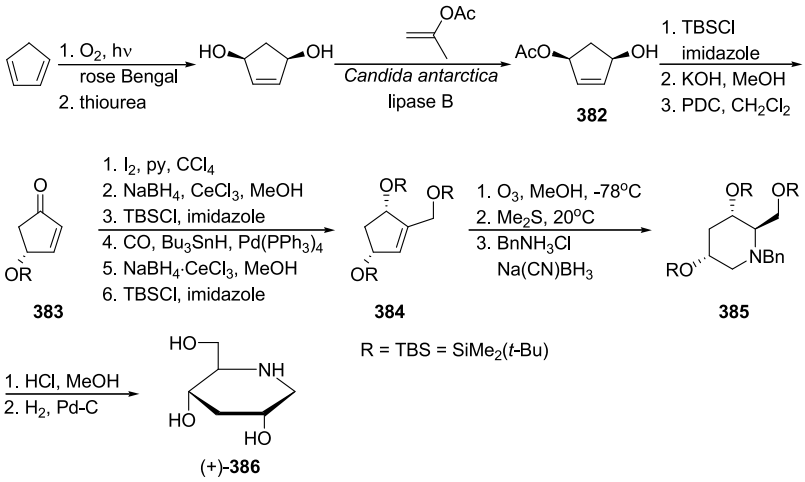
Scheme 96
Synthesis of 4,6-diamino-4,5,6-trideoxy-D-*ribo*-hexofuranose

is obtained in the same way. The 4,6-diamino-4,5,6-trideoxyhexoses are potent inhibitors of α-mannosidases [483].

9 Carbohydrates and Analogs From Achiral Polyenes

9.1 From Cyclopentadiene

Xylitol has been derived from the product of photo-oxidation of cyclopentadiene [484] which is (*Z*)-(4*RS*)-4,5-epoxypent-2-enal. An elegant total synthesis of acosamine and of daunosamine (13 steps, 15% overall yield) was developed at Roche starting from cyclopentadiene [485]. The key-step is the asymmetric monohydroboration of 5-methylcyclopentadiene with (−)-di-3-pinanylborane.



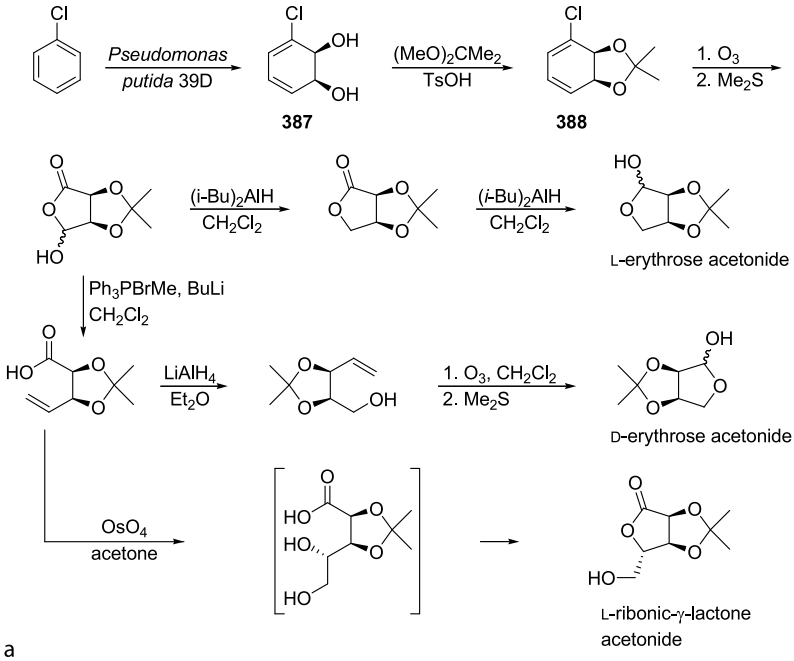
Scheme 97
Johnson's synthesis of 1,3-dideoxynojirimycin

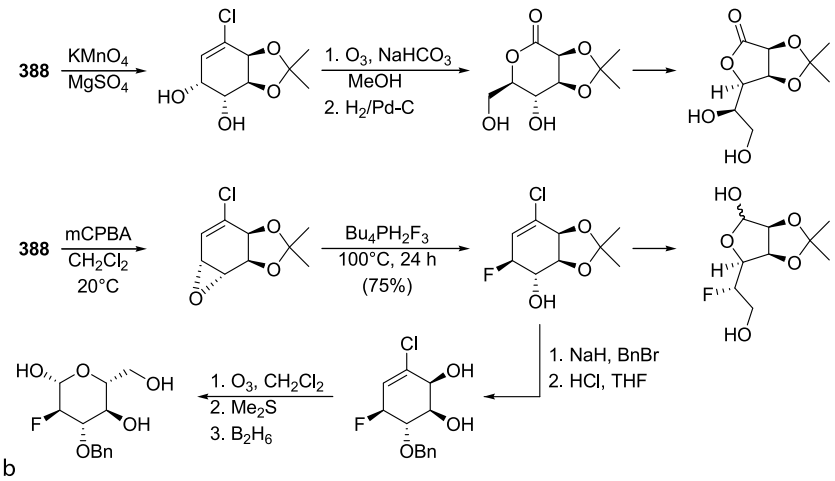
A total synthesis of 1,3-dideoxynojirimycin ((+)-**386**) starting from cyclopentadiene has been proposed by Johnson and co-workers [486]. Photooxidation of cyclopentadiene and reductive work-up with thiourea generates *cis*-cyclopent-2-ene-1,4-diol which is monoacylated with high enantioselectivity (>99% ee) with isoprenyl acetate and *Candida antarctica* lipase B (Novo Nordisk SP 435) to give **382**. After silylation of **382** and subsequent treatment with KOH and oxidation, enantiomerically pure enone **383** is obtained [487]. Treatment of **383** with iodine and pyridine leads to α-iodination [488]. Successive reduction under Luche conditions, alcohol silylation, carbonylation of the iodoalkene, reduction of the obtained enal, and alcohol silylation leads to **384**. Ozonolysis of **384** gives the corresponding keto-aldehyde which is then transformed into **385** via reductive amination with high diastereoselectivity (*syn*:*anti*> 20:1). Deprotection delivers (+)-**385** (*Scheme 97*). A similar approach has converted enantiomerically pure (2*R*,3*R*)-2,3-isopropylidenedioxycyclopent-4-en-1-one derived from cyclopentadiene [489,490] into (−)-1-deoxymannonojirimycin and (−)-1-deoxytalonojirimycin (1,5-dideoxy-1,5-imino-D-talitol) [491]. Enone **383** has been converted to (2*R*,3*S*)-2,3-bis[(*tert*-butyl)dimethylsilyloxy]cyclopent-4-en-1-one and then to (+)-1-deoxynojirimycin [492].
Mehta and co-workers have presented [493,494] a synthesis of racemic deoxynojirimycin analogs and isofagomin analogs, starting from the Diels–Alder adduct of vinyl acetate to 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene.

9.2 From Benzene and Derivatives

Dioxygenases present in the blocked mutants of *Pseudomonas putida*, a soil bacterium, degrades benzene and its derivatives into cyclohexa-3,5-diene-1,2-diols. With chlorobenzene, diol **387** is obtained with >99% ee. This compound is converted in a few chemical steps into

tetrose, pentose, and hexose derivatives (Scheme 98a) [495]. Further applications of this methodology are shown in Scheme 98b [496] and Scheme 98c [497]. A recombinant strain of *Escherichia coli* expressing naphthalene dioxygenase from *Pseudomonas* sp. NCIB





Scheme 98

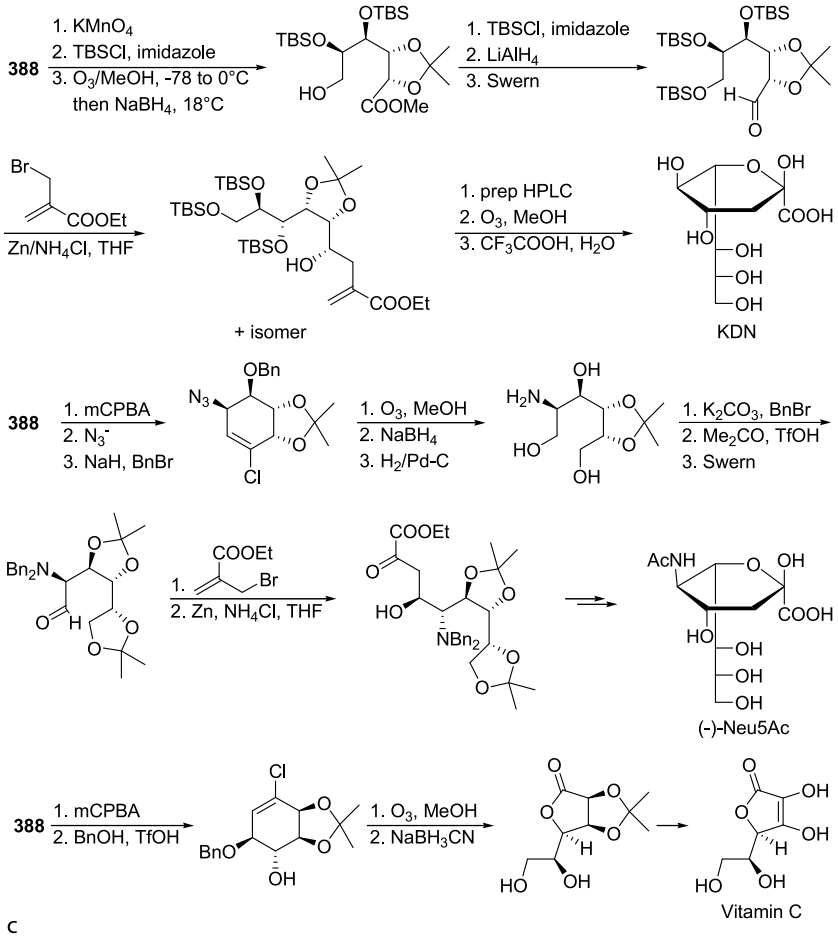


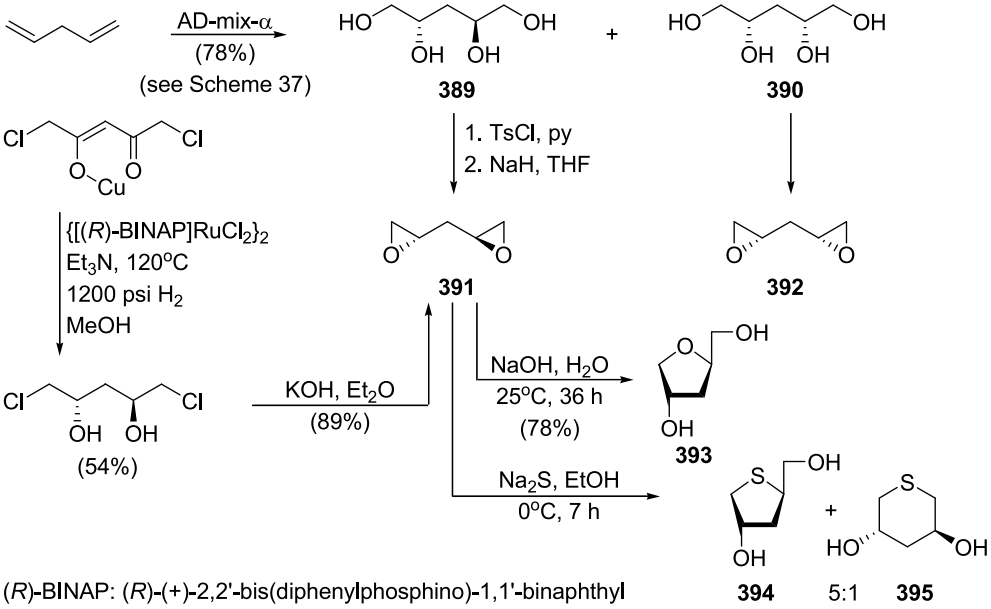
Scheme 98
(continued) Banwell's total syntheses of KDN, Neu5Ac, and Vitamin C

9816-4 has been found to oxidize specifically *N*-methyl-2-pyridone into the *cis*-5,6-dihydro-5,6-dihydroxy derivative [498].

9.3 From Cycloheptatriene and Cyclooctatetraene

Cycloheptatriene has been converted into L-glucose via *Pseudomonas cepacia* lipase-mediated desymmetrization of a *meso*-3-*O*-protected cyclohept-6-ene-1,3,5-triol using isopropenyl acetate as the solvent [499,500,501].

Cycloheptatrienone (tropone) has been converted into heptitol derivatives via the optical resolution of the (tropone)$Fe(CO)_3$ complex [502]. Racemic methyl β-allopyranoside and a 2*C*-branched analogue have been derived from cyclooctatetraene [503].



Scheme 99
Conversion of penta-1,4-diene into pentitol derivatives

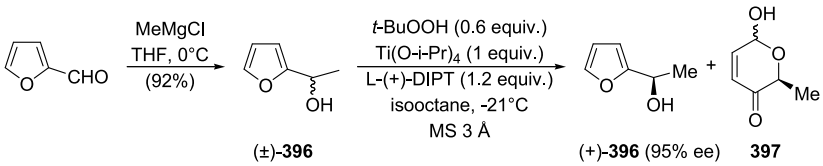
9.4 From Penta-1,4-Diene

When applied to penta-1,4-diene, the Sharpless asymmetric dihydroxylation forms a 1:1 mixture of (2*S*,4*S*)- and (2*S*,4*R*)-penta-1,2,4,5-tetrols **389** and **390** which can be converted to diepoxides **391** and **392**, respectively (*Scheme 99*) [504]. A stereo- and enantioselective synthesis of **391** is possible starting from 1,5-dichloropenta-2,4-diene applying Noyori's asymmetric hydrogenation [505]. Diepoxide **391** has been converted into alditol **393** and thioalditols **394** and **395**.

9.5 From Furfural

Furfural (furfuraldehyde) is a very inexpensive starting material obtained from the left-overs of agriculture (acidic distillation of straw and brans) [506]. It adds MeMgCl giving racemic 1-(2-furyl)ethanol ((±)-**396**) which has been resolved easily using either enzymatic methods [507,508,509] or metal-catalyzed kinetic resolution [510,511]. For instance, the reaction (±)-**396** with *t*-butyl hydroperoxide in the presence of catalytic amounts of $Ti(O\text{-}i\text{-}Pr)_4$ and L-(+)-di-isopropyl tartrate (L-(+)-DIPT) gives a mixture of optically active (+)-**396** and pyranone **397**. These compounds are separated readily and isolated in 32 and 53% yield, respectively (*Scheme 100*) [512,513].

Utilizing Novozyme 435 (immobilized on acrylic resin) to catalyze the transacetylation of (±)-**396** with isopropenyl acetate in $(i\text{-}Pr)_2O$, (−)-**396** is obtained in 36% yield and with an



Scheme 100
Oxidative kinetic resolution of 1-(2-furyl)ethanol

enantiomeric excess better than 95% (55% conversion rate). If the reaction is stopped at 45% conversion rate, ester **398** is obtained in > 97% ee. The same enzyme catalyzes the fast hydrolysis of **398** into (+)-**396** (*Scheme 101*) [514,515]. Oxidation of (+)-**396** with *N*-bromosuccinimide in THF/H_2O gives **399**. Subsequent oxidation with $CrO_3 \cdot NH_4Cl$ in CH_2Cl_2 furnishes **400** that is reduced into pure **401** under Luche's conditions ($NaBH_4/CeCl_3$) at –78 °C, and into a 2:1 mixture of **401** and **402** at 0 °C. Compound **402** is isolated and converted into pyranoses **403**–**405** as outlined in *Scheme 101* [514,515]. *C*-linked disaccharides have been derived from 1,4-di(2-furyl)butane-1,4-diol in a similar way [516].

10 Kinetic Resolution of Racemic Allylic Electrophiles

The Katsuki–Sharpless asymmetric epoxidation of racemic diol (±)-**406** (obtained by allylation of (*E*)-crotonaldehyde) gives, after chromatographic separation, the *erythro*-epoxide (+)-**407** (33% yield, > 95% ee) and (−)-**406** (*Scheme 102*). These intermediates have been converted into (+)-D-olivose and (+)-D-ditoxose [517,518,519]. In a similar manner, asymmetric epoxidation of dienol (±)-**408** leads to (+)-**409**, which has been converted into (+)-oliose, and to (−)-**408**, which has been converted into (+)-cymarose [520,521].

D- and L-Chalcose have been prepared in a similar way from the racemic mixtures of *threo*-dipropenylglycol (±)-**410** obtained by reductive dimerization of crotonaldehyde [522].

A simple, divergent, asymmetric synthesis of the four stereomers of the 3-amino-2,3,6-trideoxy-L-hexose family has been proposed by Dai and co-workers [523] which is based on the Katsuki–Sharpless asymmetric epoxidation of allylic alcohols (±)-**408**. *N*-Trifluoroacetyl-L-daunosamine, *N*-trifluoro acetyl-L-acosamine, *N*-benzoyl-D-acosamine, and *N*-benzoyl-D-nitrosamine have been derived from methyl sorbate via the methyl 4,5-epoxy-(*E*)-hex-2-enoates obtained via a chemoenzymatic method [524]. Application of the Katsuki–Sharpless enantioselective epoxidation to racemic mono-*O*-benzylated divinylglycol has allowed us to prepare enantiomerically pure L-*lyxo* and D-*lyxo*-pentoses and analogs [525,526,527,528].

Palladium-catalyzed asymmetric allylic alkylation [529] of suitable amines with two equivalents of racemic butadiene monoxide ((+)-**411**) allows for the expedient synthesis of *trans*- and *cis*-2,5-dihydropyrroles derivatives **416** and **417** that are versatile chirons towards the synthesis of a wide variety of iminosugars [530]. In the presence of 0.4% $[(allyl)PdCl)_2]$, 1.2% of enantiomerically pure diphosphine (*R*,*R*)-ligand, and Na_2CO_3 a 1:1 mixture of (±)-**411** and phthalimide reacted in CH_2Cl_2 at room temperature giving (*S*)-**412** in 99.6% yield and

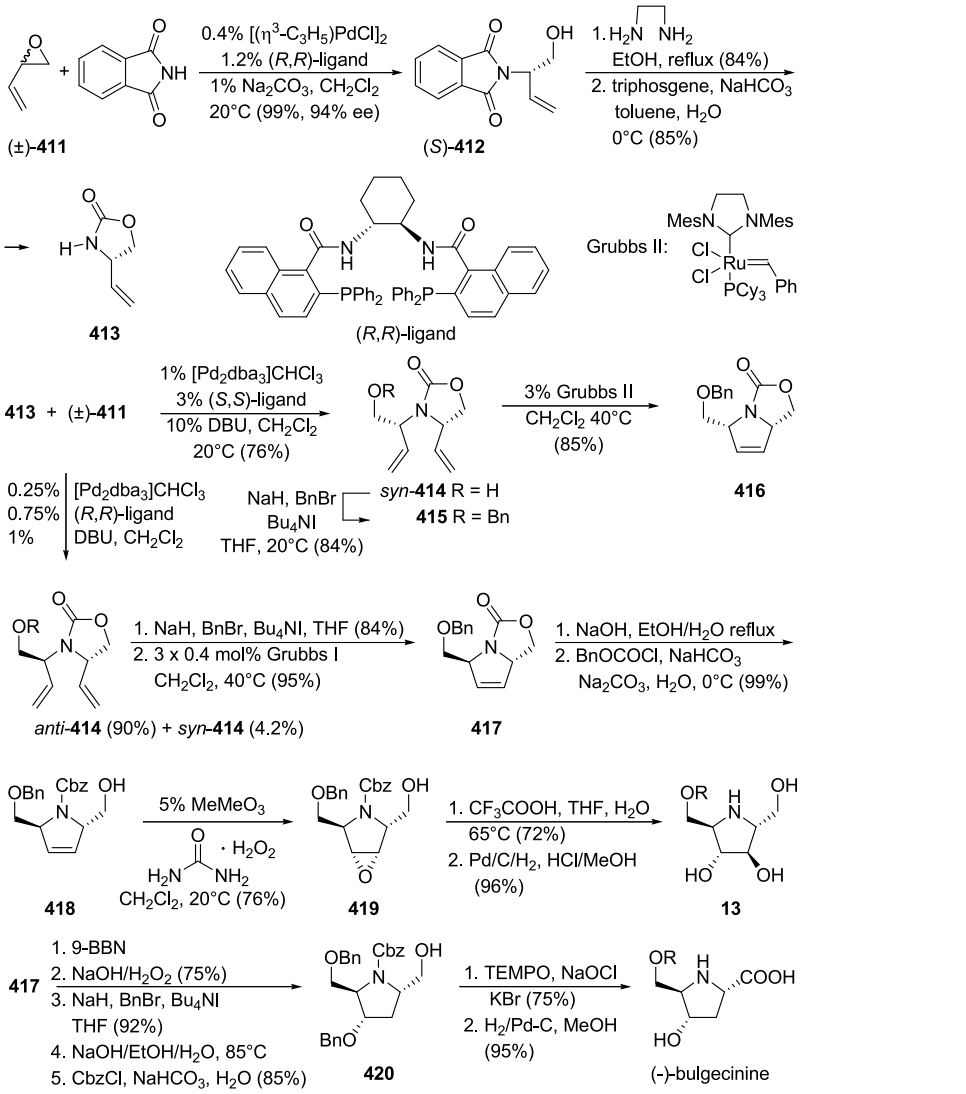


Scheme 103

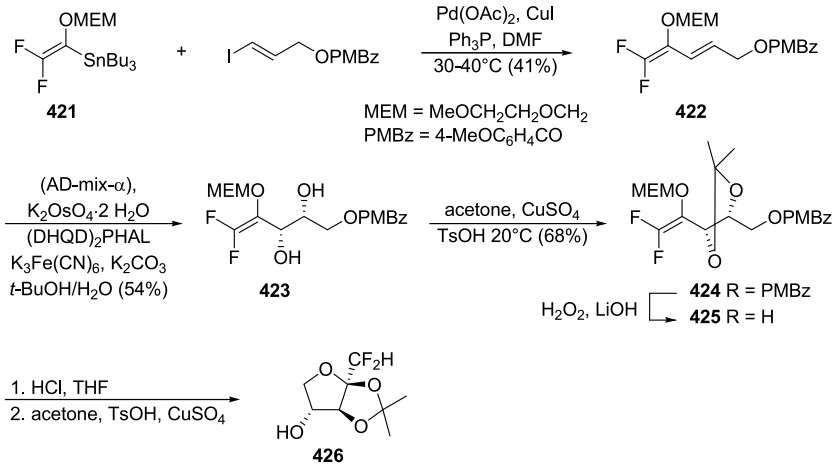
Trost's dynamic kinetic asymmetric amine allylation applied to the synthesis of 3,5-dideoxy-2,5-imino-D-mannitol and (−)-bulgecinine

94.4% ee. Under these conditions deracemization of (±)-**410** occurs and a dynamic kinetic asymmetric transformation is realized. Both enantiomers of epoxide (±)-**410** are converted into a single product of allylation (*S*)-**412**. Recrystallization from EtOH provides (*S*)-**412** with >99% ee. Unmasking of the amino group by aminolysis of (*S*)-**412**, followed by cyclization with triphosgene affords oxazolidinone **413**, the substrate for a second dynamic kinetic asymmetric reaction with epoxide (±)-**411** (*Scheme 103*). Thus, combining (±)-**411** with **413**

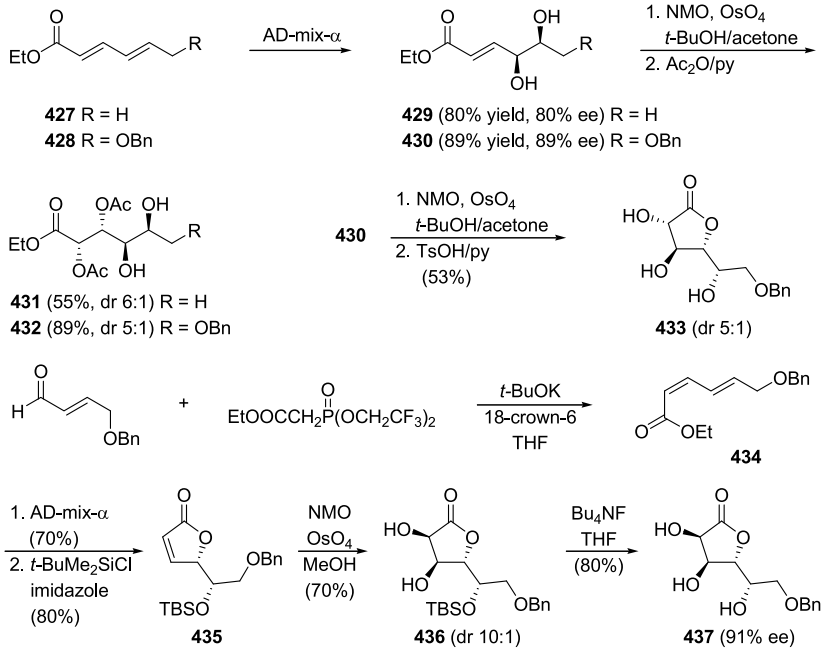
in the presence of 1% $[Pd_2dba_3]\cdot CHCl_3$ (dba = dibenzylideneacetone), 10% DBU, and 3% of diphosphine (*S*,*S*)-ligand, *syn*-**414** is obtained in 76% yield and a diastereomeric ratio (dr) (*syn* vs. *anti*) of 9:1. Ring-closing metathesis of the benzyl ether **415** (3 mol% Grubbs II catalyst) provides **416**. When using the (*R*,*R*)-ligand instead of the (*S*,*S*)-ligand in the second dynamic kinetic asymmetric reaction of (±)-**411** with **413**, *anti*-**414** is obtained in 90% yield (diastereoselectivity *anti* vs. *syn* 10:1). After benzylation and ring-closing methathesis *anti*-**414** produces **417**. Alkaline hydrolysis of carbamate **417** and subsequent amine protection delivers **418**. Its epoxidation required catalytic methyltrioxorhenium and urea·H_2O_2 giving a 76% yield in epoxide **419**. After regioselective epoxide ring hydrolysis and debenzylation iminosugar **13** is obtained (11 steps, 22% overall yield). Regio- and stereoselective hydroboration of **417** is possible using 9-borabicyclo[3.3.1]nonane (9-BBN). This leads to 75% yield of an alcohol that is benzylated. Subsequent carbamate hydrolysis and amine protection as benzylcarbamate provides **420**. Its primary alcohol moiety is oxidized into the corresponding carboxylic acid. Catalytic hydrogenolysis delivers (−)-bulgecinine (➲ *Scheme 103*) [530]. The same chemistry shown in ➲ *Scheme 103* using the (*S*,*S*)-ligand instead of the (*R*,*R*)-ligand in the first dynamic kinetic asymmetric allylation of phthalimide with racemic epoxide (±)-**411** allows us to prepare the enantiomers of **13** and (+)-bulgecinine with the same ease.

11 Enantioselective Sharpless Dihydroxylation

This extremely powerful method has already been presented in ➲ *Scheme 37* and selected examples of application are collected in this section. For instance, tetritol and tetrose derivatives have been prepared through asymmetric dihydroxylation of (*E*)-but-2-ene-1,4-diol [531] and 4-deoxy D- and L-threose are derived from benzene-1,2-dimethyl acetal of (*E*)-crotonaldehyde. Asymmetric dihydroxylation of the dimethyl acetal of 5-[(*tert*-butyldiphenylsilyl)oxy]-(*E*)-pent-3-enal generates a diol that is converted in three steps into 2-deoxyxylofuranosides with high enantiomeric excess [532]. Asymmetric dihydroxylation of 2-vinylfuran gives a diol that has been converted into (+)-isolevoglucosenone. This compound can be isomerized into (−)-levoglucosenone. The L-hexose derivatives (−)-isolevoglucosenone and (+)-levoglucosenone are obtained with the same ease [533]. Applying the same route, D- and L-mannose, have been obtained in five-step synthesis (39% overall yield) from furfural. Similarly, the same methodology has been extended to the preparation of D- and L-gulose and D- and L-talose (19% yield) [534,535,536] and to the synthesis of 2-deoxy and 2,3-dideoxyhexoses [537].
A route to difluorosugar **426** has also been developed. It includes a Stille coupling [538,539] of alkenetin compound **421** with (*E*)-3-iodoprop-2-en-1-yl 4-methoxybenzoate that generates diene **422**. Sharpless asymmetric dihydroxylation of **422** was chemoselective and provided diol **423** in 54% yield. The corresponding acetonide **424** was then saponified with H_2O_2/LiOH. After treatment with 12-M HCl in THF, the semi-protected 1-deoxy-1,1-difluoro-D-xylulose **426** was obtained (➲ *Scheme 104*) [540].
Ethyl-D-galactonates **431** and **432** have been prepared by two successive dihydroxylations of dienoates **427** and **428**, respectively (➲ *Scheme 105*). Intermediate diol **430** has been converted into L-galacto-γ-lactone **433** [541,542]. When using the (2*Z*,4*E*)-dienoate **434**, the same sequence of dihydroxylations provided L-*talo*-γ-lactone derivative **437** [543].



Scheme 104
Synthesis of 1-deoxy-1,1-difluoro-D-xylose



Scheme 105
O'Doherty's iterative dihydroxylation of dienoates

Matsushima and Kino [544] have obtained the enantiomer of **429** applying AD-mix-β-catalyzed dihydroxylation of **427**. Selective monosilylaltion with (*t*-Bu)Me_2SiCl affords **438** (93% ee). After esterification of the allylic alcohol **438** with *para*-nitrobenzenesulfonyl chloride and subsequent sulfonate displacement with NaN_3 (S_N2) azide **439** is isolated in

80% yield. Hydrogenation of azide **439** and subsequent tosylation of the intermediate amine produces sulfonamide **440**. Under acidic conditions **440** is desilylated and converted into δ-lactone **441**. Semi-reduction with $(i\text{-}Bu)_2AlH$ and Fischer glycosidation provides methyl *N*-Ts-α-D-tolyposaminide **442**. Diol of *ent*-**429** reacts with tosylisocyanate in the presence of a catalytic amount of $Pd(PPh_3)_4$ giving an *N*-tosylated isocyanate intermediate. A Pd-catalyzed allylation of the isocyanate generates the cyclic carbamate **443** (S_N with retention). Alkene hydrogenation and subsequent alkaline methanolysis affords δ-lactone **444** which has been converted into methyl 4-*epi*-*N*-Ts-α-D-tolyposaminide **445** as above for the conversion of **441** into **442**. Reduction of azide **439** with Ph_3P in aqueous THF produces the expected primary amine that is then converted into benzylcarbamate **446**. After *N*-methylation into **447**, iodocyclocarbamation provides the *trans*-product **449** in 94% yield (2% of *cis* isomer). The high stereoselectivity of this reaction can be interpreted in terms of transition state **448** which minimizes allylic strain (➲ *Scheme 106*). After reductive deiodination under radical conditions **450** is obtained. Reduction of the ethyl ester moiety of **450** into the corresponding primary alcohol, subsequent oxidation into an aldehyde with the Dess–Martin method, acetalization with methanol and cyclic carbamate hydrolysis produces **451**, a known precursor of methyl α-D-vicenisaminide [545].

Both *cis*-((±)-**454**) and *trans*-2-substituted-1,2,3,6-tetrahydropyridin-3-ol ((±)-**455**) have been prepared via an aldol condensation of tosylamide **452** with acrolein and subsequent ring-closing metathesis catalyzed by Grubbs I catalyst (➲ *Scheme 107*) [546]. Asymmetric dihydroxylation of *trans*-acetonide (±)-**455** with the Hsung–Vedejs AD-mix-β [547,548] gives (+)-**456** and (−)-**457** in 42 and 35% yield, respectively. The tosyl groups and acetonides are then removed by Red-Al and HCl/MeOH to give 1,5-dideoxy-1,5-imino-D-allitol ((+)-**458**) and 1,5-dideoxy-1,5-imino-L-mannitol ((+)-**459**). Similarly, reaction of *trans*-acetonide **455** with Hsung–Vedejs AD-mix-α affords acetonides (−)-**456** and (+)-**457** in 50 and 40% yield, respectively. The latter can be converted, as before, into 1,5-dideoxy-1,5-imino-L-allitol ((−)-**458**) and 1,5-dideoxy-1,4-imino-D-mannitol ((−)-**459**) [547,548].

Lindström and co-workers [549] have presented an efficient asymmetric synthesis of the iminoalditol **464** (➲ *Scheme 108*). The method requires only four steps in water, without the use of protecting groups. (*E*,*E*)-1,6-Dibromohexa-2,4-diene (**460**) undergoes Sharpless asymmetric dihydroxylation with formation of diol **461** (70% yield, 97% ee). Upon heating in water at 50 °C, the allyl bromide is hydrolyzed chemoselectively giving triol **462**. Epoxidation of **462** with H_2O_2 in the presence of dinuclear peroxotungstate catalyst $K_2[W_2O_3(O_2)_4(H_2O)_2]$ [550] gave **463** in 99% yield and 92% diastereomeric excess. Ammonolysis of bromide **463** in aqueous ammonia was spontaneously followed by an intramolecular ring opening of the epoxide giving **464** (60% overall yield based on **460**).

Photooxidation of (*E*,*E*)-1,4-disubstituted butadienes produces the corresponding 3,6-dihydro-1,2-dioxines **465** that are dihydroxylated into diols **466**. Upon reduction (Zn/AcOH, or H_2/Pd-C, or H_2/Pt-C Mg/I_2 (cat.), or thioureas) racemic alditols **467** are obtained. Isomerization of the dioxines catalyzed by *N*,*N*′-bis(salicylidene)ethylenediaminocobalt (II) gives the corresponding racemic uloses **468** (➲ *Scheme 109*). The method has been used to prepare (±)-psicose, (±)-1-deoxypsicose (±)-6-deoxypsicose [551].

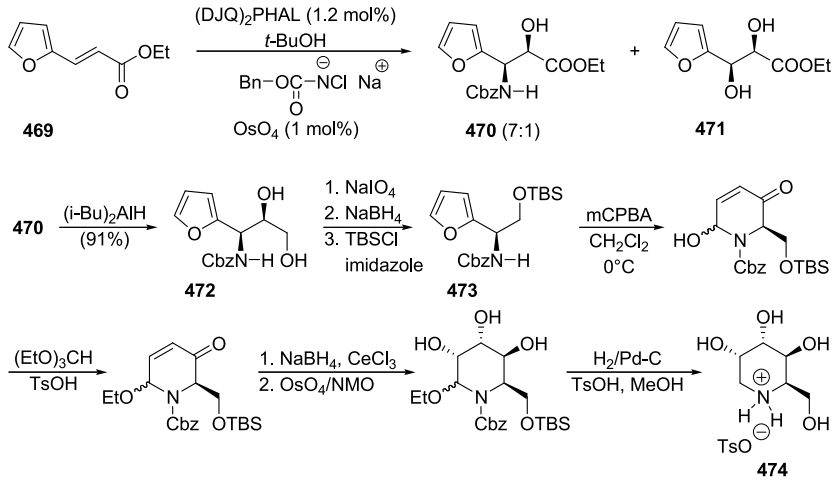
12 Enantioselective Sharpless Aminohydroxylation

The Sharpless asymmetric aminohydroxylation [552] of the electron-deficient 2-vinylfuran **469** gives a 7:1 mixture of semi-protected amino-alcohols **470** and **471** (41%). The major product **472** (ee > 86%) was reduced by diisobutylaluminum hydride giving a diol [553] which is then converted into the β-hydroxyfurylamine derivative **473**, an important synthetic building block for various biologically important compounds, including 1,5-dideoxy-1,5-imino-alditols such as **474** (*Scheme 110*). A less regioselective, but shorter way to intermediate **473** is the direct asymmetric aminohydroxylation of vinylfuran [554,555].



Scheme 110
Application of the Sharpless asymmetric aminohydroxylation and of the aza-Achmatowicz reaction to the synthesis of L-deoxymannonojimycin

13 Conclusion

For many years carbohydrates were very difficult synthetic targets because of their complexity arising from their stereochemistry and their multifunctionality. In parallel with the recent revolution in organic synthesis, a large number of complicated and rare monosaccharides have been prepared by total, asymmetric synthesis. Methods are available that allow one to reach both enantiomers of any natural or non-natural monosaccharides, including deoxyaminosugars, thiosugars, and azasugars, and this, quite often, in a few synthetic steps. Depending on the target, pure chemical procedures relying on asymmetric catalysis using either metallic or pure organic catalysts can be applied successfully, alone or in combination with chemoenzymatic methods.

4.4 Monosaccharides as Chiral Pools for the Synthesis of Complex Natural Compounds

Masaya Nakata
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Yokohama 223-8522, Japan
msynktxa@applc.keio.ac.jp

Abstract

A variety of complex natural compounds are synthesized by using monosaccharides as chiral starting materials. Exemplifying eight representative natural products, i. e., erythromycins, elaiophilin, herbimaycins, calbistrin A, lactacystin, tautomycin, FK-506, and halichondrin B, the methodology how monosaccharides are incorporated into natural product synthesis as chiral pools is described.

Keywords

Chiral pool; Natural product; Erythromycins; Elaiophilin; Herbimycins; Calbistrin A; Lactacystin; Tautomycin; FK-506; Halichondrin B

Abbreviations

AIBN	2,2′-azobisisobutyronitrile
All	allyl

TMEDA	N,N,N',N'-tetramethylethylenediamine
TMSCl	trimethylsilyl chloride

1 Introduction

Asymmetric total synthesis of natural products is one of the central subjects in the organic synthetic world. In order to reach this goal, there are two main strategies: the first uses chiral auxiliaries and the second uses chiral starting materials. The first most important task for comple-

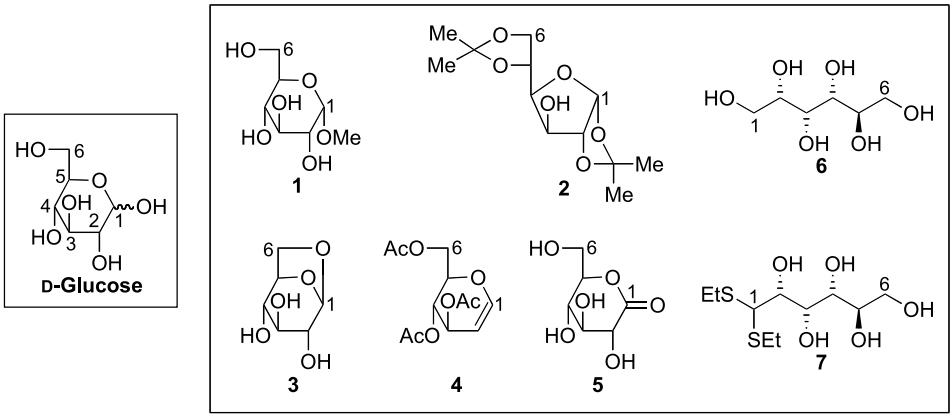

Figure 1
D-Glucose and its derivatives as chiral starting materials

tion of the total synthesis of complex natural products is reasonable disconnection of the target compound into the small starting materials by retrosynthetic analysis. Monosaccharides (carbohydrates) have been extensively used as fascinating starting materials in the enantiospecific synthesis of natural products. Some useful books on the carbohydrates-based chiral synthesis of natural products are available [1,2,3,4,5,6,7]. The advantages of using monosaccharides as a chiral pool are summarized as follows: (1) commercial availability; (2) low cost; (3) valuable carbon source (usually containing five or six carbon atoms); (4) enantiopure materials; (5) several definite chiral centers; (6) conformational rigidity which makes chemical transformations stereoselective.

As an example, several types of derivatives of D-glucose are available for starting materials (*Fig. 1*): methyl α-D-glucopyranoside (**1**), 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**), levoglucosan (**3**), tri-*O*-acetyl-D-glucal (**4**), gluconolactone (**5**), D-glucidol (**6**), and the dithioacetal derivative **7**. They are all commercially available and also easily prepared in large quantities from D-glucose.

Readily available chiral starting materials other than monosaccharides are amino acids, hydroxy acids, hydroxy esters, and terpenes. Among them, hydroxy acids and esters are often used as alternatives for monosaccharides when one requires one or two chiral centers to construct natural products (*Fig. 2*). Tartaric acid and its esters have four carbon atoms and two chiral centers. Both enantiomers, **8** (2*R*,3*R*) and **9** (2*S*,3*S*), are commercially available. Malic acid has four carbon atoms and one chiral center; both enantiomers, **10** and **11**, are commercially available although (*R*)-malic acid (**11**) is more expensive. Lactic acid and its esters have three carbon atoms and one chiral center; both enantiomers, **12** and **13**, are commercially available [(*R*)-lactic acid (**13**) is more expensive]. Glyceraldehyde and its derivatives are among the most useful members of the chiral pool, and they have three carbon atoms and one chiral center. Both enantiomers, **14** (*R*) and **15** (*S*), are available from mannitol and L-ascorbic acid, respectively; therefore, they also belong to the family of monosaccharides, but are not included in this chapter. Other familiar starting materials are methyl (*R*)- and (*S*)-3-hydroxy-2-methylpropionates, **16** and **17**. They have one chiral center bearing a methyl group and two

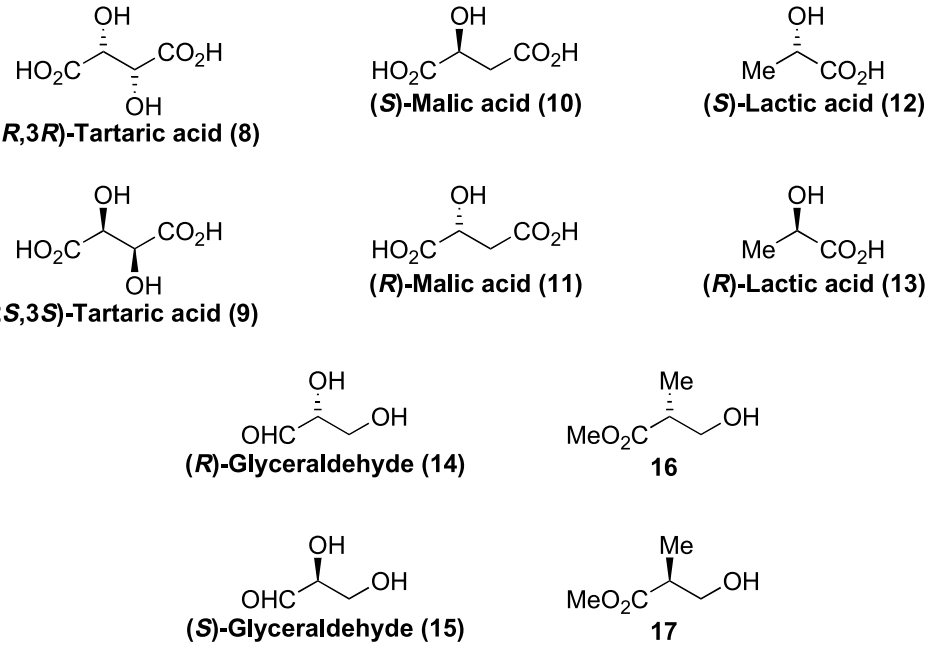

Figure 2
Hydroxy acids, esters, and aldehydes as chiral starting materials

differentiated functional groups: hydroxy and ester groups. Many natural products have been synthesized by assemblage of the synthetic intermediates prepared from monosaccharides and/or the above-mentioned chiral starting materials.

The chemical operations necessary for constructing the specified natural product from monosaccharides are the following: (1) differentiation of the hydroxy groups by selective protection; (2) oxidation of a hydroxy group; (3) deoxygenation of a hydroxy group; (4) inversion of the configuration of a hydroxy-bearing carbon; (5) addition of some nucleophiles to a carbonyl group, an epoxide, and an olefin; (6) conversion of cyclic monosaccharides to acyclic derivatives. The combination of these chemical operations makes possible the transformation of monosaccharides into the useful synthetic intermediates for completion of the total synthesis of natural products. Much useful information on individual chemical operations will be found in other chapters of this book. In this chapter, some recent examples of the synthesis of complex natural products employing monosaccharides as starting materials are described.

2 Synthesis of Natural Products

In natural product chemistry, there are three main categories of interest: isolation and structure determination, elucidation of natural phenomena, and synthesis. Among them, the synthetic community has been seeking new and efficient methods necessary for the synthesis of natural products and their analogs. In this section, we describe, exemplifying eight representative

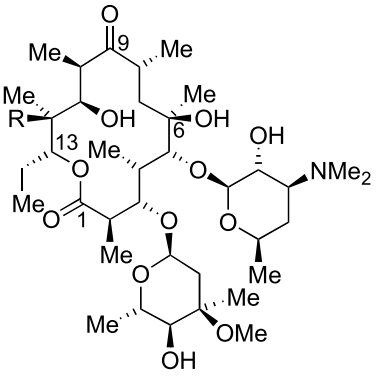
natural products, how the synthetic intermediates are prepared from monosaccharides. In the figures, the numbering system used for the natural products is employed. In the Schemes, the numbering system used for the monosaccharides is shown in parentheses in order to clarify how the starting monosaccharides are incorporated into the desired synthetic intermediates.

2.1 Erythromycins

Erythromycins, the representative and medicinally important macrolide antibiotics, have been widely studied and are still undoubtedly one of the most challenging target molecules for many synthetic organic chemists (● *Fig. 3*). Woodward and coworkers accomplished the first total synthesis of erythromycin A (**18**) in 1981 [8,9,10]. Corey and coworkers synthesized erythronolides A (**20**) and B (**21**), the aglycons of erythromycins A (**18**) and B (**19**), in 1978 [11,12] and 1979 [13].

Kinoshita, Nakata, and coworkers synthesized erythronolide A (**20**) (● *Fig. 4*) [14,15,16,17]. Erythronolide A (**20**) was divided into three segments, **22** (C1–C6), **23** (C7–C9), and **24** (C10–C13), of these fragments **22** and **24** were prepared from monosaccharides as chiral starting materials.

The C1–C6 segment **22** was prepared from methyl α-D-glucopyranoside (**1**) (● *Scheme 1*). The acetal function is a most popular protecting group of the hydroxy groups in monosaccharides. Benzylidenation of methyl α-D-glucopyranoside (**1**), which is also an acetal of D-glucose, with benzaldehyde in the presence of $ZnCl_2$ afforded the 4,6-*O*-benzylidene acetal **25**, whose C2-hydroxy group was selectively tosylated, and the resulting tosylate **26** was treated with a base to give epoxide **27**. Generally, epoxides are very useful synthetic intermediates because the rigidity of configurations makes regioselective ring-opening extremely effective. The nucleophilic attack of the methyl group to this epoxide **27** gave **28** as the sole product following the *trans*-diaxial opening rule. Inversion of the C2- and C3-configurations



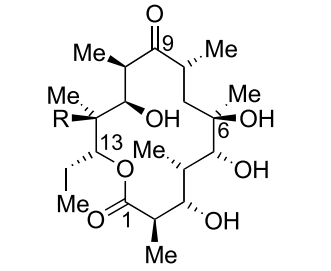


Figure 3
Erythromycins and their aglycons

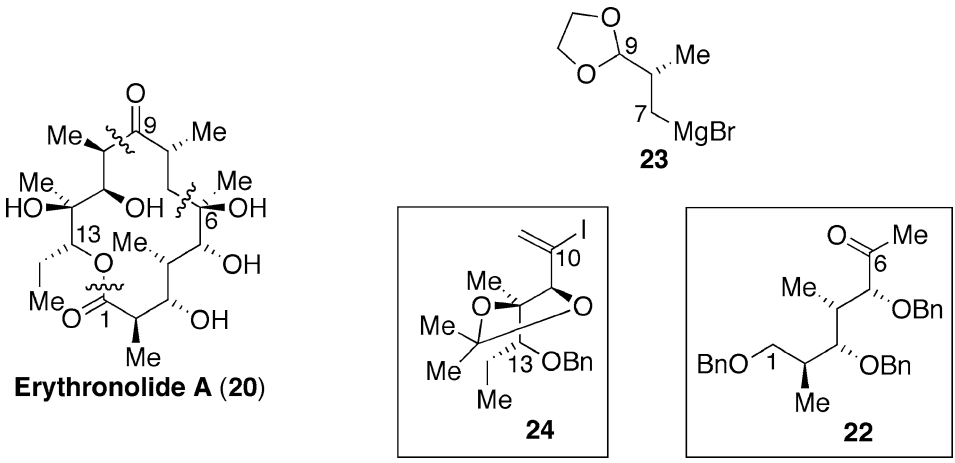

Figure 4
Segments of Kinoshita–Nakata synthesis of erythronolide A

of **28** was easily achieved by oxidation of the C2-hydroxy group, epimerization of the C3-position, and stereoselective reduction of the C2-carbonyl group, providing **29**. De-*O*-benzylidenation of **29** followed by acetolysis and hydrolysis afforded the free monosaccharide **30**. Pyranose-to-furanose conversion was realized by di-*O*-isopropylidenation of **30** with acetone in the presence of $FeCl_3$ to give the 1,2:5,6-di-*O*-isopropylidene derivative **31**. The 5,6-*O*-isopropylidene group in **31** was selectively deprotected with aqueous AcOH to afford **32**. The subsequent 6-step manipulation of **32** gave **33**. Conversion of cyclic monosaccharides to acyclic derivatives is one of the most important tasks when utilizing monosaccharides as a chiral pool in natural products synthesis. One such procedure is dialkyl dithioacetal opening. Treatment of **33** with ethanethiol in the presence of $BF_3 \cdot Et_2O$ provided **34**. Finally, the 4-step manipulation of **34** gave the C1–C6 segment **22** of erythronolide A (**20**).

The C10–C13 segment **24** was prepared from D-ribose (**35**) (*Scheme 2*). In this case, selective protection of the hydroxy groups was realized by isopropylidenation (from **35** to **36**). One of the other procedures for conversion of cyclic monosaccharides to acyclic derivatives is nucleophilic addition to the anomeric position in free monosaccharides. Grignard reagent, MeMgI, was added to **36** to provide **37** as the sole product. The subsequent manipulation of **37** to the C10–C13 segment **24**, which is not restricted in monosaccharides chemistry, is summarized in *Scheme 2*. After the completion of the synthesis of erythronolide A (**20**), Toshima, Nakata, Tatsuta, Kinoshita, and coworkers achieved the total synthesis of erythromycin A (**18**) by their own glycosidation method [18,19].

Kochetkov and coworkers synthesized erythronolides A (**20**) and B (**21**) [20,21]. They divided the target compounds into three segments, **42** (C1–C6), **43** (C7–C8), and **44** (C9–C13) or **45** (C9–C13) (*Fig. 5*).

The common C1–C6 segment **42** of erythronolides A (**20**) and B (**21**) was prepared from levoglucosan (**3**) (*Scheme 3*), which is also a very popular starting material. Selective di-*O*-tosylation of levoglucosan (**3**) gave the C2, C4-di-*O*-tosylate **46**, which was treated with a base to afford 3,4-epoxide **47**. Regioselective addition of MeMgCl to **47** in the presence of

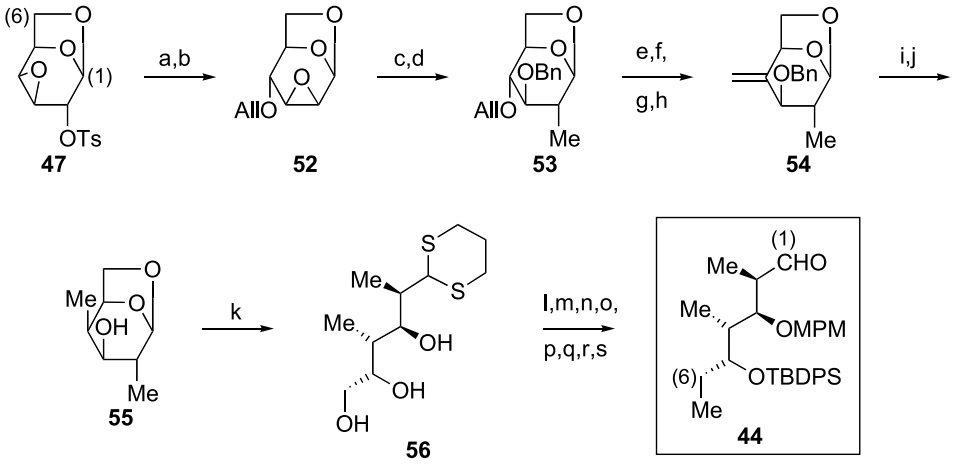
CuCl provided the C3-alcohol as the sole, *trans*-diaxial opening product, which was treated with a base to afford **48**. The 2-step reaction for introducing the second methyl group to **48** (DMSO-anion addition and reductive desulfurization) gave the doubly methylated **49** [22]. Opening of the 1,6-anhydro ring was realized by treatment of **49** with 1,2-ethanedithiol and $BF_3 \cdot Et_2O$ to give **50**. This compound was transformed into the C1–C6 segment **42** by the procedure shown in *Scheme 3*.

The C9–C13 segment **44** of erythronolide B (**21**) was prepared (*Scheme 4*) from the synthetic intermediate **47** of the C1–C6 segment **42**. Instead of the methyl group introduction,



Scheme 4

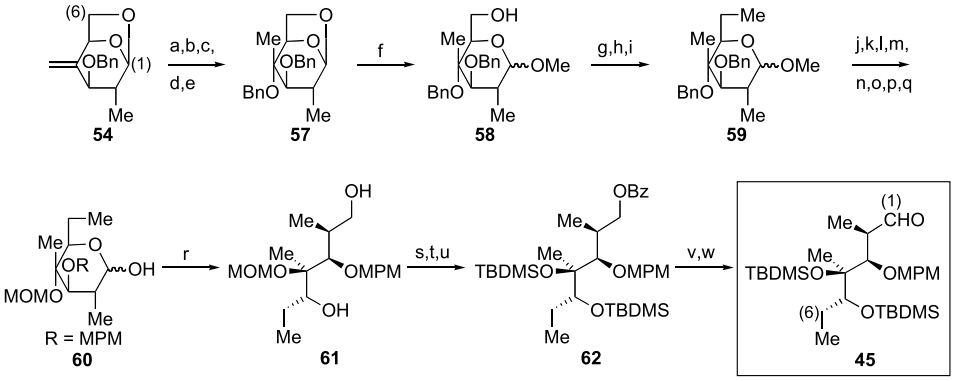
the *O*-function was introduced to epoxide **47** by acidic allyloxylation. After a base treatment, the resulting epoxide **52** was treated with Me_2Mg to provide the C2-methylated alcohol as the sole, *trans*-diaxial opening product. After benzylation, the resulting **53** was transformed into **54** by a 4-step manipulation. Stereoselective hydrozirconation of **54** followed by de-*O*-benzylation afforded the doubly methylated **55** [23,24,25]. Opening of the 1,6-anhydro ring was realized by treatment of **55** with 1,3-propanedithiol and $BF_3 \cdot Et_2O$ to afford **56**. Finally, the several-step manipulation of **56** gave the C9–C13 segment **44** of erythronolide B (**21**).

On the other hand, the C9–C13 segment **45** of erythronolide A (**20**) was prepared from **54** (*Scheme 5*), which is also a synthetic intermediate of the erythronolide B C9–C13 segment **44**. Using the double bond as a precursor of the tertiary alcohol portion, compound **54** was transformed into **57**. The 1,6-anhydro ring was once cleaved via methylglycosidation. After one-carbon elongation at the C6-position and several transformations, compound **58** was converted to the free monosaccharide **60** through **59**. Another procedure for the conversion of cyclic monosaccharides to acyclic derivatives is reduction of the anomeric carbon. $NaBH_4$ reduction of **60** gave the acyclic derivative **61**. A further 5-step manipulation provided the C9–C13 segment **45** of erythronolide A (**20**).

Kochetkov and coworkers synthesized erythronolides A (**20**) and B (**21**) via a different route [26,27,28]. There have been many reports on the syntheses of erythromycin. Among them, four examples are the Yonemitsu synthesis of erythronolide A (**20**) [29,30], featuring an extremely efficient macrocyclization (the modified Yamaguchi method); Martin's synthesis of erythromycin B (**19**) [31,32]; Evans synthesis of 6-deoxyerythronolide B [33,34], featuring the aldol-based assemblage of each synthetic segment; and the Carreira synthesis of erythronolide A (**20**), featuring the Mg-mediated cycloadditions of nitrile oxides [35].



Scheme 5

2.2 Elaiophylin

Elaiophylin (**63**) belongs to a group of C_2-symmetrical 16-membered macrodiolides. Toshima, Tatsuta, and Kinoshita synthesized elaiophylin (**63**) by the assemblage of three segments, **64** (C1–C9), **65** (C10–C15), and **66** (monosaccharide moiety) [36,37] (*Fig. 6*).

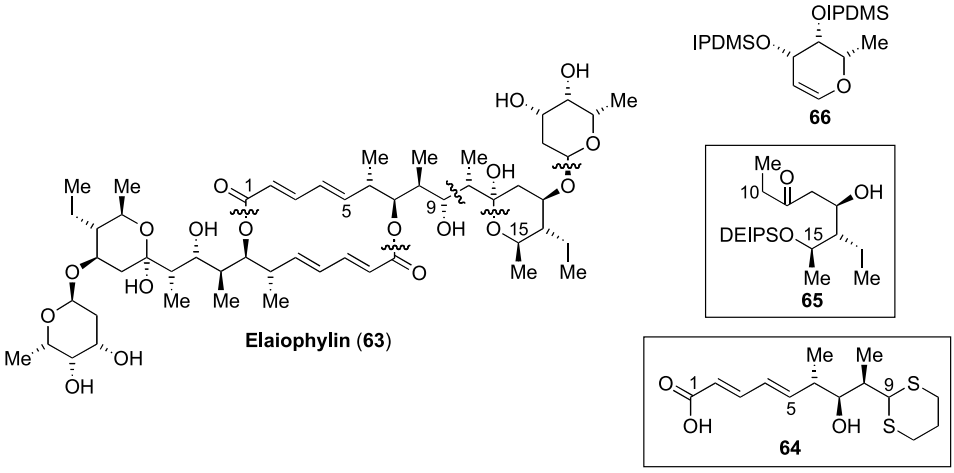

Figure 6
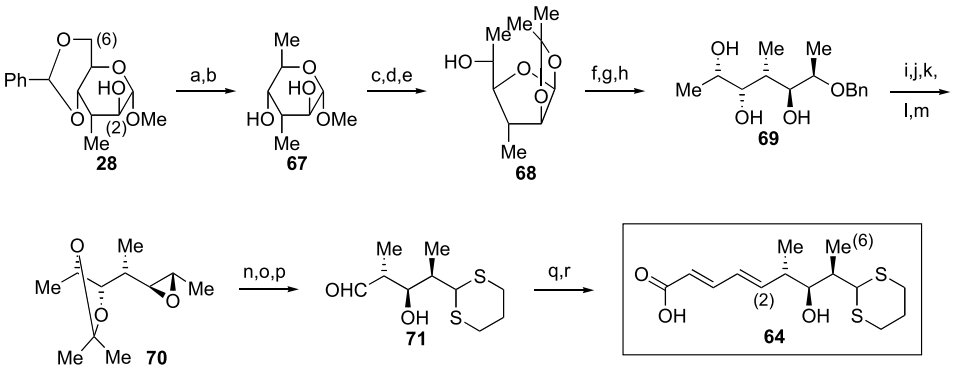
Segments of Toshima–Tatsuta–Kinoshita synthesis of elaiophylin



Scheme 6
(a) NBS, $BaCO_3$, CCl_4, heat; (b) $LiAlH_4$, THF, heat; (c) Ac_2O, H_2SO_4; (d) NaOH, aq MeOH; (e) acetone, $FeCl_3$; (f) BnBr, NaH, THF; (g) aqueous AcOH, 60 °C; (h) MeMgI, ether, heat; (i) $Me_2C(OMe)_2$, TsOH, DMF; (j) Ac_2O, DMAP, EtOAc; (k) H_2, Pd, MeOH; (l) MsCl, py; (m) NaOMe/MeOH, $CHCl_3$, 0 °C; (n) 2-lithio-1,3-dithiane, THF, 0 °C; (o) aqueous AcOH, 50 °C; (p) $Pb(OAc)_4$, KOAc, MeCN, −25 °C; (q) [(2*E*)-3-methoxycarbonyl-2-propenylidene]triphenylphosphorane, toluene, 80 °C; (r) LiOH, aqueous THF

The C1–C9 segment **64** was prepared from **28** (*Scheme 6*), which is the synthetic intermediate of erythronolide A (**20**). NBS-treatment of **28** followed by reduction gave the di-*C*-methylated compound **67**. Acetolysis of **67** followed by hydrolysis gave the free monosaccharide, which was subjected to isopropylidenation with acetone and $FeCl_3$ (pyranose-to-furanose conversion) to provide **68**. After benzylation of **68**, the 1,2-*O*-isopropylidene group was deprotected, and the resulting free monosaccharide was opened by the Grignard reaction (MeMgI) to give triol **69**. Triol **69** was transformed into the C1–C9 segment **64** by the route shown in *Scheme 6*.

The C10–C15 segment **65** was prepared from epoxide **27** (*Scheme 7*), which is also a synthetic intermediate of erythronolide A (**20**). The nucleophilic attack of the ethyl group (EtMgCl) to epoxide **27** gave **72** as the sole product following the *trans*-diaxial opening rule. Pyranose-to-furanose conversion was realized by isopropylidenation with acetone and $BF_3 \cdot Et_2O$ to afford di-*O*-isopropylidene derivative **73**. The 5-step manipulation of **73** including selective de-*O*-isopropylidenation provided **74**. Subsequent 4-step manipulation of **74** including reductive opening of furanose to the acyclic derivative gave epoxide **75**. The 2-step manipulation of epoxide **75** provided the C10–C15 segment **65**.

Wakamatsu, Ban, Shibasaki, and coworkers have succeeded in the formal total synthesis of elaiophylin (**63**) [38] (*Scheme 8*). The C1–C9 segment **64** was prepared from epoxy-tosylate **47**, which is the synthetic intermediate of Kochetkov's erythronolide synthesis. This was regioselectively *C*-allylated with allylmagnesium chloride in the presence of CuI (*trans*-diaxial opening), and subsequent base treatment gave **76**. The methyl group was introduced regioselectively to **76** by MeMgCl in the presence of CuI (*trans*-diaxial opening), giving **77** after benzylation. After the 3-step conversion, the 1,6-anhydro ring of the resulting **78** was opened with 1,3-propanedithiol, $BF_3 \cdot Et_2O$, and TFA, and the resulting acyclic derivative was transformed to the C1–C9 segment **64** by the route shown in *Scheme 8*.

Besides these two syntheses of elaiophylin (**63**), Seebach [39,40], Ziegler [41], Evans [42], and Paterson [43,44] have studied the synthesis of elaiophylin (**63**).

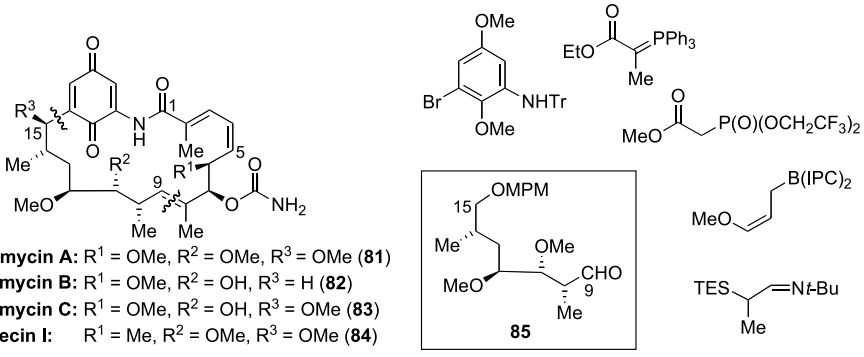
2.3 Herbimycins

Herbimycins A (**81**), B (**82**), and C (**83**), and macbecin I (**84**) belong to the benzoquinoid ansamycin antibiotics. Nakata, Tatsuta, and coworkers achieved the total synthesis of herbimycin A (**81**) [45,46] from the six segments as shown in *Fig. 7*.

The C9–C15 segment **85** was prepared from methyl α-D-mannopyranoside (**86**) (*Scheme 9*). Firstly, tritylation of **86** followed by selective mesylation gave the 2,3-di-*O*-mesylate **87**. This was treated with a base and the resulting epoxide **88** was opened with LiBr to give bromoepoxide **89**. Secondly, the regioselective opening of epoxide **89** with MeMgBr followed by a base treatment afforded **90**. Thirdly, the regioselective and reductive opening of epoxide **90** was realized by a borane reagent to provide **91**. The 6-step manipulation of **91** afforded **92**. After treatment of **92** with aqueous AcOH, the resulting free monosaccharide was opened by $NaBH_4$-reduction to provide **93**. The several-step manipulation of **93** gave the C9–C15 segment **85**.

Kallmerten and coworkers synthesized the C5–C12 segment **94** of herbimycin A (**81**) (*Scheme 10*) [47]. The starting material was 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**), which has only one free hydroxy group in its structure. Benzylation of the C3-hydroxy group of **2** followed by hydrolysis of both isopropylidene groups in **95** with acidic MeOH provided the methyl glucoside **96** in the form of its pyranoside. Tritylation and selective 2-*O*-methylation of **96** followed by C4-oxidation and stereoselective addition of Me_2CuLi afforded **97**. The 5-step transformation of **97** gave **98**. The Vasella-type reductive opening of **98** with Zn gave the free monosaccharide **99**, whose furanose structure was reductively opened with $LiBH_4$ to give **100**. Further 5-step manipulation of **100** afforded the C5–C12 segment **94**.

Panek and Carter also succeeded in the total synthesis of herbimycin A (**81**), employing their own crotylation methodology [48]. The structurally related macbecin I (**84**) was synthesized



Herbimycin A: R^1 = OMe, R^2 = OMe, R^3 = OMe (**81**)
Herbimycin B: R^1 = OMe, R^2 = OH, R^3 = H (**82**)
Herbimycin C: R^1 = OMe, R^2 = OH, R^3 = OMe (**83**)
Macbecin I: R^1 = Me, R^2 = OMe, R^3 = OMe (**84**)

by Baker [49,50], Evans [51,52], and Panek [53,54]. The formal total synthesis of macbecin I was reported by Kallmerten [55,56] and Martin [57,58]. Synthetic studies of macbecin I were reported by Marshall [59].

2.4 Calbistrin A

Calbistrin A (**101**) is a cholesterol-lowering agent (*Fig. 8*). Tatsuta and coworkers have realized the total synthesis of calbistrin A (**101**) [60]. The key synthetic Diels–Alder precursor **102** for the decalin skeleton was prepared from aldehyde **103** and two other segments shown in *Fig. 8*.

The starting material for the octahydronaphthopyranone core is **91** (*Scheme 11*), which has been used in the total synthesis of herbimycin A (**81**). It was necessary to invert the C4-configuration for the crucial intramolecular Diels–Alder reaction at a later stage. Compound **91** was oxidized to ketone **104**, which was stereoselectively reduced with L-Selectride to provide

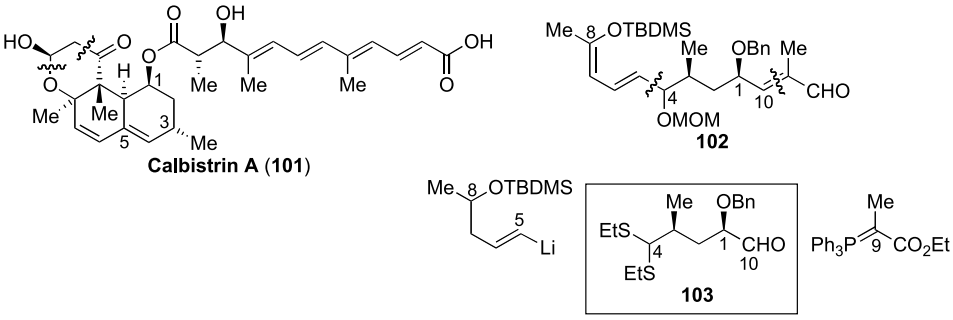

Figure 8

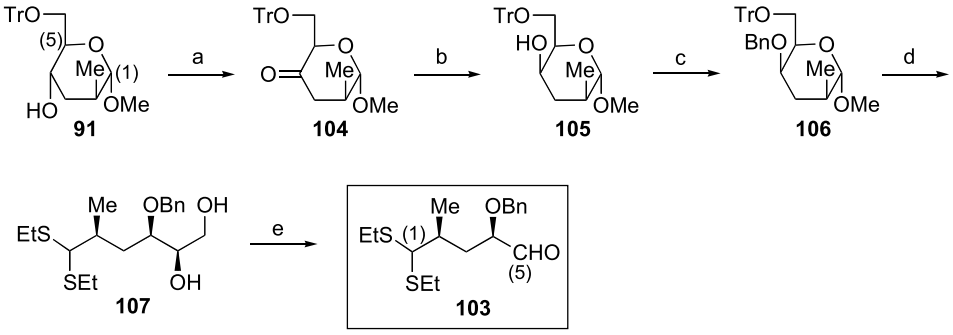

Scheme 11
(a) PDC, CH_2Cl_2; (b) L-Selectride, THF, −78 °C; (c) BnBr, NaH, DMF; (d) EtSH, $BF_3 \cdot Et_2O$; (e) $Pb(OAc)_4$, K_2CO_3, toluene

105. After *O*-benzylation of **105**, the resulting **106** was subjected to cyclic-to-acyclic conversion by treatment with ethanethiol and $BF_3 \cdot Et_2O$, giving diol **107**. This diol was cleaved with $Pb(OAc)_4$ to afford aldehyde **103**, which was transformed to **102** by several steps.

2.5 Lactacystin

Lactacystin (**108**) is the first nonprotein neurotrophic factor (*Fig. 9*). Chida and coworkers achieved the total synthesis of lactacystin (**108**), whose central core **109** was prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**) [61,62].

1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose (**2**) was oxidized with PCC, and the resulting ketone **110** was subjected to Wittig methylenation to afford **111** (*Scheme 12*). Hydrogenation of **111** stereoselectively gave **112**. After selective de-*O*-isopropylidenation of **112** with aqueous AcOH, the resulting diol was transformed into **114** through **113**. This was subjected

to the Overman rearrangement, affording **115**. Subsequent 4-step transformation of **115** gave the lactam portion **109** of lactacystin (**108**).
The groups of Corey [63,64,65,66], Omura and Smith [67,68], and Baldwin [69] have reported the total synthesis of lactacystin (**108**); the starting materials of their syntheses are amino acids. The groups of Panek [70], Hatakeyama [71], Kanai and Shibasaki [72], and Jacobsen [73] have also reported the total synthesis of lactacystin (**108**).

2.6 Tautomycin

Tautomycin (**116**) is an inhibitor of protein phosphatases (*Fig. 10*). The first total synthesis of tautomycin (**116**) was reported by Oikawa, Ichihara, and coworkers [74,75]. The second total synthesis of tautomycin (**116**) was reported by Isobe's group [76,77,78,79,80]. In Isobe's synthesis, tautomycin (**116**) was divided into three segments, **117** (C1–C16), **118** (C17–C26), and **119**, of which **117** was prepared from the monosaccharide derivatives.
The C1–C16 segment **117** was further divided into two subsegments, **120** and **121** (*Fig. 11*). The C1–C8 subsegment **120** was synthesized from levoglucosenone (**122**) (*Scheme 13*). Levoglucosenone (**122**) was subjected to conjugate addition of lithium methylcyanocuprate to give the axial methyl adduct **123**. Treatment of **123** with hydrazine and subsequent eliminative Wolff–Kishner reduction and acetylation afforded **124**. Formation of the ethyl glycoside of **124** followed by treatment of the acetylene derivative in the presence of $BF_3 \cdot Et_2O$ afforded the α-*C*-glycoside **125**. Epimerization of the anomeric center was achieved via the dicobalthexacarbonyl complex, giving **126**. Hydrosilylation of **126** followed by the 3-step conversion gave

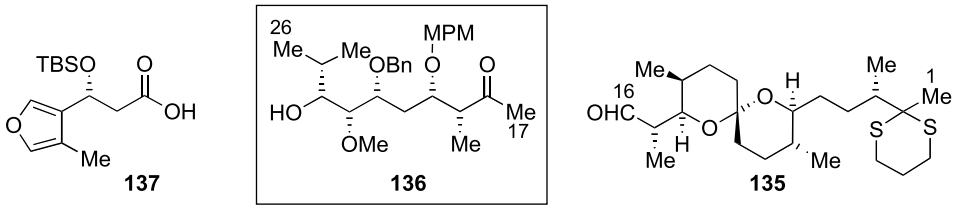

Figure 12
Segments of Shibasaki synthesis of tautomycin

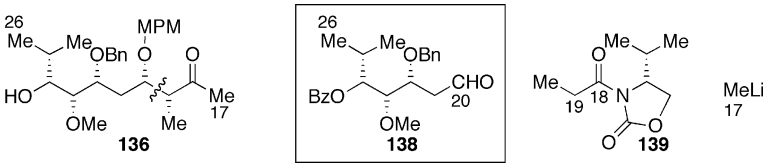

Figure 13
Subsegments of 136

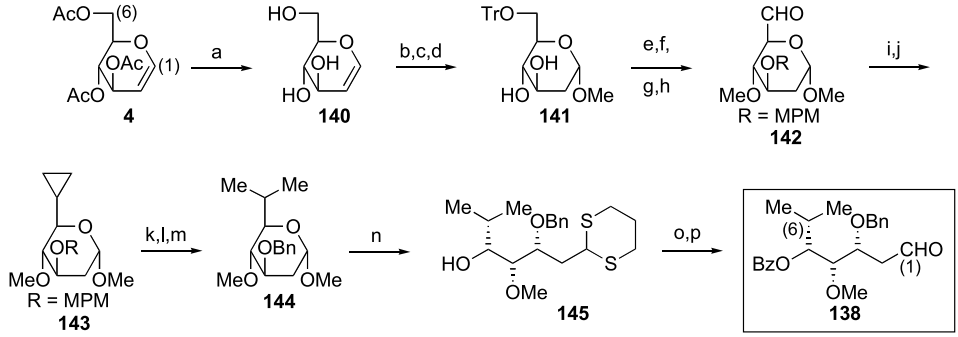
127. Diastereoselective conjugate addition of the MeLi · LiBr complex to **127** and the subsequent 2-step conversion gave **128**. The Vasella-type reductive ring-opening of **128** with Zn and the subsequent 3-step conversion gave the C1–C8 segment **120**.

The C9–C16 subsegment **121** was prepared from tri-*O*-acetyl-D-glucal (**4**) (*Scheme 14*). The Ferrier-type *O*-glycosidation of **4** with EtOH and $BF_3 \cdot Et_2O$ gave **129**. Treatment of **129** with lithium methylcyanocuprate followed by hydrogenation afforded **130**. Treatment of **130** with the acetylene derivative in the presence of $BF_3 \cdot Et_2O$ afforded the α-*C*-glycoside **131**. Epimerization of the anomeric center and the following transformation to the target was achieved via a conceptually similar route to the synthesis of the C1–C8 subsegment **120**, providing **121**.

Shibasaki and coworkers synthesized tautomycin (**116**) from three segments, **135** (C1–C16), **136** (C17–C26), and **137**, of which **136** was prepared from a monosaccharide derivative [81,82] (*Fig. 12*).

The C17–C26 segment **136** was further divided into three subsegments, **138**, **139**, and MeLi (*Fig. 13*), while the C20–C26 subsegment **138** was prepared from tri-*O*-acetyl-D-glucal (**4**) (*Scheme 15*). The acetyl groups in **4** were cleaved by methanolysis, and the resulting triol **140** was subjected to methoxymerculation and tritylation to afford **141**, which had been used as the starting material for the synthesis of *N*-methylmaysenine by Corey and coworkers [83]. Selective *O*-methoxyphenylmethylation of the C3-hydroxy group and the successive *O*-methylation, de-*O*-tritylation, and Swern oxidation afforded aldehyde **142**. The terminal isopropyl group was synthesized by cyclopropanation and reductive opening. Cyclic-to-acyclic conversion of the resulting **144** was realized by treatment with 1,3-propanedithiol and $BF_3 \cdot Et_2O$, giving **145**. Finally, benzoylation and dedithioacetalization of **145** afforded **138**.

Another total synthesis of tautomycin (**116**) by Chamberlin [84], a formal total synthesis by Marshall [85], and other synthetic studies have been reported [86,87].



Scheme 15

2.7 FK-506

FK-506 (**146**) is a clinically important immunosuppressive agent (*Fig. 14*). The first total synthesis of FK-506 (**146**) was achieved by the Merck group [88,89] using the Evans aldol technology. Danishefsky and coworkers also synthesized FK-506 (**146**) (formal total synthesis) from four segments, **147**, **148**, **149**, and **150** [90,91,92,93].

The C22–C27 segment **149** was prepared from tri-*O*-acetyl-D-galactal (**151**) (*Scheme 16*). Treatment of **151** with methanol in the presence of $SnCl_4$ afforded **152** (Ferrier-type *O*-glycosidation). Deacetylation of **152** followed by monosilylation provided **153**. Hydroxy-direct-

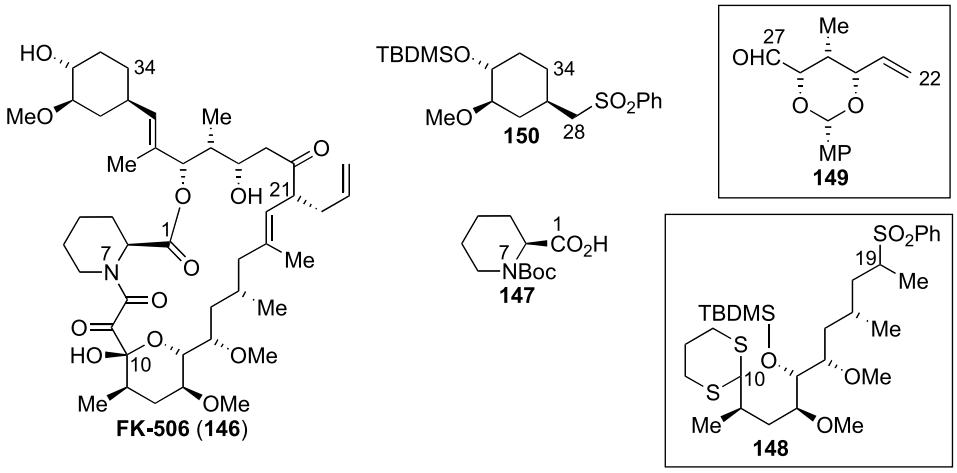

Figure 14

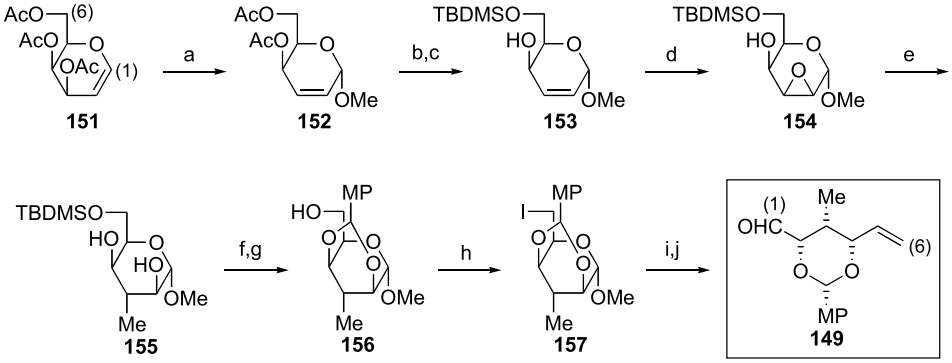

Scheme 16
(a) MeOH, $SnCl_4$, CH_2ClCH_2Cl; (b) NaOMe/MeOH; (c) TBDMSCl, Et_3N, DMAP, CH_2Cl_2; (d) *m*-CPBA, CH_2Cl_2, heat; (e) $Me_2CuCNLi_2$, ether, −78 to 0 °C; (f) $MPCH(OMe)_2$, CSA, benzene, heat; (g) TBAF, THF; (h) I_2, Ph_3P, py, benzene, 45 °C; (i) Zn, py, aqueous EtOH, heat; (j) PPTS, CH_2Cl_2

ed epoxidation of **153** with *m*-CPBA afforded **154** stereoselectively. Reaction of **154** with $Me_2CuCNLi_2$ afforded **155**, the product of *trans*-diaxial opening. Reaction of **155** with *p*-anisaldehyde dimethyl acetal in the presence of CSA followed by desilylation gave **156**. After iodination of **156**, the pyranose ring of the resulting **157** was opened through Vasella-type fragmentation and subsequent PPTS treatment for equilibrium of the methoxybenzylidene group to provide the C22–C27 segment **149**.

The C10–C19 segment **148** was prepared from methyl β-D-galactopyranoside (**158**) (*Scheme 17*). It was converted to its mono-TBDMS derivative **159**, and then via stannylation and monobenzylation to the C3-monobenzyl ether, which was methylated to afford **160**. Cleavage of both the silyl and methyl glycoside ethers of **160** afforded the free monosaccharide **161**. This was subjected to reductive ring-opening with $NaBH_4$. The resulting triol was converted to its isopropylidene derivative followed by Swern oxidation and Wittig olefination, giving **162**. This was converted to the C10–C19 segment **148** via several steps.

In the total synthesis of FK-506 (**146**), Schreiber and coworkers prepared the C10–C19 segment **163** from arabitol (**164**) via the two-directional chain synthesis strategy [94,95] (*Scheme 18*). A reaction with the Moffatt reagent was followed by acetate hydrolysis to provide a bis(epoxide) that was silylated to give **165**. Treatment of **165** with the lithium anion of ethoxyacetylene in the presence of $BF_3 \cdot Et_2O$ furnished, after workup with an acid, the bis(lactone) **166**. Methylation of the dianion of **166** proceeded with high diastereofacial selectivity to provide **167**. The corresponding benzyl ether was subjected to hydrolysis and exhaustive methylation to give the bis(methyl ester) **168**. This was transformed to the C10–C19 segment **163** as shown in *Scheme 18*.

Ireland and coworkers in their total synthesis of FK-506 (**146**) synthesized the C8–C15 segment **172** and the C23–C26 segment **173** [96,97,98] (*Fig. 15*) from appropriate monosaccharide derivatives.

The C8–C15 segment **172** was prepared from **25** (*Scheme 19*). Di-*O*-tosylation of **25** followed by a base treatment provided *allo*-epoxide **174**. Treatment of **174** with Me_2CuLi

gave **175**, the *trans*-diaxial opening product. Oxidation of the C3-hydroxy group followed by epimerization of the C2-axial methyl group and stereoselective reduction with $NaBH_4$ provided **176**. After formation of the C3-phosphorodiamidate of **176**, both the C3 oxygen function and the benzylidene protecting group were removed by reduction with lithium. Selective benzylation followed by methylation gave **177**. The anomeric methyl glycoside was cleaved, and the resulting free monosaccharide was oxidized to afford lactone **178**. The lithium anion of tetrahydropyranyl ethyl glycolate was added to **178**, providing **179**. The 4-step manipulation of **179** gave the C8–C15 segment **172**.

The C23–C26 segment **173** was prepared from **180**, which was derived from ribose (*Scheme 20*). After *O*-benzylation of **180**, the resulting benzyl ether was treated with MeMgCl and $CuBr \cdot Me_2S$ to afford **181**. Thiol acetal formation followed by selective silylation provided **182**. The dithioacetal was cleaved and the resulting aldehyde was reduced with $NaBH_4$ to afford a diol, which was subjected to direct epoxidation to provide **173**.

Smith and coworkers have used monosaccharide in their formal total synthesis of FK-506 (**146**) (*Fig. 16*) [99,100,101]. The C10–C23 segment **183** was prepared from two subsegments, **184** (C10–C15) and **185** (C16–C23), of which **184** was derived from the monosaccharide derivative.

Epoxide **27** was reduced with $LiAlH_4$ to provide **186**, the *trans* diaxial-opening product (◉ *Scheme 21*). Oxidation of **186** followed by Wittig methylenation afforded **187** [102,103]. Stereoselective hydrogenation of **187** gave the equatorial methylated product **188**. Protecting group manipulation of **188** gave **189**, whose primary alcohol was oxidized to carboxylic acid and then esterified to afford **184**.

Rama Rao and coworkers have used a monosaccharide in their synthetic studies on FK-506 (**146**) (◉ *Fig. 17*) [104,105]. They divided the C1–C20 segment **190** into three subsegments, **191**, **192**, and **193**, of which the C10–C15 subsegment **192** was prepared from the monosaccharide derivative.

The Ireland synthetic intermediate **176** was deoxygenated by the Barton procedure to provide **194** (◉ *Scheme 22*). Stepwise deprotection and protection of hydroxy groups in **194** afforded **195**. De-*O*-tritylation and Swern oxidation of **195** gave the C10–C15 segment **192**. As shown in ◉ *Scheme 22*, this aldehyde was transformed into the C10–C20 segment **197**.

Maier and coworkers focused on 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**) in their synthetic studies on FK-506 (**146**) (*Fig. 18*) [106]. The C21–C34 segment **198** was prepared from **199** and **200**, of which **199** was prepared from **2**.

The Barton deoxygenation of **2** provided **201**, which was subjected to selective hydrolysis of the 5,6-*O*-isopropylidene group and oxidative scission of the resulting diol function to provide aldehyde **202** (*Scheme 23*). Reaction of aldehyde **202** with bis(trimehylsilyl)phenylthiomethyllithium afforded vinyl sulfide, which was oxidized with *m*-CPBA to the corresponding vinyl sulfone **203**. Addition of methyllithium to **203** followed by quenching of the resulting anion with formaldehyde provided vinyl sulfone **204** as a single isomer. Elimination of phenylsulfinic acid with LDA gave alkyne. Subsequent hydrogenation led to olefin which was then converted to the C21–C26 aldehyde **199**.

Formal total synthesis of FK-506 (**146**) was reported by Sih and coworkers [107].

2.8 Halichondrin B

Halichondrin B (**205**) has received much attention due to its extraordinary in vitro and in vivo antitumor activity (*Fig. 19*). Recently, structurally simplified macrocyclic ketone analogs of halichondrin B (**205**) were found to retain the potent cell growth inhibitory activity in vitro, stability in mouse serum, and in vivo efficacy of the natural product [108,109,110].

Kishi and coworkers have succeeded in the first total synthesis of halichondrin B (**205**) [111,112,113,114,115,116,117,118,119]. They divided halichondrin B (**205**) into four segments, **206–209** (*Fig. 20*), all of which were prepared from monosaccharides.

The C1–C13 segment **206** of halichondrin B (**205**) has been recently synthesized with improvements from **210** and **211**. The C1–C11 segment **210** was prepared from L-mannonic-γ-lactone (**212**) (*Scheme 24*). Di-*O*-cyclohexylidene protection of **212** followed by DIBALH reduction and Wittig reaction gave **213**. Stereoselective dihydroxylation and acetylation of **213** provided **214**. *C*-Glycosidation of **214** with methyl 3-trimethylsilylpent-4-enoate and $BF_3 \cdot Et_2O$ afforded α-glycoside **215** exclusively. This compound was transformed into **206** via the 7-step manipulation as shown in *Scheme 24*.

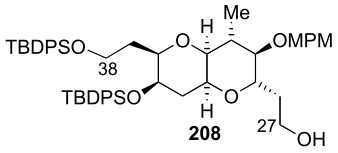
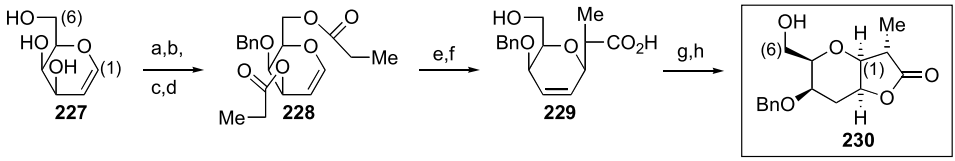
The C14–C26 segment **207** was prepared from D-arabinose **221** (*Scheme 25*). After treatment of 2,3:4,5-di-*O*-isopropylidene-D-arabinose diethyl dithioacetal (**222**), prepared from D-arabinose **221** by dithioacetalization and isopropylidenation, with *t*-BuOK, the resulting ketene dithioacetal was reduced to give **223** [120]. De-*O*-isopropylidenation of **223** followed by selective silylation and dedithioacetalization provided furanose **224**. The diacetate prepared from **224** was subjected to *C*-glycosidation with allyl trimethylsilane and $BF_3 \cdot Et_2O$ to afford **225**. Further transformation of **225** gave the C14–C21 segment **218**. Sequential treatment of **218** with the C22 and the C23–C26 segments (**219** and **220**, respectively) provided the C14–C26 segment **207**.

The C27–C38 segment **208** was prepared from D-galactal **227** (*Scheme 26*). The silyl ether, prepared from **227**, was selectively benzylated, and the resulting C3-alcohol was desilylated and propanoylated to afford **228**. After the Ireland–Claisen rearrangement of **228**, carboxylic acid **229** was subjected to iodolactonization followed by reductive removal of iodine to give γ-lactone **230**. This was converted to the C27–C38 segment **208**.

The C39–C 54 segment **209** was prepared from **231**, **232**, and **233**, of which the C44–C49 subsegment **232** was prepared from L-ascorbic acid **234** (*Scheme 27*). The α,β-unsaturated γ-lactone **235** was prepared from L-ascorbic acid **234** [121,122,123]. The conjugate addition of methylcuprate to **235** yielded the single stereoisomer **236**. Routine functional group manipulation allowed the transformation of **236** into epoxide **232**. Sequential elongation of **232** with





Scheme 26

(a) H_2, Pd/C, H_2O, 5.25 atm, 50 °C; (b) $Me_2C(OMe)_2$, $SnCl_2$, acetone, heat; (c) DMF dimethyl acetal, $CHCl_3$, heat; (d) MeI, 5 °C; (e) MeCN, heat; (f) Me_2CuLi, TMSCl, THF; (g) $LiAlH_4$, ether, 0 °C; (h) PivC, py, CH_2Cl_2; (i) MPMBr, KH, THF; (j) aqueous AcOH; (k) Ts imidazole, NaH, THF

the C50–C54 subsegment **233** and the C39–C43 subsegment **231** provided the C39–C54 segment **209**.

All segments obtained from these preparations were sequentially connected to complete the total synthesis of halichondrin B (**205**).

Salomon and coworkers described the synthetic studies of halichondrins [124,125,126,127]. They prepared three segments, **237**, **238**, and **239** (*Fig. 21*).

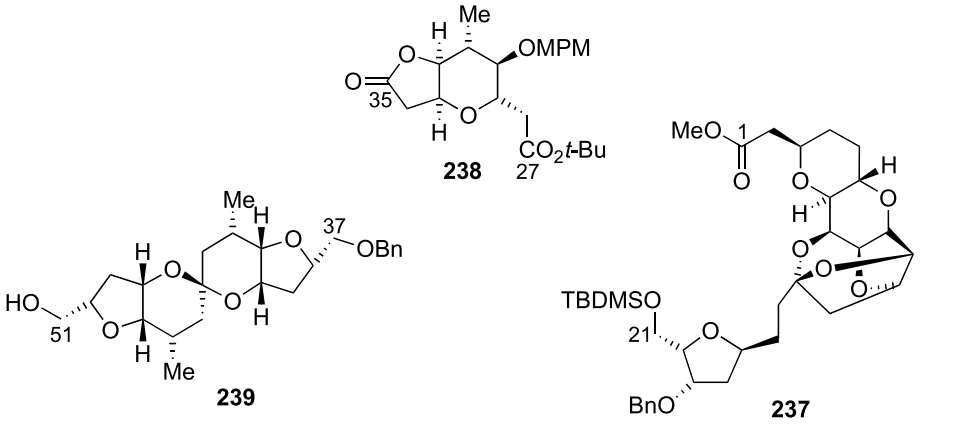

Figure 21
Segments of Salomon synthesis of halichondrin B

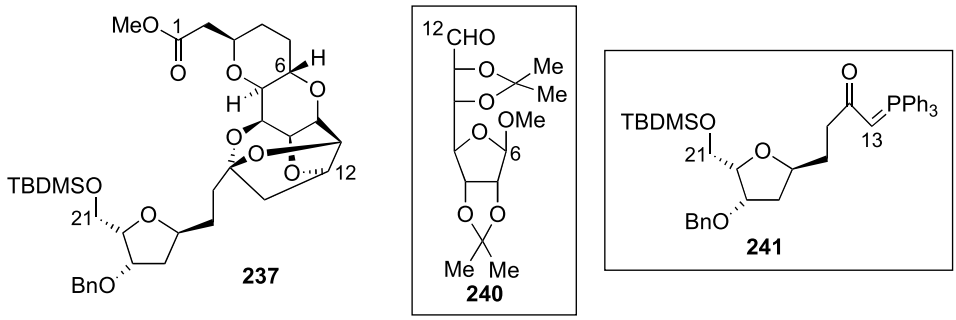

Figure 22
Subsegments of 237

The C1–C21 segment **237** was prepared from two main subsegments, **240** (C6–C12) and **241** (C13–C21) (*Fig. 22*).

The commercially available ribofuranoside **242** was oxidized, and the resulting aldehyde was subjected to Wittig reaction to afford **243** (*Scheme 28*). OsO_4-catalyzed vicinal hydroxylation of **243** gave **244** as the major product. The configuration at C6 in **244** had to be selectively inverted. This was accomplished by a regioselective nucleophilic substitution of the derived cyclic sulfate **245**. Debenzoylation of benzoate **246**, isopropylidenation of the resulting diol, and partial reduction of the ester with DIBALH delivered aldehyde **240**, the C6–C12 subsegment.

The C13–C21 subsegment **241** was prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**) (*Scheme 29*). Benzylation, selective deprotection, and tosylation of **2** gave **247**, which was converted to **248** by transacetalization and intramolecular *O*-alkylation. Barton's deoxygenation of **248** gave **249**. Deacetalization of **249** followed by the 3-step transformation provided **250**. Alkylation of **250** with α'-lithioacetonylidenetriphenylphosphorane gave **241**. These two subsegments, **240** and **241**, were coupled and transformed into **237**.

The C27–C35 segment **238** was prepared from **32** (◉ *Scheme 30*), which is the synthetic intermediate of erythronolide A. Oxidative cleavage of **32** gave aldehyde **251**, which was subjected to aldol reaction with TBDMS-enol ether and $TiCl_4$ to provide **252**. Hydrolysis of thioester and deacetalization with TFA were accompanied by furanose-to-pyranose interconversion and

lactonization to provide the *cis*-lactone **253**. Wittig olefination of **253** and heterocyclization of the intermediate α,β-unsaturated ester **254** followed by methoxybenzylation furnished the target lactone **238**.

The C37–C51 segment **239** was prepared from four subsegments, **255**–**258** (◉ *Scheme 31*). Acidic cyclization of D-mannitol (**259**) generated tetraol, which was selectively acetalized to give **260**. Hydrodehydroxylation of the derived monosilyl ether by the Barton protocol and replacement of the TBDMS group by a benzyl group afforded **261**. Reductive cleavage of **261** with DIBALH generated a 6:4 mixture of **262** and **263**; both compounds could be used in the synthesis of the C37–C51 segment **239**. Thus, **262** was oxidized under Swern conditions to give **255**. On the other hand, **263** was converted to **256** by the 5-step transformation. These two subsegments were connected step-by-step to afford the C37–C51 segment **239**.

Horita, Yonemitsu, and coworkers have described synthetic studies of halichondrin B (**205**) [128,129,130,131,132,133,134,135,136]. The C1–C15 segment **264** was prepared from **265** (*Fig. 23*)

Benzylation, selective hydrolysis, and benzoylation of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**) readily gave **266** (*Scheme 32*). Furanose-to-pyranose interconversion was realized by acidic hydrolysis of **266**, giving **267**. Opening of the pyranose ring with 1,3-propanedithiol was realized in the presence of $ZnCl_2$, providing an acyclic compound, which was treated with 4-methoxybenzaldehyde dimethyl acetal and CSA to give only a thermodynamically stable 1,3-dioxane compound. The remaining hydroxy group was then mesylated to give **268**, which was readily converted to epoxide **269** by removal of the benzoyl group followed by treatment of a base. The 5-step conversion of **269** gave **270**. Dedithioacetalization of **270** provided the C8–C13 subsegment **265**, which was converted to the C1–C15 segment **264** via a several-step manipulation.

Burke and coworkers have described the synthetic studies of halichondrin B (**205**) [137,138,139,140].

Abstract

This chapter focuses on monosaccharides and their derivatives as scaffolds for the synthesis of primarily bioactive compounds. Such carbohydrate derivatives have been designed to modulate mainly protein-protein and peptide-protein interactions although modulators of carbohydrate-protein and carbohydrate-nucleic acid interactions have also been of interest. The multiple hydroxyl groups that are present on saccharides have made pyranose, furanose and iminosugars ideal templates or scaffolds to which recognition or pharmacophoric groups can be grafted to generate novel compounds for medicinal chemistry. The synthesis of compounds for evaluations require strategies for regioselective reactions of saccharide hydroxyl groups and use of orthogonally stable protecting groups. Syntheses have been carried out on the solid phase and in solution. Also the use of uronic acids, amino sugars and sugar amino acids has facilitated the synthesis of peptidomimetics and prospecting libraries as they enable, through presence of

amino or carboxylic acid groups, chemoselective approaches to be employed in solution and on solid phase. Sugar amino acids are readily incorporated, as peptide isosteres, to generate sugar-peptide hybrids or for the synthesis of novel carbopeptoids. The synthesis of new cyclic compounds, derived in part from saccharides, and their application as scaffolds is an emerging area and recent examples include spirocyclic compounds, benzodiazepine-saccharide hybrids and macrolide-saccharide hybrids. Potent bioactive saccharide derivatives have been identified that include enzyme inhibitors, somatostatin receptor ligands, integrin ligands, anti-viral compounds, shiga toxin inhibitors and cell growth inhibitors. Some saccharide derivatives have demonstrated improved cellular permeability when compared with peptides and are in clinical trials.

1 Introduction

There is increasing activity in efforts to develop bioactive compounds which contain carbohydrate structures. In this regard the application of monosaccharides and derivatives as scaffolds has received attention. In some natural biopolymers a monosaccharide residue is considered to have an important scaffolding role, orienting the recognition or pharmacophoric groups in a defined orientation for binding to a receptor, while at the same time this saccharide residue may or may not make binding interactions with the receptor. For example, the tetrasaccharide sialyl Lewis X plays an important role in cell-cell adhesion that occurs during the immune response and inflammatory disease. The GlcNAc (*N*-acetyl-glucosamine) residue of sialyl Lewis X plays the role of a scaffold; the hydroxyl groups at C-3 and C-4 of GlcNAc facilitate the presentation of the fucose, galactose and sialic residues in a conformation so that these groups can make critical binding interactions with selectins and the glycosidic linkage at C-1 provides the mode by which the tetrasaccharide is anchored to the protein at the cell surface (◉ *Fig. 1*). The potential of sialyl Lewis X mimetics as therapeutics prompted research, most of which was published in the 1990s, towards the development of sialyl Lewis X mimetics (glycomimetics) and this area has been reviewed comprehensively [1].

That monosaccharides were also suitable for the synthesis of peptidomimetics [2] was first demonstrated by Nicolaou, Hirschmann and co-workers in 1989 who provided experimental validation that novel ligands (peptide β-turn mimetics) for peptide based on β-D-glucopyranose [3]. A conceptually similar approach suggesting the use of cyclohexane as scaffold had been initially proposed, although not investigated, by Farmer [4]. In this example, pharmacophoric groups, which correspond to the amino acid side chains of the tripeptide Phe-Trp-Lys were grafted to the pyranose, which acted as a replacement for the peptide backbone and projected the binding groups towards their respective receptor subsites (◉ *Fig. 1*). Since then, carbohydrate-based peptidomimetic development has become an active research area where the goal is to develop monosaccharide derivatives that bind to peptide receptors, with potentially better bioavailability, biostability and selectivity than endogenous or synthetic peptide ligands [5].

A cheminformatic or modelling approach has provided further indication of the potential of pyranosides as scaffolds. Meutermans and co-workers at Alchemia have investigated the structural diversity of pyranosides based on eight scaffolds (α- and β-anomers of D-glucopyranose, D-mannopyranose, D-allopyranose, and D-galactopyranose) and considered the geometric properties of these scaffolds when they display three unique substituents and compared them with tripeptide sequences in 200,000 proteins [6]. The outcome of this analysis showed that most peptides can be mimicked effectively with a subset of the pyranose scaffolds. One single scaffold [α-D-Glc or β-D-GlcNAc] provided access to many areas in the diversity space and the saccharides have the potential to access conformational space not available to peptides.

There has been significant research activity in efforts to synthesise novel bioactive molecules based on a wide range of (amino)sugar scaffolds [7], including L-sugars [6], iminosugars [8], sugar amino acids (SAAs) [9], and disaccharides [10]. Such compounds have been designed for the modulation of peptide-protein or protein-protein interactions, or for modulation of other biological recognition events including carbohydrate-protein and carbohydrate-nucleic acid interactions. A number of reviews concerning application of saccharides as scaffolds in combinatorial, bioorganic, and medicinal chemistry are available [5,11]. Many chemists have been

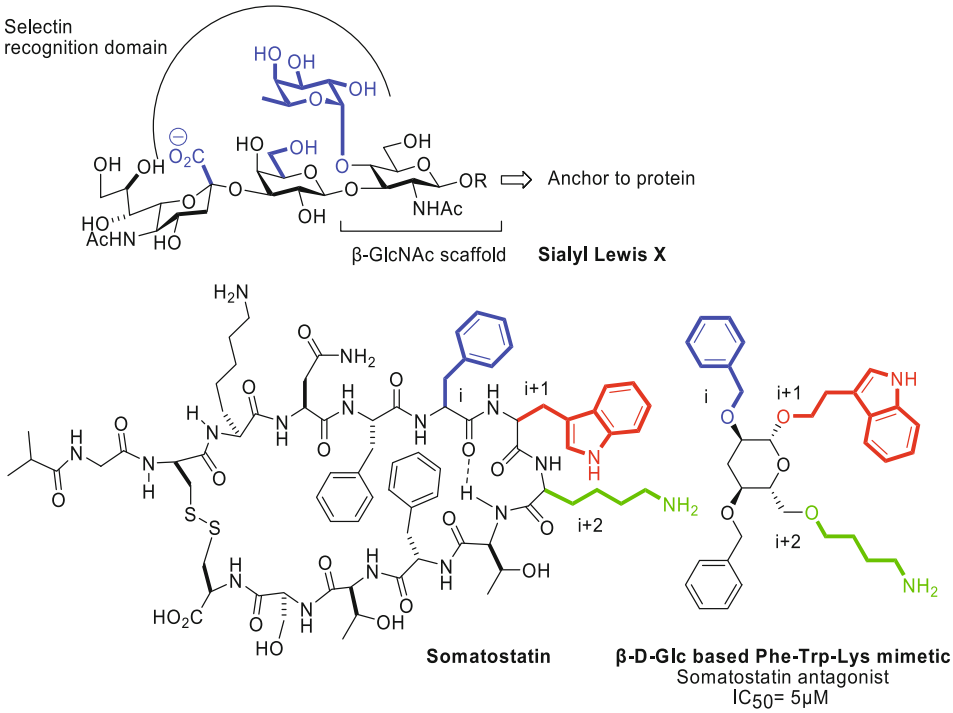

Figure 1

interested in the development of monosaccharides as scaffolds as they are chiral, they have multiple functional groups which facilitate the introduction of pharmacophoric groups and they have rigid conformation. The need for synthesis of carbon–carbon bonds is avoided as the hydroxyl groups can be converted into ethers. The introduction of SAAs, as intermediates for bioactive compound development, allows for chemoselective reactions to be applied on monosaccharide scaffolds, simplifying the synthesis of novel compounds for biological evaluation.

The purpose of this chapter is to provide an overview of the application of monosaccharides for the synthesis of novel compounds, and in particular we have focused on bioactive compounds that target protein-protein or peptide-protein interactions. We have not reviewed extensively the application of monosaccharides as scaffolds that modulate carbohydrate-protein interactions (glycomimetics or inhibitors of glycoprocessing enzymes) as these are considered elsewhere. Also it has not been possible to detail all of the work of those groups who have contributed to this area. The review is divided into two main sections: synthesis and application of monosaccharides that are SAAs and synthesis and application of monosaccharides that are not SAAs. The structures and applications of the monosaccharide building blocks are considered as are the synthesis and properties of target compounds.

2 Sugar Amino Acids

Sugar amino acids, also referred to as glycosamino acids (GAAs), are monosaccharide-based building blocks that feature both a carboxylic acid and an amine functional group. According to this definition, a great diversity of structures can be classified as SAAs or GAAs. Also included within this group of compounds are molecules featuring an azido functionality (sugar azido acids) as normally the corresponding amine can be obtained by reduction of the azide, and sometimes it is convenient to carry out synthetic transformations having the azide as a masked amino group. There has been a growing interest in SAAs and their application in synthetic chemistry and chemical biology in recent years [11e,f], [12]. On one hand, they keep the stereochemical and functional properties of carbohydrates, while on the other they can be incorporated into oligomeric structures, offering additional groups for further modifications. Examples of bioactive compounds of interest in this regard are sugar-peptide hybrids, either where the SAA is used as a peptide isostere or as a scaffold for the synthesis of non-peptide peptidomimetics or other libraries for lead compound discovery. The synthesis of foldamers (carbopeptoids) using peptide-coupling methodologies is another example of the use of SAAs. The presence of amino, azido, carboxyl and hydroxyl groups, present on the saccharide scaffolds, facilitates using chemoselective reactions which can minimise protecting group manipulations and simplify the synthesis of target compounds.

Since the introduction of SAAs by Kessler there have been numerous examples reported and representative examples of SAAs are shown in ❯ *Fig. 2*, ❯ *Fig. 3* and ❯ *Fig. 4*, depending on the functional groups being displayed on scaffolds derived from pyran [9,13,14,15,16,17,18,19,20,21,22,23], furan [22,24,25,26,27,28,29,20,31], oxetane [32], bicyclics and spirocyclics [33,34] and iminosugars [35,36,37,38], respectively. These compounds have found application as peptide isosteres, peptidomimetic building blocks, building blocks for peptoid synthesis, building blocks for synthesis of libraries for screening of glycosidases and for the synthesis of libraries for screening against a wide range of biological targets (prospecting libraries).

2.1 Synthesis of SAAs

The synthesis of a member of the SAA kit first developed by Kessler [9,13] is shown in ❯ *Scheme 1*. The reaction of glucurono-6,3-lactone with methanol in the presence of a base and subsequent acetylation with acetic anhydride and sodium acetate gave **41**. The anomeric acetate of **41** was displaced with azide when reacted with tin (IV) chloride and azidotrimethylsilane giving 1,2-*trans* glycoside **42**, with a β-configuration, which is controlled by the participating group at C-2. Subsequent reduction of the azide gave the amine **1**, which was incorporated, as a peptide isostere, into peptide-sugar hybrids.

Overhand, Overkleeft and their collaborators have synthesised a variety of SAAs [39]. The synthesis of Fmoc-protected **6** (❯ *Fig. 2*) is illustrated in ❯ *Scheme 2* [15]. Tri-*O*-acetyl-D-glucal was converted into the SAA precursor **43** in five steps. Formation of the trichloroacetimidate derivative **44** and a subsequent Overman rearrangement was used to introduce the amino group onto the pyran scaffold giving **45**. Hydrogenation of the olefin in **45** was accompanied by cleavage of the silyl ether to afford the primary alcohol which was oxidised with a catalytic amount of ruthenium (III) chloride in the presence of sodium periodate giving **46**. Subjection

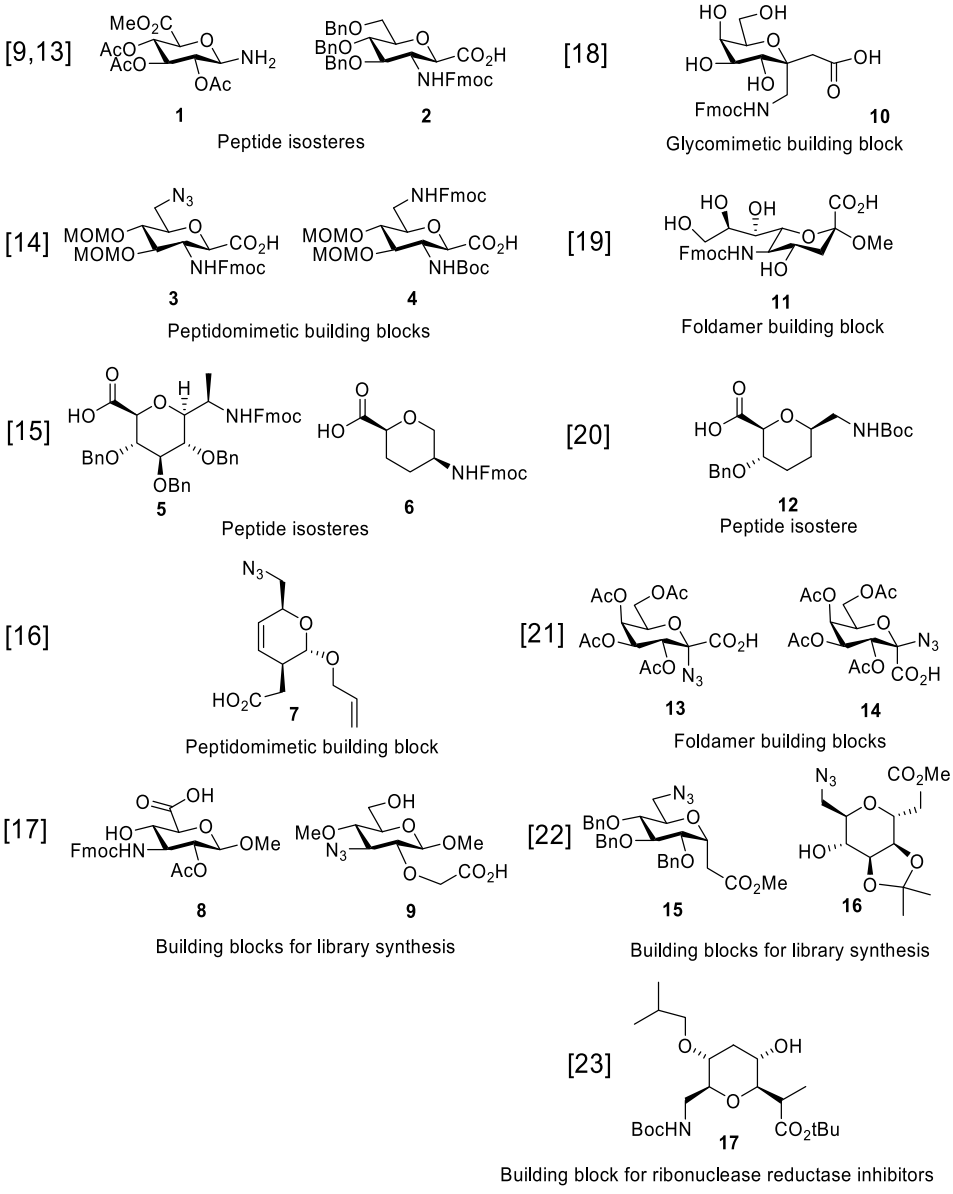

Figure 2
Examples of SAAs based on pyran scaffolds

of Boc-protected **46** to 50% TFA in dichloromethane and subsequent reaction with Fmoc-*O*-Su gave the desired amino acid **6**.

The Fleet research group developed methodologies for the preparation of α, β, γ and δ SAAs based on furan and oxetane scaffolds. The synthesis of γ and β SAAs **51** and **24**, is shown

in *Scheme 3* [29b]. The key triflate intermediate **48** was prepared via **47** in three steps from L-arabinose and this underwent ring contraction under acidic conditions in methanol, together with deprotection of the acetonide, to give the corresponding methyl ester which, was then subjected to acid-catalysed transesterification to form the stable isopropyl ester **49**. Treatment of diol **49** with a single equivalent of TBDPSCl gave a mixture of the monoprotected silyl ethers in the 3 and 4 positions **50** and **51**, respectively, with low regioselectivity. The 3-*O*-TBDPS-protected derivative **50** was converted via a triflate intermediate, to give γ-azido ester **51** with total inversion of the configuration at C-4. The β-azido ester **22** was prepared similarly from the 4-*O*-TBDPS-protected **52**.

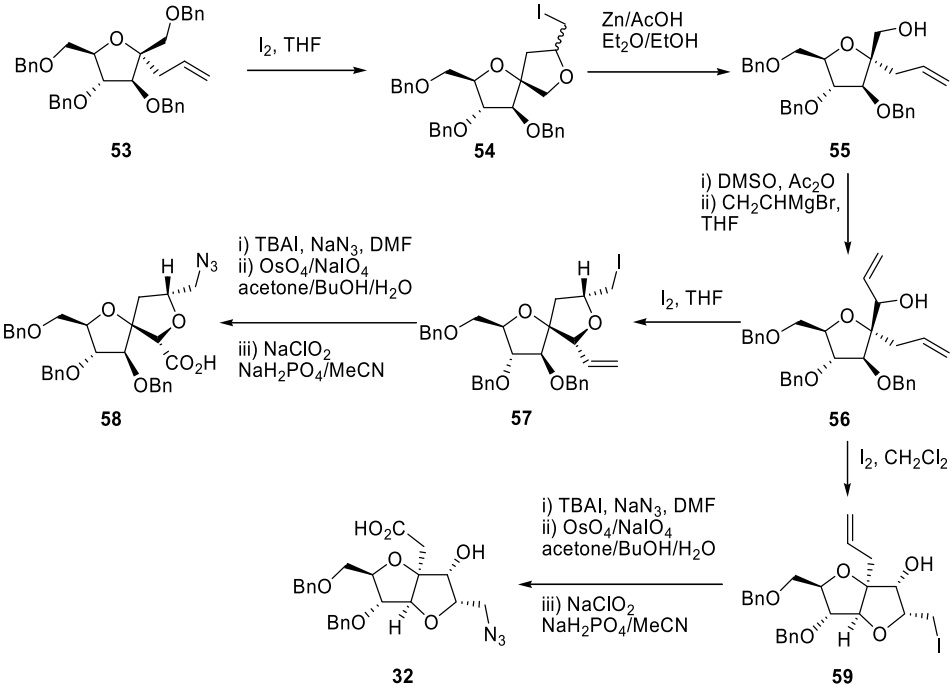
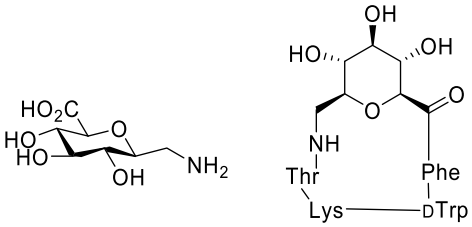


Scheme 4

Nicotra's group have synthesised SAAs based on fused bicyclic and spirocyclic compounds. The synthesis of **32** and **58** from the fructoside **53**, is shown in *Scheme 4* [33]. Treatment of fructoside **53** with I_2 resulted in a 5-exo cyclisation to give a diastereoisomeric mixture of spiro cyclic compounds **54**. The mixture was then reacted with zinc and acetic acid to give **55**, in which the double bond was regenerated with the selective deprotection of the benzyl group at C-1 having been achieved. Oxidation of the free hydroxyl to the corresponding aldehyde was followed by instalment of a second double bond through Grignard addition to give **55**. When this intermediate was treated with I_2 in THF, the reaction proceeded with attack of the free hydroxyl to give spirocyclic compound **57**. However, when the reaction of **56** with I_2 was carried out in dichloromethane as a solvent, the benzyloxy group at C-3 was involved in the cyclisation, this resulting in the formation of fused bicyclic compound **59**. Similar reaction sequences for both **57** and **58**, consisting of displacement of the iodide by sodium azide, followed by oxidative cleavage of the double bond, gave **58** and **32**, respectively.

2.2 Application of SAAs as Peptide Isosteres

The presence of amino and carboxylic acid groups conveniently protected allows for the coupling of the SAAs building blocks to form sugar-peptide hybrids. One or more amino acids of the peptidic backbone can be replaced by the sugar units, thus incorporating the conformation-



60 61

Figure 5
Kessler's SAA building block 60 was incorporated into cyclic peptide somatostatin analogue 61

al constraints inherent to the carbohydrate ring into the peptide secondary structure. Kessler and co-workers [9,13] have synthesised a collection of pyranose-based SAAs and incorporated such saccharides into linear and cyclic oligopeptides. They have studied by NMR and computational techniques the influence of the introduction of these building blocks on the conformational properties of the peptidomimetics. The different SAAs were incorporated into linear and cyclic oligopeptides. It was found that these compounds can be used as dipeptide isosteres [for example, of the natural Gly(glycine)-Gly dipeptide] and homoproline isosteres. They also mimic the linear, flexible β-turn and γ-turn peptide secondary structures. For example SAA **60** was incorporated into the cyclic peptide somatostatin (SST) analogue **61** (*Fig. 5*), which was a somatostatin mimetic in which the β-turn motif is mimicked by the SAA. The novel sugar-peptide hybrid had an IC_{50} of 0.15 µM for the inhibition of the release of growth hormone.

Kunwar, Chakraborty and co-workers have prepared a series of sugar-peptide hybrids as mimetics of a potent vasoactive intestinal peptide receptor inhibitor by incorporating furanoid SAAs into **62** (*Fig. 6*) [26]. The carbohydrate units act as dipeptide isosters of either Tyr(tyrosine)-Pro(proline) or Pro-Thr(threonine) present in the original structure. The anticancer activities of the resulting analogues were tested in a series of human cell-lines, showing similar or enhanced activities to the original peptide. The group of Overhand and Overkleeft has made a number of contributions. This has included the preparation of gramicidin S analogues containing arylated sugar amino acids such as **19** (*Fig. 3*) as replacements for D-Phe-Pro β-turn regions and the novel sugar-peptide hybrid, which proved to be as active as the parent compound as antibacterial agents and in lysing red blood cells [25]. The same group have also used SAAs to prepare 11 analogues of the *C*-terminal Ca_1a_2X motif found in the natural substrates of the prenyl transferases (PFT and PGGT-1) and a highly selective inhibitor **63** (*Fig. 6*) was identified [20]. These transferases catalyse the transfer of isoprenoid lipids from the corresponding pyrophosphates to cysteine residues at the *C*-termini of precursor proteins that are important in signal transduction. A number of inhibitors of these proteins are in clinical development. The methyl ester of the peptide mimetic was able to inhibit protein farnesylation in intact Met-18b-2 cells indicating that the methyl ester of **63** is cell permeable. Nicotra and collaborators used their bicyclic SAA **32** (*Fig. 4*) to synthesise a macrocyclic pseudopeptide incorporating the biologically relevant RGD sequence [40]; this compound inhibited adhesion of fetal bovine aortic endothelial GM7373 cells to their ligands: fibroblast growth factor, vitronectin and fibronectin indicating the compound is an antagonist

of the $\alpha_v\beta_3$ integrin receptor. Smith, Hirschmann, Cooperman and co-workers used **17** for the synthesis of the novel ribonuclease reductase inhibitor **64** (◉ *Fig. 6*) [23].
The Fleet research group has reported the preparation of a variety of δ-sugar azido esters based on oxetane-type scaffolds [32]. The sugar azido esters **65** (*cis*) and **66** (*trans*) can be regarded as building blocks for dipeptide isosteres of Gly-L-Ser(serine), although sugar-peptide conjugates based on these building blocks have not been prepared to date (◉ *Fig. 7*).
Several other groups have reported the use of SAAs as dipeptide isosteres of natural and non-natural occurring dipeptides [41].

2.3 Application of SAAs as Scaffolds for Synthesis of Pharmacophore Mapping or Prospecting Libraries

Sugar amino acids can be used for the synthesis of libraries of compounds for screening. Sofia and co-workers have made use of pyranose SAA scaffolds and combinatorial solid phase synthesis to generate pharmacophoric mapping libraries. The structure of their carbohydrate platforms is ideal to generate combinatorial molecular diversity and novel ligands for a variety of biological targets can be produced rapidly. They have prepared scaffolds containing three orthogonal functional groups. The chemoselective functionalisation of these groups reduces the need for protecting group strategies and facilitates the combinatorial introduction of the different pharmacophoric groups. In the example shown (◉ *Fig. 2*, ◉ *Scheme 5*) the pyranose scaffold **9** features a carboxylic acid, an azido and a free hydroxyl group. The scaffold was attached to a Rink amide resin derivative **67** by reaction of the carboxylic acid with the histidine free amino group to give solid supported scaffold **68**. It was then reacted with a variety of isocyanates to give carbamates at the 6 position and the azido group at C-3 was reduced using the Staudinger reaction to give amines which were coupled to carboxylic acids. A library of 48 compounds of type **69** was prepared. The same group defined a library synthesis based on Fmoc-protected SAAs [17].
The Fleet research group used furanose SAAs for the generation of solution-phase libraries [24]. The fully protected precursor **18** was prepared efficiently from L-gulonolactone. Subsequent reduction of the azide resulted in the free amine that was allowed to react with a range of isocyanates and isothiocyanates (as shown in the example in ◉ *Scheme 6*) to give the intermediate **70**. The transformation of the ester into an amide was achieved by treatment with free amine at elevated temperatures to give the final products of the library **71**. A 99-member library was prepared in this way and it has been subjected to biological screening for antibacterial activity.

2.4 Application of SAAs in Synthesis of Foldamers

There is increasing interest in the development of foldamers or polymeric structures that can adopt organised secondary structures like those of proteins, nucleic acids and some polysaccharides [42]. Sugar amino acid-based foldamer research has so far been primarily concerned with synthesis of polymers with secondary structural features. Such foldamers may find application as scaffolds for peptidomimetic development if they adopt turn, helical and strand structures observed for peptides or if derivatives can act as ligands for peptide receptors;

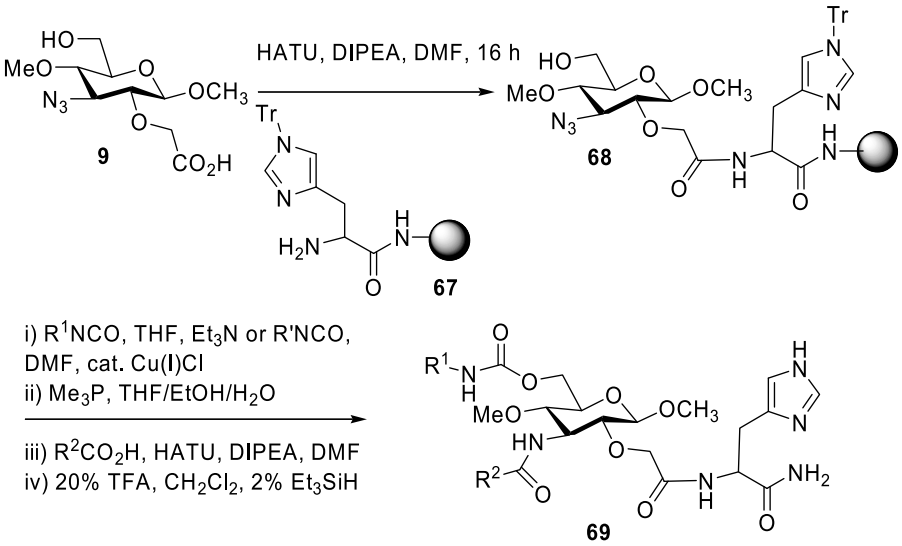
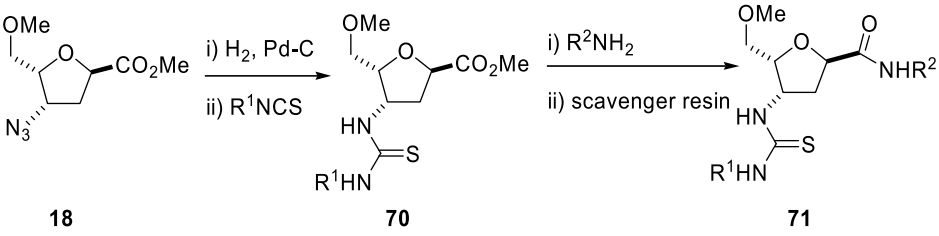


Scheme 5



Scheme 6

in such cases the additional functional groups present in SAAs could potentially be used to modify the polymer backbone to tailor the properties for binding to a target receptor. Gervay and co-workers have prepared amide-linked homo-oligomers derived from the naturally occurring SAA neuraminic acid (NeuAc) analogues [43]. They have used solid-phase peptide synthesis involving *N*-Fmoc protecting groups to generate a series of oligomers of general structure **72** (*Fig. 8*), ranging from dimeric to octameric compounds. They feature a lipid amide linker as a model for membrane-bound oligomers. The data obtained by NMR and CD

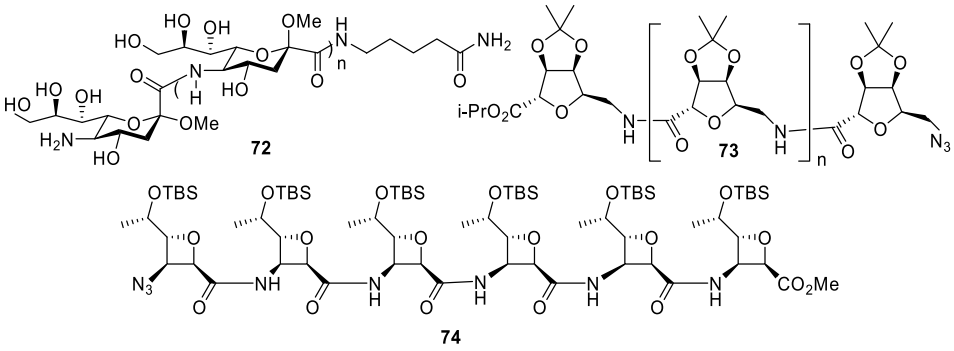


Figure 8
Foldamers prepared from SAAs

spectroscopy studies indicates that these compounds present defined secondary structures that may vary depending on their length. The corresponding homoligomers of *N*-Fmoc-protected sugar amino acids derived from α-*O*-methoxyneuraminic acid **11** (*Fig. 2*) and 2,3-dehydroneuraminic acids have been recently synthesised using solid phase methods [19]. Highly functionalised oligomers derived from other pyranosides have also been found to adopt well-defined structural conformations [44]. The Fleet research group has also reported foldamers **73** derived from furanoid sugar azido esters (*Fig. 8*). They have investigated the conformational properties in organic solvents of the corresponding tetramer and octamer. Using NMR, IR and CD spectroscopy and molecular dynamics studies, they have determined that the tetrameric compound does not adopt a hydrogen-bonded conformation whereas an octamer has a well-defined helical secondary structure stabilised by a 16-membered ring with inter-residue hydrogen bonds, similar to a π-helix [28]. Fleet and co-workers have also investigated the conformational properties of oligomers of oxetane SAAs prepared by peptide coupling techniques. The study of their secondary structure by NMR, both in $CDCl_3$ and C_6D_6, together with molecular mechanics analysis, revealed that hexamer **74** (*Fig. 8*), in which the hydroxy group is protected as a TBS ether, adopts well-defined helical structures stabilised by 10-membered hydrogen-bonded rings [32].

3 Bioactive Compounds Based on Monosaccharide Scaffolds that are not SAAs

Other pyranose, furanose and iminosugar derivatives that do not contain both amino and carboxylic acid functional groups have been of interest and are considered in this section.

3.1 Structures of Bioactive Compounds Designed for Specific Target Receptors

A selection of bioactive compounds based on furanose, pyranose and iminosugars [7,8,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69] have been synthesised and some are shown in *Fig. 9* and *Fig. 10*. The application of pyranose scaffolds

Bioactive compounds based on pyranose, furanose and iminosugar scaffolds that are not SAAs

for the discovery of novel peptidomimetics was first validated by initial work carried out by Nicolaou, Hirschmann and co-workers [3]. They designed and synthesised ligands such as **81** and **82** (*Fig. 1* and *Fig. 9*) as somatostatin mimetics based on compounds derived from β-D-glucopyranose. Somatostatin is a tetradecapeptide that regulates, through binding to its receptors (SSTR) a number of processes including the release of growth hormone and other pituitary hormones. It also plays a role in neuronal transmission. The side chains of the amino acids Phe, Trp and Lys were grafted to hydroxyl groups of the β-D-glucopyranose in an orientation designed to mimic the spatial presentation of the side chains of Phe (i), Trp (i + 1) and Lys (i + 2), respectively, of somatostatin (*Fig. 1*) and **81** and **82** were found to bind to the somatostatin receptor with IC_{50} values of 9.5 and 1.3 µM, respectively. Further refinement of the ligand structure was carried out by structural-activity relationship studies and different monosaccharides such as L-glucose and L-mannose were also investigated [7]. The introduction of different heteroaromatic moieties in the structure of the peptidomimetic led to the identification of a novel β-D-glucopyranoside-based ligand **83** (*Fig. 9*) with enhanced affinities (IC_{50} value of 53 nM) at human SSTR subtypes (SST4 and SST2) [3,52,53]. Other activities were observed for these peptidomimetics. Glucoside **81** is also a β2-adrenergic antagonist with an IC_{50} value of 3 µM and both **81** and **82** are ligands for the NK-1(neurokinin) receptor with IC_{50} values of 0.12 and 0.18 µM, respectively. Small changes in the structure of **82**, such as acetylation of the free amino group, resulted in enhanced activity as an NK-1 antagonist, with an IC_{50} value of 60 nM and complete loss of activity for SSTR. β-D-Glucopyranose was thus defined as a "privileged structure" since compounds based on this scaffold can bind to more than one type of receptor. This body of work from Hirschmann and collaborators illustrates the general approach that can be applied in the discovery of potent peptidomimetic compounds from carbohydrates and similar principles have been used by others in the design and synthesis of saccharide-based bioactive compounds and compounds that have been synthesised with a view to targeting particular receptors.

Somatostatin ligands based on iminosugar scaffolds have also been synthesised. Iminosugars are structural analogues of pyranosides, in which the ring oxygen atom is replaced by a nitrogen atom and iminosugar-based mimetics of somatostatin have been synthesised. In addition to somatostatin ligands [8,46,47], monosaccharide derivatives have been applied to the synthesis of cyclic endothelin antagonists [48], thrombin inhibitors [49], multidrug-resistant-associated protein inhibitors [50], cytomegalovirus inhibitors [51], integrin ligands [54,55,56], HIV protease inhibitors [57,58,59,60,64], fibrinogen receptor ligands [61], LPA agonists and antagonists [62], rhodopeptin mimetics [63], cysteine protease calpain inhibitors [65], RNA binding agents [66], inhibitors of the growth of human cell lines [67], multivalent carbohydrates [45] including shigatoxin inhibitors [68] and the synthesis of carbopeptides and carboproteins [69].

3.2 Selected Syntheses of Peptidomimetics Designed for Specific Target Receptors

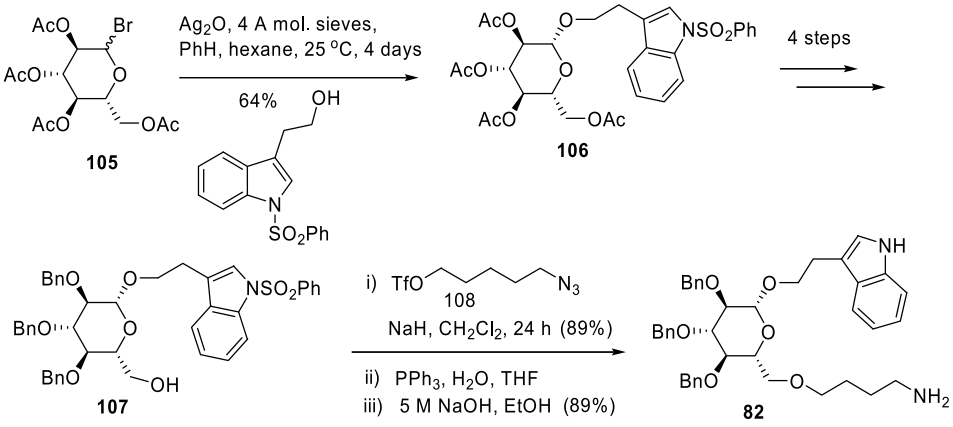
Bioactive compounds based on pyranose and furanose scaffolds that are not SAAs

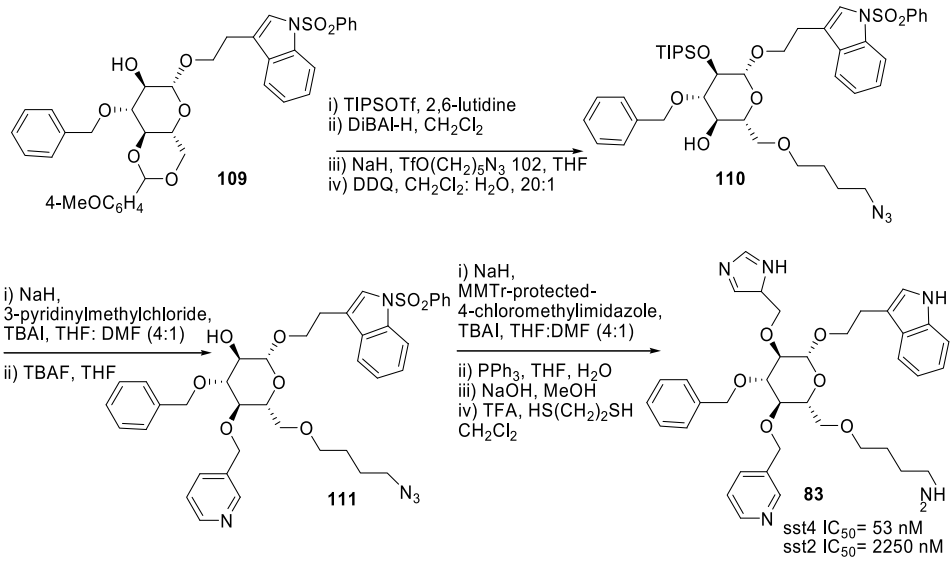
ed in the presence of a suitable alcohol acceptor using standard Koenigs–Knorr conditions to incorporate the tryptophan side chain at the anomeric carbon to give **106** (*Scheme 7*). A series of protecting group manipulations gave alcohol **107** which was subsequently reacted with triflate **108** to give an azide intermediate. The azide was then reduced in the presence of the benzyl ether protecting groups using triphenylphosphine and water, and the benzenesulfonamide was subsequently removed from the indole using aqueous sodium hydroxide, to give the β-turn mimetic **82**.

Hirschmann and co-workers have incorporated heterocyclic aromatic substituents onto the 2- and 4-OH of pyranosides structurally related to **82** to give one of the most potent saccharide-derived somatostatin ligands **83** developed to date. The synthesis of **83** is shown in *Scheme 8* from alcohol **109**. The TIPS protecting group was introduced at the 2-OH of **109** and regioselective cleavage of the methoxybenzylidene gave an intermediate where the 6-OH group is free and the 4-OH group is protected as the methoxyphenylmethyl (MPM) ether. Reaction of this intermediate with the triflate **108** and subsequent removal of the MPM ether gave **110**. The reaction of **110** with 3-picolyl chloride in the presence of sodium hydride and subsequent removal of the TIPS group gave **111**. Subsequent alkylation of **111** with *N*-monomethoxytrityl (MMTr)-protected 4-chloromethylimidazole followed by Staudinger reduction of the azide, removal of the indole sulfonamide and acidic removal of the MMT group in the presence of a dithiol scavenger gave **83**.

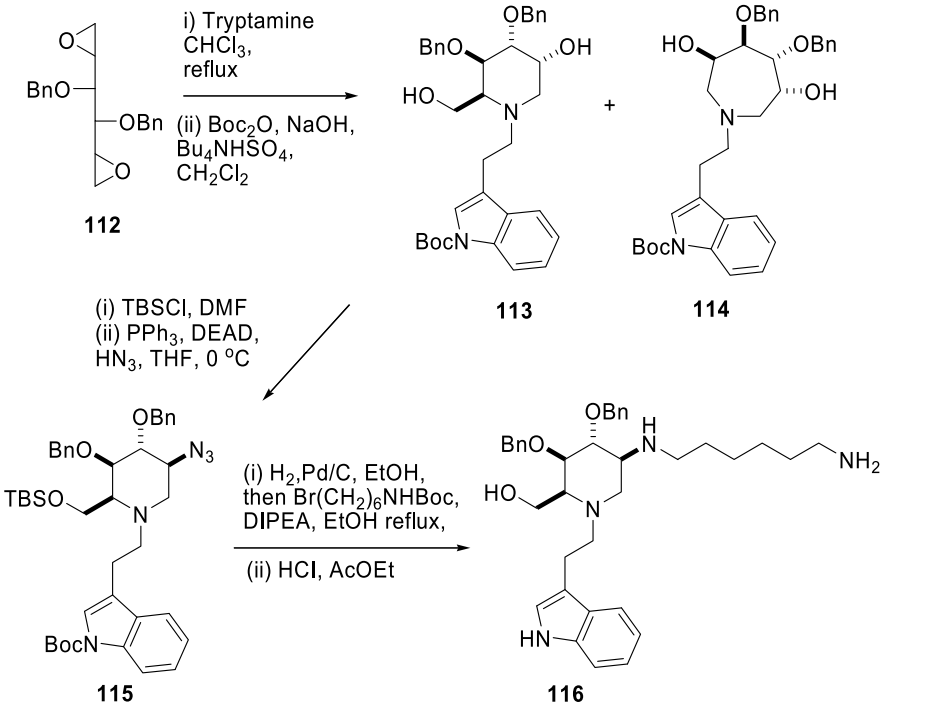
Depazay and co-workers have described the synthesis of a series of polyhydroxylated pyrrolidine, piperidine and azepanes derived from D-mannitol as novel mimetics of somatostatin [8]. The synthesis of one piperidine **116** is shown in *Scheme 9*. The authors used reaction of tryptamine with the D-mannitol derived bis-epoxide **112** followed by protection of the indole nitrogen with a Boc group to prepare the L-gulo-piperidine **113**, the azepane **114** also being formed. Selective protection of the primary alcohol followed by reaction with hydrazoic acid



Scheme 7



Scheme 8



Scheme 9

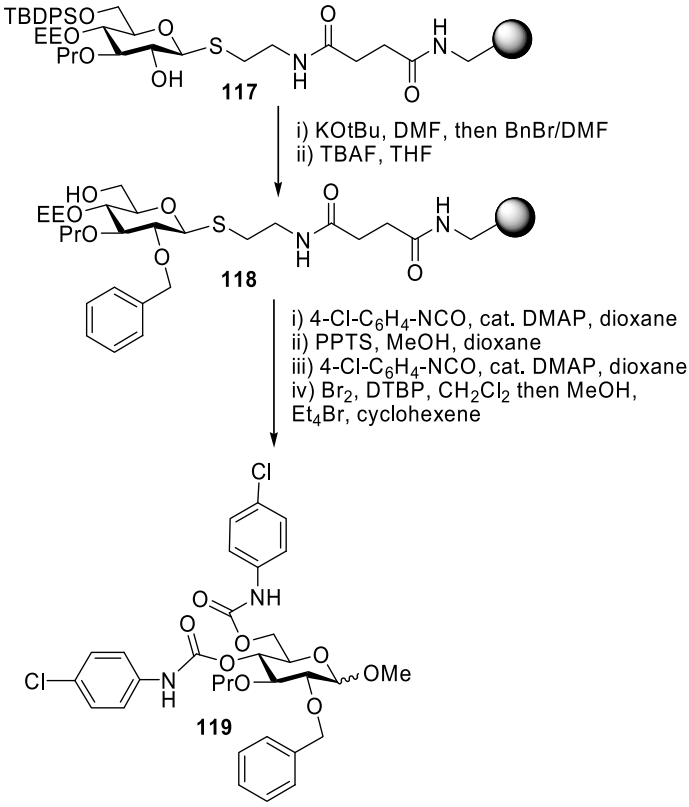
under Mitsunobu conditions gave the azide **115**. Reduction of the azide followed by introduction of the lysine side chain and subsequent removal of the protecting groups under acidic conditions gave **116**.

Gouin and Murphy have reported [47] the synthesis of the more hydrophilic dipeptide mimetic **76** (◉ *Fig. 9*) in 13 steps from 1-DMJ [70]. This DMJ derivative lacks the benzyl group in the side chain to mimic Phe, yet still displayed a K_i value of 26 μM in an unspecific SST receptor assay, and it showed preferential binding to hSSTR4 (48% at 1 μM) over hSSTR5.

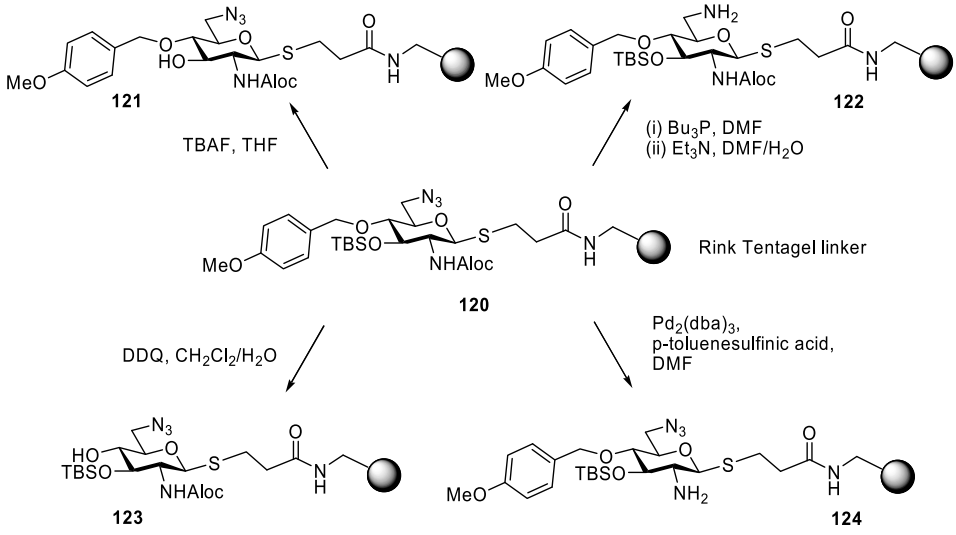
3.3 Strategies for Synthesis of Prospecting Libraries

The bioactive compounds outlined above display a wide range of bioactivities that have been observed for compounds based on monosaccharide scaffolds. Difficulties in the synthesis of novel compounds based on monosaccharides includes the ability to differentiate the hydroxyl groups from each other as they have similar reactivity and the strategies for synthesis therefore depend on the need for regioselective reactions and the use of orthogonally stable protecting groups. Selective deprotection must be available at all hydroxyl groups to be functionalised and all other protecting groups must remain unaffected during subsequent introduction of putative pharmacophoric groups. An additional complication for solid phase syntheses of such compounds is that one group is used to anchor the saccharide to the polymer support and must be stable to all chemical reagents used and then it needs to be cleaved without degrading the target compound. An alternative or complementary strategy can be the introduction of different kinds of functional groups (e. g. amine, carboxylic acid, azide, primary alcohol, secondary alcohol) to the scaffold. Then selective manipulation of these groups can be achieved on the basis of their chemoselective reactions, which forms the basis of the SAA concept discussed above. Such libraries can be focused towards an identification of a potent novel ligand for a specific target receptor or the library could be prepared with a view to screening for a range of targets. Successful syntheses of libraries on the solid phase that are not based on SAAs were published by the Kunz group [71,72]. They developed an orthogonal protection system for carbohydrate hydroxyl groups using the *tert*-butyldiphenylsilyl, acetate, allyl and ethoxyethyl protecting groups, as well as a special thioglycoside linker which doubled as a means to connect to a solid phase resin and as a glycosyl donor **117**. Each protecting group could be selectively removed and the hydroxyl group then derivatised to introduce a pharmacophoric side-chain. Substituents could be introduced at all positions of the glucopyranoside scaffold. The synthesis of a member is shown in ◉ *Scheme 10*. The 2-OH group of **117** was benzylated and then the silyl protecting group at C-6 was removed to give **118**. The 6-OH group was converted to a carbamate, the ethoxyethyl group then removed and a carbamate group then introduced at the 4 position. Finally the thioglycoside was converted to the glycosyl bromide, with concomitant removal of the saccharide from the resin, and halide-assisted glycosidation of this bromide with methanol gave **119** as a mixture of α- and β-glycosides.

More recently Kunz and co-workers described a synthesis of 2,6-dideoxy-2,6-diaminopyranoside libraries [73]. The scaffold **120** allows for selective deprotection of four positions in a manner that is independent of the sequence (◉ *Scheme 11*). Different functional groups have been incorporated at each position to give **121–4**, which can then be cleaved from the solid support. For example, the 2-*N*-allyloxycarbonyl protecting group of **120** can be selec-



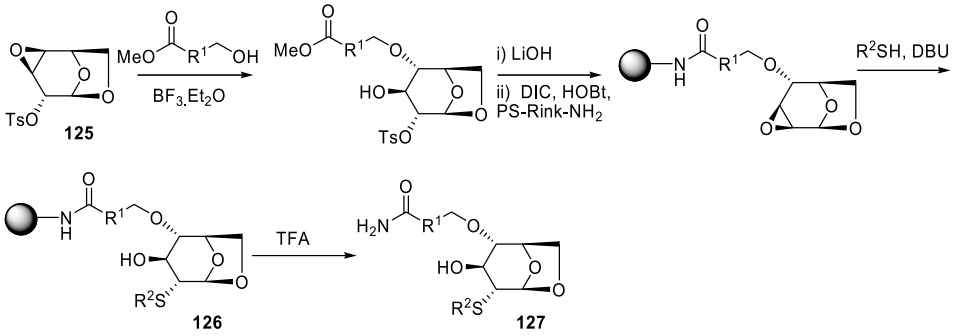
Scheme 10



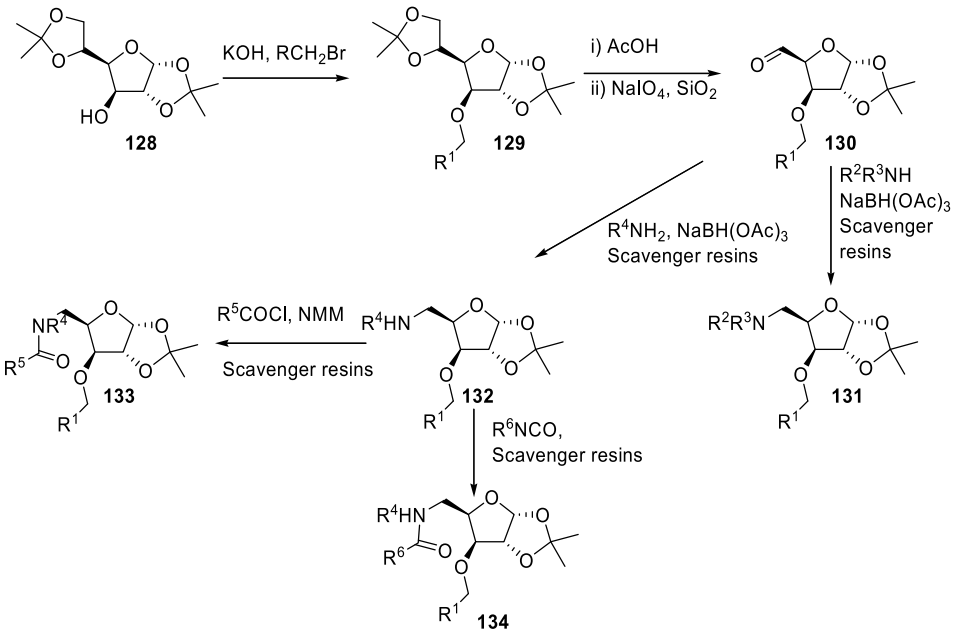
Scheme 11

tively removed by Pd (0) catalysis and then Fmoc-protected amino acids coupled to the resulting free amino group, subsequent cleavage from the Rink resin with trifluoroacetic acid in dichloromethane gives saccharide-amino acid conjugates.

Brill and co-workers used levoglucosane as a rigid scaffold to synthesise libraries both in solution [74] and solid phase [75]. The opening of epoxide **125** by different hydroxycarboxylic acid methyl esters catalysed by Lewis acid, followed by simultaneous new epoxide formation and ester hydrolysis gave the resulting free acid ready for attachment to the solid support. Epoxide opening reactions with alkoxides, amines and thiols were carried out on solid phase



Scheme 12



Scheme 13

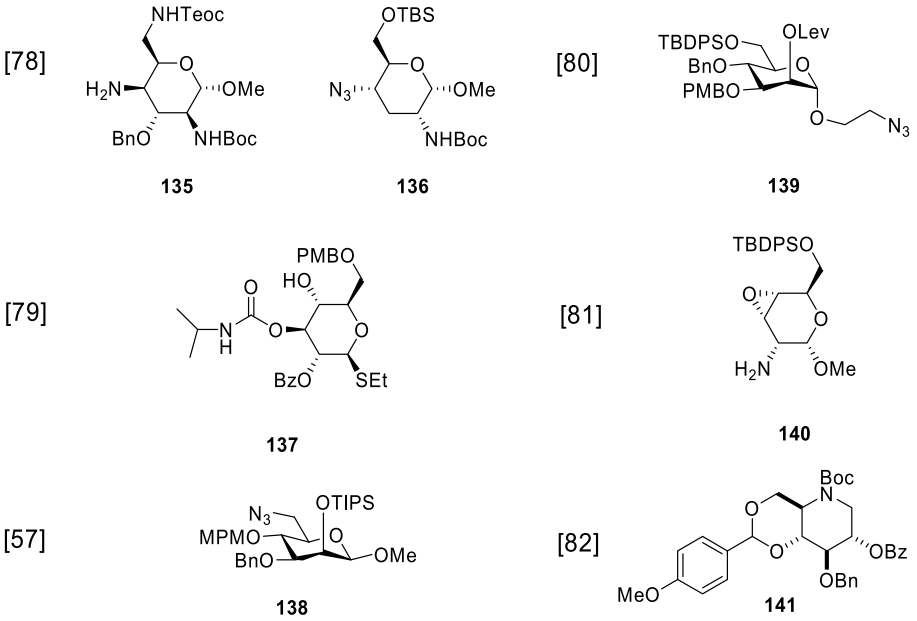


Figure 11
Examples of intermediates suitable for library synthesis

(shown for thiol giving **126**, *Scheme 12*). Cleavage from resin gave compounds such as **127**. Further derivatisation was achieved by palladium coupling reactions if these resulting compounds had aryl iodides.

Boldi and co-workers described the synthesis of a solution phase library based on furanose scaffolds [76]. Diacetone-D-glucose **128** was alkylated to give **129** and then converted in two steps to aldehyde **130**, which is the key intermediate for generation of the library. Reductive amination of **130** with secondary or primary amines gave derivatives of general formula **131** and **132**, respectively. Amines **132** could be further functionalised by reaction with various acid chlorides or isocyanates to yield compounds **133** and **134**, respectively (*Scheme 13*). In solution phase, reagents in excess were removed by using scavenger resins. Several libraries containing 5000 compounds were produced. The synthesis of the libraries on solid phase was not successful.

A selection of other orthogonally protected saccharide intermediates with potential for library synthesis is shown in *Fig. 11* [77].

3.4 Polycyclic Scaffolds and Bioactive Compounds Based on Monosaccharides

The generation of polycyclic systems from a monosaccharide (hybrid scaffolds) is a means of further increasing structural diversity [8,83,84,85,86,87,88,89,90,91,92,93,94,95,96]. Hirschmann, Smith and co-workers, for example, synthesised chimeric scaffolds such as **145** and **146** (*Fig. 12*) that are hybrids of β-D-glucopyranose and benzodiazepines and

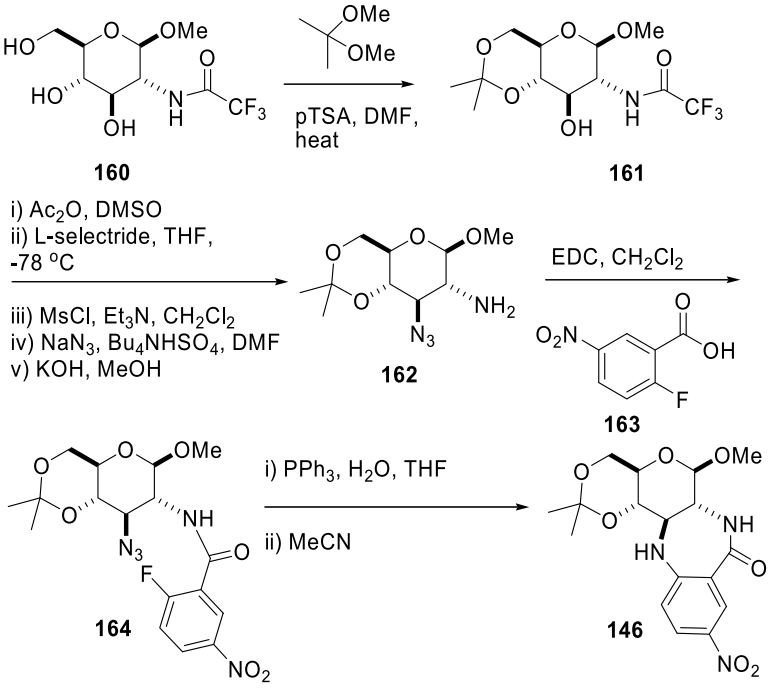
rationalised the preparation of such compounds as providing a new molecular platform for exploration of receptor space, not accessible to pyranoside or benzodiazepine scaffolds when applied individually [85]. Other examples of such compounds are provided in *Fig. 12* of novel polycyclic systems that have been synthesised, some of which are bioactive and these include tachykinin NK-1 receptor antagonist [83], SSTR receptor ligands [8], hapalosin mimetics [84], matrix metalloproteinase inhibitor [91] and Ras protein activator inhibitors [92]. Also new scaffolds have been synthesised and these include natural product-like scaffolds [86,95], spirocyclic compounds [93,94,96,100], fused polycyclic compounds for development of libraries [89,90], hybrids of sugars and *N*-heterocycles [85,87,88].

3.5 Synthesis of Polycyclic Compounds Based on Monosaccharides that are not SAAs

The synthesis of **146** illustrates the general approach to the synthesis of the hybrids from β-D-glucopyranose and benzoheterodiazepines (*Scheme 14*). D-Glucosamine derivative **160** was converted to isopropylidene derivative **161**. The 3-OH group was formally replaced with retention of stereochemistry with an azide group. This was achieved by oxidation of the secondary alcohol followed by reduction with L-selectride giving an allosamine derivative. This was converted to the mesylate, substitution with azide followed by hydrolysis of trifluoroacetamide to give the amine **162**. Coupling of this amine to acid **163** gave **164**. The azido group



160 **161** **162** **163** **164** **146**

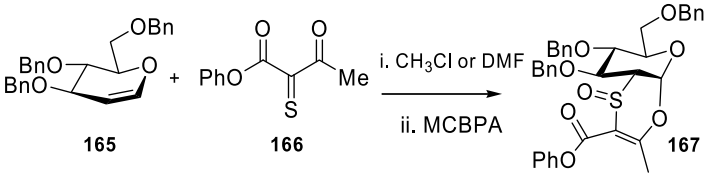
Scheme 14

was reduced using triphenylphosphine and water and cyclisation at high dilution gave the target compound **146** [85].

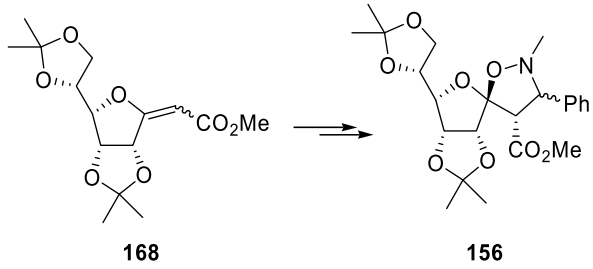
Cycloaddition reactions are also an expedient approach to the synthesis of polycyclic compounds. The synthesis of non-peptide ligands for the human tachykinin NK-2 receptor [83] was achieved by the chemo-, regio- and stereoselective [4+2] cycloaddition between glycals such as **165** and **166** followed by oxidation to provide sulfoxide **167** (● *Scheme 15*).

The cycloaddition of *exo*-glycals like **168** with nitrones and nitrile oxides provided spiroheterocylic compounds **156** (● *Scheme 16*) with good stereoselectivity and yields [93,94]. The *exo*-glycal intermediates proved also useful for the synthesis of spirocompounds based on a diazepine **155** (● *Fig. 12*).

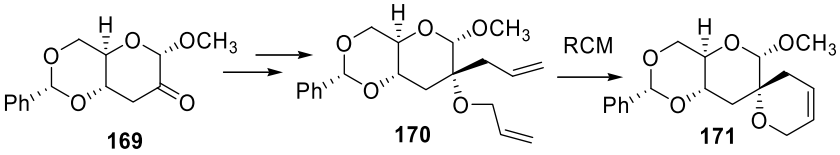
Radical cyclisations [97], Pauson–Kand cycloaddition [98] and palladium-catalysed coupling reactions [99] have been investigated to generate fused and spirocyclic carbohydrate scaffolds. Ring-closing metathesis (RCM) has recently become a major tool to produce cyclic compounds. Jenkins and co-workers have used RCM to generate five, six, seven, eight and nine-membered annelated fused sugar scaffolds and spirocyclic derivatives [100]. Reaction of ketones like **169** with various Grignard reagents of different chain length (four carbons in the



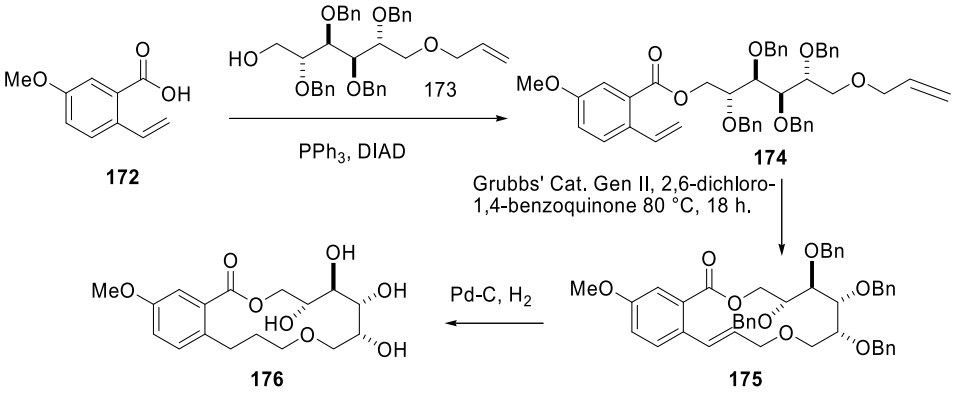
Scheme 15



Scheme 16



Scheme 17



Scheme 18

example shown in *Scheme 17*) led to olefins like **170**. Treatment with the Grubbs' catalyst gave the RCM products: in the example shown, spirofused ring derivative **171** was obtained. Using a similar methodology, the formation of a seven-membered fused ring and a seven-membered aza-sugar was also reported [88]. Leeuwenburgh, Overkleeft and co-workers have also taken advantage of the RCM methodology for the synthesis and elaboration of functionalised carbohydrate-derived spiroketals like **158** and **159** [96].

The benzomacrolactone (or resorcyclic acid lactone) structural motif can be considered a privileged or evolutionarily selected scaffold that codes properties required for binding to proteins and novel analogues thereof may provide a source of new bioactive compounds. Based on this premise the syntheses of novel polyhydroxylated oxa-macrolides, structural analogues of natural polyketide derived macrolides, have recently been described from aromatic precursors by Murphy and Matos, providing a basis for their development as scaffolds [95]. The syntheses were carried out from coupling of benzoic acids like **172** and appropriately protected D-mannitol or D-sorbitol derivatives like **173** by Mitsunobu reactions to give **174**, followed by RCM and hydrogenation to yield **175** and **176**, respectively (*Scheme 18*). Work towards application of such hybrids towards synthesis of bioactive compounds is currently underway.

4 Conclusion

There has been considerable progress in application of monosaccharide derivatives as scaffolds for bioactive molecule discovery and development and research has not been limited to discovery of compounds that target protein-carbohydrate interactions, but has led to carbohydrate derivatives that also modulate protein-protein, peptide-protein and carbohydrate-nucleic acid interactions. Progress has been facilitated by, and is continually dependant on, advances in synthetic carbohydrate chemistry both in solution and on polymer supports. Of particular interest are the development of orthogonal protecting group strategies, strategies for regioselective manipulation of saccharide hydroxyl groups and development of saccharide derivatives with a wide variety of functional groups which provides possibilities for carrying out chemose-

lective reactions on monosaccharide scaffolds. The synthesis of new cyclic compounds derived at least in part from saccharides, and their application as scaffolds is an emerging area in novel compound development. The introduction of sugar amino acids has simplified the synthesis of non-peptide peptidomimetics and libraries based on monosaccharides as well as leading to the synthesis of conformationally constrained sugar-peptide hybrids and carbohydrate foldamers and facilitates the investigation of properties of such novel derivatives. No drug molecule has been developed as of yet based on a monosaccharide scaffold. However, this goal is closer as potent ligands for receptors have been identified, it has been shown that some saccharide derivatives have improved cellular permeability over peptides and some compounds are in clinical trials.

Abstract

This chapter summarizes some recent achievements in asymmetric synthesis, which have been accomplished using sugar derivatives as chiral environments. The use of sugar derivatives as chiral auxiliaries or as chiral ligands of transition-metal catalysts for realizing the asymmetric version of synthetically important organic reactions, such as carbon–carbon bond-forming reactions, the hydrogenation of the carbon–carbon double bond and hydrocyanation, is the focus of this chapter. Prominent studies on these subjects by several research groups are especially emphasized.

Keywords

Asymmetric synthesis; Chiral auxiliary; Sugar template; Chiral ligand; Transition-metal catalyst

Abbreviations

acac	acetylacetone
BINOL	1,1′-bi-2-naphthol
Bn	benzyl
Boc	*t*-butoxycarbonyl
BSA	*N*,*O*-bis(trimethylsilyl)acetamide
***i*Bu**	*iso*-butyl
***t*Bu**	*tert*-butyl
COD	1,5-cyclooctadiene
de	diastereomeric excess
DIBAL-H	diisobutylaluminum hydride
ee	enantiomeric excess
Et	ethyl
GABA	γ-aminobutyric acid
***c*Hex**	cyclohexyl
HMPA	hexamethylphosphoramide
LDA	lithium diisopropylamide
LiHMDS	lithium hexamethyldisilazide
Me	methyl
MesCO	2,4,6-trimethylbenzoyl
NaHMDS	sodium hexamethyldisilazide
Napht	naphthyl
NBS	*N*-bromosuccinimide
NMO	*N*-methylmorpholine-*N*-oxide
NMR	nuclear magnetic resonance
Ph	phenyl
Piv	*tert*-butylcarbonyl
***c*Pr**	cyclopropyl
***i*Pr**	*iso*-propyl
***n*Pr**	*n*-propyl
RMP	(*R*)-2-methoxymethylpyrrolidine
SMP	(*S*)-2-methoxymethylpyrrolidine
TBS	*tert*-butyldimethylsilyl
TFA	trifluoroacetic acid
THF	tetrahydrofuran
TIPS	triisopropylsilyl
TMS	trimethylsilyl

1 Introduction

The development of asymmetric synthesis is the most challenging subject in current organic synthesis, as various approaches have been demonstrated by the synthetic community in the world. The most frequently employed strategies for asymmetric synthesis are categorized into two approaches, i. e., the use of catalytic chiral ligands such as BINOLs, which coordinate a variety of transition-metal complexes (intermolecular asymmetric induction) [1,2,3] or the use of chiral auxiliaries derived from readily available natural products, such as L-amino acids (intramolecular asymmetric induction) [4,5,6,7,8,9,10,11]. Concerning the former approach, the use of chiral Lewis acids, prepared by a combination of a chiral ligand and a transition metal, has been most extensively explored for carbon–carbon or carbon–heteroatom bond formation in an asymmetric fashion. On the other hand, the use of chiral auxiliaries is not as generalized as the catalytic use of chiral ligands. The inevitable use of an equivalent amount of the chiral auxiliary seems to cause this rather unpopular view of the chiral auxiliary approach. Despite this fact, the use of a chiral spatial environment constituted by a chiral auxiliary is one of the most effective means for achieving a practical asymmetric synthesis. The use of the chiral auxiliary conceptually produces a diastereomeric mixture. In general, the separation of diastereomers is not very troublesome when the current sophisticated separation methods are used. In many cases, the observed diastereomeric ratio in an organic reaction is conventionally measured by spectroscopic means, such as NMR spectroscopy. These are advantages of the chiral auxiliary approach over other asymmetric approaches. This article focuses on the development of the use of sugars for asymmetric synthesis in the past 15 years. Compared to L-amino acids, natural alkaloids, or terpenoids, sugars have been less developed as a chiral environment [12,13,14,15]. On the other hand, sugars have been recognized as excellent molecular-recognizing substances, as exemplified by the fact that glycoproteins and oligosaccharides participate in the modulation of biological function [16].

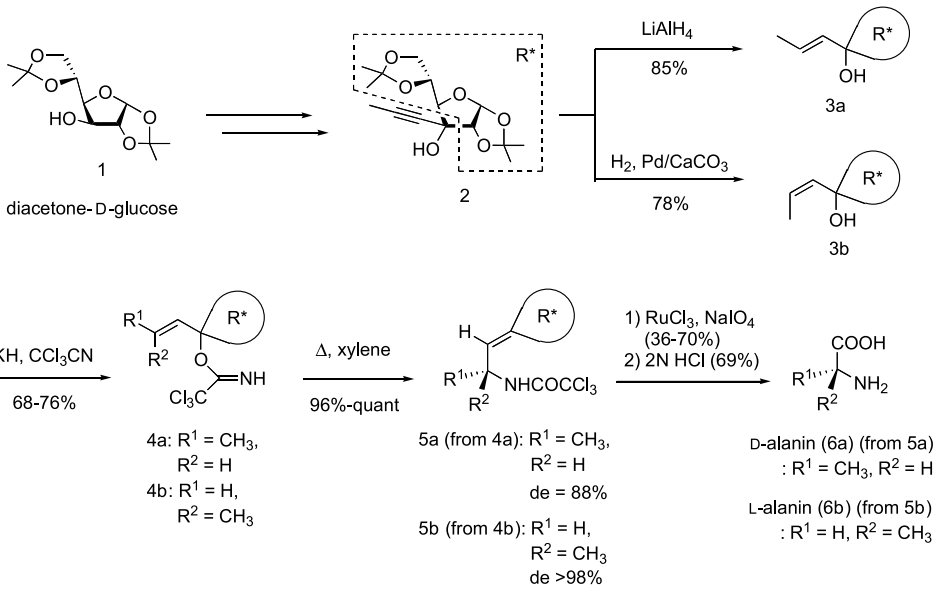
In this chapter, we summarize the above two asymmetric approaches achieved using sugar derivatives in these two decades in the order of “sugars as chiral auxiliaries” and then “sugars as chiral ligands for transition-metal-mediated organic synthesis”. In particular, the present work reviews and summarizes the work of prominent research groups whose main interest is asymmetric synthesis using sugar-based compounds. For the sake of brevity, less complete studies have not been included in this review.

2 Sugars as Chiral Auxiliaries

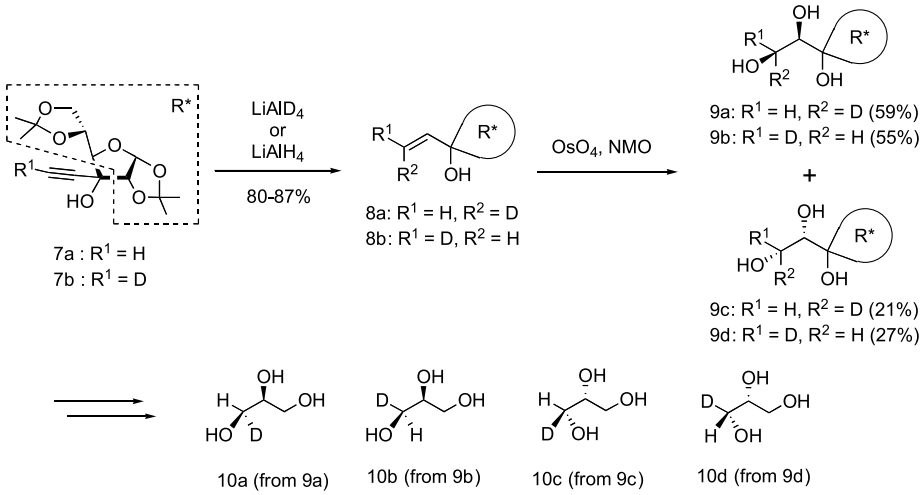
In the mid-1970s, Vasella reported the 1,3-dipolar cycloaddition reactions of nitrones incorporated into sugar templates [17,18]. The Vasella’s studies were regarded as seminal for the development of the stereoselective organic reactions achieved on sugar templates. Sugar-template-based stereoselective reactions have been actively investigated by a number of groups, especially in the past ten years [19,20,21,22,23,24,25,26,27,28,29,30,31,32]. The sugar-based templates utilized for asymmetric synthesis are mainly classified into five-membered glycofuranosidic frameworks or six-membered glycopyranosidic frameworks. Among glycofuranosidic templates, the utility of so-called diacetone-D-glucose i. e., 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, has been extensively investigated.

2.1 Studies by the Kakinuma Group

Kakinuma and co-workers have reported several results obtained using diacetone-D-glucose [33]. In the early 1990s, the Kakinuma group started to investigate the utility of diacetone-D-glucose as a useful chiral template. As an initial attempt, they used diacetone-D-glucose for the stereoselective synthesis of D- or L-alanine [34,35] (*Scheme 1*). Compound **2** was readily prepared from commercially available diacetone-D-glucose **1** by (1) oxidation to 3-ulose, (2) stereoselective addition of an ethynyl Grignard reagent, (3) temporary *O*-silylation, and (4) Li acetylide formation with BuLi and methylation with CH_3I. $LiAlH_4$ reduction of the triple bond in **2** introduced the *trans*-propenyl functionality to provide **3a** stereoselectively. On the other hand, hydrogenation of **2** in the presence of Lindlar catalyst provided the *cis*-propenyl derivative **3b**. Both **3a** and **3b** were converted to trichloroacetimidates **4a** and **4b**, respectively. The thermal Overman rearrangement (an aza version of the [3,3]-sigmatropic rearrangement) of **4a** proceeded highly stereoselectively to provide **5a** as a single rearranged product. Similarly, the Overman rearrangement of **4b** provided **5b** stereoselectively. Both stereochemistries of the double bond in substrates **4a** and **4b** completely reflected the newly created chiral center in **5a** and **5b**, respectively. Finally, the double bond in **5a** was cleaved by $RuCl_3/NaIO_4$ oxidation, followed by deprotection, providing D-alanine **6a**. Similarly, another rearranged product, **5b**, was transformed into L-alanine **6b**. Based on the kinetic and theoretical studies, the Kakinuma group proposed transition-state models to explain these highly selective chirality transfers observed in the Overman rearrangements of both **4a** and **4b**. Consequently, an enantiopure enantiomer of amino acid alanine as a tool for biological studies was prepared.



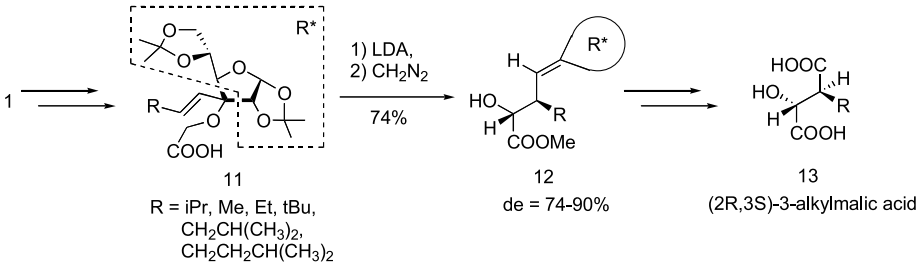
Scheme 1



Scheme 2

Using the diacetone-D-glucose derivatives **7a** or **7b** incorporating terminal hydrogen or deuterium labeled ethenyl functionality at C-3, respectively, four diastereomers of monodeuterated glycerols were synthesized [36] (*Scheme 2*). *trans*-Selective $LiAlD_4$ reduction of **7a** provided **8a**. $LiAlH_4$ reduction of the deuterium-labeled **7b** provides **8b**. *cis*-Diol unit introduction into **8a** and **8b** was carried out by OsO_4-mediated oxidation in the presence of *N*-methylmorpholine *N*-oxide. Two diols, **9a** and **9c**, were obtained from **8a** as a result of approximately 3:1 π-facial selectivity with OsO_4. Substrate **8b** provided **9b** and **9d** with analogous diastereoselectivity. From **9a–9d**, the four partially deuterated glycerols **10a–10d** were synthesized after detachment of the diacetone-D-glucofuranose unit via a 5-step reaction sequence.

The Kakinuma group explored the stereoselective dianion [2,3]-Wittig rearrangement of alkylated allyloxyacetic acids incorporated into C-3 of diacetone-D-glucose **1** for the synthesis of (2*R*,3*S*)-3-alkylmalic acids in conjunction with biochemical studies on the thermostable isopropylmalate dehydrogenase [37] (*Scheme 3*). The substrates for the [2,3]-Wittig rearrangement, compounds **11**, possessed a mono-substituted alkene moiety (R = *i*Pr, Me and others) and a (carboxy)methoxy group at C-3 of diacetone-D-glucose **1**. These substrates were synthesized from the corresponding 3-ulose by (1) addition of the respective alkyne (R = *i*Pr, Me, and others), (2) *trans*-selective triple-bond reduction with $LiAlH_4$, and (3) alkylation of the liberated 3-OH with bromoacetic acid. Treatment of **11** with LDA, followed by esterification of the resulting [2,3]-Wittig rearrangement product with CH_2N_2, provided **12** with a useful level of diastereoselectivity. Diastereomeric excess (de) of the *threo*-product (major) to the *erythro*-product (minor) varied in the range of 74 to 90%. Despite the size of the R group, each rearrangement proceeded smoothly to provide **12** efficiently. It should be emphasized that the alkyl group (= R) and the formed hydroxyl group in **12** are in an antiperiplanar relationship (*threo*-configuration) in every case. The desired stereochemically defined (2*R*,3*S*)-3-alkylmalic acids **13** (R = *i*Pr, Me, and others) were prepared from **12** by cleav-

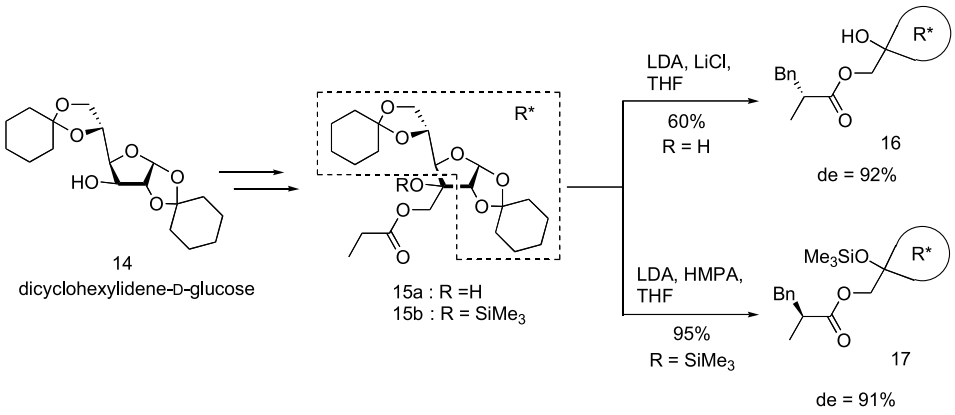


Scheme 3

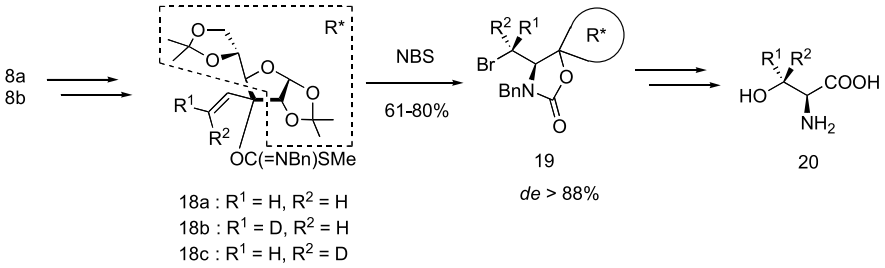
age of the carbon–carbon double bond after temporary protection of the hydroxyl group by ozonolysis, followed by further oxidative work-up with hydrogen peroxide and final deprotection.

The Kakinuma group explored the stereoselective α-alkylation of propionyl ester incorporated at C-3 of dicyclohexylidene-D-glucose **14** for investigating a remote asymmetric induction realized in the sugar template [38] (*Scheme 4*). The synthesis of propionate **15** for α-alkylation started from dicyclohexylidene-D-glucose **14** via the following reaction sequence: (1) preparation of 3-ulose by oxidation, (2) Wittig olefination with $Ph_3P{=}CH_2$, (3) OsO_4-NMO oxidation, and (4) selective acylation of the resulting diol. The substrate **15a** (R = H) was deprotonated using LDA as a base (with or without LiCl or HMPA). The resulting enolate was trapped with benzyl bromide to produce the α-benzylated propionate **16**. In the presence of LiCl, the benzylated product was obtained in 60% yield with a notably high diastereomeric excess of the (*R*)-isomer (de = 92%). Interestingly, the analogous benzylation using another substrate **15b** (R = TMS) produced α-benzylated propionate **17**, which possesses a newly introduced chiral carbon with an (*S*)-configuration in a high yield of 95%. The diastereomeric excess in this case was 91%. The occurrence of chelate formation in the transition-state governed the stereochemical course of the benzylation. Thus, the Z-enolate derived from **15a** (R = H) constituted a chelate form between the Li metal-cation and enolate-oxygen in the presence of LiCl. The formation of chelate was not possible in the case of **15b** (R = TMS). This difference in the chelate formation reflected the opposite chiralities of the newly created chiral carbon in **16** and **17**.

The potency of the diacetone-D-glucose framework as a chiral auxiliary was further demonstrated by the Kakinuma group through the stereoselective synthesis of β-deuterated L-amino acids such as (3*R*)- and (3*S*)-[3-$^2H_1$(D)]-L-serine [39] (*Scheme 5*). 3-*C*-[2-H or 2-$^2H_1$]-ethenyl-3-*O*-(*N*-benzyl)methylthioformimidoyl-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranoses **18a–18c** were synthesized from the aforementioned 3-vinyl or β-deuterated vinyl derivatives of diacetone-D-glucose (**8a** or **8b** in *Scheme 2*), by treatment of benzyl isothiocyanate and iodomethane in the presence of NaH. The halonium ion-mediated intramolecular cyclization of **18a–18c** with NBS resulted in an oxazolinone (five-membered cyclic carbamates) formation highly stereoselectively to produce **19** as a major cyclization product. Furthermore, a deuterium was placed in product **19** stereoselectively (*R* or *S*). The nitrogen in the imine structure attacked exclusively the thus formed bromonium intermediate in a *five-exo-trig* cyclization mode to produce **19**. The bromomethylene group was a synthetically versatile



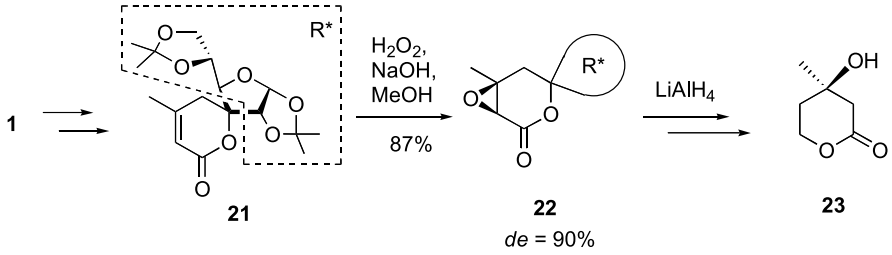
Scheme 4



Scheme 5

functionality. One example was the replacement of the bromo group by an acetoxy group. From **19**, stereochemically defined β-monodeuterated β-hydroxy-L-amino acids **20** were synthesized from the thus obtained acetate by oxazoline cleavage by alkaline hydrolysis followed by detachment of the sugar template.

Mevalonate is ubiquitous as the first biosynthetic precursor to various vertebrate and invertebrate hormones. To supply isotope-labeled mevalonate as a promising tool for biosynthetic studies, the Kakinuma group explored the highly enantioselective synthesis of (*R*)-mevalonolactone and partially deuterated (*R*)-mevalonolactone by means of the chirality-transcription strategy achieved using diacetone-D-glucose as a chiral template [40] (*Scheme 6*). The starting material of the mevalonate synthesis was compound **21**, which was in turn synthesized highly stereoselectively by the addition of the enolate derived from methyl 3-methylcrotonate (methyl senecioate) or its deuterated form to the 3-ulose of diacetone-D-glucose **1** in the presence of LDA, albeit in a modest yield of ~30%. The thus obtained unsaturated δ-lactone **21** was subjected to alkaline epoxidation with hydrogen peroxide to produce **22** as a result of the stereoselective attack (de = 90%) of the peroxide to the *Si*-face of the double bond. The epoxy-ring opening of the spirocyclic δ-lactone **22** with $LiAlH_4$ proceeded regioselectively. Acid hydrolysis of the acetals in the sugar template in the resulting 1,3-diol, followed by



Scheme 6

$NaIO_4$ oxidation eventually provided mevalonolactone **23** or deuterated mevelonolactone (not shown) efficiently.

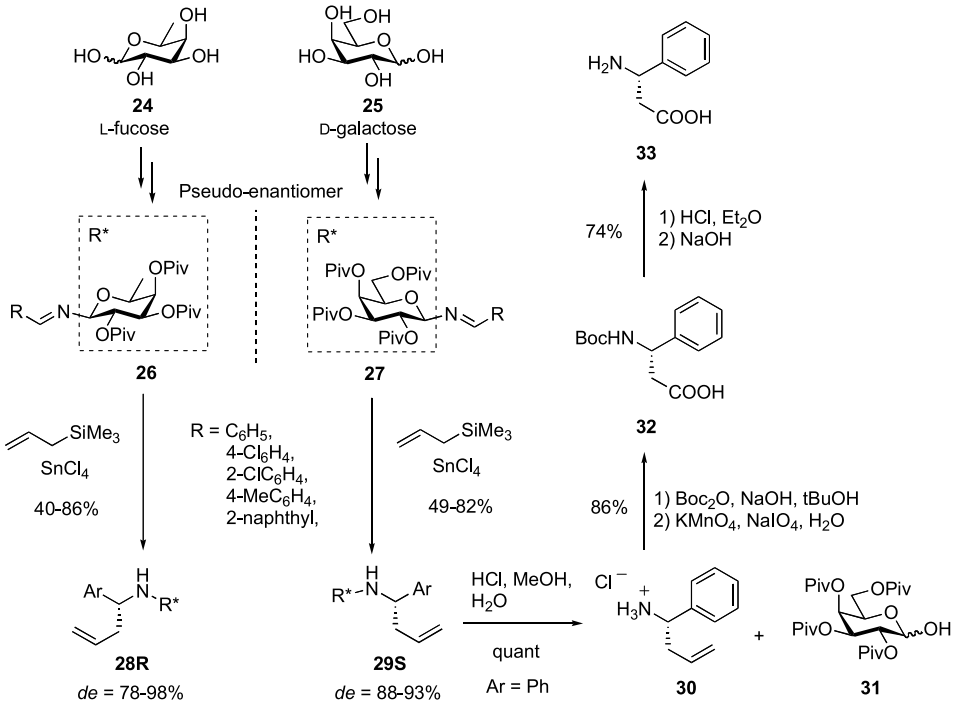
In another paper from the Kakinuma group, further result on the chirality's transfer realized using the diacetone-D-glucose template was described [41].

2.2 Studies by the Kunz Group

Since the mid-1980s, Kunz and co-workers started an exploration of asymmetric synthesis using sugar template-based chiral auxiliaries. Their early success on this topic is particularly shown by their demonstration of the utility of six-membered pento- and hexopyranose derivatives such as per-*O*-pivaloylated β-D-galactosylamine [42,43,44,45,46,47,48,49,50]. The collective studies of the Kunz group have been thoroughly reviewed [51,52].

The Kunz group has extensively explored the functionalized pyranose-based asymmetric carbon–carbon bond-forming reactions up to date. In the early 1990s, the following important results were disclosed from the Kunz group.

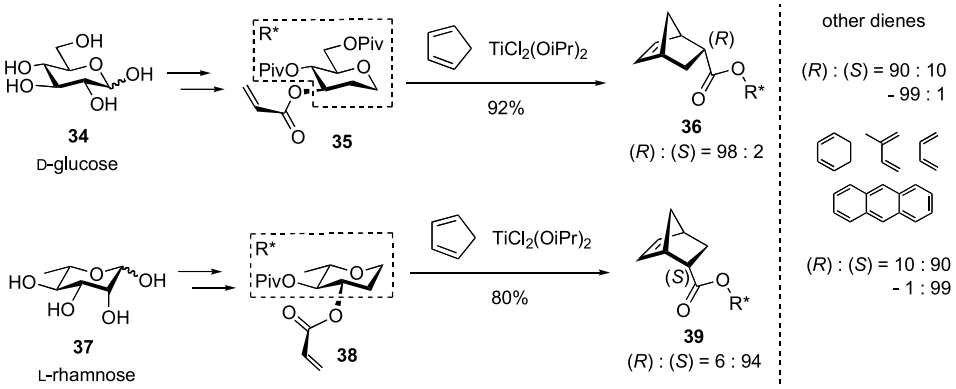
2,3,4-Tri-*O*-pivaloyl-α-L-fucopyranosylamine was prepared from L-fucose **24** and 2,3,4,6-tetra-*O*-pivaloyl-β-D-galactopyranosylamine was from D-galactose **25**. These glycosylamines were condensed with a variety of aromatic aldehydes to produce the corresponding glycosylimines **26** and **27**, respectively (*Scheme 7*). These glycosylimines were used for the diastereoselective synthesis of *N*-glycosyl-*N*-homoallylamines [53,54,55]. Therefore, per-*O*-acylated L-fucosylated arylimines **26** and D-galactosylated arylimines **27** were subjected to $SnCl_4$-mediated allylation using allyltrimethylsilane. These Lewis acid-promoted carbon–carbon bond formations proceeded with remarkable diastereoselectivity to provide the *N*-glycosyl-*N*-homoallylamines **28R** from **26** and **29S** from **27** in moderate-to-good chemical yields. Both the C-2 pivaloyloxy groups in **26** and **27** served as an effective shielding element in the course of the allylsilane approach toward imine carbon. Interestingly, the glycosylimines **26** and **27** are in a pseudo-enantiomeric relationship. Acid hydrolysis of the homoallylamine **29S** (Ar = Ph) detached the sugar template to provide α-allylated 3-butenylamine **30** (as its HCl salt), and the sugar template 2,3,4,6-tetra-*O*-pivaloyl-D-galactopyranose **31** was obtained. Protection of the amine functionality in **30**, followed by oxidative cleavage of the double bond using a combination of $KMnO_4$ and $NaIO_4$, produced (*S*)-*N*-Boc-β-phenyl-β-alanine **32**, from which (*S*)-(–)-β-phenyl-β-alanine **33** was obtained.



Scheme 7

The Kunz group explored the use of a sugar-based chiral auxiliary for stereoselective Diels–Alder reaction. For example, 3-*O*-acryloyl-1,5-anhydro-2-deoxy-4,6-di-*O*-pivaloyl-D-*arabino*-hexitol **35**, prepared from D-glucose **34**, was treated with cyclopentadiene in the presence of $TiCl_2(OiPr)_2$(3 mol equivalents to **35**) in CH_2Cl_2 at −30 °C [56] (*Scheme 8*). This Lewis acid-promoted [4+2] cycloaddition reaction proceeded with high diastereoselectivity to provide **36** possessing an (*R*)-configuration for the newly created stereogenic center. This Diels–Alder reaction using **35** as a dienophile was further explored with other dienes, such as cyclohexadiene, 2-methyl-1-3-butadiene, 1,3-butadiene and so on. In most cases, the cycloadditions took place smoothly in the presence of Lewis acid [$TiCl_4$, $TiCl_3(OPr)$], providing the adduct with remarkable diastereoselectivity. A similar Diels–Alder reaction was exemplified using 3-*O*-acryloyl-1,5-anhydro-2,6-deoxy-4-*O*-pivaloyl-L-*rhamno*-hexitol **38** as a dienophile and cyclopentadiene as a diene. The dienophile **38** was prepared from L-rhamnose **37**. The Lewis acid $TiCl_2(OiPr)_2$ was also effective in this case. More importantly, the adduct **39** possessed an (*S*)-configuration for the newly created stereogenic center. Therefore, the Diels–Alder adduct, i. e., 2-(carboxyl)bicyclo[2.2.1]hep-5-ene possessing either (*R*)- or (*S*)-chirality, can be obtained.

The aforementioned D-galactose-derived chiral imines **27** were used for the Strecker synthesis of D-α-amino nitriles and D-α-amino acids by the Kunz group. Various types of glycosylimines **27**, prepared from 2,3,4,6-tetra-*O*-pivaloyl-β-D-galacosylamine with aliphatic or aromatic aldehydes, were treated with TMSCN in the presence of $SnCl_4$, providing α-amino nitriles

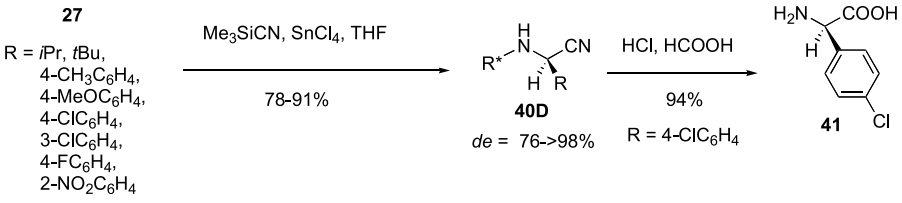


Scheme 8

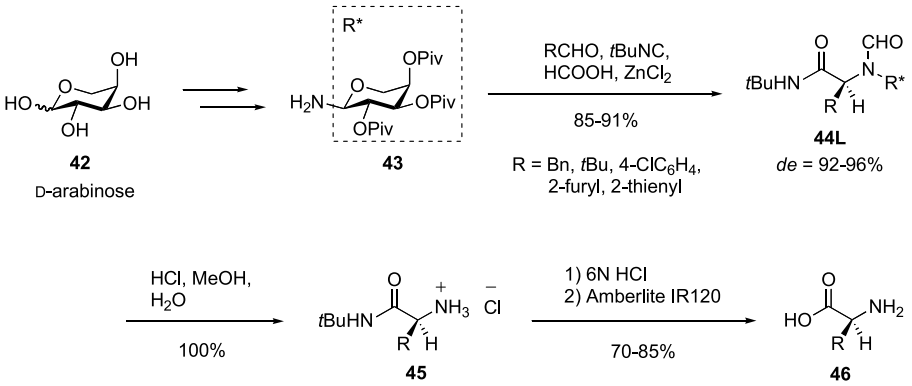
40D in good-to-excellent yields [57] (*Scheme 9*). Furthermore, these Strecker reactions provided α-amino nitriles **40D** with high diastereoselectivity in favor of the D-diastereomers. For a rational explanation of the observed high diastereoselectivity, a coordination of the imine nitrogen and the carbonyl oxygen of the 2-pivaloyl group by the metal of Lewis acid was proposed. This coordination fixed the conformation of the sugar template, to which the nitrile anion attacked from the rear side to avoid the steric hindrance caused by the bulky 2-pivaloyloxy group. Acid hydrolysis of the Strecker product, such as **40D** (R = 4-chlorophenyl), provided (*R*)-4-chloro-phenylglycine **41** in highly enantioenriched form.

The Kunz group also explored the synthesis of L-α-amino acids based on the sugar auxiliary protocol. For this purpose, the Ugi reaction was efficiently utilized [58]. As a sugar template, the Kunz group devised another glycosylamine, i. e., 2,3,4-tri-*O*-pivaloyl-α-D-arabinopyranosylamine **43**, a quasi-mirror image of the per-*O*-pivaloylated D-galactosylamine (*Scheme 10*). Glycosylamine **43**, prepared from D-arabinose **42**, was treated with a variety of aliphatic, aromatic, or heterocyclic aldehydes to produce the corresponding glycosylimines, which were further reacted with *tert*-butyl isocyanide and formic acid in the presence of $ZnCl_2$ at low temperatures. This four-component Ugi reaction provided *N*-formyl α-substituted α-L-amino acids as their amide forms **44L** in good-to-excellent yields.

The stereoselectivity of these four-component coupling reactions were remarkable in most cases. Similar Ugi reactions were studied using per-*O*-pivaloylated L-fucopyranosylamine as



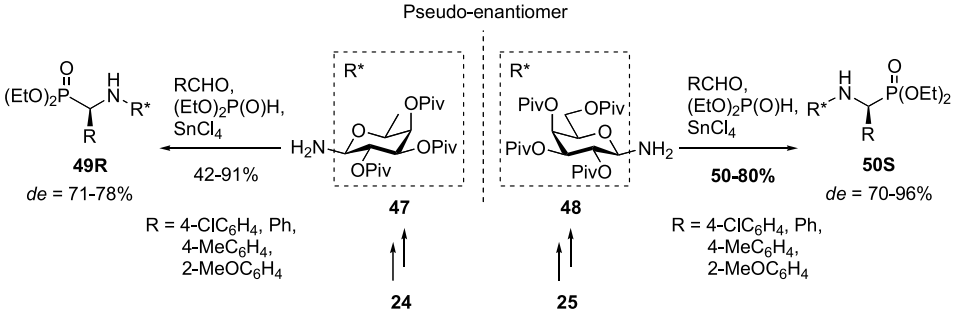
Scheme 9



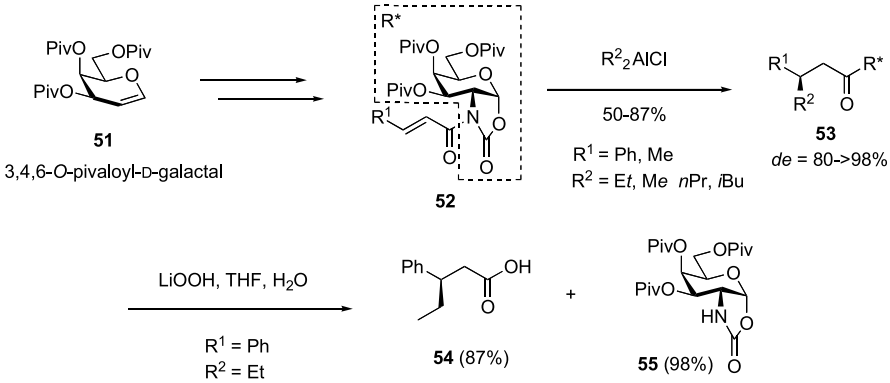
Scheme 10

a sugar template. In one case, *N*-fucosyl-(4-chlorophenyl)glycine amide was obtained in favor of the L-diastereomer with excellent stereoselectivity (not shown). The detachment of the sugar template from **44L** by acid hydrolysis provided L-α-amino acids as their *tert*-butylamides **45**, and further harsh hydrolysis of **45** provided L-α-amino acids **46**. Later, this sugar auxiliary-based Ugi-multicomponent synthesis was applied to a combinatorial approach realized on the solid phase by the Kunz group [59].

Using two glycosylamines **47** and **48**, prepared from L-fucose **24** and D-galactose **25**, respectively, the Kunz group synthesized α-aminophosphonic acid esters [60] (*Scheme 11*). The L-fucosylamine **47** reacted with a variety of aromatic aldehydes and $(EtO)_2P(O)H$ in the presence of $SnCl_4$ under one-pot reaction conditions. The *N*-glycosylated (*R*)-α-aminophosphonic acids **49R** incorporating the L-fucosyl residue were obtained as major products. The diastereoselectivity of diethylphosphite addition was in the range of 71–78%. In these cases, the Lewis acid served as an efficient stereocontrolling element through chelate formation between the imino nitrogen and the carbonyl group of 2-pivaloyl ester. On the other hand, the pseudo-enantiomeric D-galactosylamine **48** produced (*S*)-α-amino phosphonic acid derivatives **50S** preferentially under the same reaction conditions.



Scheme 11

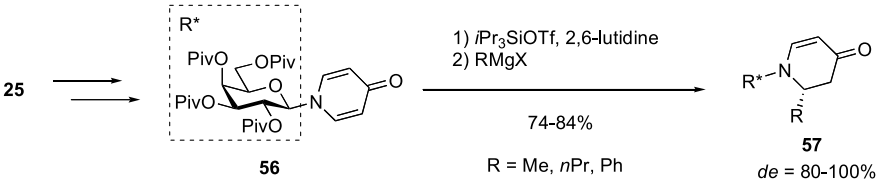


Scheme 12

The Kunz group has widely explored the utility of bicyclic oxazolidinones derived from 2-amino-2-deoxy sugars as chiral auxiliaries [61,62]. One example was a stereoselective radical 1,4-addition of organoaluminum chlorides to unsaturated carboxylic acid derivatives attached to the D-galactosamine-derived oxazolidinone (*Scheme 12*). 3,4,6-Tri-*O*-pivaloyl-1,2-dideoxy-α-D-galactopyraosido[1,2,5′,4′]oxazolidin-2′-one **55**, the sugar template for the 1,4-addition, was readily prepared from per-*O*-pivaloyled D-galactal **51** via azidonitration and hydrolysis, followed by treatment of the resulting 2-azido derivative with Ph_3P/CO_2. The resulting oxazolidinone derivative **55** was treated with MeMgBr for the deprotonation of NH of the oxazolidinone ring, followed by a reaction with an α,β-unsaturated acyl chloride such as cinnamoyl chloride to produce the *N*-functionalized oxazolidinone **52** (R^1 = Ph). Treatment of **52** with excess dialkylaluminum chloride (R^2 = Me, Et, Pr, *i*-Bu) in toluene or hexane at low temperature (−40 °C) produced the 1,4-adducts, i. e., β-alkylated carboxylic acid derivatives **53**, in good-to-excellent diastereoselectivities. In the case of Me_2AlCl, irradiation of the reaction mixture was required. In most cases, the diastereoselectivities in the 1,4-additions were remarkably high with a de of 80–98%. The removal of the sugar template from the adduct **53** (R^1 = Ph, R^2 = Et) was carried out by hydrolysis in the presence of LiOOH. As a result, (*R*)-3-phenylvaleric acid **54** was obtained in a highly enantioenriched form. In addition, the sugar template **55** was recovered almost quantitatively.

The Kunz group further demonstrated the asymmetric synthesis of β-alkylated α-halogenated (Cl or Br) carboxylic acid derivatives. For this purpose, the *N*-functionalized D-galactosamine-derived oxazolidinone **52** was treated with dialkylaluminum chloride, which was followed by addition of NXS (X = Cl, Br) to trap the intermediary enolate. Consequently, a variety of β-branched α-halo carboxylic acid derivatives were obtained with good diastereoselectivities [63].

Desymmetrization of prochiral compounds is one of the most convenient strategies for supplying enantioenriched chiral compounds. The Kunz group reported desymmetrization on the 4-pyridone tethering a sugar template at the nitrogen atom [64] (*Scheme 13*). The reaction of per-*O*-pivaloylated α-D-galactopyranosyl fluoride, prepared from D-galactose, with 4-trimethylsilyloxy-pyridine in the presence of Lewis acid ($TiCl_4$) provided *N*-(per-*O*-pivaloyl-

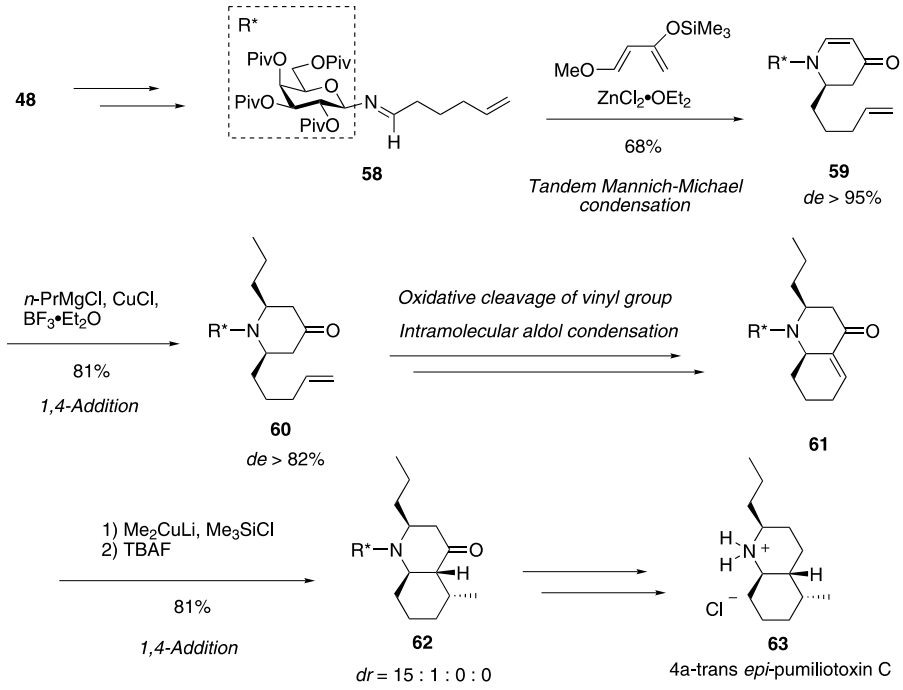


Scheme 13

β-D-galactopyranosyl)pyrid-4-one **56**. The thus obtained *N*-galactosyl pyridone **56** reacted with some Grignard reagents (R = Me, *n*-Pr, and Ph) in the presence of triisopropylsilyl trifluoromethanesulfonate and 2,6-lutidine for activation of the carbonyl. As a result, the 1,4-addition provided 2-alkyl-substituted dehydro-piperid-4-ones **57** in high yield and with good-to-excellent diastereoselectivities (de = > 80%). The sugar template directs the diastereoselectivity of the 1,4-additions at the planar 4-silyloxypyridinium intermediate; this constitutes a selective monofunctionalization and stereoselective attack at one of the two *Si*-faces of the pyridinium intermediate.

The utility of 2,3,4,6-tetra-*O*-pivaloyl-β-D-galactopyranosylamine **48** as a chiral auxiliary was further demonstrated by the Kunz group through a tandem Mannich–Michael reaction realized on the aldimine, such as **58** derived from **48** [65] (*Scheme 14*). The galactosylimine **58** was prepared by the reaction of the per-*O*-pivaloylated galactosylamine **48** and 5-hexenal. Treatment of **58** with (1-methoxy-3-trimethylsiloxy)butadiene (Danishefsky–Kitahara's diene) in the presence of $ZnCl_2OEt_2$ provided an *N*-galactosyl 2-alkylated 5,6-dehydro-piperidin-4-one **59** in excellent diastereoselectivity. This conversion of **58** to **59** included the initial Mannich reaction between the imine **58** and the siloxy diene, which was followed by the Michael addition of the intermediary amine to the resulting conjugate enone and subsequent removal of one mol of MeOH. For the construction of the 2,6-disubstituted piperid-4-one skeleton, the 1,4-addition to the enone moiety in **59** was explored. Neither Grignard reagents nor organocuprates reacted with **59**. However, a combination of the organocuprate, prepared from *n*-PrMgCl and CuCl, and boron trifluoride worked well for this purpose. Thus *cis*-2,6-dialkylated piperidinone **60**, which incorporates the sugar template at nitrogen, was obtained with excellent diastereoselectivity (> 10:1).

The Kunz group demonstrated the synthetic utility of this piperidinone **60** for the decahydroquinoline alkaloid synthesis. One example was the total synthesis of *trans*-annulated 4a-*epi*-pumiliotoxin C. Among more than 200 alkaloids isolated from a glandular secretion of a South American frog of the family *Dendrobates*, pumiliotoxin C is a representative of the biologically important *cis*-annulated decahydroquinolines. In an attempt to construct the pumiliotoxin skeleton, the piperidinone **60** was transformed as follows. Oxidative cleavage of the vinyl group in the C2-alkene moiety and base-mediated intramolecular aldol condensation of the resulting aldehyde efficiently produced an octahydroquinoline derivative **61**. The reaction of the bicyclic enone **61** with Me_2CuLi in the presence of chlorotrimethylsilane efficiently provided the 1,4-methyl adduct **62** after cleavage of the intermediary silyl enol ether. The ratio of the formed diastereo-mers was > 15:1 in favor of a *trans*-annulated decahydroquinoline **62**. This fact was in contrast to the previous result that the 1,4-addition of a cuprate to an

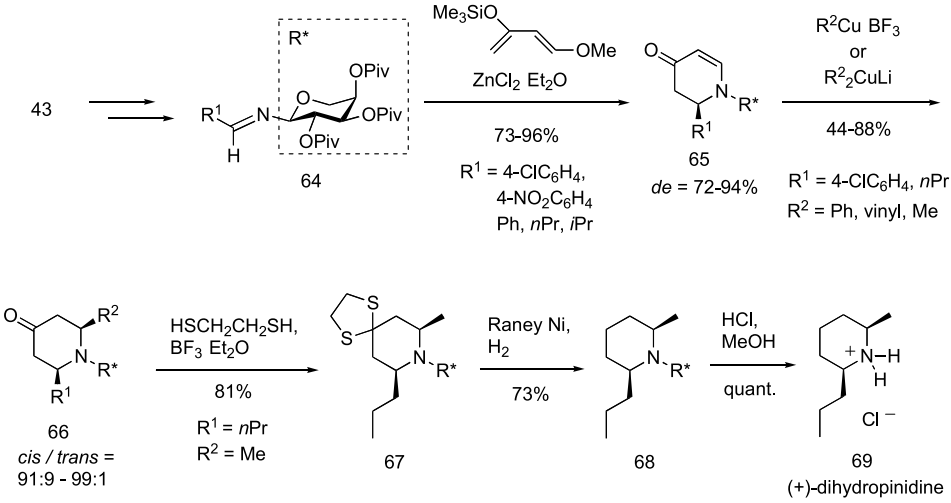


Scheme 14

N-phenoxycarbonyl bicyclic enone, which was structurally similar to **61**, exclusively provided a *cis*-annulated octahydroquinoline derivative. From the *trans*-annulated decahydroquinoline **62**, *trans*-4a-*epi*-pumiliotoxin C **63** was synthesized in a 5-step reaction sequence, including hydrogenolytic desulfurization of the dithiolane prepared by treatment of the carbonyl group in **62** with 1,2-ethanedithiol.

The Kunz group reported some glycosylamine-based chiral auxiliary approaches to the enantioselective synthesis of 2,6-*cis*-disubstituted piperidine alkaloids such as dihydropinidine [66], as well as that of the indolizidine alkaloids such as gephyrotoxin 167B [66] and *trans*-decahydroquinoline alkaloids such as *trans*-*epi*-pumiliotoxin C [67]. These approaches relied on the diastereofacial differentiation of the carbon nucleophile addition to the glycosyl aldimines through the steric, stereoelectronic, and complexing effects of sugars.

The per-*O*-pivaloylated D-arabinopyranosylamine **43** was used for asymmetric synthesis of the 2,6-*cis*-substituted piperidine alkaloid, (+)-dihydropinidine **69** by the Kunz group [68] (*Scheme 15*). The *N*-arabinosylimines **64**, prepared by the reaction of **43** with aromatic or aliphatic aldehydes, were reacted with Danishefsky–Kitahara's diene analogously to the reactions employed for **58**, as depicted in *Scheme 14*. Consequently, this zinc chloride-promoted tandem Mannich–Michael reaction provided a 5,6-didehydropiperidin-4-ones **65** in high yields and with high diastereoselectivity. It should be emphasized that *N*- arabinosyl dehydropiperidinones **65** possess the opposite configuration at C2 in the piperidinone ring, in contrast to the case of *N*-galactosyl dehydropiperidinones **59**. Furthermore, 1,4-addi-

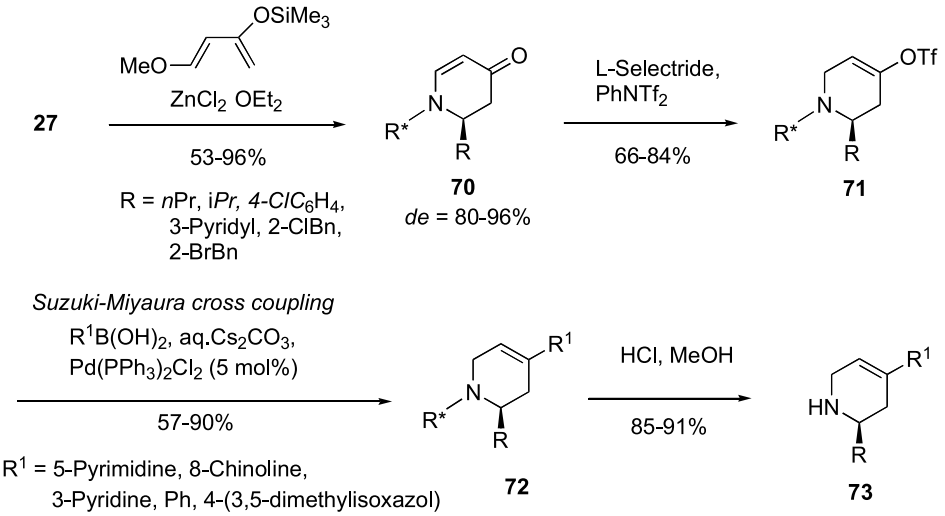


Scheme 15

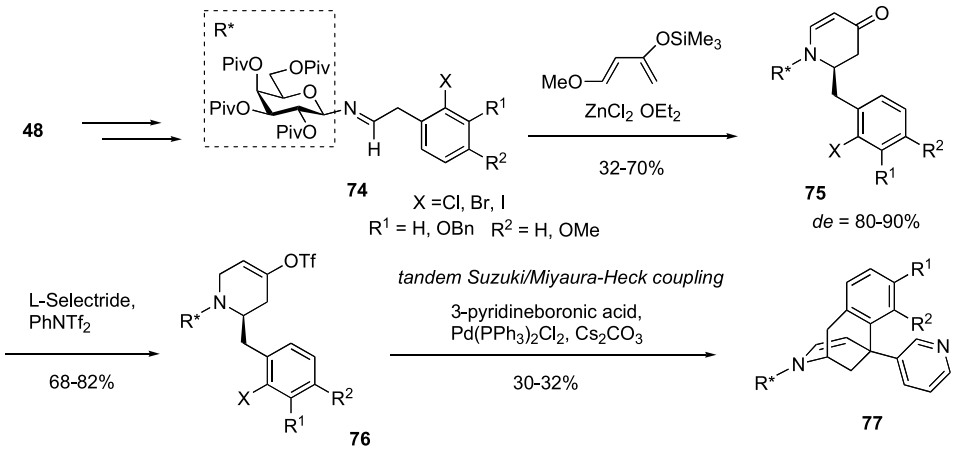
tions of organocopper/boron trifluoride complexes or organocuprates to **65** proceeded with excellent diastereoselectivity to produce 2,6-*cis*-dialkylated piperidin-4-ones **66** predominantly in moderate-to-good yields. A 4-piperidinone **66** ($R^1 = n$-Pr, R^2 = Me) was treated with ethanedithiol to provide dithiolane **67**. Hydrogenolytic desulfurization of the dithiolane in **67** with Raney nickel provided **68**. Removal of the D-arabinose moiety by acid hydrolysis eventually produced (+)-dihydropinidine **69** as its HCl salt in an enantiomerically pure form.

The palladium-catalyzed carbon–carbon coupling reaction (Suzuki–Miyaura coupling) was applied for the enantioselective synthesis of 2,4-disubstituted 4,5-dehydropiperidines by the Kunz group as an extension of the sugar-auxiliary-based dehydropiperidinone synthesis [69] (*Scheme 16*). As described in *Scheme 14*, the tandem Mannich–Michael reactions of the D-galactosylimines **27** (*Scheme 7*) with Danishfsky–Kitahara's diene provided 5,6-didehydropiperidin-4-ones **70** incorporating a variety of alkyl or aryl substituents at C-2. The thus formed piperidinones **70** were converted to the enol triflates **71** by conjugate hydride addition with L-Selectride, followed by trapping of the resulting enolate with $PhNTf_2$. The Suzuki–Miyaura coupling of the enol triflates **71** with a variety of alkyl or arylboronic acids in the presence of a catalytic amount of $Pd(PPh_3)_2Cl_2$ and Cs_2CO_3 produced the coupling products, i.e., 2-alkyl or -aryl-4-aryl (or hetero-aromatic) 4,5-dehydropiperidines **72**, in good yields. Acid hydrolysis of **72** to detach the D-galactopyranose moiety provided enantioenriched 2,4-disubstituted 4,5-dehydropiperidines **73**. The Kunz group applied the stereoselective piperidine synthesis to a combinatorial approach using a polymer-bound immobilized galactose auxiliary [70,71].

Using a similar synthetic concept as that described above (*Scheme 14* and *Scheme 16*), utility of the per-*O*-pivaloylated D-galactosylamine **48** as a chiral auxiliary was broadened to the benzomorphan synthesis by the Kunz group [72] (*Scheme 17* and *Scheme 18*). The

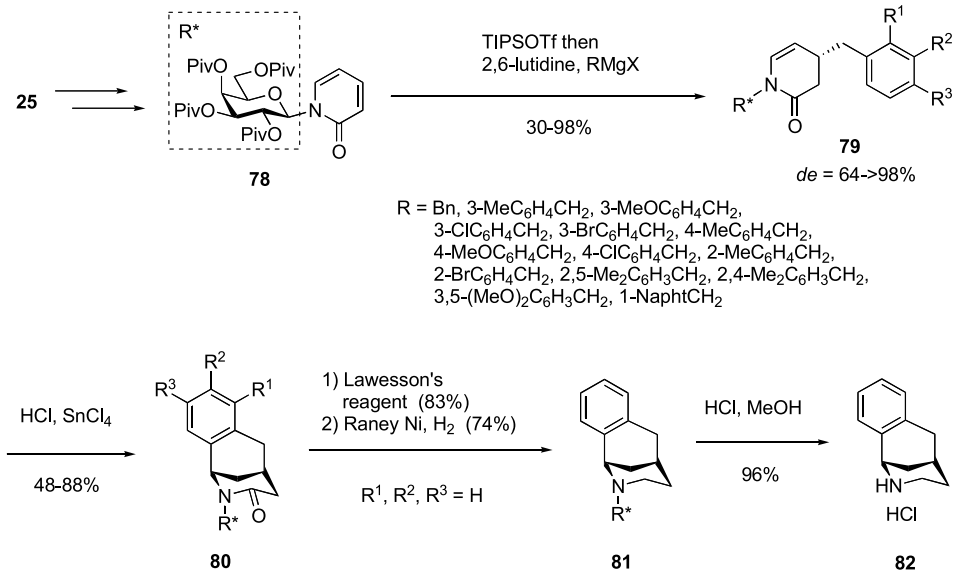


Scheme 16



Scheme 17

synthetic studies commenced with the imine **74**, prepared by the condensation of **48** with a variety of 2-halogenated phenylacetic aldehydes. The aromatic nuclei of some imines **74** possessed oxygen functionalities. The $ZnCl_2$-mediated tandem Mannich–Michael reactions of the aldimines **74** and Danishefsky–Kitahara's diene provided *N*-galactosyl 4-piperidinone derivatives **75** with useful levels of diastereoselectivity in all cases, although the yields were not necessarily high. The efficient shielding of the *Re*-face of the imine double bond by the bulky 2-pivaloyloxy group in the sugar template led to a highly stereoselective induction of the stereogenic center, i. e., an (*R*)-configuration, in the piperidinone ring. The 1,4-conjugate



Scheme 18

hydride addition to **75**, followed by trapping the resulting enolate with $PhNTf_2$, provided enol triflates **76**. The benzomorphan skeleton was constructed efficiently by a series of Suzuki–Miyaura coupling followed by Heck coupling reactions. Thus, the enol triflates **76** were subjected to palladium-catalyzed Suzuki–Miyaura coupling with 3-pyridineboronic acid, providing 2,4-disubstituted 4,5-didehydropiperidines (not shown). In the case of *o*-bromobenzyl derivatives **76** (X = Br), the reaction proceeded further after the initial Suzuki–Miyaura coupling with 3-pyridineboronic acid to construct a tricyclic benzomorphan framework. The products of these tandem reactions were **77**. The second intramolecular Heck reaction stereoselectively formed a new quaternary carbon center in the 4-position of the piperidine ring. The attack was controlled by the configuration of the benzyl substituent and thus occurred exclusively from the top face of the *endo* double bond.

An alternative strategy for the 7,8-benzomorphan synthesis was studied by the Kunz group starting from *N*-galactosyl 2-pyridone **78**, which in turn was prepared by *β*-selective *N*-glycosylation of 2-(trimethylsiloxy)pyridine with per-*O*-pivaloylated D-galactosyl fluoride in the presence of $TiCl_4$ at 70 °C (*Scheme 18*). The pyridone **78** was transformed into **79** by the regio- and stereoselective Grignard reaction with substituted benzylmagnesium halides. After activating with TIPSOTf, the Grignard addition provided **79** in moderate-to-good yields. Next the intramolecular aminoalkylation of **79** took place in the presence of a mixture of HCl and $SnCl_4$ to produce tricyclic benzazocinones **80** via the intermediary *N*-acyl iminium ion. The electrophilic attack at the phenyl ring occurred exclusively from the *cis* side. Further elaboration of the functional groups in **80** eventually provided **81**. This transformation included the reductive removal of the *δ*-lactam carbonyl via the thioamide, prepared by treatment of **80** with Lawesson's reagent followed by hydrogenolysis in the presence of Raney nickel and acid hydrolytic removal of the sugar template in the resulting **81** producing **82**.

The Kunz group used a variety of sugar derivatives as chiral auxiliaries for the [2+2] cycloadditions of ketenes and enol ethers, which produced eventually highly substituted cyclobutanol derivatives [73].

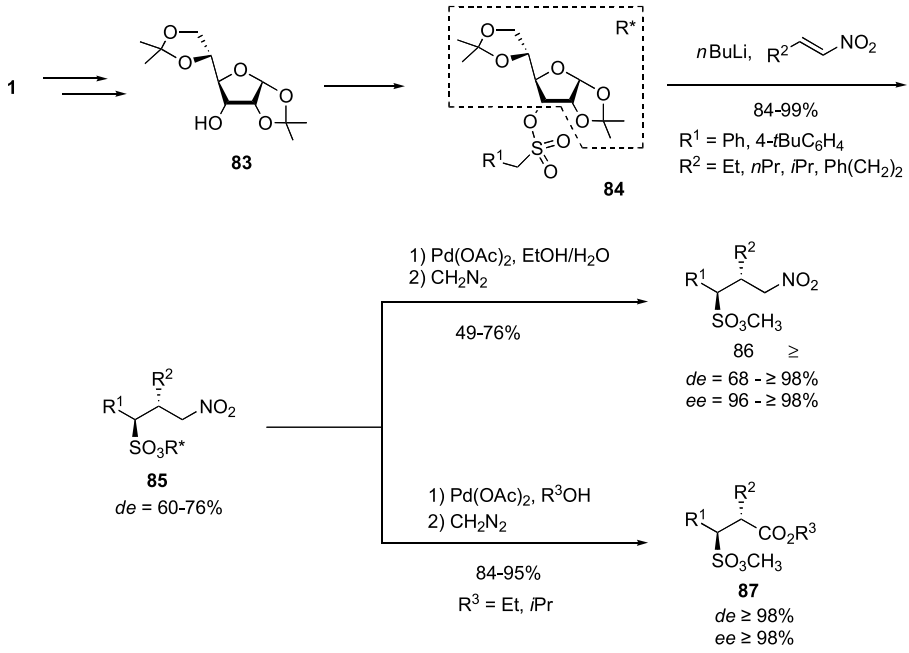
2.3 Studies by the Enders Group

Since the mid-1970s, Enders and co-workers have demonstrated the powerful abilities of (*S*)-2-methoxymethylpyrrolidine (SMP) and its (*R*)-enantiomer (RMP) as notable chiral auxiliaries. Numerous applications to symmetric synthesis using commercially available SMP and RMP have been appeared in the literatures [74,75,76]. In addition to the brilliant success of the worldwide-recognized chiral auxiliaries, the Enders group has also explored the utilization of sugar-based chiral auxiliaries since the start of the twenty-first century. The Enders group is predominantly concerned with diacetone-D-hexofuranoses as chiral templates.

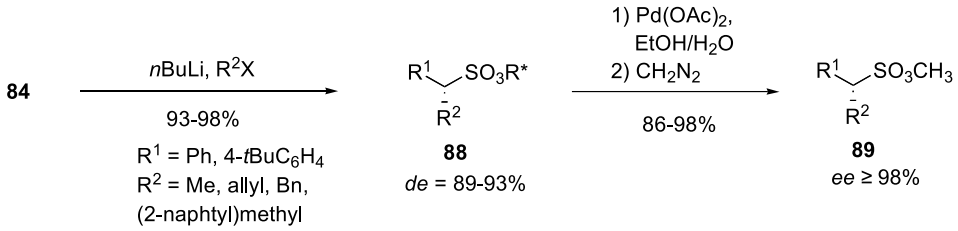
As earlier investigations on the sugar-based asymmetric synthesis, the Enders group utilized diacetone-D-allose, namely, 1,2:5,6-di-*O*-isopropylidene-α-D-allohexofuranose **83**, as a chiral auxiliary (*Scheme 19*). The Enders group first explored the diastereoselective and enantioselective synthesis of α,β-disubstituted γ-nitro methyl sulfonates using **83** to try to succeed in the asymmetric synthesis of analogues of homotaurine (3-aminopropanesulfonic acid) [77,78]. This asymmetric approach was performed starting from 3-*O*-(phenylmethyl)sulfonyl- (or -4-substituted phenylmethyl)sulfonyl-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranoses **84**, which are readily available from **83**. Deprotonation of the phenylmethyl group with BuLi produced the lithiated sulfonate, which reacted with β-alkylated nitroalkenes. The Micheal reaction proceeded smoothly to produce the 1,4-adducts **85** in good-to-excellent yields. Various nitroalkenes were examined for the Michael reaction. In most cases, the results were satisfactory enough, and chiral 2-nitromethyl-1-phenyl-2-alkyl-1-sulfonic acid esters **85** were produced in moderate diastereoselectivities. Removal of the sugar auxiliary from the Michael adducts **85** were explored in detail by the Enders group. As a result, the corresponding methyl sulfonic esters **86**, in which the nitromethyl portion remained intact, were obtained in a virtually enantiopure form by treatment of **85** with catalytic $Pd(OAc)_2$ in aqueous EtOH, followed by methyl esterification of the resulting sulfonic acid with diazomethane. On the other hand, through treatment of **85** with a catalytic amount of $Pd(OAc)_2$ in net R^3OH (without water) under reflux, interestingly the β-alkoxycarbonyl methyl sulfonates **87** were obtained in excellent yields.

Using the 3-*O*-(phenylmethyl)sulfonyl derivatives **84**, the Enders group thoroughly explored stereoselective alkylation at the α-carbon of the (phenylmethyl) sulfonyl moiety. α-Alkylation with a variety of carbon electrophiles was examined using the lithiated phenylmethyl sulfonic acid ester **84** [79,80] (*Scheme 20*). The lithiated sulfonic acid esters derived from **84** were trapped with some alkyl halides, producing the α-alkylated products **88** in excellent yields with remarkably high diastereoselectivity after recrystallization. The sugar auxiliary was removed from **88** by treatment with $Pd(OAc)_2$ (catalytic) in aqueous EtOH followed by esterification of the resulting sulfonic acids, which provided α-alkylated phenylmethyl sulfonic acid methyl esters **89** in virtually enantiopure forms.

The Enders group examined the allylation of the α-lithiated phenylmethylsulfonyl D-allofuranose **84** [81,82] (*Scheme 21*). Thus, treatment of the lithiated **84** with allyl, crotyl, or



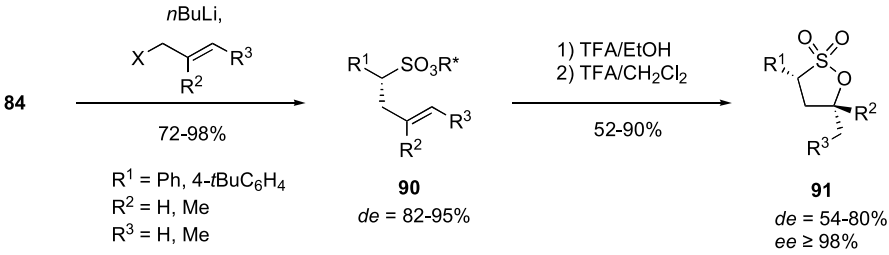
Scheme 19



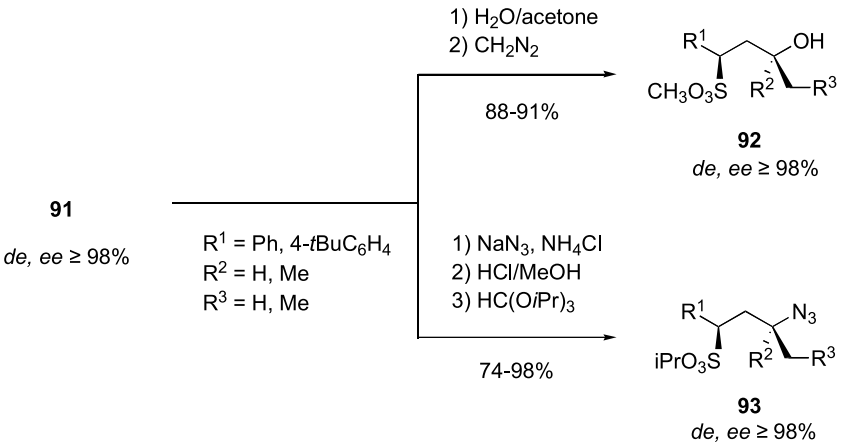
Scheme 20

methallyl chloride provided the allylated products **90** in good yields with high diastereoselectivity. Treatment of **90** with a catalytic amount of TFA in EtOH removed the sugar template to produce a sulfonic acid intermediates, which were treated with TFA in CH_2Cl_2 to produce α,γ-substituted γ-sulfones **91** (five-membered cyclic sulfonates) stereoselectively in an almost enantiopure form. To explain the stereochemical outcome of the sultone formation (the final cyclization step), it was most likely that a Markovnikov-type protonation of the olefin occurred under the acidic conditions and then a *five-exo*-cyclization proceeded through a more stable 1,3-*cis* relationship of the two bulkier substituents.

Ring opening of sultones **91** by hydrolysis in aqueous acetone produced acyclic γ-hydroxylated sulfonates **92** [83,84] (➲ *Scheme 22*). Furthermore, the S_N2 reaction of **91** with NaN_3



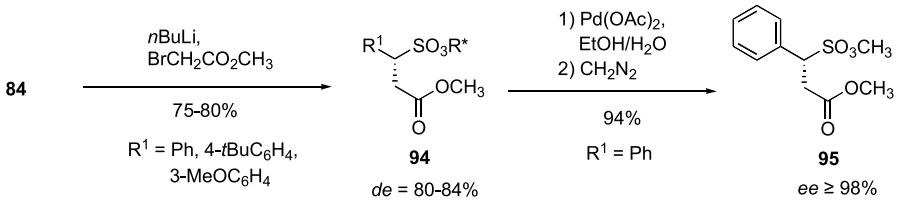
Scheme 21



Scheme 22

produced an azide-substituted product as a result of the ring opening. The sulfonic acid was then esterified to provide γ-azido sulfonic acid ester **93**.

As another example, the Enders group explored the introduction of an (methoxycarbonyl)methyl group at the α-carbon of the phenylmethyl group in **84** [85] (*Scheme 23*). Thus, the lithiated **84** reacted with methyl bromoacetate. As a result, phenylmethyl sulfonic acid esters **94** bearing a (methoxycarbonyl)methyl group at the α-position were produced in high yields with high diastereo-selectivities. A $Pd(OAc)_2$-catalyzed detachment of the sugar moiety provided **95**.



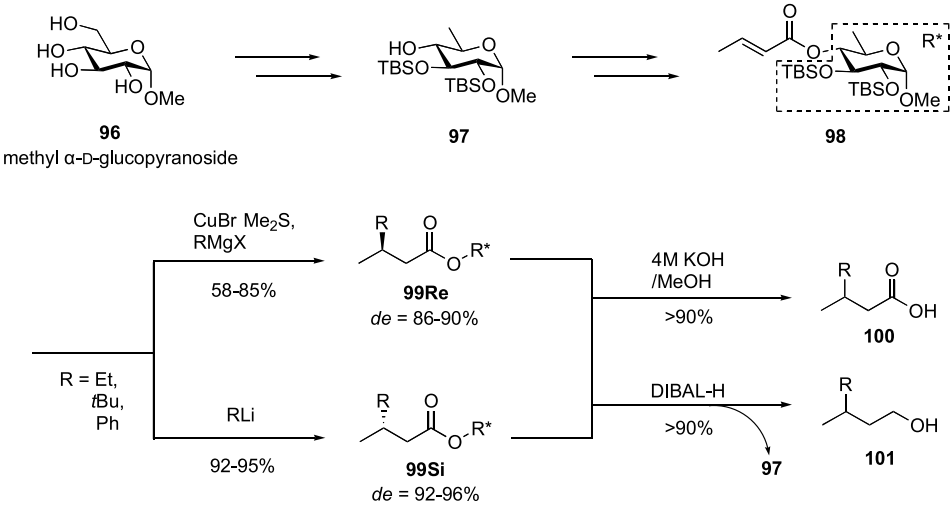
Scheme 23

2.4 Studies by the Tadano Group

Since the later half of 1990s, the Tadano and co-workers have designed and synthesized a variety of hexopyranoside-derived templates to verify their potential as efficient chiral auxiliaries for a variety of carbon–carbon bond-forming reactions. The Tadano group thoroughly explored the difference in the spatial environment constituted by each hexopyranoside configuration, which significantly affected the diastereoselectivity of the attempted organic reactions. It is generally recognized that, owing to the occurrence of anomerization, it is not easy to functionalize an anomeric position while strictly controlling the α- or β-configuration. The Tadano group synthesized a variety of chiral templates from D-glucose, D-mannose, or D-galactose, in which an unprotected hydroxyl group at C-2, -3, -4, or -6 was acylated to introduce the reaction site. These substrates were subjected to 1,4-addition reactions, alkylations, cycloadditions, and others. In each reaction, the Tadano group expected that the asymmetric induction would occur principally by the shielding effect of the bulkiness of the group neighboring the reaction site. Then, the sugar template would be removed by a basic, acidic, or reductive treatment. Consequently, a variety of α- and/or β-chiral carboxylic acids or alcohols could be obtained in the enantiomerically pure or enriched form. In addition, the used sugar templates would be recovered for recycling [86].

As the initial attempt for the asymmetric carbon–carbon bond-forming reactions using sugar templates, the Tadano group explored extensively the 1,4-conjugate additions to α,β-unsaturated esters, such as crotonyl or cinnamoyl esters incorporating at the C4 or C6 of methyl 6-iodo-, 6-deoxy-2,3-di-*O*-protected, 2,3,6-tri-*O*-protected or 2,3,4-tri-*O*-protected α-D-glucopyranosides. The 1,4-additions of the corresponding 2,3-*O*-benzyl and 2,3-*O*-acyl derivatives with a variety of organocopper reagents (RCu, R_2CuMgX) provided 1,4-adducts with moderate-to-high levels of diastereoselectivity. From these diastereomerically enriched 1,4-adducts obtained using the 4-*O*-crotonyl ester, enantioenriched β-alkylated butanoic acids were obtained by basic hydrolysis. [87]. The glycopyranoside-based diastereoselective 1,4-addition approach was further developed by the Tadano group using other hexopyranosides, such as α-D-*manno*- and α-D-galactopyranosides [88]. Some methyl 2,4,6-tri-*O*-protected 3-*O*-crotonyl-α-D-mannopyranosides provided 1,4-adducts with useful levels of diastereoselectivity in the reactions with ethyl and vinyl Grignard reagent-derived cuprates. Moreover, some methyl 2,4,6-tri-*O*-protected 3-*O*-crotonyl-α-D-galactopyranosides provided 1,4-adducts with high levels of diastereoselectivity in the reactions with ethyl, isopropyl or vinyl cuprates. A mechanistic explanation for the observed high diastereoselectivities achieved using these hexopyranoside-derived templates was proposed by the Tadano group using some transition-state models.

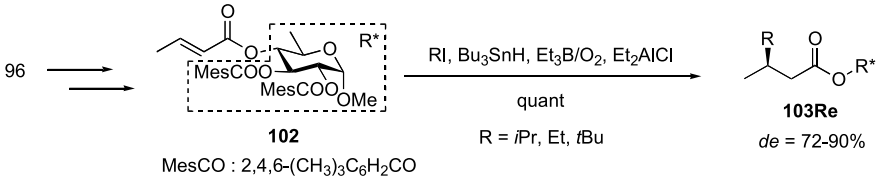
As the most effective chiral auxiliary for the 1,4-conjugate addition of organocuprates to an unsaturated ester incorporating into a hexopyranoside derivative, the Tadano group found methyl 6-deoxy-2,3-di-*O*-(*t*-butyldimethylsilyl)-α-D-glucopyranoside **97**, which was prepared from methyl α-D-glucopyranoside **96** [89] (*Scheme 24*). As a result, the 4-*O*-crotonyl derivative **98** of this sugar template **97** provided the 1,4-adduct in moderate-to-high yields with useful levels of diastereoselectivity in the reaction with alkyl (or phenyl) Grignard reagent-derived cuprates. The adducts **99Re** with an ethyl, *t*-butyl, or phenyl group at the β-carbon were preferentially obtained. The neighboring bulky 3-*O*-(*t*-butyldimethylsilyl) group effectively shielded the front side of the 4-*O*-crotonyl ester moiety. Thus, the attack of the organocopper



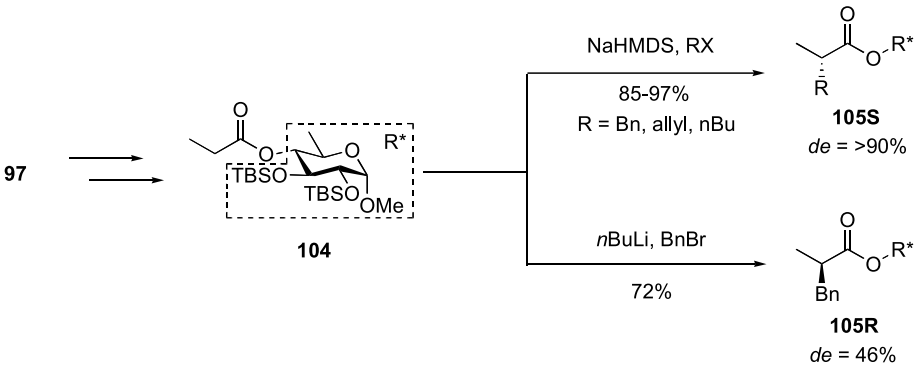
Scheme 24

reagent occurred predominantly from the less congested rear side. Furthermore, the conformation of the unsaturated ester moiety, i. e., *s-cis-syn-*, or *s-trans-syn*-conformations, governed the stereochemical outcome. Interestingly, the 1,4-additions of alkyllithiums(two alkyllithiums and phenyllithium) to **98** resulted in the formation of 1,4-adducts **99Si** (not 1,2-adducts) with the opposite configurations at the β-carbon. From 1,4-adducts **99Re** or **99Si**, β-alkyl (or phenyl) butanoic acids **100** or butanols **101** were synthesized in highly enantioenriched forms by saponification or hydride reduction, respectively.

The 1,4-additions of radical species to the 4-*O*-crotonyl derivative of methyl 6-deoxy-2,3-*O*-protected α-D-glucopyranosides were explored by the Tadano group [90] (*Scheme 25*). The radical reactions proceeded highly diastereoselectively using a traditional system of alkyl iodide, *n*-butyltin hydride and triethylborane/ oxygen in the presence of Lewis acid, such as $AlCl_3$, $BF_3{\cdot}Et_2O$, or Et_2AlCl, to produce a variety of β-alkylated butanoic acid esters tethering the sugar template. In particular, the 2,3-di-*O*-mesitoyl-type template (mesitoyl = 2,4,6-trimethylbenzoyl) **102** provided 1,4-adducts **103Re** (R = isopropyl, ethyl, *t*-butyl) most effectively.



Scheme 25

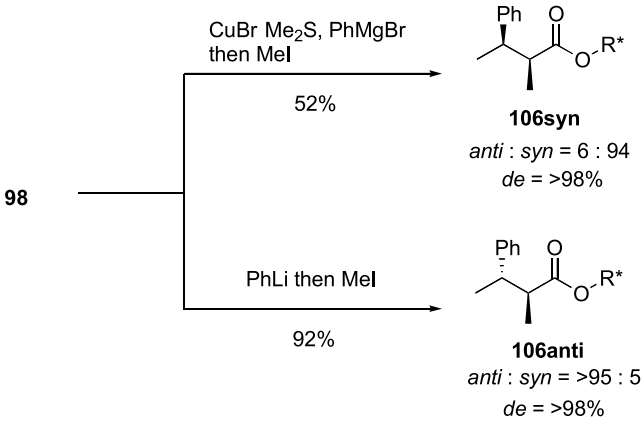


Scheme 26

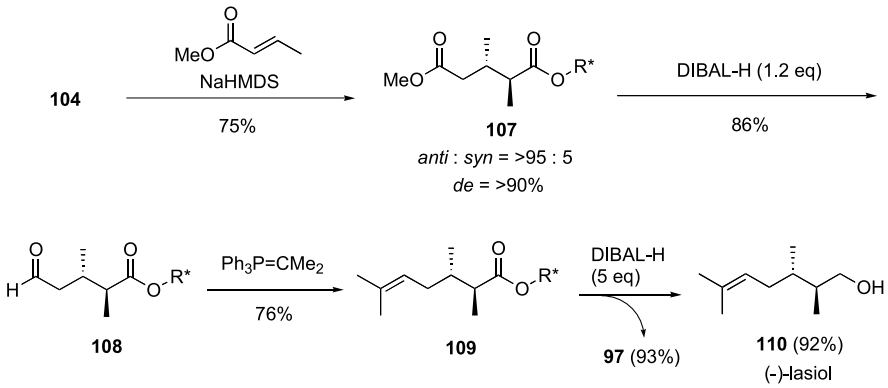
The utility of the 2,3-di-*O*-(*t*-butyldimethylsilyl)-type template was also evidenced through the α-alkylation of methyl 6-deoxy-2,3-di-*O*-(*t*-butyldimethylsilyl)-4-propionyl-α-D-glucopyranoside **104** [86] (*Scheme 26*). The propionyl ester **104** was deprotonated with a base, and the resulting enolate was trapped with benzyl, alkyl, or allyl halide to provide the α-benzylated, α-alkylated, or α-allylated products with excellent diastereoselectivity in all cases. Sodium hexamethyldisilazide (NaHMDS) was most effective base, which preferentially provided (*S*)-substituted products **105S**. The Tadano group speculated that the (*Z*)-enolate was formed preferentially from **104**, which was trapped by an electrophile, leading to the formation of (*S*)-isomers. The Tadano group also found that the deprotonation of **104** with *n*-BuLi (or LDA), followed by benzylation of the resulting enolate provided another α-alkylated product **105R**, albeit in a lower diastereoselectivity. Interestingly, the benzylated product **105R** possessed the (*R*)-configuration at the α-carbon opposite to **105S**.

The 1,4-conjugate addition of carbon nucleophiles to the 4-*O*-crotonyl ester **98** followed by α-alkylation in a one-pot process was realized with high *anti/syn*- and diastereoselectivities [89] (*Scheme 27*). Namely, the 1,4-addition of a phenyl-copper reagent, prepared from phenylmagnesium bromide and copper(I) bromide, to **98** followed by trapping of the intermediary enolate with iodomethane, provided α,β-dialkylated butanoic acid derivative **106syn** with high *anti/syn*-selectivity in favor of the *syn*-isomer. It should be emphasized that the diastereoselectivity (de) of this *syn*-adduct was almost complete. A further interesting finding was observed when using phenyllithium as a carbon nucleophile in place of the phenylcuprate. This one-pot reaction provided the *anti*-addition product **106anti** with high *anti/syn*-selectivity and diastereoselectivities.

As an application of the stereoselective α-alkylation realized using 4-*O*-propionyl derivative **104** to natural product synthesis, the Tadano group achieved the highly stereoselective total synthesis of (–)-Lasiol **110**, an acyclic monoterpene alcohol [91] (*Scheme 28*). The 1,4-addition of the enolate generated from **104** with NaHMDS to methyl crotonate proceeded highly stereoselectively to produce the 1,4-adduct **107** as a single diastereomer. The product **107** possessed an *anti*-stereochemistry for two vicinal methyl substituents at the α- and β-carbons of the ester functionality. The diastereoselectivity of the *anti*-isomers was also quite high (>90%). Natural lasiol was isolated as an insect sex-attracting pheromone, which was found



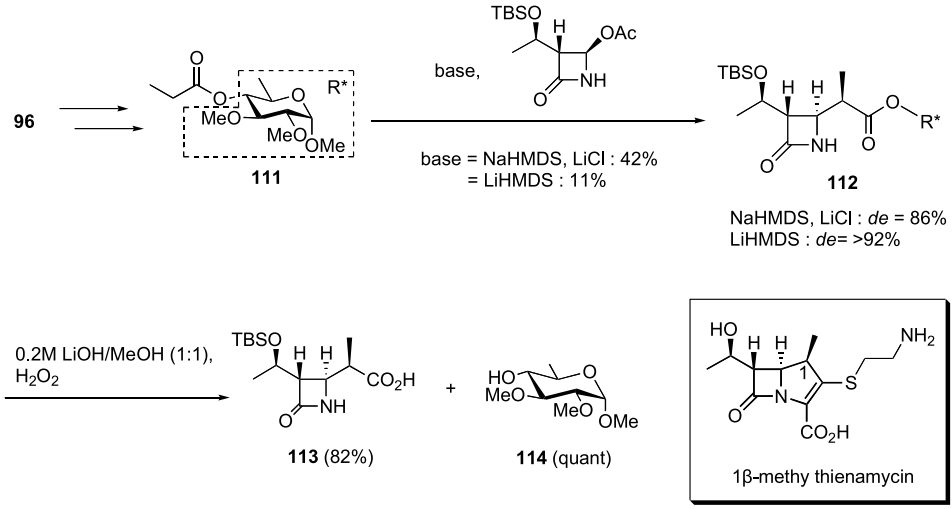
Scheme 27



Scheme 28

in the mandibular gland secretions of the male ant *Lasius meridiobalis*. The stereostructure of this pheromone was determined to be *erythro*-2,3,6-trimethyl-5-hepten-1-ol. The Tadano group synthesized (–)-lasiol conveniently from the adduct **107** as follows. Selective DIBAL-H reduction of the less-congested ester moiety in **107** efficiently produced the left-hand aldehyde **108**. A Wittig-olefination of **108** with $Ph_3P{=}C(Me)_2$ provided the 2-methylpropenylated product **109**. Reductive removal of the sugar template from **109** with excess DIBAL-H eventually provided (–)-lasiol **110**, and the sugar-template **97** was efficiently recovered.

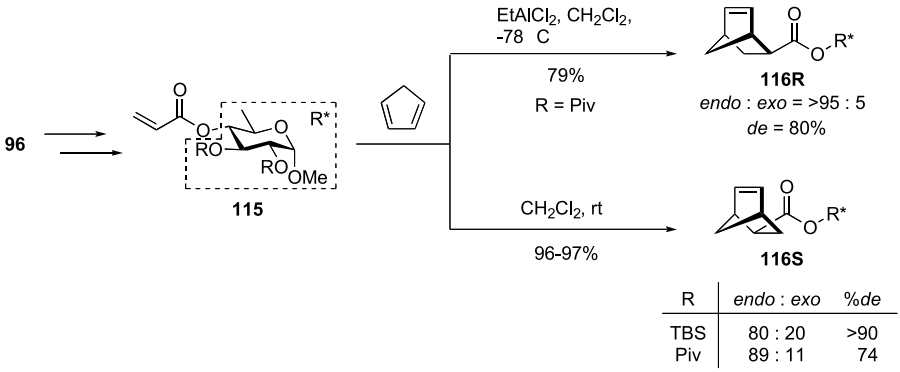
The Tadano group extended the use of the sugar-based chiral templates for the 1β-methyl carbapenem synthesis. As concerns the chemical synthesis of 1β-methyl carbapenems such as 1β-methyl thienamycin, the most common approach is a late-stage ring closure for bicyclic skeleton construction using a *C*-4 functionalized azetidin-2-one, such as **113**, namely (3*S*,4*S*)-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-4-[(*R*)-1-carboxyethyl]azetidin-2-one, which may be constructed via the Mannich-like reaction of commercial (3*R*,4*R*)-4-acetoxy-3-[(*R*)-1-(*t*-



Scheme 29

butyldimethylsilyloxy)ethyl]azetidin-2-one and the enolates generated from chiral propionic acid esters (*Scheme 29*). After throughout searching of most effective sugar template, the Tadano group found the solution to the attempted stereoselective Mannich-like reaction [92]. As a result, the Mannich-like reaction of the enolate generated from methyl 6-deoxy-2,3-di-*O*-methyl-4-*O*-propionyl-α-D-glucopyranoside **111** and the azetidin-2-one provided the desired β-configured adduct **112** stereoselectively. The effective bases for the deprotonation of **111** were found to be LiHMDS or NaHMDS. From adduct **112**, the sugar template was readily removed without epimerization by alkaline hydrolysis in the presence of H_2O_2 to obtain the desired **113**, and the sugar template **114** was efficiently recovered.

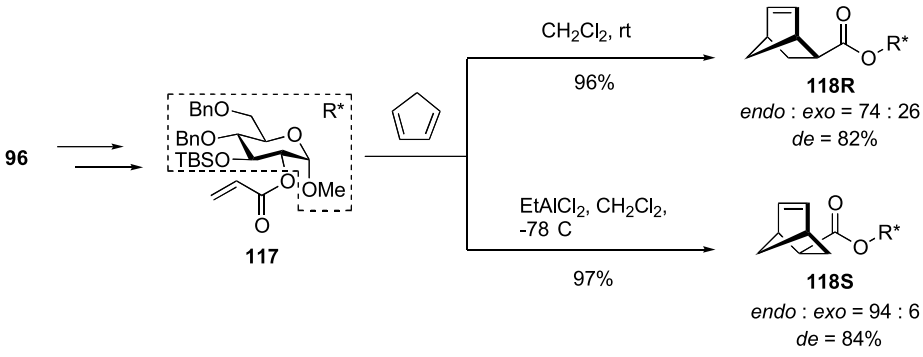
In addition to the aforementioned highly stereoselective asymmetric synthesis of the polar and radical organic reactions using a variety of sugar templates, the Tadano group extended this synthetic concept to pericyclic reactions, such as Diels–Alder reaction and 1,3-dipolar cycloaddition. Various *O*-protected methyl α-D-hexopyranosides (gluco-, *manno*- and galacto-series), in which an acryloyl ester was incorporated into an appropriate skeletal carbon, were prepared and used for thermal or Lewis acid-promoted Diels–Alder reactions [93,94]. As a representative case, the Diels–Alder reactions of the 4-*O*-acryloyl derivatives of methyl 6-deoxy-2,3-di-*O*-(*t*-butyldimethylsilyl)- and 2,3-di-*O*-pivaloyl-α-D-glucopyranoside **115** with cyclopentadiene were explored (*Scheme 30*). Under Lewis acid-promoted conditions ($EtAlCl_2$), the 2,3-di-*O*-pyvaloyl derivative **115** (R = Piv) provided one *endo*-adduct **116R** with excellent *endo*/*exo* selectivity and good π-facial selectivity (de = 80%). Under thermal conditions (rt), however, two 4-*O*-acryloyl esters **115** produced **116S** with good-to-excellent *endo*/*exo* selectivities (80:20 for 2,3-di-*O*-(*t*-butyldimethylsilyl) derivative; 89:11 for 2,3-*O*-pivaloyl derivative). Both 4-*O*-acryloyl esters **115** produced **116S** as well with good-to-excellent π-facial selectivities. From the two *endo*-adducts **116R** and **116S**, (2*S*)- and (2*R*)-enriched *endo*-5-norbornene-2-methanol were prepared by reductive removal of the sugar auxiliary, respectively.



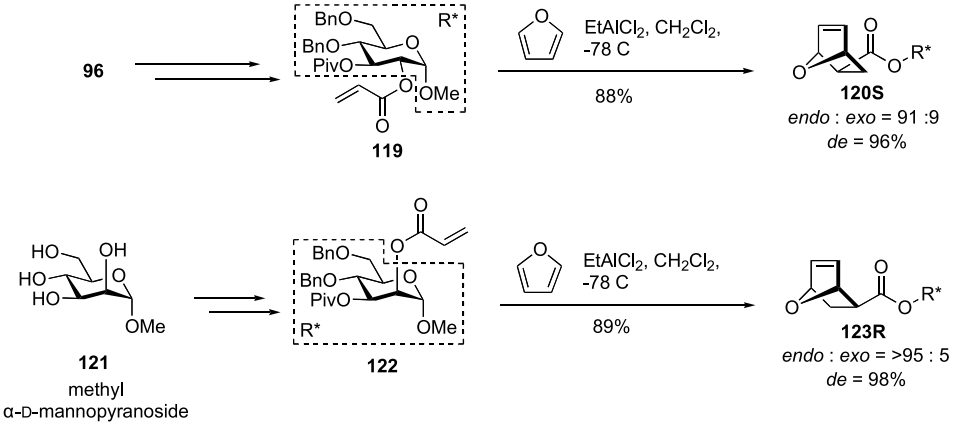
Scheme 30

As another example, the Diels–Alder reaction of 2-*O*-acryloyl derivative of methyl 4,6-di-*O*-benzyl-3-*O*-(*t*-butyldimethylsilyl)-α-D-glucopyranoside **117**, prepared from methyl α-D-glucopyranoside **96**, with cyclopentadiene, was explored under thermal or Lewis acid-mediated conditions [94] (*Scheme 31*). Under thermal (rt) conditions, the 2-*O*-acryloyl ester **117** provided one *endo*-adduct **118R** with moderate *endo/exo* selectivity (74:26) and good π-facial selectivity (de = 82%). Under Lewis acid-promoted conditions, another *endo*-adduct **118S** was a predominant product with good π-facial selectivity.

The Tadano group explored the $EtAlCl_2$-promoted Diels–Alder reactions with furan using other sugar templates [86] (*Scheme 32*). The D-gluco-type 2-*O*-acryloyl ester **119**, derived from **96**, provided an *endo*-adduct **120S** predominantly. The Diels–Alder reaction of D-*manno*-type 2-*O*-acryloyl derivative **122**, prepared from methyl α-D-mannopyranoside **121**, proceeded under the same $EtAlCl_2$-mediated conditions to provide an *endo*-adduct **123R**. Both reactions proceeded in the *endo*-mode preferentially. Most importantly, the diastereomeric excesses (π-facial selectivity) for the *endo*-adducts were magnificent, revealing that each *endo*-adduct was virtually a single diastereomer. The Diels–Alder substrates **119** and **122** differ from each other in the configuration at C-2. This difference dramatically influenced the



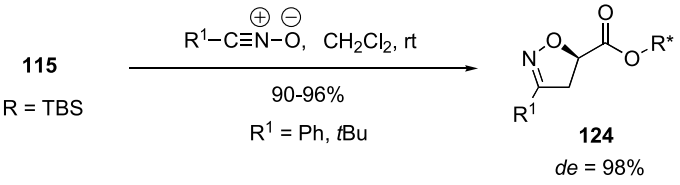
Scheme 31



Scheme 32

π-facial selectivity of the diene approach. The adducts **120S** and **123R** contain enantiomeric 7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid in their structures. 7-Oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid and related compounds are frequently used as chiral building blocks for natural products synthesis.

The 1,3-dipolar cycloaddition of nitrile oxide to an unsaturated ester is a useful synthetic strategy for the synthesis of heterocycles such as Δ^2-isooxazolines and α-hydroxy-γ-keto or γ-imino carboxylic acids. Thus, the 1,3-dipolar cyclo-addition of the 4-*O*-acryloyl derivative **115** (R = *t*-butyldimethylsilyl) with two nitrile oxides (R^1 = Ph or *t*-Bu) was explored by the Tadano group [95] (*Scheme 33*). In the case of benzonitrile oxide (R^1 = Ph), a functionalized Δ^2-isooxazoline **124** was obtained as a single isomer in excellent yield. Thus, the cycloaddition proceeded smoothly at room temperature with extreme stereoselectivity.



Scheme 33

3 Sugars as Chiral Ligands for Transition-Metal Catalysts

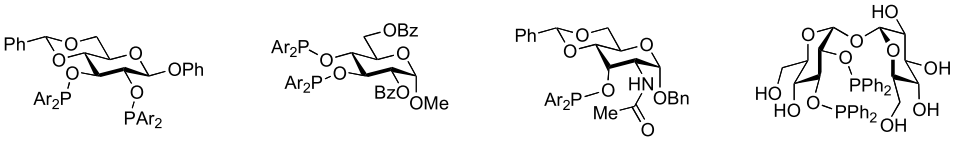
Historically the synthetic application of sugar derivatives as chiral ligands of transition-metal complexes to a variety of asymmetric reactions was initiated in the late 1970s [96,97,98,99]. The use of sugar-based chiral ligands as part of transition-metal complexes became more popular for synthetic organic chemists since the early 1990s and was thoroughly studied by several research groups [100,101,102,103,104,105,106,107,108,109,110,111,112,113,114]. Herein, some representative achievements on this subject by five research groups are summarized.

3.1 Studies by the RajanBabu Group

Since the early 1990s, the group headed by RajanBabu has achieved a variety of practical asymmetric syntheses, especially asymmetric hydrogenation, asymmetric hydrocyanation and asymmetric hydrovinylation of prochiral olefins using a variety of chiral transition-metal complexes incorporating sugar-based ligands. Several prominent papers published by the RajanBabu group since 1992 have received significant attention in the field of asymmetric synthesis [115,116,117,118,119,120,121,122,123,124,125,126,127,128,129]. Some representative examples of their studies are summarized below.

These researchers designed a variety of hexopyranose derivatives bearing mono-*O*-phosphinyl (OPR_2) or di-*O*-phosphinyl groups prepared by phosphinylation of appropriate hydroxyl group(s) in the starting mono- and disaccharide skeletons such as partially protected D-glucopyranosides. These ligands were readily prepared by treatment of appropriate sugar derivatives bearing unprotected hydroxyl group(s) with appropriate chlorodiarylphosphines. Usually, the designed sugar phophinites possess functionalized aryl (Ar) groups as substituents on the phosphorous element. Representative sugar phosphinites **125–129** developed by the RajanBabu group are shown in *Fig. 1*. Using these sugar-based phophinites as chiral ligands of transition-metal complexes (Ni, Rh, Pd), the RajanBabu group demonstrated catalytic asymmetric carbon–hydrogen and carbon–carbon bond-forming reactions. The transition-metal catalysts were in general prepared by mixing the phosphinite-type ligands and appropriate transition-metal salts such as $Ni(COD)_2$. Some of these transition-metal complexes are particularly valuable because of their water-soluble nature.

The asymmetric hydrocyanation of vinylarenes was explored by the RajanBabu group for the initial evaluation of the sugar phosphinite-type ligands as effective stereocontrolling elements. In 1992, they reported their initial results on the hydrocyanation of some vinylnaphthalenes such as 6-methoxy-2-vinylnaphthalene **130** with HCN in the presence of a catalytic amount (1.0–5.0 mol%) of Ni(0) complexes prepared from D-glucose-derived ligand **125** [115] (*Scheme 34*). The chemical yield and enantioselectivity (ee) of the hydrocyanation product **131** were both at levels of general use. To realize higher enantioselectivities in the hydrocyanation, they recognized that electron-withdrawing substituent(s), such as a CF_3 group, were requisite in the aryl groups of the phosphinites. The RajanBabu group also studied the mechanism of the hydrocyanation in depth through kinetic studies and spectral analysis of intermediary organometallic species [119]. The RajanBabu group devised other sugar phosphinites as the ligands for the hydrocyanation of vinylarenes [120]. In 2006, the RajanBabu group reported



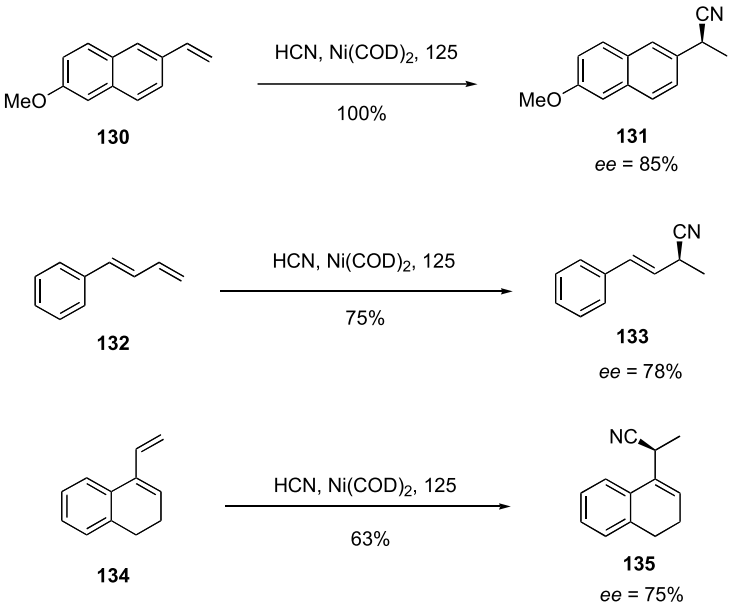
125 : Ar = 3,5-$(CF_3)_2$-C_6H_3
126 : Ar = 3,5-Me_2-C_6H_3

127
Ar = 3,5-Me_2-C_6H_3

128
Ar = 3,5-Me_2-C_6H_3

129

Figure 1
The sugar phosphinites designed by the RajanBabu group

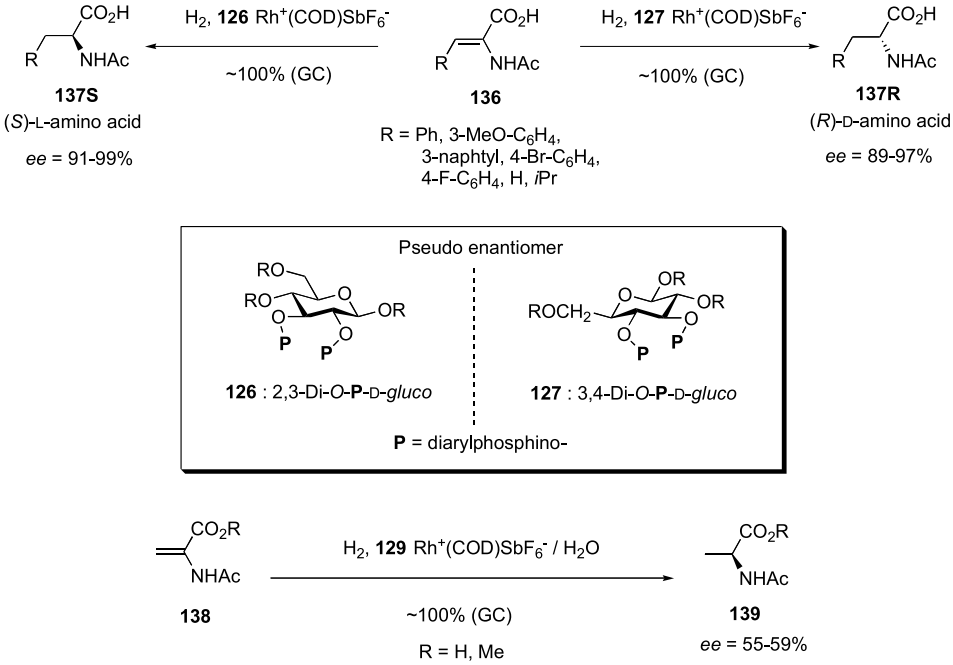


Scheme 34

the Ni(0)-catalyzed asymmetric hydrocyanation of 1,3-dienes using the ligand **125** [129]. As shown in *Scheme 34*, the asymmetric hydrocyanation of 1-phenyl-1,3-butadiene **132** proceeded regioselectively to provide the 1,2-adduct **133** exclusively in good chemical yield. The enantiomeric excess of the product was 78%. The similar hydrocyanation of 1-vinyl-3,4-dihydronaphthalene **134** using the ligand **125** provided **135** in somewhat lesser yield and enantioselectivity.

In addition, the RajanBabu group explored the Rh(I)-catalyzed asymmetric hydrogenation of a variety of dehydroamino acids, i. e., β-arylated α-acetamido-acrylic acid esters or acrylic acids **136**, using the sugar diphosphinite-based ligands, to prepare L- or D-amino acids [117,121] (*Scheme 35*). As in the cases of the asymmetric hydrocyanation of vinylarenes, sugar phosphinites, such as **126** and **127**, served as excellent stereocontrolling elements to produce either functionalized (*S*)- or (*R*)-phenylalanines with high-to-excellent enantioselectivity.

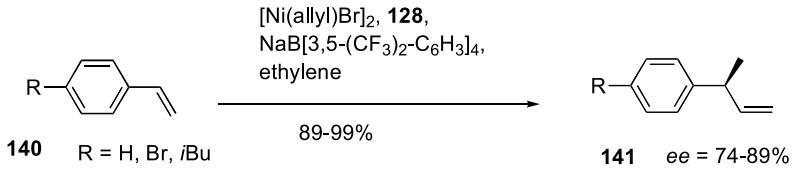
Interestingly, the sense of the chirality (*R* or *S*) of the produced phenylalanine derivatives **137** was dependent on the relative juxtaposition of the vicinal diphosphinites on a sugar backbone. Thus, the hydrogenation (H_2 under 30–40 psi) of **136** in the presence of a catalytic amount of Rh(I)(COD)SbF_6 complex with a 2,3-bis-*O*-[(diphenyl)phosphino]-D-glucopyranoside-type ligand **126** produced predominantly (*S*)-L-phenylalanine derivatives **137S**. Importantly, the electronic tuning of a ligand system has resulted in an enhancement of enantioselectivity. On the other hand, a 3,4-bis-*O*-[(diphenyl)phosphino]-D-glucopyranoside-type ligand **127** produced the corresponding (*R*)-D-amino acid **137R** with excellent enantioselection. Therefore, these sugar phosphinites **126** and **127** are in a pseudo-enantiomeric relationship as chiral ligands for the Rh(I)-catalyzed hydrogenation of dihydroamino acids. In sharp contrast to the



Scheme 35

hydrocyanation of vinylarenes, the ligands with electron-withdrawing groups in the aromatic rings, such as **125**, decreased in the enantioselectivity of hydrogenation. The asymmetric hydrogenation of dehydroamino acids was explored further using other D-fructofuranose-type diphosphinites with less enantioselectivity. As an extension of the sugar phosphinite-based asymmetric hydrogenation, the RajanBabu group successfully explored the hydrogenation of dimethyl itaconate [123]. Furthermore, disaccharide phosphinites, i. e., the α,α'-trehalose-derived diphosphinites **129**, were used as water-soluble catalysts for the Rh(I)-catalyzed hydrogenation of dehydroamino acids **138** to prepare (*S*)-alanine derivatives **139**; however, the observed enantioselectivity was unremarkable [122,125].

A D-allosamine-derived monophosphinite **128** served as a good chiral ligand for the asymmetric Ni(0)-catalyzed hydrovinylation of styrene derivatives **140** with ethylene as shown in *Scheme 36* [126,127,128]. Among some 2-acetamido-2-deoxy-3-*O*-diarylphosphinyl derivatives prepared from D-hexopyranoses, the ligand **128** revealed a useful level of enantios-



Scheme 36

electivity, which produced (*S*)-1-(methyl)allylbenzenes **141** with high enantioselectivity. One of the hydrovinylation products, i. e., 1-bromo-4-[(*S*)-1-methylallyl]benzene, was converted to (*R*)-ibuprofen, a pharmacologically important 2-arylpropionic acid.

3.2 Studies by the Diéguez/Ruiz/Claver Group

Since the late 1990s, the group consisting of Diéguez, Ruiz and Claver in Spain has explored asymmetric synthesis using sugar diphosphites [general formula = $OP(OR)_2$], sugar phosphine-phosphites, or sugar thioether-phosphinites as chiral ligands of transition-metal complexes. Representative ligands are shown in ❯ *Fig. 2*. Most of these sugar-derived ligands contain one/two phosphite moieties consisting of 2,2′-dihydroxy-1,1′-biphenyl or 2,2′-dihydroxy1-1,1′-binaphthyl moieties. Using these D-*aldo*-hexo- or pentofuranose derivatives as chiral ligands of a Cu, Rh, or Ni catalyst, asymmetric hydroformylation, hydrogenation, 1,4-addition, or hydrosilylation of prochiral olefins and asymmetric allylic alkylation was achieved [130,131,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146,147,148,149,150,151,152,153]. The results obtained by this group are summarized below.

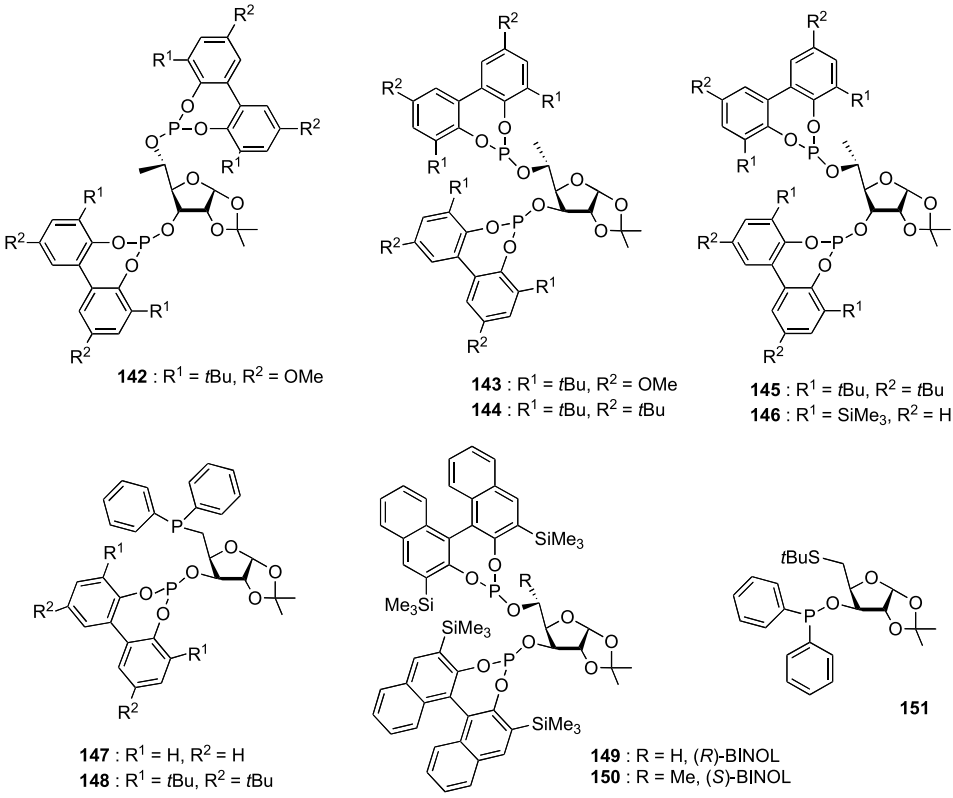


Figure 2
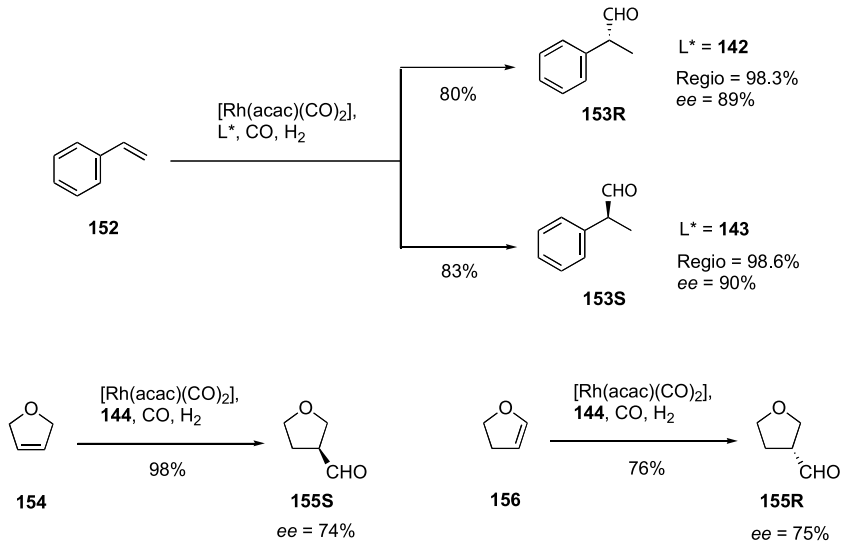
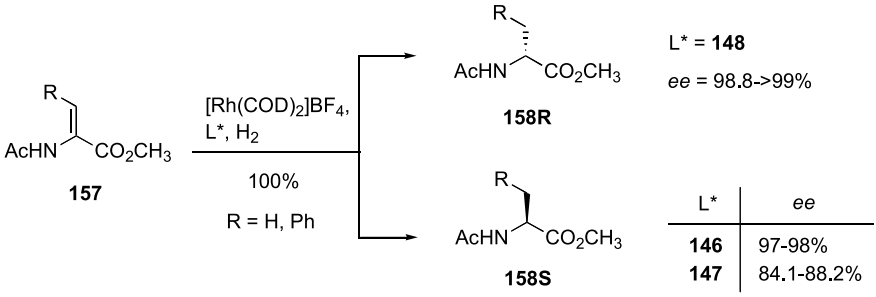
The sugar-derived chiral ligands designed by the Diéguez/Ruiz/Claver group

Asymmetric Rh-catalyzed hydroformylation of vinylarenes has attracted much attention as a convenient tool for obtaining enantiopure or -enriched functionalized aldehydes. The Diéguez/Ruiz/Claver group demonstrated the efficiency of the sugar-derived ligands as regio- and stereocontrolling elements for the Rh-catalyzed hydroformylation of vinylarenes or dihydrofurans [133,138,140,142,147]. Representative achievements reported by the Diéguez/Ruiz/Claver group on the asymmetric hydroformylation are shown in ❯ *Scheme 37*. Using ligand **142**, the hydroformylation of styrene **152** with CO/H_2 (10 bar) in the presence of an $Rh(acac)(CO)_2$ catalyst (0.1 mol%) in toluene provided (*R*)-2-phenylpropanal **153R** with 89% enantiomeric excess. The ligand **142** was prepared from D-glucose as follows. Deoxygenation of the C-6 hydroxyl group and stereochemical inversion of both C-3 and C-5 configurations of 1,2-*O*-isopropylidene-α-D-glucofuranose provided 6-deoxy-1,2-*O*-isopropylidene-L-talofuranose. Treatment of this sugar derivative with appropriate diarylated phosphorochloridite $[(ArO)_2PCl]$ in pyridine afforded the ligand **142**. Even more interestingly, a similar Rh-catalyzed hydroformylation of styrene in the presence of **143**, a 6-deoxy-D-glucofuranose-type ligand, produced (*S*)-2-phenylpropanal **153S** with a high ee of 90%. The configurations at C-3 and C-5 in the sugar part of the ligand, thus, direct the absolute configuration of the product of asymmetric hydroformylation.

The Diéguez/Ruiz/Claver group demonstrated another application of the sugar diphosphite-based asymmetric synthesis to the hydroformylation of two types of dihydrofurans. The Rh-catalyzed hydroformylation of 2,5-dihydrofuran **154** with CO/H_2 in the presence of ligand **144**, a modified **143**-type ligand with two bulky *tert*-butyl substituents in both biphenyl parts, produced (*S*)-3-formyltetrahydrofuran **155S** with moderate enantioselectivity (74% ee). When 2,3-dihydrofuran **156** was treated under the same hydroformylation conditions using the same



Scheme 37

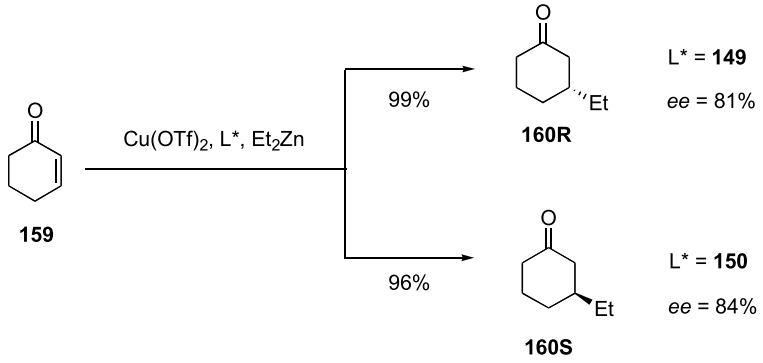


Scheme 38

ligand **144**, the opposite (*R*)-3-formyltetrahydrofuran **155R** was obtained with 75% ee. Thus, the sugar phosphite-based ligand **144** could discriminate the π-face in two substrates, **154** and **156**.

The utility of the phosphorus-containing chiral ligands has been expanded to the transition-metal-catalyzed asymmetric hydrogenation of prochiral olefins by the Diéguez/Ruiz/Claver group [132,134,137,143,146]. Some studies on this subject, which resulted in the achievement of high enantioselectivity, are shown in *Scheme 38*. Some *N*-acetyldehydroamino acid esters **157** were subjected to Rh(I)-catalyzed hydrogenation in the presence of sugar phosphine-phosphite-type ligands **147** and **148**. The ligands **147** and **148** were prepared from 1,2-*O*-isopropylidene-α-D-xylofuranose via the ring opening of the corresponding 3,5-anhydrosugar (a 3,5-oxetane derivative) by a PPh_2 anion and the subsequent phosphite formation of C-3 hydroxyl with an appropriate diarylphosphorochlorite. Using the catalyst consisted of the ligand **148** and $[Rh(COD)_2]BF_4$. *N*-acetylated (*R*)-alanine methyl ester or *N*-acetylated (*R*)-phenylalanine methyl ester **158R** was obtained quantitatively with excellent enantiomeric excess. On the contrary, the (*S*)-enantiomers of these amino acids **158S** were obtained in a highly enantioenriched form by switching the chiral ligand **148** to those derived from a sterically less congested sugar phosphine-phosphite or 1,2-*O*-isopropylidene-α-D-glucofuranose-derived diphosphite, i. e., **147** or **146**, respectively.

The asymmetric 1,4-addition of a carbon nucleophile, such as an organometallic species, to prochiral α,β-unsaturated esters (Michael reaction) is one of the most actively investigated areas in current organic synthesis. Consequently, synthetically relevant β-functionalized carbonyl compounds can be prepared in an enantiopure or -enriched form. For this purpose, several ligands for transition-metal catalysts have been developed so far by structural tuning of chiral compounds from natural or unnatural sources. Using some sugar diphosphite-type ligands, the Diéguez/Ruiz/Claver group investigated Cu(II)-catalyzed enantioselective 1,4-addition of organometallic species to α,β-unsaturated compounds [130,131,135,139,150]. Representative results on the Cu(II)-catalyzed 1,4-addition to cyclohex-2-enone **159** with sugar diphosphite-based catalysts are shown in *Scheme 39*. The nucleophilic addition of diethylzinc to **159** in the presence of a catalytic amount of $Cu(OTf)_2$ in CH_2Cl_2 at 0 °C proceeded almost exclusively in a 1,4-addition fashion. With the ligand **149**, this 1,4-addition produced (*R*)-3-ethylcyclohexanone **160R** quantitatively in 81% enantiomeric excess. The ligand **149** contains two (*R*)-1,1′-binaphthol skeletons, both carrying two bulky trimethylsilyl groups at

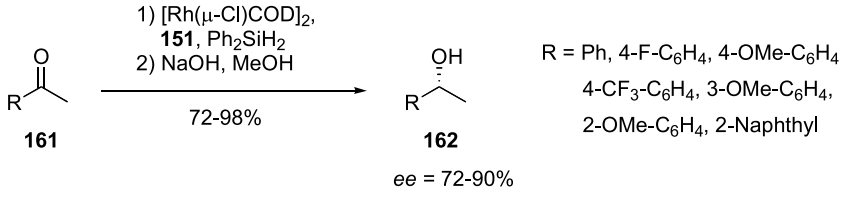


Scheme 39

C-2 and C-2′. The ligand **149** was prepared from 1,2-*O*-isopropylidene-α-D-xylofuranose with a methodology similar to that used for the preparation of **143** and **144**. By switching the chiral ligand **149** to **150**, the 3,5-diphosphites of 6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose with two (*S*)-BINOLs, the 1,4-addition of diethylzinc to **159** produced the (*S*)-enantiomer **160S** with a remarkable enantiomeric excess of 84%.

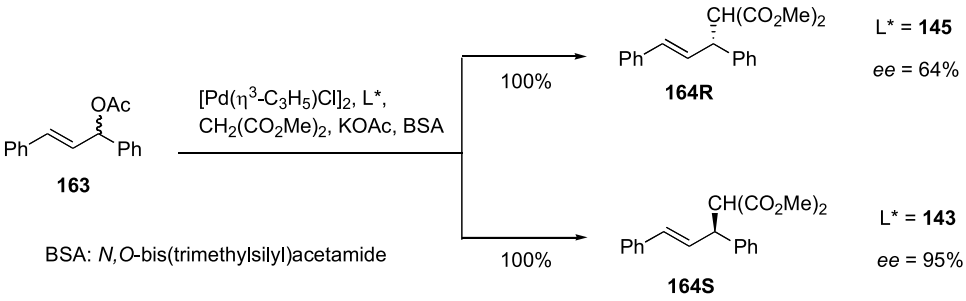
As a surrogate of the hydride-reduction of carbonyl compounds, the transition-metal-catalyzed hydrosilylation of ketones has been actively investigated in current organic synthesis. The Diéguez/Ruiz/Claver group has explored the Rh-catalyzed asymmetric hydrosilylation of ketones [141,151]. As shown in *Scheme 40*, a variety of acetophenones were subjected to $[Rh(\mu\text{-}Cl)COD]_2$-catalyzed hydrosilylation with Ph_2SiH_2 in the presence of a sugar-based chiral ligand. After considerable experimentation, the Diéguez/Ruiz/Claver group found that a novel sugar-based ligand, namely a D-xylofuranose-type thioether-phosphinite **151**, worked well as an effective stereocontrolling element for the aimed hydrosilylation. Using the sugar thioether-phosphinite **151**, various acetophenones **161** were converted to (*R*)-1-arylated ethanols **162** with moderate-to-high enantiomeric excesses after methanolysis of intermediary silyl ethers. A bulky group (*tert*-butyl) on the thioether moiety of the ligand was essential for the realization of the observed high enantioselectivity.

Besides the transition-metal-catalyzed asymmetric addition reactions to prochiral olefins, the substitution reaction of a carbon nucleophile to allylic esters has been investigated using a variety of chiral transition-metal catalysts. Using the aforementioned sugar diphosphites



Scheme 40

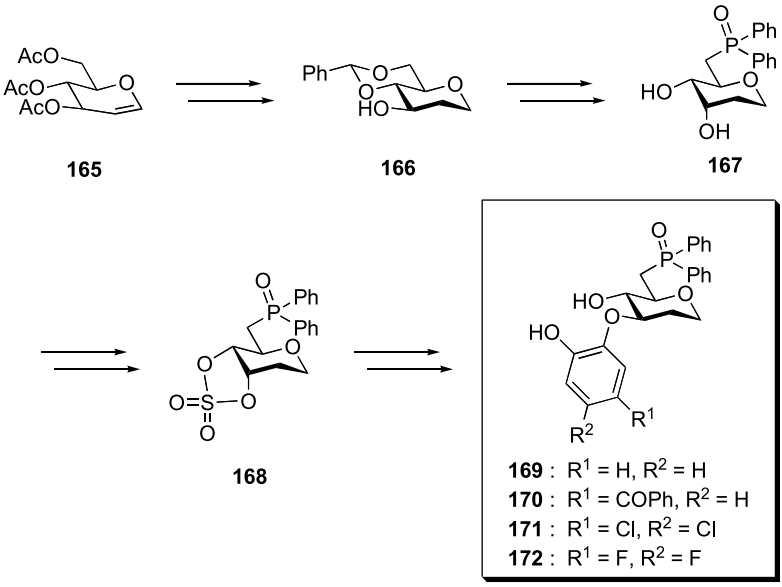
as effective and enantioselective ligands, the Diéguez/Ruiz/Claver group developed highly stereoselective Pd(0)-catalyzed allylic alkylations [136,148,149,152,153]. As shown in *Scheme 41*, racemic 1,3-diphenyl-3-acetoxyprop-1-ene **163** was treated with the anion of dimethyl malonate in the presence of a catalytic amount of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ to produce the desired allylic substitution product **164**. The use of **145** resulted in the preferential formation of (*R*)-enantiomer **164R** with moderate stereoselectivity. On the other hand, the ligand **143** provided the (*S*)-enantiomer **164S** with a high enantiomeric excess of 95%.



Scheme 41

3.3 Studies by the Shibasaki/Kanai Group

Among the sophisticated approaches to the asymmetric synthesis catalyzed by a Lewis acid–Lewis base bifunctional system, the Shibasaki/Kanai group designed and used new sugar-based chiral ligands of metallic catalysts to achieve synthetically important carbon–carbon bond-forming reactions. In 2000, they reported a sugar phosphine oxide prepared from D-glucose, which demonstrated its possible use as a scaffold for the anticipated Lewis acid–Lewis base bifunctional system. Since then, the Shibasaki/Kanai group has actively explored the structural tuning of the original sugar-based ligand, which could result in the improvement of the enantioselectivity of the carbon–carbon bond-forming reactions. Using the modified ligands, the Shibasaki/Kanai group has reported a number of remarkable asymmetric carbon–carbon bond-forming reactions, such as the cyanosilylation of prochiral carbonyl compounds, the Strecker reaction of ketoimines, and the conjugate addition of cyanides to α,β-unsaturated *N*-acylpyrroles. The Shibasaki/Kanai group has utilized some enantiopure products obtained by the attempted asymmetric approaches for the synthesis of pharmacologically important natural products [154,155,156,157,158,159,160,161,162,163,164,165,166,167,168,169,170,171,172,173]. Some of the sugar-based ligands for transition-metal catalysts are shown in *Scheme 42*. The improved and practical synthesis of sugar phosphine oxides **169–172** was started from tri-*O*-acetyl-D-glucal **165**. Via a 4,6-*O*-benzylidene-2-deoxy-1,5-anhydro sugar derivative **166**, a 6-deoxy-6-diphenylphosphine oxide ($P(O)Ph_2$) derivative **167** was obtained by treatment of the 6-*O*-tosyl derivative with Ph_2PK and subsequent oxidation with H_2O_2, followed by formation of the 3-*O*-catechol ether using the 3,4-cyclic sulfate **168**. Some acyl- or halogen-substituted catechols were used for the last S_N2 ring-opening

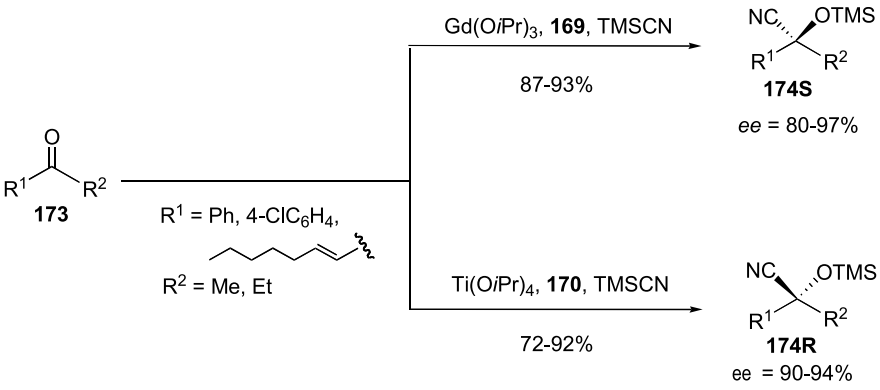


Scheme 42

of the cyclic sulfate **168** [159]. Recently, the synthesis of these ligands from racemic allyl oxirane and 3-butenol, was reported by the Shibasaki/Kanai group using the Trost's asymmetric dihydropyran formation as a key step [169]. Initially, the Shibasaki/Kanai group used the 2,3-diol-6-phosphine oxide derivative as a ligand for cyanosilylation. This type of ligand was less effective for the cyanosilylation of benzaldehyde with TMSCN in the presence of Et_2AlCl [154].

The enantioselective cyanosilylation of a variety of functionalized ketones has been explored using the above ligands in the presence of Al, Ti, Yb, Gd, Sm, La, or Zr-centered organometallic compounds [155,157,158,164]. Such studies included the treatment of aromatic and unsaturated ketones **173**, such as acetophenone, with TMSCN in the presence of a catalytic amount of the Lewis acid–Lewis base bifunctional catalysts prepared from $Gd(OiPr)_3$ and a sugar-based ligand, such as **169** or **170** (*Scheme 43*). Using the chiral catalyst prepared from $Gd(OiPr)_3$ and ligand **169**, trimethylsilylated cyanohydrines with (*S*)-configuration **174S** were obtained with high-to-excellent enantiomeric excesses. On the other hand, the chiral catalysts prepared from $Ti(OiPr)_4$ and other sugar phosphine oxide **170** produced the (*R*)-enantiomers **174R** with excellent enantiomeric excesses.

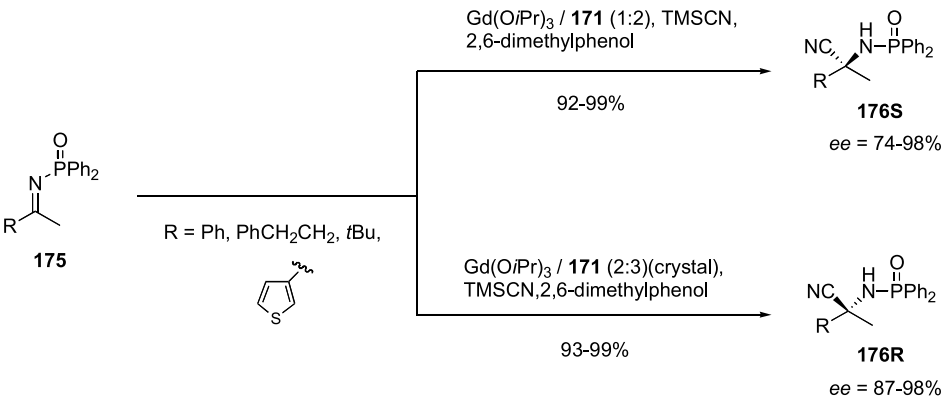
With the establishment of the highly stereoselective cyanosilylation of functionalized ketones using these sugar-based ligands, the Shibasaki/Kanai group applied the developed methodologies to the synthesis of medicinally and biologically important compounds, such as (1) the key intermediate for the (20*S*)-camptothecin family [158,160,164], (2) essential building blocks for the HIV protease inhibitor and bestatin [156], (3) a muscarinic receptor antagonist (*S*)-oxybutynin [161,168], (4) a novel antitumor agent and highly selective serine/threonine phosphatase PP2A inhibitor fostriecin [162], and (5) 2-[(2*R*)-arylmorpholin-2-yl]ethanol, a key intermediate of neurokinin receptor antagonists [163].



Scheme 43

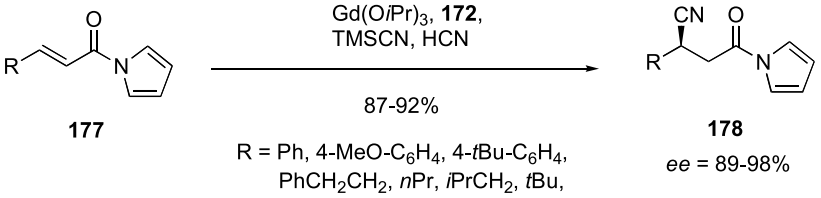
The Shibasaki/Kanai group has explored the catalytic enantioselective Strecker reaction of ketoimines for the extension of utility of the sugar-based ligands [165,166,167]. The products of the attempted Strecker reaction were converted to enantioenriched α-differentially disubstituted amino acids, synthetically valuable building blocks, by conventional functional group manipulation. As shown in *Scheme 44*, under optimized conditions using the Gd(O*i*Pr)$_3$/ligand **171** in a ratio of 1:2 or 2:3, the Strecker reaction of a variety of *N*-diphenylphosphinoyl ketoimines **175** with TMSCN proceeded with high-to- excellent enantioselectivity [173]. Interestingly, the ratio of Gd(O*i*Pr)$_3$ to the ligand governed the sense of enantioselectivity; thus, the 1:2 complex predominantly produced (*S*)-enantiomers **176S**. On the other hand, the 2:3 complex provided the (*R*)-enantiomers **176R** with high-to-excellent enantioselection.

A sugar-based ligand such as **172** served as a promising chiral ligand for the catalytic enantioselective conjugate addition of cyanide to α,β-unsaturated *N*-acylpyrroles as shown in



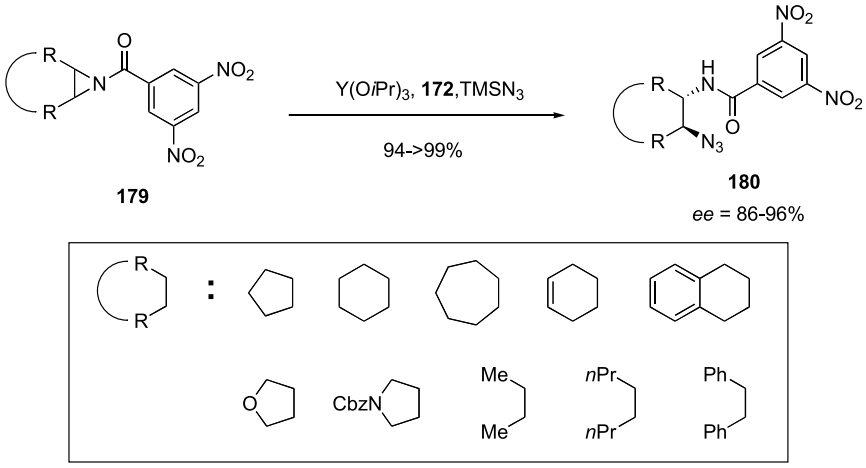
Scheme 44

Scheme 45 [170]. Thus, treatment of several α,β-unsaturated *N*-acylpyrroles **177** with TMSCN/HCN (0.5 or 1:2) in the presence of Gd(O*i*Pr)$_3$/**172** provided β-cyano-β-arylated or β-cyano-β-alkylated *N*-propionyl pyrroles **178** in good yields with excellent enantioselectivities. Some of the 1,4-adducts were efficiently converted to several pharmaceuticals, such as β-phenyl-GABA or (*ent*)-pregabalin.



Scheme 45

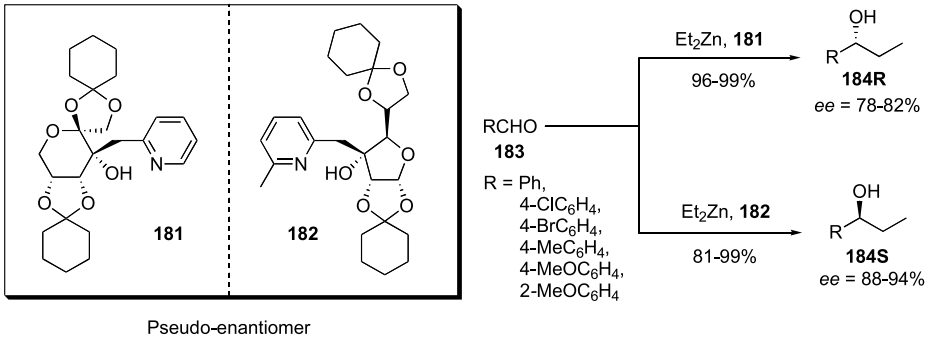
The potential of sugar-based ligand **172** as an enantiocontrolling element for asymmetric synthesis has been recently enhanced by the catalytic asymmetric ring opening of *meso*-aziridines. The results of the Y(O*i*Pr)$_3$/**172**-catalyzed ring opening of *meso*-aziridines **179** in the presence of $TMSN_3$ are shown in *Scheme 46* [172]. Similar to the aforementioned enantioselective reactions, the ring opening reactions proceeded smoothly with high enantioselectivity to produce azide compounds **180**. From one of the ring-opened products, an orally active anti-influenza drug, Tamiflu (oseltamivir phosphate), was prepared.



Scheme 46

3.4 Studies by the Zheng/Chen Group

As a ubiquitous chiral scaffold existing in nature, D-fructose is a readily available sugar, like as D-glucose. Since 2003, Zheng, Chen, and co-workers have investigated the utility of



Scheme 47

D-fructose-derived compounds as efficient chiral ligands for stereoselective carbon–carbon bond-forming reactions [174,175,176,177,178,179]. The remarkable results found by the Zheng/Chen group are summarized below.

The initial achievement was the highly enantioselective addition of diethylzinc to aldehydes, as shown in *Scheme 47* [174,175]. The Zheng/Chen group has developed several novel sugar-based ligands. Two representative new sugar-based ligands **181** and **182** are shown in *Scheme 47*. Ligand **181** was prepared from 1,2:4,5-di-*O*-cyclohexylidene-β-D-fructopyranose via the nucleophilic addition of the lithium anion generated from 2-methylpyridine to the corresponding 3-ulose. On the other hand, ligand **182** was prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose in a similar way to that used for **181**, using the monolithio anion of 2,6-dimethylpyridine instead of 2-methylpyridine. Treatment of a variety of aromatic aldehydes **183** with diethylzinc in the presence of **181** produced (*R*)-adducts **184R** in high yields and with moderate-to-high enantiomeric excesses in all cases. By switching the ligand to **182**, the same addition conditions produced the (*S*)-enantiomers **184S** efficiently. Therefore, ligand **181** and **182** seem to be in a pseudo-enantiomeric relationship. The enantioselective additions of diethylzinc to aliphatic or cinnamyl aldehydes in the presence of **181** produced respective (*R*)-adducts in lower enantiomeric excesses.

In addition, the Zheng/Chen group has studied the usefulness of some sugar monophosphites as efficient chiral ligands for the catalytic asymmetric hydrogenation of prochiral olefins [176,177,178,179]. Some of the sugar monophosphites designed by the Zheng/Chen group are shown in *Fig. 3*. Ligands **185** were prepared from 1,2:4,5-di-*O*-cyclohexylidene-D-fructofuranose via stereoinversion of C-3, followed by phosphite formation at the C-3 hydroxy group with PCl_3 and then optically active BINOL. The ligand **185(*R*)** possesses (*R*)-BINOL, while **185(*S*)** possesses (*S*)-BINOL in their phosphite parts. Other sugar-based ligands, **186(*R*)** and **186(*S*)**, were prepared from 1,2:5,6-di-*O*-cyclohexylidene-α-D-glucofuranose by treatment with PCl_3 and then (*R*)- and (*S*)-BINOL, respectively. Finally, ligands **187(*R*)** and **187(*S*)** were prepared from 1,3:4,6-di-*O*-benzylidene-D-mannitol, a readily supplied sugar alcohol, via selective *O*-methylation and subsequent treatment with PCl_3 and then (*R*)- and (*S*)-BINOL, respectively.

Using these sugar-based ligands, the Zheng/Chen group has explored a variety of asymmetric hydrogenation of prochiral olefins. Three types of hydrogenation examined are

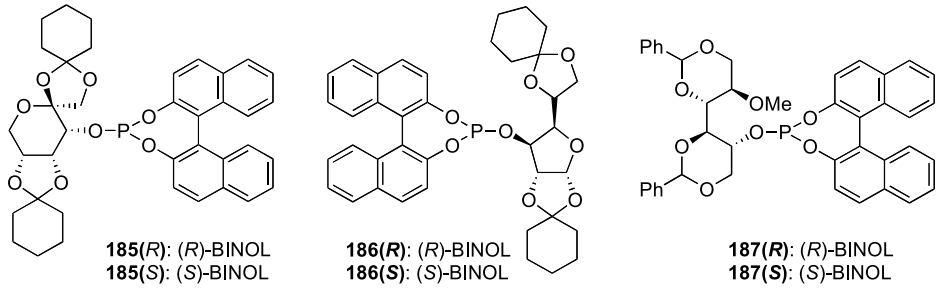


Figure 3
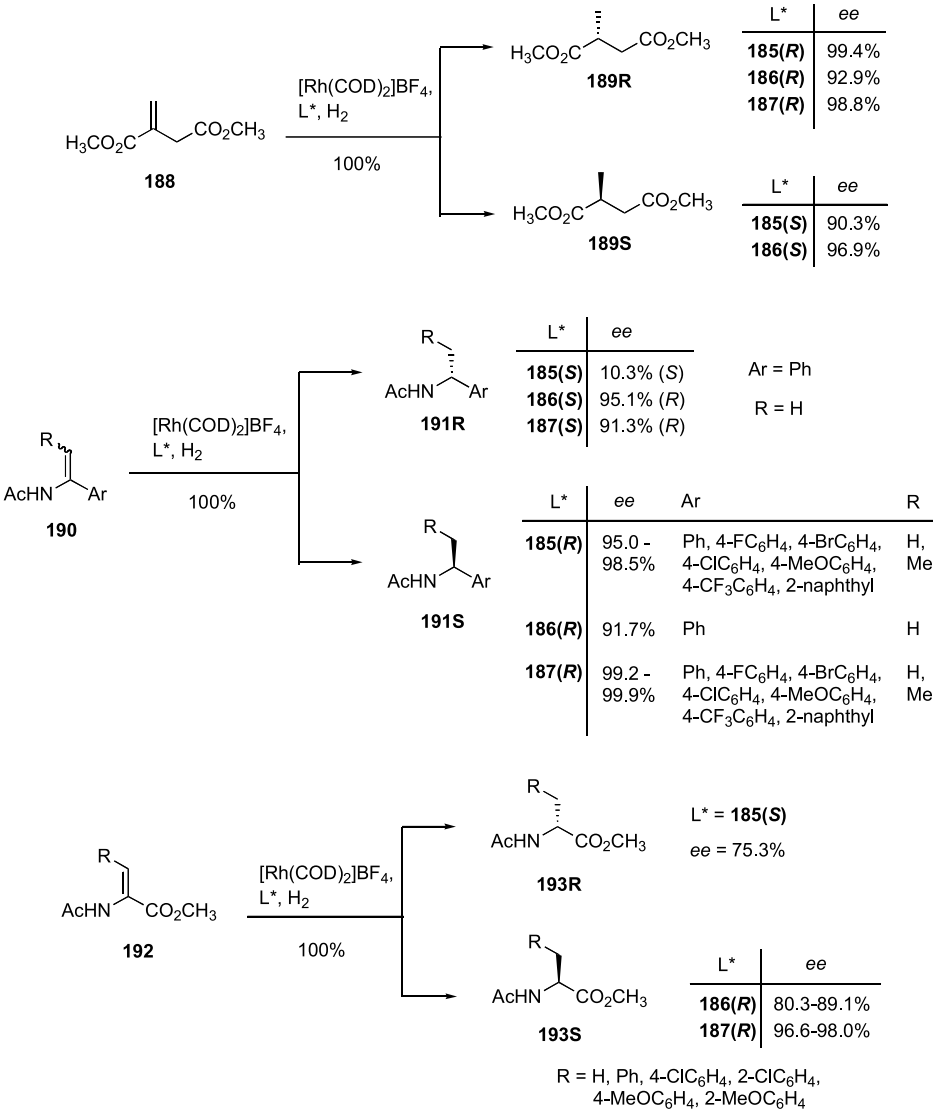
The sugar monophosphinites designed by the Zheng/Chen group

shown in *Scheme 48*. The hydrogenation of dimethyl itaconate **188** in the presence of a transition-metal complex consisting of $[Rh(COD)_2]BF_4$ and ligands carrying (*R*)-BINOL, i. e., **185(*R*)**, **186(*R*)**, or **187(*R*)** produced dimethyl (*R*)-2-methylsuccinate **189R** all quantitatively with excellent enantiomeric excesses. The hydrogenation of **188** in the presence of $[Rh(COD)_2]BF_4$/**185(*S*)** or **186(*S*)** quantitatively produced the (*S*)-enantiomer of **189** with more then 90% ee. Employing the same chiral catalysts **185**–**187**, the hydrogenation of 1,1-disubstituted α-arylenamides [-C=C(NHAc)Ar] **190** was investigated. Except for the case performed in the presence of **185(*S*)**, all ligands produced (*R*)-α-aryl-*N*-acetylalkylamines **191R** or (*S*)-α-aryl-*N*-acetylalkylamines **191S** with excellent enantiomeric excesses. The ligands incorporating (*S*)-BINOL produced **191R**, while those incorporating (*R*)-BINOL produced **191S**. These sugar-based ligands also served as excellent stereocontrolling elements for the Rh-catalyzed asymmetric hydrogenation of β-substituted or unsubstituted α-dehydroamino acids **192**. The results achieved using the same Rh-complex are as follows: (1) ligand **185(*S*)** produced **193R** with moderate enantioselectivity; (2) both **186(*R*)** and **187(*R*)** produced **193S** with moderate-to-excellent enantioselectivity.

3.5 Studies by the Davis Group

Recently, amino sugars such as D-glucosamine derivatives have been studied as sugar-based ligands for transition-metal-catalyzed asymmetric synthesis by Davis and co-workers. The results obtained by the Davis group are summarized below. The amino sugar-based ligands introduced by the Davis group are shown in *Fig. 4*. Ligands **194** to **197** were prepared from methyl 2-acetamino-4,6-*O*-benzylidene-2-deoxy-α- or β-glucopyranoside, readily available from D-glucosamine, via modification of the 2-amino group and stereoinversion of C3 (for **196**, a D-allosamine derivative). Using these ligands, asymmetric diethylzinc addition to aldehydes, asymmetric Reformatsky reactions, and asymmetric alkynylation of aldehydes were explored.

Using these ligands, the Davis group has reported the asymmetric additions of diethylzinc to aromatic aldehydes as the initial exploration of the asymmetric induction realized by amino sugar-based ligands [180]. As shown in *Scheme 49*, three aromatic aldehydes **198** were treated with diethylzinc in the presence of **194** or **195**. The addition products **199** were obtained in



Scheme 48

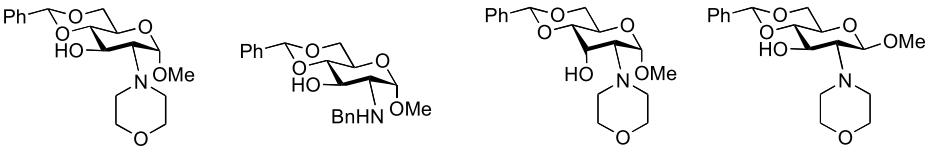


Figure 4

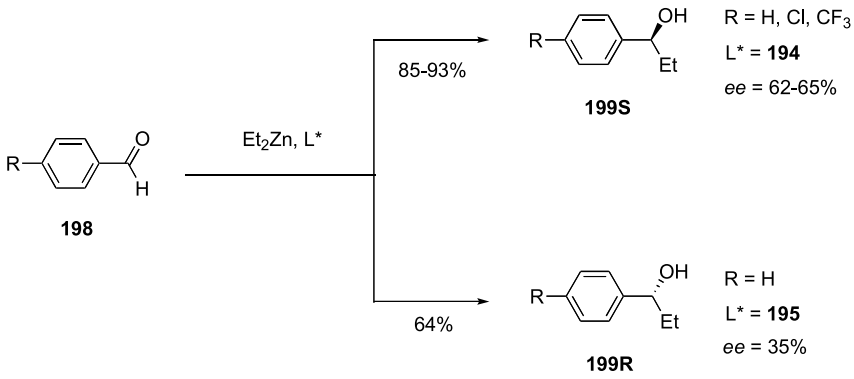
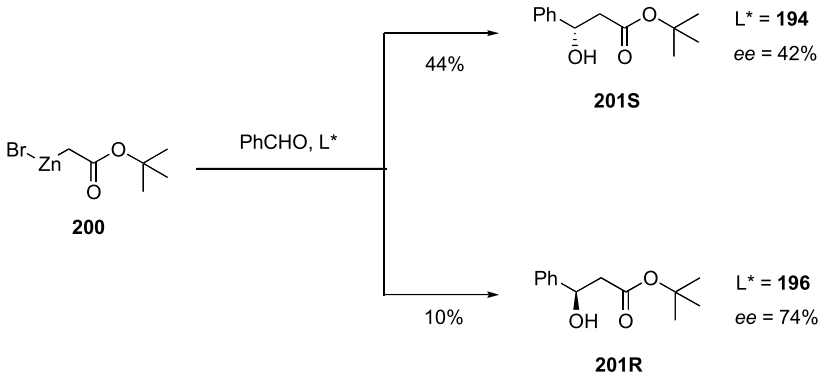


Scheme 49

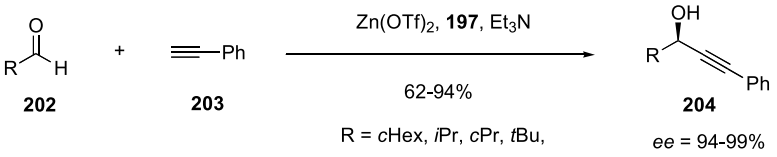
good yields. The enantiomeric excesses observed were not so remarkable in these cases. The major adducts **199S** possess an (*S*)-configuration. On the other hand, the analogous addition reactions using **195** produced the enantiomeric product **199R** as a major product, although neither the yield nor the enantiomeric excess was necessarily useful. The precise mechanistic consideration of the transition-states for these amino sugar-based diethylzinc additions to aldehydes was proposed by the Davis group.

The Reformatsky reaction is one of the promising surrogates of the aldol reaction. The Davis group developed the sugar-based asymmetric Reformatsky reaction for the synthesis of β-hydroxy esters, as shown in *Scheme 50* [181]. Thus, treatment of the *tert*-butyl bromoacetate-derived Reformatsky reagent **200** with benzaldehyde in the presence of **194** provided the desired alcohol **201S** with an (*S*)-configuration in a 42% enantiomeric excess. A similar Reformatsky reaction in the presence of **196** produced the enantiomeric (*R*)-isomer **201R** in improved enantioselectivity. Consequently, the D-glucosamine-type ligand **194** provided the (*S*)-aldol **201S** with a low level of enantioselectivity. On the other hand, the D-allosamine-type ligand **196** provided the (*R*)-aldol in 74% ee but in 10% yield.



Scheme 50

The asymmetric alkynylation of aldehydes is a current highlighted organic synthesis. The Davis group has explored the stereoselective alkynylation of aldehydes using transition-metal complexes incorporating amino sugar-based ligands [182]. As shown in *Scheme 51*, the alkynylation of phenylacetylene **203** with four types of aliphatic aldehydes in the presence of sugar-based ligands was investigated. The most efficient ligand was found to be **197**, a methyl β-D-glucosaminide-type ligand. Using this ligand, the $Zn(OTf)_2$-catalyzed asymmetric alkynylation of aldehydes **202** and phenylacetylene **203** produced propargylic alcohols **204** with excellent enantioselectivity.



Scheme 51

4 Concluding Remarks

As described above, a number of novel sugar-derived compounds as remarkable chiral scaffolds for asymmetric organic reactions have been developed in the past two decades. Various hexofuranose- and hexopyranose-derived templates have been devised as chiral auxiliaries or chiral ligands for transition-metal complexes. Using chiral scaffolds with potentially efficient sugar-derived templates, various asymmetric organic reactions have been realized. Representatives of the asymmetric synthesis achieved using sugar-based chiral auxiliaries are as follows: [3,3]-sigmatropic rearrangement, [2,3]-Wittig rearrangement, α-alkylation of esters, epoxidation of α,β-unsaturated γ-lactones, allylation of imines, 1,4-addition of α-lithiated sulfonates to nitroalkenes, tandem 1,4-addition/α-alkylation, 1,4-radical addition, Strecker reaction, Ugi reaction, Diels–Alder reaction, and 1,3-dipolar cycloaddition. Representatives of the asymmetric synthesis achieved using sugar-based chiral ligands for transition-metal catalysts are as follows: hydrogenation of dehydroamino acids or enamines, hydrocyanation, hydrovinylation, or hydroformylation of functionalized olefins, 1,4-addition of diethylzinc to cyclohexenone, hydrosilylation or cyanosilylation of ketones, allylic alkylation, Strecker reaction of imines, and Reformatsky reaction.

From the current scientific viewpoint, sugars are considered to be prominent biological-functional molecules and have been widely studied in the biosciences. In many cases, the role of sugars as an interface among a variety of biomolecules in living cells has been identified. Most of the synthetic concepts introduced in this chapter rely on the use of monosaccharides to facilitate the recognition of small molecules, such as organometallic species or low-molecular organic substances. It is to be expected that the scientific value of sugar-based asymmetric synthesis will be appreciated through further search for more efficient templates which constitute more effective chiral environments for stereoselective organic reactions.

Chapter-DOI 10-1007/978-3-540-30429-6_24:

Abstract

This review discusses the structural chemistry of metal complexes of carbohydrates and their derivatives with the focus on crystal structure and NMR data of stable solution species. There is evidence that the stability of these complexes is markedly increased when the carbohydrates operate as chelating polyolato ligands, this is, when they are multiply deprotonated polydentate ligands. The 1,2-diolato coordination mode resulting in five-membered chelate rings is most commonly observed. Small torsion angles within the 1,2-diolato moiety enable the chelation of small atoms while larger torsion angles are usually needed for the complexation of large atoms. Hence, as a consequence of the limited flexibility of the pyranose ring, pyranoidic 1,2-diols merely form less-stable complexes with small metal centers in marked contrast to furanoidic 1,2-diols. An additional contribution to the stability arises from hydrogen bonds, especially intramolecular ones, with the deprotonated ligator oxygen atoms acting as strong hydrogen-bond acceptors.

1 Introduction

A central problem in the chemistry of carbohydrates is their polyfunctionality which usually leads to several possible coordination sites for metal atoms. As a consequence, in basic research the carbohydrates are often replaced by model ligands of reduced functionality in order to investigate the structure of carbohydrate–metal complexes. The most reliable structural information about solution and solid-state species is obtained by NMR spectroscopy and X-ray structure analysis of single crystals, respectively, both methods having developed significantly in the last years. Hence, we will focus on the structures of carbohydrate–metal complexes based on unambiguous data obtained by these two methods. The following carbohydrates and carbohydrate derivatives are included in this review: sugar alcohols, aldonic and

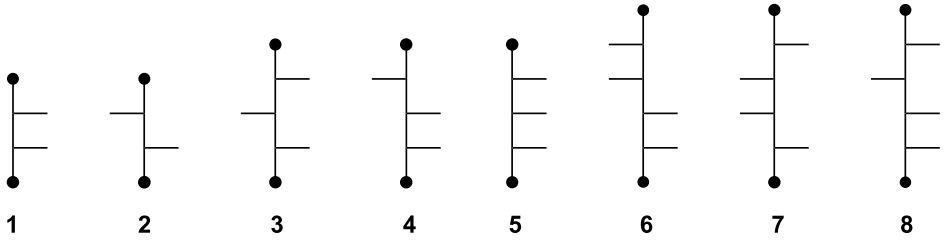
aldaric acids, anhydroerythritol, inositols, anhydro-sugars, glycosides, and reducing carbohydrates such as aldoses, ketoses, and glycuronates. Among the glycosides, the pyranosides and furanosides (mostly alkyl derivatives), nucleosides, non-reducing disaccharides, cyclodextrins, and polysaccharides are viewed. The nucleosides are the only non-*O*-glycosides considered in this review. Structures of simple addition products of carbohydrates and metal salts are not included either. Structures which should be included in this review, according to the requirements stated above, but have been reviewed elsewhere already, will mostly not be discussed again. Publications written in Chinese, Japanese, or Russian are not cited herein.

A summary of the historical development of reviews regarding carbohydrate–metal complexes can be found in a review written by Verchère et al. in 1998. Besides NMR and crystal structure data, they also consider other methods such as calorimetry and EXAFS spectroscopy [1]. Here a short listing of a selection of reviews written in the ensuing years: Complexes of the metals nickel(II), cobalt(III), and manganese(II,III) with *N*-glycosides derived from tris(2-aminoethyl)amine and aldoses have been reviewed by Yano [2] who has also written a summary on the structure and biological activity of complexes of transition metals with glycosylamines derived from sugar molecules and polyamines [3]. Nagy et al. discuss the coordination equilibria of carbohydrate–metal complexes in aqueous solution together with crystal structures [4,5] and summarize the application of EXAFS and XANES methods in the coordination chemistry of carbohydrates [6]. Solid-state and solution complexes with platinum-group metals are reviewed by Steinborn and Junicke [7]. The coordination chemistry of modified carbohydrates has been summarized by Alexeev et al. in two reviews [8,9]. The kinetics of proton-release reactions of aluminum(III) complexes with D-ribose and their stability has been reviewed by Petrou [10]. Chakravorty et al. describe heteroleptic vanadate chelate esters of monoionized diols and carbohydrates with tridentate auxiliary ligands [11]. The formation and the synthetic applications of carbohydrate-iron complexes possessing Fe–C bonds are discussed by Zamojski [12]. The metallation sites of nucleosides and nucleotides in ternary systems with polyamines has been summarized by Lomozik [13]. The metal complexation of oligo- and polysaccharides has also been reviewed. Metal-containing supramolecular catalytic systems may be achieved based on cyclodextrins and their derivatives (“cavitand” ligands) [14,15,16]. The metal-binding ability of chitosan under various conditions is discussed by Varma et al. [17].

In order to elucidate the coordination chemistry of individual carbohydrates, the following review will be carbohydrate-oriented instead of metal-oriented, that is, the structures of individual carbohydrates or, if only few structures are known, of a group of related carbohydrates are discussed en-block. We will start with complexes of simpler carbohydrates such as sugar alcohols or anhydroerythritol in order to derive the basics of metal coordination and will then proceed to typical carbohydrates.

2 Sugar Alcohols

The solution and solid state structures of the following sugar alcohols are discussed in separate sections: erythritol **1**, D-threitol **2**, xylitol **3**, D-arabitol **4**, ribitol **5**, D-mannitol **6**, dulcitol **7**, and D-sorbitol **8**.



Carbon numbering: C1 is situated at the top of each chain. ● = CH_2OH
Chiral sugar alcohols are depicted in their D-configuration.

2.1 Erythritol

Erythritol **1** is a tetraol with a central *erythro*-configured diol group. In combination with the terminal hydroxyl functions there are several conformations to act as a chelate ligand. In most of its characterized solid-state structures, erythritol is coordinated to two central atoms by acting as a bis-1,2-diolato ligand, at which the deprotonation of the hydroxyl groups is a consequence of the synthesis from alkaline solutions and/or complexation of more or less Lewis acidic central atoms. A complex of this type is obtained upon the reaction of erythritol with two equivalents of $[(NH_3)_2Pd(OH)_2]$ in aqueous solution which leads to the centrosymmetric structure of **9** (❯ *Fig. 1*) [18].

In **9**, the C_4 chain of erythritol adopts a zigzag conformation with a torsion angle of 180° which is as much forced by the inversion symmetry of the complex as is the torsion angle of the central *erythro*-diolato group (180°). The terminal oxygen atoms are oriented to the same side of the C_4 chain as their adjacent *erythro*-oxygen atoms. The torsion angle of the resulting chelating diolato group is 46.2°. The solutions mentioned above contain **9** as the main species which is confirmed by a downfield shift ("coordination induced shift", CIS) of about 12 ppm of the carbon atoms involved in the five-membered chelate ring. The asymmetric monometallated complex **11** which might be stabilized by an intramolecular γ hydrogen bond (the donor and acceptor oxygen atoms are separated by a C_3 chain), is detected as a byproduct whereas **11** becomes the main species and **9** a byproduct in equimolar solutions of erythritol

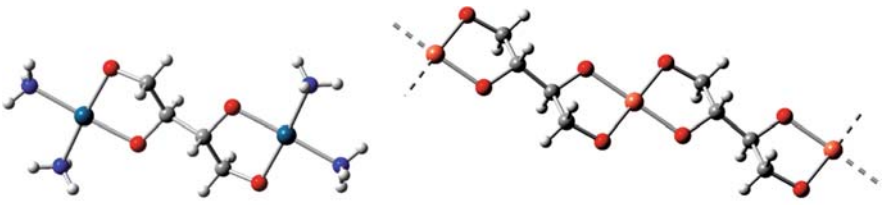


Figure 1
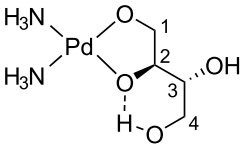
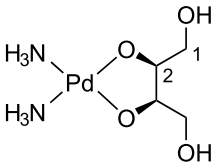
Molecular structure of $[\{(NH_3)_2Pd\}_2(ErytH_{-4})]$ 9 in crystals of $9 \cdot 2\ H_2O$ and a section of the linear coordination polymer built up by $[Cu(ErytH_{-4})]^{2-}$ 10 units in crystals of $Na_2$10 · Eryt · $12\ H_2O$

and $[(NH_3)_2Pd(OH)_2]$ (CIS of the chelating carbon atoms 1 and 2 in **11**: 10.9 and 9.8 ppm, respectively, non-chelating carbon atoms 3 and 4: 0.9 and 1.0 ppm, respectively). A minor species of these equimolar solutions is the symmetric monometallated complex **12** (C1 CIS: −0.9 ppm, C2 CIS: 10.0 ppm).



11



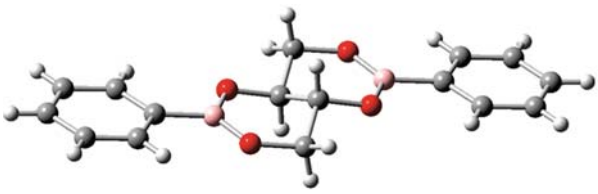
12

A similar species distribution is found for $[(en)Pd(OH)_2]$/erythritol solutions, and a crystal structure containing a binuclear complex analogous to **9** has been determined [19]. A solid-state structure of this type is also formed by ethylenediamine-copper(II) [20]. In strong alkaline aqueous solutions, the ethylenediamine-copper bond is cleaved and the formation of homoleptic complexes such as the linear coordination polymer **10** (◉ *Fig. 1*) is enabled [21].

The reaction of $(dppp)Pt(CO_3)$ with four equivalents of erythritol produces the (dppp)Pt derivative of **11** as the major species, while the corresponding *erythro*-derivative **12** is obtained in small yield only (11%) [22].

While palladium(II) and copper(II) build solely 1,2-diolato complexes with erythritol which leads to five-membered chelate rings, boron(III) is involved in the six-membered rings as in the bis(phenylboronic acid ester) **13** (◉ *Fig. 2*). Erythritol adopts a zigzag conformation similar to that in **9** but the oxygen atoms are grouped alternatively on opposite sites of the C_4-chain. The six-membered chelate rings in half-chair conformation provide a suitable bond pattern for a boron center involved in the delocalized π-bond system of the phenyl substituent.

In solution, **13** is merely a minor species which is identified by a significant difference in the chemical shifts of its two symmetrically independent erythritol-C atoms: the terminal carbon atom is shifted by 2.8 ppm downfield while the inner carbon atom which is involved in two chelate rings is shifted by 2.8 ppm upfield. Most of the phenylboronic acid is bound in five-membered chelate rings similar to **9** (^{13}C shifts: 5.3 ppm for terminal C atoms, 6.5 ppm for inner C atoms) [23].



13

14

◘ Figure 2
The crystal structure of $(PhB)_2(ErythH_{-4}$-$O^{1,3},O^{2,4})$ 13 and the molecular structure of $[Mo_2O_5(ErythH_{-4})]^{2-}$ 14 in crystals of $[N(n\text{-}Bu)_4]_2$14

In order to group all its hydroxyl functions on the same side of the C_4 chain, erythritol has to adopt a sickle conformation which is established as in the dimolybdate complex **14** (*Fig. 2*). The torsion angle of the C_4 chain is 49.5°, the torsion angle of the central *erythro*-configured diol function is 34.4°. The sickle conformation allows the asymmetric facial coordination of two molybdenum centers with one terminal and one inner alkoxido function in a bridging mode. A dimolybdate complex with only triply deprotonated erythritol has been crystallized from more acidic solutions. The structure largely resembles the one in **14**, but the remaining proton at the bridging terminal hydroxyl function causes markedly increased Mo–O distances of 2.50 and 2.53 Å (in **14**: 2.27 and 2.29 Å [24]. NMR experiments reveal that the dimolybdate structure is retained in solution. All carbon atoms show a more or less strong downfield shift ($\Delta\delta$ between 6.6 and 18.5 ppm) [25,26]. Similar shifts are obtained for a ditungstate complex ($\Delta\delta$ between 6.1 and 18.1 ppm) whose asymmetry could be additionally characterized by the existence of two different ^{183}W signals [27]. The sickle conformation is also adopted by doubly and triply deprotonated erythritol in a Fe_{14} oxocluster which is stabilized by calcium(II) ions (torsion angles: 49.0°, 47.2° (C_4 chain), 44.2°, 48.7° (*erythro*-diol)) [28].

2.2 Threitol

Threitol **2** is a tetraol with a central *threo*-configured diol group. While erythritol has to adopt a sickle conformation in order to locate all its oxygen atoms on the same side of the C_4 chain, threitol attains this in its zigzag conformation.

In **15** and **16** (*Fig. 3*), the zigzag conformation of L-threitol comes along with an approximately parallel alignment of the planes of carbon and oxygen atoms, respectively. The torsion angle of the C_4 chain is about 170° and the oxygen atoms occupy the corners of a rhomb.

Fourfoldly deprotonated L-threitol acts as a bis-1,3-diolato ligand in the V-shaped bis(phenylboronic acid ester) **15** (*Fig. 3*), while the *erythro*-configured erythritol leads to the planar ester **13** (*Fig. 2*). The significant CIS of the carbon atoms in **13** was also detected in solutions of **15** (2.1 ppm (terminal C), −5.9 (inner C)), however, 1,2-diolato species could not

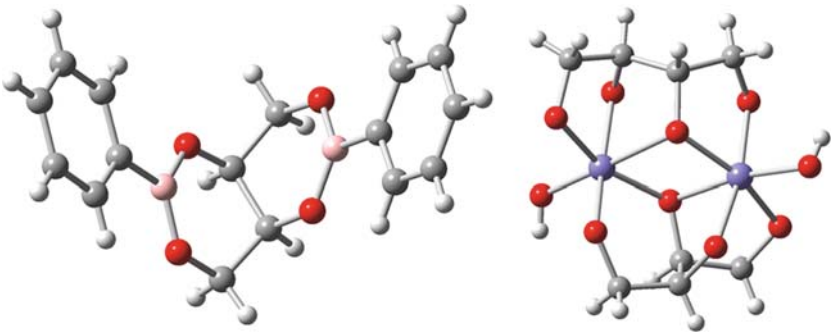


Figure 3
The crystal structure of $(PhB)_2$(L-ThreH$_{-4}$-$O^{1,3},O^{2,4}$) 15 and the molecular structure of $[Fe_2$(L-ThreH$_{-4})_2(OH)_2]^{4-}$ 16 in crystals of $Ba_2$16 · 12.5 H_2O

be ascertained [23]. A structure of the type of **15** was also obtained with the bis(3,4-dibromomethyl) derivative of phenylboronic acid [29]. Five-membered chelate rings are described in the homoleptic borate ester **17** with doubly deprotonated D- and L-threitol in which the deprotonation occurs at the chelating central *threo*-configured diol group. Depending on the involved enantiomeric pairs of threitol (**17** presents the (*R*,*R*)-(*R*,*R*) form), three different complexes are formed. The CIS of the *threo*-C atoms are reported with 3.3 and 3.4 ppm, the terminal C atoms show a smaller CIS of 0.8 and 1.5 ppm [30].

In the sandwich-type complex anions **16** (● *Fig. 3*), eight out of ten oxygen atoms for the formation of an edge-sharing $(FeO_5)_2$-dioctahedron are provided from two fourfoldly deprotonated L-threitol ligands which show manifold complexing abilities. One of the *threo*-configured oxygen atoms of the two ligands is in the μ_2 mode, the others bind to one iron(III) center only. Both of the threitolato ligands act in the *fac*-1,2,3-triolato mode; additionally one acts as a 1,2-diolato and one as a 1,3-diolato ligand. The O–O distances in the chelate rings vary between 2.65 Å (five-membered ring) and 2.95 Å (six-membered ring). The O–C–C–O torsion angles are between 35° and 50° [31].

A more bent zigzag chain with a C_4 torsion angle of about 104° is present in the dinuclear C_2-symmetric rhenium(I) complex anion **18** (● *Fig. 4*). The terminal oxygen atoms of triply deprotonated L-threitol are in a bridging mode whereas the terminal oxygen atoms bind to one center only. A very short intermolecular distance between the latter non-bridging oxygen atoms of just 2.36 Å indicates a strong hydrogen bond between them and thus only triply deprotonated L-threitol is present. The torsion angle of the central *threo*-configured diolato group is 133.4°, the terminal diolato groups form torsion angles of about 56°. This complex has also been found in aqueous solution as well as in acetonitrile at a Re:L-Thre ratio of 2. The latter solution contains a minor trinuclear species which becomes the main species upon the addition of methanol and a Re:L-Thre ratio of 3. Deduced from a trinuclear complex with triply deprotonated glycerol, triply deprotonated L-threitol is expected to be in a μ_3 mode [32].

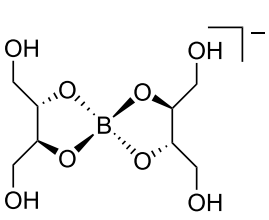
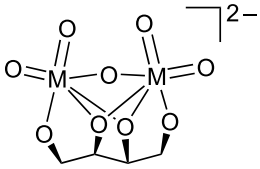
With rubidium as the counterion, a mononuclear, approximately C_2-symmetric homoleptic silicate complex anion **19** (*Fig. 4*) is formed by three L-threitolato ligands which are deprotonated at their central *threo*-configured chelating hydroxyl functions. The three polyols adopt two different conformations. Two ligands use their non-deprotonated hydroxyl functions to act as donors in intramolecular hydrogen bonds with deprotonated hydroxyl functions as acceptors. The acceptor functions of the two remaining deprotonated hydroxyl groups are used in hydrogen bonds to two water molecules. The third threitolato ligand adopts a conformation with a torsion angle of the C_4 chain of 95.1° which is significantly smaller than those observed for the other two ligands (144.6° and 136.2°, respectively). With cesium as counterion, a D_3-symmetric threitolato silicate anion $[\Lambda\text{-Si(D-Thre2,3H}_{-2})_3]^{2-}$ is obtained with all terminal hydroxyl groups being involved in intramolecular hydrogen bonds of the type in **19**. The torsion angles of the chelating *threo*-configured diolato group is in the range of 17–24° causing a bite of about 2.5 Å [33].

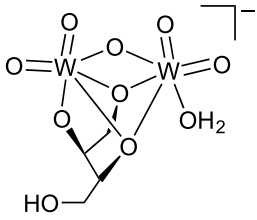


17



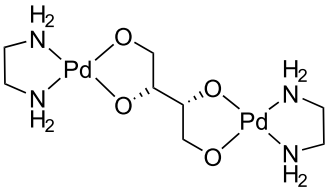
20

M = Mo,W

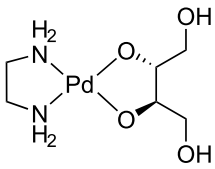


21

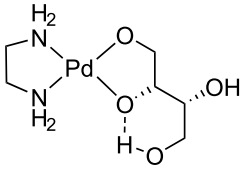
D- and L-threitol have been shown to form the C_2-symmetric dimolybdate **20** in which each molybdenum is facially coordinated by a 1,2,3-triolato group. The CIS of the *threo*-configured carbon atoms is reported with 9.8 ppm, the terminal carbon atoms have a CIS of 12.2 ppm [25,27]. This type of complexation is confirmed in a crystal structure with L-dithiothreitol as ligand [34]. The type of ditungstate complex formed with D- and L-threitol proves to be pH-dependent. At pH 7, the C_2-symmetric ditungstate **20** is formed (CIS *threo*-C: 9.2 ppm, terminal C: 10.5 ppm), while at pH 8–9 the asymmetric ditungstate **21** dominates. One terminal hydroxyl function is not involved in the complexation (CIS 1.8 ppm) while the other one now is in a bridging mode (CIS 9.5 ppm) together with one of the *threo*-configured hydroxyls (CIS 9.4 ppm). The second *threo*-configured hydroxyl is bound to one tungsten solely (CIS 13.1 ppm) [27,35].



22



23



24

$[Pd(en)(OH)_2]$ forms the solution species **22**–**24** with D-threitol with the species distribution strongly depending on the Pd:D-threitol molar ratio. In 1:1 solutions **23** is the main

species besides a minor fraction of **24**. Obviously the formation of chelate rings with a *threo*-configured diol group is more favored above an *erythro*-diol chelate formation such as in **12**, which was merely a minor species in the corresponding erythritol solutions. In 3:1 solutions the dimetallated complex **22** and the monometallated complex **23** coexist as main species [19]. Two monometallated products in the molar ratio of 3:2 are reported for the reaction of (dppp)Pt(CO_3) with four equivalents of *rac*-threitol. The major part corresponds to the (dppp)Pt-derivative of the*threo*-complex **23**, while in the minor part the terminal diol is coordinated similarly to **24** [22].

2.3 Xylitol

Xylitol **3** is a non-chiral, all-*threo*-configured pentitol which allows grouping of all its hydroxyl functions on the same side of the C_5 chain with a zigzag conformation. In the dinuclear cobalt(III) complex **25** (*Fig. 5*) two entirely deprotonated zigzag conformers provide a proper O_{10} set of an edge-shared Co_2O_{10} dioctahedron, whereas in the similar diferrate(III) **16** (*Fig. 3*) with the smaller all-*threo* configured L-threitol, two hydroxyls are required to complete the dioctahedron [36].

Fourfoldly deprotonated xylitol acts as a bis-1,2-diolato ligand in the dinuclear palladium(II) complex **26** (*Fig. 5*). The remaining terminal hydroxyl function is employed in a short intramolecular δ hydrogen bond. The enhanced stability thereby makes **26** the dominating species in [Pd(en)$(OH)_2$]/xylitol solutions of the molar ratio 3:1 and even 2:1, whereas in the corresponding 3:1-solution with D-threitol the dimetallated species and the monometallated species **12** are formed in approximately equal amounts. The main species in equimolar solutions of [Pd(en)$(OH)_2$] and xylitol is the monometallated, *threo*-chelate complex [Pd(en)(Xylt2,3H_{-2})] which is the hydroxymethyl homolog of the predominant [Pd(en)(Thre2,3H_{-2})] complex. The isomeric complex with a terminal chelate formation, [Pd(en)(Xylt1,2H_{-2})], is formed in small amounts only [19].

From solutions of (dppp)Pt(CO_3) and xylitol in a molar ratio of 1:4 two monometallated species are obtained. The formation of the 2,3-*threo* bound isomer (86%) is significantly preferred over the 1,2-terminal bound isomer (14%) [22].

Three doubly deprotonated xylitol molecules act as 1,2-diolato ligands in the hexacoordinate silicate $[Si(Xylt2,3H_{-2})_3]^{2-}$ **27** (Fig. 6) which is the hydroxymethyl derivative of the threitolato complex **19** (Fig. 4) and, as a consequence, shows the same stabilizing intramolecular hydrogen bonds [33].

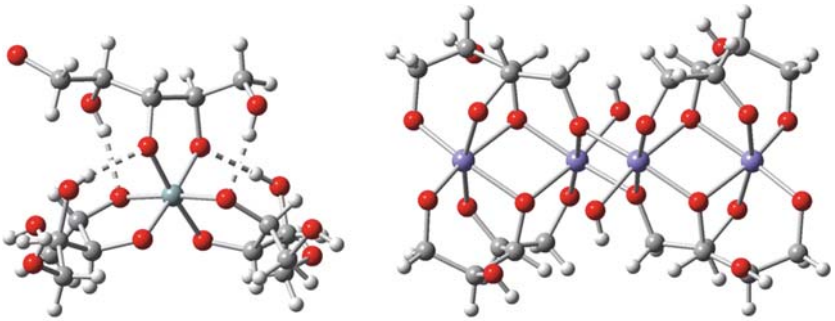

Figure 6
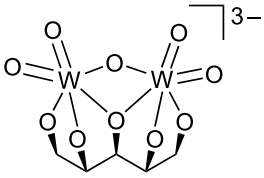
The molecular structures of $[Si(Xylt2,3H_{-2})_3]^{2-}$ 27 in crystals of Cs_2 27 · 2 H_2O and $[Fe_4(rac\text{-}Arab1,2,3,5H_{-4})_4(OH)_2]^{6-}$ 29 in crystals of $Sr_4$29(CO_3) · 33 H_2O. *Dashed lines*: hydrogen bonds

A hydroxymethyl derivative of the threitolato dimetallates **20** is also formed with the higher homolog xylitol, whereas the ditungstate proves to be stable at pH 7. At pH 8–9 xylitol acts as chelating ligand using its secondary hydroxyl functions similarly to **21**, while the primary hydroxyl functions are not employed for metal coordination.



28

In the pH range of 9–12 the ditungstate **28** is formed with an entirely deprotonated xylitol exhibiting the same coordination pattern as in **25** (Fig. 5): both metal centers are facially coordinated with the central alkoxido function in the μ_2 mode [25,26,27,35].

2.4 Arabitol

Arabitol **4** is a chiral pentitol bearing a *threo*- as well as an *erythro*-configured diol group. The centrosymmetric, tetranuclear ferrate(III) **29** (Fig. 6) consisting of four edge-sharing FeO_6-octahedrons is formed by four fourfoldly deprotonated *rac*-arabitols in a conformation which enables coordination to the iron(III) centers with the terminal and the *threo*-configured oxygen atoms. The coordination sphere of the inner two iron centers is completed by a hydroxide lig-

and each—a structural feature adopted by the closely related threitolato complex **16** (◉ *Fig. 3*) as well [31].

A comparison of the structures **29** (◉ *Fig. 6*) and the palladium(II) complex **30** (◉ *Fig. 7*) clarifies the flexibility of arabitol to adopt a conformation which satisfies the structural requirements of the metal centers: in **29**, arabitol acts as a 1,3-diolato ligand and as a 1,2,4 triolato ligand with C3 in a μ_2 mode to achieve an octahedral coordination geometry, while D-arabitol acts as a bis-1,2-diolato ligand in **30**. The diolato moieties are *erythro*-linked, hence **30** could be considered a hydroxymethyl-Pd(en) derivative of **9** (◉ *Fig. 1*), with the hydroxyl forming a stabilizing intramolecular γ hydrogen bond. This species is also predominant in [Pd(en)$(OH)_2$]/D-arabitol solutions with excess [Pd(en)$(OH)_2$] and still is a minor species in equimolar solutions. Those contain the *threo*-complex [Pd(en)(D-Arab2,3H_{-2})] as the only monometallated species [19].

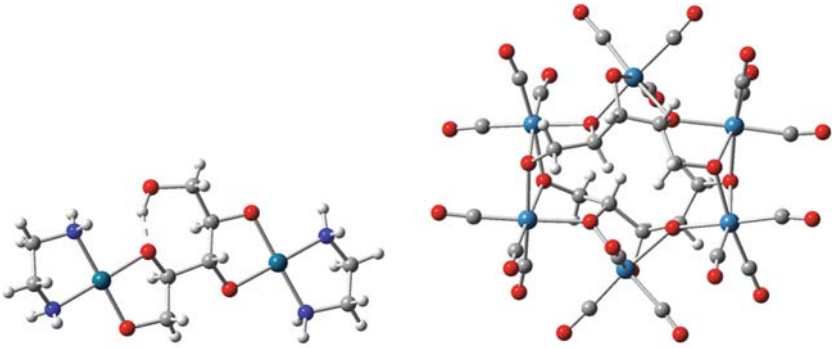


Figure 7
The molecular structures of $[Pd_2(en)_2$(D-Arab1,2;3,4H_{-4})] 30 in crystals of 30 · 7 H_2O and $[Re_6(CO)_{18}$(D-ArabH_{-5})$_2]^{4-}$ 31 in crystals of $(NEt_4)_2(DBUH)_2$31. *Dashed line*: hydrogen bond

Two entirely deprotonated D-arabitol ligands are employed to connect the $Re^{I}(CO)_3$ centers in the hexanuclear cluster **31** (◉ *Fig. 7*). All but the central alkoxido function at C3 are in a bridging mode [32].

The dimolybdates and ditungstates found with arabitol are closely related to the complex anions **14** and **21**. Two dimolybdates are formed with D-arabitol ligands which adopt a sickle conformation with their *erythro*-configured end as in **14** (◉ *Fig. 2*), this is the C_4 chain from C2 to C5, in each case. The isomers differ in the coordination pattern: one isomer has C2 and C4 in the μ_2 mode, the other one C3 and C5 [25]. These isomers are the main species with tungsten(VI) as well, but a minor species is additionally formed in which the *threo* end of D-arabitol, this is C1 to C3, is used for complexation closely related to **21** [26,37].

2.5 Ribitol (Adonitol)

Ribitol **5** is a completely *erythro*-configured pentitol. No crystal structure analyses of a ribitol complex have been reported so far. However, solution studies have been performed with palladium(II) and with molybdenum(VI) and tungsten(VI).

Studies with palladium(II) revealed that in [Pd(en)$(OH)_2$]/ribitol solutions with a molar ratio of 3:1 or 2:1 the dimetallated complex [Pd_2(en)$_2$(Ribt1,2;3,4H$_{-4}$)] is formed as main species. The remaining terminal hydroxyl function is employed in an intramolecular δ hydrogen bond to O2 causing the enhanced stability compared to the minor, bis(terminal) species [Pd_2(en)$_2$(Ribt1,2;4,5H$_{-4}$)]. The monometallated terminal complex [Pd(en)(Ribt1,2H$_{-2}$)] is the main species in equimolar solutions. The detection of the isomeric complex [Pd(en)(Ribt2,3H$_{-2}$)] as a minor species gives reason to state that terminal chelation in *erythro* polyols is more favorable than a chelation with two adjacent secondary hydroxyl functions [19]. This is confirmed by the observation that (dppp)Pt^{2+} forms the terminal 1,2-diolato complex with ribitol with marked excess compared to the 2,3-*erythro* bound isomer (molar ratio 83:17, respectively) [22].

Molybdenum(VI) and tungsten(VI) are found to form only one of two possible isomeric *erythro*-type dimetallates analogously to **14** (◉ *Fig. 2*) with fourfoldly deprotonated ribitol. One of the terminal hydroxyl functions is not part of the coordination site. Even the formed isomer proves to have low stability due to unfavorable steric interaction between the terminal carbon atoms of the sickle conformer [25,26,37].

2.6 Mannitol

D-Mannitol **6** is a chiral hexitol having two terminal *erythro*-configured diol groups and a *threo* link between them.

Aqueous solutions containing [Pd(en)$(OH)_2$] and D-mannitol in a molar ratio of 3:1 or 2:1 yield the dinuclear complex **32** (◉ *Fig. 8*) as main species. The structure corroborates earlier described preferences of Pd(en) in sugar alcohol complexes: the complexation occurs at two *erythro*-linked diol groups, one of which is *threo*-configured, the other one a terminal diol function. A δ hydrogen bond of the type O–H···O^- similar to those in **26** (◉ *Fig. 5*) and **30** (◉ *Fig. 7*) stabilizes the complex, while the remaining terminal hydroxyl function is not involved in intramolecular hydrogen bonding. In 3:1 solutions this hydrogen bond is cleaved to an observable extent as the minor, trimetallated species [Pd_3(en)$_3$(D-Mann1,2;3,4;5,6H$_{-6}$)] is formed. Besides **32** (◉ *Fig. 8*), two mononuclear, *threo*-coordinated complexes are observed in equimolar solutions: [Pd(en)(D-Mann1,2H$_{-2}$)] and [Pd(en)(D-Mann3,4H$_{-2}$)]; *erythro* coordination is not detected [19].

A more complex intramolecular hydrogen bond system is built in the platinum(II) complex **33** (◉ *Fig. 8*) in which the central *threo*-configured diol is the chelation site. A γ and a δ hydrogen bond, each starting at one of the terminal donor hydroxyl functions, end at one and the same alkoxido function. The other one is an acceptor in a more strained β hydrogen bond [22].

Affirmed by DFT calculations, the completion of an octahedral coordination sphere of trimethyl-platinum(II) in a dinuclear complex is accomplished with facial tridentately bonded D-mannitol (coordination mode: μ-κ^3O^1,O^2,O^4:κ^3O^3,O^5,O^6) [38].

In **34** (◉ *Fig. 9*), the silicon center is hexacoordinated through three central, *threo*-configured diol groups. The adjacent hydroxyl functions at C2 and C5 form stabilizing intramolecular hydrogen bonds similar to **19** (◉ *Fig. 4*) and **27** (◉ *Fig. 6*) [33].

Bonding through terminal- and *threo*-configured diol groups, which are *erythro*-linked, is observed in the tris(phenylboronic acid) ester **35** (◉ *Fig. 9*) while six-membered chelate rings

were formed with erythritol and L-threitol in **13** (● *Fig. 2*) and **15** (● *Fig. 3*), respectively [39]. Van Bekkum et al. suggest the formation of boron-mannitol monoester through bonding via the *erythro*-configured O2,O3 diol as well as via the *threo*-configured O3,O4 diol. The latter configuration is existent solely in the diester [30,40].

Two crystal structures of dimolybdates with different cations have been described. Both are of the type of **36** (● *Fig. 10*) and could be considered a dihydroxyethyl derivative of the erythritol complex **14** (● *Fig. 2*), whereas D-mannitol is only triply deprotonated in **36** similarly to an erythritol complex described above [24,41,42]. The structure of **36** (● *Fig. 10*) is retained in solution in two isomeric forms for molybdenum as well as for tungsten in a way similar to D-arabitol whose configuration matches the one of the coordination site of D-mannitol [25,26,37,43].

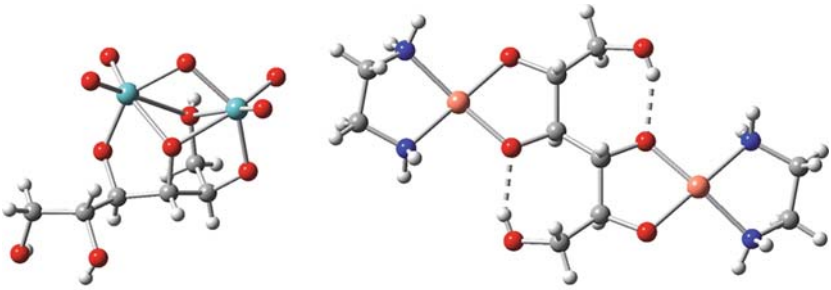

Figure 10

2.7 Dulcitol (Galactitol)

Dulcitol **7** is a non-chiral hexitol with two *threo*-configured diols linked by a central *erythro*-configured diol group. To emphasize the analogies in the coordination patterns, dulcitol may be regarded as a 1,4-di(hydroxymethyl) derivative of erythritol **1**. Ethylenediamine-copper(II), for example, is found to form the dinuclear complex **37** (*Fig. 10*) which contains an erythritol substructure described above. The terminal hydroxymethyl groups form intramolecular δ hydrogen bonds resulting in an enhanced rigidity of the now *S*-shaped dulcitol [44]. This structural motif is found in several dulcitolato complexes of copper(II), nickel(II), and palladium(II). The strength of the established hydrogen bonds and thus the distances between the corresponding donor–acceptor pairs are basically a consequence of the Lewis acidity of the bonded metal-ligand fragment. In **37** the O–O distance is 2.53 Å while with the less Lewis-acidic $(tren)Ni^{2+}$ and $(Me_3tren)Ni^{2+}$ residues this distance is shortened to about 2.45 Å and 2.42 Å respectively [44]. In the copper-dulcitol compounds **37** (*Fig. 10*) as well as in the linear coordination polymer comprising the substructure **10** (*Fig. 1*) the donor–acceptor distances are about 2.62 Å [21].

Just a few species have been detected in solutions with ethylenediamine-palladium(II) at various Pd:dulcitol ratios. The only monometallated complex in equimolar solutions is $[Pd(en)(Dulc2,3H_{-2})]$ with Pd bound by a *threo*-configured diol moiety. Besides, a minor part is bonded in the dimetallated species $[Pd_2(en)_2(Dulc2,3;4,5H_{-4})]$, which is the main species in 2:1 and 3:1 solutions and whose solid-state structure resembles **37** (O–O distance 2.68 Å *Fig. 10*). A similar structure was obtained with ethylenediamine replaced by methylamine and isopropylidene-methyl-imine (O–O distance 2.54 Å. The fact that entirely deprotonated ducitol is obtained neither with $Cu(en)^{2+}$ nor with $Pd(en)^{2+}$ in solutions even with a metal:dulcitol ratio of 3 or higher, indicates the extraordinary stability of the *S*-conformation fixed by two intramolecular hydrogen bonds. The latter bonds are cleaved with the supporting ligand 1,3-bis(2′-dimethylaminoethyl)hexahydropyrimidine (tm-21:32-tet) which provides a suitable N_4 set to bind two palladium(II) centers which, in turn, could be bonded by a 1,2,3-bis-diolato moiety with the middle alkoxo function in a μ_2 mode. As a result a tetranuclear complex **38** (*Fig. 11*) with entirely deprotonated dulcitol is obtained [19].

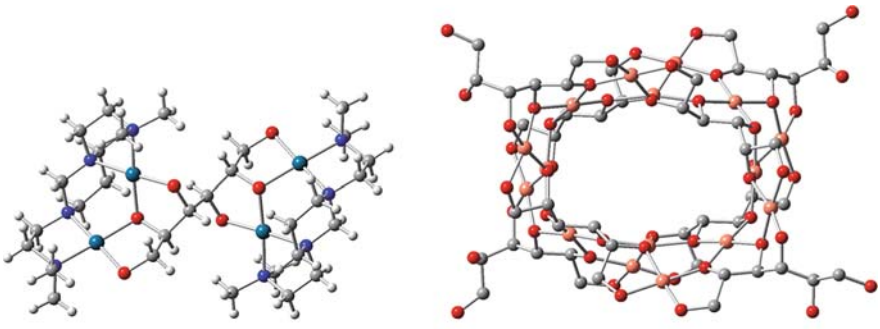

Figure 11
The molecular structures of $[Pd_4(tm\text{-}2,1{:}3,2\text{-}tet)_2(DulcH_{-6})]^{2+}$ 38 in crystals of $38Cl_2 \cdot 16\ H_2O$ and $[Cu_{16}(D\text{-}SorbH_{-6})_4(D\text{-}Sorb1,2,3,4H_{-4})_4]^{8-}$ 39 in crystals of $Li_8$39 $\cdot 46\ H_2O$

Coordination via the *threo*-configured diol at O2 and O3 is also favored by $(dppp)Pt^{2+}$. Species using the central *erythro*-diol or one of the terminal non-stereogenic diols have been detected in small amounts only [22].
Molybdenum and tungsten also use the central tetraol set of dulcitol, however, in a sickle conformation, to form dimolybdates respectively ditungstates with a coordination pattern similar to that found in the erythritol complex **14** (*Fig. 2*) [25,26,27,43].

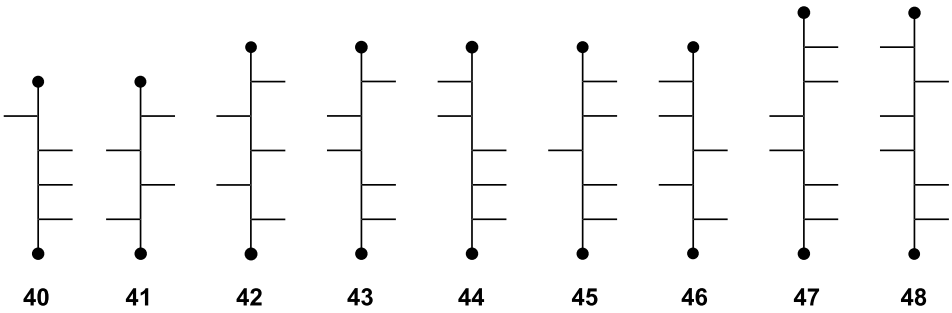
2.8 Sorbitol (Glucitol)

D-Sorbitol **8** is a hexitol with its diol functions from C2 to C5 configured with the sequence *threo*, *threo*, *erythro*. The resulting C_1 symmetry is possibly the reason for the rather small number of characterized complexes since the crystallization as well as the NMR spectroscopic characterization is hampered by the usually obtained mixture of species.
To the best of our knowledge, published crystal structure data are available merely for a toroidal, hexadecanuclear copper(II) complex **39** (*Fig. 11*) with eight multiply deprotonated D-sorbitol ligands. Half of them are completely deprotonated η^6,μ_5 hexaanions, the other half acts as μ_3 tetraanions with their *xylo*-configured C1–C4 subset. It was found that the magnetic coupling behavior is determined by the distribution of Cu–O–Cu angles and correlates with the ligand configurations of the chelating 1,2-diol entities [45].
Molybdenum is found to form four different dimolybdate(VI) complexes, all having proportions in the range of 21 to 32%. These are: two complexes with a central *threo*-configured diol of the type **20** with one of them using the C1–C4 subset, the other one using the C2–C5 subset, and two *erythro*-complexes of the type **14** (*Fig. 2*) with the C3–C6 subset in two reversed orientations [25,26].
Coordination to the *xylo*-configured site C2–C4 similar to **21** is mainly observed for tungsten. Two minor species are the *erythro*-complexes employing the C3–C6 subset as molybdenum [27,37].

Boronic acid is reported to form esters with D-sorbitol in alkaline solution. Van Bekkum et al. suggest the formation of a monoester involving the *erythro*-configured diol while a mono- and a diester may be formed over a *threo*-configured site [40]. Tridentate D-sorbitol is found to occupy three of four coordination sites of the boron center in a ferrocene derivative with its hydroxyl functions at C2, C3, and C5 [46].

2.9 L-Iditol and Higher Sugar Alcohols

Further NMR studies were performed of molybdate(VI) and tungstate(VI) complexes with the hexitols **40** and **41**, the heptitols **42**–**46**, and the octitols **47** and **48**.



Carbon numbering: C1 is situated at the top of each chain. ● = CH_2OH

An *erythro* complex similar to **14** (❯ *Fig. 2*) is established with the C2–C5 coordination site of D-altritol **40** [26]. L-Iditol **41** forms a C_2-symmetric dimolybdate(VI) complex in the pH range 5–10 using the all-*threo*-configured C2–C5 chelation site resulting in a structure similar to the threitol-complex **20**. A structure of the same type emerges with *meso*-glycero-ido-heptitol **42** with the all-*threo*-configured chelation site C2–C5. The corresponding ditungstate(VI) complexes are formed only at neutral pH ≤ 7. In the pH range 8–9, the hexitol **41** acts as a tridentate ligand with the chelation site C2–C4 to give a ditungstate(VI) of the type **21**, while the heptitol **42** acts as a pentadentate ligand in two isomers with a structure similar to **28**: the more stable isomer uses the C2–C6 chelation site, the other one uses the site C1–C5. In the pH range 9–12, the hexitol **40** also forms a complex similar to **28** [35].

D-glycero-D-galacto-heptitol **43** (perseitol) was first found to form a pair of isomers using the C2–C5 galacto site of chelation in dimolydate- and ditungstate complexes having a structure similar to **14** (❯ *Fig. 2*) [26,43]. A mixed bis-ditungstate complex was detected later. In this complex, one ditungstate is bound at the *erythro*-chelation site C4–C7, while the other ditungstate is coordinated through the *threo*-site C1–C3. The local structures at the two different sites resemble the structure types **14** (❯ *Fig. 2*) and **21**, respectively [37]. Bis-dimolybdate complexes have been observed with the octitols *meso*-erythro-*manno*-octitol **47** and D-erythro-L-gluco-octitol **48**, both comprising a C3–C8 perseitol **43** subset. In **47**, each of the two *eythro* chelation sites C1–C4 and C5–C8 is bound to a dimolybdate (for local structures compare with **14**, Fig 2). In contrast **48** binds one dimolydate in a *threo* complex at the chelation site C1–C4, the other is bound at the *erythro* chelation site C5–C8 (local structures **20** and **14**,

respectively). A less stable species with both ligands **47** and **48** uses the central *galacto* site C3–C6 to give *erythro* complexes (local structure compare with **14**, ◉ *Fig. 2*) [47].
D-Glycero-D-*manno*-heptitol **44** (volemitol) forms identical dimolydate and ditungstate complexes. The main species comprises the *arabino* chelation site C1–C4 with the local structure **14** (◉ *Fig. 2*) in two isomers. The same local structure is established in the other species which uses the C3–C6 chelation site. The reduced stability of the latter species is caused by the unfavorable steric interaction of the chelation site and the side chain [48].
Ditungstate complexes with the local structures **21** and **28** are observed with the ligands *meso*-glycero-gulo-heptitol **45** and D-glycero-L-gulo-heptitol **46**. The main species with tridentate **45** involves the central *xylo*-configured chelation site at C3–C5 resulting in a local structure **21** (at pH 9.9). A less stable complex is formed with the coordination site C2–C6 of pentadentate **45** (local structure **28**). Two isomers with the latter local structure **28** are obtained with **46** at pH 11.7. One uses the C3–C7 chelation site, the other binds ditungstate at the C2–C6 site. Local structure **21** is formed at pH 10.6, where **46** acts as tridentate ligand using its C4–C6 coordination site [49].

2.10 Regioselectivity and Stability

Though sugar alcohols provide various metal-binding sites, their complexation behavior is not as unpredictable as one might expect. Rules determining the chelation sites in ethylenediamine-palladium(II) complexes with discrete chelate rings, that is with neither chelating alkoxo function being in a bridging mode, seem to count for other metal complexes of these type as well [19]:

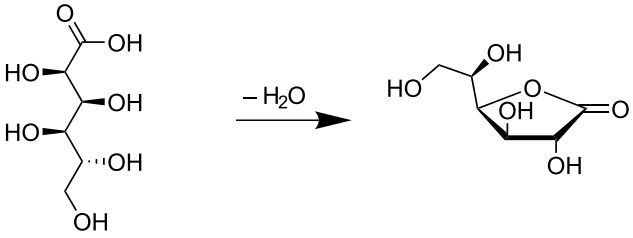
1 The stability of chelate rings formed by *threo*-configured, *erythro*-configured and terminal diols increases in the sequence: *erythro* < terminal < *threo*.
2 The *erythro*-linked adjacent chelating diol functions are more stable than *threo*-linked ones.
3 An additional stability gain emerges upon intramolecular hydrogen bonding between donor hydroxy and an acceptor alkoxido moiety. The most stable type of hydrogen bond is the δ type, that is, a C_4-chain separates the hydrogen bond donor from the acceptor.

The prediction of chelation sites of sugar alcohols in multinuclear metal complexes with alkoxido functions in a bridging mode is rather difficult due to the influence of further factors such as the metal size and oxidation state or the distance of the O atoms of the ligand. However, based on a wealth of NMR solution data and supported by some crystal structures, rules regarding the regioselectivity and stability of the well-investigated dimolydate- and ditungstate-complexes of sugar alcohols could be established [25,27,35,37,43,48,49,50].

3 Aldonic and Aldaric Acids

The oxidation of the primary hydroxyl function at C1 of a sugar alcohol to a carboxyl function leads to the corresponding aldonic acid. Further oxidation of the remaining terminal hydroxyl function of an aldonic acid to a carboxyl function leads to an aldaric acid. Both, aldonic and aldaric acids easily form lactones through intramolecular condensation reactions. As an exam-

ple, the formation of D-gluconic acid γ-lactone **50** (also known as D-glucono-1,4-lactone) starting from D-gluconic acid **49** is depicted in ● *Scheme 1*.

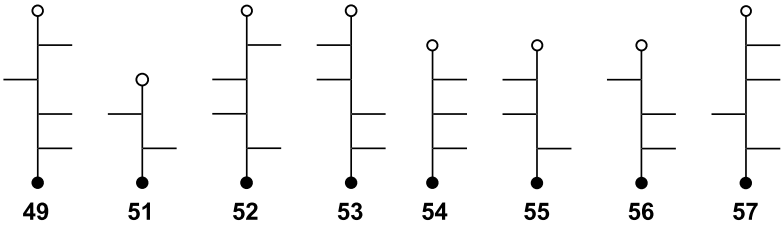


49 **50**

■ **Scheme 1**

3.1 Aldonic Acids

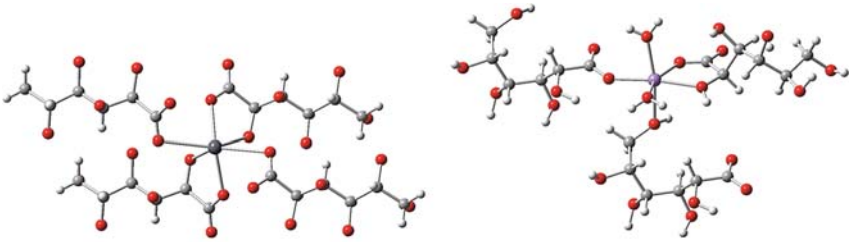
In most of the D-gluconic acid **49** complexes known from the literature, the metal centers are bonded through the α-hydroxycarboxylate moiety and five-membered chelate rings are formed. While the carboxyl function is always deprotonated in these structures, it depends on the Lewis acidity of the metal or the pH of the solution, whether the α-hydroxyl residue is deprotonated or not. No deprotonation of the latter occurs in the solid-state structures of lead(II)- and manganese(II) D-gluconate (**58** and **59**, respectively, ● *Fig. 12*). Furthermore D-gluconic acid binds to both metal centers by a single carboxylate oxygen atom and to the manganese central atom in **59** (● *Fig. 12*) by the terminal alcoholic hydroxyl function which leads to a coordination polymer [51,52]. $Co^{III}(en)_2$ is also chelated by the α-hydroxycarboxylato moieties of D-gluconic acid and L-mannonic acid, respectively [53]. Magnesium(II) is reported to be coordinated by the α-hydroxycarboxylato moiety and the adjacent hydroxyl function at C3 [54].



49 **51** **52** **53** **54** **55** **56** **57**

Carbon numbering: C1 is situated at the top of each chain. ● = CH_2OH ○ = COOH

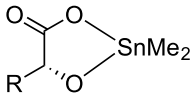
A stronger Lewis acid such as Me_2Sn^{2+} forces deprotonation of the α-hydroxyl function even at pH 5.5 (**60**). This coordination mode is also suggested for a copper(II)-D-gluconic acid complex [55]. In more alkaline solution (pH 8), the hydroxyl function at C4 is also deprotonated and Me_2Sn^{2+} is coordinated by the α-alkoxidocarboxylato moiety and O4 of tridentate



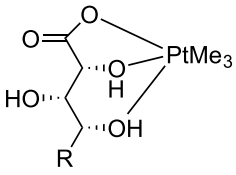
58 59

Figure 12
Coordination of the central metals in the crystal structures of Pb(D-Glc1A1H$_{-1}$)$_2$ 58 and Mn(D-Glc1A1H$_{-1}$)$_2$ · 2 H$_2$O 59

D-gluconate [56]. This coordination mode is also observed in a praseodymium(III) complex in the pH range of 8–10 and an equimolar ratio of metal and ligand. At pH 6–7 and a molar ratio of ligand:metal greater than 2:1, complete deprotonation of all the hydroxyl functions at C1, C2, and C4 is not achieved. Now the praseodymium(III) center is coordinated by two tridentate D-gluconate ligands with three of four coordinating alcoholic hydroxyl functions not being deprotonated [57]. A similar coordination pattern is reported for the trimethyl-platinum(IV) complex **61** which was obtained from aqueous solution. Just the carboxyl function is deprotonated while the coordinating hydroxyl groups at C2 and C4 remain non-deprotonated. A D-threonic acid **51** derivative has been shown to bind to an octahedrally coordinated platinum(IV) center through its α-hydroxycarboxylate moiety [58]. The metals manganese, cobalt, nickel, copper, cadmium, mercury, lead, and zinc in the oxidation state +II are also reported to be coordinated by the O1,2,4 set of D-gluconic acid [59].



60
R = (CH(OH))$_3$CH$_2$OH



61
R = CH(OH)CH$_2$OH

In the pH range of 5–10, the trivalent metals aluminum, gallium, and indium are coordinated by the deprotonated hydroxyl function of C1–C4 of tetradentate D-gluconic acid [60]. Coordination with involvement of the carboxylate moiety is also reported for bismuth(III) in acidic solution. In alkaline solution, however, D-gluconic acid acts as a tetradentate ligand using its deprotonated secondary hydroxyl functions only [61]. Recently the crystal structure of [Cu$_4${μ-(α-D-Glc-1P)}$_2$(μ-Glc1A1H$_{-1}$)$_2$(bpy)$_4$](NO$_3$)$_2$ has been reported in which the α-hydroxycarboylato moiety of gluconic acid is coordinated to one copper ion resulting in a five-membered chelate ring similar to **58** and **59** (*Fig. 12*). Additionally the carboxylato oxygen atom links two copper ions. A linear coordination polymer complex is obtained with D-glucarate [62].

While structural information on complexes of molybdenum(VI) and tungsten(VI) with sugar alcohols is available for solid-state as well as for solution species, crystal structures have not been determined so far for the corresponding complexes with aldonic and aldaric acids (compare ● *Sect. 3.2*), that is, the following structural description is based solely on NMR spectroscopic data.

At pH 5–7 and with an excess of ligand, tungsten(VI) is coordinated by the α-alkoxidocarboxylato moiety of **49** similarly to **60**. However, a dinuclear species chelated by the alcoholic hydroxyl set of C3–C6 is observed when there is an excess of tungsten. Since the central diol at C4 and C5 is *erythro*-configured, the local structure might be similar to **14** (● *Fig. 2*). Additionally, coordination through the alcoholic hydroxyl functions at C2, C3, C5, and C6 is reported [63].

The α-alkoxidocarboxylato moiety of **49** is the chelation site in peroxido-complexes of molybdenum and tungsten as well. Similar structures are obtained with D-galactonic acid and L-mannonic acid [64].

Molybdenum and tungsten are coordinated by the α-alkoxidocarboxylato moiety of **52** in solutions with a molar ratio of ligand:metal of 2:1 in a pH range of 3–9. The stability of these chelates decreases with increasing pH. At a molar ratio of ligand:metal of 1:2 and with maximal stability at about pH 7.5, dinuclear complexes structurally similar to those formed by galactitol become the main species. The metal coordination is now established by the secondary alkoxido functions with a local structure similar to **14** (● *Fig. 2*). Additional species are found for molybdenum(VI) in weakly acidic solutions with a molar ratio of molybdenum:ligand of 2:1. Entirely deprotonated, hexadentate D-galactonic acid is bonded to two molybdenum centers through the alkoxido functions of the C1–C3 subset and the C4–C6 subset, respectively. Two molybdenum atoms may be bonded by fivefold deprotonated D-galactonic acid which acts as a pentadentate ligand through its secondary alkoxido functions in a sickle conformation and the carboxylate function [65].

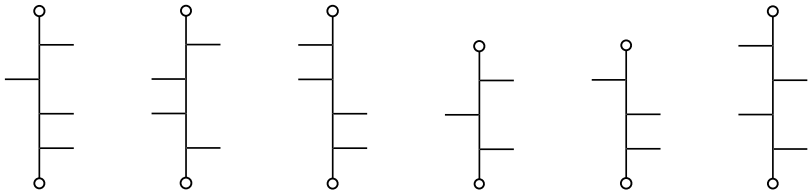
L-Mannonic acid (L-enantiomer of **53**) is found to form similar complexes with molybdenum(VI) described above for D-galactonic acid, but additional species are found for tungsten(VI). An excess of ligand preferentially leads to the formation of mononuclear complexes with the α-alkoxidocarboxylato moiety of **53** as the chelation site, especially in the pH range of 3–6, while di- and tetranuclear species are enriched in solutions with an excess of metal. Three dinuclear species structurally analogous to those formed with D-mannitol are observed in neutral and weakly alkaline solutions. Coordination of the alkoxido functions in the positions 3 to 6 in a sickle conformation leads to a dimetallate complex with a local structure similar to **14** (● *Fig. 2*), while a zigzag conformation of the C2–C5 subset results in a structure similar to **20**. With L-mannonic acid these complexes are also detected with tungsten(VI). Finally a complex using the C1–C4 subset in a sickle conformation is observed mainly with molybdenum in solutions of a pH in a range of 3–7 [66].

Several structures of borate esters of aldonic acids have been described based solely on NMR spectroscopic data. Borate mono- and diesters are preferentially formed at the *threo*-configured diol sites of D-gluconic acid. Less stable esters are formed by bonding at the *erythro*-configured diol at C4 and C5. Still less stable are six-membered borolane rings as a result of bonding via O2 and O4. The 3,4- and 5,6-positions are occupied by borate anions resulting in a diborate ester. D-mannonic acid forms borate monoesters and two diastereomeric diesters preferentially through the *threo*-configured diol at position 3 and 4, while the *erythro*-configured diol at C4

and C5 leads to less stable esters. Additionally the formation of a diborate ester is also reported. The two borate moieties are bonded at the *threo*-configured 3,4-position and at the terminal diol in 5,6-position. Borate monoester- and diester formation has also been investigated with D-ribonic acid **54**, D-lyxonic acid **55**, D-arabinonic acid **56**, D-gulonic acid **57**. Four borate esters of ribonic acid have been found but further interpretation was prevented due to the large number of ^{13}C NMR signals. The *threo*-3,4-diol site is preferred in borate esters of lyxonic acid and gulonic acid, whereas the *threo*-2,3-position proves to be the most stable one in borate esters of arabinonic acid [40,67].

3.2 Aldaric Acids

Reactions in approximately neutral aqueous solutions lead to three solid-state structures of complexes of D-glucaric acid **62** (also known as D-saccharic acid) with the central metals aluminum(III), zinc(II), and copper(II), all exhibiting similar structure features: (a) both α-hydroxycarboxylate moieties of D-glucaric acid act as chelation sites, (b) deprotonation occurs at the carboxylate group and, in the case of bonding to the stronger Lewis acid aluminum(III), additionally at both α-hydroxy functions, and (c) the central hydroxyl functions in 3,4-position are never involved in metal coordination. A dinuclear complex **69** (*Fig. 13*) is formed with aluminum(III) with one of the two α-alkoxido functions in a μ_2 mode [68], whereas coordination polymers are formed by the zinc(II) complex **68** (*Fig. 13*) and by the copper(II) complex, for which no crystallographic data are available [69,70].



62 **63** **64** **65** **66** **67**

Carbon numbering: C1 is situated at the top of each chain. o = COOH

Both α-hydroxycarboxylate moieties of galactaric acid **63** (also known as mucic acid) act as a chelation site for magnesium centers in the solid-state structure **70** (*Fig. 14*), in which the galactarate is centrosymmetric and adopts a zigzag conformation [71]. Four galactarate molecules acting as bis(α-alkoxidocarboxylato) ligands and eight hydroxido ligands coordinate to six aluminum centers in a cyclic hexaaluminate **71** (*Fig. 14*). This structure is obtained from a reaction in strongly alkaline solutions and combines carboxylato-, hydroxido- and alkoxido bonding to the aluminum centers.

Copper(II), however, shows a different complexation behavior with galactaric acid in strong alkaline media. A coordination polymer **72** (*Fig. 15*) is formed by the copper atoms and the galactarate ions which act as *threo*-bis-diolato ligands. A polymer of the same type is formed with erythritol (compare **10**, *Fig. 1*) [72]. Carboxylato or hydroxido bonding is not observed in this copper complex. In weakly acidic solution with a pH of 4, however, copper(II) is chelated through an α-hydroxycarboxylate moiety of galactaric acid. Deprotonation

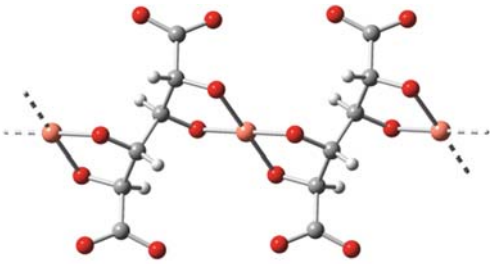
of the α-hydroxyl function is reported to occur at pH 7.5 [73]. These observations indicate for copper(II) that carboxylato bonding becomes more and more unfavorable with increasing pH. The following structures of complexes with aldaric acids are solely based on NMR spectroscopic data. Several complexes with both α-alkoxidocarboxylato residues of glucaric acid **62** as chelation sites are discussed with molybdenum(VI) and tungsten(VI) as central metals. Both β-hydroxyl functions are deprotonated in a less acidic solution of pH 4.5–6 and a double molar excess of metal whereupon a dinuclear complex is formed. At a higher pH of about 6–8.5, coordination through the carboxylato residue becomes unfavorable and chelation through the alkoxido functions at C2–C5 leads to a *threo*-complex similar to that described above for D-sorbitol [74]. As with D-galactonic acid, two molybdenum(VI) atoms are chelated through the alkoxido functions of the C1–C3 subset and the C4–C6 subset, respectively, of entirely deprotonated galactaric acid **63** in weakly acidic solutions with a molar ratio of molybdenum:ligand of 4:1. Obviously the strong Lewis acidity of molybdenum(VI) enables the carboxylate oxygen atom of galactaric acid to take over the part of the terminal, less acidic



72

Figure 15

alcoholic hydroxyl function in galactonic acid. The central diol functions are not involved in complexation in equimolar solution. However, in neutral solutions with an excess of molybdenum, the central diol function in combination with the adjacent alcoholic hydroxyl functions are arranged in a sickle conformation and form a dinuclear *erythro*-complex also found for galactitol [75]. Most of the complexes just described are also formed with tungsten(VI) as central metal [76].

Both, glucaric acid **62** and galactaric acid **63** form mono- and dinuclear peroxido complexes with molybdenum(VI and tungsten(VI). In all of them one or two α-alkoxidocarboxylato moieties are chelating the metal centers. The dinuclear species is predominantly formed in solutions with a molar ratio of metal:ligand of 2:1 [64].

The coordination behavior of molybdenum(VI) with D-mannaric acid **64** is similar to that with galactaric acid: two molybdenum atoms are bonded either by the two α-alkoxidocarboxylato moieties of fourfoldly deprotonated D-mannaric acid or by the alkoxido functions of the C1–C3 subset and the C4–C6 subset, respectively, of entirely deprotonated D-mannaric acid. Due to the *threo*-configuration of the central diol residue, a *threo* complex is established in neutral solutions with a molar ratio of Mo:ligand of 4:1 instead of an *erythro* complex which was observed with galactaric acid (compare structure **20** and **14** (◉ *Fig. 2*), respectively) [75]. The latter *threo* complex as well as a complex with the α-alkoxidocarboxylato moieties as chelation sites is also formed by tungsten(VI) [76].

In alkaline solutions of a pH of 11.5 containing calcium ions, aluminum(III) forms C_2-symmetric dinuclear sandwich-type complexes. D-glucaric acid **62** has to adopt a conformation which allows all coordinating alkoxido functions to point in the same direction. The aluminum centers are bonded by the *threo*-configured 2,3-site as well as by the *erythro*-configured 4,5-chelation site. Two *threo*-3,4-diolato moieties of two mannaric acid **64** ligands are the bonding sites of the tetrahedrally coordinated aluminum center. Tetrahedrally coordinated aluminum is also present in the bis-diolato complexes with xylaric acid **65** and D-arabinaric acid **66**, respectively; both complexes are formed in calcium-containing solutions. Xylaric acid is bonded to aluminum through its C2–C3 *threo*-diol function, at which the central hydroxyl function at C3 is in the μ_2 mode and is bonded to a calcium ion as well. A C_2-symmetric dinuclear complex is formed with D-arabinaric acid. The aluminum centers are coordinated to a C1–C2 α-hydroxycarboxylate moiety from one ligand and to a C3–C4

erythro-diol function from the other ligand. The complex formation is supported by calcium ions which are bonded at several sites of the complexes just described [77].
Borate mono- and diesters are preferentially formed of the *threo*-3,4-diol functions of glucaric acid **62** [40,67,78]. Several cations have been shown to have different effects on the borate-ester equilibria. Monovalent ions such as Na^{I}, K^{I}, and Ag^{I} hardly show any effect, whereas divalent cations with moderate polarizing abilities (Mg^{II}, Ca^{II}, Co^{II}, Ni^{II}, Sr^{II}, Cd^{II}, Ba^{II}) increase the diester formation. Strongly polarizing cations such as Al^{III}, Cu^{II}, Zn^{II}, Pr^{III}, and Pb^{II} induce dissociation of the borate diesters [79]. Monoesters and diesters with galactaric acid **63** are formed mostly through the *threo*-configured diols at 2,3-position. Diborate ester formation is also observed in which the two borate anions are bonded at the equivalent *threo*-configured diols in 2,3- and 4,5-position [40,67].

3.3 Regioselectivity and Stability

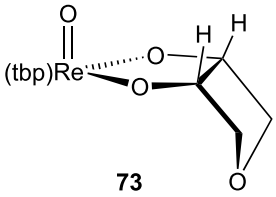
The electron-withdrawing effect of the carboxyl group markedly enhances the acidity of the adjacent α-hydroxyl group. As a consequence, the α-hydroxycarboxylate moiety becomes an attractive ligand mainly in acidic and neutral solutions in which sugar alcohols form complexes of low stability only, especially with metals of weak Lewis acidity. In alkaline solutions, however, the less acidic alcoholic hydroxyl functions are mostly preferred in complex formation. For these solutions the rules referring to the regioselectivity and stability of sugar-alcohol complexes may be valid for aldonic and aldaric acids as well.

4 Anhydroerythritol

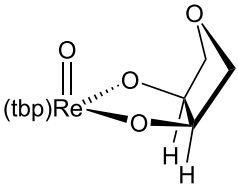
Anhydroerythritol (AnEryt) or *cis*-oxolane-3,4-diol is a particularly well-suited ligand to investigate the coordination chemistry of carbohydrates as it can be considered to be a molecular cutout of important glycosides such as the nucleosides. On the one hand, its acidity is about the same as that of the glycosides, on the other hand, AnEryt is easily obtainable, configurationally stable in the entire pH range of interest, and chemically stable under alkaline conditions. AnEryt shares the latter two properties, which are critical for the glycoses, with the glycosides. Contrary to even glycosides, as a *meso* compound AnEryt gives rise to particularly simple ^{13}C NMR spectra. Finally, AnEryt is achiral, a property that is found to be beneficial for the crystallization of its complexes.
Usually the diolato κ^2O,O'-AnErytH$_{-2}$ ligand forms five-membered chelate rings in the coordination compounds, the central atoms spanning a size range from boron(III) to lead(II). The unusual versatility of the AnErytH$_{-2}$ ligand is the result of the variability of a furanoidic ligand's bite, AnEryt being the prototype of this kind of ligand.
Coordination of central metal atoms with auxiliary ligands so that only two free binding sites remain, leads, in most cases, in combination with the deprotonation of the diol functions of AnEryt, to a predictable binding mode of κ^2O,O' as in the cases of cobalt(III), $\{RuNO\}^6$, oxorhenium(V) and palladium(II).
Four of the six binding sites of the octahedrally coordinated cobalt(III) in [(en)$_2$Co(AnErytH$_{-2}$)] are occupied by ethylenediamine ligands, κ^2O,O'-AnErytH$_{-2}$ binds over the remaining two sites [80]. Caused by the *cis* conformation of the two diol functions of

AnEryt, the five-membered chelate ring is flat. An intramolecular hydrogen bond between the O1 atom of the AnEryt ring and an en ligand is responsible for the conformation of the complex (the conformation of the oxolane ring is $^{C4}T_{O1}$, distorted in the direction of E_{O1}). The Co–O bond length averages 1.88 Å.

Comparable conditions can be found for the structure of [*mer*-(dien)(NO)Ru(AnErytH$_{-2}$)] $BPh_4 \cdot 2\ H_2O$ where four of six coordination sites were occupied by NO and *mer*-dien so that κ^2O,O'-AnErytH$_{-2}$ is once again the ligand for the remaining two binding sites with a O–C–C–O angle of −22.1° [81]. Diolate-Ru(NO) bonding is governed by the *trans*-influence of the nitrosyl ligand. The Ru–O(*trans*) distance is with 1.94 Å markedly shortened compared with the Ru–O(*cis*) distance with 2.05 Å, the Ru–O(*trans*)–C angle is with 117.9° always more obtuse than the Ru–O(*cis*)–C angle with 112.1° and, most remarkably, considering the usual features of polyolato-metal structures, the O(*trans*) center does not act as a hydrogen-bond acceptor. On the other hand, O(*cis*) is a hydrogen-bond acceptor, as is usual. [(tpb)ReO(AnErytH$_{-2}$)] is also an octahedrally coordinated complex and built from equal amounts of two isomers, which differ in the orientation of the oxolanediolato ligand with respect to the (tbp)ReO fragment [82] (**73**, **74**).



73



74

As known from the structure of [(en)$_2$Co(AnErytH$_{-2}$)], the O1 atom of the AnEryt ring in the *anti* isomer **73** of [(tpb)ReO(AnErytH$_{-2}$)] builds a hydrogen bond with the tpb ligand. No intramolecular hydrogen bonding can be found in the *syn* isomer **74**, the Re–O bond averages 1.93 Å in both cases. In contrast, the O–C–C–O angles of AnErytH$_{-2}$ differ in the case of *syn* and *anti* coordination, in compound **73** the angle amounts to −1.6° and in **74** to −19.3°.

In the dinuclear anion $[Re_2(CO)_6(\mu\text{-OMe})_2(\mu\text{-AnErytH}_{-1})]^-$ **75**, AnEryt differs from the currently known coordination pattern [32]. A single monodentate κO-μ-AnErytH$_{-1}$ ligand takes one of the three alkoxido positions in the usual hexacarbonyl-trialkoxo-dirhenate(I) anion, leaving the other two for methoxido groups, as shown in ❯ *Fig. 16*. The second diol function forms an intramolecular hydrogen bond to the deprotonated diol function. The distances of the coordinated O atom to the two Re atoms average 2.17 Å and the O–C–C–O angle of AnErytH$_{-1}$ is 42.6°.

For the square-planarly coordinated palladium, the use of an auxiliary ligand leads to the expected κ^2O,O'-coordination of one AnErytH$_{-2}$. There are two known characterized complexes with [(bpy)Pd(AnErytH$_{-2}$)] $\cdot$ 6.5 H_2O and [(en)Pd(AnErytH$_{-2}$)] $\cdot$ 4 H_2O [83,84]. Two binding sites of the square-planarly coordinated palladium are occupied by bpy or en and two sites bind to the deprotonated AnErytH$_{-2}$. In both cases the Pd–O bond length averages 1.99 Å With 43.0°, the O–C–C–O angle of [(bpy)Pd(AnErytH$_{-2}$)] $\cdot$ 6.5 H_2O and 38.7°, the O–C–C–O angle of [(en)Pd(AnErytH$_{-2}$)] $\cdot$ 4 H_2O, the angles are closer to that of the κO-μ-AnErytH$_{-1}$ ligand than to the angles of the compounds introduced so far.

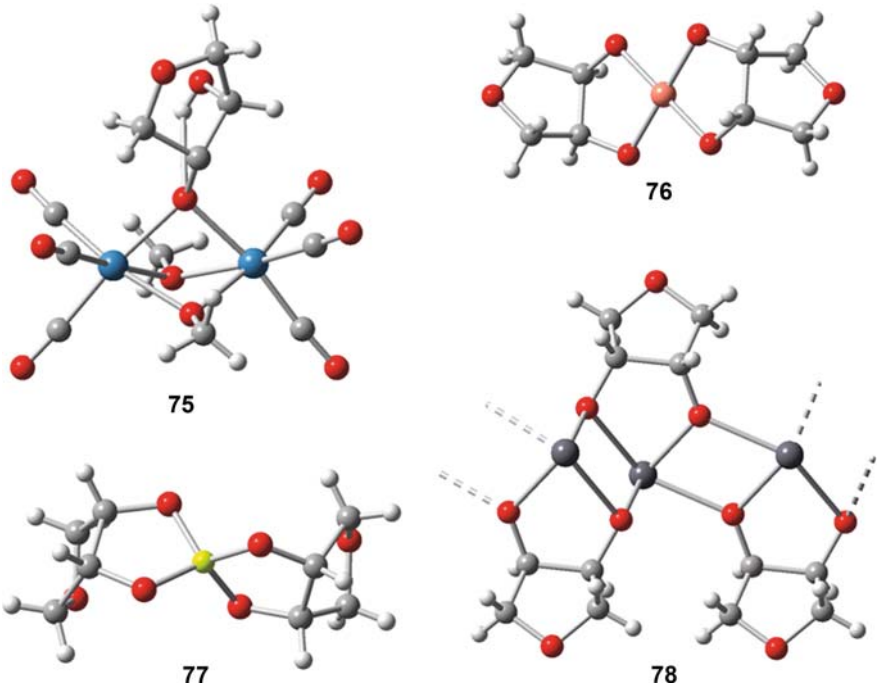


Figure 16
X-ray structures of the anionic $[Re_2(CO)_6(\mu\text{-}OMe)_2(\mu\text{-}AnErythH_{-1})]^-$ 75 in [K([18]crown-6)]75, $[Cu(AnErythH_{-2})_2]^{2-}$ 76 in $A_2$76 **· 4 H_2O (A = Li, K, Na), $[B(AnErythH_{-2})_2]^-$ 77 in K77 · H_2O and a section of the linear coordination polymer built by $Pb(AnErythH_{-2})$ 78 in 78 · H_2O**

When the central metal atom is free of auxiliary ligands there are more possibilities for coordination of AnEryt. Keeping to the square-planar coordination Cu(II) builds complexes with two AnEryt, as shown in ❯ *Fig. 16*. Three structures of the type $A_2[Cu(AnErythH_{-2})_2] \cdot 4\ H_2O$ (A_2**76** $\cdot 4\ H_2O$) with A = Li, Na and K [85,86] have been determined. The structures of Na and K on the one hand and Li on the other hand differ in the coordination of the alkali ions to the deprotonated diol functions of the $Cu(AnErythH_{-2})$ substructure. The Cu–O bond length averages 1.93 Å and the O–C–C–O angle of $AnErythH_{-2}$ grows in dependence on the cation from 33.7 (Li) to 35.4° (K).

Comparable coordination schemes with two $AnErythH_{-2}$ ligands exist for tetrahedrally coordinated metal centers, too. Boron(III), beryllium(II) and lead(II) build structures where the metal center is tetrahedrally coordinated with two $AnErythH_{-2}$ ligands [87,88], for example the structure of $K[B(AnErythH_{-2})_2] \cdot 2\ H_2O$ (K**76** $\cdot 2\ H_2O$) in ❯ *Fig. 16*.

According to the increasing atom size, the bond length increases from the B–O bond length with 1.47 Å over the Be–O bond length with 1.63 Å to an Pb–O bond length between 2.25 Å to 2.39 Å The boron compound shows two similar O–C–C–O angles of 12.0°, the beryllium compound an angle of 26.8° and a second of 0.8°.

As shown in ❯ *Fig. 16*, lead(II) forms not only monomers of $[Pb(AnErythH_{-2})_2]^{2-}$ but also polymers of $Pb(AnErythH_{-2}) \cdot H_2O$ (**78** $\cdot H_2O$), which are chains of Pb(II) coordinated by

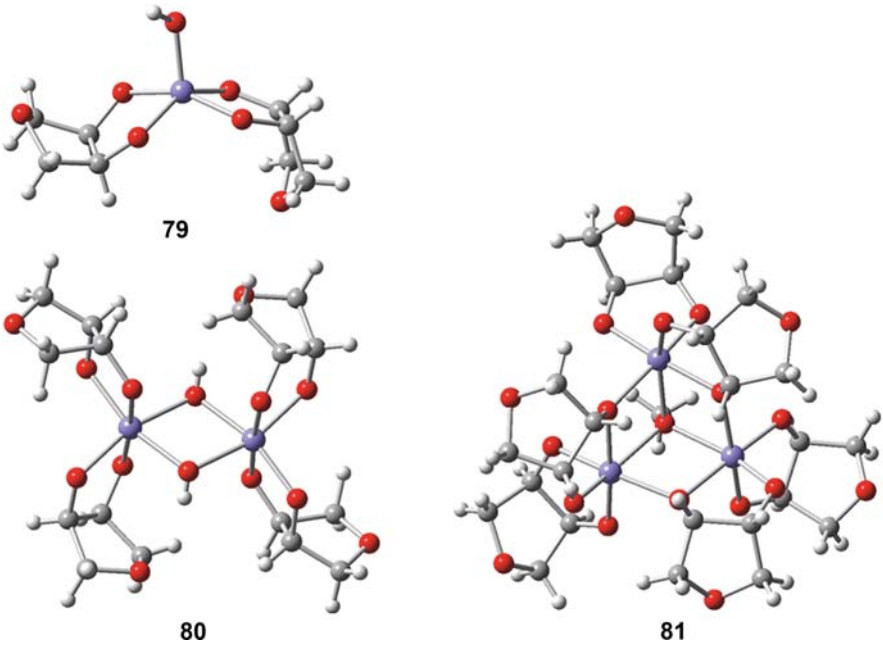

Figure 17
X-ray structures of 79 in $Na_2[Fe(AnErythH_{-2})_2(OH)] \cdot 0.5\ NaNO_3 \cdot 3.5\ H_2O$, 80 in $Ba_2[Fe_2(AnErythH_{-2})_4(\mu\text{-}OH)_2] \cdot 12\ H_2O$, and 81 in $Na_4[Fe_3(AnErythH_{-2})_6(OMe)] \cdot 2.5\ NaNO_3$

four bridging *O*-atoms [89]. In contrast to the monomeric $[Pb(AnErythH_{-2})_2]^{2-}$, the Pb–O distances range between 2.24 and 2.47 Å the O–C–C–O angle of $AnErythH_{-2}$ averages 20°. $[Fe(AnErythH_{-2})_2(OH)]^{2-}$ **79**, $[Fe_2(AnErythH_{-2})_4(\mu\text{-}OH)_2]^{4-}$ **80** and $[Fe_3(AnErythH_{-2})_6(OMe)]^{4-}$ **81** are three anionic compounds with doubly deprotonated $AnErythH_{-2}$ ligands and iron(III) [90]. The three compounds are shown in ❯ *Fig. 17*. In the case of **79** there are two isomers caused of *syn* and *anti* orientation of AnEryt ligands. ❯ *Figure 17* only shows the *syn/anti* isomer, although the structure of the *anti/anti* isomer is also known. In **79**, iron(III) is square-pyramidally coordinated by two $AnErythH_{-2}$ and one hydroxido ligand. Nevertheless the ideal geometry varies at one coordinate of the Berry-pseudorotation at about 16.6% for the *syn/anti* isomer and at 27.6% for the *anti/anti* isomer. **80** is a $(\mu\text{-}OH)_2$ bridged dimer of **79** where both iron centers now are coordinated sixfold. Species **81** is a three-centered tetraanion where three of six diolato ligands bind to one of the iron atoms, the other three diolato ligands build $\eta^1{:}\eta^1,\mu_2$-bridges to a central μ_3-methoxidotriiron unit.

The distances between the iron centers and the O atoms vary depending on the compound. In **79**, the O atoms of the AnEryt ligands have distances between 1.93 and 1.98 Å to the iron center, in **80** the distances range from 1.96 to 2.02 Å and in compound **81** from 1.94 to 2.09 Å (❯ *Fig. 17*).

Similarly to iron(III), there are known mono-, di- and trinuclear compounds with silicium. Almost identical to **79** are the structures of $[M(AnErythH_{-2})_2(OH)]^-$ with M = Si **82** and Ge [91]. In $[SiPh(AnErythH_{-2})_2]^-$ [92] **83** a phenyl substituent occupies the apical position of the pyramidal coordination sphere instead of a hydroxyl residue (❯ *Fig. 18*).

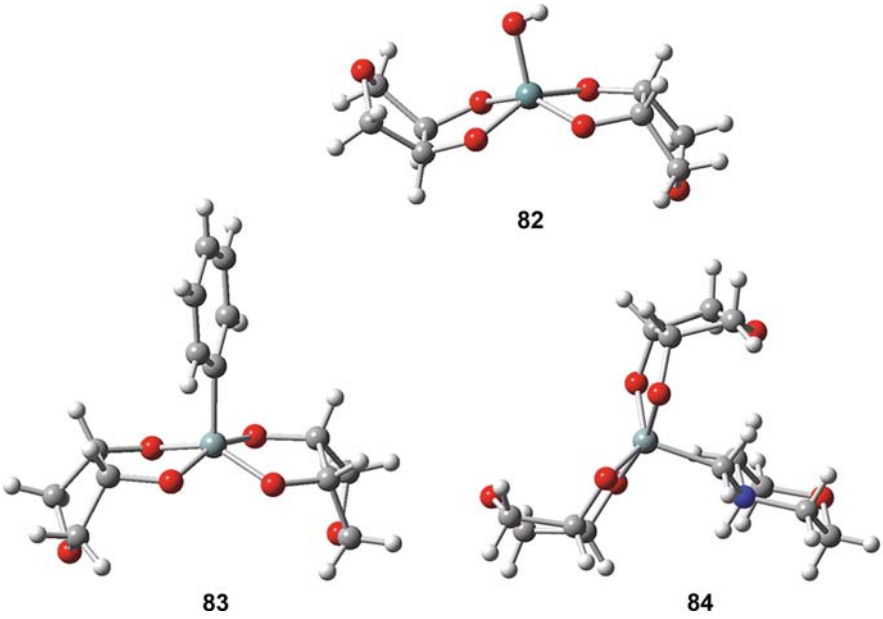

Figure 18
X-ray structures of 82 in $Li[Si(AnErytH_{-2})_2(OH)] \cdot H_2O$, 83 in $K[SiPh(AnErytH_{-2})_2] \cdot 1.5$ MeOH, and 84 in $[(AnErytH_{-2})_2SiCH_2NHC_4H_8O]$

The anionic complex **82** crystallizes with different alkali cations which results in different conformations of the Si center in the crystal structure. In the case of **83**, *anti/anti* and *syn/anti* coordinated silicium centers exist in the crystal structure in equal parts.
The Si-O($AnErytH_{-2}$) distances average 1.70 Å (Li) and 1.73 Å (Na, K, Cs), the $AnErytH_{-2}$ O–C–C–O angles are 14.1 and 9.7° for sodium and two times −3.5° for cesium.
In the case of silicium not only the various possibilities of coordination are of interest, the hydrolytic stability in neutral aqueous solution and the resulting biochemical relevance is of much greater importance. One approach in this direction is the introduction of a positive charge next to the Si center [93].
As can be observed in *Fig. 18*, the Si coordination polyhedra of $[(AnErytH_{-2})_2SiCH_2NHC_4H_8O]$ **84** and additionally $[(AnErytH_{-2})_2SiCH_2NHC_4H_8O] \cdot H_2O$ in the crystal are strongly distorted trigonal bipyramids, in which each bidentate ligand spans one axial (O1, O3) and one equatorial site (O2, O4). The Si–O distances of the SiO_4C skeletons of **84** and **84** $\cdot H_2O$ range from 1.68 to 1.76 Å and the axial Si–O bonds (1.73–1.76 Å are significantly longer than the equatorial ones (1.68–1.71 Å. As seen in *Fig. 18*, the *syn/anti* geometry is observed in the crystals of **84**.
Taking into account the different possible orientations of the two oxolane rings, relative to the apical ligand, for the three compounds **82**, **83** and **84**, the existence of *syn/syn* isomers in addition to *syn/anti* and *anti/anti* isomers must be considered. Although there is some confusion in the literature [92,93,94,95,96,97] about the correct interpretation of the NMR data of silicate complexes, there is no doubt that the three above-mentioned compounds exist in solution. In *Fig. 19*, ^{29}Si and ^{13}C (DEPT-135) NMR spectra of **82** and **83** are shown.

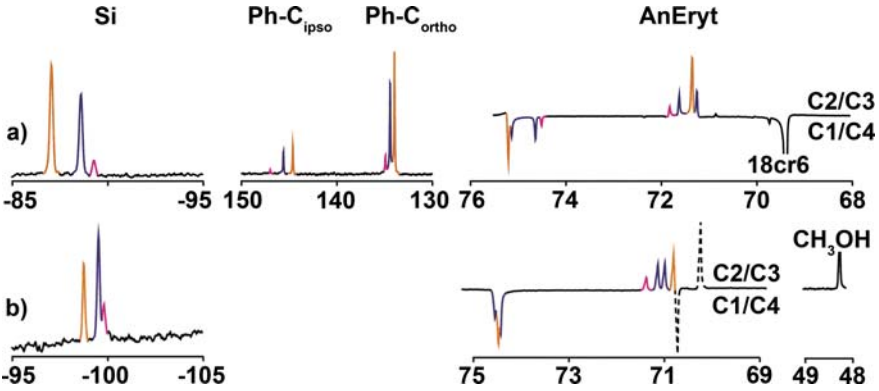

Figure 19
^{29}Si and ^{13}C (DEPT-135) NMR spectra of pentacoordinate AnEryt–silicate species prepared from the diol, $SiPh(OMe)_3$ or $Si(OMe)_4$, and base at the molar ratio given in a) and b). Color code: orange: anti/anti; violet: syn/anti; pink: syn/syn isomer of the respective $[Si(R)(AnErytH_{-2})_2]^-$ ion. a) R = Ph; base: KOMe/[18]crown-6; solvent: methanol; molar ratio: 2:1:2; total Si concentration: 0.38 mol kg^{-1}. AnEryt region in DEPT mode referenced to the [18]crown-6 signal. b) R = OH; base: LiOH; solvent: water; molar ratio: 3:1:1; total Si concentration: 0.54 mol kg^{-1}. The methanol signal stems from hydrolysis of the $Si(OMe)_4$ starting material and may be used as a reference for DEPT assignment. *Dashed line*: free AnEryt [92]

The ^{29}Si NMR spectrum in ❯ *Fig. 19* a) exhibits the signals of two major and one minor pentacoordinate species. According to the species in crystal structure, the two main signals are assigned to the *anti/anti* and*syn/anti* isomers, the minor peak to the *syn/syn* isomer.
In light of this assumption, interpretation of the ^{13}C NMR spectrum is straightforward. The ^{13}C DEPT-135 NMR spectrum is shown in ❯ *Fig. 19* a) on the right side. Both, the *anti/anti* and the *syn/syn* isomer have apparent C_{2v} symmetry and should thus give rise to one signal for C2/C3 and one signal for C1/C4. The *syn/anti* isomer on the other hand, with its apparent C_s symmetry, will show twice the number of signals. A special feature of the phenylsilicate spectra will gain significance in more complicated cases. ❯ *Figure 19* a) shows the ^{13}C NMR signals of the phenyl residue in addition to the diol signals. It should be noted that both the signals stemming from the *ipso*-carbon atom as well as the signals from the two *ortho*-carbon atoms mirror the ^{29}Si NMR spectrum.
The corresponding spectrum of an aqueous diolatosilicate solution is shown in ❯ *Fig. 19* b). The same rules could be applied to the ^{29}Si and ^{13}C NMR spectra of **84** in solution. Here the two main and one minor signals in the ^{29}Si NMR spectrum are found, too [97].
Contrary to prior interpretation [93], hydrolysis products dominate the NMR spectra of aqueous solutions of **84** at a pH value near to neutrality, particularly at a higher dilution, so the introduction of a positive charge next to the Si center does not prevent hydrolysis.
The properties of four-coordinate Si centers bonded to an alkylenedioxy substituent derived from a furanoidic diol also were investigated with the two isomeric oxolane-3,4-diols AnEryt and L-anhydrothreitol [92]. Thus, substitution of silicium with two phenyl residues leads to $Ph_2Si(AnErytH_{-2})$ **85** in the case of AnEryt. The molecular structure is that of a monomer. The five-membered chelate ring is almost planar, with a diol torsion angle close to 0°. Such geometrical parameters cannot be met by L-AnThre. However, this diol provides another example

that the inability to form a chelate ring must not be confused with a lack of reactivity. Thus, the solid-state structure of $Ph_2Si(\text{L-AnThreH}_{-2})$ **86** is not that of a monomeric chelate. Instead, an unstrained molecule with all bonding angles close to their ideal values is observed in a trimeric structure (*Fig. 20*). Although 0° torsion is outside the range of achievable diol torsion angles, the great flexibility of furanoidic rings is obvious from the L-AnThre structure as well. To build the trimer, the diol torsion angles span almost the entire available 100° range of a furanoidic diol, with the actual values being between 82° and 165°.

According to the above-mentioned tetrahedrally coordinated compounds silicium could also build complexes with two AnErytH_{-2} ligands, shown in *Fig. 20*, $Si(\text{AnErytH}_{-2})_2$ **87** [92]. The average Si–O bond length amounts to 1.63 Å and is comparable to the bond length of $[Be(\text{AnErytH}_{-2})_2]^{2-}$, the O–C–C–O torsion angles of the AnErytH_{-2} ligands are −0.8 and −1.2° which differ from the Be compound noticeably. Furthermore there is a dimer form of **87** [92], also shown in **88** in *Fig. 20*. Here the Si–O bond length increases up to 1.72 Å and the O–C–C–O angles to −2.8 and −16.8°.

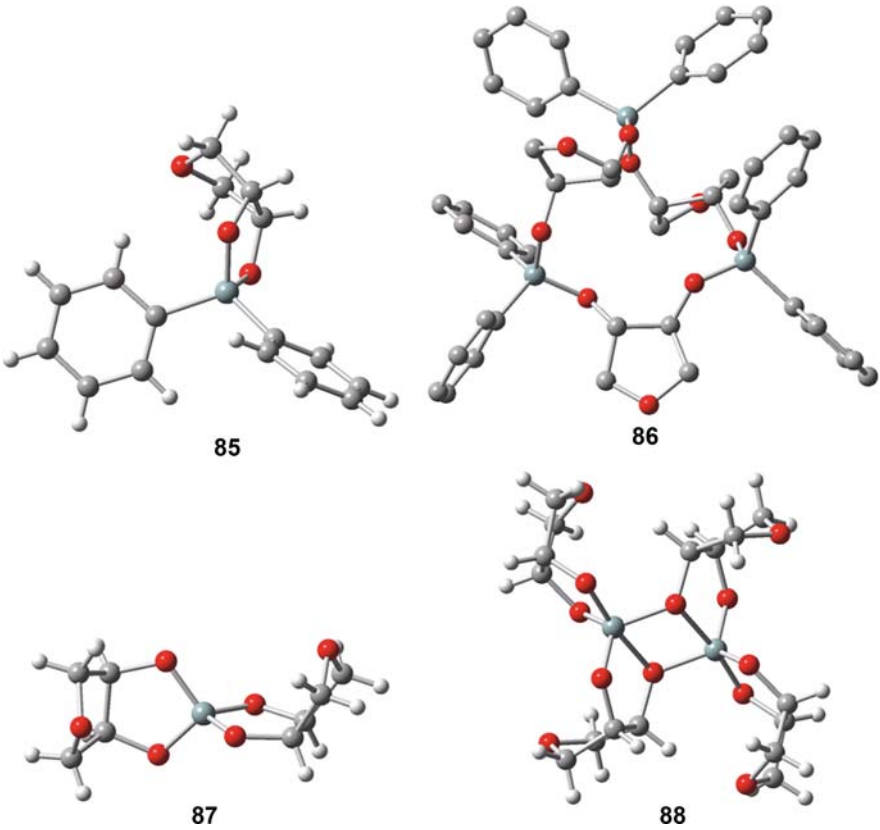

Figure 20
X-ray structures of $Ph_2Si(\text{AnErytH}_{-2})$ 85, $Ph_2Si(\text{L-AnThreH}_{-2})$ 86, $Si(\text{AnErytH}_{-2})_2$ 87, and $[Si(\text{AnErytH}_{-2})_2]_2$ 88

In summary it may be said that AnEryt has a special position compared to the other polyols. The fact that AnEryt models a furanoside and not a pyranoside is of particular importance for dealing with small central atoms. Because of the smaller O–C–C–O torsion angle in the range from 0 to approximately 40°, the steric demand is smaller than that of pyranoses as could be shown for cobalt(III) complexes [80]. A *cis*-furanoidic diol thus appears to be a better choice than open-chain diols and, particularly, pyranoidic diol functions. The reason for the conformational flexibility of a furanose ring is its balance of strain. While open-chain diols experience Pitzer strain when twisted into an eclipsed conformation, and pyranoses are burdened with ring strain on being twisted towards 0° torsion, a furanose is characterized by a balance of the various types of strain over a pronounced range of torsions.

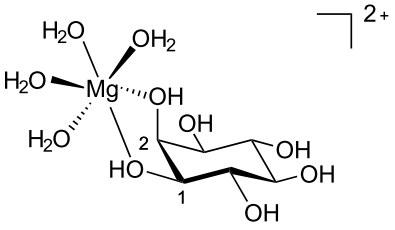
5 Inositols and Anhydro-Sugars

5.1 Inositols

There are nine various inositols or cyclohexane-1,2,3,4,5,6-hexaols, including one pair of isomers. The *myo*-inositol is the most widespread isomer of inositol and, excluding *allo*-, *cis*-, *epi*- and *muco*-inositol, all other inositols are of natural occurrence.

Myo-inositol is also the inositol, which is most investigated in connection with metal coordination. First of all, there are three known structures with magnesium, praseodymium and neodymium with the specific feature that the metal atoms coordinate to *myo*-inositol without deprotonation of the affected hydroxyl groups.

The magnesium atom in $[Mg(myo\text{-Ins})(H_2O)_4]Cl_2$ (**89**Cl_2) [98] is coordinated to two *cis*-vicinal hydroxyl groups and four water molecules in an octahedral geometry. As a consequence of cation binding, the cyclohexane ring geometry in the vicinity of the coordination site is distorted. Deviations of nearly 15° from the norm occur in some torsion angles.



89

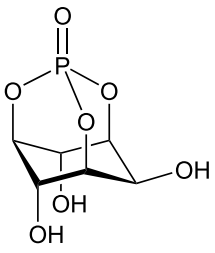
The intramolecular $O_{eq}1$ to $O_{ax}2$ distance is shortened 0.33 Å and that for $O_{eq}3$ to $O_{ax}2$, 0.11 Å from a normal value of 2.89 Å [99]. The decrease in the C–C–O angles for the C1–C2 bond could be an effect of the magnesium ion attraction to the hydroxyl groups. The torsion angles for bond C1–C2 differ by as much as 14° from those of *myo*-inositol.

Praseodymium and neodymium built almost identical structures with *myo*-inositol. In the crystal structures of $[Pr(myo\text{-Ins})]Cl_3 \cdot 9\ H_2O$ [100] and $[Nd(myo\text{-Ins})]Cl_3 \cdot 9\ H_2O$ [101], by trivalent lanthanide cations complexed *myo*-inositol, each Pr or Nb is coordinated to nine oxygen atoms, two from the inositol (two adjacent hydroxyl groups) and seven from water molecules

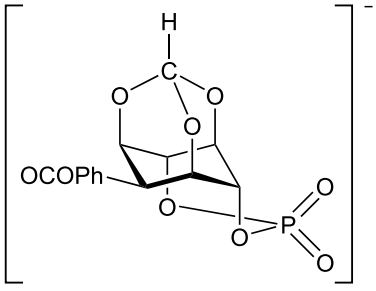
in a tricapped trigonal prism geometry, with Pr–O distances ranging from 2.47 to 2.69 Å and Nb–O distances ranging from 2.45 to 2.68 Å. The other two water molecules are hydrogen-bonded. No direct contacts exist between Pr/Nd and Cl.

These metal–hydroxyl interactions generally produce small conformational changes in the sugar at the metal-binding sites. Comparing uncomplexed *myo*-inositol with the Nd-inositol complex, the C–C, C–O distances and bond angles have only small changes.

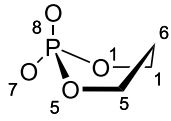
In the complex of [(PO)(*myo*-InsH$_{-3}$)] **90** [102], the cyclohexane ring adopts the expected chair conformation, with the 2-, 4- and 6-hydroxyl groups being axial, equatorial and axial, respectively. There is an intramolecular hydrogen bond between the O6 atom as donor and O5 as acceptor. The three P–O single bonds, of average length 1.58 Å are all equivalent within significant error, as are the P–O–P bond angles with an average of 104.5°.



90



91a



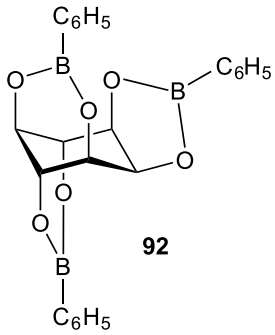
91b

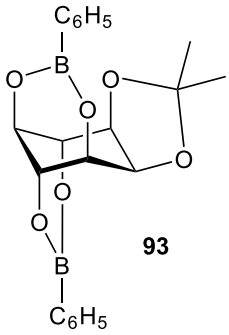
The six-membered 1,3,2-dioxaphosphorinane ring in the anionic 2-*O*-benzoyl-1,3,5-*O*-methylidyne-*myo*-inositol-4,6-cyclophosphate **91a** [103], however, has a boat rather than a chair conformation. The P–O bond distances involving the inositol residue are normal but longer than the mean value of 1.58 Å found by Neidle et al. [102] in **90**. Conspicuously, in **91b**, the six-membered 1,3,2-dioxaphosphorinane ring adopts a boat conformation, with P and C6 on the same side at distances of 0.61 and 0.68 Å respectively, from the mean plane through C1, C5, O1 and O5. This is different from the situation found in **90**, where all three six-membered 1,3,2-dioxaphosphorinane rings have chair conformations.

Furthermore, from *myo*-inositol and 1,2-*O*-isopropylidene-*myo*-inositol two tetracyclic phenylboronic esters [$B_3(C_6H_5)_3$(*myo*-InsH$_{-6}$)] **92** and [$B_2(C_6H_5)_2(C_3H_6)$(*myo*-InsH$_{-6}$)] **93** have been prepared [104], whereas **92** was determined by crystal structure, the structure of **93** was proved by ^{11}B and ^{13}C NMR spectroscopy. Compound **92** is a tetracyclic derivative of the less stable conformer of inositol (five axial hydroxyl groups and one equatorial) with two dioxaboroline rings at opposite faces of the six-membered ring and a dioxaborolidine ring bridging the C1 and C2 atoms at axial and equatorial positions. A similar structure was found for **93** with the difference that, bridging C1 and C2, there is a dioxolane ring. The boron atoms are planar with their attached atoms and stabilized by retrocoordination between the boron and oxygen and carbon atoms, respectively. The two phenyl rings that are in the same face of the molecule are essentially parallel, with a dihedral angle between planes of 28.3 ± 0.8°.

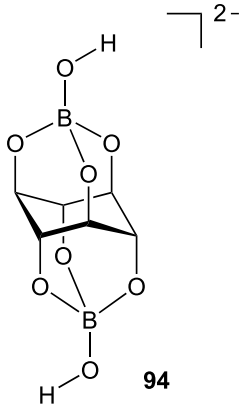
With *scyllo*-inositol boron builds a complex $Na_2[B_2(OH)_2$(*scyllo*-InsH$_{-6}$)] · 9 H_2O (Na_2**94** · 9 H_2O) [105], where an all-*cis*-*scyllo*-inositol builds a hexaoxadiamantane-like structure with two boron centers. The *scyllo*-inositol diborate anion itself comprises a rigid cage structure,

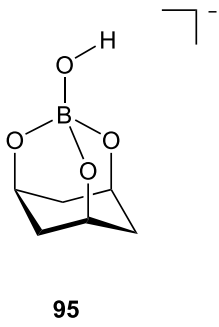
the C atoms in the inositol ring are in a chair conformation with normal distances and angles. The two B atoms, situated on either side of the ring, are each bonded axially to alternate ring C atoms via three O atoms with B–O bond distances of 1.48 to 1.51 Å and C–O distances of 1.42 to 1.45 Å. Completing the tetrahedral coordination, each B atom is bonded also to an OH at 1.42 Å.

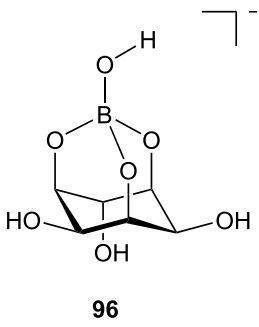




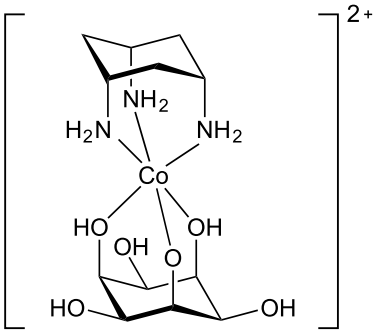
Corresponding to structure **94**, in aqueous alkaline solutions the existence of the two anionic tridentate borate esters [B(OH)(all-*cis*-1,3,5-triol-chxnH$_{-3}$)]$^-$ **95** and [B(OH)(*epi*-InsH$_{-3}$)]$^-$ **96** is proved by ^{11}B NMR spectroscopy [40]. The borate ester of all-*cis*-cyclohexane-1,3,5-triol has a chemical shift of −18.1 ppm, the ester of *epi*-inositol a chemical shift of −19.4 ppm.



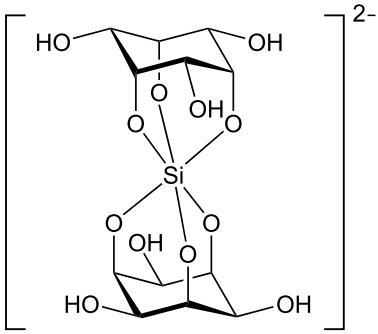




In the structure of [Co(tach)(*cis*-InsH$_{-1}$)](NO$_3$)$_2$ (**97**(NO$_3$)$_2$) [106], cobalt(III) is bound to the three amino groups of all-*cis*-1,3,5-triaminocyclohexane and to three axial oxygen donors of *cis*-inositol. The structure shows that only one of the coordinated hydroxyl groups of *cis*-inositol is deprotonated. Consequently, the Co–O$_H$ distance of 1.90 Å is significantly shorter than the corresponding Co–OH distances of 1.94 Å. Moreover, the C–O bond lengths of the coordinated alcoholic groups are slightly longer than the corresponding bond distance of the coordinated alkoxido group. In turn, the Co–N distance, which is *trans* to the alkoxido group, is significantly elongated, indicating a stronger *trans* influence of RO$^-$ compared with ROH.



97



98

Without tach as auxiliary ligand $Cs_2[Si(cis\text{-}InsH_{-3})_2]$ (Cs_2**98**) [92] shows a bis-tridentate 1,3-diolate binding-*cis*-inositol complex. In contrast to the finding that a pyranoidic 1,2,3-triol like $^1C_4$-Me-β-D-Rib*p*, with its large torsional angles, is not so efficient an Si-chelator as a furanoidic diol, the significant enrichment of aqueous alkaline silicate solutions by hexacoordinate species on addition of *cis*-inositol is remarkable.

Besides these, to one metal atom coordinated *cis*-inositol complexes, there are two related fields of research. One is the complex coordination of metal atoms to the polyaminoalcohols, especially 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol, since the amino group can either act as additional donors for metal binding or serve as internal bases, facilitating the deprotonation and coordination of the hydroxyl groups [107].

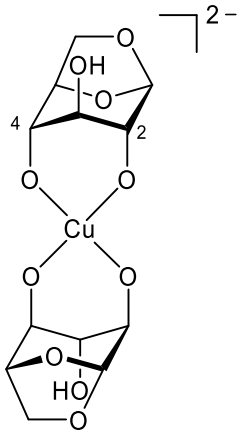
The other field of research deals with *cis*-inositol-coated polyoxometalate clusters [108,109, 110]. $[OFe_6\{(cis\text{-}Ins)_6\text{-}21H\}]^{5-}$ and $[Ta_7O_{12}(cis\text{-}InsH_{-3})_6]^{7-}$ build polyoxometalate cores which are coordinated to *cis*-inositol on the outer binding sites. In the case of $[OFe_6\{(cis\text{-}Ins)_6H_{-21}\}]^{5-}$ there are five different modes of coordination of *cis*-inostiol to the Fe atoms, so that there is no preferred coordination mode recognizable. In the case of $[Ta_7O_{12}(cis\text{-}InsH_{-3})_6]^{7-}$, *cis*-inositol binds over the three *cis*-standing hydroxyl groups to the Ta atoms.

5.2 1,6-Anhydro-β-D-Glucose (Levoglucosan)

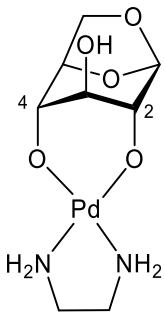
Currently there are three known structures of metal-coordinated 1,6-anhydro-β-D-glucose (Glc1,6An; levoglucosan). The cuprate anion of $Li_2[Cu(Glc1,6An2,4H_{-2})_2] \cdot 8\ H_2O$ is a homoleptic mononuclear 1,3-polyolato(2-) complex.

Generally, in terms of flexibility a chelate ligand is of limited variability, particularly when the ligator atoms are attached to a further cyclic fragment and above all, to a six-membered ring in its energetically favored chair conformation. In the coordination chemistry of carbohydrates, this general statement may be quantified for 1,2-diol fragments incorporated in pyranose rings. In cuprate(II) or cobalt(II) complexes of β-D-galactose, α-D-mannose and β-D-xylose, the mean O–O distance of the ligating diol groups is 2.67 $\pm$ 0.01 Å. This corresponds to a 0.19 Å reduction of the respective mean distance of 2.85 $\pm$ 0.02 Å in the uncomplexed methyl glycopyranosides.

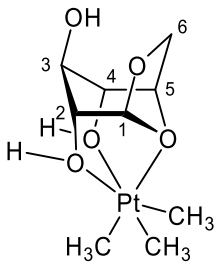
Assuming that a bicyclic pyranoidic carbohydrate will also be of restricted flexibility, the twofold reduction of the ligator atom distance (0.38 Å on coordination of cupric ions by 1,6-anhydro-β-D-glucose, compared with the above-mentioned 1,2-diolates, was unexpected due to the large O–O separation of 3.30 Å in the free anhydro sugar [111].



99



100



101

In the mononuclear cuprate(II) anion **99** (4 + 2)-coordinated Cu^{II} forms six-membered rings with doubly deprotonated levoglucosan ligands at a shorter Cu–O distance (Cu–O2, 1.95 Å Cu–O4, 1.99 Å. Two longer contacts are established with the O5 atoms of the pyranose rings. The chelate bonding mode is enabled by the astonishingly enhanced flexibility of the bicyclic ligand compared with simple pyranoses [112].

[(en)Pd(Glc1,6An2,4H_{-2})] · H_2O (**100** · H_2O) is formed in a reaction from Pd-en and 1,6-anhydro-β-D-glucose [84]. Levoglucosan again can act as a 1,3-diolato ligand by bonding through O2 and O4. The distances between Pd–O2 and Pd–O4 amount to 2.04 Å and 2.05 Å the angle between O2–Pd–O4 to 97.0°. In fact, **100** is a six-membered-ring chelate complex and the molecular structure of **100** again shows flexibility of the bicyclic ligand, which undergoes distortion of the pyranose chair towards a boat conformation. In this distortion, greater flattening of the pyranose ring at C3 corresponds to an increasing O2–O4 distance. Conversely, in **100** the respective hydroxyl groups occupy a more axial position, and the 'bite' is smaller than in the free anhydro sugar. This can be compared with the even smaller O–O distance in Li_2**99** · 4 H_2O.

In [$PtMe_3$(Glc1,6An)]BF_4 (**101**BF_4) 1,6-anhydro-β-D-glucose acts as a neutral tridentate ligand which is coordinated through two hydroxyl groups (O2, O4) and an acetal oxygen atom (O5) of the glucopyranose ring. Thus, two five-membered rings and one six-membered 1,3,2-dioxaplatinacyclohexane ring are formed exhibiting a distorted half-chair and chair conformation, respectively. The cyclic system is not free from angle strain which is revealed particularly by the O–Pt–O angles. Two of them are distinctly smaller than 90° (O2–Pt–O5, 73.6°; O4–Pt–O5, 75.6°), whereas the C–Pt–C angles remain nearly orthogonal (88.1–89.9°). The two Pt–O bonds to the hydroxyl groups are almost equal (Pt–O2/O4, 2.25 Å. Contrarily, the Pt–O bond to the acetal oxygen is significantly longer (Pt–O5, 2.29 Å. This may be

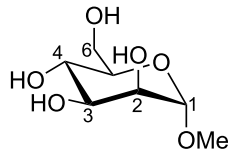
explained in terms of the very low donor capability of the acetal oxygen atom and of the high *trans* influence of the methyl ligand [113].

6 Glycosides

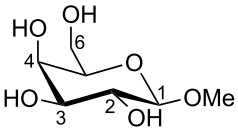
Glycosides are obtained by conversion of the cyclic semiacetal form of aldoses and ketoses to an acetal. We will focus on the metal complexes and esters of the following glycosides: alkyl pyranosides, alkyl furanosides, non-reducing disaccharides, polysaccharides, and finally the nucleosides as a member of the group of *N*-glycosides.

6.1 Pyranosides

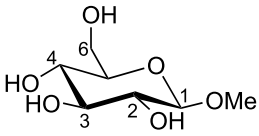
In the following, solid-state and solution structures of the pyranosides **102**–**107** and their protected derivatives will be described.



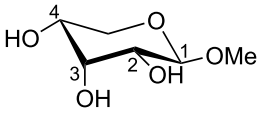
102



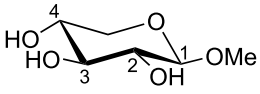
103



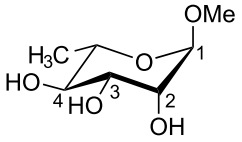
104



105



106



107

Methyl-α-D-mannopyranoside (Me-α-D-Man*p*) **102** is one of the structurally best-investigated compounds among the pyranosides. The reaction of equimolar amounts of $Cu(OH)_2$, ethylenediamine, and **102** in aqueous solution leads to a blue solution and crystals of the heteroleptic copper(II) complex [(en)Cu(Me-α-D-Man*p*2,3H$_{-2}$)] · 2 H_2O. The crystal-structure determination reveals that the copper center is coordinated in a square planar geometry (compare **37**, **39**, **72**) with two of the four coordination sites occupied by the *cis*-$O2_{ax}$,$O3_{eq}$ diolato moiety of **102** in a $^4C_1$-conformation (ax = axial, eq = equatorial) [20]. The homoleptic cuprate **108** (❯ *Fig. 21*) is obtained by a reaction of $Cu(OH)_2$ with the double-molar amount of **102** in strong alkaline solution. The coordination pattern of the carbohydrate is similar to that observed in the just described heteroleptic complex: both pyranosides are in a $^4C_1$-conformation and act as *cis*-$O2_{ax}$,$O3_{eq}$ diolato ligands. The preference of the *cis*-$O2_{ax}$,$O3_{eq}$ chelation site to the *trans*-$O3_{eq}$,$O4_{eq}$ site may be explained by the acidity of the hydroxyl functions (the acidity decreases in the sequence O2-H > O3-H > O4-H) as well as by the difference of the corresponding O–C–C–O torsion angles in **108** and in free methyl-α-D-mannopyranoside, respectively. The torsion angles of the chelating diolato moieties in **108** are 47.5° and 47.8°, respectively, which is about 8° less than the $O2_{ax}$–C–C–$O3_{eq}$

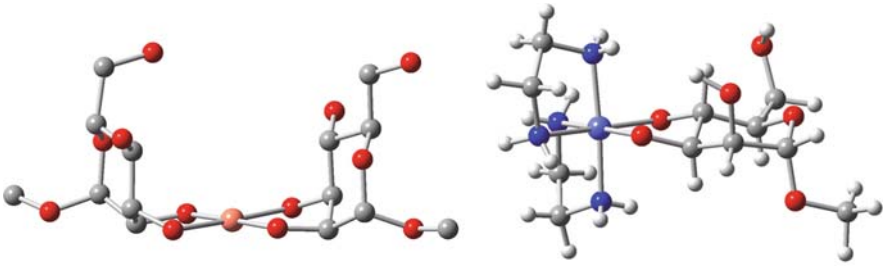


Figure 21
The molecular structures of [Cu(Me-α-D-Man*p*2,3H$_{-2}$)(Me-α-D-Man*p*2,3,4H$_{-3}$)]$^{3-}$ 108 in crystals of $Li_3$108 · 5 H_2O and Δ-[(en)$_2$Co(Me-α-D-Man*p*3,4H$_{-2}$)]$^+$ 109 in crystals of 109ClO_4 · $NaClO_4$ · 2 H_2O (hydrogen atoms omitted for clarity in 108)

torsion angle and about 20° less than the $O3_{eq}$–C–C–$O4_{eq}$ torsion angle in free $^4C_1$-methyl-α-D-mannopyranoside [114]. Obviously the diol residue causing less conformative strain of the pyranoside is chosen as the chelation site [85].

Besides the conformative strain and acidity of the hydroxyl functions, however, steric factors may also influence the selection of a chelation site. In the complex cation **109** (● *Fig. 21*), the cobalt(III) center is coordinated by the *trans*-$O3_{eq}$,$O4_{eq}$ diolato moiety of **102**. The latter forms a torsion angle of 53.9° which is just about 1.8° less than the *cis*-$O2_{ax}$,$O3_{eq}$ torsion angle of free $^4C_1$-methyl-α-D-mannopyranoside. Thus only little deformation of the pyranoside would be necessary with a *cis*-$O2_{ax}$,$O3_{eq}$ chelation site. However, a comparison of the structures **108** and **109** (● *Fig. 21*) reveals that the latter site is unfavorable in **109** for steric reasons. The involvement of an axially bonded oxygen atom in a five-membered chelate ring results in an approximately perpendicular orientation of the planes of the chelate ring and the pyranose ring (compare **108**), while the planes are coplanar with two equatorially bonded oxygen ligator atoms (compare **109**). The perpendicular orientation is hampered in **109** by amino groups of ethylenediamine below and above the CoO_2N_2 plane, while it is enabled in **108** in which the coordination sites below and above the copper center are not occupied [80].

A three-dimensional, triply connected network is established in **110** (● *Fig. 22*) with tridentate $^4C_1$-methyl-α-D-mannopyranoside **102** and bismuth(III) (the figure shows the symmetrically independent bismuth atoms and mannopyranosides). Each of the carbohydrates acts as triolato ligand and is bonded in five-membered chelate rings formed by the *cis*-$O2_{ax}$,$O3_{eq}$ as well as by the *trans*-$O3_{eq}$,$O4_{eq}$ diolato moieties to two bismuth centers with O3 in the μ_2 mode. The torsion angles of the *cis*-diols (48.3°, 49.4°) are smaller than those of the *trans*-diols (55.4°, 57.4°) as is found in **108** (● *Fig. 21*) and in free methyl-α-D-mannopyranoside. The two independent bismuth atoms bonded to the *trans*-$O3_{eq}$,$O4_{eq}$ diolato moieties are located on sites which possess site symmetry 3 and are the branching points of the network [115].

Moreover, several vanadate chelate esters with O4- and O6-protected derivatives of $^4C_1$-methyl-α-D-mannopyranoside have been structurally characterized. In all these esters the remaining unprotected hydroxyl functions of the *cis*-$O2_{ax}$,$O3_{eq}$ diol residue act as the chelation site. The dinuclear vanadate chelate ester **111** (● *Fig. 22*) is obtained with methyl-4,6-*O*-benzylidene-α-D-mannopyranoside. The two VO_2^{2+}-centers are bridged by two O2-alkoxido

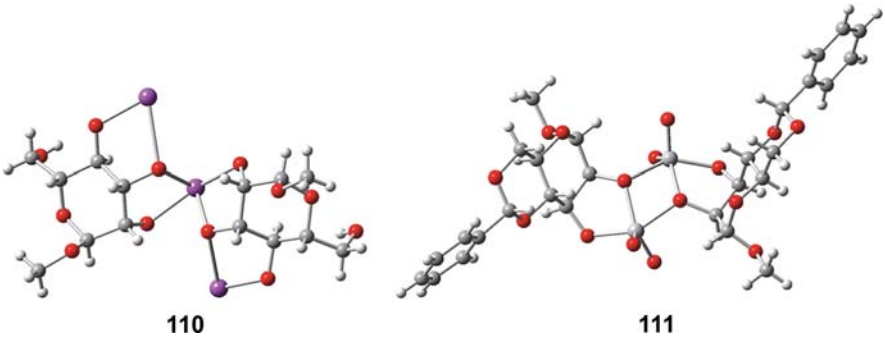

Figure 22
The molecular structures of $[Bi_{5/3}(Me\text{-}\alpha\text{-}D\text{-}Manp2,3,4H_{-3})_2]^-$ 110 in crystals of $Na_2$110(OH) · 12 H_2O and $[\{VO_2(Me\text{-}4,6\text{-}O\text{-}benzylidene\text{-}\alpha\text{-}D\text{-}Manp2,3H_{-2})\}_2]^{2-}$ 111 in crystals of $[NBu_4]_2$111

functions and have a distorted trigonal-bipyramidal geometry. As a consequence of the small crystal radius of 0.60 Å of a penta-coordinated vanadium(V) [116] the torsion angles of the chelating *cis*-$O2_{ax}$,$O3_{eq}$ diolato functions are just 39.5° and 40.1° with O2–O3 distances of 2.49 Å and 2.50 Å respectively [117]. Only one of the two hydroxyl functions of the chelating *cis*-$O2_{ax}$,$O3_{eq}$ diol residue is deprotonated in the vanadate esters of methyl-4,6-di-*O*-methyl-α-D-mannopyranoside [118,119,120], and methyl-4,6-*O*-benzylidene-α-D-mannopyranoside [121], namely the one located in the *trans*-position to the *N*-ligator atom of the auxiliary ligands bonded tridentately to the vanadium(V) centers. A comprehensive review concerning this type of vanadate chelate esters has been written by Chakravorty et al. [11].

Methyl-β-D-galactopyranoside (Me-β-D-Gal*p*) **103** in its $^4C_1$-conformation comprises two adjacent diol functions: a *trans*-$O2_{eq}$,$O3_{eq}$ diol and a *cis*-$O3_{eq}$,$O4_{ax}$ diol. Analogously to methyl-α-D-mannopyranoside in **109** (*Fig. 21*), methyl-β-D-galactopyranoside acts as chelating ligand in a bis(ethylenediamine)cobalt(III) complex through its *trans*-$O2_{eq}$,$O3_{eq}$ diolato moiety for sterical reasons [80]. A torsion angle of just 32.3° (55.6° in free Me-β-D-Gal*p* [122]) is formed by the chelating *cis*-$O3_{eq}$,$O4_{ax}$ diolato group of methyl-β-D-galactopyranoside in the rhenium(V) complex **112** (*Fig. 23*) while the torsion angle of the *trans*-$O2_{eq}$,$O3_{eq}$ diol is enlarged to 75.7° (62.9 in free Me-β-D-Gal*p*). A comparably strained pyranoside is present in methyl 3,4-*O*-isopropylidene-β-D-Gal*p* [123]. NMR-experiments reveal that the oxolane ring is oriented towards the rhenium-bonded oxo group (*syn*-isomer) in solution as well, while the *anti*-isomer is detectable as intermediate only [82].

The *cis*-$O3_{eq}$,$O4_{ax}$ diol group of 2,6-*O*-protected derivatives of methyl-β-D-galactopyranoside is also reported to act as a chelation site in a vanadate ester [120], and in the phosphinite **113** (*Fig. 23*) which incorporates a five-membered dioxophospholane ring [124].

Glucopyranosides include two almost equivalent *trans*-configured diol functions: the $O2_{eq}$, $O3_{eq}$ site and the $O3_{eq}$,$O4_{eq}$ site. This may cause the formation of mixtures of metal derivatives and be the reason for very limited structural information on metal complexes of unprotected glucopyranosides. Methyl-β-D-glucopyranoside (Me-β-D-Glc*p*) **104** is found to be coordinated to a (tren)Ni^{2+}-center (tren = tris(2-aminoethylamine)) by its $O3_{eq}$,$O4_{eq}$ diolato moiety in the solid state [125]. More structures are characterized for 4,6-*O*-protected glucopyranosides since their complexation behavior is more calculable. The dinuclear titanium(IV)

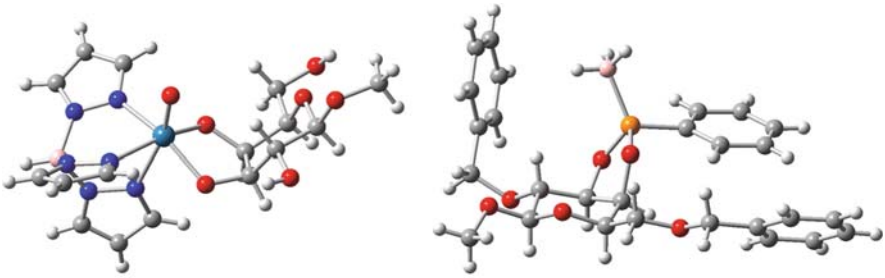

Figure 23
The crystal structures of [(tpb)ReO(Me-β-D-Gal*p*3,4H$_{-2}$)] 112 and methyl 2,6-di-*O*-benzyl-3,4-*O*-phenylphosphinediyl-β-D-Gal*p* (P–B)borane 113

complex **114** (*Fig. 24*) is formed with the 4,6-*O*-benzylidene derivative of **104** (a complex similar to **114** is obtained with the 4,6-*O*-naphthylmethylidene derivative of **104**), in which the latter acts as a bidentate but not as a chelating ligand [126]. Obviously the titanium(IV) center (crystal radius 0.56 Å [116]) is too small to be chelated by a *trans*-configured diol of a (gluco)pyranoside, while the next-in-size homolog zirconium(IV) (crystal radius for hexacoordinated Zr^{IV}: 0.86 Å [116]) is chelated in a dinuclear complex with the carbohydrate used in **114** [127]. Pentacoordinated tin(IV) (crystal radius 0.76 Å [116]) is of a size suitable to be chelated by such a ligand as well. In the dinuclear complex **115** (*Fig. 24*) which has a constitution comparable to **111** (*Fig. 22*), the *trans*-O2$_{eq}$,O3$_{eq}$ diolato chelation site is coordinated to a (n-Bu)$_2$Sn^{2+} center while a second (n-Bu)$_2$Sn^{2+} center is bonded by the bridging O3-alkoxido function [128]. NMR studies reveal that the chelation of pentacoordinated vanadium(V) (crystal radius 0.60 Å [116]) with the *cis*-configured O2$_{ax}$,O3$_{eq}$ diolato site of mannopyranoside is preferred over the *trans*-configured O2$_{eq}$,O3$_{eq}$ diolato site of glucopyranoside [117].

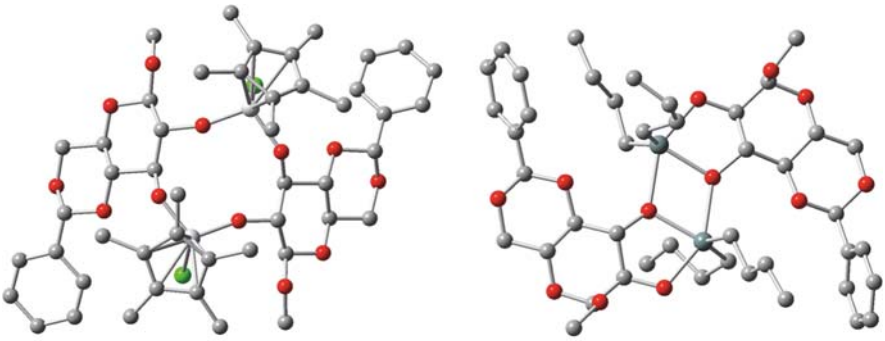

Figure 24
The crystal structures of [(Cp*TiCl)-μ-(methyl 4,6-*O*-benzylidene-β-D-Glc*p*2,3H$_{-2}$)]$_2$ 114 and [(Sn(n-Bu)$_2$)-μ-(methyl 4,6-*O*-benzylidene-α-D-Glc*p*2,3H$_{-2}$)]$_2$ 115 (hydrogen atoms omitted for clarity)

A homoleptic cuprate similar to **108** (◉ *Fig. 21*) is formed with the $^{1}C_{4}$-conformer of methyl α-L-rhamnopyranoside **107** with the *cis*-$O2_{ax}$,$O3_{eq}$ diolato moiety acting as the chelation site [129]. However, chelation with the *trans*-$O2_{eq}$,$O3_{eq}$ diolato moiety of methyl-β-D-xylopyranoside (Me-β-D-Xyl*p*) **106** is observed in the heteroleptic copper(II) complex **116** (◉ *Fig. 25*), in which a water molecule is bonded to the now pentacoordinated copper center with a distance of 2.26 Å [130]. According to Shannon, the crystal radii of penta- and tetracoordinated (in a square planar geometry) copper(II) are 0.79 Å and 0.71 Å respectively [116]. A transformation of the more stable $^{4}C_{1}$-conformer of free methyl-β-D-ribopyranoside (Me-β-D-Rib*p*) **105** to the $^{1}C_{4}$-conformer is observed in the trinuclear rhenate **117** (◉ *Fig. 25*). A suitable arrangement of oxygen ligator atoms is provided by the all-*cis*-$O2_{ax}$,$O3_{eq}$,$O4_{ax}$ triolato moiety which is bonded to the Re_3-core with all alkoxido functions in the μ_2 mode [32].

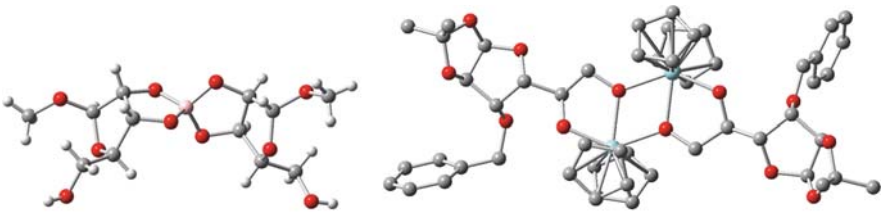
6.2 Furanosides

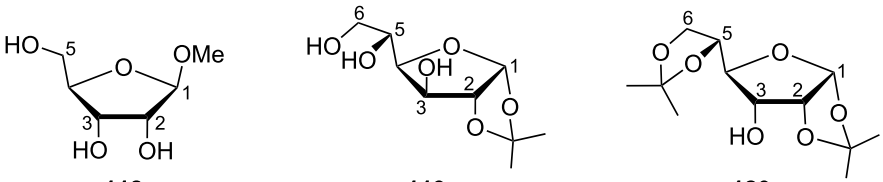
Methyl-β-D-ribofuranoside (Me-β-D-Rib*f*) **118** comprises a *cis*-O2,O3 diol group and often shows a complexation behavior like its non-chiral analog anhydroerythritol, the complexes of which have been described above. A bis(diolato) borate similar to **121** (◉ *Fig. 26*), for example, is also formed with anhydroerythritol. The boron center is tetrahedrally coordinated by two chelating *cis*-O2,O3 diolato groups which form torsion angles of 12.8° and 9.2° with O2–O3 distances of 2.32 Å and 2.30 Å respectively. These rather small angles and distances are accessible by furanoidic diol groups but not by pyranoidic diol groups as a consequence of the small boron atom. Solutions with a molar ratio of B:**118** of 1:2 contain two diastereomeric forms of **121** (◉ *Fig. 26*) as well as monodiolato-dihydroxo borate [87]. In the ruthenium complex cation [(*mer*-dien)(NO)Ru(Me-β-D-Rib*f*2,3H$_{-2}$)]$^{+}$, the O3 and O2 ligator atoms of the diolato moiety occupy two equatorial sites trans to NO and the central nitrogen atom of dien, respectively. The *trans*-influence of the NO group results in a Ru–O distance which is



121 122

Figure 26
The molecular structures of [B(Me-β-D-Ribf2,3H$_{-2}$)]$^-$ 121 in crystals of Na121 · 2 H_2O and [{Zr(Cp)$_2$(3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-Glcf5,6H$_{-2}$)}$_2$] 122 in crystals of 122 · C_7H_8. The hydrogen atoms have been omitted for clarity in 122

about 0.15 Å shorter than the other Ru–O distance. Two species have been identified in the mother liquor, both showing a ^{13}C NMR downfield shift of about 15 ppm for the carbon atoms of the chelating diolato residue [81]. Three isomers already described for silicate complexes of anhydroerythritol have also been identified in solutions of [SiR(Me-β-D-Ribf2,3H$_{-2}$)2]$^-$ (R = Ph, OMe): *anti/anti*, *syn/anti*, and *syn/syn*. A downfield shift of 1.4–2.5 ppm is observed for the carbon atoms of the chelating diolato moiety [92].

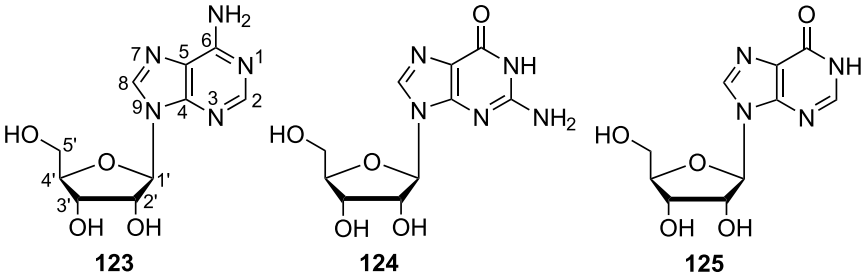


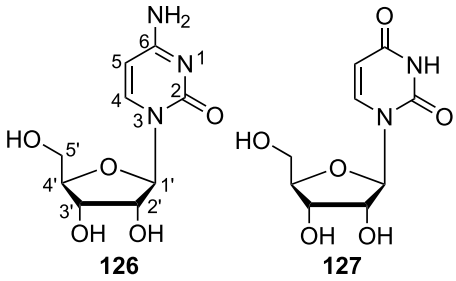
118 119 120

The 5-methyl-protected derivative of **118** has been found to act as a chelating ligand in vanadate esters in which only one of the two coordinating hydroxyl groups of the *cis*-diol moiety is deprotonated [119,120]. 1,2-*O*-isopropylidene-α-D-glucofuranose **119** is bonded to a $Ru_3(CO)_8^{2-}$ residue as a tetradentate ligand, namely through the hydroxyl function at C6, two μ_2-alkoxido functions at C3 and C5, respectively, and the oxygen atom of the furanose ring [131]. The three hydroxyl oxygen atoms of **119** act as facially coordinating sites in an octahedral platinum(IV) complex, which is, interestingly, also obtained when the 5,6-*O*-isopropylidene derivative of **119** is used as the starting material. The same complexation behavior is shown by 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose **120** [132,133]. These and many more furanoside and other carbohydrate complexes with platinum-group metals have been described already in a comprehensive review written by Steinborn and Junicke [7].
The two remaining hydroxyl functions at C5 and C6 of the 3-*O*-benzyl derivative of **119** are deprotonated and act as the chelation site in the dinuclear zirconium(IV) complex **122** (*Fig. 26*) in which the less-stressed terminal alkoxido functions are in a bridging mode in the solid state as well as in solution [134].

6.3 Nucleosides

An *N*-glycosidic linkage between β-D-ribose and the nucleobases adenine, guanine, hypoxanthine, cytosine, and uracile leads to the ribonucleosides adenosine (ado) **123**, guanosine (guo) **124**, inosine (ino) **125**, cytidine (cyd) **126**, and uridine (urd) **127**, respectively. In the following, complexes and esters using the chelating sites of the ribose moiety are discussed.





In the 1970s structural investigations of osmium(VI) and uranium(VI) complexes with adenosine **123** and its 5′-phosphate derivatives emphasized the chelation ability of the furanoidic *cis*-diol group. In the crystal structure of the mononuclear heteroleptic complex $[OsO_2(py)_2(Ado2',3'H_{-2})]$ (py = pyridine), adenosine acts as diolato ligand with its ligator atoms O2′ and O3′ being *trans* to the nitrogen atoms of the two coordinating pyridine molecules. The reported π stacking of the adenine bases is a structural feature typical for solid-state nucleoside complexes [135]. With 2,2′-bipyridyl instead of the two pyridine molecules, osmium(VI) complexes similar to that described above are also obtained in neutral aqueous solution with 5′-phosphate derivatives of adenosine **123** and uridine **127**, respectively [136]. Di- and tetranuclear UO^{2+} complexes are formed at pH 11 with adenosine-5′-monophosphate with O3′ of the chelating diolato moiety bridging between two uranium centers (compare dinuclear VO^{2+} complex **128**, ❯ *Fig. 27*) while at pH 7.5 the uranium centers are coordinated by phosphate oxygen atoms only [137]. The same behavior is also shown by adenosine-5′-di- and -triphosphate with the exception that no dinuclear species is observed with the diphosphate [138]. The dimeric dinuclear solid-state structure of the vanadium(V)-adenosine complex anion **128** (❯ *Fig. 27*) has been found to be maintained as the main species besides several minor products in a solution of pH 6.5 [139]. The dimeric structure has been suggested by most of the groups working on the investigation of the solution structures of vanadium

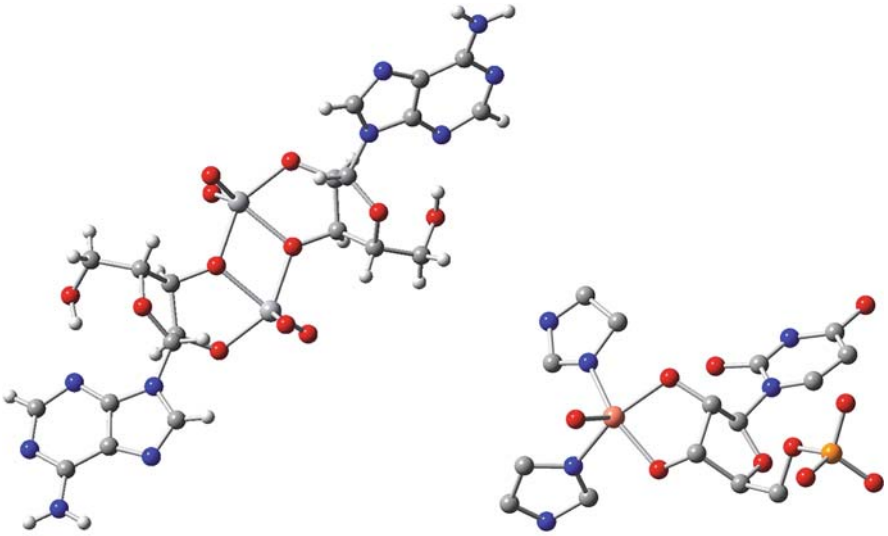


Figure 27
The molecular structures of $[\{VO_2(Ado2',3'H_{-2})\}_2]^{2-}$ 128 in crystals of $[NEt_4]_2$128 · 4.74 H_2O and [Cu(5′-UMP2′,3′H$_{-2}$)(im)$_2$(H_2O)] 129 in crystals of 129 · 4 H_2O (hydrogen atoms omitted for clarity). Abbreviations: UMP = uridine monophosphate, im = imidazole

complexes with the nucleosides **123**–**127** as well as their 5′-derivatives in the years before the detection of **128** (◉ *Fig. 27*) [117,140,141,142,143,144,145,146].
Dinuclear subunits similar to **128** are also found in the octanuclear copper-uridine complex anion $[Cu_8(Urd3,2',3'H_{-3})_8]^{8-}$, in which two square-planar coordinated copper atoms are linked by two O2′ ligator atoms of two triply deprotonated uridine moieties. The coordination sphere of the copper centers is completed by a nitrogen atom (N1) of the nucleobase of uridine [147]. The mononuclear copper complex **129** (◉ *Fig. 27*) is formed with uridine-5′-monophosphate in neutral aqueous solution in which the diol is deprotonated as a result of the chelation at the copper center while the non-coordinating nucleobase is not deprotonated under these conditions [148]. 3-Acetamidophenylboronic acid reacts with the diol group of adenosine to a cyclic monoester with tricoordinate boron [149], whereas the reaction of boric acid and guanosine in strong alkaline aqueous solution leads to reaction products similar to those described above for the boron-anhydroerythritol system: two stereoisomers of bis(diolato)borates (compare **121**, ◉ *Fig. 26*) exist in addition to monodiolato-dihydroxo borate ester [87]. The coordination behavior of $CpMo^{2+}$ towards the ribonucleosides **123**, **124**, **126**, and **127** and the corresponding 5′-monophosphates has been shown to be pH-dependent. At a pH of 9, the molybdocene centers are chelated exclusively by the diolato moiety, while in neutral solution a coordination of the nucleobase and phosphate oxgen atoms is also observed [150].

The reaction of cytidine **126** with [*mer*-(dien)(NO)$RuCl_2$]PF_6 in an aqueous solution of a pH of 12.5 leads to two isomers of diolato complexes similar to those described above with **118** while guanosine and uridine—both providing deprotonated amide functions under these conditions—are bonded to the ruthenium center by their nucleobases [81].

Homoleptic bis(diolato) bismuthates and antimonates are formed with adenosine as well as with guanosine in alkaline solutions with a pH of at least 11. The coordination pattern of all the complexes resembles the one in the bis(adenosinato)antimonate **130** (◉ *Fig. 28*): two nucleosides act as diolato ligands and occupy four of five coordination sites of the metal centers which are coordinated in a distorted trigonal-bipyramidal geometry with the stereochemically active lone pair in an equatorial orientation. Being identical in all the structures, the packing of the guanosinato complex anions is stabilized by two intermolecular hydrogen bonds of the type N2–H···N3 between two adjacent guanine base pairs. A CIS of 3–6 ppm of the carbon atoms C2′ and C3′ involved in the five-membered chelate ring formed by bismuth(III) and antimony(III) with adenosine **123**, guanosine **124**, and inosine **125** indicates that the coordination mode is maintained in alkaline solution [151,152].

The formation of several penta- or hexacoordinated silicate complexes is observed on the addition of adenosine, guanosine, and cytidine to aqueous alkaline silicate solutions. Hexacoordination is favored by an increase of the pH and high molar ratios of furanoidic cis-diol:silicon [94]. Hexacoordinate silicon is present in the homoleptic tris(diolato)silicate **131** (◉ *Fig. 28*) with cytidine **126** as chelating ligand. Pentacoordinate methoxy- or phenyl-bis(nucleosidato)silicates of the type $[SiR(Nuc2',3'H_{-2})2]^-$ (R = Ph, OMe) are obtained with the nucleosides (Nuc) adenosine and cytidine in methoxide-containing methanolic solutions. Different *syn/anti*-isomers similar to those observed with anhydroerythritol or methyl-β-D-ribofuranoside can be identified by ^{29}Si- and ^{13}C NMR data [92].

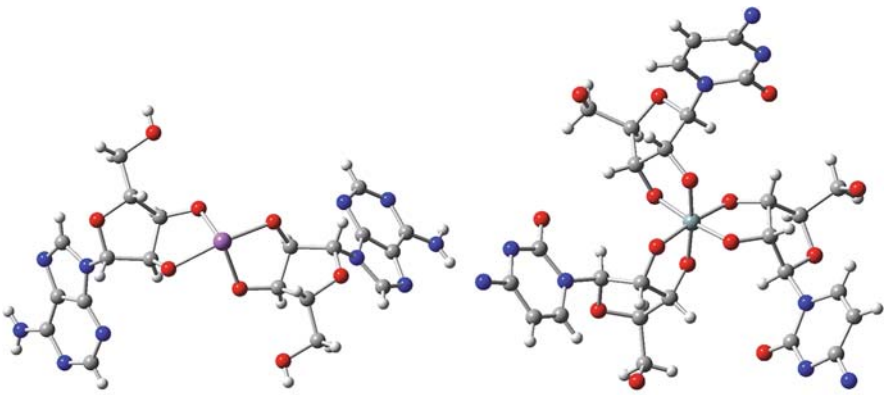

Figure 28

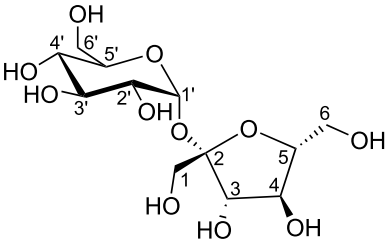
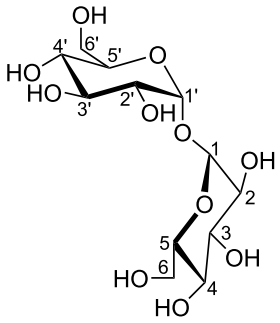
6.4 Non-Reducing Disaccharides

Metal complexes of non-reducing disaccharides such as sucrose (β-D-Fru*f*-(2↔1)-α-D-Glc*p*) **132** or α,α-trehalose (α-D-Glc*p*-(1↔1)-α-D-Glc*p*) **133** not only deserve interest in their own right but also as model compounds for the corresponding complexes with oligo- and polysaccharides. Thus the action of the coordinating cellulose solvents [Pd(en)$(OH)_2$] (Pd-en), [Cu(en)$(OH)_2$] (Cu-en), [Ni(tren)$(OH)_2$] (Ni-tren), and [Cd(tren)$(OH)_2$] (Cd-tren) on the polysaccharide were derived from crystal structures with **132** and **133** (compare ❯ *Sect. 6.6*).



132



133

In the dinuclear complex **134** (❯ *Fig. 29*), two Pd^{II}(en) moieties are chelated by the Glc*p*-O3′,O4′- and the Fru*f*-O1,O3-diolato moieties of sucrose **132**, that is, in five- and six-membered chelates, respectively. The selection of the Glc*p*-O3′,O4′ site instead of the similar Glc*p*-O2′,O3′ site is reasonable since an intramolecular hydrogen bond of the type O2′–H···$O1^-$ stabilizes the sucrose residue in a conformation which is also found for the free carbohydrate (there with a hydrogen bond of the type O1–H···O2′ in the reversed direction) [84,153]. A similar coordination and hydrogen-bond pattern is found with Cu^{II}(en) [153]. However, only a mononuclear complex with the Ni^{II}(tren) residue bonded to the Glc*p*-O2′,O3′ diolato site is obtained in a reaction of Ni-tren and sucrose in molar ratio of 2:1. In this complex, the intramolecular hydrogen bond O1–H···O2′ which is also found in free sucrose is retained [125,153]. A dicationic Δ-configured complex is formed by sucrose and bis(phenanthroline)cobalt(III) in which the metal center is involved in an eight-membered ring with the Glc*p*-O2′- and the Fru*f*-O1 chelation sites. NMR data reveal that O2′ is deprotonated and they support the structure of the Δ-configured complex by the observation of an NOE involving the sucrose and phenanthroline residues [154].

Two crystal structures of metal complexes of α,α-trehalose **133** are reported. Two Cd^{II}(tren) residues are chelated by the Glc*p*-O2,O3 and the Glc*p*-O2′,O3′ diolato moieties, respectively, in the dinuclear complex **135** (❯ *Fig. 29*). As in free α,α-trehalose in the crystalline state, direct intramolecular hydrogen bonds are not found due to conformational restraints, but two sequences of the type $O2^-$···H–O^w···H–O6′ with a linking water molecule H_2O^w are observed (the reversed direction is found in free α,α-trehalose) [153]. Only one of the two Glc*p*-O2,O3-chelation sites of α,α-trehalose is chosen in a mononuclear complex with Ni-Me_3tren, the *N*,*N*′,*N*″-trimethyl analog of Ni-tren, in which no support by an intramolecular

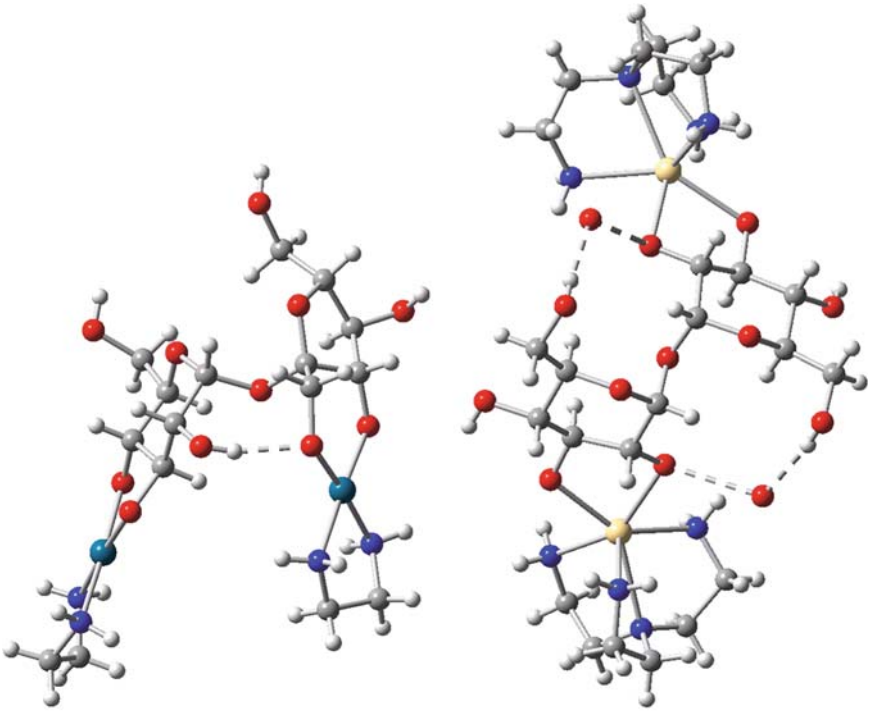


Figure 29
The molecular structures of $[(en)_2Pd_2(Suc1,3,3',4'H_{-4})]$ 134 in crystals of 134 · 11 H_2O and $[(tren)_2Cd_2(\alpha,\alpha\text{-}Tre2,3,2',3'H_{-4})] \cdot 2\ H_2O$ 135 in crystals of 135 · 15 H_2O. *Dashed lines*: hydrogen bonds

hydrogen bond is observed. It seems that in this case the chelation is governed by the enhanced acidity of the Glc*p*-O2,O3 site compared to the Glc*p*-O3,O4 site [125].

6.5 Cyclodextrins

Cyclodextrins (CD) are cyclic torus-shaped oligosaccharides with n α-(1↔4)-glycosidic-linked glucose molecules ($n = 6$: α-CD, $n = 7$: β-CD, $n = 8$: γ-CD) (**136**). All the Glc*p*-O2,O3 diol functions are oriented to the same side of the torus resulting in a regularly arranged coordination site pattern. This enables the formation of sandwich-type complexes in which the metal centers are enclosed between the bisdiol moieties of two CD molecules (double torus). The number of metals being chelated by the diol functions depends on factors such as the Lewis acidity of the metal or the size of the alkali counterion. Six bismuth(III) centers are bonded by six bisdiolato moieties provided by two α-cyclodextrin molecules in the electrically neutral C_2-symmetric structure **137** (*Fig. 30*, a = view through the double torus, b = view onto the double torus) though a molar ratio of bismuth:α-CD of 3:2 was present during the reaction in aqueous sodium hydroxide. This indicates that the reaction is governed less by stoichiometry than by molecular recognition, and, as a consequence, **137** (*Fig. 30*) may

be considered a supramolecular assembly. The Lewis acidity of the bismuth(III) atoms is sufficient to force complete deprotonation of the bisdiol moieties (compare the structures with adenosine, guanosine or methyl-α-D-mannopyranoside, for example). This leads to almost square O_4 patterns between adjacent bisdiolato moieties which are suited to coordinate sodium ions located within the double torus (**138**). The coordination sphere of the six sodium ions is completed by six water molecules, respectively, which are arranged in a homodromic hexaqua cycle (**137a**, ❯ *Fig. 30*). A similar structure is obtained with oxo-vanadium(IV) instead of bismuth(III) in which the oxo group bonded to the vanadium atom replaces the stereochemically active lone pair of the bismuth(III) centers [155]. Complete deprotonation of two γ-CD tori is also observed in the hexadecanuclear lead(II) complex $[Pb_{16}(\gamma\text{-CDH}_{-16})_2]$ which has been crystallized from a reaction mixture containing excessive γ-CD. Eight lead atoms each are located within the double torus (compare the sodium sites in **137**, ❯ *Fig. 30*) and outside the double torus (compare the bismuth sites in **137**, ❯ *Fig. 30*), respectively. The resulting lead-alkoxido substructure is comparable to that observed in **78** (❯ *Fig. 16*) [156].

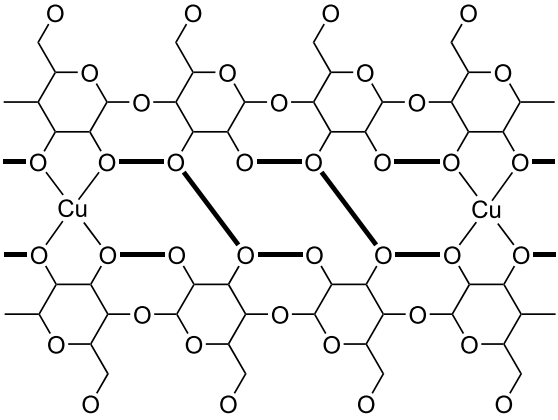
Less Lewis acidic metals such as iron and manganese in their oxidation states +II cannot afford complete deprotonation but three of them are bonded by every second bisdiolato moiety in an α-CD double torus with the formula $[Li_6(H_2O)_6M_3(H_2O)_3(\alpha\text{-CDH}_{-12})_2]^{5-}$ (M = Mn, Fe). The fact that Fe^{II} or Mn^{II} are chelated by diolato functions of cyclodextrins might be surprising since no diolato complexes with simpler carbohydrates are known, but is comprehensible on a closer look at the structure **139**. The increased acceptor functions of the deprotonated diolato sites are stabilized by hydrogen bonds as well as by Li cation contacts. One of the adjacent not iron- or manganese-bonded glucose units is tilted towards a chelating glucose unit resulting in a shortening of the O2′–O3′ hydrogen bonds (O2′–O3′ distance about 2.5 Å in **139**). This way two optimal sites for the coordination of two lithium ions are generated between two bisdiolato moieties. Each of the six lithium ions occupying these sites bears an additional water molecule which, in turn, is arranged in a homodromic hexaqua cycle comparable to that in **137a** (*Fig. 30*) [155]. A similar coordination and hydrogen bond pattern is established in a sandwich-type tetracuprate with β-CD, $[Li_7(H_2O)_7Cu_4(\beta\text{-CDH}_{-11.5})_2]^{4-}$. However, one lithium ion is bonded to the O_4 site between two adjacent bisdiolato-cuprates comparable to the sodium atoms in **137** (*Fig. 30*) [157].

Trinuclear sandwich-type cuprates of the type $[A_3(H_2O)_3Cu_3(\alpha\text{-CDH}_{-6})_2]^{6-}$ are formed with lithium and sodium as counterions A, whereas dinuclear $[Cu_2(\alpha\text{-CDH}_{-4})_2]^{4-}$ are isolated as potassium and rubidium salts. The lithium- and sodium cuprates contain the substructure **140** in which the copper atoms are coordinated by two bisdiolato moieties in a slightly distorted square planar geometry and the alkali ions mainly occupy the bisdiol sites located between two cuprates. Stabilizing hydrogen bonds of the type O–H···O^- between non-deprotonated diol moieties and the adjacent diolato moieties are formed. Each of the alkali ions bears a water molecule as a fifth ligand. These bonds are directed towards the outside of the cylindic tricuprates (compare the in-torus bonded aqua ligands in **137**, *Fig. 30*). In the less-

deprotonated dicuprates, however, no incorporation of the larger, less-polarizing alkali metals potassium and rubidium is observed. These compounds are stabilized by short cooperative hydrogen bonds depicted in **141**. The anhydroglucose units not bearing a copper atom have to be tilted slightly to enable inter-cyclodextrin hydrogen bonds of the type O3–H···O3 [158].



bold lines: hydrogen bonds

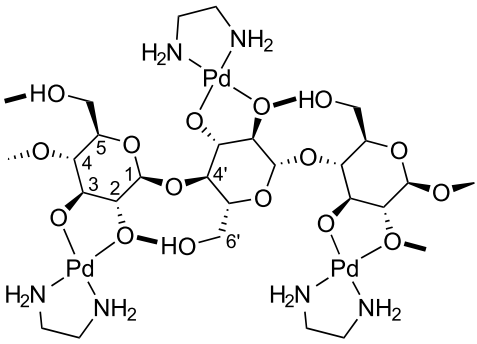
hydrogen atoms omitted for clarity

141

$Co^{III}(en)_2$ and Co^{III}(cyclen) (cyclen = 1,4,7,10-tetraazacyclododecane) residues are coordinated by a diolato moiety of α-CD or β-CD in an aqueous alkaline solution (compare $Co^{III}(en)_2$ complexation by a pyranosidic diolato moiety in **109**, ❯ *Fig. 21*). This coordination mode could be confirmed by a large downfield shift of the the carbon atoms involved in the five-membered diolato-chelate ring [159].

6.6 Polysaccharides

The disaccharide structures described above give first evidence of how cellulose, a polymer formed by (1↔4)-glycosidic linking of β-D-glucose molecules, is present in coordinating solvents like Pd-en, Cu-en, Ni-tren, or Cd-tren. Supporting information could be gained by ^{13}C NMR data obtained from Pd-en solutions of DP 40 cellulose (cellulose with an average degree of polymerization of 40). A downfield coordination-induced shift of about 10 ppm of the carbon atoms C2 and C3, which is also observed for the 1,2-diolate complexation of sucrose (compare 6.4), and unsplit main signals of all of the glucose carbon atoms strongly indicate the formation of entirely palladated and molecularly dispersed cellulose **142**. The formation of intramolecular hydrogen bonds of the type O6′–H···$O2^-$ leads to a significant increase in chain stiffening [84,160]. The same coordination mode is suggested for Cu-en and cuoxam, an aqueous solution of copper(II)-hydroxide in ammonia, as well as for Ni-tren and Cd-tren [161,162].

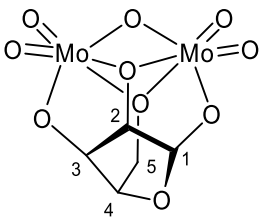


142

7 Reducing Carbohydrates

Although there are many data for model compounds for carbohydrates, relatively little is known about the reducing carbohydrates as ligands in metal complexes. One of the reasons for this may be the high reactivity of the reducing sugars. Furthermore their ease of oxidation and their instability in alkaline solution must be accounted for, and most importantly the monosaccharides are mixtures in solution. When a coordinating metal moiety is exposed to glucose, for example, it is hardly predictable whether the sugar will react through its α- or β-furanose, α- or β- pyranose or a less stable form. Nevertheless, the number of structurally characterized coordination compounds with reducing carbohydrates is increasing.

From the reaction between ammonium molybdate and the pentose xylose, a complex composed of a dimolybdenum core and one sugar moiety **143** [163] could be obtained.



143

As Bilik [164,165,166] has demonstrated Mo(VI) will catalyze epimerization of pentose sugars at C2. So it is not surprising that with a reducing sugar, the first structure analysis with a transition metal complex shows lyxose as the monosaccharide in complex. The metal center is dinuclear with a triple oxygen bridge linking the two molybdenum atoms without remarkable Mo–O distances. The dinuclear metal center fixes the lyxose in an unusual furanose form, the β-D-lyxofuranose. The pseudo-rotation formulae have been applied to this form of lyxose. A phase angle of 247.7° together with a normal amplitude of pucker (reflecting the degree of non-planarity of the ring) of 35.6° is calculated. The conformation of lyxose is thus midway between the discrete descriptions ^{C4}E and $^{C4}T_{O1}$.

As the pentose sugar is able to provide an O_4 rhomb, structure analyses have shown that the O_5 pattern provided by β-mannofuranose turned out to be an ideal building block of M_2O_{10} double octahedra of binuclear metallates(III).

Thus, a series of isotypic sugar complexes of trivalent metals with the formula $Ba_2[M_2(\beta\text{-D-Man}f\text{H}_{-5})_2] \cdot n\ H_2O$ (M = Fe, V, Cr, Al, Ga, Mn; n ≈ 13), as shown for Mn^{III} in ❯ *Fig. 31*, has been developed [167,168].

The compounds contain a homoleptic sugar-metal complex as anion, which includes no hydroxido or oxido ligands. Instead, all the protons of the five hydroxyl groups of mannose are split off to form a pentaanionic polyolato ligand. The polyolate is derived from the β-furanose form of mannose, which is insignificant in solution [169], but is the only form with all the hydroxyl groups on one side of the ring. According to the already described epimerization of xylose towards lyxose in the presence of oxidomolybdenum(VI), D-fructose and D-glucose isomerize to the sugar ligand with the highest possible denticity, the β-mannofuranose [167].

The environments of the two metal atoms in **144** are not equivalent. M1 forms five- and six-membered chelates with the open-chain part of the ligand, whereas M2 is surrounded by two oxolanetriolato fragments in a distorted E_2 conformation. $[Fe_2(rac\text{-Man}f\text{H}_{-5})_2]^{4-}$ **145** [31] with iron as the central metal is also known. In contrast to **144**, in the C_i symmetric **145** the two Fe centers are equivalent. Besides the structure of $[Mn^{III}{}_2(\beta\text{-D-Man}f\text{H}_{-5})_2]^{4-}$ there is an additional structure with two different oxidation states, $[Mn^{IV}Mn^{III}(\beta\text{-D-Man}f\text{H}_{-5})_2]^{3-}$ [168]. The unexpected oxidation state +VI for one of the central atoms was unambiguously assigned and became apparent for the mean Mn–O bond length in the octahedral MnO_6 coordination. For Mn^{III}, the mean Mn–O distance is 2.01 ± 0.13 Å and for Mn^{VI}, it is 1.89 ± 0.03 Å.

In the structures, introduced so far, an O_4 rhomb or O_5 patterns turned out to be ideal building blocks for carbohydrate-metal complexes. The most important monosaccharide, D-glucose, in any of its hemiacetal forms does not exceed the simple O2 diol pattern (a consequence is the epimerization reaction of glucose to β-mannofuranose in the presence of trivalent metal ions).

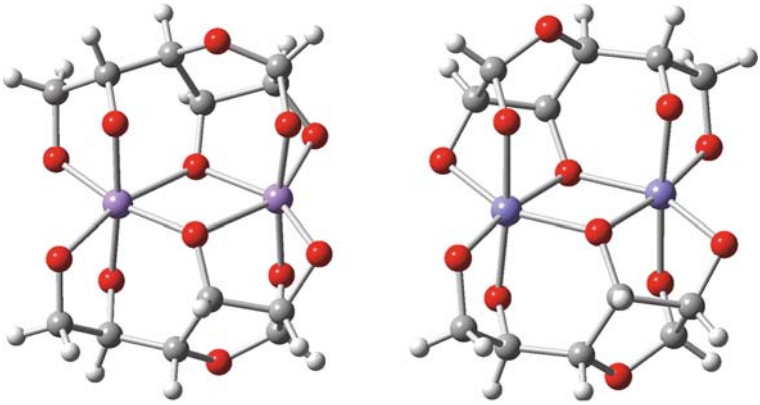


Figure 31
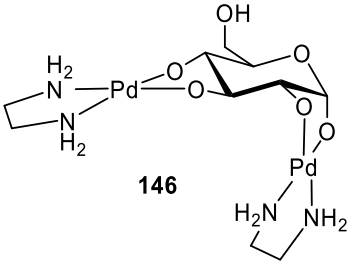
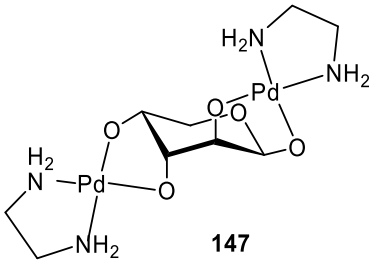
Molecular structures of the tetraanions $[Mn^{III}{}_2(\beta\text{-D-Man}f\text{H}_{-5})_2]^{4-}$ 144 and $[Fe_2(rac\text{-Man}f\text{H}_{-5})_2]^{4-}$ 145 in crystals of $Ba_2[Mn^{III}{}_2(\beta\text{-D-Man}f\text{H}_{-5})_2] \cdot 13\ H_2O$ and $Ba_2[Fe_2(rac\text{-Man}f\text{H}_{-5})_2] \cdot 13\ H_2O$

This steric restriction is taken into account by exclusively providing the (en)Pd^{II} moiety, which is a diol chelator.

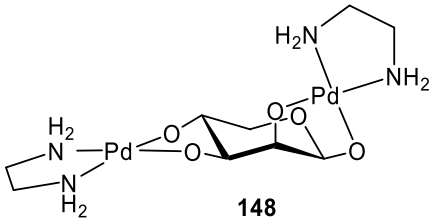
Although palladium is a good oxidant, oxidation of the aldose could be avoided to such an extent that even crystallization became possible. The first crystal structure of a metal derivative of glucose, [(en)$_2$Pd$_2$(α-D-Glc*p*1,2;3,4H$_{-4}$)] · 7 H_2O (**146** · 7 H_2O) was obtained from a solution with a 3:1 Pd:D-glucose molar ratio [170]. **146** shows the O1–O4 deprotonated α-D-glucopyranose tetraanion, which is coordinated as a bis(chelate) ligand to two palladium(II) central atoms with the Pd–O distance averages at 2.00 Å, the O–C–C–O angles are 43 and −50°. ^{13}C NMR data give evidence for the existence of an additional species [(en)$_2$Pd$_2$(β-D-Glc*p*1,2;3,4H$_{-4}$)] in solution. Reduction of the Pd:D-glucose molar ratio to 1:1 results in a mixture of monometallated glucoses. The 1,2-metallated species are of particular significance, owing to the maximum acidity of the hydroxy group at C1.



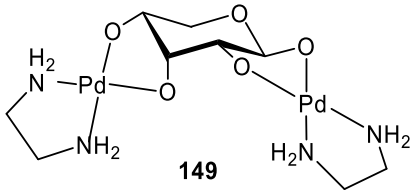
146



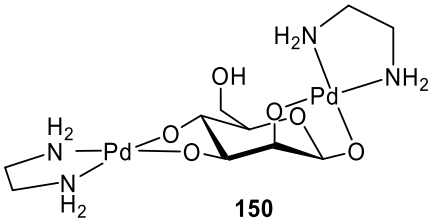
147



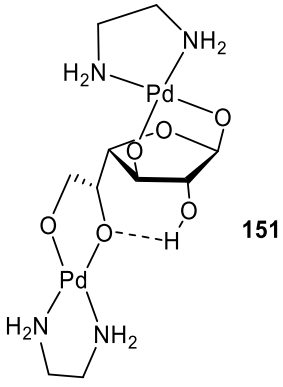
148



149



150



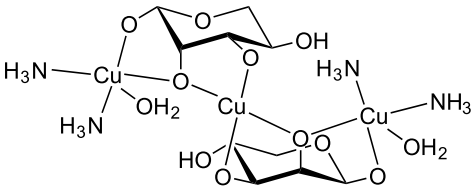
151

In this way several Pd_2 complexes 2[171,172], namely $[(en)_2Pd_2(\beta\text{-D-Ara}p1,2;3,4H_{-4})] \cdot 5\,H_2O$ (**147** $\cdot 5\,H_2O$), $[(en)_2Pd_2(\beta\text{-D-Lyx}p1,2;3,4H_{-4})] \cdot 7\,H_2O$ (**148** $\cdot 7\,H_2O$), $[(en)_2Pd_2(\beta\text{-D-Rib}p1,2;3,4H_{-4})] \cdot 6.5\,H_2O$ (**149** $\cdot 6.5\,H_2O$), $[(en)_2Pd_2(\beta\text{-D-Man}p1,2;3,4H_{-4})] \cdot 9.4\,H_2O$ (**150** $\cdot 9.4\,H_2O$), which are the main species in solution, and $[(en)_2Pd_2(\beta\text{-D-Gal}f1,3;5,6H_{-4})] \cdot 5\,H_2O \cdot C_2H_5OH$ (**151** $\cdot 5\,H_2O \cdot C_2H_5OH$) could be obtained.

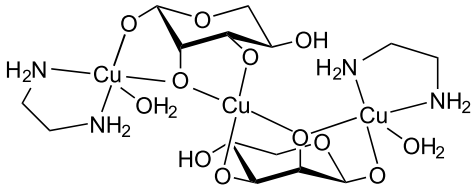
With the exception of **151** one of the two Pd(en) ligands binds to the O1 and O2 and the other to the O3 and O4 diol function of the β-D-pyranose form of the carbohydrate in all compounds. Further, the Pd–O distances and the O–C–C–O angles are in comparable ranges, too. **151**, however, shows a furanose form of D-galactose. Contrary to the other pyranose structures with Pd(en) moieties, a strong intramolecular hydrogen bond of the O–H···O^- type is established with O2-H as the donor and O5 as the acceptor. One of the palladium atoms is coordinated by a 1,3-diolato(2-) ligand. Though this bonding mode is unusual, it is not unique, as shown for levoglucosan which binds to palladium(II) in a similar way. The second Pd(en) ligand binds to the remaining diol fragment with O5 and O6.

^{13}C NMR data show, that there exist in solution more palladium–carbohydrate species than could be obtained in crystals. Besides the above-mentioned compounds there are signals for the following species identified by the palladium induced shift of about 8 to 15 ppm: $[(en)_2Pd_2(\alpha\text{-D-Ara}p1,2;3,4H_{-4})]$, $[(en)Pd(\beta\text{-D-Lyx}p1,2H_{-2})]$, $[(en)Pd(\beta\text{-D-Lyx}p2,3H_{-2})]$, $[(en)_2Pd_2(\alpha\text{-D-Rib}p1,2;3,4H_{-4})]$, $[(en)_2Pd_2(\alpha\text{-D-Xyl}p1,2;3,4H_{-4})]$, $[(en)_2Pd_2(\beta\text{-D-Xyl}p1,2;3,4H_{-4})]$, $[(en)_2Pd_2(\alpha\text{-D-Gal}p1,2;3,4H_{-4})]$ and $[(en)_2Pd_2(\beta\text{-D-Gal}p1,2;3,4H_{-4})]$. The dimetallation of the carbohydrates influences the distribution of the different forms of sugars in solution in contrast to the forms in equilibrium without coordination. Formation of dimetallated pyranoses requires two diol functions that are not *trans*-diaxial. Hence, for lyxopyranose and its homologue mannopyranose, only the β-anomer in its $^4C_1$ conformation can be dimetallated. The major dimetallated species in solutions of ribose and galactose can be predicted as well, since the most stable form of the free sugars in aqueous solution (β-pyranose) provides two diol functions that are well suited for palladium bonding without rearrangement. The same appears to hold true first glance for the xylose/glucose pair. However, the actual anomer distribution deviates from that of the free sugars by a shift of the concentrations towards the α-anomer. The bonding modes of dimetallated arabinopyranoses cannot be predicted. Suitable bisdiol conformations are adopted for the β-anomer both in its $^1C_4$ and $^4C_1$ conformations (two axial substituents in each case) and in its $^1C_4$-α-anomer, the latter and the $^4C_1$-β-anomer being handicapped by an anomeric effect when the findings in the xylose/glucose case are generalized. In fact, the spectra show the β-form is preferred.

While (en)Pd fragments bind to diol groups without loss of the ethylenediamine ligand (nitrogen ligation is clearly favored over alkoxide bonding), at cupric centers the prediction of a particular structure is complicated by the ability of diolato ligands to substitute nitrogen ligands. In crystals of $[(NH_3)_4Cu_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2] \cdot 4\,H_2O$ [172] (**152** $\cdot 4\,H_2O$), two bridging lyxose ligands adopt the β-pyranose form in C2 symmetrical, trinuclear molecules; they are each threefold deprotonated along the *cis-cis* sequence of the hydroxy groups with C1, C2, and C3.



152

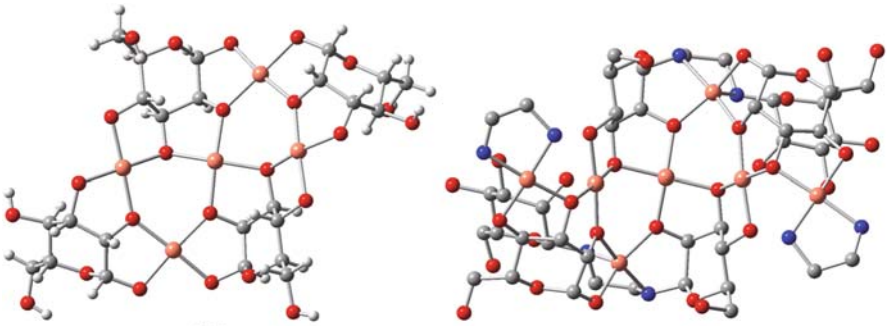


153

The coordination chemistry of the cupric centers is normal, that is, the bis-diolato-bonded Cu1 atom is square-planar coordinated with no further ligands, whereas Cu2, which is coordinated by a diolato ligand derived from the anomeric and the epimeric hydroxy groups, is surrounded by a square pyramid consisting of the two alkoxy oxygens, two ammine ligands and a water ligand at a longer distance. Intramolecular hydrogen bonds are established from N2–H donors and O3 acceptors. The ability of a polyolato ligand to replace ammine ligands is a prerequisite for the formation of **152**. The molecular structure of $[(en)_2Cu_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2] \cdot 4\ H_2O$ [172] (**153** $\cdot$ 4 H_2O) resembles that in the ammine complex, including the detail of intramolecular hydrogen bonding from amine donors to alkoxide acceptors. The structure determination demonstrates that the stronger ethylenediamine ligand is also replaced by the lyxose anions.

More examples for the higher reactivity of copper centers, in relation to the preference of diolato ligands to substitute nitrogen ligands, are given in structures **154** and **155** [173], shown in ❯ *Fig. 32*.

Complex **154** is an anionic homoleptic complex in which the five square-plane-coordinated copper(II) atoms are exclusively bound to the deprotonated β-D-mannopyranose in $^4C_1$ conformation. The increased redox stability therefore is not a consequence of the spatial separation of the oxidizing Cu(II) atoms and the half-acetal function of the monosaccharide. However, it is a consequence of the involvement of the O atoms, at the anomer C atoms, in the coordination of copper, as it is for the homoeptic lyxose complexes.



154 155

Figure 32

Structure of $[Cu_5(\beta\text{-D-Man}p)_4H_{-13}]^{3-}$ (154) in K_3 154 $\cdot$ α-D-Man$p$ $\cdot$ 16.5 H_2O and $[(en)_2Cu_7(\beta\text{-D-Man}p1,2,3,4H_{-4})_2(L2,3,4H_{-3})_2]$ (155) in 155 $\cdot$ 26.6 H_2O with L = *N*,*N*'-bis(β-D-mannopyranosyl)-ethylendiamine

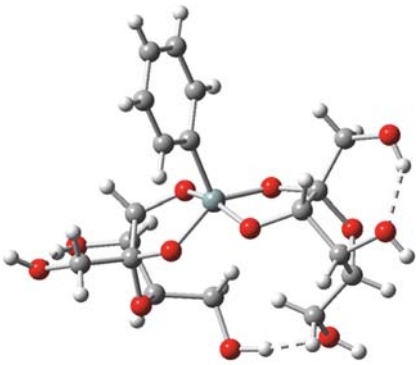
In contrast to the other aldoses, the copper atoms find an especially favorable coordination environment for lyxose and mannose. Cu(II), indeed, has the ability to build stable complexes with the pyranoid *trans*-diol fragments, shown for the complexed 3,4-diol functions, but the more flat chelate five-membered rings, which are built with the with pyranoid *cis*-diol fragments, seemed to be more favorable for copper centers.

The *cis,cis*-orientation of the triol function with O1, O2 and O3 probably leads to an increased complex stability in the environment of the anomeric center and, as a consequence, to decreased tendency for reduction of copper.

A second compound, **155**, contains a reaction product with ethylenediamin and two moieties of mannose. Although the structure of the pentacuprate is quite complex, the composition of **155** could be derived from the simple educts. Besides oxidation, the building of *N*-glycosides is another reaction of the aldoses.

For silicon, the metal-coordinating properties, as found in AnEryt, should, in principle, be shared by each of the monosaccharides. A particular monosaccharide is expected to act as a good ligand if its *cis*-furanose form is of considerable stability, so that the stability constant of the complex is not charged with the isomerization energy of the ligand. In fact, almost all of the monosaccharides enrich alkaline aqueous silicate solutions with five- and six-coordinate silicon species, to some extent. However, the determination of the compositions and structures of the involved species is largely complicated by the mere number of the species in equilibrium. This has recently been demonstrated for D-ribose solutions by Kinrade et al., who detected a vast amount of various five- and six-coordinate species in such solutions [94]. For monosaccharides other than D-ribose, the situation is not any better.

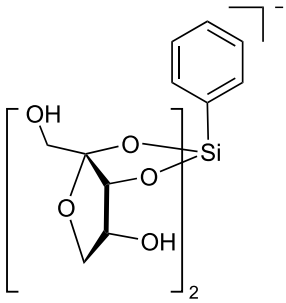
To avoid these problems, the hydroxide ligand is substituted by an inert phenyl residue. In this way a series of phenylsilicates was crystallized. Five complexes have been isolated and characterized with two ketoses and three aldopentoses [174]. The silicon central atom in [K([18]crown-6)]**156** · MeOH is part of two chelate rings, with the ligands being O^2,O^3-β-D-fructofuranose dianions (*Fig. 33*).



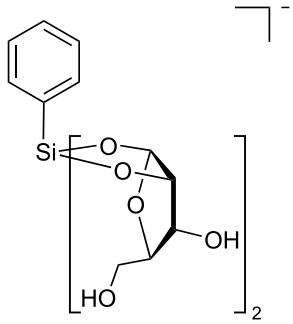
156

Figure 33
Structure of the anion [PhSi(β-D-Fru*f* 2,3H$_{-2}$)$_2$]$^-$ 156 in the crystal structure of [K([18]crown-6)][PhSi(β-D-Fru*f* 2,3H$_{-2}$)$_2$] · MeOH

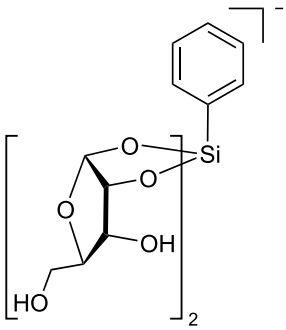
The β-furanose isomer is best suited for silicon ligation because it exhibits a torsion angle close to 0° for the most acidic diol function, thus assuring a flat chelate ring. The same structural principles are also found in the anions [PhSi(a-D-Rul*f*2,3H$_{-2}$)$_2$]$^-$ **157**, [PhSi(β-D-Ara*f*1,2H$_{-2}$)$_2$]$^-$ **158**, [PhSi-(a-D-Rib*f*1,2H$_{-2}$)$_2$]$^-$ **159** and [PhSi(a-D-Xyl*f*1,2H$_{-2}$)$_2$]$^-$ **160**.



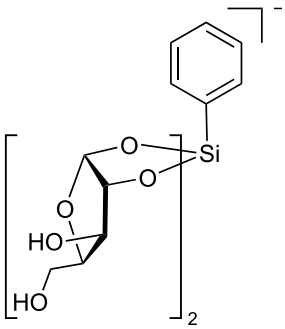
157



158



159



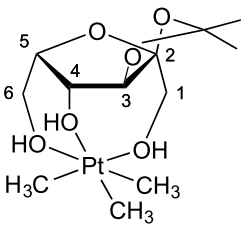
160

Continuing with the furanoses, in **161** [133] 2,3-*O*-isopropylidene-α-L-sorbofuranose acts as a neutral tridentate ligand which is coordinated by three hydroxyl groups (κ^3O^1,*O*^{4},*O*^{6} coordination).

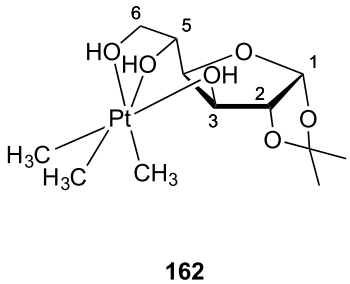
The six-, seven-, and eight-membered 1,3,2-dioxaplatinacyclohexane rings exhibit boat, chair, and distorted chair conformations, respectively. The cyclic system is not free of bond angle strain, as indicated by the O–Pt–O angles in particular. One of these angles is distinctly smaller than 90° (O4–Pt–O6 = 82.5° vs. O1–Pt–O6 = 95.3° and O1–Pt–O4 = 91.2°. Two Pt–O bonds (O1, O4) average 2.25 Å and are equivalent to those in **162**. In contrast, the Pt–O6 bond with 2.16 Å is significantly shorter. The furanose ring assumes an envelope conformation in which C4 is displaced from the C5,O4,C2,C3 plane by 0.37 Å. A similar distortion of 0.57 Å but in the opposite direction is observed in the furanose ring of 1,2-*O*-isopropylidene-α-D-glucofuranose in **162** [133].

In **163** [133], 2,3;4,5-di-*O*-isopropylidene-β-D-fructopyranose acts as a neutral bidentate ligand which is coordinated by the hydroxyl group (O1) and the acetal oxygen atom (O6) of the pyranose ring (κ^2O^1,*O*^{6} coordination). The octahedral coordination of the platinum is com-

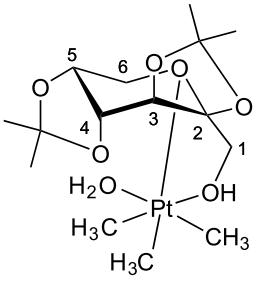
pleted by an aqua ligand. The five-membered 1,3,2-dioxaplatina cyclohexane ring exhibits a half-chair conformation. This ring is not free of bond angle strain, which is revealed by the small O1–Pt–O6 angle (75.3°) and the Pt–O bonds average 2.24 Å. The pyranose ring of the free ligand 2,3;4,5-di-*O*-isopropylidene-β-D-fructopyranose exhibits a $^2S_0$ conformation in the solid state [175]. In contrast, in the crystal structure of **163** [133], the twisted boat conformation of the pyranose ring is distorted due to complexation with platinum. This distortion is caused by changes in the dihedral angles in the sugar ring; in particular, the dihedral angle C3–C4–C5–C6 is reduced by 7° and C4–C5–C6–O6 is increased by 6°. Another structurally characterized β-D-fructopyranose is $[B_2(C_6H_5)_2(\beta\text{-D-Fru}p2,3;4,5H_{-4})] \cdot$ acetone [176], shown in *Fig. 34*.



161

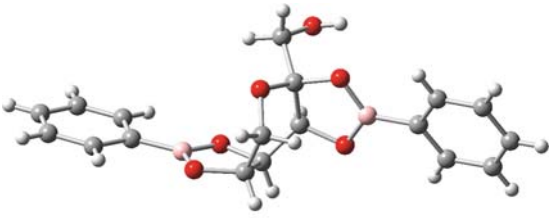


162



163

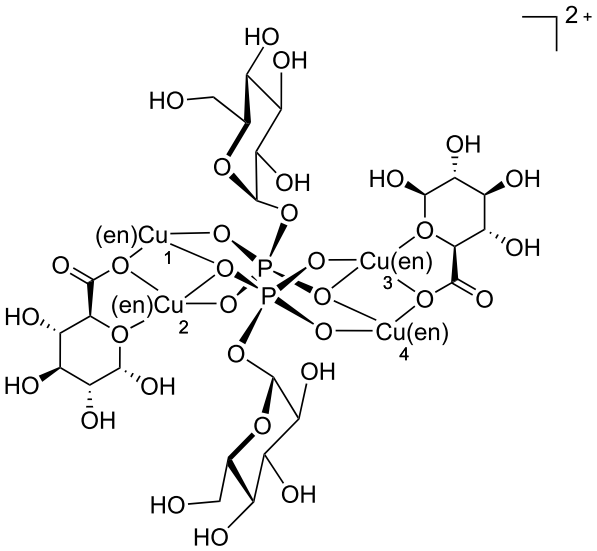
In **164**, phenylboronic acid forms five-membered cyclic boronates with the 2,3 and 4,5 diol function of the β-D-fructopyranose.



164

Figure 34
Stucture of $[B_2(C_6H_5)_2(\beta\text{-D-Fru}p2,3;4,5H_{-4})]$ (164) in crystals of $[B_2(C_6H_5)_2(\beta\text{-D-Fru}p2,3;4,5H_{-4})] \cdot$ acetone

In **165** [62], two D-glucoronate anions are introduced onto a tetracopper(II) scaffold of $[Cu_4\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4]^{4+}$.



165

Of the two D-glucoronate ligands, one adopts the α-D-pyranose form, bridging the Cu1 and Cu2 ions, and the other adopts the β-D-pyranose form, connecting the Cu3 and Cu4 atoms. The C6 carboxylate group of each D-glucoronate connects the two Cu atoms in a η^1,η^1 monoatom bridging mode. The five-membered chelation by axial coordination is completed of the C5 cyclic O atom. The metal binding of the pyranose ring-O atom of D-glucoronate may accelerate interconversion between the α and β anomers through an intermediate open-chain form in solution.

Besides these complexes characterized by crystal-structure analysis, there is an extensive number of compounds containing reducing sugars, investigated only by various spectroscopic methods. Examples include borate esters of carbohydrates that have been investigated in depth by ^{11}B and ^{13}C NMR spectroscopy [177,178]. Furthermore, there is a great deal of literature that provides NMR spectroscopic data for molybdenum and tungsten complexes of carbohydrates as reviewed in [1]. However, it has remained as an ambitious goal for future work to support the NMR-derived conclusions by solid-state work. Hence, the above-mentioned oxidomolybdenum-lyxose complex, which demands an O_4 rhomb pattern for coordination, provides the only crystal-structure analysis in this substance class.

8 Concluding Remarks

While structural information about metal complexes of reducing carbohydrates was only sparsely available 10 years ago, a considerable increase has been observed in recent years.

In our opinion, this development was facilitated mainly by two key factors: the technical progress of all analytical methods, particularly in the fields of NMR spectroscopy and X-ray diffractometry, and the plenty of structural data meanwhile available for metal complexes of model compounds of carbohydrates. The basic research on the structural chemistry of the latter complexes followed by a transfer of the thereby gained knowledge in stability and regioselectivity of metal coordination into reducing carbohydrates has proved to be very successful. By this way, the improvement of existing and the development of new applications of metal complexes of carbohydrates, which provide a cheap and renewable feedstock, is merely a matter of time.

Oligosaccharides

5.1 Oligosaccharides: Occurrence, Significance, and Properties

Zbigniew J. Witczak
Department of Pharmaceutical Sciences, Nesbitt School of Pharmacy, Wilkes University, Wilkes-Barre, PA 18766, USA
zbigniew.witczak@wilkes.edu

Abstract

This chapter is exclusively devoted to the occurrence, significance and physical and randomly selected chemical properties of various group of disaccharides, trisaccharides, tetrasaccharides, pentasaccharides and hexasaccharides.

Keywords

Disaccharides; *C*-Disaccharides; Thio-disaccharides; Oligosaccharides

Abbreviations

CD circular dichroism
ROA Raman optical activity

In: *Glycoscience*. Fraser-Reid B, Tatsuta K, Thiem J (eds)
Chapter-DOI 10-1007/978-3-540-30429-6_25:

1 Introduction

Naturally occurring oligosaccharides including disaccharides and trisaccharides have attracted enormous attention in the last few years. Multidisciplinary efforts of biochemists and medicinal chemists have led to new developments [1,2,3,4,5] in the field, which are based primarily on the phenomenal physical properties such as stability, crystallinity, and solubility. Chemical properties include selective reactivity towards various reagents such as oxidative and reducing agents and this has opened up new possibilities for functionalization and derivatization of value-added oligo- and polysaccharides.

This chapter is entirely devoted to the selected physical and chemical properties of those derivatives, which should always be considered as critical factors for any preparative manipulation or functionalization and conversion into desired target derivatives possessing highly practical application as pharmaceuticals, food ingredients, and industrial intermediates.

2 Occurrence of Oligosaccharides

Oligosaccharides occur in the living system as free compounds as well as being linked to many other plant constituents, such as phenols, saponins, steroids, flavonoids, as their corresponding glycosides.

Many natural oligosaccharide antibiotics, for example aminoglycoside antibiotics or macrolide antibiotics, are composed of specific monosaccharides such as deoxy-sugars and amino-sugars as well as cyclitols including streptamine. These monosaccharide components are linked via naturally occurring and important linkages such as (1→4)-, (1→2)-, (1→3)-, (1→6)-, and (1→1)-. The variety of natural sources of oligosaccharides is presented in ❯ *Table 1*.

3 Significance of Oligosaccharides: Industrial Utilization and Application

Among the disaccharides it is sucrose that reaches the status of commodity as it is a cheap industrial raw material. Any other di- or tri- saccharides are rarely used as chemical intermediates. In ❯ *Table 2* a list of existing and potential products through derivatization of sucrose is presented. With regards to high-value products, compounds with pharmacological activity can also be made from sucrose, for example, the anti-ulcerative drug Sucraflate (aluminum sucrose octasulfate) which reduces stomach acidity.

Lactose and maltose, readily available in large quantities from whey and starch, have some application in the form of their reduction products maltitol and lactitol, which are sweetening agents.

4 Disaccharides

Among the disaccharides the most important are sucrose, maltose, and lactose as cheap and valuable sources of renewable materials for industrial applications. Stability and reactivity are important factors for the selective functionalization and future application in the production

Table 1
Name, structure, and occurrence of selected natural oligosaccharides (Compiled from Carbohydrates (1987) Collins PM (ed) Chapman and Hall Chemistry)

Name	Structure	Occurrence
Disaccharides		
Cellobiose	β-D-Glc*p*-(1→4)-D-Glc*p*	Cellulose unit
Digilanidobiose	β-D-Glc*p*-(1→4)-D-Digitoxose	Cardiac glycosides of Lanta
Gentiobiose	β-D-Glc*p*-(1→6)-D-Glc*p*	Amygdalin, crocin glycosides
Isomaltose	α-D-Glc*p*-(1→6)-D-Glc*p*	Amylopectin unit of starch
Kojibiose	α-D-Glc*p*-(1→2)-D-Glc*p*	Free sugar in honey
Laminaribiose	β-D-Glc*p*-(1→3)-D-Glc*p*	Free sugar in honey
Lactose	β-D-Gal*p*-(1→4)-D-Glc*p*	Free sugar in milk
Lactulose	β-D-Gal*p*-(1→4)-D-Fru*f*	Degradation product of lactose
Lycobiose	4-β-D-Glc*p*-(1→4)-D-Gal*p*	Sugar component of glycoside tomatin
Maltose	α-D-Glc*p*-(1→4)-D-Glc*p*	Free sugar of malt, beer, fruits, honey, unit of starch
Maltulose	α-D-Glc*p*-(1→4)-D- Fru*f*	Free sugar in malt, beer, honey
Mannobiose	β-D-Man*p*-(1→4)-D-Man*p*	Unit of the guaran polysaccharide
Melibiose	α-D-Gal*p*-(1→6)-D-Glc*p*	Free sugar in Cocoa beans, degradation product of raffinose
Neohesperidose	α-L-Rha*p*-(1→2)-D-Glc*p*	Sugar component of flavonoid glycosides, neohesperidin, naringin
Neotrehalose	α-D-Glc*p*-(1→1)-β-D-Glc*p*	Free sugar in koji extract
Nigerose	α-D-Glc*p*-(1→3)-D-Glc*p*	Free sugar in honey, beer
Palatinose	α-D-Glc*p*-(1→6)-D-Fru*f*	Microbiological conversion of sucrose
Primverose	β-D-Xyl*p*-(1→6)-D-Glc*p*	Free sugar in carob fruits, glycoside of *Primula officinalis*
Robinobiose	α-L-Rha*p*-(1→6)-D-Gal*p*	Sugar component of Robinin
Rutinose	α-L-Rha*p*-(1→6)-D-Glc*p*	Sugar component of flavonoid glycosides, hesperidin
Scillabiose	β-D-Glc*p*-(1→4)-l-Rha*p*	Sugar component of glycoside *Scilla maritime*
Solabiose	β-D-Glc*p*-(1→3)-β-D-Gal*p*	Sugar component of glycoside β-Solanin
Sophorose	β-D-Glc*p*-(1→2)-D-Glc*p*	Sugar component of glycoside *Sophora Japonica L* and Stevioside
Strophanthobiose	β-D-Glc*p*-(1→4)-D-Cymarose	Sugar component of K-strophantin
Sucrose	β-D-Fru*f*-(2→1)-D-Glc*p*	Free sugar in sugar cane, sugar beet, plants, fruits
Trehalose	α-D-Glc*p*-(1→1)-α-D-Glc*p*	Free sugar in mushrooms and in the blood of a few insects and of grasshoppers
Turanose	α-D-Glc*p*-(1→3)-D-Fru*p(f)*	Free sugar in honey
Vicianose	α-L-Arab*p*-(1→6)-D-Glc*p*	Sugar component of glycoside Viciaanin
Trisaccharides		
Centose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→2)-Glc*p*	Free sugar in honey
Erlose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→2)-β-Fru*f*	Free sugar in honey

Table 1 (continued)

Name	Structure	Occurrence
Gentianose	β-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→2)-β-Fru*f*	Free sugar in the rhizomes of Gentiana
Isomaltotriose	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→6)-D-Glc*p*	Free sugar in honey
Isopanose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→6)-D-Glc*p*	Free sugar in honey
1-Kestose	α-D-Glc*p*-(1→2)-β-D-Fru*f*-(1→2)-β-D-Fru*f*	Free sugar in honey
6-Kestose	α-D-Glc*p*-(1→2)-β-D-Fru*f*-(6→2)-β-D-Fru*f*	Free sugar in honey
Lycotriose	β-D-Glc*p*-(1→2)-β-D-Glc*p*-(1→4)-Gal*p*	Sugar component of glycoside Tomatin
Maltotriose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)-D-Glc*p*	Degradation product of amylose
Manninotriose	β-D-Gal*p*-(1→6)-β-D-Gal*p*-(1→6)-α-D-Glc*p*	Free sugar in Manna, degradation product of stachyose
Melezitose	α-D-Glc*p*-(1→3)-β-D-Fru*f*-(2→1)-α-D-Glc*p*	Free sugar in honey, manna, exudates of lime and pine
Panose	α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→4)-D-Glc*p*	Free sugar in honey, degradation product of amylopectin
Planteose	*O*-β-D-Gal*p*-(1→6)-β-D-Fru*f*-(2→1)-α-D-Glc*p*	Free sugar in seeds of Plantago varieties
Raffinose	α-D-Gal*p*-(1→6)-α-D-Glc*p*-(1→2)-β-Fru*f*	Free sugar in plants and leguminose seeds: soja beans, mung beans
Solatriose	β-D-Glc*p*-(1→3)-β-D-Gal*p*-(1→2)-α-L-Rha*p*	Sugar component of glycoside solanin
Strophantotriose	β-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→4)-D-Cymarose	Sugar component of h-strophanthoside
Umbilliferose	α-D-Gal*p*-(1→2)-α-D-Glc*p*-(1→2)-β-Fru*f*	Free sugar in the roots of Umbilliferae
Tetrasaccharides		
Lychnose	α-D-Gal*p*-(1→6)-α-D-Gal*p*(1→2)-β-D-Fru*f*-(1→1)-α-D-Gal*p*	Free sugar in rhizomes of *Lychnis doica*
Maltotetraose	α-D-Glc*p*-(1→4)-α-D-Glc*p*-(1→4)-D-Glc*p*-(1→4)-D-Glc*p*	Free sugar in starch hydrolysates
Stachyose	α-D-Gal*p*-(1→6)-α-D-Gal*p*(1→6)-α-D-Glc*p*(1→2)-β-D-Fru*f*	Free sugar in rhizomes of the Japanese artichoke
Pentasaccharides		
Verbascose	α-D-Gal*p*-(1→6)-α-D-Gal*p*(1→6)-α-D-Gal*p*-α-D-(1→6)-Glc*p*-(1→2)-β-D-Fru*f*	Free sugar in the rhizomes of wool plant, and seeds of cow peas, winged and lima beans
Hexasaccharides		
Ajugose	[α-D-Gal*p*-(1→6)]$_4$-α-D-Glc*p*(1→2)-β-D-Fru*f*	Free sugar in the roots of *Verbascum thapsiformae* and *Ajuga nipponensis*

Table 2
Commercial and potential products from sucrose

D-Glucose + D-Fructose	
D-Sorbitol (D-Glucitol) +D-Mannitol	
Products of fermentation or enzymatic degradation	Acids (gluconic, itaconic, levulinic, citric)
	Ethanol
	Antibiotics
	Favor enhancers
	Gums (Dextrans, fructans, xanthan)
	Polyhydroxybutyrate and analogs
	Oligosaccharides (Neosugars, isomaltulose)
Sucrose tricarboxylic acid	
Sucrose dialdehyde	
Sucrose anhydrides	
Sucrose polyesters (***Olestra***)	
Derivatives:	Carboxylic acid esters

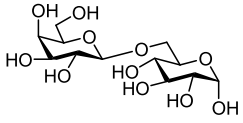
Sophorose



Vicianose

Scheme 1

of value-added and consumer products [6,7] such as "Olestra" and "Sucralose". Owing to the rapid development of modern analytical method, namely mass spectrometry and NMR spectroscopy, an immense number of oligo- and polysaccharides have been characterized in detail. Taking into account the fact that even a small number of different monosaccharides can be combined to form a huge number of distinct oligosaccharides and that each oligosaccharide can also adopt several conformations, it seems certain that they have many varied physicochemical properties. This section summarizes some of the important disaccharides with the specific elements of their chemical properties and a selection of the protecting groups that were developed for the synthesis of oligosaccharides and complex carbohydrates. Some of the representative disaccharides are shown in *Scheme 1*.

4.1 Chemical Properties, Reactivity, and Protecting Groups

Disaccharides contain a high concentration of polar functional groups and in many cases the preferred strategy for the synthesis depends on the different levels of reactivity of primary and secondary hydroxyl groups. More complex sugar moieties are found in oligosaccharide-containing antibiotics. For example amino, nitro, deoxy-sugars, branched-chain and thio-sugars are found as constituents of complex glycosylated derivatives such as anthracyclines, calichemicins, aureolic acid, orthosomycins and most importantly, aminoglycosides. The physicochemical properties of these disaccharide components of complex oligosaccharides are listed in *Table 3*.

Several of the complex oligosaccharides (including macrolide and aminoglycoside antibiotics) and glucosaminoglycans (low molecular weight heparin and heparan) have become very valuable drugs of critically important commercial value. This is one of the reasons that synthesis of these important oligosaccharides and their specifically functionalized analogs is one of the main focuses of new developments in the fields of glycomimetics and particularly the chemical aspects of glycobiology.

Synthetic approaches to these classes of higher oligosaccharides normally demand a regiospecific protecting group in order to leave only those primary or secondary hydroxyl groups free that are to be further functionalized. This particular strategy may give enhanced (or targeted) hydroxyl group reactivity because of the increased accessibility of the targeted hydroxyl group to be functionalized.

One of the first and most important protecting groups to emerge for facilitating selective transformations was the isopropylidene acetal and today, acetals remain the principal means of preserving 1,2- and 1,3-diols. A number of reviews dealing with the various aspects of the chemical reactivity [56,57,58,59] as well as providing extensive accounts on stability, selective formation [57], and selective cleavage [59] have been published.

Acetals, including benzylidene, cycloxehylidene, and cyclopentylidene, reveal virtually unlimited stability to basic conditions, which is an important chemical property that is crucial for any synthetic strategy requiring those conditions. On the other hand all the acetals are quite sensitive towards acid. This specific chemical property derives from participation of a lone pair on the adjacent oxygen atom in the cleavage of a resonance stabilized and protonated intermediate, known as an oxonium ion.

Table 3

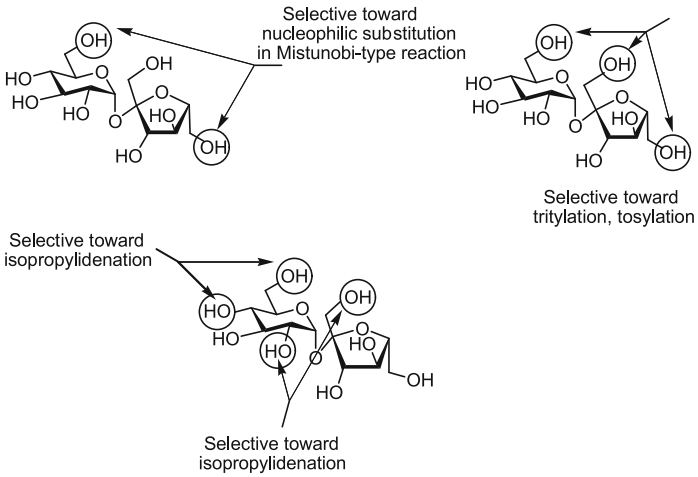
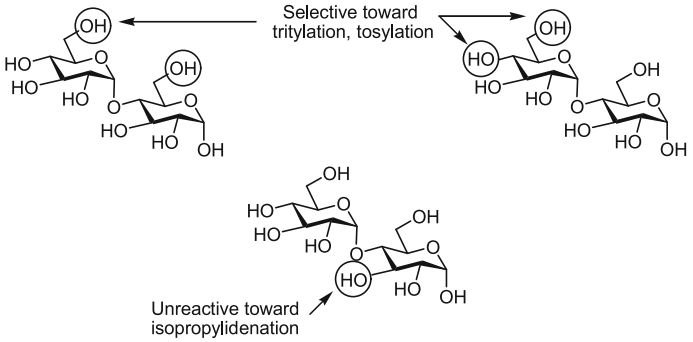
Since the various protecting groups, for example *O*-protection by acetalization, acylation, allylation, and benzylation, can be removed under completely different reaction conditions (acidic/basic, reductive) it is relatively easy to obtain the desired substitution pattern via a suitable and relatively stable protection group strategy. Extensive protection group strategies have been based on the different level of reactivity of primary and secondary hydroxyls. Classical examples of disaccharide functionalization through selective protection/deprotection are sucrose isopropylidenation [60], selective tritylation, or tosylation [61]. Particularly important and practically useful is functionalization of sucrose at 6 and 6′ during Mitsunobu-type nucleophilic substitution as demonstrated during the clever synthesis of 1-deoxynojirimycin by de Raadt and Stutz [62]. This very important approach allows selective substitution of two of the three primary hydroxyl groups (*Scheme 2*).

The totally different steric environments of the two primary hydroxyl groups in maltose allows the selective functionalization of the C-6′ position due to its greater steric hindrance relative to the C-6 position. Thus, maltose can be selectively tosylated and tritylated exclusively on the C-6′ position. Also, configurational factors create unusual selectivity during acetylation or benzylation of maltose, confirming that the C-3 position is the least reactive secondary group and remains free and unacetylated under the reaction conditions.



Scheme 2



Scheme 3
Selective functionalization of maltose

Thus, the differential reactivity of the hydroxyl groups at various positions can be a considerable factor for the preparation of suitably functionalized synthetic intermediates. The general rules of conformation as it influences reactivity should be followed in any synthetic strategy.
Firstly, equatorial hydroxyl groups are more reactive and much easier to functionalize through conventional esterification and etherification. New functional *equatorial* groups are more susceptible to cleavage and to attack by hydrolytic agents than those on *axial* positions.
Secondly, the primary hydroxyl groups on C-6, being essentially exocyclic, are far more reactive than any of the ring/chain hydroxyls and can be functionalized further without the necessity of blocking other functional groups.
Thirdly, the presence of particularly bulky functional groups can render adjacent secondary hydroxyl groups relatively unreactive even when they are in equatorial orientations. The previously mentioned unreactivity of the C-3 position during maltose acetylation is one of the classical examples of such a peculiar rule.
Moreover, the electronegativity of the ring oxygen makes substitution at the neighboring hydroxyl more likely than at either position C-3 or position C-4 as is observed during benzylation of methyl α-D-maltoside or even methyl α-D-glucoside. This is a general effect of the ring oxygen during the reaction carried out at the C-2 hydroxyl group. On the other hand, it can also be predicted that electron deficiency will promote the efficiency of the reaction, the C-3 hydroxyl group is more reactive than the hydroxyls at C-3 and C-4. This is most likely due to preferential reaction at C-2 followed by steric hindrance at C-3 if C-4 is axial and functionalized as well.
Neighboring group participation is also another important factor for predicting the reactivity of secondary hydroxyl groups, particularly at the C-2 position. Under basic conditions, the C-2 hydroxyl tends to be more acidic than the C-3 hydroxyl and this may be advantageously exploited in certain cases such as partial benzylation under phase-transfer catalysis. The latter reaction conditions also contribute to the relatively good selectivity for substitution at a primary hydroxyl group in preference to a secondary one at either C-3 or C-4.
The protection of the anomeric hydroxyl group is of primary importance for the selective functionalization of other remaining secondary hydroxyls and must be treated separately from other protections. It can be considered as either protection of the acetal hydroxyl group or protection of the acetal, C-1, carbon.

In the synthesis of the precursor of a glycosyl donor, the anomeric hydroxyl group is usually protected as an acetal. Thus, the protective group must be removed in order to introduce the leaving group at the anomeric position in this case.

The introduction of thioglycosides to carbohydrate chemistry reversed the idea of protection of the anomeric hydroxyl group. Thioglycosides as protective groups of acetal carbon are generally stable under Lewis acidic conditions used to activate other leaving groups in glycosylation reactions. Most importantly, they can be selectively activated under oxidative conditions to give an active glycosylating agent, the oxocarbonium ion. Thioglycosides therefore are extremely useful not only as protective groups of acetal carbons but also as excellent leaving groups [63].

Recently, a new intramolecular-type approach for the regioselective debenzylation or protection of a secondary hydroxyl group in disaccharides has been reported by Madsen and Bols [64].

4.2 ^{1}H and ^{13}C NMR Spectroscopy

The specific correlations of functional groups with the chemical shifts of carbon and associated protons are always important tools for structure elucidation of simple sugars as well as complex oligosaccharides. The conformational behavior [65,66] of a particular disaccharide and oligosaccharide in solution is determined not only by intramolecular interactions but also by potential interactions that exist between the oligosaccharide and its environment. In particular, the nature of the solvent or more generally the environment in which the compound finds itself, can profoundly affect its geometry. Two such important factors, namely the fully solvated state (i. e. the molecule free in solution) and the molecule "solvated" by a macromolecular receptor (i. e. the molecule bound to the active site of the protein) contribute to the preferred conformation.

Nonselective spin-lattice relaxation rates (s^{-1})* for the anomeric protons of selected oligosaccharides are listed in *Table 4*.

An extensive NMR study of various 1→4-linked disaccharides with D- and L- monosaccharides mixed in disaccharides has been reported [66]. Each group of disaccharides exhibits specific changes in chemical shifts due to glycosidations of the C-4 hydroxy group, which are different between the groups. The differences in chemical shifts were correlated to the preferred conformations of the disaccharides and used to predict the ^{1}H and ^{13}C NMR chemical shifts of 1→4-linked oligo- and polysaccharides.

Table 4

4.3 *C*-Disaccharides

C-disaccharides [67] are special classes of disaccharides with a nonhydrolyzable C–C bridge at various positions. *C*-disaccharides are extremely stable entities that will not be fragmented by biological or chemical hydrolysis [68,69]. Perhaps the major difference between *C*- and *O*-glycosides is found within chemical reactivities. The major difference is the absence of anomeric effects for *C*-disaccharides and incapability of forming hydrogen bonds. Another large difference between physical constants is in the dipole moments. Interestingly, *O*- and *C*-disaccharides exhibit similar coupling constants in their ^{1}H NMR spectra.

C-Disaccharides have become important target molecules because they are potential reversible inhibitors of glycosidases and disaccharidases [69]. Some of the important representatives of this class of derivatives are listed in ❯ *Scheme 4*.

Interestingly, conformational studies of synthesized *C*-disaccharides [70,71,72,73,74,75,76] still furnish new evidence regarding the unpredictability or at least difficulty to properly verify or predict conformation based on steric effect. As an example, the NMR study of the conformation of *C*-glycofuranosides and *C*-glycopyranosides reported by Brakata et al. [77] clearly demonstrated that the $^{1}H_{1'-2'}$ coupling constants were limited in their abilities to define conformations. Other analogs of *C*-disaccharides including a special class of *aza*-*C*-disaccharides, which can be regarded as being closest in structure to the natural sequences, have also been synthesized. Selected representatives of this important class of nonhydrolyzable disaccharides are listed in ❯ *Table 5*.

4.4 Thiodisaccharides

One way to increase the stability of the anomeric linkage is to replace the inter-glycosidic oxygen atom with the sulfur to furnish thio-disaccharides or with a methylene group to furnish a *C*-disaccharide. There has been some debate over the validity of this concept since the conformation may not be the same as that of the parent *O*-saccharide [78]. Indeed, the conformation of thio-disaccharides including (1→2-thiodisacharides) based on the molecular model, clearly confirms the stereogeometry and the difference to the parent *O*-saccharide [79]. All the measurements are similar to the calculation for the sulfur bridge of other thio-disaccharides and are substantially different to that of the oxygen counterpart as previously postulated in the literature [80,81].

Despite these differences, thio-disaccharides with sulfur as the connecting bridge of two sugar moieties are popular as convenient probes for enzyme-inhibition studies [82,83,84,85]. These biological and physicochemical properties are attributed to the different electronic properties of the sulfur (electronegativity) and oxygen atoms. The specific chemical character of the sulfur, particularly the size and the electron density of the sulfur atom, which is more dispersed, creates significant differences. Moreover, the C–S bond is longer (ca. 1.8 Å) and the C-S-C angle (ca. 95–100°) is smaller than the corresponding oxygen-containing structures. One thus can apply rational design rather than empirical experimentation in the optimization of synthetic targets, i. e. thio-disaccharides. When comparing the chemical properties of oxygen and sulfur analogs, two other factors must be considered. Firstly, their ability to undergo a wide variety of reduction and oxidation reactions makes them convenient intermediates in many synthetic approaches to other important disaccharides such as deoxy or branched-chain analogs. Secondly, sulfur derivatives such as thiols can be oxidized easily to form disulfides. These two chemical characteristics of thio-disaccharides are primary factors in considering any synthetic strategies and are the potential biochemical mechanisms for forming natural products containing sulfur. Selected representatives of this family of nonhydrolyzable thio-disaccharides are presented in ❯ *Scheme 5*.

Conformational equilibria of thio-oligosaccharides revealed that the most important thiodisaccharide (4-thio-α-maltoside) has a conformation similar to that of the parent maltosyl residue and that the thioglycoside linkage presents a high degree of flexibility. Interestingly, the C–S

bond in 4-thio-α-maltoside is longer than the corresponding C–O bond by ca. 0.4 Å. Among the first thiodisaccharides, thio-trehalose was synthesized in 1914. Other physical properties of new important analogs of thio-disaccharides are listed in *Table 6*.

5 Physical Properties

Specific optical rotation, circular dichroism (CD), and the newly developed exciton chirality method [96] for functionalized carbohydrates bearing specific chromophores are particularly

useful for the determination of absolute configuration not only of monosaccharides but also more complex carbohydrates including disaccharides.

Among other physical properties of the above-mentioned classes of disaccharides, one of the particularly important properties is Raman optical activity (ROA).

Carbohydrates (disaccharides) in aqueous solution are favorable examples for ROA studies furnishing an informative band structure over a wide range of the vibrational spectrum. Their complex and highly coupled normal modes generate strong ROA bands that produce patterns characteristic of the various types of structural units. ROA data can be used to confidently specify the central component of carbohydrate stereochemistry. For disaccharides [92] ROA can provide the nature and conformation of the glycosidic link, and can also probe extended secondary structures of oligosaccharides [93].

The conformation of di-, oligo-, and polysaccharides center on the glycosidic link, for which several distinct ROA signatures have been identified. The most important and critical one is a couplet centered at $\sim 917\,\mathrm{cm}^{-1}$, positive at lower and negative at higher wavenumbers, which originates in C-O-C stretch modes of the common α-(1→4) glycosidic link present in maltose.

5.1 Polarimetry

The determination of sugars by polarimetry is carried out preferably with analytically pure derivatives in higher concentration. Mono-, di-, and smaller oligosaccharides are optically active as a result of the presence of their chiral centers and rotate the plane of the polarized light. The highly specific rotation of disaccharides is dependent not only on the wavelength of the light and temperature, but also to a small extent on the concentration as shown by two common examples of simple disaccharides such as maltose and sucrose.

Maltose behaves as a normal reducing sugar, showing mutarotation and existing finally in aqueous solution as an equilibrated mixture of the α-form and the β-form. Modern ideas about connections between optical rotation and structure are reported in the literature [105].

6 Oligosaccharides

Oligosaccharides such as those found in plant material (see *Table 1*) or on surfaces of cells are assembled through the actions of specific enzymes. The enzymes involved in these biochemical processes belong to various classes of glycosyl transferases and glycosidases. The stability of glycosidic linkages as well as the sequence of assembling monosaccharide components as designed by nature are extremely difficult to reproduce in the laboratory. This is one of the main reasons that laboratory oligosaccharide synthesis starting from basic monosaccharide units through specifically protected di- and trisaccharide fragments is developing so rapidly [106,107,108,109,110,111,112]. The synthetic approaches to oligosaccharides normally demands regiospecific protection group (of disaccharides) schemes which will leave only those hydroxyl groups free that are to be further functionalized. Alternatively, certain other hydroxyl groups may be left unprotected. Simultaneously, however, such a strategy requires regioselective functionalization through glycosylation by attaching another larger fragment of sugar moiety, as was developed in the synthesis of tri- and tetrasaccharides. Oligosac-

charides bound to proteins, as complex glycoprotein carbohydrate groups, are classified into *N*- and *O*-glycoprotein based on the presence of functional groups at different positions. Specific sequences of the core fragments can be determined by ^{13}C-NMR methods [113]. Moreover, combinations of homo- and hetero-nuclear shift correlated 2D NMR techniques have been used to assign ^{1}H and ^{13}C signals of oligosaccharides related to arabinoxylan [114]. ^{13}C-NMR chemical shifts of oligosaccharides have been compiled and tabulated according to their linkages [115]. ^{1}H-NMR methods were used to determine the branching patterns of ceramide pentadecasaccharides with distinctive differences between the parent spectrum and that of partially degraded products [116].

6.1 Trisaccharides

The most common trisaccharides were isolated from natural sources and were identified as partial components of complex oligosaccharides and are listed below in ❯ *Table 7*.

7 Complex Oligosaccharides

Complex oligosaccharides as complex carbohydrates are classified into specific classes based on the presence and sequence of various multiple sugar moieties linked via functional groups at totally different positions. One of the specific functionalities of tetra-, penta-, and hexasaccharides is their water solubility, highly dependant on the presence of a number of *O*-glycosylated and *N*-acetamido moieties of individual fragments. One well-known example of this classical functionality is heparin pentasaccharide. The physical properties of the most important selected complex oligosaccharides, such as tetra-, penta-, and hexasaccharides, are listed in ❯ *Table 8*.

7.1 Tetrasaccharides

Few tetrasaccharides are well known; they have been isolated from natural sources such as plant and animal tissues or through fermentation and enzymatic synthesis. The biological, chemical, or physical properties of an oligosaccharide are largely determined by what is exposed on the outer surface. Most interactions with other molecules will occur at the surface of the molecules.

The conformational studies and physical properties of tetrasaccharides along with representative examples of disaccharides and *O*- and *N*-oligosaccharides have been reported by Meyer [65].

7.2 Pentasaccharides

Among the most common pentasaccharides, the most important is verbascose:*O*-α-D-Gal*p*-(1→6)-*O*-α-D-Gal*p*(1→6)-*O*-α-D-Gal*p*-*O*-α-D-(1→6)-Glc*p*-(1↔2)-α-D-Fru*f* isolated from plant material, particularly from the rhizomes of wool plant and the seeds of cow peas (see also ❯ *Table 1*).

[a]Compiled from original references

7.3 Hexasaccharides

The most common representatives of this class of oligosaccharides are ajugose and cellohexaose, also isolated from plant material, the roots of *Verbascum thapsiformae* and *Ajuga nipponensis*.

Abstract

Sucrose (α-D-glucopyranosyl-(1↔2)-β-D-fructofuranoside) is the most common low-molecular-weight sugar found in the plant kingdom. It is ubiquitously known as common table sugar and primarily produced industrially from sugarcane (*Saccharum officinarum*) and sugar beet (*Beta vulgaris*); the basics of the industrial manufacture of sucrose are outlined in this chapter. Commercial sucrose has a very high purity (>99.9%) making it one of the purest organic substances produced on an industrial scale. Value-addition to sucrose via chemical and biotechnological reactions is becoming more important for the diversification of the sugar industry to maintain the industries' competitiveness in a world increasingly turning to a bio-based economy. The basis for the chemical reactivity of sucrose is the eight hydroxyl groups present on the

Chapter-DOI 10-1007/978-3-540-30429-6_26:

molecule, although, sucrose chemical reactivity is regarded as difficult. Increasing use of enzymatic biotechnological techniques to derivatize sucrose is expected, to add special functionalities to sucrose products like biodegradability, biocompatibility, and non-toxicity. Analysis of sucrose by colorimetric, enzymatic, oxidation-reduction and chromatography methods are discussed. Oligosaccharides related to sucrose are outlined in detail and include sucrose-based plant, honey and *in vitro* oligosaccharides.

1 Introduction

Sucrose (α-D-glucopyranosyl-(1↔2)-β-D-fructofuranoside) is the most common low molecular weight sugar found in the plant kingdom: it is a major product of the photosynthetic activity of leaves and a major transportable source of organic carbon - found in the phloem saps of all plants. Sucrose serves as an essential reserve and energy source for non-photosynthetic tissues, and provides carbon for the synthesis of storage compounds, including starch and less frequently fructosyloligosaccharides (fructans) [1]. For a complete description of the biosynthesis and degradation of sucrose in plants the reader is referred to the review by Madore [1].
Sucrose is ubiquitously known as common table sugar and the sugar industry is actually the "sucrose" industry. Sucrose is primarily produced industrially from sugarcane (*Saccharum officinarum*) and sugarbeet (*Beta vulgaris*), but is also produced from sugar palm (*Arenga pinnata*), and sugar maple (*Acer saccharum*) for smaller, specialty markets. On a worldwide

basis, household sucrose consumption accounts for approximately 55% of the total consumption.

Like for other carbohydrates, the human body utilizes sucrose as a fuel to obtain heat and form adenosine triphosphate (ATP), the basic molecule of the energy system for all organisms.

2 Industrial Sucrose Production

Commercially available sucrose has very high purity (> 99.9%) making it one of the purest organic substances produced on an industrial scale. To obtain such a pure product, from both sugarcane and sugarbeet, rather complex isolation and purification processes are followed. Industrial sucrose production is essentially a series of separations of non-sucrose compounds (usually termed non-sugars or impurities) from sucrose, and the chemistry of the sequential process units is designed for maximum removal of non-sugars with minimum destruction of sucrose. Sugarcane processing often occurs in two stages. Firstly, the juice is extracted from sugarcane (sucrose yields range between 10–15% weight of sugarcane) and converted to inedible raw sugar (~97–98% pure sucrose; golden yellow/brown crystals) at factories (mills) in tropical and sub-tropical areas where sugarcane is grown. Secondly, after raw sugar has been transported to a refinery, it is refined using very similar unit processes used in raw sugar manufacture, to the familiar white, refined edible sugar (> 99.9% sucrose). In some tropical areas of the world, particularly Asia, plantation white, mill white, or direct white sugar (> 99% sucrose with more color than white, refined sugar) is produced directly from sugarcane. There have been recent developments in some countries to produce high quality raw sugar (VHP sugar and Blanco Directo sugar) directly from sugarcane juice at the factory. In comparison to sugarcane, sugarbeets are grown in temperate areas and are processed directly into white sugar (> 99.7% sucrose) at nearby factories.

2.1 Raw Sugar Manufacture from Sugarcane

A brief outline of the typical unit processes in the manufacture of raw sugar from sugarcane at the factory is shown in *Fig. 1*. Harvested sugarcane (either whole-stalks or billets, depending on the country) is delivered to the factory; the chemical composition and processing characteristics of the delivered sugarcane are dependent on the variety [2]. Juice is extracted from the sugarcane either by tandem milling or, less frequently, diffusion. Imbibition water is applied to one or more of the later mills in the tandem and recirculated to improve extraction. Industrial mill extraction can vary between ~89–97%, depending on many factors including the tandem design. Diffusion, in comparison to milling, often gives greater extraction of sucrose (~93–98%), but also of non-sucrose impurities that increases the loss of sucrose to molasses; more imbibition water is also required in diffusion compared to tandem milling. Extracted juice is then purified in the clarification unit process. Clarification processes can vary, but typically hot lime clarification gives the best results [3]. Juice is first heated up to ~93 °C to allow natural floc formation from the coagulation of colloids and macromolecules, including polysaccharides and proteins. Lime (as milk of lime or calcium saccharate) is added to neutralize organic acids in the juice and to form a heavy precipitate, primarily of calcium phosphate bridged flocs. After flashing at ~102 °C to remove interfering bubbles, this precipitate is settled with the aid

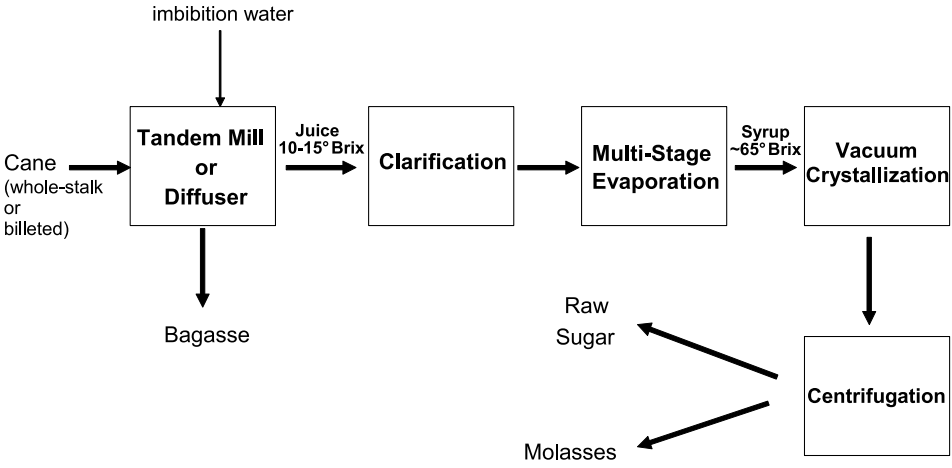

Figure 1
Basic scheme of the raw sugar manufacturing process in a sugarcane factory

of polyelectrolyte flocculants in a large clarification tank, and impurities are precipitated out. The clarification process transforms dark, cloudy sugarcane juice into a clear (clarified) juice (13–18% dissolved solids). This clarified juice is then concentrated through a series of multiple-effect evaporators to syrup of ~65% dissolved solids. By far the most common used type of evaporator in raw sugar manufacture is the simple Robert's-type conventional calandria, rising film evaporator [4], although occasionally more sophisticated evaporators such as Kestner (long tube, rising film) and plate (falling film) evaporators are utilized.

Syrup from the evaporation unit process is then further concentrated, under vacuum at lower temperature than in evaporation to minimize the chemical degradation of sucrose, and crystallized (*Fig. 1*). The vacuum pans are seeded with finely ground sucrose to allow larger sucrose crystals to form. A mixture of sucrose crystals and mother liquor (massecuites) is produced that is then separated in centrifuges, and the mother liquor is re-concentrated and re-crystallized to give two more crops or strikes of crystals. The final liquor is the by-product molasses. Crystallization is often regarded as an industrial "art" and is the major purification step in the manufacture of sugar [5]. The raw sugar obtained is washed (sprayed with water during centrifugation), dried on belts, and then stored in bulk in large warehouses. Raw sugar is transported to the refinery by truck, rail car, or ship.

2.2 Refined Sugar Production from Raw Sugar

Unlike sugarcane factories that are limited to operation during the sugarcane harvest season, raw sugar refineries operate year round. Raw sugar contains ~1–3% non-sugars and the aim of refining is to remove them from the sucrose; typical mean compositions of raw and refined sugars are listed in *Table 1*. Because the production of refined sugar from raw sugar at the refinery is also a series of separations of non-sugars from sucrose (*Fig. 2*), it consists of many similar processes as in raw sugar manufacture (*Fig. 1*).

Table 1
Typical analysis of raw and refined sugar from sugarcane. From [6]

Component	Raw sugar	Refined sugar
Sucrose (%)	97.73	99.95
Invert (%)	0.56	0.006
Ash (%)	0.45	0.007
Organic non-sugars (%)	0.62	0.014
Water (%)	0.64	0.023
Color (ICUMSA units)	2000–5000	10–50

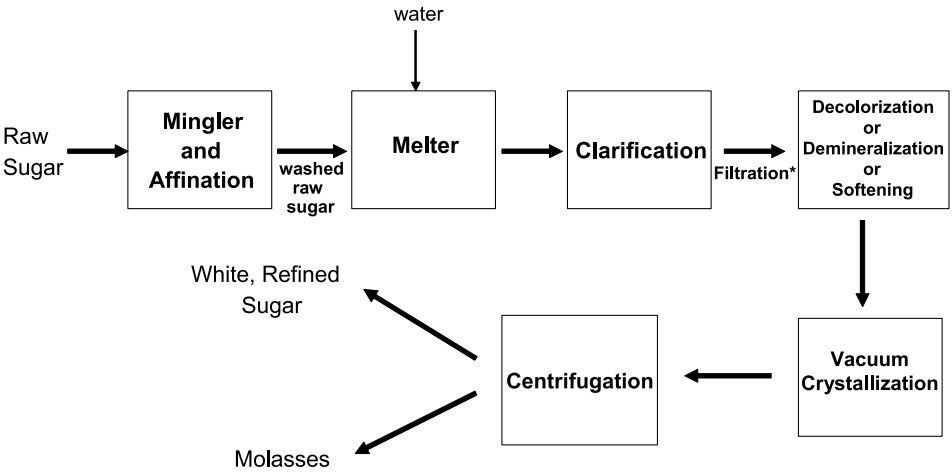

Figure 2
Basic scheme of the white, refined sugar manufacturing process in a raw sugar refinery. Clarification can be phosphatation or carbonation, and decolorization can be with granular carbon, bone char, or ion-exchange resins. *Filtration is not required if phosphatation clarification is utilized

The first stage of the refining process is affination where the raw sugar is mixed with syrup (magma) and then centrifuged and washed with water, to remove the molasses layer around the raw sugar crystals. The affined (or affinated) sugar is dissolved (melted) in water to create a melt liquor of 68–73 °Brix (% dissolved solids). The melt liquor is then clarified by either a phosphatation or carbonatation (carbonation) process [7], followed by decolorization. To obtain refined sugars with low levels of color, 80–90% of color must be removed from the yellow, clarified liquor. Traditionally, bone char and granular activated carbon adsorbents have been used, but many modern refineries now use ion-exchange resins. Bone char and desalting ion-exchange resins remove inorganic salts as well as color, and all adsorbents remove some turbid particles [6]. Multi-stage crystallization is the final purification process at the refinery to produce white, refined sugar which is sold to household and industrial markets; industrial users purchase it preferably in bulk or as liquid sugar in tank trucks.

2.3 Refined Sugar Production from Sugarbeet

Production of refined sugar from sugarbeets has some similarities to refined cane sugar production, as both are a series of process units aimed at separating and removing impurities from the sucrose. However, dissimilarities exist as sugarbeet is a tuberous root and sugarcane a grass. Moreover, because sugarbeet juice contains less invert sugar (glucose and fructose) but more nitrogen-containing compounds than sugarcane juice, sugar beet processing occurs at alkaline pH's compared to the more acidic pH's in sugarcane processing. This is deliberate, as the complete decomposition of invert sugar in beet sugar manufacture is desirable to reduce Maillard color forming reactions between amino acids and invert sugars. In comparison, in sugarcane processing, it is considered an advantage to maintain a small concentration of invert sugar, because it has the net effect of lowering sucrose losses to final molasses [8].

Sugarbeets are harvested defoliated and delivered to the factory. Often sugarbeets are harvested at a rate in excess of factory processing capacity and excess sugarbeets are stored in long-term storage piles on factory or remote grounds. Sugarbeets from the storage piles are introduced to the factory, washed, and sliced into "V" shaped cossettes. Cossettes are added to a counter-current diffuser which may be of a horizontal drum, sloped vat, or vertical cylindrical tower design [9]. Sucrose and impurities are extracted with hot water; approximately 98% sucrose is extracted in the counter-current diffusion operation. Diffusion juice contains ~12% sucrose and 2% soluble impurities on sugarbeet weight, and is heated to ~85 °C before it is purified with a double-carbonatation clarification process. Milk of lime and carbon dioxide are added during clarification. In some sugarbeet factories, sulfur dioxide is added to filtered, clarified juice to minimize color formation during subsequent processing. The resulting clarified "thin" juice is then concentrated from ~14% to ~60–65% °Brix ("thick" juice) across multiple-effect evaporators (Robert's-type and Kestner evaporator designs are favored), then triple-crystallized and centrifuged to produce white, refined sugar (>99.7% purity). In some sugarbeet factories additional purification steps are employed, such as softening, demineralization, or color removal with ion-exchange resins or carbon adsorbents. Additionally, sucrose and betaine are also recovered from beet molasses with chromatography, a process that is much easier in sugarbeet than sugarcane processing.

For more detailed information on the industrial production of sucrose from sugarcane and sugarbeet, the reader is referred to other comprehensive texts [7,10,11,12,13].

2.4 By-Products of Industrial Sucrose Production

The major by-products of industrial sucrose production are bagasse, beet pulp, and molasses. By volume, bagasse from cane sucrose manufacture, is the most important by-product and is the primary source of fuel for the generation of steam and electricity (cogeneration) in sugarcane factories. If there is a surplus of bagasse it can be used to produce value-added products including paper and chipboard and, more recently, there has been much research on the production of cellulosic bioethanol from treated bagasse although, this is not a technological or commercial reality yet. Beet pulp is a source of animal feed as wet pulp, pressed pulp silage, dried pulp, with or without added molasses [14]. Molasses is currently the most valuable by-product of sugar manufacture. It exists in a range of grades: edible molasses (high test

molasses), cane and beet molasses, and refinery molasses. It is used as an animal feed additive, in the industrial production of rum and other beverage alcohols, and bakers' yeast and citric acid [14]. Molasses is also used as an organic feedstock in various other fermentation processes.

3 Chemical and Physical Properties of Sucrose

Sucrose occurs in different physical forms (crystalline, amorphous, and liquid). Sucrose is utilized primarily because of three functional properties: (1) nutritional value, (2) sweetness, and (3) bulking ability, although it imparts many more functional properties that are listed in *Table 2*.

Sucrose consists of two monosaccharides, glucose and fructose, joined by a glycosidic bond between carbon atom 1 of the glucose unit and carbon atom 2 of the fructose unit (*Fig. 3*). Since it contains no free anomeric carbon atom (*Fig. 3*), it is a non-reducing sugar. Some basic chemical, physical, and physico-chemical properties of pure sucrose are listed in *Table 3*.

Structure-function studies on sucrose have been accomplished. In 1956, Lemieux and Huber [16] reported the first chemical synthesis of sucrose by the reaction of 1,2-anhydro-

α-D-glycopyranose triacetate with syrupy 1,3,4,6-tetra-*O*-acetyl-D-fructose. The molecular geometry realized in the crystal is characterized by two intramolecular hydrogen bonds between the glucose and fructose molecules [17] that are shown in *Fig. 4*. In aqueous solution, the intramolecular bonds in sucrose remain [18], with an insertion of a water molecule between the glucosyl-2-OH and fructosyl-1-OH [19], which is also shown in *Fig. 4*.

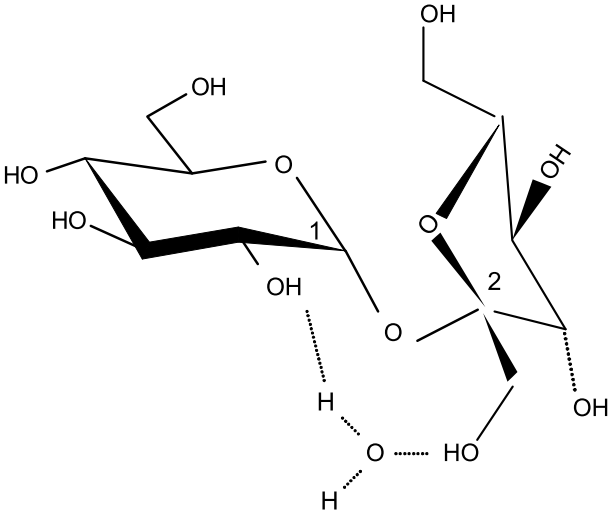

Figure 4
Sucrose structure in aqueous solution. The two sugar units are similarly disposed towards each other, caused by insertion of a water molecule between the glucosyl-2-OH and fructosyl-1-OH groups and the water bridge is fixed by hydrogen bonding. From [20]

4 Analysis of Sucrose

It is not the role of this chapter to give a detailed review of the different analytical techniques used to analyze pure sucrose, and sucrose in technological products. For this the reader is referred to comprehensive reviews by Robyt and White [21], Lescure [22], Eggleston and Côté [23], and Folkes and Jordan [24]. Furthermore, scientific associations exist such as the Association of Official Agricultural Chemists (AOAC) and the International Commission for Uniform Methods in Sugar Analysis (ICUMSA), which provide validated official methods for the analysis of sucrose in different products. ICUMSA provides official methods for use in the sugar industry trade.

Physical and chemical techniques can be used to analyze pure sucrose and sucrose in technological products. Physical spectroscopic techniques, not usually found in routine, industrial laboratories are used to identify sucrose. These include vibrational spectroscopy that is capable of rapidly generating a "fingerprint" of the product. Fourier-transform infrared (FT-IR) spectroscopy can provide information on the anomeric bond and hydroxyl groups [25,26] and, in spite of a wide range of water absorption in the near-infrared (NIR) region, it can be used to accurately identify pure sucrose [27]. Laser-Raman spectroscopy has been used to study the structure of concentrated sucrose solutions and a table is available with characteristic frequency bands and corresponding intensities [28]. Proton NMR spectroscopy is a powerful tool to identify and distinguish sucrose. The ^{1}H NMR spectrum of sucrose reveals the anomer proton bound to the carbon located between the two oxygen atoms (see ❯ *Fig. 3*), and protons bound to other carbons of the rings or the hydroxyl methyl groups of sucrose [29]. ^{1}H NMR spectroscopy, in combination with pattern recognition techniques, has been used to detect the adulteration of orange juices with beet invert sugar [30]. Fourier transform ^{1}H NMR has been used to determine the sucrose content of beet press juice [31] based on time decay of water resonance in the presence of Cr (III). The ^{13}C NMR spectrum of sucrose has also been elucidated [27,32].

Other physical techniques used to measure sucrose in technological products are polarimetry (optical rotation) and NIR spectroscopy. Polarimetry is very important in the sugar industry and is still ubiquitously used for sugarcane or sugarbeet payments to growers, for trade, and custom controls. For this reason, it has been necessary to establish an industrial operation method and measuring instrument scale, i. e., to directly obtain the concentration of sucrose "pol" in 26 g sugar/100 mL water at 20 °C, which corresponds to 100°Z (latest 1986 scale agreed by ICUMSA). This scale was obtained from extremely accurate measurements performed by the Physikalisch-Technische Bundesanstalt (PTB) in Germany and by the Bureau of Standards in the USA [22]. 100°Z corresponds to the optical rotation of pure sucrose at the wavelength of the green rays of the isotope ^{198}Hg ($\lambda = 546.2271$ nm in vacuo; 20.00 °C; 200-mm path length). ICUMSA has also approved the measurement of sucrose "pol" at 880 nm, which allows for more accurate measurements of dark factory juices [33]; dual wavelength polarimeters at 546 and 880 nm are readily available. The drawback of using "pol" to measure sucrose, however, is that it represents a cumulative measurement of all optically active compounds in the solution. Eggleston et al. [34] reported that "pol" can *over-estimate* sucrose and, consequently, *underestimate* sucrose losses across industrial process units. Thus, "pol" values in technological products are precise but often inaccurate. Double polarization methods [35,36,37] are available to remedy the presence of other optically active substances

in the sugar solution. A second polarization of the solution is incorporated after sucrose is selectively hydrolyzed to form an equimolar mixture of glucose and fructose (invert). Sucrose is then calculated by dividing the change in "pol" before and after hydrolysis with an algebraic constant [22]. Although double polarization methods are convenient for industrial laboratory use, in practice selective hydrolysis with acids or enzymes is very difficult. In recent years, NIR spectroscopy (750 to 2500 nm) has been of continued interest to the world-wide sugar industry [38] to measure sucrose, and other sugar quality parameters such as fiber and % dissolved solids, because of its ease of use and speed. However, this technique is dependent on the instrumentation used and generated calibrations. For sucrose analysis the calibration is based on "pol" values, so is only as accurate as polarimetry.

The physical methods described above tend to be more accurate for pure sucrose solutions than complex industrial sugar solutions; for the latter, chemical methods are more accurate. Chemical methods are broadly divided into those based on (i) colorimetric reactions, (ii) enzymatic reactions, (iii) oxidation-reduction properties, or (iv) chromatography separations.

4.1 Colorimetric Methods

For colorimetric methods, most reactions are conducted in the presence of sulfuric acid. Dehydration reactions occur after hydrolysis by warm drying, leading to the formation of deoxyulose and subsequent 5-hdroxymethyl-2-furaldehyde (HMF) which is easily measured at 280 nm. The Molisch reaction is well-known [21,22]: the addition of α-naphthol and concentrated sulfuric acid to the solution causes the formation of a violet-red ring that is used in qualitative determinations. Anthrone can be used as a chromophore at 585 nm, but has been mainly replaced by a simpler phenol-sulfuric acid method using a 480 nm wavelength; both of these methods are quantitative. It must be noted, however, that these colorimetric methods are often tedious and not highly selective for sucrose as they are applicable to most sugars [21,22]. *Table 4* lists the relative differences of colorimetric methods with other chemical methods.

4.2 Enzymatic Methods

Enzymatic methods to determine sucrose are more specific and increasingly being used [22]. Sucrose is readily hydrolyzed with β-fructofuranosidase (invertase) at pH 4.5. Fructose can then be quantitatively determined by phosphorylating with adenosine-5′-triphosphate (ATP) using hexokinase (HK), then converting fructose-6-phosphate to glucose-6-phosphate (G-6-P) by phosphoglucose isomerase. Glucose-6-phosphate is then oxidized to 6-phosphogluconate in the presence of nicotinamide-adenine dinucleotide (NAD) by glucose-6-phosphate dehydrogenase (G6P-DH); NADH is formed which is easily measured at 340 nm. Glucose can also be quantitatively determined by phosphorylation with ATP and HK to G-6-P, then oxidized to 6-phospho-gluconate in the presence of NAD and G6P-DH, with measurement of formed NADH. Glucose can also be determined by oxidation with glucose oxidase to form hydrogen peroxide, which is then reacted with a dye in the presence of peroxidase. The colored product is measured spectrophometrically. Kits with immobilized or non-immobilized enzymes are available for such enzymatic methods. However, enzymes are relatively expensive and the

enzymes have a limited shelf-life (◉ *Table 4*). Special instrumentation is required if immobilized enzymes are used.

4.3 Oxidation-Reduction Methods

Oxidation-reduction methods to determine "% apparent sucrose" are based on the reducing properties of the free carbonyl group of sucrose hydrolysis products, glucose and fructose. Sucrose, therefore, has first to be hydrolyzed by acid. The reducing sugars are reacted with copper solutions in alkaline medium. The most widely used copper reduction methods are Lane and Eynon and Luff Schoorl titration methods [39]. Although copper reduction methods are precise [39] and require no expensive equipment or high degree of technical proficiency, they can be labor intensive and potentially dangerous (◉ *Table 4*). Furthermore, they tend to *over-estimate* sucrose because of over-titrations and because all reducing substances present are measured [39].

4.4 Chromatographic Methods

The most accurate techniques for the analysis of sucrose are those based on chromatographic separations. Gas chromatography (GC) or gas-liquid chromatography is considered the most accurate technique (K. Schaffler, Sugar Milling Research Institute, South Africa, personal communication) and based on the sample being vaporized at high temperatures, injected onto a column and transported through, and separated on, a column by the flow of inert gas. Because

sucrose and other sugars do not sublime at high temperatures, derivatization is required. Silylation [40] and silylation-oximation derivatization [40] are common. As GC is time consuming (*Table 4*), other chromatographic techniques have become more popular, particularly high performance liquid chromatography (HPLC) with cation-exchange columns (sodium or potassium forms) or aminopropyl-silica columns both with refractive index detection, and ion chromatography (IC) with anion-exchange columns and pulsed amperometric detection (a.k.a. HPAEC-PAD). The advantage of IC is that it is very sensitive, but can be relatively unstable. Eggleston and Côté [23] recently reviewed the use of chromatographic techniques for sucrose and other oligosaccharides.

5 Value-Added Products from Sucrose

Value-added products from sucrose that meet existing needs can increase the demand, value, and consumption of sucrose. However, only a small percentage of the sugar produced in the world is used in non-food applications, with ~1.7% at present in the US [41]. This is unfortunate as much research effort and funds have been expended on the identification and development of value-added products from sucrose. Part of the reason for such little impact of this research is that the scientists inventing the products have not fully considered the market, and do not have the business acumen to sell such products to industry. More involvement by industry, particularly at the conception phase, would help to gain more impact. This is becoming increasingly more important, as value-addition to sucrose and diversification of the sugar industry are becoming a greater necessity in the maintenance of the industries' competitiveness in a world increasingly turning to sustainable agriculturally derived chemicals to replace petrochemically derived chemicals (bio-based economy).

Sucrose is a source for many value-added products because of its chemical and enzymatic reactivity. The basis for the chemical reactivity of sucrose is the eight hydroxyl groups present on the molecule (*Fig. 3*). However, sucrose chemical reactivity is regarded as difficult [20,42] because the selective introduction of other functional groups into sucrose is usually possible only in non-aqueous solvents or by using a cost-intensive protecting group chemistry, and the sucrose molecule is susceptible to degradation. Three of the hydroxyl groups are in the primary positions ($-CH_2OH$) and five in secondary positions (–CHOH) (*Fig. 3*). Generally, the three primary hydroxyls have greater reactivity but they often prove a hindrance as they are difficult to react exclusively [20,42]. The synthesis of an enormous number of sucrose derivatives is possible; substitution with just one group type could theoretically give 255 different compounds! Moreover, the alcohol group can be derivatized to form esters, ethers, and substitution derivatives [44]. Sucrose can be readily degraded by acids, oxidizing agents, alkalis, and catalytic hydrogen to compounds of lower molecular weight.

Sucrose is also an exceptional molecule for enzymatic synthesis reactions [41] and such biotechnological methods are finding increasing use for the selective derivitization, functionalization, and rearrangement of the sucrose molecule [42]. Sucrose often acts as a donor molecule for enzymatic transfer reactions to form oligosaccharides and polysaccharides. The advantages of biotechnological methods over chemical methods are that the reactions occur in water and without expensive protecting group chemistry [42], the field of biotechnology is rapidly advancing, particularly in the industrial production of enzymes that can be read-

ily utilized, they are environmentally friendly (waste is biodegradable), and more efficient conversions occur. Furthermore, the use of biotechnological methods will allow the addition of special functionalities to the sucrose molecule like biodegradability, biocompatibility, and non-toxicity, which are becoming important in the emerging bio-economy. Products formed from chemical and enzymatic reactions will be discussed in a later section of this chapter.

5.1 Current Commercial Value-Added Products from Sucrose

The several value-added commodity chemicals that are currently commercially produced from sucrose feedstocks include sucrose esters and fat substitutes, sweeteners, polyurethane foams, organic acids, polyols, and polysaccharides and oligosaccharides [20,41,42,43,44]. The eight hydroxyl groups in sucrose (*Fig. 3*) can be reacted with many fatty acid groups to form sucrose esters. Sucrose esters are ideal non-ionic surfactants; they are non-toxic and biodegradable. Sucrose esters used in the food industry include sucrose stearate, palmitate, laurate, behenate, oleate, and erucate; the quality and application depends on the percentage monoester content [43,45]. Sucrose can also be reacted with fatty acids to form a liquid sucrose polyester (hexa-through octa-substituted fatty acid esters of sucrose), a dietary fat-substitute that is marketed as Olestra^{TM} or Olean^{TM}. Olestra has properties similar to liquid vegetable oil with no calorific value and is often used in snack foods [41]. Sucrose acetate isobutyrate (SAIB) is a commercial mixture of sucrose esters that is used in the industrial, food, cosmetic, and pharmaceutical industries [43]. Sucrose octanoate esters are also currently being registered as "green" biopesticides and may have a bright and worthwhile future [46]. With the recent biotechnological advances in the production of new and better industrial enzymes [47], there is considerable interest in the improved production of sucrose esters (normally chemically synthesized) with enzymes [44,48].

Selective chlorination of sucrose, by which three of sucrose's hydroxyl groups are substituted with chlorine atoms, produces sucralose (1,6-dichloro-1,6-dideoxy-β-D-fructofuranosyl-(2↔1)-4-chloro-4-deoxy-α-galactopyranoside) sweetener sold as Splenda^{TM} [49]. Sucralose is approximately 650 times sweeter than sucrose and can be used in baking. Its synthesis involves treatment of a partially acetylated sucrose with sulfuryl chloride; the initially formed chlorosulfate esters act as leaving groups and undergo nucleophilic displacement by chlorine [20]. Sucralose was first approved for use in Canada in 1991; as of 2006, it has been approved in over 60 countries.

Other commercial sweeteners formed enzymatically from sucrose include isomaltulose (α-D-glucopyranosyl-(1→6)-D-fructose) or Palatinose^{TM}, and isomalt (a mixture of α-D-glucopyranosyl-(1→6)-D-mannitol and α-D-glucopyranosyl-(1→6)-D-glucitol) or Palatinit^{TM}, both produced on a large scale by Palatinit GmbH, a subsidiary of Sudzucker AG. Mitsui Sugar C. of Japan and Cargill Corp. of the US also produce isomaltulose. These enzymatically produced sweeteners are marketed as natural, non-cariogenic, low-glycemic index sweeteners [44].

Polyurethane polymers used in numerous industries including the paint, cotton, rubber, and metal industries [43] are mostly manufactured by the reaction of a polyol produced from sucrose with di-isocyanate. The polyol is produced from the reaction of sucrose with an alkylene oxide (such as ethylene, propylene, or butylenes oxide). Resulting polyurethane foams

can be used for packaging and insulation. Commercial products include Veranol™ (Dow Polyurethanes) and Pluracol™ 975 Rigid Polyol (BASF Chemicals) [43].

Currently, there are a few commodity chemicals produced by the fermentation of sucrose feedstocks. These include organic acids, polyols and, on a smaller scale because of the cost of production limiting the potential market, polysaccharides and oligosaccharides [43]. Advantages of fermentations (whole-cell or enzymatic) over traditional chemical synthesis are lower energy costs, higher yields, product specificity, and environmental friendliness. Some important value-added products of sucrose manufactured from fermentation reactions, are shown in *Fig. 5*. For a full description of all these products, the reader is referred to the recent reviews by Walford and Morel du Boil [43] and Côté [44]. Citric acid (E330) is an approved flavor compound, preservative, and buffer used in many industries. It is produced from a submerged fermentation of *Aspergillus niger* with sucrose or molasses (sugarcane or sugarbeet) as the substrate [50]. L-Ascorbic acid or Vitamin C is now increasingly being produced by fermentation as well, using sucrose or glucose as the substrate [51]. Lactic acid is utilized in numerous industries; it can be chemically synthesized to produce a racemic mixture (D and L forms) or produced as either the D or L form by fermentations. Sucrose, molasses, and corn syrup have been the preferred substrate feedstocks [52] with the latter being currently preferred. Sugar alcohols and polyols have traditionally been manufactured by the hydrogenation of sugars, including sucrose, using a nickel catalyst. Production of commercial sugar alcohols is now tending to enzymatic fermentation. Sucrose is also used as a feedstock for the fermentative production of a wide variety of microbial polysaccharides and oligosaccharides. Some microbial polysaccharides and oligosaccharides are synthesized uniquely from sucrose and depend on the action of glucansucrases. Examples of such products include dextran (α-(1→6)-linked-D-glucans) used in the pharmaceutical industry, and fructooligosaccharides (FOS) marketed as prebiotic nutraceuticals in the food industry (*Fig. 5*).

5.2 Possible Future Value-Added Products from Sucrose

The large-scale and economic diversification of sucrose into industries other than the food industry, is not a reality. However, this may change in certain countries as the concept and use of renewable carbohydrate feedstocks for biotransformations is growing rapidly. This is because carbohydrates are the most abundant organic materials in nature, they are renewable, and because of surging costs of traditional petroleum and natural gas feedstock in the chemical industry. Sucrose fits well into the renewable carbohydrate feedstock concept because of its availability, high purity, and because sugarcane and sugarbeet are amongst the plants giving the highest yields of carbohydrates per hectare. Products of sugarcane and sugarbeet, including sucrose are, therefore, ideal raw materials for the production of new biomaterials such as bioethanol, although commercialization will depend mostly on economic factors, such as government subsidies. Some countries are already producing bioethanol from sugarcane (and to a lesser extent sugarbeet) juice and/or molasses, particularly Brazil, but much more world-wide production is expected in the next 20 years. Other bioproducts will likely include biopolymers as viable alternatives to common plastic polymers. For example, lactic acid production as an intermediate for polymer and plasticizer manufacture could be from sucrose feedstocks [43]. Other example biopolymers from sucrose, are sucrose hydrogels (sucro acrylate gels) that are

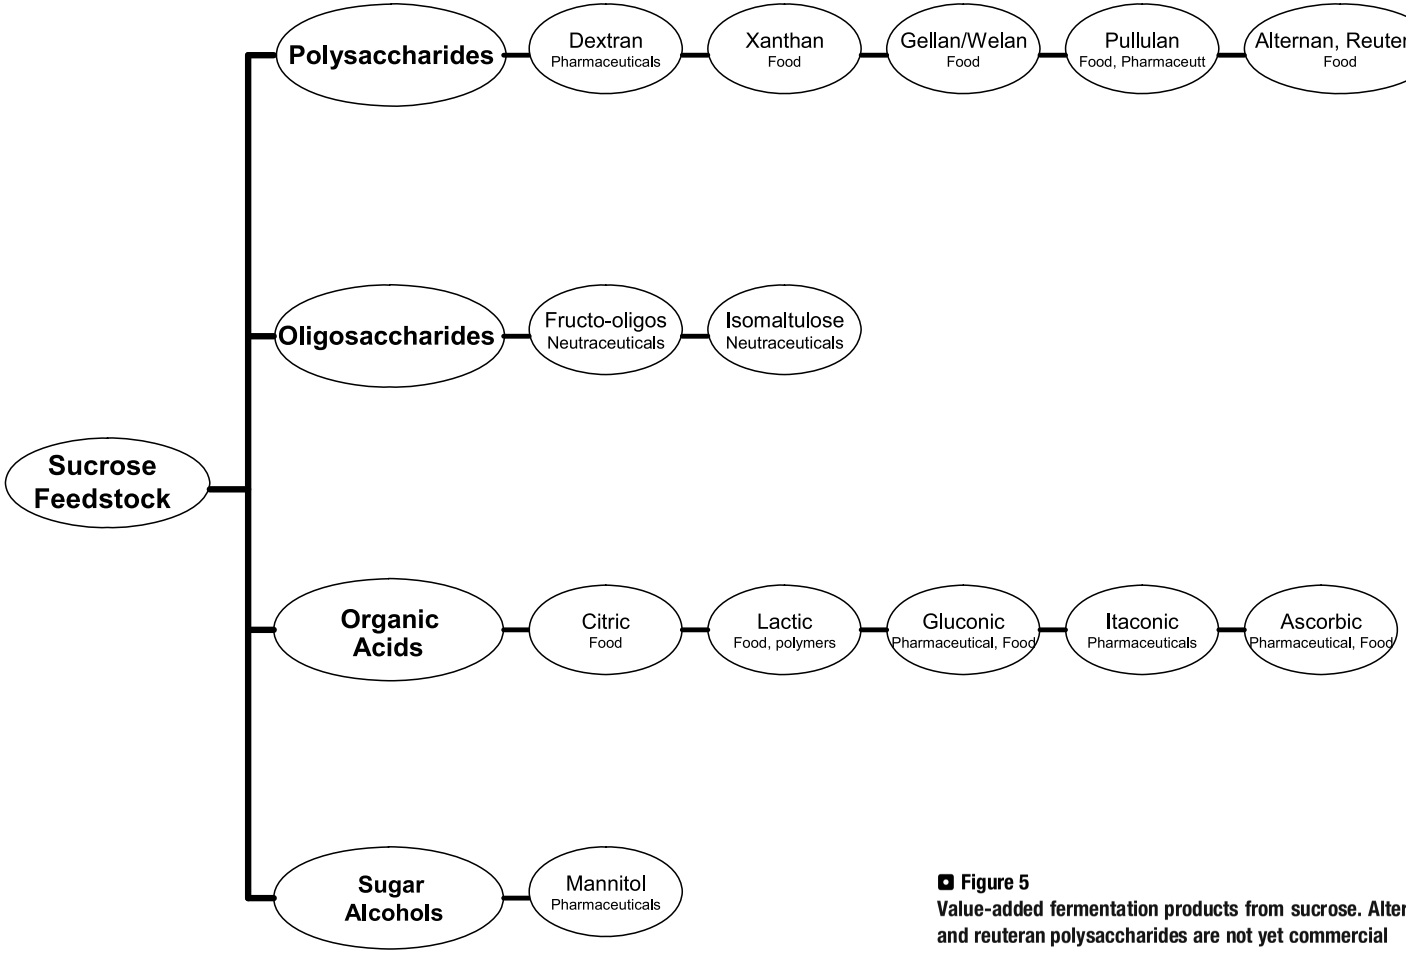

Figure 5
Value-added fermentation products from sucrose. Alternan and reuteran polysaccharides are not yet commercial

super-porous and fast-swelling. Sucrogels can be made in any size and shape and could find many industrial applications [41,53,54]. Epoxy sucrose-based products that can replace petrochemically derived diepoxide used in epoxy resins [55] also have potential, but so far have not been commercialized. With recent and expected biotechnology advances in the production of industrial enzymes [47], more enzymatically formed value-added products from sucrose are envisaged, similar to those discussed in the above section.

6 Oligosaccharides Related to Sucrose

Sucrose oligosaccharides, including isomers of sucrose are found in nature and others can be manufactured enzymatically. The following is a description of the most important sucrose related oligosaccharides.

Oligosaccharides can be grouped into two distinct classes: primary and secondary oligosaccharides [56]. Primary oligosaccharides are synthesized *in vivo* or *in vitro* from a mono- or oligosaccharide and a glycosyl donor by the action of a glycosyl transferase. Sucrose, and primary oligosaccharides based on sucrose, are the most ubiquitous plant primary oligosaccharides. In comparison, secondary oligosaccharides are formed *in vivo* or *in vitro* by hydrolysis of higher oligosaccharides, polysaccharides, glycoproteins, and glycolipids [23]. More detailed descriptions of secondary oligosaccharides can be found in other reviews by Côté [44], Eggleston and Côté [23], and Doner and Hicks [57].

6.1 Sucrose-Based Plant Oligosaccharides

Primary oligosaccharides based on sucrose are formed by the transfer of galactose (D-galactopyranosyl), glucose (D-glucopyranosyl), or fructose (D-fructofuranosyl) residues to sucrose with a glycosyl transferase. Series of families of homologous sucrose-related plant oligosaccharides exist, of which the "raffinose" and "kestose" series are the best known and most widespread [23]. The raffinose series of sucrose-related oligosaccharides is illustrated in ❯ *Fig. 6*. The trisaccharide raffinose is formed by the addition of galactose to the glucose moiety in the sucrose molecule via an α-(1→6) glycosidic linkage. The series is formed by the continual attachment of a galactose residue via an α-(1→6) linkage to the galactose moiety of the previous oligosaccharide in the series (❯ *Fig. 6*) and continues up to a nonasaccharide. These oligosaccharides act as important carbohydrate reserves in the vegetative storage organs and seeds of many plants, and also play an important role in sugar translocation [23,58]. They are found in soy products and cottonseed meal.

The kestose or fructan series of sucrose-related oligosaccharides is found in at least 12% of vascular plant species [23]. Kestoses contain one glucose moiety per oligosaccharide chain, derived from the parent sucrose molecule by the action of fructosyltransferases. The simplest kestose, monofructosyl-sucrose is a trisaccharide that exists as three isomers: 1-kestose (1^F-β-D-fructofuranosylsucrose), 6-kestose (6^F-β-D-fructofuranosylsucrose), and neo-kestose (6^G-β-D-fructofuranosylsucrose). These isomers form the basis of three major kestose subseries with different linkage patterns [23].

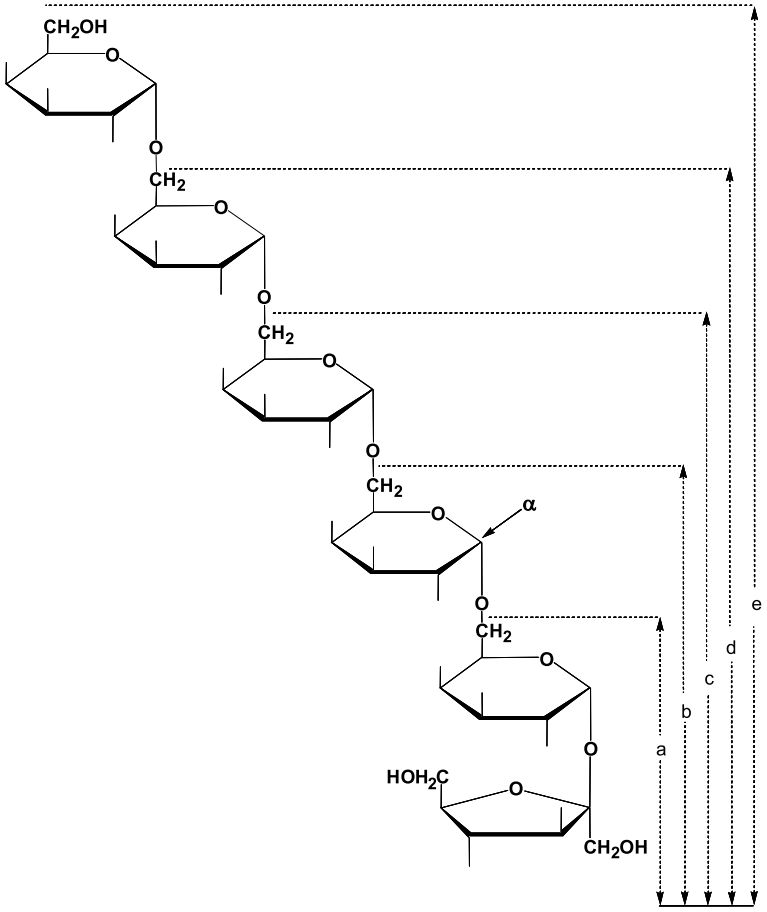

Figure 6
Raffinose series of oligosaccharides, (a) sucrose, (b) raffinose, (c) stachyose, (d) verbascose, (e) augnose

Planteose is a trisaccharide comprising sucrose and galactose (*O*-α-D-galactopyranosyl-(1→6)-*O*-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside) that is found in certain plants. It acts as a short-term storage carbohydrate in *Actinidia* leaves [59].

6.2 Sucrose-Based Honey Oligosaccharides

Honey represents the greatest source of oligosaccharides from plant material attacked by insects, and the sucrose content can range from 1 to 15% [59,60]. There are two types of honey: floral and honeydew. Floral honey originates from the nectar of flowers. Honeydew is obtained by the honeybee indirectly from sweet syrups excreted by various hemipterous insects feeding on tree sap. Honey oligosaccharides are presumed to arise from the action

of glycosidases from the bees [44], and have been the subject of comprehensive reviews by Doner [61] and Doner and Hicks [57]. Glycosidases catalyze transglycosylation reactions with sucrose, as well as condensation reactions. α-D-glucopyranosidases and β-D-fructofuranosidases present in honey cause not only the hydrolysis of sucrose in nectar, but also the formation of a variety of glucose and fructose containing oligosaccharides [44]. The most common oligosaccharides in honey include the glucose disaccharides: maltose (α-l→4 linked), kojibiose (α-1→2 linked), isomaltose (α-1→6 linked), and α,α-trehalose (α1↔α1 linked). Marked quantities of sucrose-related oligosaccharide isomers found in honey are: isomaltulose (α-D-glucopyranosyl-(1→6)-D-fructose), leucrose (α-D-glucopyranosyl-(1→5)-D-fructose), maltulose (α-D-glucopyranosyl-α-1→4-D-fructse), and turanose (α-D-glucopyranosyl-1→3-D-fructose). Glycosylated sucrose oligosaccharides are also found in honey and include erlose, melezitose, theanderose, and kestoses, which are discussed in more detail here.

Erlose (α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl-(1↔2)-β-D-fructofuranoside) is produced by the action of honey invertase on sucrose. Melezitose is an unusual oligosaccharide found in honey. Its structure is α-D-glucopyranosyl-(1→3)-β-D-fructofuranosyl-(2↔1)-α-D-glucopyranoside, which is illustrated in ❯ *Fig. 7*. Melezitose also occurs in honeydew plant exudates and various types of "manna" (white, crystalline substances) that periodically cover trees, particularly larch and Douglas fir trees [62]. Melezitose is produced from the action of aphids and other insects in the sap of plants [63]. Although melezitose has been consumed by humans for many years, little is known of its nutritional or health benefits [44].

Theanderose(α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl-(1↔2)-β-D-fructo-furanoside) is also referred to as isomaltosucrose. It is synthesized in honey from the transferase action of β-D-fructofuranosidase on sucrose. It can also be found in certain plants, including sugarcane, and has been used as a marker to differentiate sugarcane refined sugar from sugar beet refined sugar [64]. It has also been proposed as a non-cariogenic sweetener [65]. Kestoses are discussed in the previous section.

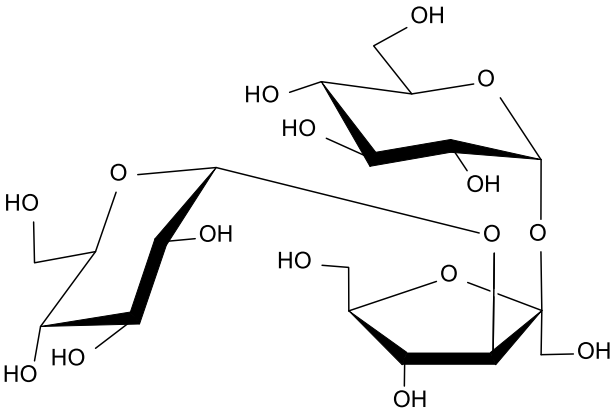

Figure 7
Structure of melezitose

6.3 Sucrose-Based In Vitro Oligosaccharides

Short chain fructooligosaccharides (scFOS; same as the kestose group discussed in the section above) can be prepared in vitro from the reaction of a microbial fructosyltransferase on sucrose. Up to 3–5 degrees of polymerization can be formed. These products have been studied extensively as prebiotic nutraceuticals [44].

Leucrose (α-D-glucopyranosyl-(1→5)-D-fructopyranose) is formed by dextransucrase-catalyzed transfer of glucosyl units to fructose acceptors. Dextransucrase occurs naturally in *Leuconostoc mesenteroides* lactic acid bacteria. The nominal reaction of dextransucrase is to incorporate the α-D-glucopyranosyl units from sucrose into dextran, an α(1→6)-linked D-glucan. Fructose is liberated in this reaction, and this fructose is used to produce leucrose in a side acceptor reaction. Leucrose is used as a sweetener, being approximately half as sweet as sucrose, and is non-cariogenic, resistant to acid hydrolysis, and releases glucose into the bloodstream only slowly [44]. It is manufactured commercially using immobilized dextransucrase, with Pfeifer and Langen of Germany the major producer. Other sucrose-based oligosaccharide sweeteners are xylosucrose (α-D-xylopyranosyl-(1↔2)-β-D-fructofuranoside) and lactosucrose (β-D-galactopyranosyl-(1→4)-α-D-glucopyranosyl-(1↔2)-β-D-fructofuranoside).

Xylosucrose is formed by the action of levansucrase on sucrose: D-fructofuranosyl units from sucrose are transferred to a xylose acceptor [66]. Xylosucrose can also be produced by the transferase action of β-D-fructofuranosidase. Lactosucrose has been studied [44] as a dietary ingredient for its prebiotic effect, and is produced commercially in Japan. It can be synthesized enzymatically via the fructosyltransferase reaction of either levansucrase or β-D-fructofuranosidase, with the latter reaction used in commercial production.

Oligosaccharides are also synthesized during the acid-catalyzed hydrolysis of sucrose, particularly under conditions of weak acid and high sucrose concentrations [67]. Oligosaccharides formed include kestoses [67] and IS1 (*O*-α-D-glucopyranosyl-(1→3)-D-fructose), IS2 (*O*-β-D-fructofuranosyl-(2→6)-D-glucose), and IS3 (*O*-α-D-glucopyranosyl-β-D-glucopyranoside) oligosaccharides. The mechanism for the formation of IS1-3 oligosaccharides was recently published by Thavarajah and Low [68].

5.3 Oligosaccharides in Food and Agriculture

Michelle E. Collins, *Robert A. Rastall**
Department of Food Biosciences, The University of Reading,
Reading RG6 6AP, UK

Abstract

Oligosaccharides are an integral part of the daily diet for humans and animals. They are primarily used for their nutritional properties, however they are currently receiving much attention due to their physiological effect on the microflora of the gastrointestinal tract. Galacto-oligosaccharides and the fructan-type oligosaccharides, namely FOS and inulin are well established as beneficial to the host and are classified as prebiotic based on data from clinical studies. These compounds dominate this sector of the market, although there are oligosaccharides emerging which have produced very interesting in vitro results in terms of prebiotic status and human trials are required to strengthen the claim. Such compounds include pectic oligosaccharides, gluco-oligosaccharides, gentio-oligosaccharides, kojio-oligosaccharides, and alternan oligosaccharides. The raw materials for production of these prebiotic compounds are derived from natural sources such as plants but also from by products of the food processing industry. In addition to being prebiotic these compounds can be incorporated into foodstuffs due to the physiochemical properties they possess.

1 Introduction

Carbohydrates are an intrinsic part of the daily diet for mammals. In nature they exist in many forms, however it is oligosaccharides which are of interest here. The production of oligosaccharides for use in food (or as part of the diet) is either by direct extraction from plants [1], controlled hydrolysis of polysaccharides [2], or by enzymatic synthesis using enzymes which possess hydrolytic or transglycosylation activity [3,4]. Oligosaccharides are composed of 2 to 20 monosaccharide units joined together by glycosidic bonds and exist as a linear or branched arrangement.

Awareness of the health benefits of certain food-grade oligosaccharides has increased in recent years and has received particular interest in Japan followed by the United States and Europe.

Table 1
Prebiotic oligosaccharides

Prebiotic oligosaccharides	Structure
Fructo-oligosaccharides	
Table 1
(continued)

Prebiotic oligosaccharides	Structure
Xylo-oligosaccharides	Lactulose	Lactosucrose	Gentio-oligosaccharides	Isomalto-oligosaccharides	
Such oligosaccharides include the fructan-type oligosaccharides; inulin and fructose oligosaccharides (FOS), galacto-oligosaccharides (GOS), isomalto-oligosaccharides (IMO), lactulose, gentio-oligosaccharides, soybean oligosaccharides (SOS), xylo-oligosaccharides (XOS), and lactuosucrose (*Table 1*). Some occur naturally in several foods such as leek, asparagus,

chicory, Jerusalem artichoke, garlic, onion, wheat, banana, and oats, as well as soybean. However, these foods contain only trace levels of oligosaccharides, so developments in functional foods have taken the approach of removing the active ingredients from such sources and adding them to more frequently consumed products [5]. The oligosaccharides listed are classified as prebiotic. Defined by Gibson and Roberfroid [6], a prebiotic is "a non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and / or activity of one or a limited number of bacteria in the colon that have the potential to improve host health." A prebiotic dose of 5 g day^{-1} should be sufficient to elicit a positive effect upon the gut microbiota (in some exceptional cases this may be nearer to 8 g day^{-1}). Doses below 5 g day^{-1} are not likely to be effective as the overall dietary carbohydrate load into the gut will mask any prebiotic effect. A possible side effect of prebiotic intake is intestinal discomfort from gas production. However, the beneficial bacteria cannot produce gas as part of their metabolic process. Therefore, at a rational dose, of up to 20 g day^{-1}, gas distension should not occur. If gas is being generated then the carbohydrate is not acting as an authentic prebiotic. This is perhaps because dosage is too high and the prebiotic effect is being compromised, i. e. bacteria other than the target organisms are becoming involved in the fermentation [6].

It is apparent that the indigenous microflora can dictate the well being of the host in synergy with diet. However, exercise also has a role in health and longevity. The microflora of the gastrointestinal tract are thought to comprise around 95% of the total cells in the body [7]. In mammals there exists variability in bacterial numbers and populations between the stomach, small intestine, and colon. The total bacterial count in gastric contents is usually below 10^3 g^{-1}, with numbers in the small intestine ranging from about 10^4 ml^{-1} contents to about 10^6–10^7 at the terminal ileum. The colon is the most heavily populated area of the gastrointestinal tract (GIT), with numbers typically in the region of 10^{12} g $contents^{-1}$ [8]. The majority of bacteria are non-sporulating anaerobes and can be categorized as being either beneficial or potentially pathogenic due to their metabolic activities and fermentation end products. The resident GIT organisms ferment substances that cannot be digested by the host in the small intestine. These include resistant starch, non-digestible carbohydrates, oligosaccharides, proteins, and mucins. The two main types of fermentation that are carried out in the gut are saccharolytic and proteolytic. Saccharolytic fermentation is more favorable than a proteolytic fermentation due to the metabolic end products that are formed. The main products of saccharolytic fermentation are the short chain fatty acids, acetate, propionate, and butyrate. All contribute towards the host's daily energy requirements. Acetate is metabolized in systemic areas like muscle and used to generate ATP, while propionate is transported to the liver. Butyrate is an important source of energy for the colonocytes and has anti-tumor properties. The end products of proteolytic fermentation on the other hand, include toxic metabolites (such as phenolic compounds, amines, and ammonia) some of which are carcinogens [9].

Bifidobacteria and lactobacilli are considered to be beneficial bacteria. They positively influence the host and are associated with immunostimulation, improved digestion, and absorption, syntheses of vitamins, inhibiting the growth of potential pathogens, reducing cholesterol, and lowering gas production. These bacteria are classified as probiotic [10] and as they are indigenous to the host they can be selectively promoted by the consumption of prebiotics.

Of the prebiotics listed some have received extensive investigation whereas efficacy data on others may not be so abundant. The fructan-type oligosaccharides, GOS and IMO will be discussed in further detail here. Pectic oligosaccharides would be considered as emerging prebi-

otics. Although their effect in vivo has not been fully investigated, results from in vitro studies are interesting and exciting and thus this oligosaccharide will also be discussed. Reviews on the remaining oligosaccharides are available [11].

2 Fructan-Type Oligosaccharides

Inulin, levan, graminan, phlein, and kestoses are classified as fructans [12]. Inulin exists either as a linear, branched, or cyclic fructan whereas the structure of the remaining fructans are linear and branched (*Table 2*) [13].

Fructans occur naturally, are predominantly found in plants, fungi, and are produced extracellularly by bacteria such as *Streptococcus mutans* [13]. Plants are the most likely source of inulin for the production of material to be incorporated into foodstuffs due to its abundance in plants and also from a safety perspective. Inulin is found in the tubers and roots of the plant family *Compositae* which includes aster, dandelion, dahlias, comos, burdock, goldenrod, chicory, lettuce, and Jerusalem artichoke [14,15]. Van Loo et al. [16] identified the quantity of inulin in various plants as well as their degree of polymerization (*Table 3*). An extensive review of occurrence and distribution of fructans in nature is provided [16,17,18].

Niness [19] describes the commercial production of inulin from chicory roots where the inulin is extracted using processes similar to those employed for the extraction of sucrose from sugar beet. Chicory inulin is a linear β-(2→1)-linked fructan and is composed of a mixture of oligosaccharides in which the DP (degree of polymerization) varies from between 2 to 65 monosaccharide units with an average DP of 12. The final spray dried product consists of 6–10% sugars constituting glucose, fructose, and sucrose [12,19].

Fructo-oligosaccharides are produced by the enzymatic hydrolysis of inulin with an endoinulinase (EC 3.2.1.7) or by the transfructosylation activity of a β-fructofuranosidase (EC 3.2.1.26 and EC 3.2.1.80) using sucrose as the substrate. The latter method can utilize a batch system using soluble enzymes or a continuous system using enzymes or whole cells immobilized, for example, onto a suitable ion-exchange resin [20]. For synthesis of FOS β-fructofuranosidase (β-FFase) from Aspergillus species, *A. niger* and *A. japonicus* are often used due to their high fructosyltransferase activity. As well as being used as soluble enzymes their enzymes have been immobilized onto various matrixes such as gluten [21], oxirane containing polymeric beads [22], and ceramic membranes [23]. Cheng et al. [24] immobilized β-FFase from *A. japonicus* by entrapment in calcium alginate gel in a packed bed reactor. After 25 days

Table 2
Fructan structures

Name	Linkage	Structure	Origin
Inulin	β (2–1)	Linear, branched, cyclic	Plant, bacteria, fungi
Levan	β (2–6)	Linear, branched	Plant, bacteria, fungi
Phlein	β (2–6)	Linear, branched	Plant
Graminan	β (2–1) and β (2–6)	Linear, branched	Plant
Kestoses	β (2–1) and β (2–6)	Linear, branched	Plant

Table 3
Inulin content and chain length in plants

Natural food	% Fructan on fresh	DP
Onion (*Allium cepa*)	1.1–7.5 (Avg. 3.6)	1–12
Jerusalem Artichoke (*Helianthus tuberosus*)	17–20.25	2–19 = 74%, 19–40 = 20%, >4 = 6%
Globe artichoke (*Cynara scolymus*)	1.8% (fresh), 1.7% (cooked)	> 5 = 95%
Chicory (*Cichorium intybus*)	15.2–20.5 (Avg. 16.2)	2–19 = 55%, 19–40 = 28%, >40 = 17%
Asparagus (*Asparagus officinalis*)	2.6 (shoots), 0.1 (fresh plant)	
Leek (*Allium ampeloprasum*)	2.9 (fresh leaves)	12
Garlic (*Allium sativum*)	12.98	> 5 = 75%, Avg. DP = 15
Salsify	4.2	> 5 = 75%
Banana (*Musa cavendishii*)	0.7	< 5 = 100%
Wheat (*Triticum aestivum*)	1.17 (white flour)	7–8
Rye (*Secale cereale*)	0.6%	
Barley (*Hordeum vulgare*)	22.1 (young kernals), 1.1 (mature kernals)	
Dandelion (*Taraxacum officinale*)	12.8 (leaves)	

DP = degree of polymerization

17% of enzyme activity was lost, however, appreciable amounts of FOS were formed. Park et al. [25] report on the production of neo-FOS using immobilized whole cells of *Penicillium citrinum* as an alternative to immobilizing the actual enzyme. Continuous production of FOS was successfully maintained in a packed bed reactor for 50 days thereby indicating the potential for use in an industrial scale. Others have demonstrated the effect of a mixed enzyme system for FOS production. Sheu et al. [26] used a β-fructofuranosidase from *A. japonicus* and a glucose oxidase enzyme. During the synthesis reaction glucose is released as a by-product which is subsequently inhibitory to the activity of β-fructofuranosidase. However, the presence of glucose oxidase converted the residual glucose to gluconic acid which was then precipitated to calcium gluconate. The final mixture contained >90% w w^{-1} FOS on a dry weight basis with small amounts of glucose, sucrose, and calcium gluconate. As for all synthesis reactions the source of enzyme, the pH, the reaction temperature and substrate concentration will influence the yield and type of product. These oligosaccharides are composed of 1-kestose (GF2), nystose (GF3), and 1F-fructofuranosyl nystose (GF4), in which fructosyl residues are bound at the 2-OH position of the fructofuranosyl moiety of sucrose (GF) [19,27].

Inulin and FOS are commercially produced in Japan and Europe (*Table 4*) and have widespread applications as food ingredients. However, in the context of this chapter the application of inulin and FOS will be discussed as a functional food ingredient beneficial for the gastrointestinal tract of humans and animals.

Stimulating the growth of the beneficial bacteria resident in the colon is a prerequisite for any oligosaccharide to be considered as a prebiotic. In vitro studies using pure or mixed cultures and fructan oligosaccharides as the sole carbon source provide initial results to support

Table 4
Commercial fructan-containing products

Product	Type	Source	Content / DP	Fructose glucose sucrose
Beneo™ ST	Powder	Chicory	Inulin >90%, average DP ≥ 10	Fructose and glucose ≤4%, sucrose ≤8%
Beneo™ HP	Powder	Chicory	Inulin > 99.5%, average DP ≥23	≤ 0.5%
Beneo™ oligofructose	Powder	Partial enzymatic hydrolysis of chicory inulin	Oligofructose ≥93.2%, DP 2–8	≤ 6.8%
Actilight 950S and 950P	Syrup	Sugar beet	GF2 37% ±6%, GF3 53% ±6%, GF4 10% ±6%	5% ±2%
Meioligo	Syrup	Sucrose	GF2 25–30%, GF3 10–15%, GF4 5–10%	25–50%

Actilight products are manufactured by Beghin-Meiji Industries (France)
Meioligo™ products are manufactured by Meiji Seika Kaisha (Japan)
DP = degree of polymerization
GF2 = 1-kestose
GF3 = nystose
GF4 = fructofuranosylnystose

the prebiotic effect of these compounds. Gibson and Wang [28] observed that the growth of *Bifidobacterium infantis* was better on oligofructose compared to the effect on seven other bifidobacteria strains. Observations were based on changes in specific growth rates, culture pH values, and enzyme production. Others have also observed the preference of bifidobacteria for oligofructose compared to inulin, for example *B. animalis* was more efficient at fermenting oligofructose than inulin [29]. Marx et al. [30] investigated the effect of FOS derived from levan on the growth of *Bifidobacterium adolescentis*, *B. longum*, *B. breve*, and *B. pseudocatenulatum*. Of these bifidobacteria species the growth of *B. adolescentis* was better, additionally high concentrations of organic acids were produced by this strain. The FOS derived from hydrolysis of inulin is β-(2→1)-linked whereas levanoligosaccharides are β-(2→6)-linked. This difference in structure could ultimately affect their fermentability by the indigenous microflora, the chemical nature of the FOS and the degree of depolymerization will also influence the extent of fermentation. The DP of levanoligosaccharides is approximately 20 whereas that of FOS from inulin has a DP of 2–8. Yamamoto et al. [31] used FOS from levan which had a DP of 37; no increase in growth was observed; therefore in this study it could be the molecular mass which was hindering the metabolism of FOS rather than the source of FOS. The ability of various lactobacillus species to ferment short chain purified FOS was determined in pure culture studies [32]. Of the 16 strains selected 12 of these utilized FOS and *Lactobacillus rhamnosus* GG, a well studied and commercially used probiotic, did not. The effect on bifidobacteria species was also investigated and *B. bifidum* did not grow; this observation does not corroborate with Rossi et al. [33] who confirmed the growth of various types of this species on Raftilose P95. As bifidobacteria and lactobacillus species are reported to exert beneficial effects on the host [34]

these strains are of particular interest in in vitro studies to determine if they grow and how well they grow on various substrates which may be potential prebiotics. Rossi et al. [33] grew pure bifidobacteria cultures in a basal media containing FOS or inulin; of the 55 strains tested only seven utilized inulin whilst all strains utilized FOS. The DP of FOS was 2–10 whereas that of inulin was 25; as previously mentioned the longer chain may influence the extent of fermentability. Roberfroid et al. [29] reported results from in vitro studies whereby molecules with a DP greater than 10 are not fermented as quickly as those molecules with a DP of 10 or less.

Pure culture studies are not sufficient to confirm the efficacy of a potential prebiotic. Batch cultures [35], single-stage continuous cultures [36], or a three-stage continuous culture [37], the latter representing the human colon, further validate the claim. However, the ultimate confirmation comes from the results obtained from human clinical trials. Various trials have been performed where inulin or FOS has been incorporated into the diet and the main outcomes from these studies are described in the following text

A balanced multiple crossover trial incorporated Raftilose P95 at two concentrations (5 g day^{-1} and 10 g day^{-1}) into the diet of healthy men [38]. Fecal samples were analyzed for changes in pH, SCFA, and weight. However, analysis of the fecal microflora were not determined at the beginning and the end of the study. Catabolism of the FOS was confirmed as no FOS could be recovered in the feces or urine. Breath H_2 excretion increased on consumption of the supplements and higher levels were detected in individuals consuming 10 g day^{-1} of FOS, therefore suggesting the effect is dose dependent. Flatulence also increased at the higher dose. SCFA in feces could not be detected, which is not surprising as it is more probable they were absorbed by the colonic mucosa [39]. Bouhnik et al. [40] investigated the effect of short FOS (SC-FOS: 44% GF_2, 46% GF_3, and 10% DF_4) in healthy individuals. The suggested dose for FOS was identified as 10 g day^{-1} due to the mild side effects of excess flatulence and bloating. Levels of bifidobacteria increased as the concentration of FOS in the diet increased. Bifidobacteria express high levels of β-fructosidase which hydrolyze terminal, non-reducing β-D-fructose residues in fructans. Traditional microbiological tools were utilized to ascertain the prebiotic effect. Kruse et al. [41] investigated the effect of inulin in healthy individuals. A dose of 22–34 g day^{-1} of inulin was administered. Fluorescent in situ hybridization (FISH) was used to enumerate changes in the bacterial population and bifidobacteria numbers significantly increased. There was a moderate increase in flatulence, bloating, and lipids in blood and levels of SCFA remained unchanged. Until now the studies have used inulin or FOS as an additive to diets. Tuohy et al. [42] performed a trial with biscuits, containing partially hydrolyzed guar gum and FOS. Thirty-one volunteers were recruited and changes in bacterial populations of feces were determined by FISH. Although the overall results from the study suggest a bifidogenic effect compared to the placebo and control, no differences in bifidobacteria levels were identified in those individuals who had high levels of bifidobacteria at the beginning of the study. Thus, the health benefits of prebiotics may be more applicable to those suffering from IBS, elderly patients who are in hospital and at risk of nosocomial infections and antibiotic acquired diarrhea. Infants are a segment of the population who could also benefit from prebiotics at an early age. It is well established that babies who are breast fed have higher levels of bifidobacteria compared to those on a formula diet. This implies that breast fed babies may be less susceptible to enteric infections compared to their counterparts on infant formula. Thus, the supplementation of formula with a prebiotic is an attractive approach to

overcome these problems. Moro et al. [43] fed infants a FOS-GOS formula containing either 0.4 g day^{-1} or 0.8 g day^{-1} FOS. A significant increase in bifidobacteria was evident at the end of the study and was dose related. Lactobacillus also increased, pH of feces decreased and stools were softer as the dose of FOS-GOS increased. Guesry et al. [44] studied FOS as the only supplement in a formula for term infants. Dose was 3 g day^{-1}, almost ten times higher than that administered by Moro et al. [43]. No bifidogenic effect was observed and no side effects were recorded. The gold standard for a clinical trial is a double blind placebo controlled randomized study. The trials discussed above did not always follow this standard. Volunteers for studies are often healthy and consuming a Western diet. It is apparent that the parameters assessed at the beginning, middle or end of a trial do include (1) changes in bacterial populations using either traditional or molecular methods, (2) pH of feces and SCFA composition, (3) stool characteristics e. g. weight and frequency, (4) side effects e. g. bloating, flatulence, excessive breath hydrogen. However, the methods used to assess these parameters are not always consistent and it is particularly important when enumerating changes in the bacterial population. Molecular methods such as FISH, DGGE, and qRT-PCR are superior to traditional microbiological methods. Additional functionalities of fructan-type oligosaccharides are reported [45].

3 Galacto-Oligosaccharides

Lactose (4-O-β-D-galactopyranosyl-D-glucopyranose) is a simple sugar naturally found in milk and also in whey. Disposal of whey, a by-product of cheese manufacturing, used to be an environmental problem due to its high biological oxygen demand. However, whey is now used as a valuable source of lactose. A variety of products can be derived from lactose [46]. Hydrolysis yields the monosaccharides D-glucose and D-galactose which are sweeter and more soluble than lactose. Additionally, they are digested and absorbed in the small intestine, a desirable attribute, as 70% of the world's population are reported to be lactose intolerant, i. e., deficient in the enzyme β-galactosidase. Chemical treatment of lactose produces lactulose, lactitol, or lactobionic acid formed by isomerization, reduction, or oxidation reactions, respectively [47]. Although these products are reported to have beneficial effects on the host [48], it is the synthesis of galacto-oligosaccharides (GOS) from lactose which is of particular interest to this chapter as they are purported to be prebiotic. GOS are produced by galactosyl transfer catalyzed by the transgalactosylation activity of β-galactosidases. These enzymes (EC 3.2.1.23 β-D galactoside galactohydrolase) are isolated and purified from various organisms including *Aspergillus oryzae* [49], *A. niger* [50], *Bacillus circulans* [51], *Kluyveromyces lactis* [52], *K. fragilis* [53], *Streptococcus thermophilus* [54], *Escherichia coli* [55], *Lactobacillus* spp. [56], and *Bifidobacteria* spp. [57].The source of the enzyme will influence its optimal pH and temperature. Fungal β-galactosidases have an optimal pH between 2.5 and 4.5, whereas the optima for yeast and bacterial β-galactosidases are 6–7 and 6.5–7.5, respectively. Factors influencing the production and yield of GOS include pH, temperature, enzyme concentration, and processing conditions. For efficient transgalactosylation activity the initial concentration of lactose is the most significant factor [58]. The higher the concentration the higher the yield of GOS as the amount of available water is low. In reactions where low levels of lactose are used (e. g. 5% w v^{-1}), hydrolysis occurs due to the large amounts of water present as it acts

as an acceptor. GOS are found naturally in human milk and to a smaller extent in bovine milk [59]. These compounds mainly consist of galactosyl galactose and galactosyl glucose and are classified as prebiotic as they are not digested by the β-galactosidase from the human small intestine, and they are reported to selectively stimulate the beneficial bacteria of the colon.

Structures of GOS products isolated from the transgalactosylation reaction mixture have been elucidated. Gel permeation chromatography and charcoal chromatography are tools used to separate the different oligomers, whereas methylation analysis, FAB-MS and NMR are used to confirm the structure. Yanahira et al. [60] confirmed that the predominant linkage of GOS disaccharide products produced using the β-galactosidase from *B. circulans* was β-(1→6), however Usui et al. [61] reported the formation of β-(1→4) linked disaccharides. β-Galactosidases extracted from various bifidobacteria species predominantly produced β-(1→6) oligomers [57] whereas those from *Lactobacillus reuteri* produce both β-(1→6) and β-(1→3) linked oligomers [56]. These structures confirm that the enzyme source influences the structure of the oligosaccharides (*Table 5*).

Table 5
Oligosaccharides formed by transgalactosylation activity of β-galactosidase

The prebiotic effect of GOS may be more pronounced if GOS is synthesized using β-galactosidases from probiotic bacteria. Rabiu et al. [57] used bifidobacterial β-galactosidases to produce GOS and subsequently investigated the effect of these products on the growth rate of the corresponding bifidobacteria strain. As expected the growth rate was highest when the corresponding oligosaccharides were used. This approach could be investigated in further in vitro studies as well as in vivo. To confirm the selectivity of GOS for certain probiotic strains, species specific primers or probes would be required. Commercial GOS currently available include Oligomate 55® and Vivinal produced by Yakult (Japan) and Borculodomo Ingredients (The Netherlands), respectively. The prebiotic efficacy of these products has been investigated in in vitro, animal, infant, and human studies [62]. Of particular interest to those purchasing GOS for incorporation into foods are the data from clinical trials, but unfortunately the results from these investigations are mixed. Early studies [63] indicated an increase in bifidobacteria at the end of the feeding period (43 mg kg^{-1} day^{-1}). This effect was further confirmed in two studies by Ito et al., who administered GOS at 15 g day^{-1} [64] and 2.5 g day^{-1} [65]. In the latter study the initial levels of bifidobacteria in the volunteers were low and significantly increased during the consumption of GOS, but numbers returned to starting levels after discontinuing the treatment. A longer feeding study was carried out by Bouhnik et al. [66]. Volunteers received 10 g GOS day^{-1} for 21 days and again, a significant increase in bifidobacteria levels was observed. Conversely, Teuri et al. [67] did not detect a change in bifidobacteria levels when individuals consumed yogurt containing 15 g GOS on a daily basis. The methods used to enumerate the changes in the bacterial population were traditional microbiology techniques and these do have their limitations, whereas the introduction of molecular tools is advantageous (68). Human studies which suggest GOS did not have a prebiotic effect were performed by Alles et al. [69], Alander et al. [70], and Satokari et al. [71] even though the dosage of GOS was comparable to the earlier in vivo studies. These results indicate the necessity for further clinical trials, possibly introducing a more standardized approach as well as stringent analytical conditions, thus enabling a direct comparison between studies. Additionally, the current data is generated from healthy individuals and not those who would be more likely to benefit from such treatment, such as the elderly or those suffering from acute or chronic gastrointestinal disorders.

4 Isomalto-Oligosaccharides

Starch, cellulose, and murein are three of the most abundant organic compounds found on earth. Starch is of particular interest as it is the starting material for production of IMO. Starch exists as a mixture of amylose and amylopectin. Amylose, is a linear polysaccharide comprised of D-glucose units linked α-(1→4) to each other and amylopectin is a branched polysaccharide composed of D-glucose units linked α-(1→4), with 5% of linkages α-(1→6) [72]. The starch component of many plants is a mixture of amylose and amylopectin, although the starches from waxy varieties of maize, rice, sorghum, and barley are completely composed of amylopectin.

In the manufacture of IMO the starch is initially hydrolyzed by α-amylase (EC 3.2.1.1) to malto-oligosaccharides followed by treatment with pullulanase (EC 3.2.1.41) and β-amylase (EC 3.2.1.2) and finally α-glucosidase is added. The α-glucosidase (EC 3.2.1.20) catalyzes

a transglucosylation reaction whereby the α-(1→4) malto-oligosaccharides are converted into α-(1→6) IMO [73]. Isomalt 900, a commercial IMO product, has been produced this way and the mixture consists of isomaltose (α-D-Glc*p*-(1→6)-D-Glc), isomaltotriose (α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→6)-D-Glc) and panose (α-D-Glc*p*-(1→6)-α-D-Glc*p*-(1→4)-D-Glc). By definition, IMO are "glycosyl saccharides containing one or more α-1,6 glucosidic linkages with or without α-1,4 glucosidic linkages" [74]. Non-commercial IMO are also produced, the starting material is dextran rather than starch [2,75]. These typically contain a much higher percentage of α-(1→6) linkages, often to the exclusion of other types.

α-Amylases for use in IMO production have been isolated and purified from *Bacillus subtilis* [76] and *B. stearothermophilus* [77]. α-D-Glucosidases possessing hydrolytic and transglucosylation activity are mainly isolated from Aspergillus species including *A. niger* [78] and *A. carbonarious* [79,80]. *Aureobasidium pullulans* also produces an α-glucosidase [81]. As in the manufacture of many oligosaccharides, the source of enzyme, substrate concentration and processing conditions influence the yield of product. A product of high purity demands a higher price. Pan and Lee [74] have used yeast cells to ferment residual glucose from an IMO mix.

The prebiotic properties of IMO have been reported. Kohmoto et al. [73] used pure cultures of bifidobacteria species. The growth rate increased for all except *Bifidobacterium bifidum*. Additionally this strain did not ferment the individual substrates; panose, isomaltose, and isomaltotriose. Olano-Martin et al. [82] used a non-commercial IMO mix (oligodextrans) in a three-stage continuous system to monitor the in vitro effect in the proximal (vessel 1), transverse (vessel 2), and distal (vessel 3) regions of the colon. Bifidobacteria and lactobacilli were stimulated, with highest levels detected in vessel 1. However, bacteroides species predominated the bacterial populations in all three vessels. High concentrations of the SCFA butyric acid were produced. This acid is an end fermentation product of eubacteria and clostridia and its production is favored due to its effects on colonocytes [39]. Clinical trials substantiated the prebiotic claim associated with IMO's. Irrespective of dose (6–20 g day^{-1}) of the commercial IMO product, Isomalt 900, an increase in bifidobacteria was observed; however, increases were only significant when the dose was ≥15 g day^{-1} [73,83,84]. Although a prebiotic effect was observed it is unlikely that the disaccharide (isomaltose) contributes to this effect as it was probably digested in the small intestine.

IMO's occur naturally in some fermented Japanese foods, e. g. soybean sauce and sake. Levels in these products may be considerably lower than those used in the human studies, thus consumption of Isomalt 900 would contribute to a healthier microflora and thus enhance host well being.

5 Pectic Oligosaccharides

Pectin, a waste product of the fruit juice industry, has many applications in the food ingredients sector. It forms gels in the presence of Ca^{2+} ions and its solubility is determined by its molecular weight and degree of esterification as well as solution pH and temperature. Pectin can be incorporated into jams, jellies, low calorie foods as a fat or sugar replacer, and frozen foods [85]. Found in the cell wall of all plants, concentrations are higher in the fruits rather than the rest of the plant. Some fruits contain higher amounts of pectin than others; for

instance apple pulp contains 10–15% w w^{-1} pectin whereas orange and lemon peel contain 20–30% w w^{-1} [72]. The reader is referred to Chap. 6.4 for a discussion of pectin structure. The American Association of Cereal Chemists define dietary fiber as "the edible parts of plants or analogous carbohydrates that are resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine" [86]. Pectins are classified as dietary fiber. The enzymes associated with degradation of pectin into its corresponding oligosaccharides are mainly endo-type pectate lyases (EC 4.2.2.10) as well as pectate hydrolases (EC 3.2.1.15). Studies have identified this enzyme from bacteria indigenous to the gastrointestinal tract and thus they exhibit the ability to degrade pectin [87,88,89]. Intestinal bacteria include *Bacteroides thetaiotaomicron* which produce pectate lyase and pectate hydrolase and the *Clostridium butyricum–Clostridium beijerinckii* group produces endo-type pectate lyase [90]. Endo type pectate lyases are found in human feces. These bacteria digest pectin to 4–5 unsaturated digalacturonic acid, which is subsequently fermented to short chain fatty acids, namely acetic. Such acids are absorbed across the intestinal wall and used as an energy source. *C. butyricum* has been safely used as a probiotic for many years in Eastern Asia [91] and are reported to produce high levels of SCFAs in the gut lumen and in vitro [92]. Pectin is desirable as a food ingredient—it has excellent gelling properties and is degraded by certain indigenous bacteria. However, the by-products from the preparation of pectin could also be incorporated into the diet. Manufacture of pectic oligosaccharides from citrus or apple pectins by enzymatic hydrolysis (1) or steam injection [93] are desirable and inexpensive approaches to producing a food ingredient with added functionality.

Pectic oligosaccharides are good candidates to be considered for prebiotic testing as they are derived from pectin which arrives at the colon intact. This attribute could also be considered for pectin hydrolysis products, but no results are available yet to confirm this. There are few studies which have investigated the prebiotic potential of POS, and although they are in vitro, results are promising. Olano-Martin et al. [94] were the first to compare the effect of pectin and POS on the growth of pure cultures of various species indigenous to the gastrointestinal tract. Selection criteria for potential prebiotics include "selective stimulation of the beneficial bacteria" and pure culture studies would demonstrate this well. The pectin used was high methyl (60–66%) citrus pectin (HMP) and low methyl (8%) apple pectin (LMP). Their corresponding oligosaccharides were produced in a membrane reactor by controlled enzymatic hydrolysis of pectin using an endo-polygalacturonase [1]. All bacteria (bifidobacteria sp., lactobacillus sp., bacteroides sp., clostridium sp., and *E. coli* sp.) tested grew well on the LMP and the oligosaccharides derived from LMP. A follow-up study was performed using pH-controlled fecal batch cultures [94]. A bifidogenic effect was observed for pectins and their products, as bifidobacteria numbers significantly increased as the fermentation progressed until 24 hours, after which numbers started to decline. It is interesting to note that bacteroides numbers remained constant when POS was used as the carbon source but increased when LMP was used, suggesting the degree of esterification influences the fermentation by gut bacteria. As bacteroides did not change in the presence of POS it strengthens the prebiotic claim—failure to sustain the growth of potentially detrimental bacteria while promoting the growth of beneficial bacteria. Manderson et al. [95] determined the prebiotic properties of POS derived from orange albedo using in vitro batch cultures. HPAEC-PAD analysis confirmed that the degree of polymerization was probably greater than the POS used by Olano-Martin et al. [94]. However, an increase in bifidobacteria numbers was also observed, thus supporting observations of previous studies.

Additionally, *Eubacterium rectale* levels increased with a concomitant increase in butyric acid. Presence of this SCFA is desirable due to its health promoting properties in the gastrointestinal region [39]. POS produced by enzymatic treatment of bergamot peel were evaluated for prebiotic properties in fecal batch cultures [96]. The degree of polymerization was between 3 and 7 and the carbohydrate composition was markedly different from the POS derived from orange albedo. Although differences in composition and structure compared to other POS, the POS from bergamot peel increased the numbers of bifidobacteria and lactobacilli, whereas levels of clostridia decreased, thus corroborating with results from previous studies. A beneficial effect from in vitro studies was observed.

However, to further substantiate the claim of the prebiotic efficacy of POS, more rigorous in vitro investigations are required and ultimately in vivo studies will validate the claim. The disadvantages of in vitro methods are the absence of synergistic, antagonistic, and/or competitive effects as well as the absence of an immune system. Pectic oligosaccharides are an exciting new development in prebiotics as they can be cheaply manufactured from agricultural waste materials. As well as the reported prebiotic effect, POS have additional functionalities including repression of liver lipid accumulation in rats [97], action as anti-fungal phytoalexin-elicitors in plants [98], activity as anti-bacterial agents [99], protection of colonocytes against *E. coli* verocytotoxins [100] and stimulation of apoptosis in human colonic adenocarcinoma cells [101].

6 Novel Prebiotics

Despite the range of prebiotic oligosaccharides on the market (described above), there is much interest in developing novel forms of oligosaccharides as prebiotics. In most cases, these novel forms have only been evaluated using in vitro systems and are awaiting human data to confirm their efficacy.

6.1 Gentio-Oligosaccharides

Gentio-oligosaccharides (GeOS) are a commercial product manufactured by Nippon Shokuhin Kako in Japan. They contain mainly β-(1→6)-linked D-glucose units. They are claimed to be prebiotic but there is very little information available. One study has shown that they have prebiotic potential in vitro [102]. In 24 hour fecal batch culture [103], GeOS were compared to fructo-oligosaccharides (FOS) and the GeOS resulted in the largest increases in bifidobacteria, lactobacilli, and total bacteria. FOS, however, were more selective as they did not stimulate the growth of non-probiotic bacterial groups. GeOS also produced the highest levels of SCFA and the lowest gas production.

6.2 Gluco-Oligosaccharides

Gluco-oligosaccharides (GlcOS) can be made by the action of an enzyme, dextran dextrinase produced by *Gluconobacter oxydans* on maltodextrins. They have been made in whole-cell bioreactors [104] and evaluated in fecal batch cultures [105] and in three-stage gut models [106]. Mountzouris et al. [104] used methylation analysis to determine the linkages of

the GlcOS as being a mixture of 1→6 and 1→4 linked with some 1→4→6 branching. GlcOS increased numbers of bifidobacteria and lactobacilli within 24 hour in batch culture. Bacteroides, clostridial and eubacterial populations were slightly decreased by 48 hour. The same materials have also been studied in a three-stage continuous model of the human colon. GlcOS resulted in increases in numbers of bifidobacteria and lactobacilli in all three vessels, representing the proximal, transverse, and distal colonic areas. The prebiotic indices of the glucooligosaccharides were 2.29, 4.23, and 2.74 in V1, V2, and V3, respectively. Palframan et al. [107] established the quantitative index based on the in vitro fermentation of carbohydrates by key bacterial groups. Furthermore, the PI is a relationship between changes in the "beneficial" and "undesirable" elements within the microflora, all of them related to their starting levels.

6.3 Alternan Oligosaccharides

The bacterium *Leuconostoc mesenteroides* produces a range of enzymes which produce dextran-type polysaccharides from sucrose [108]. *L. mesenteroides* NRRL B-21297 produces an alternansucrase enzyme which can transfer glucose from sucrose onto acceptor oligosaccharides such as maltose. In this way a series of α-(1→6) and α-(1→3)-linked oligosaccharides can be produced. After size fractionation, oligosaccharide fractions with average DP values of 3, 4, 5, 5.7, 6.7, and 7.4 were obtained and tested using pure cultures or a fecal batch culture system. In pure culture, most of the bacteria tested failed to grow well on DP6.7 and DP7.4 fractions and grew best on DP3 [109]. In mixed fecal culture, DP3 resulted in the highest prebiotic effect, followed by DP4 and DP6.7. DP7.4 was not selectively fermented [110].

6.4 Functionally Enhanced Prebiotics

As we study the fermentation properties of an increasing range of oligosaccharides we are starting to unravel the structure-function relationships in these molecules [111]. This, coupled with advances in carbohydrate bioengineering, will allow the knowledge-based design of prebiotics with specific functional enhancements.

7 Oligosaccharides in Animal Feed

Extensive data are available on the prebiotic efficacy of oligosaccharides from in vitro models representing the human colon and from human clinical trials. Whether results from these studies can be extended to animals needs to be determined. The physiology and microflora of the gastrointestinal tract will vary from animal to animal and in most cases there may be limited or no knowledge of the microecology.

As antibiotics at subtherapeutic levels are banned in many countries, the addition of prebiotics to animal feed is becomes increasingly attractive. This is more to improve the well being of the animal nutritionally rather than improve or sustain a healthy microflora. Withdrawal of antibiotics from feed may leave livestock more susceptible to enteric infections. Pigs, calves, poultry, and rabbits often suffer from Clostridia-associated infections, whereas broilers are prone to Campylobacter and Salmonella infections, pigs are also at risk from pathogenic

E. coli infections. If a prebiotic can be added to the daily feed and it subsequently stimulates the beneficial bacteria in the colon at the expense of pathogens, it is most probable that these bacteria, namely bifidobacteria and lactobacilli, adhere to sites on epithelial cells and ultimately prevent the binding of pathogenic bacteria [112]. In diets containing reasonable quantities of carbohydrates saccharolytic fermentation will prevail, thus the pH of the GIT will remain stable and subsequently reduce the onset of Clostridia infections, as a more alkaline pH is required by species of this genus. Inulin added to rabbit feed was fermented in the cecum, produced SCFA, and reduced the risk of clostridiosis [113].

Literature on the effect of prebiotics in livestock animals is currently not widely available, although this may change with time as the necessity for addition of prebiotics to feed is increasing. Tzortzis et al. [114] investigated the efficacy of a novel GOS mixture in a parallel continuous randomized pig trial. Pigs were fed one of the following diets; (1) a commercial diet, (2) a diet supplemented with 1.6% w w^{-1} GOS, (3) a diet supplemented with 4% w w^{-1} GOS or (4) a diet supplemented with 1.6% w w^{-1} inulin. The feeding period lasted 34 days after which samples were collected for enumeration of bacteria, SCFA, and pH. A bifidogenic effect was found in those pigs consuming a diet supplemented with 4% w w^{-1} GOS, and an increase in acetate and a decrease in pH was observed. These findings are similar to those reported by Smiricky-Tjardes et al. [115]. However, in vitro studies suggest the microflora of swine feces produce lower levels of acetate when GOS is added to the fermentation, whereas higher levels of acetate were produced when raffinose, stachyose, or xylo-oligosaccharides were used as the carbon source [116].

Lactulose (β-D-Gal*p*-(1→4)-D-Fru) is also considered to be prebiotic in humans at sublaxative doses [48]. Decreased levels of *Clostridium perfringens* were associated with the inclusion of lactulose into the diet of perioparturient sows [117]. Interestingly, counts remained low 10 days after the supplementation ended. Furthermore, high antibody levels of IgG to *C. perfringens* phospholipase C developed and these were passed to the piglets via the colostrum.

Enteric diseases in livestock (pigs, poultry sheep, calves, and others) are becoming a concern more so today than in previous years due to the increased resistance of certain pathogens to antibiotics [118] and also due to the banning of subtherapeutic antibiotic administration in Europe. This ban could eventually extend to the USA [119]. As previously mentioned prebiotics are an alternative and if these are combined with probiotics, thus resulting in a synbiotic preparation, a very desirable substitute will be available. However, extensive testing may be required in animal models other than rats due to the complex structure of the GIT and diverse microflora. Some animals may have shorter transit times compared to others, and the pH of the region may vary somewhat. Overcoming these hurdles and others will result in a healthier livestock for human consumption.

8 Physical Properties of Oligosaccharides and their Application in Foods

In addition to exerting a beneficial effect on host health, prebiotics can be incorporated into foods as they possess various physiochemical properties. Playne and Crittenden [48] identified desirable attributes for these oligosaccharides (*Table 6*). Currently the Japanese are the market leaders as regards prebiotic food stuffs, but America and Europe are slowly catching up.

Table 6
General properties of oligosaccharides

Reduced sweetness (typically 0.3–0.6 times that of sucrose)
Not digested by brush border enzymes of the small intestine, pancreatic juices and enzymes
Selectively stimulate the indigenous beneficial bacteria of the gastrointestinal tract
Modify the viscosity and freezing points of foods
Influence emulsification, gel formation, and gel binding
Exhibit bacteriostatic properties
Favorably alter the color of foods
Possess properties similar to dietary fiber
Low caloric value
Act as an anti-caries agent
Stable at high temperatures and at various pH values
Act as a humectant and control moisture

This realization of a gap in the market for such products has stemmed from the emphasis on health and longevity and all sections of the population can be targeted, from preterm infants to the elderly. The prebiotics dominating worldwide markets are inulin, FOS, and GOS. Suppliers of the fructan-type oligosaccharides include Orafti, Sensus, Cosucra, Beghin Meiji, and BioNeutra Inc. Yakult, Borculodomo Ingredients, Snow Brand Milk Products, and Nissin Sugar are suppliers of GOS. Foods in which these prebiotics can be added to are bakery products, breakfast cereals, table spreads, frozen desserts, and dairy products. The latter food group have seen the addition of inulin and FOS to yogurts and as well as exhibiting a prebiotic effect, the oligosaccharides can influence the mouthfeel and sweetness of the product. In bread, GOS is added to prevent starch retrogradation, additionally the GOS is not fermented by the yeast and therefore the bread has an acceptable taste and texture. GOS and FOS have also been incorporated into infant formula by Nutricia and Milupa who market Omneo and Conformil products, respectively. The physiochemical properties of inulin are well documented and are widely added to foods [120]. A white odorless product with a bland taste, inulin is often added to bread mixes and baked goods to retain moisture and replace sugar. Inulin has also been used as a fat replacer where high performance inulin shows better functionality than the standard chicory inulin [121].

To summarize, the established prebiotics have a dual functionality and it is likely this could also be extended to the less established and emerging prebiotics.

Abstract

This chapter will focus on recent achievements in the combinatorial approach to glycobiology. Significant advances in polymer-supported synthesis as well as chemoenzymic methods have led to the assembly of complex oligosaccharides in a combinatorial fashion even on desired positions of target peptides or proteins. The successful application of oligosaccharide libraries and carbohydrate mimetics to glycobiology such as elucidation of the immunobiological function of glycoconjugates or the discovery of carbohydrate/protein interactions on the basis of microarrays will also be discussed.

Troc	2,2,2-trichloroethoxycarbonyl
UDP	uridine diphosphate

1 Introduction

Combinatorial chemistry (CC) is acknowledged as a technology for synthesizing compound libraries and screening them for desirable properties. It has become established in drug discovery and various drug leads have been found and optimized by CC. In addition, many biological processes have been analyzed by using bioactive compounds found by CC. Carbohydrate-based and carbohydrate-related libraries are a growing trend in CC, because various oligosaccharides and glycoconjugates play important roles in cellular recognition, adhesion, cell differentiation/proliferation, tumor metastasis, inflammation, pathogen/host recognition, and so on. In recent years, both solution and solid phase strategies for oligosaccharide synthesis have been developed to prepare oligosaccharide libraries for biological investigation. The use of carbohydrates as scaffolds in the generation of combinatorial libraries has also been reported. In this chapter, we focus on the following two categories, (1) the oligosaccharide library including libraries of analogues and modified oligosaccharides and (2) the library of carbohydrate mimetics. Their use for glycobiology is also described.

2 The Oligosaccharide Library Including Libraries of Analogues and Modified Oligosaccharides

Usually, natural oligosaccharides and glycoconjugates exist in heterogeneous mixtures that are difficult to isolate in pure form. Even if the purification is possible, only small amounts are obtained in general. Not all aspects of glycobiology, now often termed glycomics, are well understood in comparison to genomics and proteomics. One of the reasons is that oligosaccharides and glycoconjugates are much more difficult to synthesize than nucleic acids, peptides, and proteins. The recent development of oligosaccharide and glycoconjugate synthesis, however, has enabled the preparation of complex natural oligosaccharides as well as chemically modified oligosaccharide structures. Synthetic oligosaccharides and glycoconjugates are now used to study their roles in biologically important processes such as inflammation, cell–cell recognition, immunological response, metastasis, and fertilization. In this section, preparation of oligosaccharide and glycoconjugate libraries and their use for glycobiology are described [1,2,3,4]. The combinatorial synthesis of oligosaccharides especially on the solid-phase, is also reviewed in Chap. 5.5, "Polymer-Supported and Tag-Assisted Methods in Oligosaccharide Synthesis."

2.1 Synthesis of Oligosaccharides Libraries

A one-pot solution synthesis of oligosaccharides, first realized by Wong and co-workers [5], greatly expanded the possibility of automation for library synthesis [6]. They have prepared more than 100 differently protected *p*-methylphenyl thioglycosides and their reactivity data for glycosylation, i. e., based on armed and disarmed concepts, were programmed on the computer with OptiMer. The program chooses the best reactants for the one-pot synthesis of the target oligosaccharide, namely, providing a glycosylation sequence to the target by reacting from the most to the least reactive thioglycosides. One-pot synthesis has been applied to a large number of oligosaccharides including Globo-H hexasaccharide, known as a cancer antigen [7]. Since protecting group manipulation is not necessary for the present one-pot synthesis, the method has opened up the path to automated library synthesis with a great diversity in structures.

Takahashi and co-workers have also been investigating solution-phase one-pot glycosylation, which led to both linear- and branched oligosaccharides, by using a combination of different leaving groups, e. g., bromide or phenylthio groups to be activated by AgOTf and NIS-TfOH, respectively. They have prepared a 72-trisaccharide library consisting of glucosides, galactosides, and mannosides with the Quest 210^{TM} manual synthesizer [8] as well as the library of H-type 1 and 2 trisaccharides [9] (*Scheme 1*). Their one-pot protocol has also been applied to the synthesis of the glycosyl amino acid derivatives **1–3** [10,11].

Hindsgaul and co-workers have reported the library synthesis of oligosaccharides based on the random glycosylation strategy [12,13,14]. In this method, the lactosyl or glucosamyl acceptors with all free hydroxyls were glycosylated "randomly" with the appropriate donors, such as fucosyl trichloroacetimide, to give glycoside isomers with all possible anomeric configurations and linkage positions. Kanie and co-workers have further improved this idea of orthogonal oligosaccharide synthesis, in preparing a library consisting of a complete set of Fuc-Gal-Glu isomers, the partial structures of blood type antigens, tumor antigens, or *H. Pylori* ligands (*Scheme 2*) [15,16,17]. For the first orthogonal glycosylation, they

used perbenzylated phenylthiofucopyranoside loaded on the polymer-support TentaGel as the donor, and tri-*O*-benzyl-galactopyranosyl fluorides bearing single hydroxyls either at the 2-, 3-, 4-, or 6-position as the acceptors. The glycosylation was performed by using SMTST (dimethyl(methylthio)sulfonium trifluoromethanesulfonate) as a selective activator of the phenylthio leaving group in the presence of fluoride. The fluoride leaving group at the reducing end of the resulting disaccharides was then activated by $Cp_2Hf(OTf)_2$ to effect the second orthogonal glycosylation with tri-*O*-benzylated phenylthioglucopyranoside. After *n*-octanol as a hydrophobic tag was introduced via glycosylation, the trisaccharides were released from the resin, and the global deprotection of the *O*-benzyl groups successfully provided a Fuc-Gal-Glu library with a complete set of regio- and stereoisomers. These isomers were separated by HPLC with a C18 column with the help of the hydrophobic octanol tag. During the present orthogonal synthesis, they also achieved a stationary solid-phase reaction, without the need for mixing or flowing of the reaction mixtures.

Solid- or soluble polymer-supported synthesis using more than one linker that is cleaved under different conditions has also been applied for library synthesis. Takahashi and co-workers developed a strategy for the combinatorial solid-phase synthesis of the tree-type carbohydrate clusters using three types of orthogonally cleavable linkers (Chap. 5.5, Fig. 1), namely, the photo-cleavable 2-nitrobenzyl-type linker (orthogonal cleavage site 1), base-cleavable ester linker (orthogonal cleavage site 2), and cobalt complexation/acid-cleavable alkyne linker (orthogonal cleavage site 3) [18]. The combined use of three types of spacers, two types of carbohydrates, and two types of orthogonally cleavable linkers provided 12 members of the carbohydrate cluster library (six dimers and six tetramers).

Boons and co-workers introduced the three galactosyl acceptors **4–6** with the free hydroxyls at different positions on soluble polymeric supports (amino-modified MPEG) via three different linkers (*Scheme 3*) [19]. After the reaction with thiogalactosyl donor **7** using NIS/TMSOTf in the mixed solvents of CH_2Cl_2-diethyl ether, the resulting mixtures of three disaccharides on the identical supports were released in turn, in response to the specific reaction conditions. Thus, the treatment of **8** firstly with H_2O_2 and Et_3N liberated **9** from the MPEG-bound oligosaccharides **10** and **11**, which were collected by the precipitation from diethyl ether. Subsequent treatment of the polymer-supports with NaOMe in MeOH gave **10** and polymer-bound **11**, which was finally released by the treatment with TFA in CH_2Cl_2.

2.2 Screening Method for Glycosylation

Ito and co-workers have developed a high-throughput screening method for glycosylation using Bn-d_7 as the protecting group of the hydroxyls (*Scheme 4*) [20]. Since the ^{1}H NMR signals of benzylic methylene protons overlap with those of anomeric protons at 4–5 ppm, the use of deuterated benzyl groups allows the anomeric selectivity to be determined easily by NMR. In addition, the incorporation of Bn-d_7, either on the acceptor or donor, increases the molecular weight by 7 as compared to the normal Bn group, and therefore, in the presence of the non-labeled donor or acceptor, the MS spectrum of the reaction mixture provides a quantitative estimate of the product yields and substrate recovery. They have screened over 240 conditions for α(1–3) linkage formation between the glucose residues **12** and **13**, and optimum conditions for **14** giving the quantitative yield and high selectivity were found.

2.3 Combinatorial Synthesis of Complex Oligosaccharides and Glycopeptides

A recent study has revealed the fundamental roles of the endoplasmic reticulum (ER) related high-mannose-type glycans in protein quality control, such as folding, transport, and degradation. Ito and co-workers have achieved the convergent and comprehensive synthesis of these *N*-linked high mannose-type glycans (*Scheme 5*) [21,22,23,24]. Their strategy is based on (i) synthesis of an invariant hexasaccharide fragment **15** via intramolecular aglycon delivery developed in this laboratory, (ii) synthesis of the oligomannose **16**, (iii) preparation of the oligoglucose fragments **17**, and (iv) systematic union of the fragments **15–17** to the desired high mannose-type glycans. During the synthesis of these complex oligosaccharides, they successfully used the pentafluoropropionyl or trifluoroacetyl groups as a temporary hydroxyl protection [25], while a new concept of glycosylation and deprotection of TBDPS under the frozen conditions has also been developed [26]. The synthesized oligosaccharides and their non-covalent conjugates with dihydrofolate reductase (DHFR) will be used to investigate the interaction with the lectins inside and on the ER membrane, e. g., $Man_8GlcNAc_2$ and α-$Glc_1Man_8GlcNAc_2$ for the interaction with MLP (mannosidase-like protein) during the protein degradation process, or $Glc_2Man_9GlcNAc_2$ and $Glc_3Man_8GlcNAc_2$, after the introduction of the dolichyl pyrophosphate moiety, for the interaction with OST (oligosaccharyltransferase) during the translocation process across the ER membrane. Actually, they have succeeded in observing the interaction of α-$Glc_1Man_9GlcNAc_2$ with CRT (calreticulin) by NMR [22], an ER-resident lectin-chaperon that specifically recognizes the monoglucosylated glycans as the initial checking point for proper folding of the proteins.

While the biological roles of high-mannose-type *N*-glycans have been gradually elucidated, partly due to the synthetic achievements such as Ito's work mentioned above, those of a variety of more complex *N*-glycans, such as complex-type *N*-glycans, still remained to be clarified. New methods on the solid-supports, together with the accumulation of the information on the acceptor/donor reactivity in the solution-phase, led to the synthesis of even more complex *N*-glycans on the solid-supports. Schmidt and co-workers have achieved solid phase synthesis

of a small library of *N*-glycans (described in detail in Chap. 5.5, Scheme 10) [27]. They used the hydroxymethylbenzyl benzoate linker attached to the Merrifield resin. Glycosylation on the resin was successfully performed using the monosaccharide units of the trichloroacetimidate, which allow chain extension, branching, and chain termination for the preparation of a variety of *N*-glycans, while the tedious β-mannosyl linkage was constructed in advance in solution. Their solid-phase synthesis involves (i) glycosylation under the TMSOTf catalyst, (ii) selective removal of the temporary protecting groups for the sugar extension on the solid-phase, namely, Fmoc by Et_3N and the phenoxyacetyl group by 0.5 equivalents of NaOMe in $MeOH/CH_2Cl_2$, and (iii) product cleavage from the resin by 4.0 equivalents of NaOMe in $MeOH/CH_2Cl_2$ and then *O*-acetylation for convenient product isolation. These precise designs of linker, protecting group manipulations, and stereoselective glycosylation on the resin enabled the successful preparation of a small library of 17 *N*-glycan structures (*Fig. 1*).

Seeberger and co-workers have also achieved a solution-phase synthesis of several linear and branched high-mannose oligosaccharides **18–23** in order to investigate the detailed interaction of the HIV viral surface envelope glycoprotein, gp120 with the anti-HIV protein, cyanovirin-*N* (*Fig. 2*) [28]. On the basis of the microarray analysis, these oligosaccharides were also found to show high specificity to the microvirin (MVN), which shares 33% identity with the cyanovirin-*N*; MVN might be involved in cell–cell recognition and cell–cell attachment of *Microcystis* [29]. The automated solid-phase synthesis of high-mannose oligosaccharides has also been realized by the same group, which is described in detail in Chap. 5.5.

The malaria parasite *Plasmodium falciparum* accounts for about 100 million clinical cases and the deaths of more than two million people annually due to inflammation caused by the malaria toxin. The inflammatory cascade of malaria is triggered by glycosylphosphatidylinositol (GPI) on the cell surface and the GPI is responsible for much of malaria's morbidity and mortality. Seeberger and co-workers have synthesized the malaria GPI glycan of the sequence NH_2–CH_2–CH_2–O–PO_3–(Manα1,2)6Manα(1,2)Manα(1,6)Manα1,4)Glc$NH_2$$\alpha$1,6)myo-inositol-1,2-cyclic-phosphate and its related structures (*Fig. 3*) [30,31]. They employed a flexible synthetic strategy that relies on a late-stage coupling between oligomannosides of various lengths and the pseudo-disaccharide glycosyl acceptor to readily access various malarial GPI structures. Mice that were treated with chemically synthesized GPI attached to the protein were substantially protected from death by malaria. Recipients were substantially protected against malarial acidosis, pulmonary edema, cerebral syndrome, and fatality. Anti-GPI antibodies neutralized proinflammatory activity by *P. falciparum* in vitro. These glycans are currently under development as anti-toxin malaria vaccines.

They succeeded in synthesizing these hexasaccharide glycans by using a combination of automated solid-phase methods and solution-phase fragment coupling in a matter of days, compared with several weeks for a comparable solution-phase synthesis [32]. They also synthesized fully lipidated GPI anchors of *P. falciparum* by employing a highly convergent strategy [33]. This strategy utilized three orthogonal protecting groups, which can be chemoselectively deprotected and functionalized in the late stage of the synthesis. The synthetic GPI is currently used as a molecular probe for the study of malarial pathogenesis and aspects of fundamental immunology.

Proteoglycans are major components of the extracellular matrix in animal cells. They are composed of core proteins and glycosaminoglycan polysaccharides. Heparin and heparan sulfate are the most complex glycosaminoglycans, a family of molecules that also includes chon-

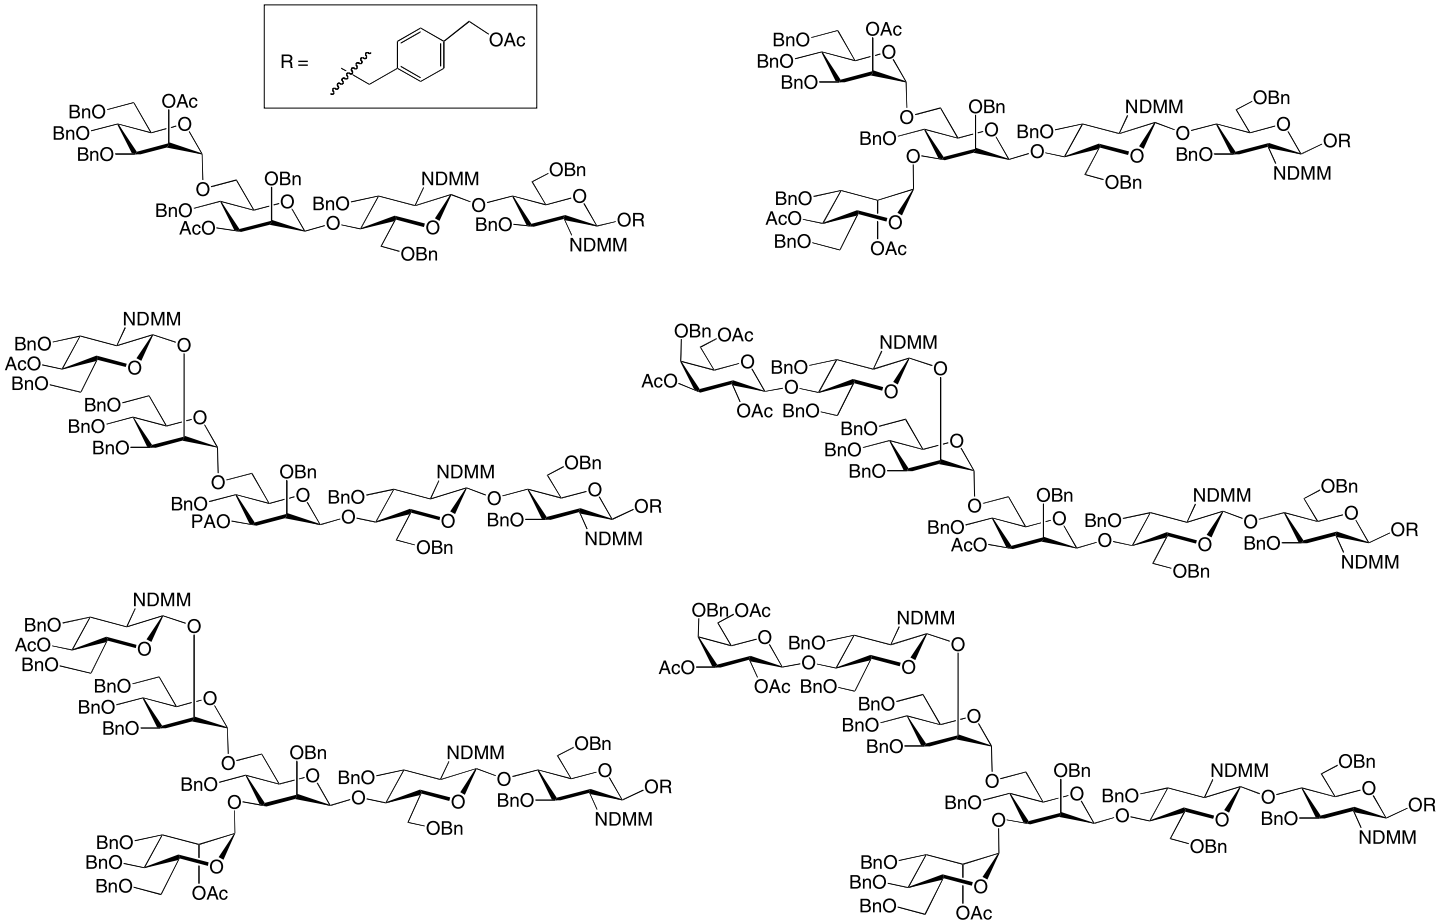

Figure 1
***N*-glycan library by Schmidt and co-workers**

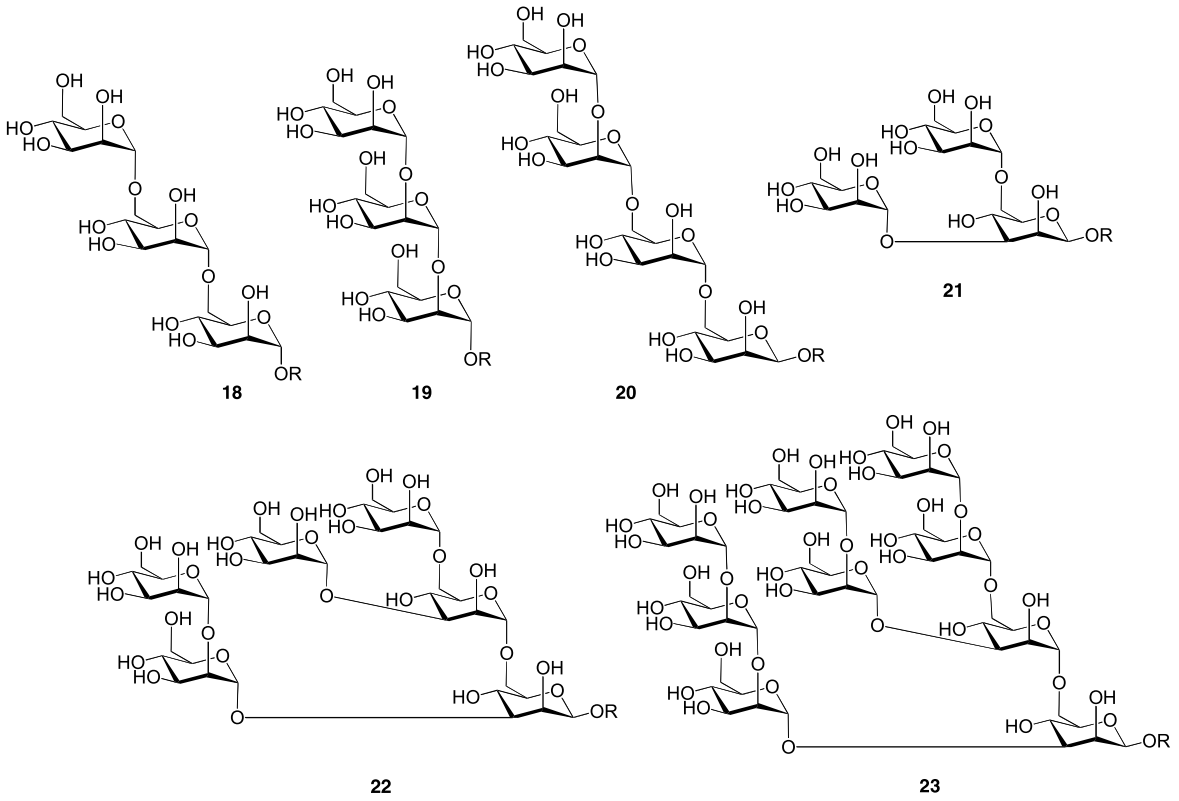

Figure 2
Linear and branched high-mannose oligosaccharides synthesized by Seeberger and co-workers

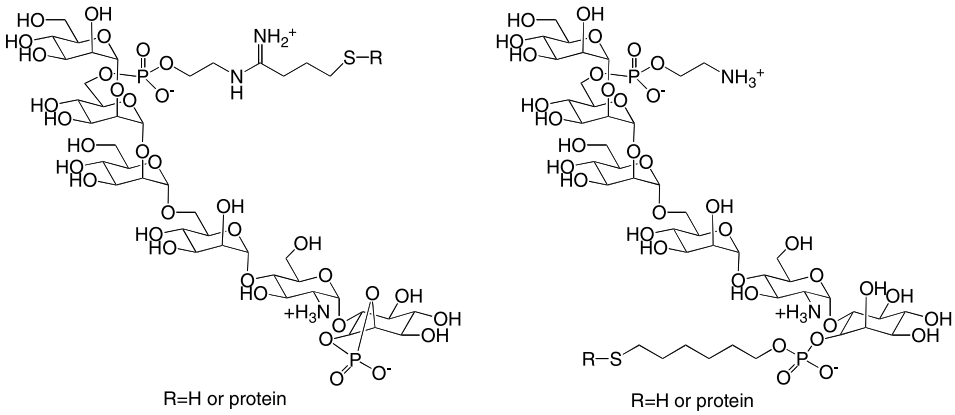

Figure 3
Structures of malaria vaccine candidates

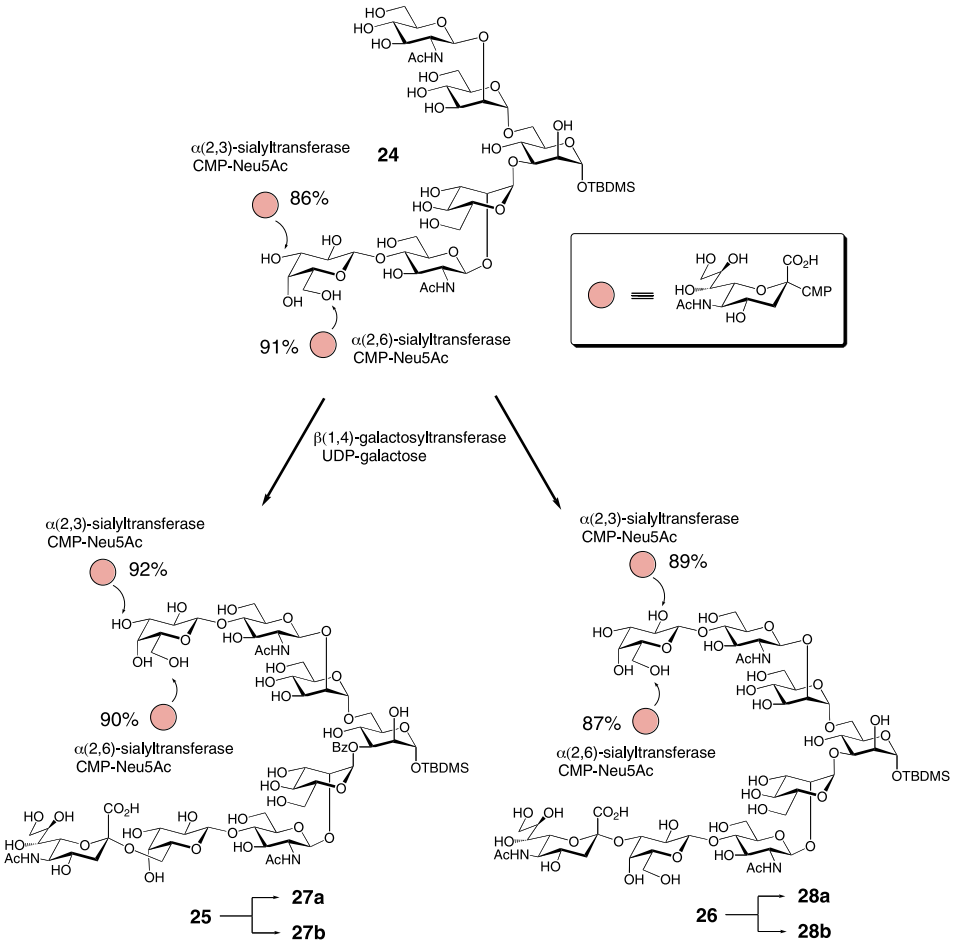
droitin sulfate, keratin sulfate, and dermatan sulfate. Glycosaminoglycan has important biological functions by binding to different growth factors, enzymes, morphogens, cell adhesion molecules, and cytokines. Heparin, a heterogeneous sulfated glycosaminoglycan found only in the mast cell, has been widely used as an injectable anticoagulant. Heparin consists of a repeating disaccharide unit composed of a uronic acid 1,4-linked to a D-glucosamine. Heparan sulfate is widely distributed in different cell types and tissues. Heparan sulfate contains less *O*-sulfates but is more heterogeneous than heparin. The major uronic acid in heparin is L-iduronic acid whereas that in heparan sulfate is the D-glucuronic acid unit. Since heparin and heparan sulfate are very heterogeneous molecules and have many biological functions that depend on specific sequences with particular modifications and sulfations, defined heparin and heparan oligosaccharides have been required to investigate their precise biological functions. The purification of oligosaccharides after enzymatic digestion or enzymatic reconstruction of glycosaminoglycan chains has provided libraries of oligomers that have been used for biological investigations [34,35,36,37,38,39,40,41,42,43,44,45].

Chemical synthesis of heparin fragments and analogues has been used for biological studies and to define structure-activity relationships [46]. For example, the heparin-antithrombin III interaction [47,48,49,50,51,52,53], which is responsible for the anticoagulant activity of heparin, has been studied in detail by using synthetic fragments. The interaction of heparin with FGF-1, FGF-2, platelets [54,55,56,57,58,59,60,61,62,63,64], and the Herpes Simplex virus, has also been studied by using synthetic specimens.

A modular assembly approach has been developed for the synthesis of a broad range of heparin/heparan sulfate oligosaccharide fragments [65,66]. Polymer-supported syntheses of heparin oligosaccharides have also been developed toward the preparation of libraries as described in Chap. 5.5 [67,68,69].

Since the chemical synthesis of oligosaccharides requires many synthetic steps including protection and deprotection procedures, the enzymatic approach has attracted much attention for the rapid synthesis of oligosaccharides. In addition, the perfect regio- and stereoselectivities of enzymatic methods with glycosyltransferases are quite attractive. Several trans-

ferases such as β(1,4)-galactosyltransferase, α(1,3)-fucosyltransferase, and α-sialyltransferase have been used for the enzymatic synthesis. Ito and co-workers have successfully synthesized α(2–3)- and α(2–6)-sialylated biantennary glycans **24–28**, the branched positions of typical complex-type *N*-glycans, based on the polymer-supported strategy and enzymic glycosylation (*Scheme 6*) [70]. The common hexasaccharide **24** was prepared by the combination of (i) MPEG (monomethyl polyethylene glycol; *M*w 750)-supported synthesis and (ii) capture-release protocol using the Boc-cystein loaded on Merrifield resin, developed in their laboratory (see Chap. 5.5, Scheme 13). Hexasaccharide **24** was diverged to monosialylated **25** and **26** and then to disialylated **27** and **28** by the enzymic glycosylation using the commercially available α(2,3)- or α(2,6)-sialyltransferase and β(1,4)-galactosyltransferase together with the appropriate sugar nucleotides.



Scheme 6

Nishimura and co-workers took good advantage of the combination of chemical and enzymatic synthesis, especially by using α(2,3)- or α(2,6)-sialyltransferases from porcine and rat livers, and a variety of the biologically relevant glycopeptides, glycosphingolipids, and glycomimetics has successfully been prepared [71,72]. Their library-directed synthesis based on this approach involves, e. g., (a) sialyl Lewis X-based glycoclusters on the β-cyclodextrin which strongly inhibit protein–carbohydrate interaction, such as that of E-selectin and SLeXn-BSA [73,74,75], (b) mucin-like glycoprotein mimics of the antifreeze proteins [76,77,78,79], (c) triantennary-type sialolacto- and sialolactosamine polymers which exhibit much higher anti-influenza virus activity than monovalent-type glycopolymers [80], (d) conical-type sialolacto-peptides as the inhibitors of influenza hemagglutinin [81], and (e) glycoconjugates of insulins with dendric sialolactosamines, which exhibit a prolonged glucose-lowering effect in hyperglycemic mice [82]. Recently, they developed the catch-and-release strategy between solid-phase and water-soluble polymer supports, the so-called "polymer blotting method", which allows for the rapid and efficient synthesis of glycopeptides [83,84]. The method involves (i) conventional solid-phase synthesis of glycopeptides that contain mono-, di-, and tri-saccharides on Thr or Ser residues and Blase (glutamic acid specific protease)-sensitive amino acid sequence, (ii) removal of the protecting groups and release from the resin, (iii) attachment of the released glycopeptides to the water-soluble polymers via an oxime anchor, (iv) sugar elongations using glycosyltransferases, and (v) cleavage of the desired glycopeptides from the soluble supports by Blase-mediated hydrolysis. They applied three glycosyltransferases, namely, β(1,4)-galactosyltransferase, α(2,3)-(*O*)-sialyltransferase, and α(2,3)-(*N*)-sialyltransferase, and successfully prepared six kinds of parallel and 36 kinds of combinatorial libraries of MUC1 mucin glycopeptides (*Fig. 4*) [83]. The chemoenzymatic synthesis of glycopeptides and proteins, such as HIV-1 V3 glycopeptides and CD52 glycoproteins, have also been reported by Wang and co-workers [85,86].

Kajihara and co-workers have reported the chemoenzymic library synthesis of *N*-linked glycans, by adapting the branch specific exo-glycosidases digestion of the monosialyloligosaccharides obtained from the biantennary complex-type sialylundecasaccharide **29** (from egg yolk) by acid hydrolysis of one molecule of Neu5Ac (*Fig. 5*) [87,88,89,90,91,92]. The isolation of two mono-Neu5Ac derivatives by ODS HPLC column was efficiently achieved by applying the Fmoc and benzyl protecting groups, and the resulting pure mono-Neu5Ac oligosaccharides were gradually disintegrated into 24 oligosaccharide derivatives by α-D-neuraminidase, β-D-galactosidase, *N*-acetyl-β-D-glucosaminidase, and α-D-mannosidase, respectively. Oligosaccharides thus obtained were successfully conjugated to the aspartic acid residue, and *N*-linked glycoproteins, having sialyl-undeca- and asialo-nonasaccharides, were synthesized on the solid-support, HMPA-PEGA resin [87].

A totally synthetic approach to glycopeptides as well as glycoproteins, on the basis of glycal-based oligosaccharide synthesis without the use of transferases, has been thoroughly investigated by Danishefsky and co-workers. Their recent successful works feature, e. g., (a) preparation of *N*-linked glycopeptides presenting the H-type 2 human blood group determinants [93,94], (b) synthesis of normal and transformed PSA (prostate specific antigen) glycopeptides in an attempt to produce the PSA antibody for cancer diagnosis purposes [95,96], (c) synthesis of high-mannose- and hybrid-type *N*-glycopeptides as well as their dimerized peptides of the envelope protein gp120 in pursuit of carbohydrate-based HIV vaccines [97,98,99], and (d) coupling of the glycopeptides toward total synthesis of the

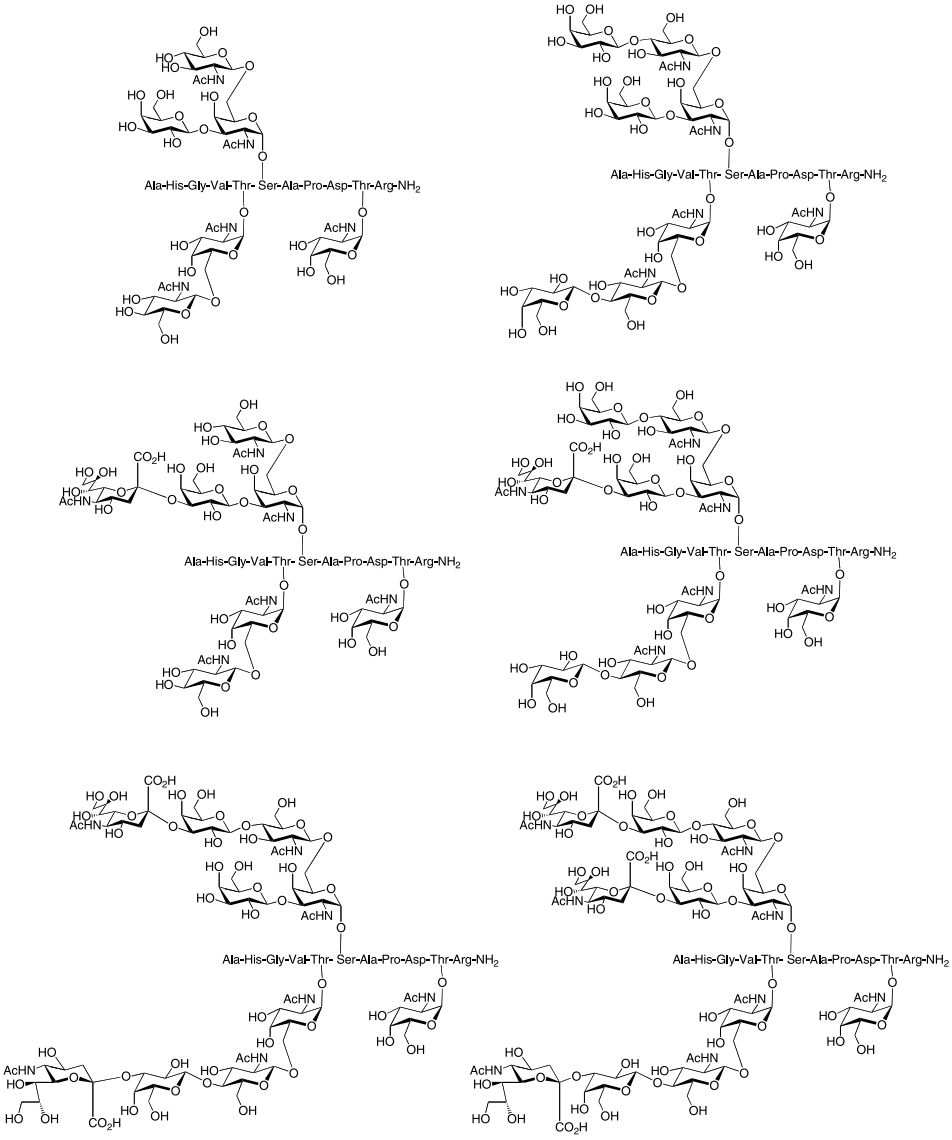


Figure 4
Chemoenzymic synthesis of glycopeptide library by Nishimura and co-workers

glycoproteins, such as EPO (erythropoietin), based on the new chemical ligation methods developed in the same laboratory [100,101,102,103]. Furthermore, on the preparation of glycopeptide-based cancer vaccines, they have displayed different cancer-related carbohydrate antigens on a single peptide backbone, and examined to induce immunological responses (*Fig. 6*) [104,105,106,107,108,109,110,111,112,113,114,115]. Among several vaccines

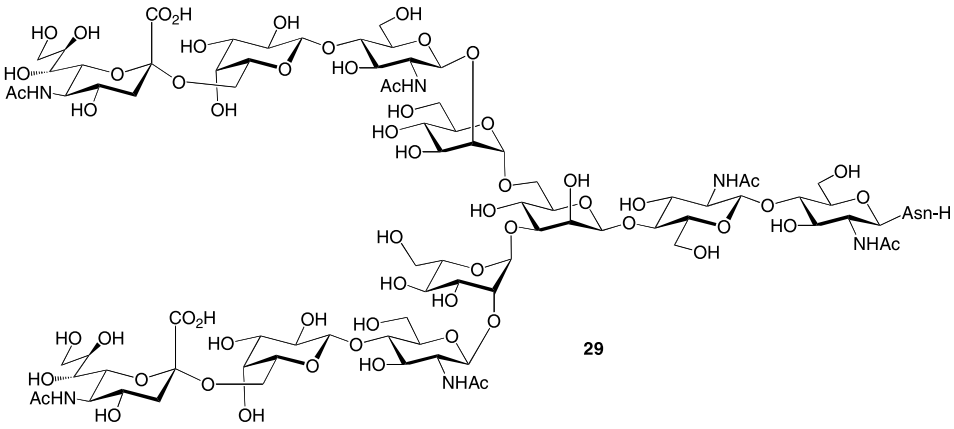

Figure 5
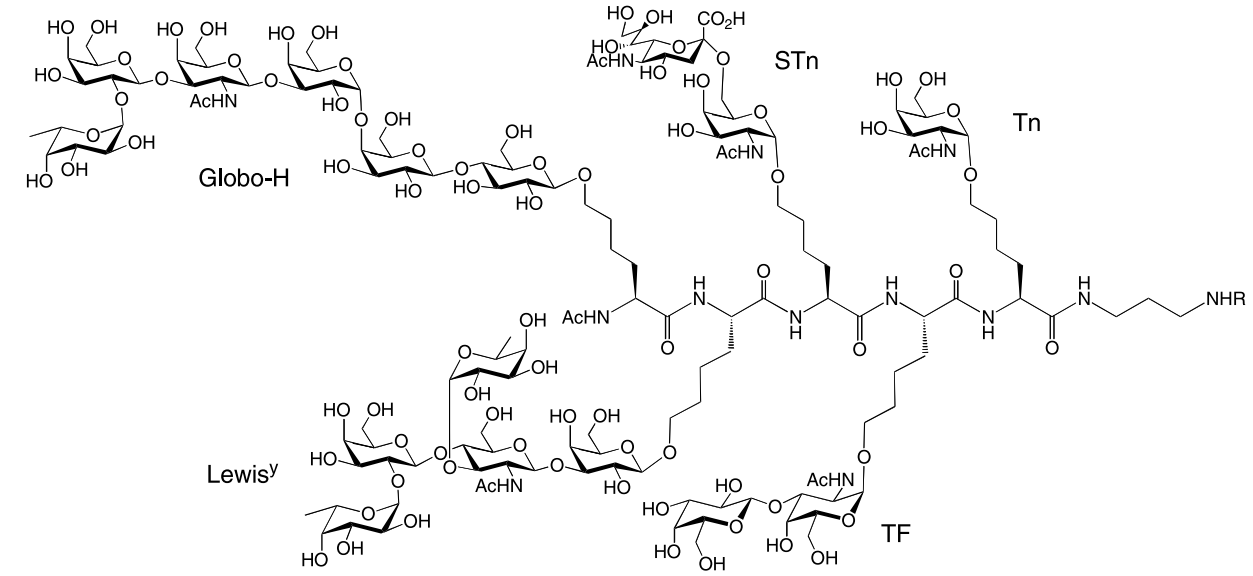
Biantennary complex-type sialylundecasaccharide from egg yolk

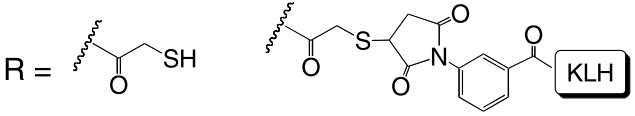
prepared, the glycopeptide **30** was conjugated to the carrier molecules, i. e., KLH (keyhole limpet hemocyanin) **31** and Pam_3Cys **32**. The cumulative data suggest that the immunological properties of the individual antigen in **30**, namely, Globo-H, Le^y, STn, TF, and Tn antigens, each of which is overexpressed on prostate and breast cancer cell surfaces, are preserved [104]. Thus, the highly elaborate vaccines constitute a promising category for clinical applications.

Nakahara and co-workers have investigated the solid-phase synthesis of the prototype glycopeptidyl fragments of serglycine, a proteoglycan with the repeating peptide sequence of L-seryl-L-glycine, by the condensation of the glycosyl amino acid unit on Sieber amide resin (*Scheme 7*) [116]. They have developed the allyl ester-type linker, which can be cleaved by a $Pd(PPh_3)_4$ catalyst, leading to the efficient preparation of various lengths of [*O*-(2,3,4-tri-*O*-acethyl-D-xylosyl)-L-seryl-L-glycine]$_n$ (n = 1–8). The same linker on the Sieber resin was also applied to the solid-phase synthesis of mucin-type glycopeptide [117] and human leukosialin segment [118]. The Ig domain of emmprin has also been synthesized by the same group, through the successful preparation of the thioester fragment with *N*-linked core pentasaccharide by a modified Fmoc solid-phase method [119].

Meldal and co-workers have investigated direct glycosylation of a variety of glycosyl trichloroacetimidates with the amino acid side chain of serine, threonine, and tyrosine in peptides on solid-supports, pursuing the efficient synthesis of a glycopeptide library (*Fig. 7*) [120]. The peptides were linked to either $POEPOP_{1500}$ (polyoxyethylene-polyoxypropylene) or $SPOCC_{1500}$ (super-permeable organic combinatorial chemistry) resins via a photolabile linker, which facilitates glycosylation analysis by both MALDI-TOF mass spectrometry and nanoprobe MAS (magnetic angle spinning) NMR spectroscopy. On the basis of these analytical systems, nearly quantitative yields were concluded for the reactions of acceptor peptides on the solid-phase with glucose, galactose, mannose, and fucose trichloroacetimidates **33–37**.

Schmidt and co-workers have investigated the synthesis of a series of *S*-linked glycopeptides, which are expected to be more stable to glycosidases than the naturally occurring *N*- and





30

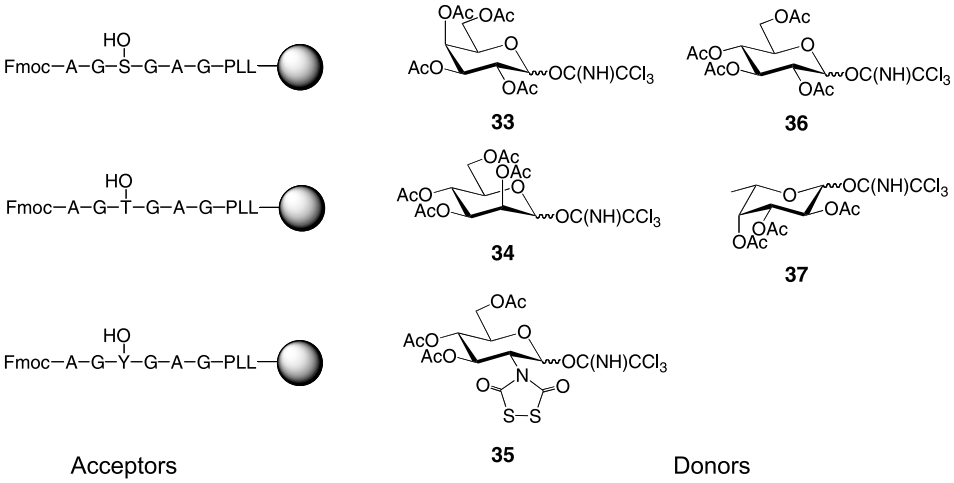

Figure 7
Direct glycosylation strategy for a glycopeptide library by Meldal and co-workers

O-linkages with the peptide backbone (◉ *Scheme 8*) [121,122,123,124]. They have developed three conjugation methods of sugar moieties to the peptides; (i) direct *S*-glycosylation of cystein or homocystein residues with glycosyl halides or glycosylthiomethyl bromides, (ii) *S*-alkylation of the 1-thiosugars with β-bromoalanine or γ-bromohomoalanine residues, and (iii) reaction of glycosylthiomethyl azides with asparatate or glutamate thio acids. These reactions can be performed in water and provide the *S*-linked glycopeptides in excellent yields. Bertozzi and co-workers prepared *N*-linked glycopeptide analogs that replace the glycosidic linkages extending from the core pentasaccharide with thiomethylamides, being amenable to rapid assembly of the complex-type *N*-linked glycopeptide mimetics (◉ *Fig. 8*) [125,126].

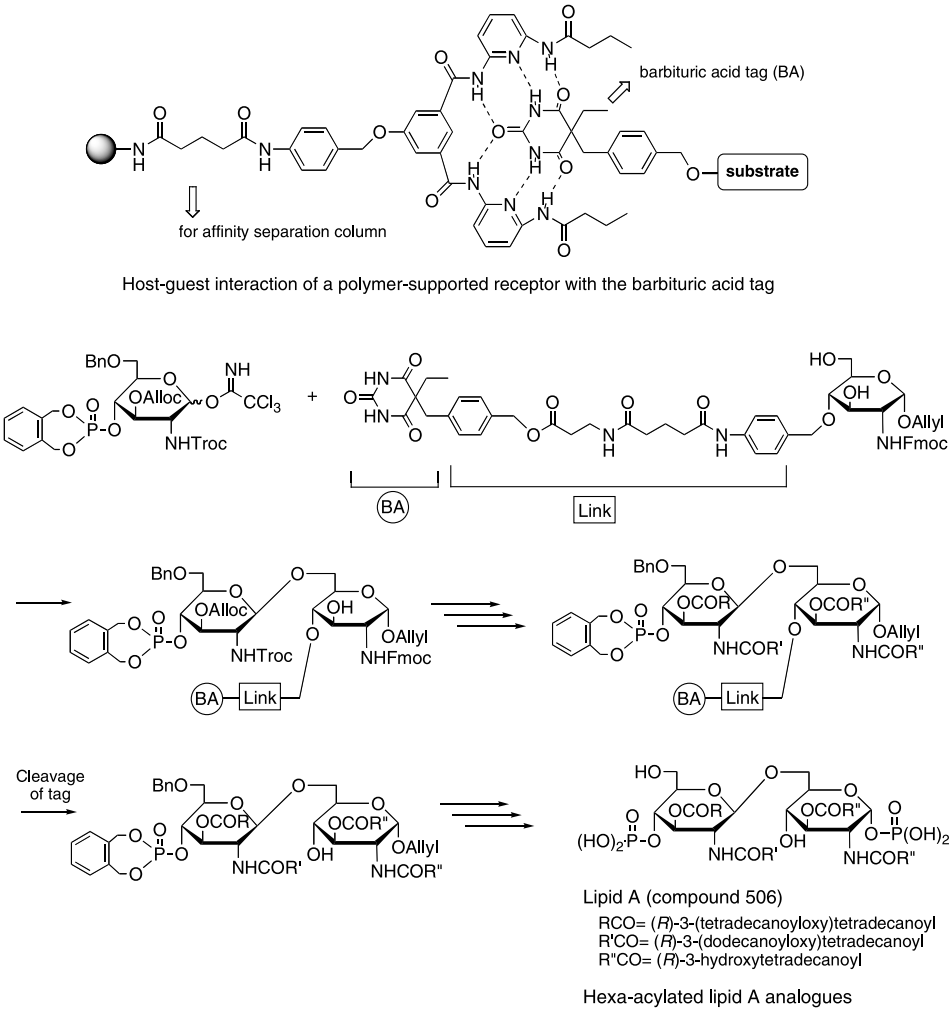
2.4 Combinatorial Synthesis of Glycoconjugates for Elucidation of Immunobiological Function

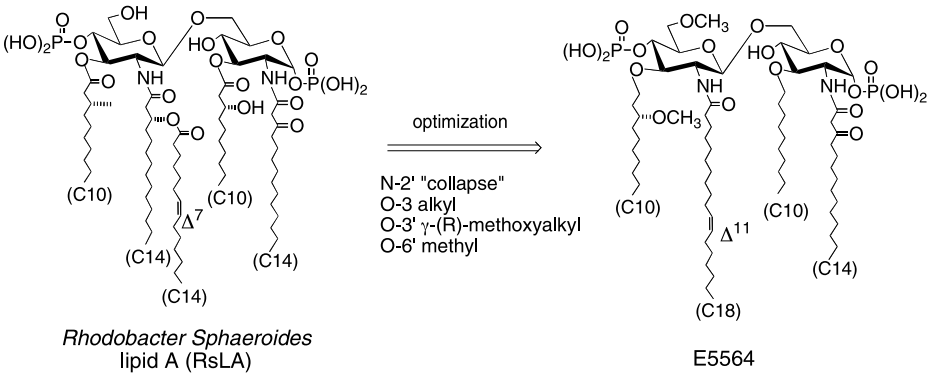
The concept of CC has also been applied to the investigation of the biological function of glycoconjugates including glycolipids and glycopeptides. An example is the synthesis of bacterial lipopolysaccharide (LPS) and its partial structures including terminal glycolipid moiety lipid A, which have potent immunostimulatory activity to stimulate the innate immune system. Fukase and Kusumoto prepared the library of lipid A analogues to elucidate the structural requirements for the immunostimulatory and antagonistic activity with the diversity on



Scheme 9

the fatty acids and the acidic groups of lipid A [127,128]. They prepared lipid A analogues which have hexaacyl groups with different acylating patterns, utilizing a barbituric acid tag for affinity separation, based on their "synthesis based on affinity separation (SAS)" method (*Scheme 9*) [129,130]. The principle of the SAS method and other applications using ether-type tags are explained in Chap. 5.5. With this method a focused library of lipid A analogues was efficiently obtained, which showed how structural differences at the acyl part of lipid A affect biological activity.

A library of acidic amino-acid-substituted monosaccharide lipid A analogues was also prepared for elucidation of the structural basis to biological function [131]. The library of lipid A analogues was also used for the crystallization of the coreceptor MD-2, which constitutes the receptor complex with Toll-like receptor 4 (TLR4). The antagonistic tetraacylated lipid A (the



Scheme 10

biological precursor lipid IVa, compound 406) is bound to MD-2 and effectively led the protein to be crystallized to observe the first crystal structure by X-ray analysis [132].

Since the potent immunostimulation of LPS often causes sepsis when an overwhelming infection is present, the antagonist of LPS is a candidate for a therapeutic agent; an effective drug has so far not been available. Eisai's group have developed E5531 [133] and E5564 from a library of a series of antagonists based on natural antagonistic lipid As from *Rhodobacter capsulatus* (RcLA) and *Rhodobacter sphaeroides* (RsLA), to improve the potency of the biological activity and the stability of the compounds [134]. As for E5564, the structural modification from the ester to ether linkage at the 3- and 3'-positions, methylation at the 6-position and also "collapsing" the unsaturated acyloxy group at the 2'-position made the molecule more stable and also more synthetically accessible (*Scheme 10*). The resultant analogue, E5564 demonstrated enhanced antagonistic activity over E5531, and did not have detectable agonistic activities. E5564 is now at the stage of phase III clinical trials.

One of the glycolipids that has drawn much interest is α-D-galactopyranosylceramide (α-GalCer), which has potent immunostimulatory and anti-tumor activities, found by Kirin Brew's group. They developed analogues with enhanced activity [135,136,137]. α-GalCer acts as a specific ligand presented by CD1d to a receptor of natural killer T-cells (NKT cells) to lead the immunostimulation, and Wong and co-workers have synthesized analogues for further investigations on biological function [138,139,140,141]. Franck and co-workers have also sought improved compounds with the modification of the structure to that of *C*-glycoside, and succeeded in obtaining analogues with much enhanced activity [142,143,144].

Rademann and co-workers have applied the hydrophobically assisted switching phase (HASP) synthesis for a glycolipid library [145]. The HASP method is further explained in Chap. 5.5. They used the method for the synthesis of immunostimulative rhamnolipids to observe proinflammatory activities in human mononuclear cells.

Fukase and co-workers have synthesized peptidoglycan (PG) partial structures in order to investigate their mechanism of action in immunostimulation [146,147]. Since peptidoglycan and its fragments derived from natural sources may be contaminated with other immunostimulating components, the precise mechanism of action of PG was evaluated by using structurally defined synthetic specimens. By using an efficient synthetic strategy, mono-, di-, tetra-, and octasaccharide fragments of PG were synthesized in good yields (*Scheme 11*).

Scheme 11

They revealed that not only glycan but also peptide were essential for expression of the immunostimulating activity [148]. Toll-like receptor 2 (TLR2), which is one of the candidates for PG receptor, was not stimulated by the series of synthetic PG partial structures. On the other hand, intracellular receptor Nod2 recognized the partial structures containing the muramyl (MurNAc) dipeptide (MDP) moiety. These results indicated that Nod2 is the intracellular receptor of muropeptides derived from peptidoglycan and the minimal ligand of Nod2 is MDP [149].

Synthetic PG partial structures have also been used for elucidation of the structure recognized by peptidoglycan recognition proteins (PGRPs). PGRPs constitute a large group of proteins found in insects and mammals that bind to bacterial PG. Dziarski et al. reported that human PGRP-L is *N*-acetylmuramoyl-L-alanine amidase, which hydrolyzes the amide bond between MurNAc and L-Ala of bacterial PG. The minimum PG fragment hydrolyzed by PGRP-L is MurNAc-tripeptide.

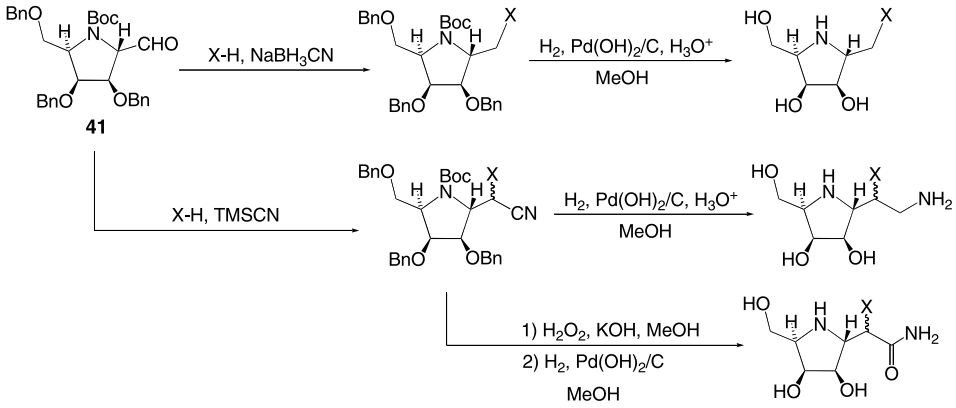
Ezekowitz and co-workers have revealed that human PGRP-S binds to and inhibits the growth of bacteria. PGRP-S co-localized with lysozyme in neutrophil extracellular traps and the antimicrobial effect of PGRP-S was synergistic with lysozyme [150]. PGRP-S bound to the tetrasaccharide having two tripeptide chains and the tetrasaccharide having two tetrapeptide chains, suggesting that the third amino acid in the peptide chain determines the binding affinity to PGRP-S.

Melanin synthesis of the arthropods is essential for defense and development. The melanization cascade is activated by bacterial PG or fungal β-1,3-glucan. Lee and co-workers reported that the tetrasaccharide tetrapeptide functioned as a competitive inhibitor of the natural PG-induced melanization reaction [151]. By using a tetrasaccharide tetrapeptide-coupled column, the *Tenebrio molitor* PG recognition protein (Tm-PGRP) was purified without activation of the prophenoloxidase.

2.5 Combinatorial Approach to Glycoenzyme Inhibitors and Lectin Ligands

A potential usefulness of the library as a source of inhibitors of glycoenzymes has been clearly exemplified by Kanie and co-workers (*Scheme 12*) [152]. A combinatorial approach based on the five-membered iminocyclitols with a *galacto*-configuration has been investigated; a small library of 27 iminocyclitol derivatives was prepared by either reductive amination or Strecker reaction of the aldehyde **41**. They have found that the introduction of a C10-alkyl group remarkably enhanced the inhibitory activity against α-mannosidase up to 10 μM, compared with its parent iminocyclitol and deoxymannojirimycin. Furthermore, the compounds bearing the phenylethyl group showed an extremely strong inhibitory activity against α-galactosaminidase (*Ki* value: 29.4 nM).

Schmidt and co-workers have been investigating a series of potent inhibitors of α(2,6)-sialyltransferase (*Fig. 9*). They developed the transition analog **42** [153], based on the proposed mechanism of the sialyl transfer, that involves the partial dissociation of the CMP and the formation of the planer oxocarbenium ion structure in the transition state. They also found that the planer neuraminyl moiety in **42** can be replaced by the aromatic groups, leading to the readily accessible aromatic inhibitors of α(2,6)-sialyltransferase from rat liver. Further library



Scheme 12

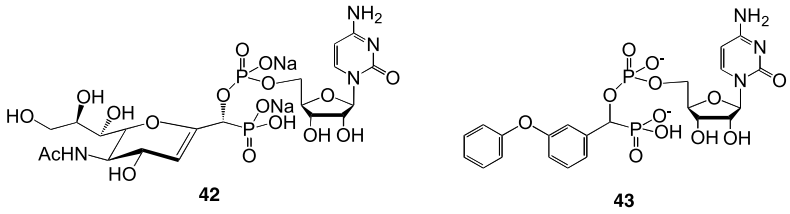


Figure 9
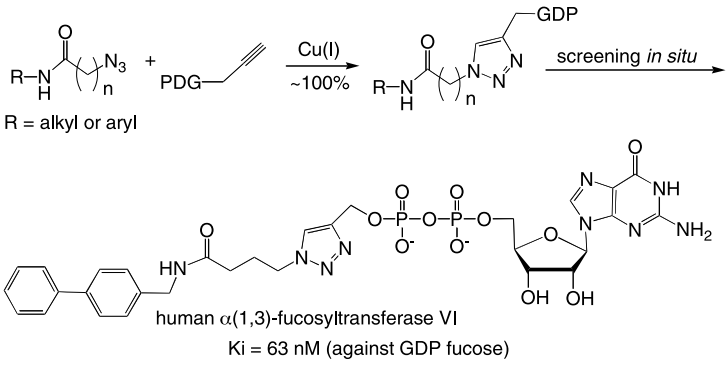
α(2,6)-Sialyltransferase inhibitors by Schmidt and co-workers

synthesis led to the development of **43** [154], which mimics a planer anomeric carbon, a large distance between the anomeric carbon and the CMP group, and two negative charges in the transition state, showed a *Ki* value down to 70 nM.

A potent inhibitor against human α(1,3)-fucosyltransferase VI was identified from a GDP-triazole library of 85 compounds, which was produced by the Cu(I)-catalyzed [2 + 3] cycloaddition reaction between azide and acetylene, followed by in situ screening without product isolation (*Scheme 13*) [155]. Kinetic evaluation of the purified inhibitor (*Scheme 13*) showed that it is a competitive inhibitor against GDP-fucose with $Ki = 62$ nM, which would make this compound the first nanomolar and most potent inhibitor of Fuc-Ts.

The polypeptide *N*-acetyl-α-galactosaminyltransferases (ppGalNAcTs) initiate mucin-type *O*-linked glycosylation and therefore play pivotal roles in cell–cell communication and protection of tissues. Bertozzi and co-workers screened a 1338-member uridine-based library to identify small molecule inhibitors of ppGalNAcTs (*Fig. 10*) [156]. Using a high-throughput enzyme-linked lectin assay (ELLA), two inhibitors of murine ppGalNAcTs-1 (*Ki* approximately 8 μM) were identified that also inhibit several other members of the family. The compounds did not inhibit other mammalian glycosyltransferases or nucleotide sugar utilizing enzymes, suggesting selectivity for the ppGalNAcTs. Treatment of cells with the compounds abrogated mucin-type *O*-linked glycosylation but not *N*-linked glycosylation and also induced apoptosis. These uridine analogs represent the first generation of chemical tools to study the functions of mucin-type *O*-linked glycosylation.



Scheme 13

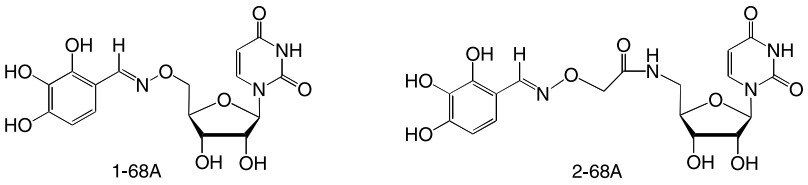


Figure 10
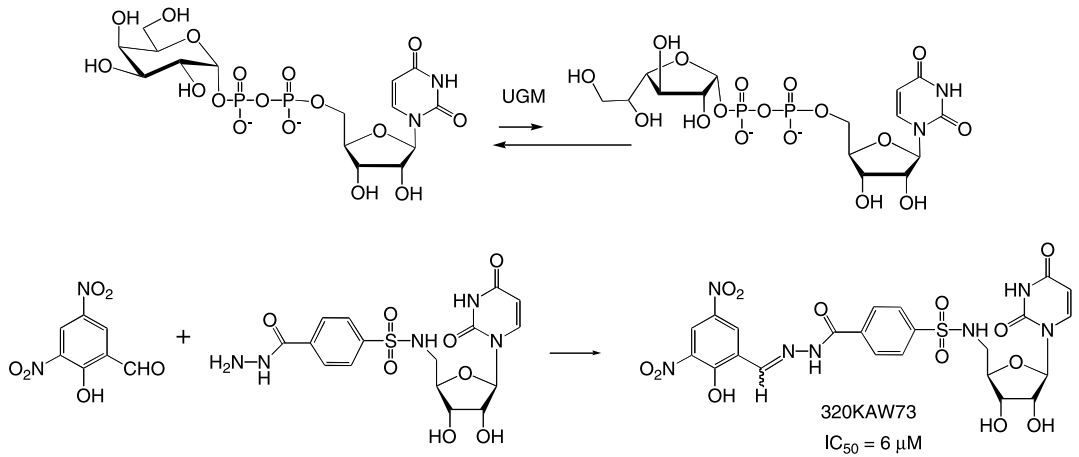
Uridine-based inhibitors of ppGalNAcTs by Bertozzi and co-workers

The flavoenzyme UDP-galactopyranose mutase (UGM) plays a key role in the cell wall biosynthesis of many pathogens, including *Mycobacterium tuberculosis*. McNeil and co-workers developed a microtiter plate assay for UGM (*Scheme 14*) [157]. The assay is based on the release of tritiated formaldehyde from UDP-galactofuranose but not UDP-galactopyranose by periodate and was used to identify a uridine-based enzyme inhibitor from a chemical library. The potent inhibitor 320KAW73 ($IC_{50} = 6\,\mu M$) was identified.

Kiessling and co-workers screened 16,000 compounds in a fluorescence polarization assay by using a synthetic fluorescent ligand; effective inhibitors of UGM were identified (*Fig. 11*) [158].

Kiso and co-workers have succeeded in the total synthesis of a series of gangliosides and sialic acid-containing glycosphingolipids as well as their derivatives, and revealed their biological functions at the molecular level. Among them, they have found that the cholinergic neuron-specific Cho-1 (α-series) gangliosides are high affinity ligands for neural siglecs (sialic acid-binding Ig-like lectins) (*Fig. 12*). α(2–3)-Linked sialic acid at Gal (II^3) and α(2–6)-linked sialic acid at GalNAc(III^6) greatly enhance the siglec-mediated cell adhesion, and especially, GQ1bα showed a remarkably high affinity to myelin-associated glycoprotein (MAG, siglec-4a). On the basis of the interesting finding through structure-activity studies that these internal sialic acids can be substituted by other anionic groups, they have synthesized three sulfated GM1b analogs **44–46**, as the structural mimics of GQ1bα [159,160]. Surprisingly, **46** bearing the β(1–4)linkage between GalNAc(III) and Gal(IV), being different from the natural β(1–3)



Scheme14

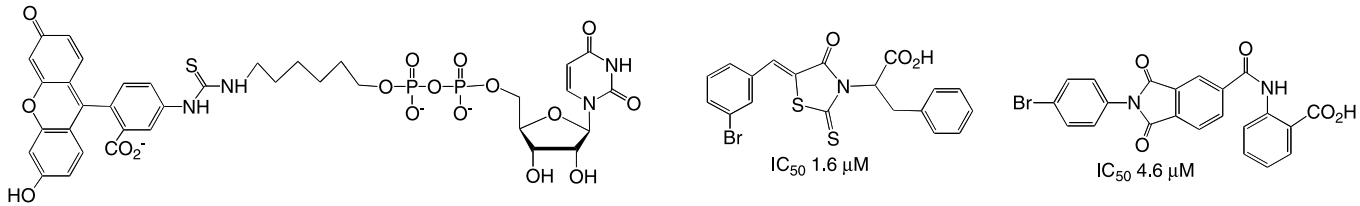


Figure 11
UGM Inhibitors by Kiessling andco-workers

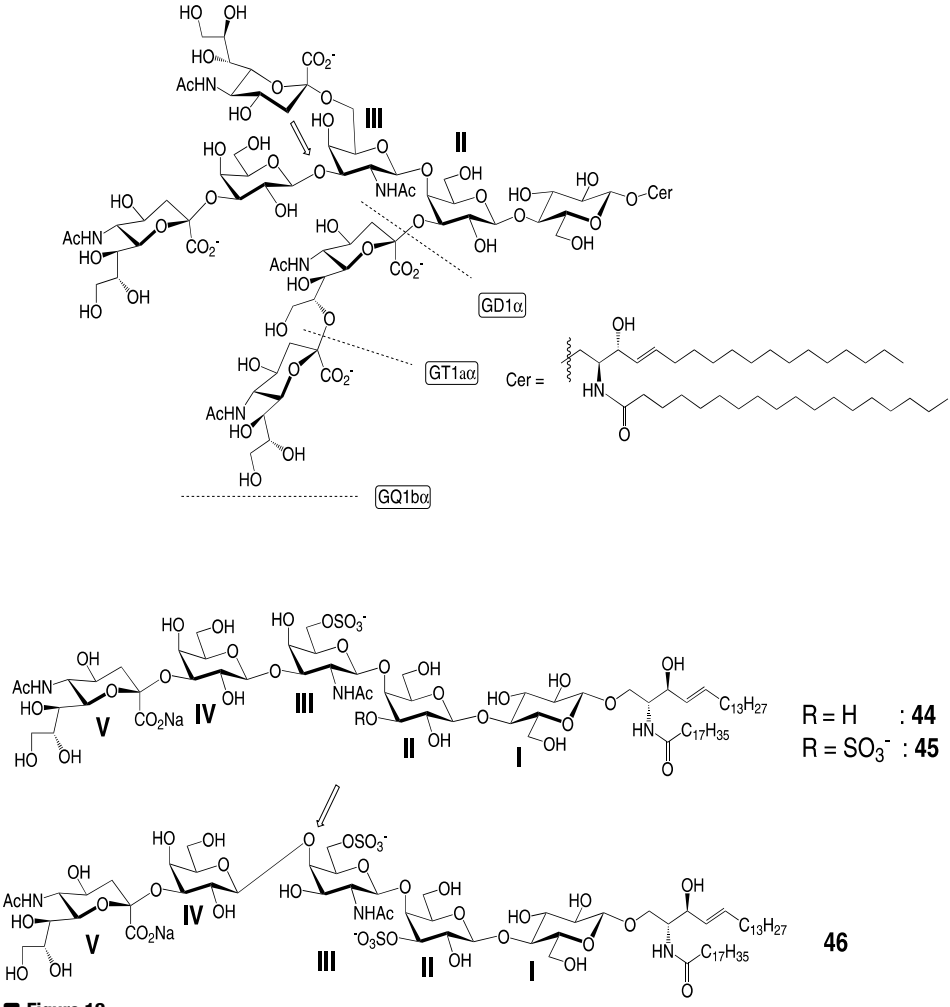

Figure 12
Cholinergic neuron-specific Cho-1 (α-series) gangliosides and sulfated GM1b analogs by Kiso and co-workers

linkage in GQ1bα (see *arrows* in *Fig. 12*), exhibited the most potent MAG binding affinity tested to date. The derivative **46** was also found to be the most potent inhibitor of NADase activity of leukocyte cell surface antigen CD38, inconsistent with the requirement of the internal α(2–3)-linked sialic acid in GQ1bα for NADase inhibition. The structures of **46** and **45** calculated using CAChe software revealed that both sulfate groups and the terminal sialic acid in **46** make the negative charge cluster, which might be easily recognized by MBP-CD38, while the terminal sialic acid in **45** protrudes from the anion cluster of sulfates. Future investigations on the synthetic sulfated gangliosides will open new perspectives on their structure-function relationships.

2.6 Application of the Oligosaccharide Library to a Microarray

Seeberger and co-workers examined the interaction between heparin oligosaccharides and fibroblast growth factors (FGF-1 and FGF-2) on the microchip, which are involved in developmental and physiological processes, including cell proliferation, differentiation, morphogenesis, and angiogenesis (*Scheme 15*) [161]. The 2-aminoethylsulfonyl linker in **47–51** was introduced by the reaction of the pentenyl moiety of the heparin derivatives, being generated during their automated synthesis, with 2-(benzyloxycarbonylamino)-1-ethanethiol in the presence of AIBN followed by air oxidation of sulfide and deprotection of the benzyloxycarbony group. After the amine-functionalized **47–51** were covalently attached to the amine-reactive CodeLink slides that are coated with a hydrophilic polymer with *N*-hydroxysuccinimidyl ester, the FGF-binding assay was performed using the anti-human FGF polyclonal antibodies and a secondary antibody labeled with an Alexa 546 dye. The basic FGF-2 strongly bound to **48** and **49** based on the highest fluorescence intensities, while monosaccharide constituents **50** and **51** were not bound. Similar results were obtained for the acidic FGF-1, but interestingly, they found that **50** exhibited a fluorescent intensity comparable to those of **48** and **49**; the presence of an unnatural 2,4-*O*-sulfation pattern might be responsible for this interaction.

Seeberger and co-workers have also investigated the glycan-based interaction of HIV-1 envelope glycoproteins on the microarray pursuing vaccines and agents that interfere with HIV events [162]. Screening of the seven high mannose-type oligosaccharides on the slides, prepared by total synthesis, revealed established the five relevant gp-120 binding proteins, including the dendric cell lectin DC-SIGN (Dendric Cell-Specific Intercellular Adhesion Molecule-1-Grabbing Nonintegrin), the HIV-inactivating protein scytovirin, and the human antibody 2G12. The present microarray analysis also included the synthetic neoglycoproteins, which gave additional information on the gp-120 interaction, regarding the importance of the peptide backbone to which the high mannose oligosaccharides are attached.

Similarly, Wong and co-workers have studied carbohydrate specificity to the anti-HIV-1 antibody, 2G12 using a carbohydrate microarray and ELISA (solution-phase Enzyme-Linked Immunosorbent Assay) [163]. The azide group introduced on the reducing end of the oligosaccharides [164] were covalently attached to a microplate via a Cu(I)-mediated 1,3-dipolar cycloaddition reaction (Meldal/Sharpless click reaction) through a disulfide linker [165]; the use of the cleavable S-S linker enabled the quantification of the oligosaccharides immobilized on the slides by mass spectrometry or the phenol-sulfuric acid test (*Fig. 13*). The study revealed that the antibody 2G12 bound both D1 and D3 arms of the $Man_9GlcNAc_2$ structure, thus providing important information for the design of HIV vaccines.

They also developed a detection method for oligosaccharides on the slides by desorption/ionization on silicon mass spectrometry (DIOS-MS) without the matrix [166]. An amine-containing antigen N3 minor was prepared by their one-pot synthesis and it was printed on the surface of modified porous silicon with a photocleavable linker. The linker can be cleaved by a laser ($\lambda = 337$ nm) during the mass spectrometric measurements, thereby enabling direct characterization of the released and ionized carbohydrates on the porous silicon with a minuscule amount of sample. The new method will greatly expand the high-throughput analysis of a large glycan array, which will be prepared by their programmed one-pot oligosaccharide synthesis based on the use of designer thioglycoside building blocks with defined relative reactivity values (RRVs) that are collected in the Optimer database (*Sect. 2.1*).

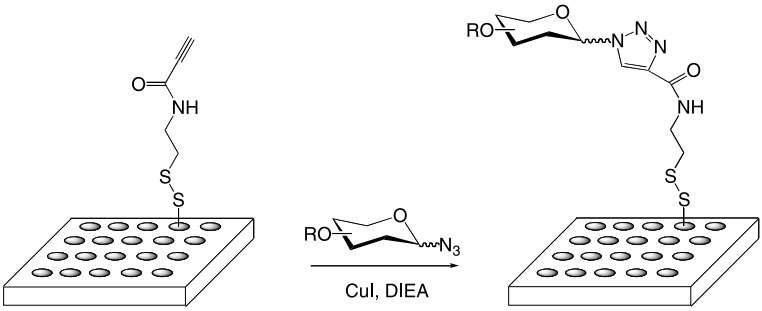

Figure 13
Covalent attachment to a microplate by Wong and co-workers

Schmidt and co-workers have also immobilized the mannose derivatives to the commercially available glass slides under reductive amination or acylation conditions [167]. Their study showed that the ConA interaction was in accordance with those obtained in aqueous solution and other immobilization methods, and non-specific protein binding to the functionalized glass slides was negligible. The same carbohydrate microarray plate could also be tested for other lectins, therefore the "precious" immobilized carbohydrates can be reused.
Fluorous-based non-covalent immobilization on the slide surface has also been reported recently [168]. Fluorous-tags containing oligosaccharides, which were prepared by the fluorous-based synthesis, were printed on the fluorous-coated glass slides, and the slides were screened by fluorescein-labeled lectins as a model of carbohydrate–protein interactions. Although the method avoids the extra derivatization steps for the immobilization on the slides, the lack of applicability of the current fluorous-based synthesis to the biologically relevant oligosaccharides, i. e., complex glycans consisting of more than four sugars, as well as weak fluorous/fluorous interactions being problematic during the washing steps on the microchips, still remains to be improved.

2.7 Libraries Using Carbohydrate Scaffolds and Miscellaneous

Another important subject in combinatorial chemistry of carbohydrates is the use of carbohydrates as scaffolds. So far various libraries using carbohydrates as scaffolds have been developed and many bioactive compounds have been found towards various targets including the somatostatin receptors (SSTR), integrins, HIV-1 protease, matrix metalloproteinases (MMP), multidrug resistance-associated protein (MRP), and as RNA binders [169]. Montesarchio and co-workers have also prepared cyclic phosphate-linked oligosaccharides in order to investigate their conformational properties [170], as well as the sucrose-oligonucleotide hybrids [171], in an attempt to increase chemical and enzymic stability of the oligonucleotides without interfering with the duplex formation and with the ability of G-rich sequences to adopt a quadruplex structure. Takahashi and co-workers have reported a parallel synthesis of a enediyne-oligosaccharide library, using silyl-linked solid-support [172]. Combinatorial approaches to the glycopolymers and glycoclusters, based on the asparaginyl template [173], ε-sugar amino acid templates [174], and cyclo-β-tetrapeptides [175], have also been reported.

3 Conclusions

In this chapter, we focused on the synthesis of oligosaccharide libraries and carbohydrate mimetic libraries and their use for glycobiology. Recently, oligosaccharide synthesis including solid-phase synthesis has been dramatically improved and various complex oligosaccharides and glycoconjugates have been synthesized for investigation of their biological functions. Many efforts will be continued to establish efficient synthesis of oligosaccharides. The library approach based on chemical synthesis will become a generally accepted method for elucidation of oligosaccharide functions, since chemical synthesis can provide a series of compounds in pure states without contamination by other bioactive components. In addition, oligosaccharide and glycoconjugate libraries will lead to an understanding of the biological importance of carbohydrate structural diversity with the advent of glycobiology.

5.5 Polymer-Supported and Tag-Assisted Methods in Oligosaccharide Synthesis

Katsunori Tanaka, *Koichi Fukase*
Department of Chemistry, Graduate School of Science, Osaka University, Osaka 560-0043, Japan
koichi@chem.sci.osaka-u.ac.jp

Abstract

Recent advances in polymer-supported synthesis of oligosaccharides, i. e., solid-phase synthesis, polymer-supported synthesis, and tag-assisted solution synthesis, are overviewed. A variety of new methods on polymer-supports, combined with accumulation of information on oligosaccharides synthesis in solution, has led to the assembly of complex oligosaccharide structures in the solid-phase, and even to a programmed automation system. A continuous flow synthesis of oligosaccharides using a microreactor, a newly appearing protocol for glycosylation analysis, high-throughput- and combinatorial synthesis, and even for production-scale synthesis, will also be described.

1 Introduction

Synthesis of oligosaccharides and glycoconjugates has played an important role in elucidation of their biological functions. However, substantial time and efforts are often needed, since it requires multiple step transformations involving iterative deprotection-glycosylation

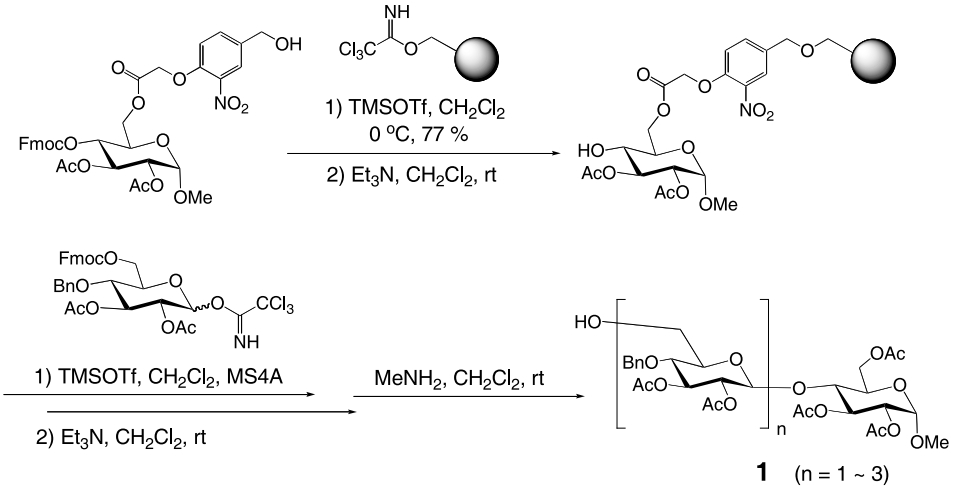
procedures. Extensive efforts therefore have been made to establish an efficient synthesis of oligosaccharides by means of a solid-phase method and a polymer-supported solution method. In solid-phase synthesis, the starting material binds to the polymer support, which allows the product to be isolated by filtration after each reaction. Finally, the product is cleaved from the resin. The operation is simple and rapid and hence solid-phase synthesis enables rapid preparation of a large number of compounds and thus increases the speed of development of a lot of functional molecules including new drugs and new materials. However, there have been several critical issues for solid-phase oligosaccharide synthesis, e. g., the synthetic intermediate cannot be purified. Each glycosylation and deprotection therefore must proceed in a high yield. Recent progress in glycosylation and protective group manipulation has solved these problems and made solid-phase synthesis of oligosaccharides practical [1]. In this chapter, the authors focus not only on solid-phase synthesis but also polymer-supported solution synthesis as well as tag-supported synthesis, both of which have been proved useful for rapid preparation of oligosaccharides.

2 Solid-Phase Methods for Synthesis of Oligosaccharides

2.1 New Linkers and Protection Groups for Solid-Phase Synthesis of Oligosaccharides

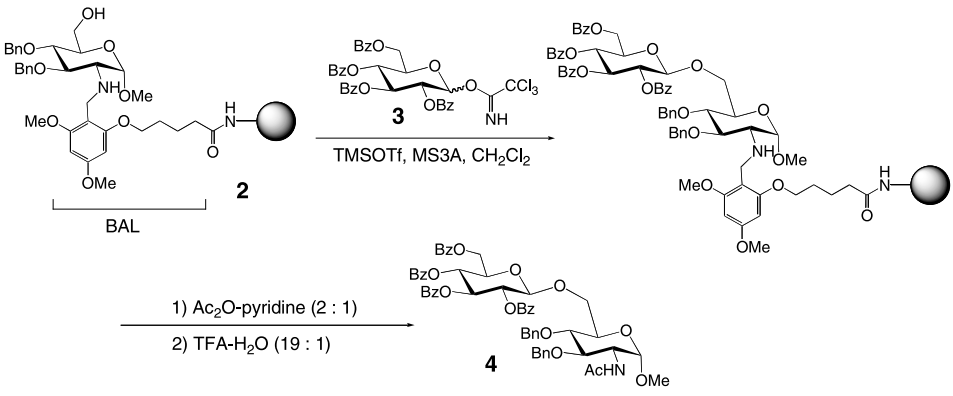
The choice of linkers is critically important for both solid-phase and polymer-supported solution synthesis. Selective cleavage of the linkers, leaving other protecting groups intact, and then purification and final deprotection is a rational strategy for oligosaccharides synthesis. This is distinctly different from the solid-phase synthesis of peptides, in which all the side-chain protecting groups and linkers are removed simultaneously at the end of the synthesis on the solid-supports. In the case of oligosaccharides, the purification in protected forms is generally more preferable owing to the hydrophilic properties of completely deprotected oligosaccharides. Traditionally, the linkers have been directly attached to the anomeric positions as thioglycoside, 1-*O*-acyl, photolabile *o*-nitrobenzyl glycoside, *p*-alkoxybenzyl glycoside, base-labile 9-hydroxymethylfluorene, or silylethyl glycoside [1]. On the other hand, ester-type, silyl ether-type, or *p*-acylaminobenzyl-type linkers have also been used to obtain the anomerically pure oligosaccharides after cleavage from the resins. More recently, unique linkers, which are bifunctional, temporary, and cleavable in a completely chemoselective manner through recently developed transition metal-catalyzed reactions, have been developed and successfully applied to the solid-phase synthesis of oligosaccharides. The development of such linkers enabled quite challenging oligosaccharide assembly on solid-supports, such as *N*-glycans or glycosylphosphatidylinositol of complex and branched structures, even using automated systems, which will be described in *Sect. 2.2*.

Schmidt and co-workers have developed the *o*-nitro-phenoxyacetate linker, which can be readily and quantitatively cleaved by treatment with methylamine under mild conditions (*Scheme 1*) [2]. By repeating the sequences of glycosylation with glucosyl trichloroacetimidate in the presence of TMSOTf, and Et_3N-induced deprotection of the Fmoc group, an efficient solid-phase synthesis of di- to pentasaccharides **1** containing glucose β(1–4) and β(1–6) linkages has been achieved.

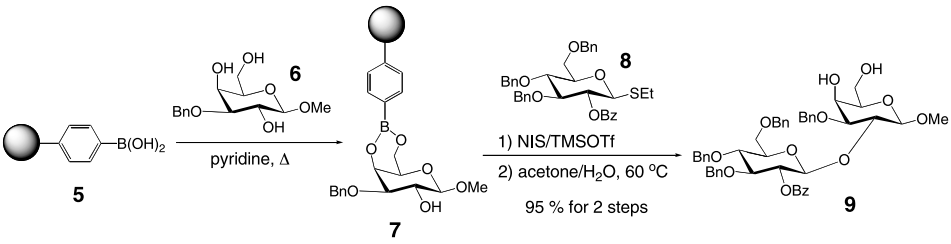


Scheme 1

Jensen and co-workers have developed the tris(alkoxy)benzylamine linker (BAL) on a polystyrene support, which is introduced to aminosugars by reductive amination of the corresponding aldehyde in the presence of $NaBH_3CN$ in DMF-AcOH (*Scheme 2*) [3,4]. This linker proved to be stable to concentrated TFA and other Lewis acids, but was readily cleaved by TFA-H_2O (19:1) after *N*-acetylation. Thus, polystyrene-bound glucosamine derivative **2** was glycosylated with glucosyl trichloroacetimidate **3** using TMSOTf as an activator. After the acetylation of the C2-amino group by Ac_2O in pyridine, β(1–6)-linked disaccharide **4** was liberated from the solid support in 82% yield by TFA treatment. The high stability of the linker under strongly acidic conditions allows for the use of excess Lewis acid for glycosylations on the solid-phase.



Scheme 2



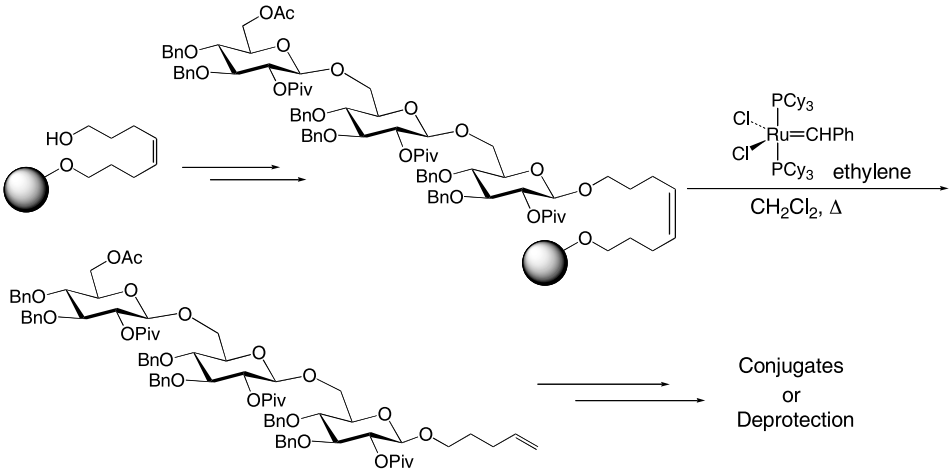
Scheme 3

The *N*-1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl linker has also been introduced between the C2-amino group of the glucosamine and a solid-support [5]. This linker was stable during glycosylation with thioglycoside in the presence of methyl trifluoromethane sulfonate, but readily cleaved by hydrazine, primary amines, or even ammonia.

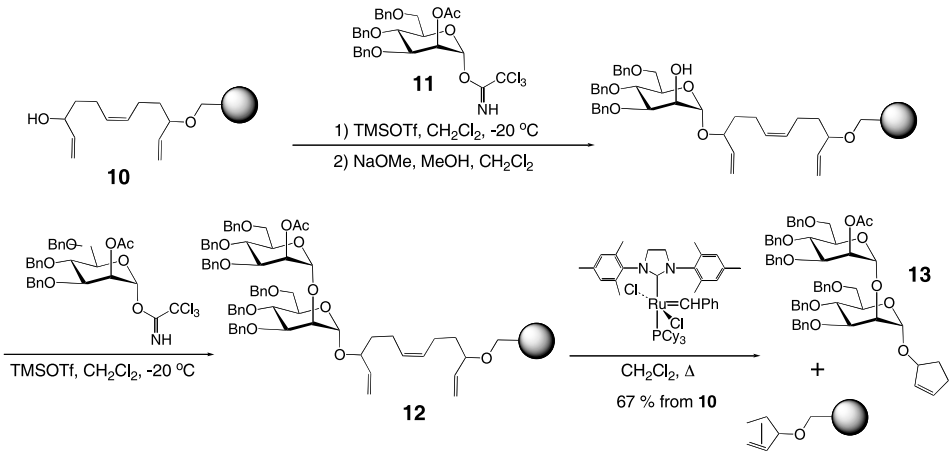
Boons and co-workers used polystyrylboronic acid as a temporary polymeric support for oligosaccharide synthesis (*Scheme 3*) [6,7]. Polystyrylboronic acid **5**, easily prepared from the corresponding bromide by treatment with trimethyl borate and *n*-BuLi in high loading capacity, was introduced on the 4,6-*O*-positions of the acceptor **6** by heating in pyridine. The immobilized boronate acceptor **7** was glycosylated with thioglycoside donor **8** by using NIS/TMSOTf as the promoter to give the β(1–2)-linked disaccharide **9** in 95% yield, after in situ cleavage from the solid support by heating in acetone/water. The polystyrylboronic acid was recovered and re-used for subsequent loading to the acceptors and glycosylation.

Recent exciting progress in the development of efficient and stable metathesis catalysts and their use in metathesis reactions both in solution-phase and solid-phase, have prompted several groups to investigate the metathesis-based linker for solid-supported synthesis. Olefin-based linkers have attracted a great deal of attention for solid-phase oligosaccharide synthesis since the isolated olefins are inert under a wide range of acid-catalyzed glycosylation and deprotection conditions, and at the end of the synthesis, these linkers can be cleaved under mild and olefin-selective conditions by both intramolecular and intermolecular metathesis. Seeberger and co-workers have applied the octanediol linker, which is readily prepared from cycloocta-1,5-diene, to solid-phase oligosaccharide synthesis, especially to programmed automated synthesis (see *Sect. 2.2*). The octanediol linker is cleaved from the resin by cross (intermolecular) metathesis with ethylene gas in the presence of the Grubbs' first generation catalyst to give *n*-pentenyl glycosides (*Scheme 4*) [8]. The *n*-pentenyl moiety thus generated can be used as a glycosylating donor or an anchor to connect the synthesized oligosaccharides to proteins, labels, or the surface of the solid support during preparation of oligosaccharides microarrays [9,10].

Van der Marel and co-workers have designed a self-cleavable linker via tandem ring-closing metathesis (*Scheme 5*) [11]. Their triene linker on Merrifield resin **10** was glycosylated twice with mannosyl trichloroacetimidate **11** in the presence of TMSOTf in CH_2Cl_2 at $-20\,^{\circ}C$ to provide the α-linked disaccharide **12**, which was treated with Grubbs' second generation ruthenium catalyst to liberate the cyclopent-2-enyl mannnoside **13** in 67% yield from **10** (average 90% for each step). A cyclopent-2-enyl moiety was then isomerized to the corresponding vinyl ether glycoside by treatment with $(PPh_3)_3RhCl$ and DBU in EtOH, which was hydrolyzed by



Scheme 4

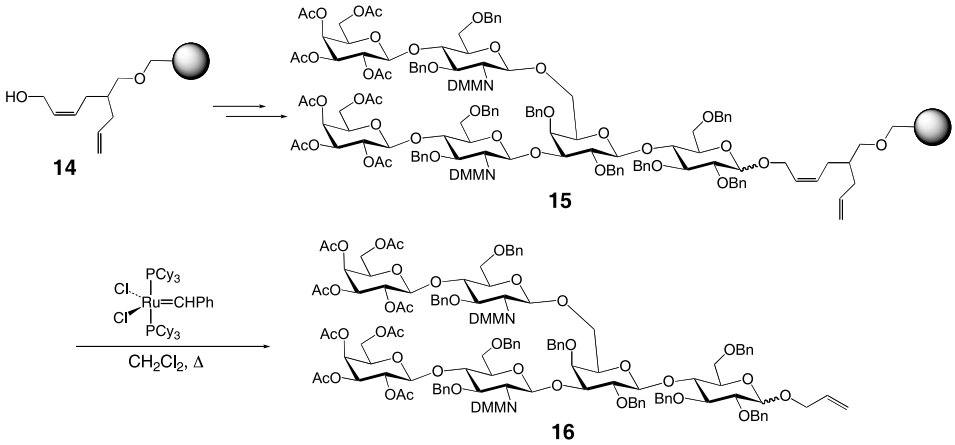


Scheme 5

I_2 in THF-H_2O. The self-cleavable linker **10**, which provides the thermodynamically stable cyclopentene both on solid supports and on the products, prevents catalyst deactivation due to covalent attachment of the ruthenium catalyst to either the solid-support or the products via C=C double bonds during the metathesis reaction.

Schmidt and co-workers have also independently developed the self-cleavable diene linker **14** and solid-phase synthesis of the branched hexasaccharide **16** has been achieved (*Scheme 6*) [12]. The ring-closing metathesis of **15** provided the allyl glycoside **16** from which the allyl protecting group was readily removed by Ir-mediated isomerization followed by hydrolysis.

Fukase and co-workers have developed two types of alkyne linkers (*Scheme 7*) [13]. A propargyl glycoside-type linker between a sugar residue and a solid support was formed

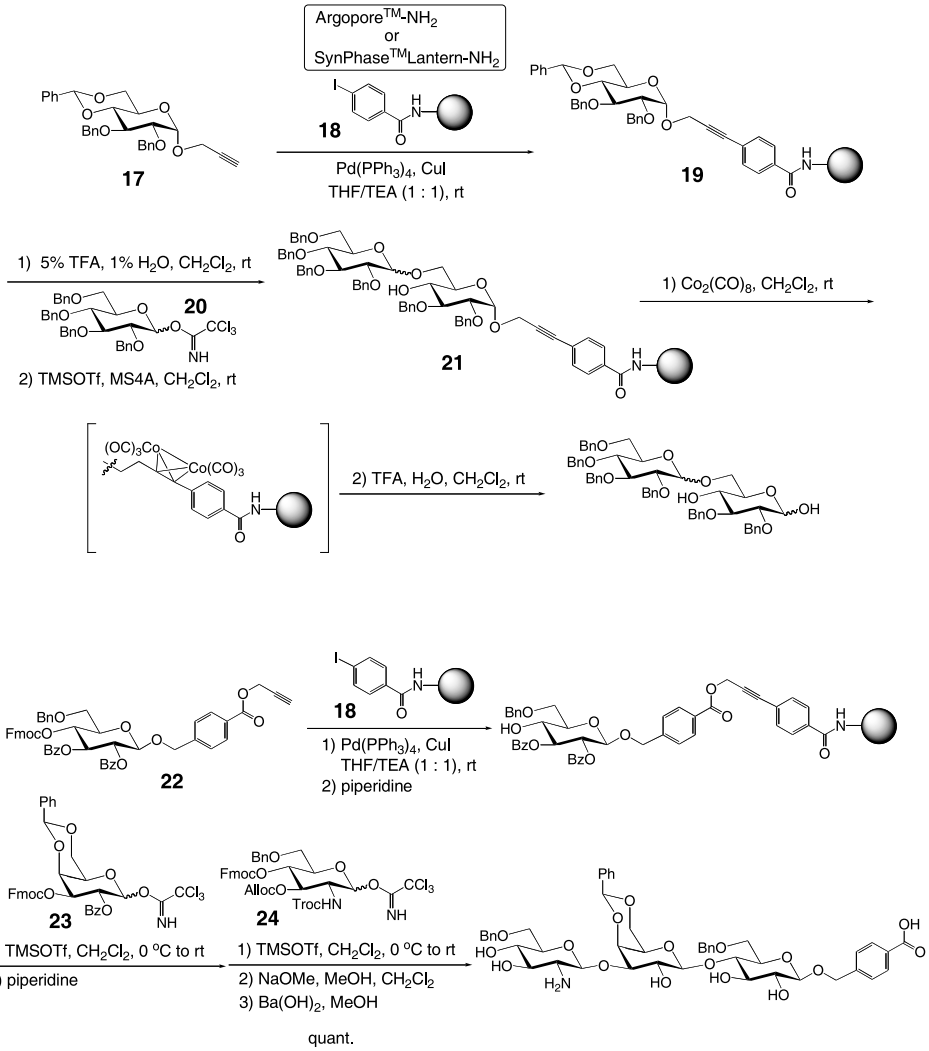


Scheme 6

by the Sonogashira reaction; the propargyl glycoside **17** was treated with polymer-supported iodobenzene **18** in the presence of $Pd(PPh_3)_4$ and CuI in THF/Et_3N to provide **19**. After the 4,6-*O*-benzylidene group was removed by treatment with TFA, the liberated C6-hydroxyl was glycosylated with glucose trichloroacetimidate **20** using TMSOTf as a promoter to give the disaccharide **21**. The alkyne-based linker is thus stable during the glycosylation or the TFA treatment, but can be readily cleaved with TFA after the conversion to the corresponding alkyne-cobalt complex by reacting with $Co_2(CO)_8$. Alternatively, a propargyl ester-type linker was also generated by the same Sonogashira reaction of a 4-(propargyloxycarbonyl)benzyl glycoside **22** with the polymer-supported iodobenzene **18**. After a sequence of glycosylation reactions with imidates **23** and **24**, the trisaccharide was released from the resin by treatment with TFA of the corresponding alkyne-cobalt complex. The latter ester-type linker is generally advantageous since the carboxybenzyl glycoside, liberated from the resin under mildly acidic conditions, is readily purified and the linker can also be cleaved under nucleophilic conditions (NaOMe in MeOH/CH_2Cl_2). Noteworthy is that the Sonogashira reaction was found to proceed only at spatially reactive sites on the solid support to which the reagents can access readily, so that the subsequent reactions including glycosylation and Fmoc deprotection on the solid-phase proceeded smoothly and quantitatively, resulting in high total yields of the desired oligosaccharides.

The peptide-based linker has also been investigated by Warriner and co-workers (*Scheme 8*) [14]. Since the solid-phase synthesis of peptide is well established, both glycosyl acceptors and donors were initially conjugated to the 3-hydroxyproline template, and introduced on the Aminomethyl Novagel™ resin using standard Fmoc peptide coupling protocol (a sequence of amide formation by using HOBt, HBTU, and DIPEA, followed by Fmoc deprotection by piperidine). They examined the stereoselectivities of glycosylation between acceptors and donors that were loaded to a peptide template, and 12 members of the disaccharide library were constructed.

Based on a library-directed approach, Takahashi and co-workers developed a synthetic strategy for the combinatorial solid-phase synthesis of tree-type carbohydrate clusters using three types



Scheme 7

of orthogonally cleavable linkers, namely, a photo-cleavable 2-nitrobenzyl-type linker (orthogonal cleavage site 1), a base-cleavable ester linker (orthogonal cleavage site 2), and a cobalt complexation/acid-cleavable alkyne linker (orthogonal cleavage site 3) (*Fig. 1*) [15]. The combined use of three types of spacers, two types of carbohydrates, and two types of orthogonally cleavable linkers provided 12 members of a carbohydrate cluster library (6 dimers and 6 tetramers).

In addition to the importance of linkers described above, the precise choice of protecting groups is also an important factor for oligosaccharide assembly to be successful on solid-supports. Utilization of protecting groups that are stable under glycosylation conditions but can

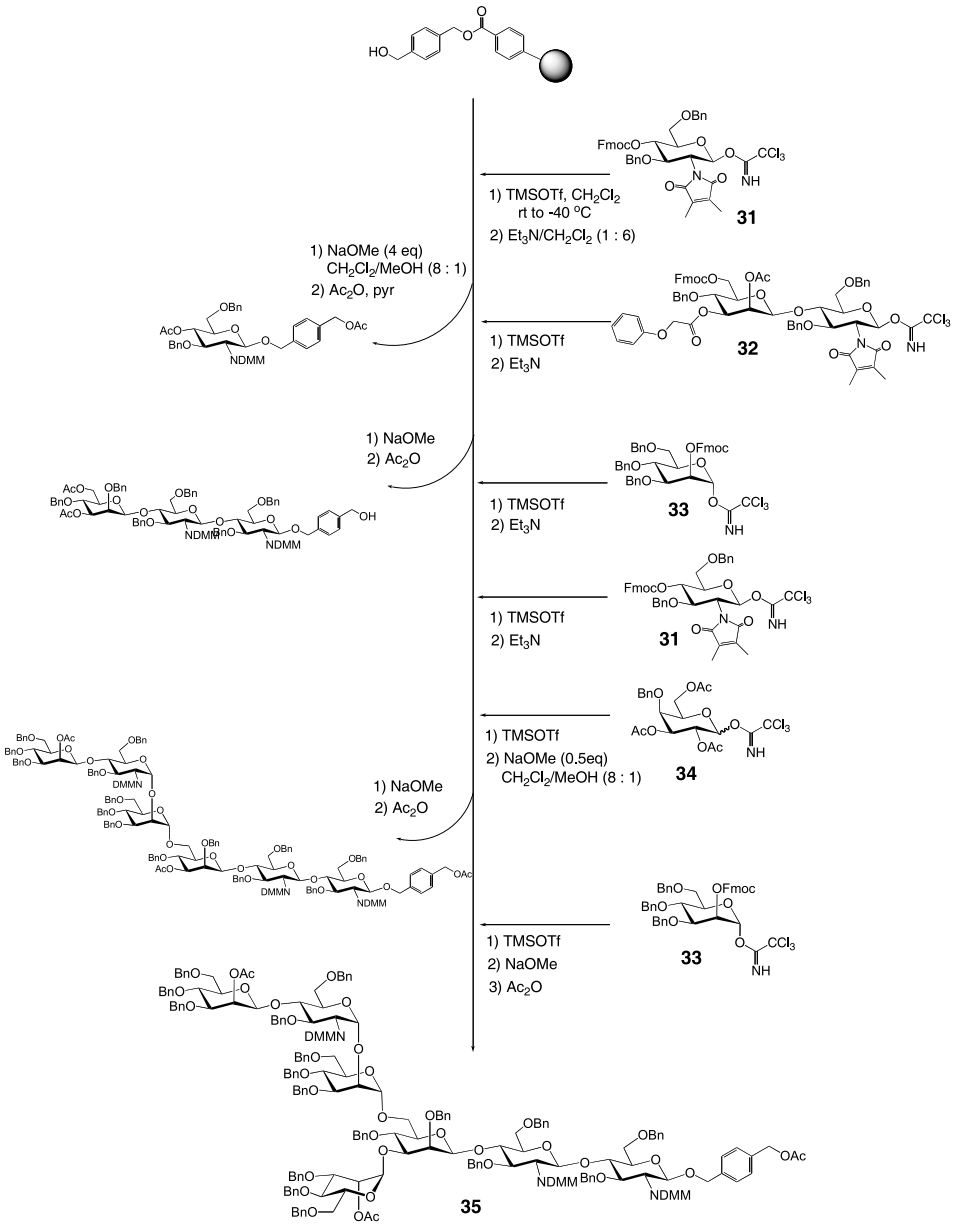
be readily removed under mild conditions and that are compatible to other protecting groups and linkers is highly desirable for combinatorial and high-throughput oligosaccharides synthesis. The excellent orchestration of protecting group manipulation, leading to the construction of complex oligosaccharide structures will be discussed in *Sect. 2.2*. It is also preferable if the protecting group serves as a tag to identify the compounds as well as to indicate their protection states. Kasumi and co-workers have reported unique protecting group manipulations, by using (N-α-1-ethylpropylglycine)$_n$ [(EPG)$_n$], for both solution- and solid-phase synthesis of oligosaccharides (*Scheme 9*) [16]. The hydroxyl groups of oligosaccharides were protected by an (EPG)$_n$ group with a different degree of polymerization, which can be uniquely identified. The (EPG)$_n$ groups were then deprotected successively from the highest to the lowest degree of polymerization by repeating the Edman degradation cycle. Thus, the galactose derivative **25** with (EPG)$_3$ at the C6-hydroxyl and (EPG)$_1$ at the C4-hydroxyl, was subjected to the Edman degradation, i. e., by (i) Fmoc deprotection with 20% piperidine, (ii) phenyl isothiocyanate treatment, (iii) degradation by TFA, and (iv) Boc protection of the newly appearing amino group to provide the acceptor **26** having (EPG)$_2$ at the C6-hydroxyl, in 69% yield over four steps. This acceptor was glycosylated with thiogalactose **27** bearing one EPG at the C3-position by using NIS and TfOH as the activators to give **28** in 89% yield. Repetition of the Edman degradation cycle liberated the C3′-hydroxyl in 70% yield, which was further sialylated with thioglycoside **29** to give **30** in 13% yield. They applied this protecting group manipulation to solid-phase oligosaccharide synthesis.

2.2 Solid-Phase Synthesis of Complex Oligosaccharides

New methods for solid-supports, together with the accumulation of information on acceptor/donor reactivity in the solution-phase, have led to the synthesis of complex oligosaccharides on solid-supports [17,18,19,20,21]. Schmidt and co-workers have achieved solid-phase synthesis of a small library of N-glycans (*Scheme 10*) [22,23,24]. They used the hydroxymethylbenzyl benzoate linker attached to the Merrifield resin. Glycosylation on the resin was successfully performed using the glycosyl trichloroacetimidates [25], such as glucosamine **31**, mannosylβ(1–4)glucosamine **32**, mannose **33**, and galactose **34** which allow chain extension, branching, and chain termination for the synthesis of heptasaccharide N-glycan **35**; the tedious β-mannosyl linkage in **32** was constructed in advance in solution phase. O-Benzyl and O-benzoyl groups were used as permanent, while O-Fmoc and O-phenoxyacetyl groups were used as temporary protecting groups for the sugar extension on the solid-phase. The N-dimethylmaleoyl group was selected for the protection of glucosamine **31**, since not only the neighboring effects ensure β-selective glycosylation, but also this protecting group confers high reactivity on glucosamine **31** as an acceptor on the polystyrene [26]. Their solid-phase synthesis involves (i) glycosylation under the TMSOTf catalyst, (ii) selective removal of the temporary protecting groups, Fmoc by Et_3N and the phenoxyacetyl group by 0.5 equivalents of NaOMe in MeOH/CH_2Cl_2, and (iii) cleavage of products from the resin by 4.0 equivalents of NaOMe in MeOH/CH_2Cl_2 and then O-acetylation for convenient product isolation. These precise designs of linker, protecting group manipulations, and stereoselective glycosylation on the resin enabled the successful preparation of a small library of 17 N-glycan structures.

The assembly of oligosaccharides on solid-supports gave a quite exciting and promising opportunity for automation. Seeberger and co-workers have designed the first automated oligosac-



Scheme 10

charide synthesizer for the solid-phase (*Scheme 11*) [27,28,29,30,31,32,33,34,35,36]. A peptide synthesizer was re-engineered to function as an automated oligosaccharide synthesizer and to provide easy access to structures as large as dodecasaccharides about 20-times faster than previously reported manual methods. Even oligosaccharides with branched struc-

tures are now accessible and a series of oligosaccharides of biological relevance, i. e., glycosylphosphatidylinositol (GPI) [37], *N*-glycan core pentasaccharide [38], or Lewis blood group oligosaccharides [39], have been prepared. The solid-phase synthesizer utilizes the glycosyl phosphate building blocks and the octanediol linker attached to the resin which allow for a simple automated coupling/deprotection cycle for oligosaccharide assembly. The released oligosaccharides from solid-supports were applied for biological purposes, i. e., bioconjugation or a microarray [9,10]. An example of the automated synthesis of Lewis blood group oligosaccharide **41** is shown in *Scheme 11* [39]. Five monomer units **36–40**, which allow for the stereoselective construction of five different glycosidic bonds in **41**, were designed for the automated synthesis of **41**. Especially, fucosyl phosphate **39** was selected based on the solution study; this donor showed excellent selectivity in constructing the difficult α(1–2)-*cis* and α(1–3)-*cis* fucose linkages common to the Lewis antigens. The octanediol linker was attached to the resin by an ester linkage that is cleaved by nucleophilic bases such as NaOMe. Fmoc was used as the temporary protecting group for hydroxyls not only because it is quite stable under the glycosylation conditions and easily cleaved by the non-nucleophilic amines, but also it facilitates the qualitative evaluation of the efficiency for each glycosylation and deprotection cycle by monitoring the UV/Vis of the dibenzofurubene derivative after deprotection; this monitoring method is especially valuable for the automated synthesis. For the branching linkage of **38**, levulinoyl ester, being cleaved by hydrazine treatment, was chosen as another temporary protection group for elongation of sugar-chains. General automated cycles involve (i) glycosylation by activating the phosphate donors with TMSOTf in CH_2Cl_2 at $-15\,^{\circ}C$ and (ii) selective removal of temporary protecting groups, Fmoc by 20% piperidine in DMF, and the levulinoyl group by 10% hydrazine in DMF, as shown in *Scheme 11*. If the glycosylation was not completed by the dibenzofurubene UV analysis, another cycle of glycosylation was performed, i. e., double glycosylation. Importantly, a series of washing steps was performed after each deprotection to swell the resin and purge any remaining basic materials for the next glycosylation cycles. At the end of the synthesis, the product was cleaved from the resin by treatment with 10 equivalents of NaOMe in MeOH/CH_2Cl_2, and by this automated method, **41** was produced in 6.5% overall yield in as short as 23 hours. Further improvements of the automated synthesis might allow everyone, even nonchemists, to prepare complex and biologically relevant oligosaccharides, similar to the peptide and nucleotide synthesizers, which will speed up the elucidation of their biological functions as well as clinical applications of oligosaccharide-based vaccines.

2.3 Solid-Phase Methods for Purification of Synthesized Oligosaccharides

The isolation of products is sometimes a tedious and time-consuming procedure. Especially in the area of combinatorial synthesis of oligosaccharides either in solution or on solid-phase, a simple and effective isolation method is necessary because many compounds are handled at the same time. For instance, chromatography is a quite popular method for isolation of the products of organic synthesis. However, it is somewhat tedious and consumes a considerable amount of solvents, and optimization of the separation conditions sometimes requires much time. Therefore, techniques for polymer-supported purification such as “catch-and-release”

purification methods, polymer-bound reagents, and scavenger resins, have been developed. Fukase and co-workers have developed the 4-azido-3-chlorobenzyl (ClAzb) group not only as a safety catch-type protection group of hydroxyls but also as a tag for catch-and-release purification (*Scheme 12*) [40,41]. A desired compound possessing the ClAzb group can be selectively caught by a solid-supported phosphine by the specific reaction between the azido function and the phosphine, and the product on the polymer-support was separated from the other compounds simply by rinsing. The desired compound was then released by treatment with DDQ (*Scheme 12*). A glucose acceptor bound to a macroporous polystyrene (ArgoPore^{TM}-NH_2) **42** was glycosylated with thioglycoside **43** using NBS and $Sn(OTf)_2$ in the presence of MS4A to give a mixture of disaccharide **44** and unreacted **42**. The resin was treated with NaOMe in MeOH to cleave the linker, and a mixture of disaccharide **45**, monosaccharide **46**, and other by-products was obtained. The mixture was treated with triphenylphosphine-(polyethyleneglycol-polystyrene-copolymer) resin in MeOH and the resulting solid-supported disaccharide **47** was treated with DDQ. With this procedure, a highly pure disaccharide **48** was obtained in 38% yield from **42**.

Ito and co-workers have combined soluble polymer-supported synthesis with the catch-and-release protocol using the chloroacetyl (ClAc) tag (*Scheme 13*) [42,43,44]. A glucosamine acceptor bound to a low molecular weight poly(ethylene)glycol (PEG) **49** was glycosylated with a thiogalactoside donor **50** in the presence of dimethyl(methylthio)sulfonium triflate (DMTST) in CH_2Cl_2 to provide the disaccharide **51** in 94% yield. **51** was then successfully captured by the Fmoc-cystein-loaded Wang resin at the ClAc tag in the presence of diisopropylethylamine. After washing the resin, **52** was released from the resin by Fmoc-deprotection with 4-(aminomethyl)piperidine followed by spontaneous intramolecular cyclization to afford **53** with excellent purity (82% for two steps). The reduction of the nitro group of the PEG linker to amine by reaction with acetylacetone and Zn/Cu, followed by acetylation and DDQ oxidation gave the disaccharide **54** in 86% yield for two steps.

The idea of "catch-and-release" was applied to the solid-phase synthesis of α-linked trimannose **61** by Guo and co-workers (*Scheme 14*) [45]. The mannose acceptor **55**, loaded on the PEG-grafted polystyrene via an amide linkage, was glycosylated twice with the mannosyl trichloroacetimidate donors by using TMSOTf as an activator in CH_2Cl_2, i. e., firstly with **56** and secondly with **57** bearing the ester (precursor of carboxylate) group as a tag. After cleavage from the resin and hydrolysis of the ester-tag under basic conditions (NaOMe, CH_2Cl_2/MeOH, and then NaOH, THF/MeOH), a trimannose derivative **58** was efficiently caught out from mono-, di-, and other by-products by the amino-functionalized "fishing" resin **59** by acylation. The pure compound **61** was then released from the solid-support by the treatment of **60** with TFA.

On the other hand, an efficient polymer-assisted method for deprotection of the protected oligosaccharides has been demonstrated by Takahashi and co-workers (*Scheme 15*) [46]. The deprotection of the synthesized oligosaccharides, including the cleavage of various *O*-protecting groups and the replacement of *N*-protecting groups with an *N*-acetyl group is sometimes troublesome under the standard conditions. Furthermore, the complete deprotection of the synthesized oligosaccharides frequently requires careful selection of the reaction solvents to prevent the partially deprotected intermediates from precipitating. They first loaded the synthesized oligosaccharide **62** to the aminomethyl ArgoPore through a tetrahydropyranyl (THP) linker. The protected oligosaccharide on polymer-support **63** thus obtained was subject-

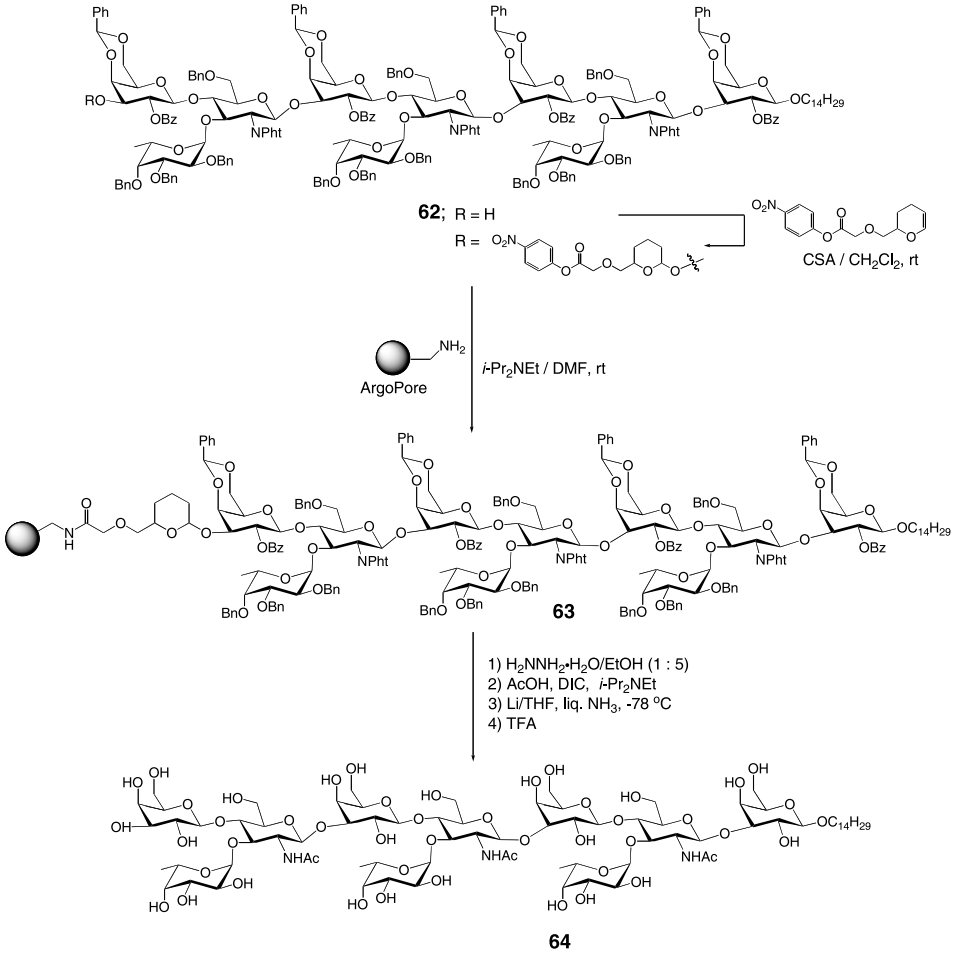
ed to (i) deprotection of *N*-phthalimide groups by hydrazine, (ii) acetylation of the resulting free amino groups, (iii) removal of the benzyl groups by Birch reduction, and (iv) deprotection of 4,6-*O*-benzylidene acetal groups and simultaneous cleavage from the THP linker by TFA, to provide the fully deprotected trimeric Lewis X epitope **64** in 58% overall yield from **62**. Although loading and release of the synthesized oligosaccharides might be accompanied by slight loss of the materials, this method allows the practical library synthesis of complex oligosaccharides.

The polymer-supported methods for removal of the unreacted acceptors during the glycosylation process also provide rapid access to automated synthesis and the parallel library synthesis of oligosaccharides. Ley and co-workers applied the polymer-supported tosyl chloride (PS-TsCl) to remove the hydroxyl-containing contaminants, including the acceptors [47].



Scheme 15

The unreacted acceptor was also sequestered and recovered by Dondoni and Massi based on catch-and-release protocols [48]. By this method, the hydroxyls of the unreacted acceptors were reacted with the trichloroacetyl isocyanate under neutral conditions, and the resulting trichloroacetyl carbamates (urethanes) were extracted by the highly basic and non-nucleophilic polymer-supported BEMP (2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine on polystyrene) by making use of the strong ionic interactions. The pure acceptor was released from the resin by KOH treatment and used again for glycosylation. Seeberger and co-workers have successfully used two capping methods to remove the unreacted acceptors during their automated synthesis of oligosaccharides (*Scheme 16*, and see *Sect. 2.2*) [49]. Both 2-azido-2-methylpropionic acid anhydride **65** (A-tag) and (heptadecafluorodecyl)diisopropylsilyl triflate **66** (F-tag) were applied to cap the hydroxyls of unre-

acted glycosyl acceptors during each incomplete glycosylation step. At the end of the synthesis, the tagged compounds were efficiently removed after the cleavage from the resin by cross metathesis with ethylene. For the A-tag, the azide moiety was reduced by tributyl phosphine and the resulting amino-derivative was fished out by an isocyanate silica gel scavenging resin. On the other hand, the F-tagged compounds were removed by column chromatography packed with tridecafluoro($Si(CH_2CH_2C_6F_{13})_3$)-functionalized silica gel. By this method, they successfully simplified the purification process for the automated synthesis of β-linked (1–6)-triglucose and α-linked (1–2)-mannose.

2.4 Monitoring of Solid-Phase Reactions

Real-time monitoring of the polymer-supported reaction is nearly impossible by simple and routine methods such as TLC and HPLC. In the case of solid-phase peptide synthesis, the end of the reaction can be readily checked by the ninhydrin test. In the solid-phase synthesis of oligosaccharides, a convenient method for checking the hydroxyl group on the polymer support has not been developed yet. In most cases, the reaction is checked after small-scale cleavage of the products. If the Fmoc protecting group is used, the efficiency in glycosylation and deprotection on the resins can be evaluated by UV absorption of dibenzofurubene derivatives when it is deprotected by the mild bases, such as piperidine or Et_3N.

Recent advances in NMR have proven to be effective for direct and nondestructive monitoring of the progress in oligosaccharide synthesis. Wong and Kanie used the inverse gated decoupling technique of ^{13}C NMR to monitor the glycosylations on the TentaGel resin, in which two ^{13}C-enriched carbonyl tags were introduced both on the glycine linker as an internal standard and on the acetyl protecting group of the introducing glycosyl donors [50]. Sialy Lewis X branched tetrasaccharide was synthesized by this monitoring method.

In a similar way, Kihlberg and co-workers have applied the ^{19}F-tag both on the linker and the protecting groups, i. e., *p*-fluorinated benzyl ethers, benzoates, and benzylidene acetals of the glycosyl reagents (❯ *Scheme 17*) [51,52,53]. The gel-phase ^{19}F NMR allowed highly sensitive, simple, and quantitative analysis of the oligosaccharide assembly via continuous glycosylation and deprotection process on the resin. ArgoGel resin with a 3-fluoro-4-hydroxymethyloxybenzamide linker was esterified with glucosyl derivative **67**, which was protected with two *o*-fluorobenzoates and 4,6-*O*-*p*-fluorobenzylidene acetal. The loading yield was easily evaluated based on the integration of the resonances from the fluorine atoms in the linker ($\delta = -134.4$ ppm), the 4,6-*O*-*p*-F-benzylidene acetal group (–113.2 ppm), and two *o*-F-benzoyl groups (–109.0 and -110.1 ppm). Followed by the reductive opening of the 4,6-*O*-*p*-F-benzylidene acetal group by $NaCNBH_3$ in the presence of HCl gas, the acceptor **68** was glycosylated with thiogalactoside **69** and subsequently with **70**, each bearing the fluorine tag in different positions of the 4,6-*O*-benzylidene acetal groups, i. e., either ortho- ($\delta = -120.9$ ppm) or meta-positions ($\delta = -113.9$ ppm) of the aromatic groups. The sequence of reactions provided the trisaccharide **71**, α-Gal epitope (Galα(1–3)Galβ(1–4)Glc), which is responsible for hyperacute rejection in xenotransplantation of porcine organs. Each step was evaluated to proceed quantitatively based on this ^{19}F NMR analysis.

Ito and co-workers have developed a practical and convenient method for the real-time monitoring of solid-phase oligosaccharide synthesis based on the “on-resin color tests”,

which enable side-by-side detection of glycoside bond formation and acceptor consumption (◉ *Scheme 18*) [54]. They used two color test systems: the modified Taddei's test with the cyanuric chloride-Disperse Red conjugate **78** was applied for detection of the presence of nucleophilic free hydroxyl and amino groups on the resin, whereas the chloroacetyl (ClAc) group was used as a "temporary" hydroxyl protecting group, which can be detected by a red color generated by the action of *p*-nitrobenzylpyridine (PNBP) **79** under basic conditions. On the basis of these monitoring methods, the repeating units of the immuno-active oligosaccharide schizophyllan was synthesized (◉ *Scheme 18*). The TentaGel-loaded acceptor **72**, which is negative for the PNBP test and positive for the Disperse Red test, was glycosylated with 3- and 6-*O*-ClAc-protected trichloroacetimidate **73** in the presence of BF_3OEt_2 in CH_2Cl_2 to provide β(1–3)-linked disaccharide **74**. The completion of the reaction was easily checked by the positive response for the PNBP test and the negative response for the Disperse Red test. After the selective deprotection of the ClAc group by hydrazinedithiocarbonate treatment, the free hydroxyls at 3′- and 6′-positions were subjected to further glycosylation with glucosyl trichloroacetimidate **75** to give resin-bound tetrasaccharide **76**, which was easily detected by the deep red color for the PNBP test.

3 Polymer-Supported and Tag-Assisted Oligosaccharide Synthesis in Solution

A phase tag strategy has been developed for high-throughput synthesis as a hybrid system that combines the merits of solid-phase synthesis (easy separation) and solution-phase synthesis (homogeneous reaction conditions). In this strategy, a compound having a tag group is easily separated from untagged molecules. Various phase tags such as soluble polymers, fluorous, hydrophobic, and basic tags have been reported.

3.1 Polymer-Supported Synthesis of Oligosaccharides

Polymer-supported solution synthesis has several advantages over solid-phase synthesis. The reaction can be carried out in solution and the solubility of the reactants allows reaction kinetics and anomeric stereocontrol similar to those observed in solution chemistry. Furthermore, in some cases, the process of the reaction can be easily checked by the conventional TLC or MALDI-TOF-MS. Out of a large number of polymer-supported syntheses so far reported, polyethylene glycol monomethyl ether (MPEG) has been widely used for oligosaccharide synthesis [55,56]. Polyethylene glycol is soluble in a variety of solvents such as CH_2Cl_2 and the protic solvents but insoluble in diethyl ether. The polymer-bound products are therefore isolated by precipitating the polyethylene glycol supports using ether. Martin-Lomas and co-workers have succeeded in the synthesis of heparin-like oligosaccharide **86** using both MPEG as a soluble polymer support and Merrifield-type resin (polyethylene glycol-grafted polystyrene) as a solid-support used for scavenging the unreacted acceptors (◉ *Scheme 19*) [57,58]. The disaccharide acceptor **80** bound to MPEG through a succinic ester linkage at the uronic acid carboxylate, was glycosylated with the trichloroacetimidate donor 81 acceptor **81** in the presence of TMSOTf to provide the α(1–4)-linked tetrasaccharide **82** with complete stereoselectivity. This glycosylation step was followed by capping with the Merrifield-type resin **83** functional-

ized with carboxylic acid in order to esterify the unreacted C4-hydroxyl group of the acceptor **80**. The outcome of the α-stereoselectivity and the ensuring glycosylation could directly be monitored by NMR. Removal of the benzylidene acetal group of **82** by EtSH in the presence of *p*-TsOH, benzoylation of the C6-hydroxyl, a second glycosylation with **84**, and capping of the unreacted acceptor **82** with scavenger resin **83** provided the key intermediate **85**, which was successfully transformed to hexasaccharide **86**.

Ito and co-workers have reported the MPEG-supported synthesis of the trisaccharide **90**, the outer branching fragment of the tetraantennary complex-type glycan chain, by applying the self-cleavable Wang resin-type linker (*Scheme 20*) [59]. The mannosyl acceptor **87** loaded on the MPEG was glycosylated with the lactosamine-derived trichloroacetimidate **88** by using TMSOTf, providing β-glycoside **89** in 77% yield. MPEG-bound trisaccharide **89** was then treated with $Sn(SPh)_2$ in the presence of thiophenol to release **90** from the soluble-support via selective reduction of the nitro group followed by spontaneous intramolecular cyclization.

A simple formylacetal (CH_2) has also been used as a linker for oligosaccharide synthesis on MPEG. This small linker allows the hindered hydroxyls, such as the 4-hydroxy group of glucose, to be installed on the MPEG [60]. The formylacetal linker is stable under the acidic conditions mostly used for glycosylation, but it is readily cleaved by Lewis acids (TMSI or $Ce(OTf)_x$) or trifluoroacetic acid. A simplified work-up and purification procedure was also reported by use of the solid acid catalyst.

3.2 Tag-Assisted Synthesis of Oligosaccharides

Tag-assisted methods in solution-phase, other than MPEG supports, have also emerged as an attractive strategy for combinatorial and/or high-throughput synthesis of oligosaccharides. A highly fluorinated compound is soluble in fluorous solvents such as perfluorohexane, and is readily separated from nonfluorinated compounds through simple fluorous-organic solvent partitioning. Therefore, the fluorous synthesis is an attractive alternative to solid-phase synthesis, directed towards combinatorial chemistry and parallel synthesis. Although several fluorous protecting groups are reported for this purpose, their application is limited to the synthesis of simple small molecules because the fluorine content in each fluorous protecting group is low [61]. Inazu and co-workers have developed fluorous tags with high fluorine content and applied them to oligosaccharide synthesis (*Scheme 21*) [62,63]. They initially investigated the Bfp-OH tag (bisfluorous chain type propanoyl), which was introduced at three of four hydroxyls on the glycosyl acceptors for the synthesis of a simple tetrasaccharide as well as the Gb3 oligosaccharide. Later, the Hfb-OH tag (hexakisfluorous chain type butanoyl) with more fluorous chains was designed in order to enhance the efficiency in fluorous extraction; a rapid synthesis of trisaccharide **97** was achieved by introducing only one fluorous tag (*Scheme 21*). The Hfb tag was first attached to the anomeric hydroxyl of the glucose derivative **91** by using PyBOP and DMAP, and the deprotection of the TBDPS group by HF-pyridine in THF provided the glucose acceptor **92**. Compound **92** was then glycosylated with glucosyl trichloroacetimidate **93** by using TMSOTf in a mixed solvent of $EtOC_4F_9$ and Et_2O to provide disaccharide **94**. The fluorous tag-containing **94** was extracted with the fluorous solvent FC-72 by partitioning the product mixtures between FC-72 and an organic solvent. No additional purification, such as silica gel chromatography, was carried out. After removing the TBDPS group of **94** with HF-pyridine treatment in THF, the second glycosylation was performed with **95** to provide trisaccharide **96** after the partitioning by the fluorous/organic solvents. Finally, the Hfb group of **96** was removed by the treatment with NaOMe in $EtOC_4F_9$/MeOH to afford the crude **97**, which was extracted into the MeOH layer from the partitioning mixture of CF-72 and MeOH. By this method, pure **97** was obtained in 67% yield from **91** after silica gel chromatography, while the methyl ester derivative of the Hfb-OH tag, which was extracted into the CF-72 layer during the partitioning process, was collected and reused after hydrolysis with NaOH.

Fukase and co-workers have developed a concept termed "Synthesis based on Affinity Separation (SAS)", in which the desired tagged compound is separated from the reaction mixture by solid-phase extraction using specific molecular recognition (*Scheme 22*) [64,65,66,67]. They first employed the interaction between a crown ether (32-crown-10) as a tag on the desired compounds and the ammonium ion for SAS. After each reaction cycle, the reaction mixture was applied to the column loaded with aminomethylated polystyrene resin [trifluoroacetic acid (TFA) form]. By using nonpolar eluents such as CH_2Cl_2 and toluene, the tagged compound was selectively absorbed on the column, whereas other untagged impurities were washed off. Subsequent desorption by CH_2Cl_2-Et_3N or CH_2Cl_2-MeOH (1:1) afforded the desired compound with high purity. However, since the crown ether tag needed to be prepared by the tedious synthesis, the commercially available short-chain polyethylene glycol (PEG) was used as the second-generation tag. Since Triton X-100 is a detergent having a PEG chain and a hydrophobic moiety, the tagged compounds show good solubility in many organic sol-

vents. However, the chain length of Triton X-100 is heterogeneous and Triton X-100 with the shorter chain length only showed weak binding. A podand-type ether with a pseudo-benzo-31-crown-10 structure, introduced as the third generation tag, was much easier to synthesize and found to show high affinity to the ammonium ion on the solid-support [67]. The present SAS method has been successfully applied to oligosaccharide synthesis (*Scheme 22*). The glycosylation between acceptor **98**, having the tag moiety via an acylaminobenzyl linker, and the *N*-Troc glucosamine trichloroacetimidate **99** was effected by using TMSOTf. After the affinity separation, the resulting disaccharide **100** was further subjected to glycosylation with an excess amount of the donor **99**. Although the affinity separation could not remove a small amount of the unreacted disaccharide **100** from the desired trisaccharide **101** (since both bear the tag moieties), subsequent separation by silica-gel column chromatography afforded pure **101** in 61% yield from **100**. Cleavage of the acylaminobenzyl linker in **101** was achieved by treatment with excess DDQ followed by the affinity column separation to provide the pure trisaccharide **102** in 82% yield.

Alternatively, Rademann and co-workers have combined solid-phase and solution-phase reactions for the synthesis of oligosaccharides by using the hydrophobic tag, a concept called "Hydrophobically Assisted Switching Synthesis (HASP)" (*Scheme 23*) [68,69]. They applied a sufficiently long, double C18-hydrocarbon chain **103** as a fully reversible tag for the reactions both in solution and on the solid-support. The hydrophobic tag was introduced to the anomeric position of L-rhamnose, and α(1–2)-selective glycosylation was conducted first in solution (CH_2Cl_2) with rhamnosyl trichloroacetimidate **104** in the presence of TMSOTf as a Lewis acid (quantitative yield). The C-18 silica support was then added to the reaction mixture, solvents were evaporated, and all untagged materials were easily removed by washing with MeOH/H_2O. After the 2-*O*-phenoxyacetyl group was deprotected on the solid-support by the reaction with NaOMe in MeOH/H_2O (92%) followed by the washing step, a sufficiently pure compound was released from the solid-support by addition of $MgSO_4$ and eluting by CH_2Cl_2. After the HASP cycle was repeated a few times, the 3,4-*O*-butane-2,3-diacetal protecting group was removed by TFA. Finally, hydrogenation provided α(1–2)-liked oligorhamnose **105**, with an average yield of 94% per step. Each reaction could be directly followed by TLC and MS for this HASP method.

3.3 Polymer-Supported Enzymatic Synthesis of Oligosaccharides

Since the chemical synthesis of oligosaccharides requires many synthetic steps including protection and deprotection procedures, the enzymatic approach has attracted much attention for the rapid synthesis of oligosaccharides. In addition, the perfect regio- and stereoselectivities of enzymatic methods with glycosyltransferases are quite attractive. Several transferases such as β(1,4)-galactosyltransferase, α(1,3)-fucosyltransferase, and α-sialyltransferase have been used for polymer-supported enzymatic synthesis [70,71,72,73,74,75]. The selection of the polymer support is very important for the polymer-supported enzymatic synthesis of oligosaccharides.

Nishimura and co-workers have developed the catch-and-release strategy between solid-phase and water-soluble polymer supports, the so called "polymer blotting method", which allows for the rapid and efficient synthesis of glycopeptides [76]. The method involves (i) conven-

tional solid-phase synthesis of glycopeptides that contain mono-, di-, and tri-saccharides on Thr or Ser residues and Blase (glutamic acid specific protease)-sensitive amino acid sequence, (ii) removal of the protecting groups and release from the resin, (iii) attachment of the released glycopeptides to the water-soluble polymers via an oxime anchor, (iv) sugar elongations using glycosyltransferases, and (v) cleavage of the desired glycopeptides from the soluble supports by Blase mediated hydrolysis. They have applied three glycosyltransferases, namely, β(1,4)-galactosyltransferase, α(2,3)-(*O*)-sialyltransferase, and α(2,3)-(*N*)-sialyltransferase, and successfully prepared six kinds of parallel and 36 kinds of combinatorial libraries of MUC1 mucin glycopeptides. Applications of the method to other glycopeptides have also been reported (see Chap. 5.4).

Wong and co-workers investigated enzymatic oligosaccharide synthesis on a thermo-responsible polymer support (*Scheme 24*) [77]. The copolymers of *N*-*i*-propylacrylamide (NIPAm) and functionalized monomers are thermo-responsible and exhibit inverse temperature-dependent solubility in water; they are soluble in cold water but become insoluble and precipitate from the solution when the temperature is higher than their lower critical solution temperature. The NIPAm polymer-support greatly simplified the purification process for oligosaccharide synthesis in water; carbohydrate acceptors attached to the NIPAm support were used for enzymatic glycosylation, and the glycosylation products can be isolated simply by thermal precipitation and centrifugation. The availability of direct NMR analysis also makes the method attractive. Galactosylation of the immobilized GlcNAc **106** was performed by using 100 mU bovine milk β(1,4)-galactosyltransferase with 1 equivalent of UDP-galactose donor in *N*-(2-hydroxyethyl)-piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) buffer at pH 7.4. Followed by the precipitation of the product by heating the solution to 55 °C, it was further fucosylated using the bovine α(1,3)-fucosyl transferase and GDP-fucose donor. After cleavage from the NIPAm support by CAN treatment, the trisaccharide Le^X **107** was obtained in 60% yield for three steps without chromatographic separation of the intermediates. They also have immobilized several enzymes on the same NIPAm polymers, such as subtilisin BPN′, which were found to show comparable activities to their soluble forms. For example, after the NIPAm-subtilisin conjugate was used for proteolysis of a modified form of the glycoprotein ribonuclease (RNase B), the immobilized enzyme can be easily recovered for reuse by gentle heating and precipitation. The methods are expected to be applied to glycosyltransferases and this thermo-responsible polymer-supported procedure will greatly facilitate enzyme-catalyzed organic synthesis.

3.4 Microfluidic Methods for Oligosaccharides Synthesis

Continuous flow synthesis using a microfluidic system has emerged as an innovative technology in organic synthesis, i. e., from small-scale optimization of the reaction conditions, high-throughput synthesis, to large-scale production. This method has various advantages in terms of reaction control, such as fast mixing, effective temperature control, and precise residence time control. Since the reaction can be performed under the flow process, the method is readily applicable to library construction by preparing the stock solutions of glycosyl acceptors and donors and flowing each by each through syringe- or HPLC-pumps. On the other hand, once the reaction conditions are optimized for small-scale operation, the same condi-

tions are directly applied to large-scale synthesis, i. e., for process synthesis on an industrial scale, by using several microreactors under the flow process. Seeberger and co-workers reported the first application of the microfluidic system to optimize the glycosylation on an analytical scale [78]. The reaction performed in a microreactor was monitored by HPLC, which is directly connected to the microreactor. The products composition was analyzed by changing the concentration, reaction time, and temperature; the optimal conditions for α-mannosylation and the different reactivity due to the protection patterns of acceptors have been determined.

Fukase and co-workers have combined a microreactor and their SAS protocol (Synthesis based on Affinity Separation, ❯ *Sect. 3.2*) in pursuit of high-throughput oligosaccharide synthesis (❯ *Fig. 2*) [67]. They used a combination of an IMM micromixer and a stainless tube reactor, equipped with a stainless column as an affinity separation unit. The glycosylation was carried out in the micromixer by combining the CH_2Cl_2 solution of acceptor **108** and donor **109** with the solution of TMSOTf in CH_2Cl_2 under continuous flow. The mixture was directly introduced to the stainless steal affinity column and the flow channel was switched to wash the column with CH_2Cl_2. The desired disaccharide **110** was trapped in the column, but then eluted with CH_2Cl_2-MeOH (1:1); the product **110** was obtained in 91% yield.

A successful α-sialylation under microfluidic conditions has also been reported by the same group; the reactivity was totally different from that observed under the batch conditions [79]. The highly reactive sialyl donor developed in this laboratory, bearing the *N*5-phthalyl group and the *N*-phenyl trifluoroacetimidate leaving group [80], could not be used for large-scale α-sialylation with a galactose acceptor in a batch apparatus. Because of inadequate mixing and inefficient heat transfer under the batch conditions, the exposure of the reactive sialyl donor to Lewis acid mainly leads to glycal formation. They have circumvented these problems by using microfluidic systems and realized quantitative α-sialylation with perfect α-selectivity, even at a large-scale. The increase in yield was also observed with the lactose acceptors under the microfluidic α-sialylation.

These leading examples will not only open up a new path to high-throughput and combinatorial library syntheses, favorably by combination with the programmed automation of glycosylation-analysis sequences, but also provide new insights into the reactivity of glycosylation. Once an oligosaccharide of biological relevance has been found from the microfluidic reactions, it will be provided at an industrial-scale by the same apparatus [81].

4 Conclusions

Synthetic oligosaccharides and glycoconjugates often play a decisive role in elucidation of their biofunctions, since chemical synthesis can provide homogeneous preparations without contamination of other bioactive compounds. For the clinical application, the use of synthetic specimens is also important to avoid side-effects due to possible contamination. Although oligosaccharide synthesis has seen dramatic developments as described above, a high level of technical expertise is still required. Further improvement of oligosaccharide synthesis is expected to establish general and efficient methods, which will speed up elucidation of the biological functions of oligosaccharides as well as clinical applications of oligosaccharide-based drugs.

5.6 Stereoselective Synthesis of *β-manno*-Glycosides

Akihiro Ishiwata, *Yukishige Ito*
RIKEN (The Institute of Physical and Chemical Research),
Saitama 351–0198, Japan
yukito@riken.jp

Abstract

Among the various types of *O*-glycosides with biological relevance, the β-glycoside of D-mannose (*β-manno*-glycoside) has been considered as one of the most challenging targets from a synthetic point of view. The majority of synthetic approaches to *β-manno*-glycoside can be put into two categories (the direct glycosylation and the glycosylation-inversion approaches). Additionally, a variety of intriguing approaches have been investigated with substantial success (alkylative glycosylation of 1,2-stannylene acetal, reductive manipulation of orthoester, intramolecular aglycon delivery, and enzymatic glycosylation). In this chapter, progress in the conceptually demanding β-mannosylation technology will be discussed, including current state of the art, with particular focus upon applications related to the synthesis of glycoprotein-related oligosaccharides.

Keywords

Mannose; Glycoprotein; Glycosylation; Stereoselective

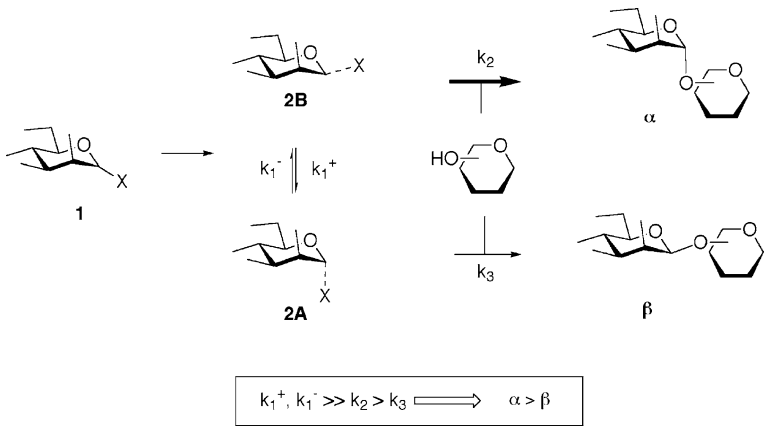
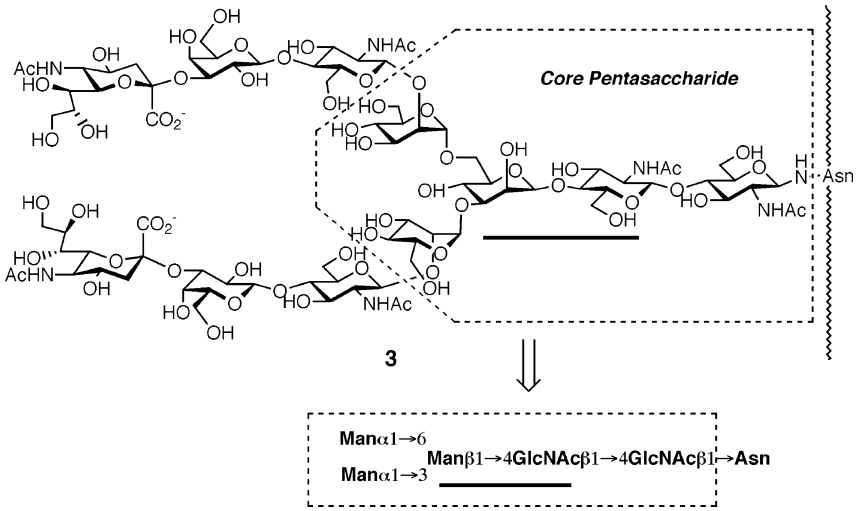
1 Introduction

In the last three decades or so, various types of so-called modern glycosylation reactions have been developed, which can be clearly distinguished from the classical methods [1]. These reactions utilize glycosyl donors **1** [X = F, $OC(NH)CCl_3$, SR, S(O)Ph, $OP(OR)_2$, etc.], which are relatively stable but can be activated into highly reactive glycosylating entities, under mild reaction conditions. For example, glycosyl fluorides, which used to attract little attention in synthetic carbohydrate chemistry, have proved to be powerful glycosyl donors, once exposed to appropriate activation conditions [2]. Likewise, thioglycosides [3] and trichloroacetimidates [4] have gained solid reputations as highly versatile glycosyl donors in oligosaccharide synthesis. The combination of these methodologies allows us to design synthetic routes to even more highly complex oligosaccharide structures [5]. However, these methodologies are still not free of stereochemical problems in a general sense.

Among the various types of *O*-glycosides with biological relevance, the β-glycoside of D-mannose (β-*manno*-glycoside) has been considered as one of the most challenging targets from a synthetic point of view [6]. This difficulty arises from its unique stereochemical array at the *C*-1/2 positions which is addressed in the simplified reaction pathway of *O*-glycosylation depicted in ❯ *Scheme 1*. Starting from the glycosyl donor **1**, expulsion of the leaving group **X** generates an oxocarbenium ion-like species, which usually exists as a rapidly equilibrating mixture of α- (**2A**) and β- (**2B**) ion pairs. Since the pseudo-axially oriented **2A** is more stabilized by the anomeric effect [6,7], **2B** preferentially reacts with an aglycon to give the α-glycoside as a major product, provided that the equilibration between **2A** and **2B** is rapid



Scheme 1

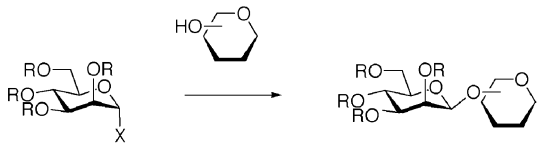


Scheme 2

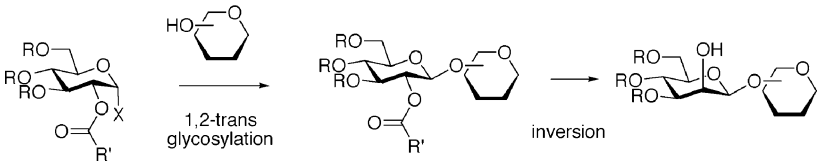
enough. Additionally, β-*manno*-glycoside has a 1,2-*cis* relative stereochemistry, formation of which cannot be effected by neighboring group participation of the *C*-2 substituent.

The biological importance of β-*manno*-glycoside is obvious from its widespread occurrence in glycoproteins [8]. Namely, all types of asparagine (Asn)-linked glycoprotein oligosaccharides have a so-called "core" pentasaccharide which includes β-configurated mannose (β-Man) linked to the 4-position of *N*-acetylglucosamine (GlcNAc), as can be seen in the undecasaccharide **3**, which is a typical complex type oligosaccharide (*Scheme 2*). Therefore, in order to pursue synthetic approaches to glycoproteins and related molecules, the stereocontrolled synthesis of β-Man is a fundamental requirement.

Direct Glycosylation Approach



Glycosylation-Inversion Approach



Scheme 3

The majority of synthetic approaches to β-*manno*-glycoside can be put into one of two categories (Scheme 3). Schematically, the most straightforward is the direct glycosylation approach using the mannosyl donor. Since the formation of β-*manno*-glycoside is disfavored under normal conditions (see above), a promoter possessing a special property in combination with a certain type of leaving group is required for its synthesis.

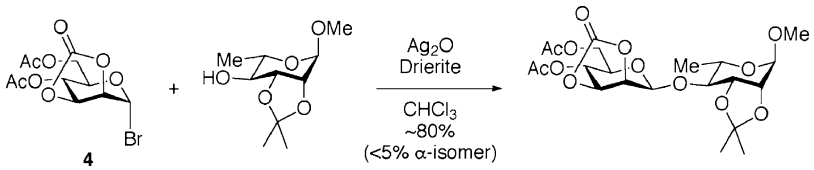
In a general sense, the more predictable tactic has been the glycosylation-inversion approach, which consists of β-gluco(1,2-*trans*)-glycosylation followed by the inversion of *C*-2 stereochemistry through oxidation-reduction or by an S_N2-type reaction.

Additionally, a variety of intriguing approaches have been investigated with substantial success [9,10,11,12,13].

In this chapter, progress in the conceptually demanding β-mannosylation technology will be discussed, including current state of the art, with particular focus upon applications related to the synthesis of glycoprotein-related oligosaccharides.

2 Direct Glycosylation Approach

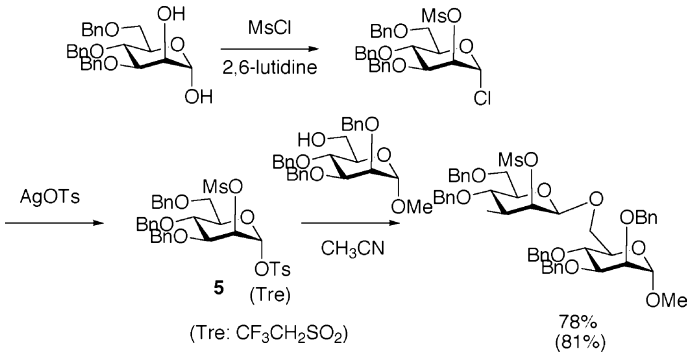
Direct β-selective glycosylation was achieved as early as 1961 by Gorin and Perlinupon, using the bromide **4** [14]. In this case, silver oxide was used as the promoter and the presence of the 2,3-di-*O*-carbonyl group seems to be the critical feature for a successful β-selective reaction. The same donor was used in a more efficient manner by Bebault and Dutton to prepare β-Man1→4Rha, which corresponds to the disaccharide segment of a constituent of the *Salmonella* type D_2 and E cell surfaces [15] (Scheme 4).



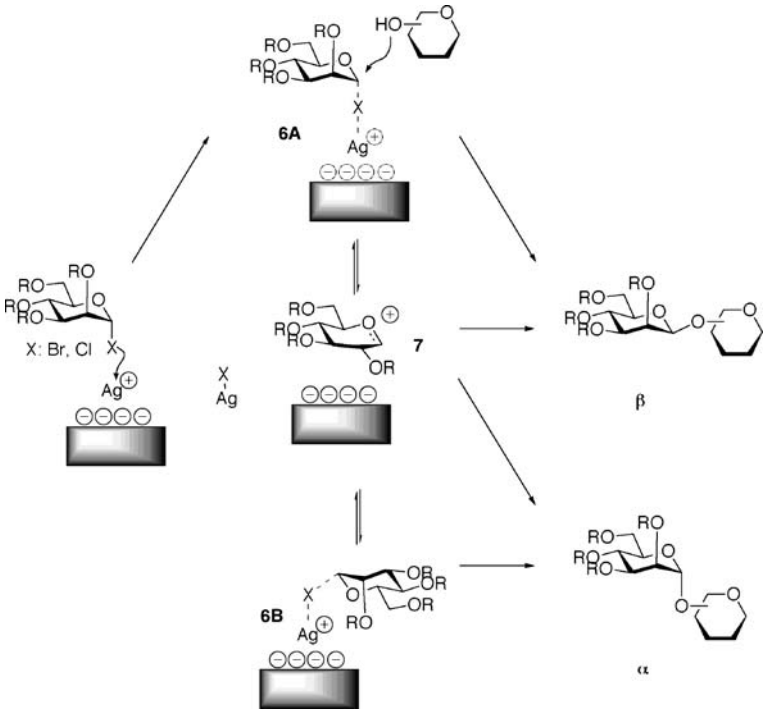
Scheme 4

S_N2-type conditions were investigated by Srivastava and Shuerch [16], who used the 2-*O*-mesyl-protected glycosyl sulfonate **5** (Scheme 5). The reactions were performed in acetonitrile without any promoter. The presence of the strongly electron-withdrawing mesyl group at *C*-2 seems to be essential. The corresponding 2-*O*-benzoate gave an α-linked product exclusively, presumably due to the neighboring effect of the benzoyl group. Although this method gave quite satisfactory results when applied to reactive acceptors, its further applicability to more challenging structures has not been demonstrated. A potential drawback from the practical point of view would be the conditions required for deprotection of the mesyl group (Na/liq NH_3).

As a more generally useful methodology, the direct β-mannosylation can be effected by a combination of a mannosyl halide with an "insoluble" silver salt [6]. The selectivity can



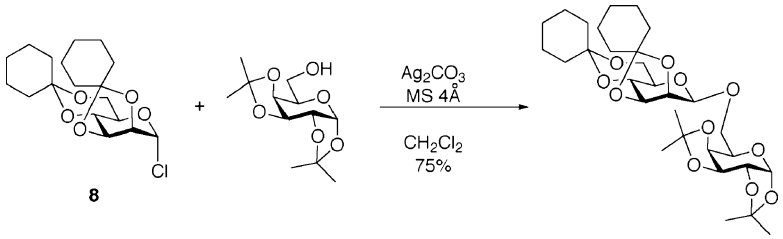
Scheme 5



Scheme 6

be explained by the mechanism depicted in *Scheme 6*. Thus, the surface-bound, activated bromide **6A** is attacked by the hydroxy group in an S_N2-like fashion. Under these conditions, stereochemical scrambling of the anomeric center to give **6B** via the free carbenium ion **7** can be minimized and inversion of configuration predominates in the glycosylation reaction.

For example, Garegg and Iversen demonstrated that Ag_2CO_3 was effective for the activation of mannosyl chloride **8** having 2,3–4,6-di-*O*-cyclohexylidene protection [17]. Reaction with



Scheme 7

a primary alcohol gave β-glycoside in high yield (*Scheme 7*). However, only poor results were obtained when this strategy was applied to the glycosylation of a secondary alcohol. Since the Ag_2CO_3-mediated glycosylation inevitably generates water as it proceeds, this reagent may not be optimal as a promoter.

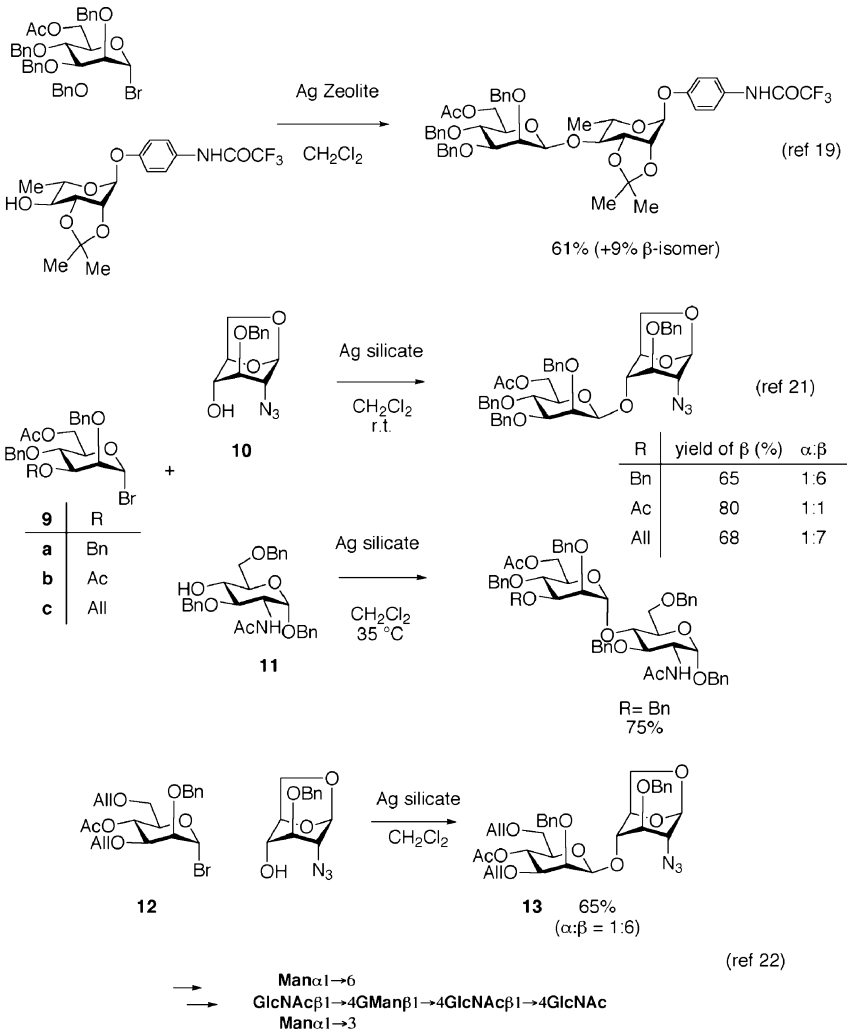
More widely used promoters for this purpose are silver zeolite and silver silicate, which were developed by Paulsen [18] and Garegg [19], respectively. Although not being commercially available, these reagents can be conveniently prepared from silver nitrate and proved to be quite powerful. More recently, van Boeckel developed the use of silver silica-alumina, which was reported to be more reactive than other insoluble salts and to have an enhanced cation capacity [20]. Representative examples of successful β-mannosylation by using insoluble salts are depicted in *Scheme 8* [19,21,22].

As can be expected from the proposed mechanism (*Scheme 6*), the stereoselectivity of insoluble silver salt-mediated reactions is quite sensitive to the steric hindrance of the acceptor. In those cases where the OH group is not sufficiently reactive, the surface-bound glycosyl donor is liberated into the solution to give the more reactive oxocarbenium ion **7**, which reacts in a manner that favors the formation of the undesired α-glycoside. Alternatively, reassociation with the negatively charged surface gives a mixture of α- and β-ion pairs (**6A** and **6B**) and subsequent reaction with the alcohol proceeds in a non-selective manner.

This aspect was very clearly demonstrated by a series of reactions performed by Paulsen et al. [19,20,21,22,23,24,25], in the course of their synthetic studies on Asn-linked oligosaccharides (*Scheme 8*). When using the bromide **9a**, the high selectivity (α:β = 1:7) obtained by reaction with **10** completely disappeared when **11** was used as an acceptor. It should be noted that, having a fixed $^1C_4$ conformation, the OH group of **10** has a reduced steric hindrance compared to that in **11**. The slightly modified donor **12** afforded a similar result (α:β = 1:6) and the β-linked disaccharide product **13** was converted into the bisecting GlcNAc-containing hexasaccharide.

Ogawa and coworkers have also extensively described synthetic studies on glycoprotein oligosaccharides and mannose-containing glycosphingolipids using similar reactions [26,27,28,29] (*Scheme 9*). For instance, the reaction of **14** with disaccharide **15** afforded **16** (α:β = 1.1:1), which was used as the key intermediate in their first chemical synthesis of a sialic acid-containing complex-type undecasaccharide [30].

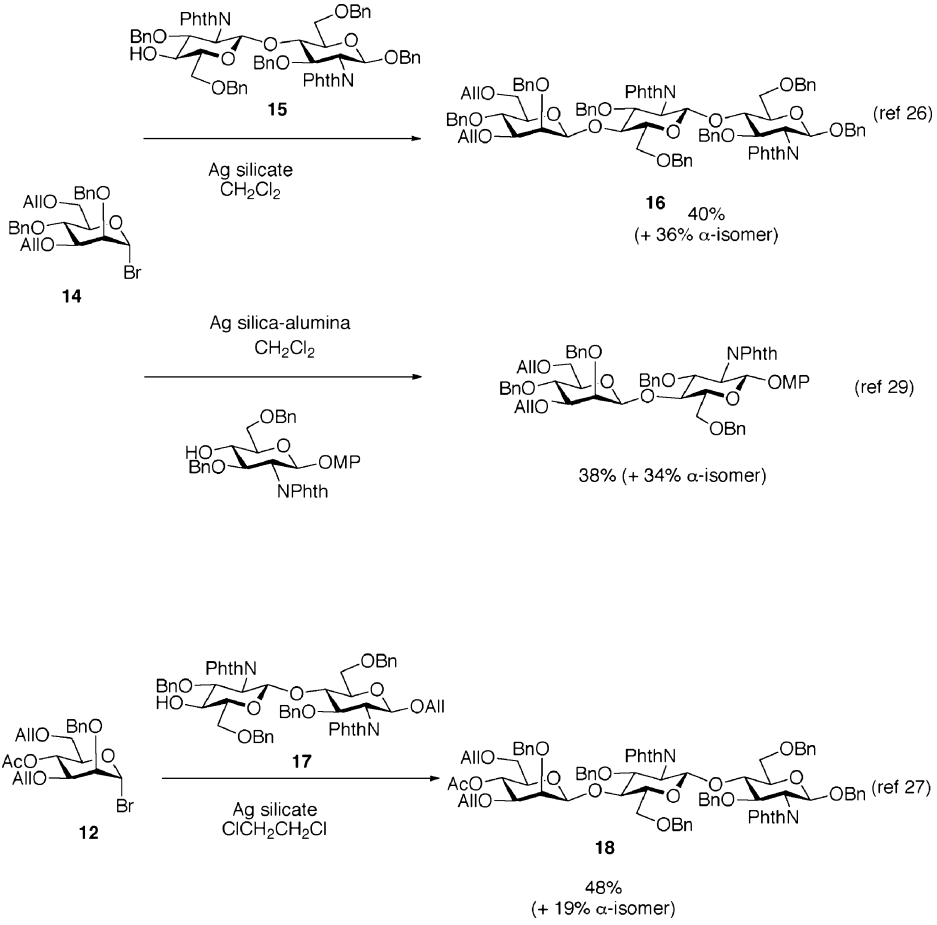
The stereoselectivity of the insoluble silver salt-mediated glycosylation is also affected by the protecting groups on the glycosyl donor. It is well known that the reactivity of the glycosyl donor is enhanced as the number of ether-type protecting groups (i. e. benzyl, allyl,



Scheme 8

etc.) increases, while the ester-type (i. e. acetyl, benzoyl, etc.) group deactivates the glycosyl donor [6,31]. Since the successful β-mannosylation requires a rapid nucleophilic displacement (see *Scheme 6*), it can be anticipated that a mannosyl donor having an acyl protecting group should be less β-selective. In fact, the mannosyl bromide **9b** having two acetyl groups was shown to give nearly equal amounts of α- and β-linked disaccharides, in sharp contrast to the reaction using **9a** [21] (see *Scheme 8*).

The effect of the electron-withdrawing acyl group on the stereoselectivity seems to be position-dependent. Systematic studies by van Boeckel and coworkers revealed an interesting effect of the acyl group in the variously protected mannosyl bromide **19** [32] (*Scheme 10*). Compared



Scheme 9

to the tri-*O*-benzyl-protected bromide (entry 2), β-selectivity increased from 6:1 to 9:1 when an additional acetyl group was introduced at the 4-position (entry 4), while a 3-*O*-acetylated donor gave no stereoselectivity (entry 1). This effect was also confirmed by Ogawa et al., who demonstrated that the 4-*O*-Ac carrying bromide **12** gives a significant level of β-selectivity (β:α = 2.5:1), even when applied to the sterically hindered acceptor **17** [27] (see *Scheme 9*). The resultant trisaccharide **18** was converted into the octasaccharide which has a bisecting GlcNAc as well as a fucose residue linked to the innermost GlcNAc.

An even more impressive result was reported by Takeda and coworkers [33] (*Scheme 11*). In their synthetic studies on the spermatozoa-derived glycolipid, the disaccharide donor **20** was coupled with **21** by the action of silver silicate. The reaction proceeded in a remarkably selective manner (α:β = 1:7) to afford the desired disaccharide in 70% yield. This is one of a very few examples of the direct formation of a β-*manno*-glycoside using an oligosaccharide

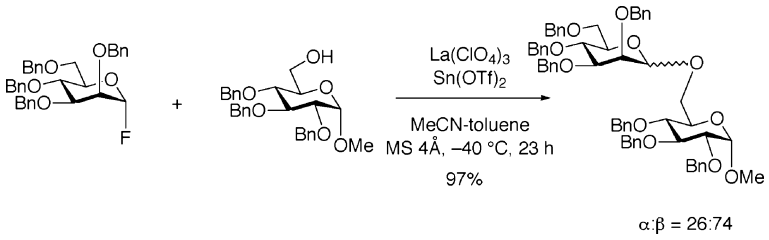
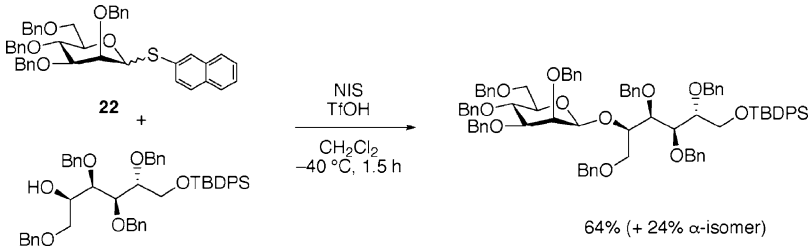
donor and nicely underscores the beneficial effect of the 4-*O*-Ac group. In this particular case, silver zeolite gave significantly better results as compared to silver silicate (α:β = 1:2.7).
The insoluble silver salt method was also applied to the β-selective syntheses of gluco, galacto, 2-deoxy-2-azido, and 2-deoxy glycosides [34,35,36].
Toshima and coworkers reported a novel type of insoluble promoter (SO_4-ZrO_2) which is effective for the modestly selective synthesis of β-*manno*-glycoside from the fluoride [37] (● *Scheme 12*). Interestingly, the β-selectivity observed in diethyl ether was completely lost when the reaction was performed in acetonitrile which gives the α-glycoside with high selectivity. It should be noticed that the usually observed directing effects of diethyl ether and acetonitrile are reversed in this particular system.
A partially successful β-mannosylation with a fluoride was also reported by Shibasaki and coworkers [38]. As depicted in ● *Scheme 13*, $La(ClO_4)_3$-$Sn(OTf)_2$ was effective, promoting the reaction with a primary alcohol in a β-selective manner (α:β = ~1:3).



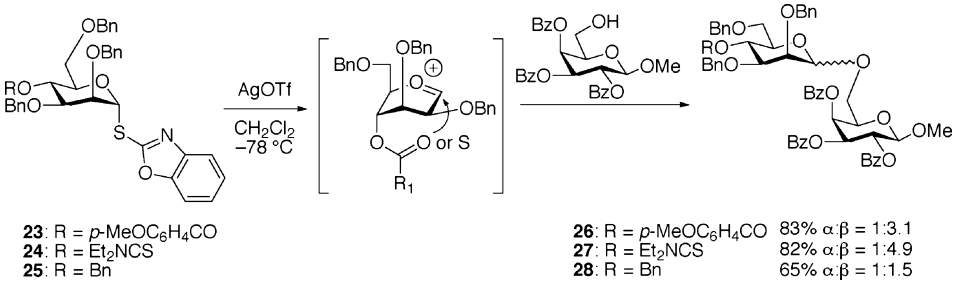
● Scheme 13

Tatsuta and Yasuda reported the interesting use of the naphthylthio glycoside **22** which gives the β-manno isomer stereoselectively, by the action of NIS-TfOH [39] (● *Scheme 14*). The origin of this selectivity still awaits clarification by further systematic investigations.



● Scheme 14

Demchenko et al. developed 1-*S*-benzoxazolyl (SBox) mannoside **23**–**25** as potent donors for the synthesis of β-mannoside [40]. They demonstrated that an acyl or thiocarbamoyl group at the *C*-4 position gave a favorable effect, possibly by participating to the *C*-1 position. Nucleophilic attachment of an acceptor occurs predominantly from the β-face [40] (● *Scheme 15*).



Scheme 15

These direct glycosylations with non-conventional donors have so far met with only limited success. However, subtle modification of the reaction conditions might further enhance their efficiency to a generally useful level, as can be seen in the case of sulfoxide-based technology developed by Crich and coworkers.

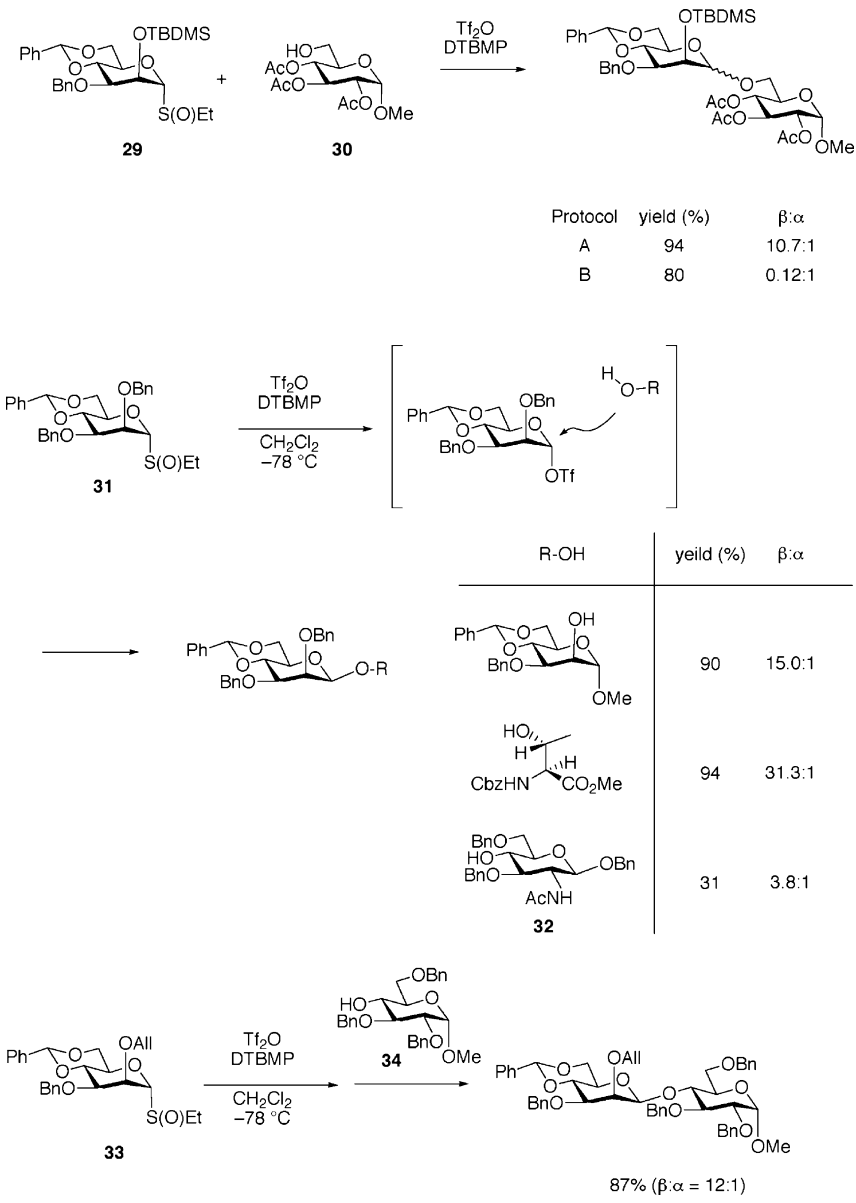
Glycosyl sulfoxide was originally developed by Kahne and proved to be an extremely powerful glycosyl donor that can be activated at low temperature by Tf_2O [41]. Initial attempts by Crich and Sun to apply this methodology to β-mannosylation were performed by using **29** in diethyl ether-benzene at −78 °C [42] (*Scheme 16*). When the acceptor **30** was added to a solution of the sulfoxide preactivated by Tf_2O and 2,6-di-*tert*-butyl-4-methylpyridine (DTBMP), the predominant formation of the β-isomer was observed (Protocol **A**). On the other hand, addition of Tf_2O to the mixture of **29**, **30**, and DTBMP afforded the α-glycoside as the major product (Protocol **B**). A higher β-selectivity was obtained when **31**, having a less bulky substituent at the 2-position, was used as a donor in dichloromethane [43] (*Scheme 16*).

The authors hypothesized the in situ formation of α-glycosyl triflate which reacts with the glycosyl acceptor in an S_N2 manner to give the β-glycoside. Although the reaction with the 4-hydroxy group of *N*-acetylglucosamine **32** proceeded with lower efficiency, the glucose-derived acceptor **34**, which is also known to be a hindered aglycon, was very successfully reacted with **33** to afford the corresponding disaccharide with an excellent β:α ratio [44]. Further transformation into the trisaccharide component of *Hyriopsis schlegelii* glycosphingolipid has been achieved.

Furthermore, these authors were also able to perform the β-mannosylations with the thioglycoside **35** under the action of PhSOTf [45] or 1-benzenesulfinyl piperidine (BSP)-Tf_2O [46] (*Scheme 17*). In the cases of both glycosyl sulfoxide and thioglycoside, protection of the 4- and 6-positions by a cyclic acetal is critical. The corresponding perbenzylated donors gave poor β-selectivity [47].

Mechanistic analysis based on the kinetic isotope effect suggested that the reaction proceeds through an oxocarbenium ion-like intermediate, such as the contact ion pair **37**, although the covalent linked α-triflate **36** was detected by NMR [48] (*Scheme 18*). They systematically investigated the effects of protective groups [49,50,51,52,53,54], including 2-*O*-propargyl ether (**38**) [52,53], and 3-*O*-1-naphthylpropargyl ether (**40**) [54] (*Scheme 19*).

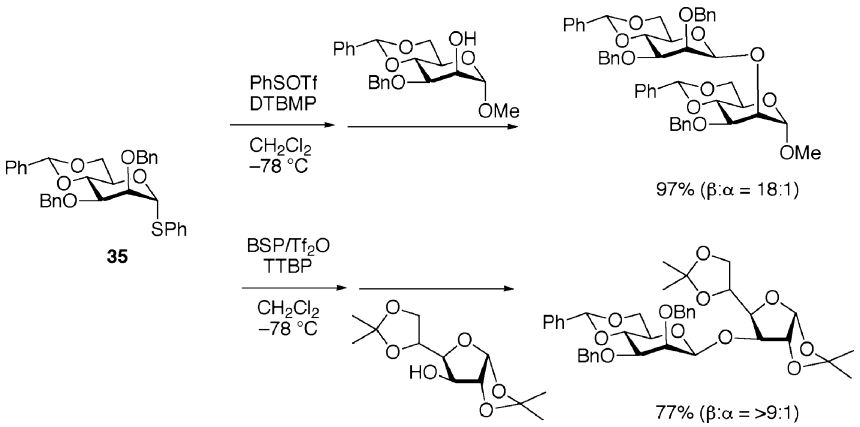
The practicality of direct glycosylation methodology was demonstrated in the context of the synthesis of β-mannan [55,56] and β-rhamnoside (6-deoxy-β-mannoside) [57,58,59]. In the latter case, a construction of the β-mannoside by the sulfoxide method was followed by



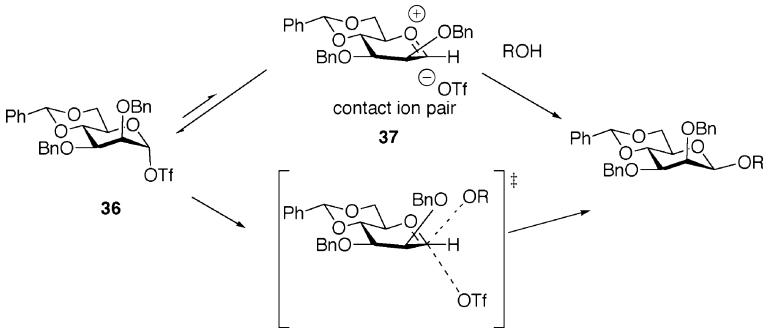
Scheme 16

reductive radical fragmentation of the 4,6-cyclic acetals. The methodology was also applied L-glycero-β-D-mannoheptopyranoside [60,61].

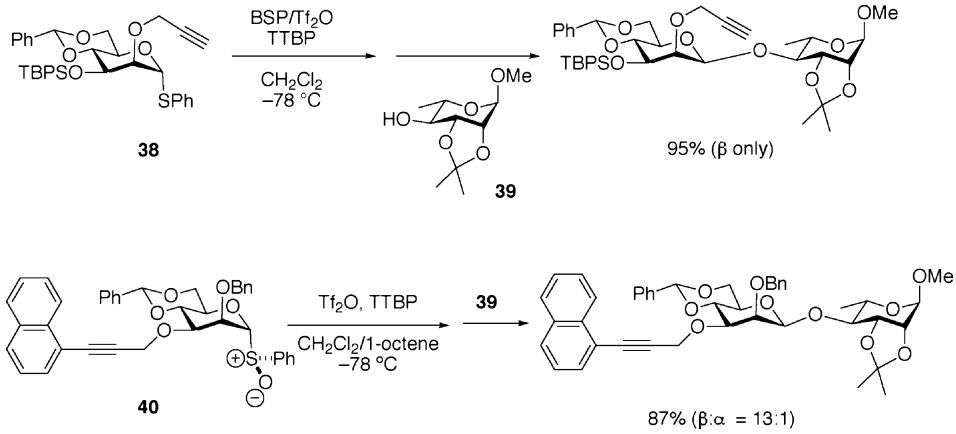
An intriguing system using mannosyl dimethylphosphinothioate **41** was developed by Inazu and coworkers [62] (*Scheme 20*). When reacted with glucose-derived acceptor **42** in the



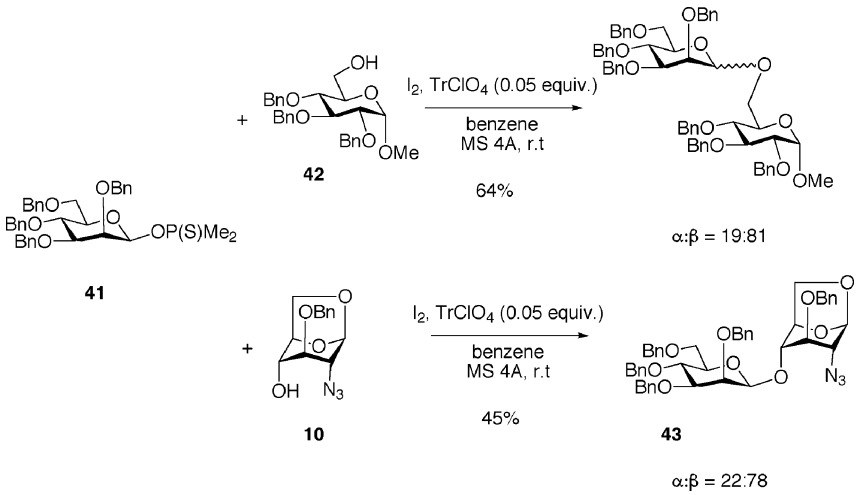
Scheme 17



Scheme 18



Scheme 19



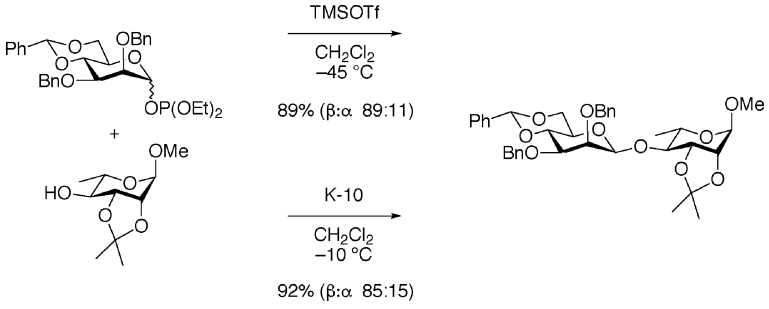
Scheme 20

presence of a catalytic amount of $TrClO_4$ together with 1 equiv. of I_2, the β-glycoside was obtained as the major isomer in a ratio of 81:19. Masked β-Man1→4GlcNAc **43** can also be prepared with a substantial level of selectivity in the same manner.

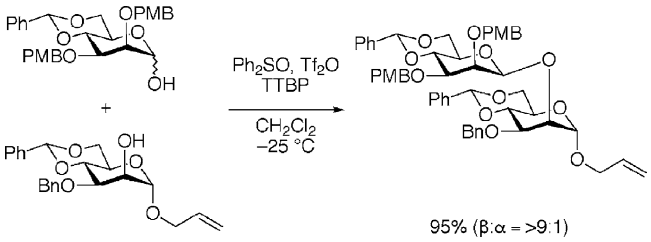
Hashimoto and coworkers successfully applied their phosphite method to selective β-mannosylation [63,64,65] (*Scheme 21*). Similar to the case of Crich's mannosylation, cyclic protection at the 4- and 6-positions is essential. Mannosyl phosphate and phosphoramidate were also investigated [65,66]. Toshima et al. used the glycosyl phosphites activated with a solid acid catalyst to give β-mannoside predominantly [67,68].

Dehydrative glycosylation, which utilizes reducing sugar as a donor, was developed by Gin et al. [69]. Seeberger et al. demonstrated that this reaction can be applied to the formation of β-mannosidic linkages [70] (*Scheme 22*).

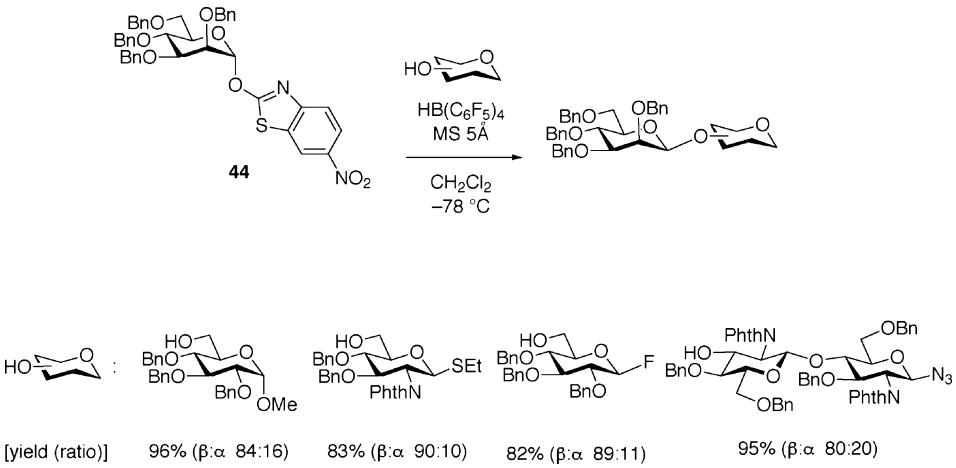
Mukaiyama et al. examined 6-nitrothiazolyl mannoside **44** as a glycosyl donor [71,72] (*Scheme 23*). They reported that in the presence of a catalytic amount of $HB(C_6F_5)_4$,



Scheme 21



Scheme 22

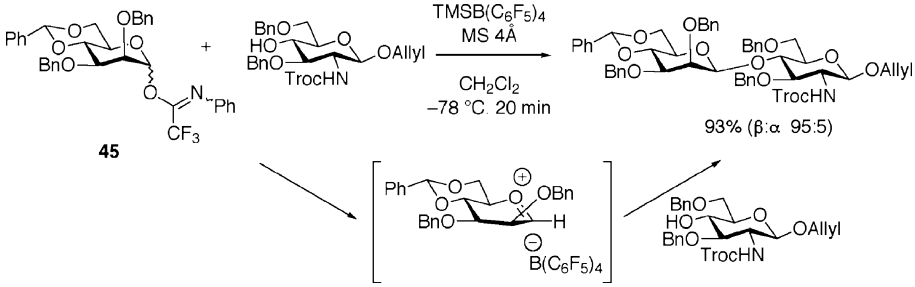


Scheme 23

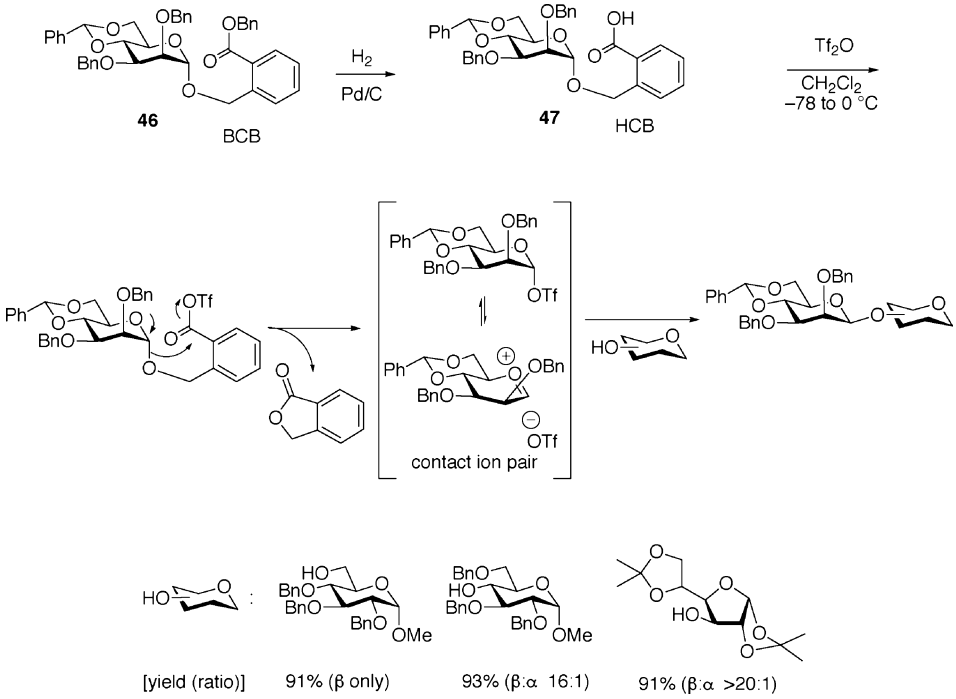
this donor gave β-mannoside in a substantially selective manner. This method was also applied to the synthesis of the core pentasaccharide of *N*-glycan [73].

Trichloroacetimidate developed by Schmidt has been recognized as one of the most powerful glycosyl donors that has ever been developed. They examined its suitability for β-mannosylation [74]. It was demonstrated that preferential β-mannoside formation was observed, when 4,6-*O*-benzylidene protection was introduced to the donor. More recently, Fukase et al. found that the β-mannoside was obtained with high stereoselectivity from the mannosyl-*N*-phenyltrifluoroacetimidate **45** by the action of a catalytic amount of $TMSB(C_6F_5)_4$, which was prepared from $AgB(C_6F_5)_4$ and TMSCl [75] (*Scheme 24*). The counter anion, $B(C_6F_5)_4^-$, would shield the α-face of the glycosyl cation, possibly due to the steric repulsion with the OBn group at the 2-position. They reported that the corresponding trichloroacetimidate gave lower selectivity.

2-(Hydroxycarbonyl)benzyl (HCB) mannoside **47**, developed by Kim et al. was shown to be a potent donor for the synthesis of β-mannosides [76]. It was generated from 2-(benzyloxycarbonyl)benzyl (BCB) derivative **46** through catalytic hydrogenolysis (*Scheme 25*).



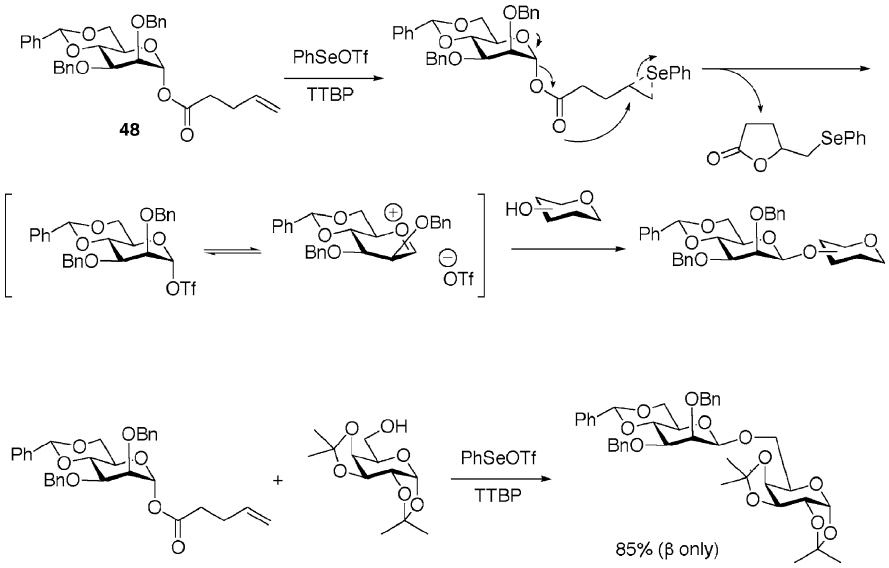
Scheme 24



Scheme 25

In a similar manner, syntheses of other types of 1,2-*cis*-glycosides, such as β-arabinofuranoside and α-galactofuranoside were achieved with high stereoselectivity [77,78].

Kunz et al. and Fraser-Reid et al. explored glycosyl pentenoate as a novel type of donor [79,80]. Kim et al. applied it to the highly stereoselective synthesis of β-mannosides [81]. In this case, mannosyl pentenoate **48** was treated with PhSeOTf [82] in the presence of 2,4,6-tri-tert-butylpyrimidine (TTBP) (*Scheme 26*).



Scheme 26

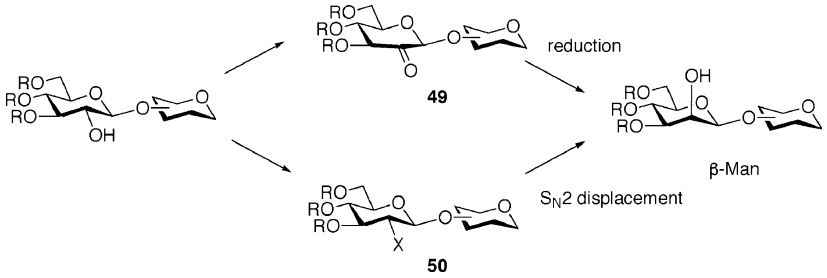
3 *C*-2 Inversion Approach

3.1 Reduction of 2-Oxo Sugars

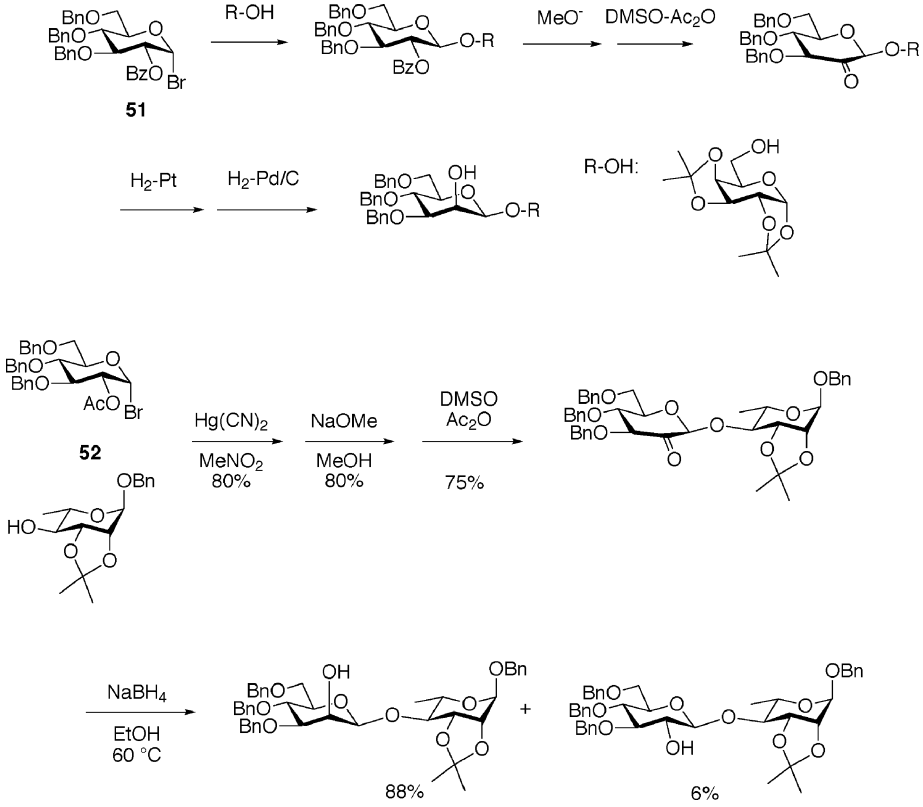
Since the β-gluco glycoside can be readily synthesized stereoselectively [6], the use of an initial glycosylation product having this configuration as a precursor of β-*manno*-glycoside is a rational tactic. Two possibilities can be considered to achieve the overall transformation of a gluco- into a *manno*-isomer (*Scheme 27*). The first option is oxidation-reduction in which the 2-uroside **49** is the key intermediate. The drawback of this approach would be that the stereoselectivity of the reduction step is not always perfect and the product often contains the β-D-gluco-isomer as a minor component. An alternative approach consists of derivatization of the 2-OH into certain leaving groups (X in **50**) that is to be subjected to an S_N2-type displacement by an *O*-nucleophile.

Whichever tactic is employed, the protecting groups should be strategically chosen so that the C2 position can be selectively manipulated.

Historically, the oxidation-reduction protocol was the only reliable method to prepare the β-*manno*-glycoside until the insoluble silver salt method was established. In 1972, Ekborg et al. reported the use of the 2-*O*-benzoylated glucosyl bromide **51** for this purpose [83] (*Scheme 28*). Glycosylation with diacetone galactose and selective deprotection of the 2′-position followed by DMSO oxidation afforded the 2-uroside which was reduced by hydrogenation over Pt. The use of the 1,2-*O*-orthoester for the same purpose was also reported [84].



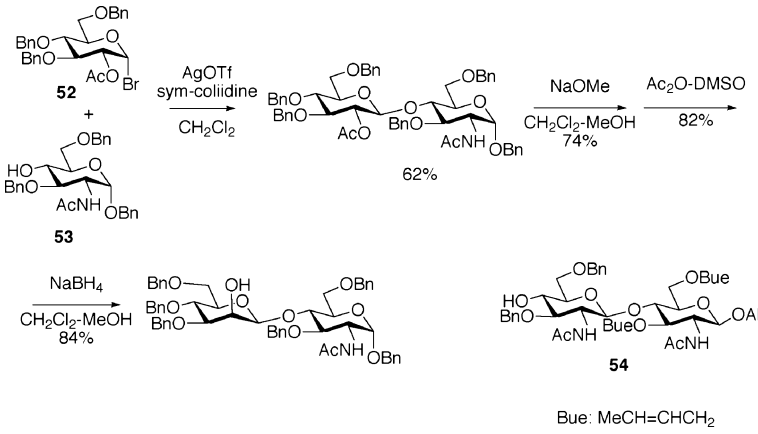
Scheme 27



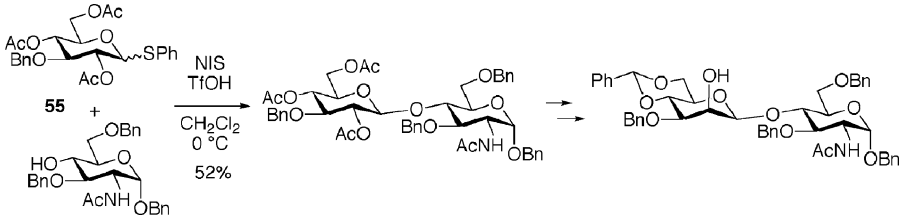
Scheme 28

Subsequently, Kochetkov used the 2-*O*-acetylated **52** and demonstrated that stereoselective reduction can be realized conveniently by $NaBH_4$ [85] (*Scheme 20*).

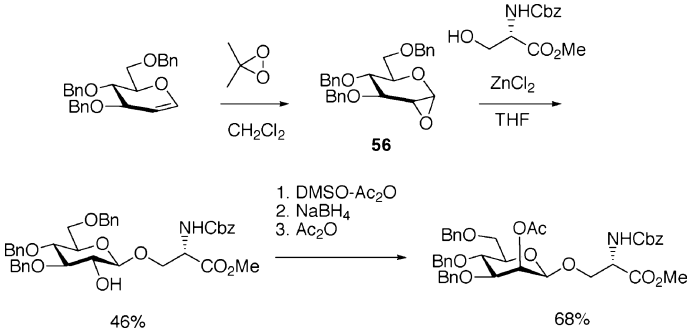
A similar strategy was used by Jeanloz and coworkers in their synthesis of the trisaccharide unit (β-Man1→4-β-GlcNAc1→4GlcNAc) of an Asn-linked oligosaccharide [86,87] (*Scheme 29*). Coupling of **52** with the mono- (**53**) and the disaccharide (**54**) acceptor afford-



Scheme 29



Scheme 30



Scheme 31

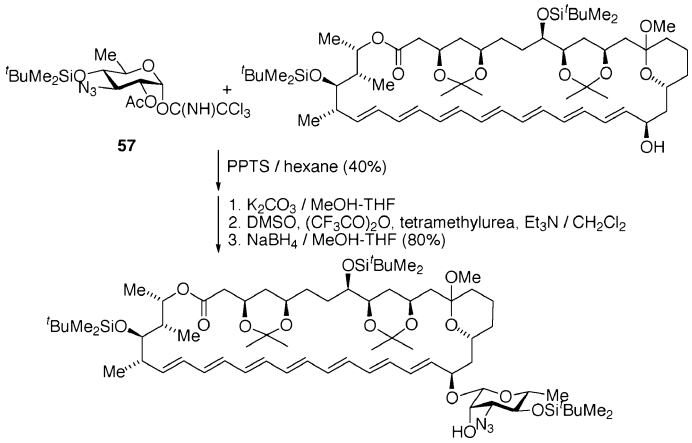
ed the corresponding β-glycosides. Subsequent oxidation and borohydride reduction afforded the β-*manno*-glycosides.

As a more recent example, Khan and Matta utilized the thioglycoside **55** [88] (*Scheme 30*). Glycosylation with the GlcNAc component was effected by NIS-TfOH.

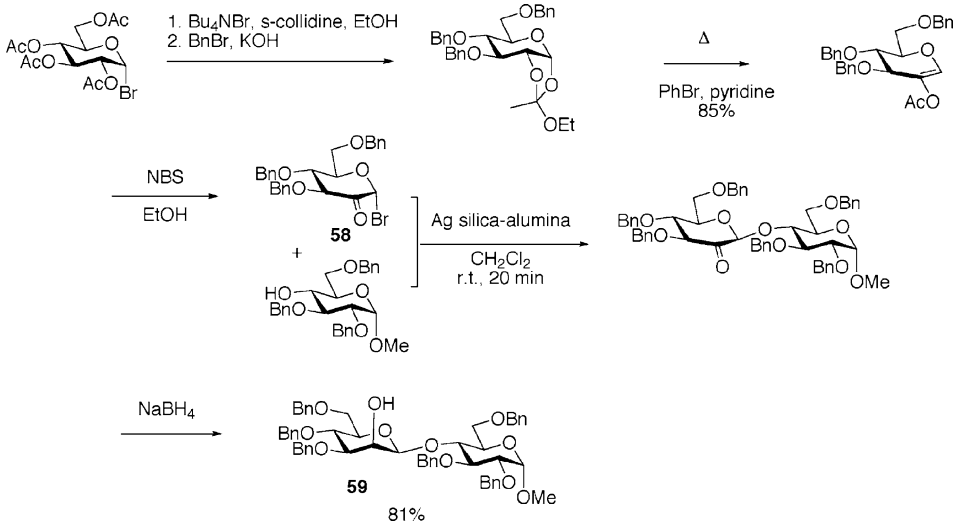
In combination with the oxidation-reduction protocol, the glycal-based oligosaccharide assembling strategy [89] which has been extensively developed by Danishefsky gives an expedient

synthetic route to β-*manno*-glycoside [90] (› *Scheme 31*). The glucal-derived 1,2-anhydro sugar **56** was coupled with a glycosyl acceptor to afford the β-glycoside that has a free 2-OH group. Subsequent transformation to the β-*manno*-glycoside was performed in a standard manner.

Fraser-Reid et al. have reported the utilization of the *n*-pentenyl orthobenzoate for the synthesis of octa-β-1,2-mannan through the repetition of β-selective glucosylation followed by the oxidation-reduction protocol [91].



Scheme 32



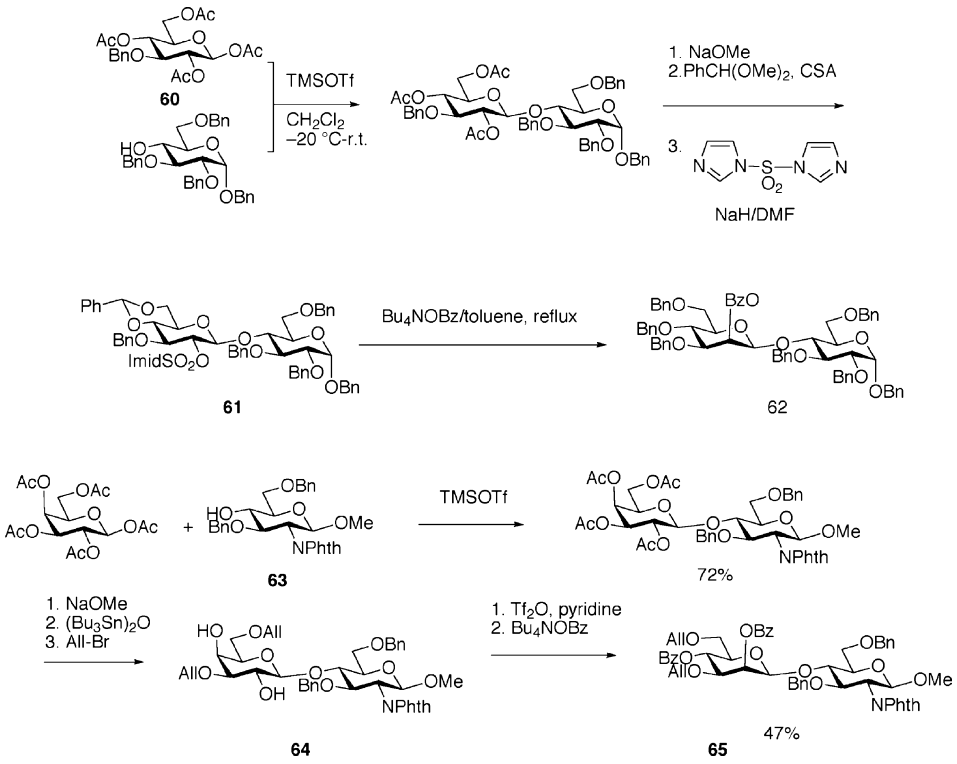
Scheme 33

In their landmark total synthesis of polyene macrolide Amphotericin B [92], Nicolaou and coworkers designed a mycosamine precursor **57** and coupled it with a highly functionalized aglycon (◉ *Scheme 32*). Inversion of the C2-OH followed by the azide reduction and deprotections competed the total synthesis.

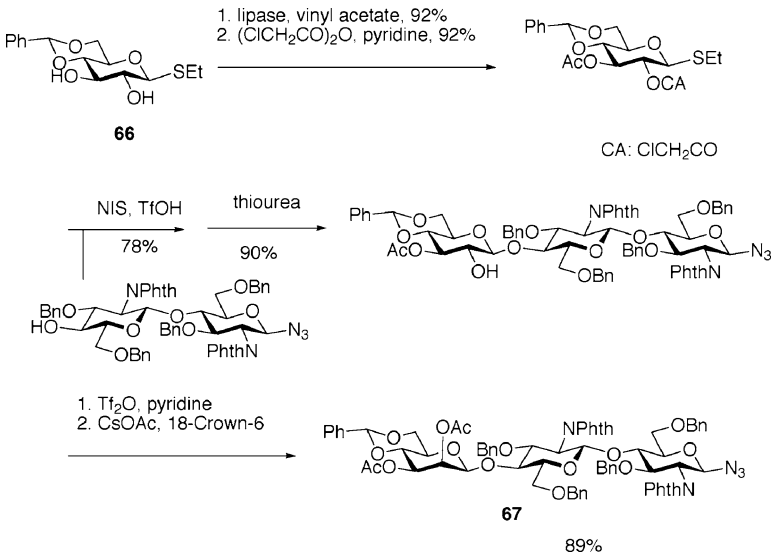
A smart variant of the oxidation-reduction approach was developed by Lichtenthaler and coworkers, who used 2-urosyl bromide as a donor [93,94,95]. On account of the α-halo ketone structure, an S_N2-like reaction at the anomeric position is facilitated. The required bromide **58** can be very conveniently prepared from acetobromoglucose (◉ *Scheme 33*). As expected, Ag salt-promoted glycosylation afforded the β-glycosides that can be reduced selectively to give the β-mannoside **59**.

3.2 S_N2-Type Inversion of the 2-Position

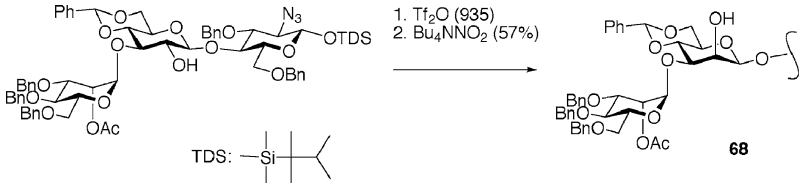
Inversion of the *C*-2 stereochemistry can be performed by S_N2-type displacement, after installing a proper leaving group at this position. In their series of publications, David and coworkers used the imidazyl and the triflate groups for this purpose in two different ways [96,97] (◉ *Scheme 34*). They used the 3-*O*-benzylated glucosyl acetate **60** as a donor



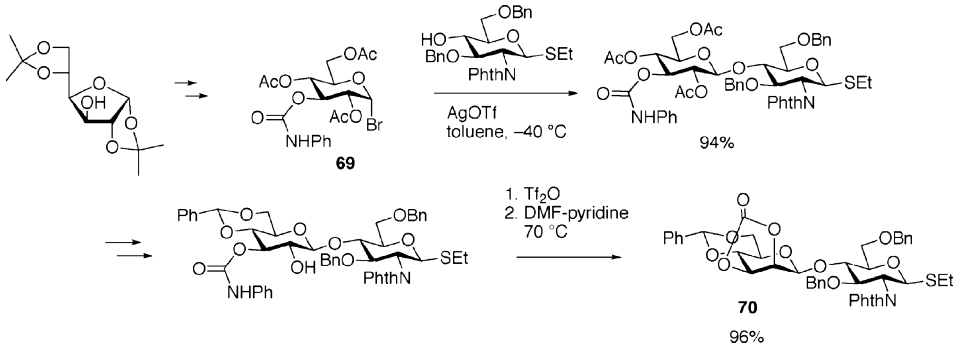
◘ **Scheme 34**



Scheme 35



Scheme 36



Scheme 37

which was coupled with an acceptor by the action of trimethylsilyl triflate (TMSOTf). Subsequent derivatization into the 4,6-*O*-benzylidene-protected 2-*O*-imidazylate **61**, followed by nucleophilic displacement with Bu_4NOBz afforded **62** in high overall yield. Alternatively, glycosylation of **63** was performed with galactose pentaacetate. Subsequent regioselective protection was achieved by using the tin oxide method to give **64**, which was transformed into the di-*O*-triflate. Treatment with Bu_4NOBz gave doubly inverted product **65**.

The double stereochemical inversion of β-Gal to β-Man, demonstrated by Sato et al., can be performed more conveniently by using a 3,6-di-*O*-pivalyl-protected 2,4-di-*O*-triflate that was treated with CsOAc to afford the β-mannoside [98].

Ajisaka et al. has developed a remarkably efficient synthetic route to the core trisaccharide of Asn-linked oligosaccharide, by the combined use of enzyme-assisted regioselective protection and glycosylation-inversion protocols [99]. Thus, starting from the 4,6-*O*-benzylidene-protected thioglycoside **66**, transformation into the 3-*O*-acetate was achieved in high yield by using lipase from *Pseudomonas fluorescens* (Amano AK^{TM}) in the presence of vinyl acetate. Chloroacetylation, glycosylation with a chitobiose derivative, deprotection of the 2-position and triflation and S_N2 inversion with CsOAc in the presence of 18-crown-6 gave **67** (*Scheme 35*).

Schmidt reported the versatile strategy for the synthesis of complex type, Asn-linked oligosaccharides in which the core trisaccharide **68** was prepared as depicted in *Scheme 36*. In their case, inversion of the *C*-2 position was performed by using Bu_4NNO_2 as a nucleophile [100].

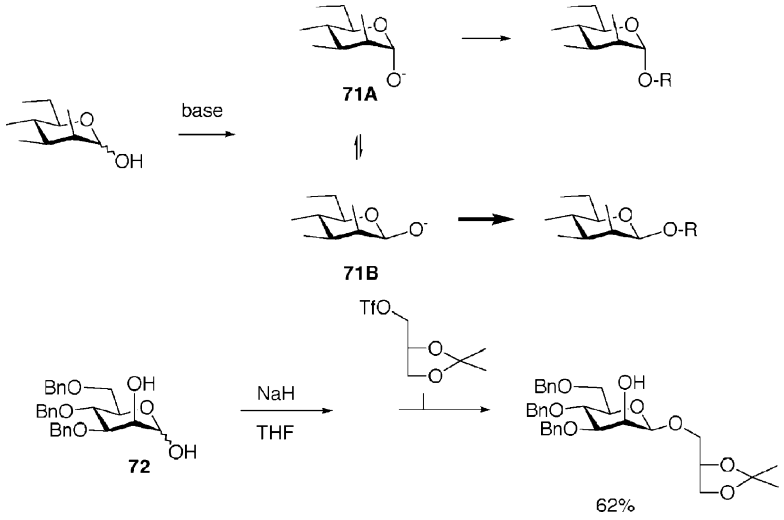
Gunther and Kunz developed a highly efficient, intramolecular S_N2-type reaction for the conversion of β-glucoside into a β-mannoside [101,102] (*Scheme 37*). Starting with glucosyl donor **69** equipped with a 3-*O*-phenylcarbamoyl group, the 1,2-*trans* glycoside was prepared. Further transformation into the corresponding 2-*O*-triflate was followed by heating to 70 °C in DMF-pyridine, which afforded the β-mannoside **70** after acidic work-up. Application of this highly efficient protocol to various types of Asn-linked oligosaccharides was extensively investigated by Unverzagt [103,104,105,106,107,108,109].

4 Other Approaches

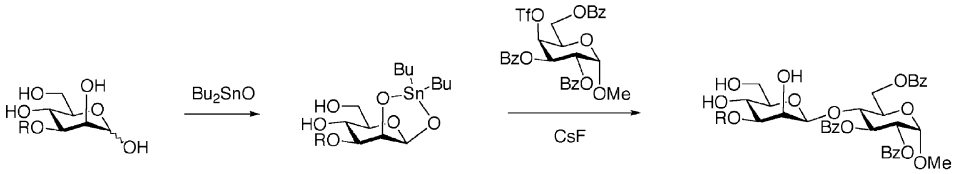
4.1 *O*-Alkylation Method

Stereochemical control in *O*-alkylative β-glycosylation relies on the kinetic anomeric effect [110]; namely, that the oxyanion derived from a reducing sugar is more reactive in its β-oriented form **71B** than the corresponding α-anion **71A** which should be more abundant. This tactic has met with partial success in cases of reactive substrate [111] (*Scheme 38*). For example, reaction of **72** with a primary triflate in THF in the presence of NaH afforded the β-glycoside in 62% yield.

Srivastava and Schuerch [112] and Dessings et al. [113]. reported on the potential utility of 1,2-*O*-stannylene acetals in β-*manno*-glycoside synthesis. Recently, Hodosi and Kovác established a highly efficient β-mannosylation process involving alkylation of a 1,2-*O*-stannylene acetal with the triflate derived from an aglycon [114] (*Scheme 39*). A remarkable feature of this method is its extreme simplicity. Even free mannose can be used as a precursor of



Scheme 38



73	R
a	H
b	Bn

74	R	solvent	yield (%)
a	H	DMSO	59
b	Bn	DMF	67

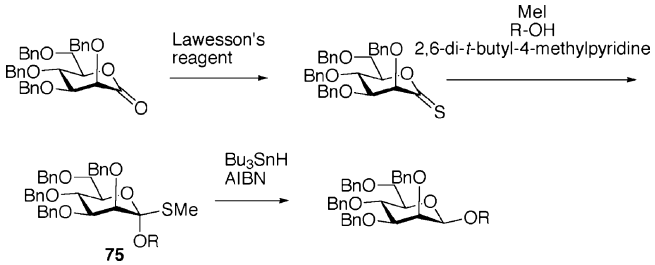
Scheme 39

stannylene acetal which was reacted with galactose 4-*O*-triflate to give the β1→4-linked disaccharide **74a**. However, a significantly higher yield was obtained by using the 3-*O*-protected mannose **73b**, because stannylene acetal migration (from 1,2- to 2,3-positions) can be blocked in this way [115]. Undoubtedly, this method can be seen as one of the most practical and efficient methods for the synthesis of β-*manno*-glycoside.

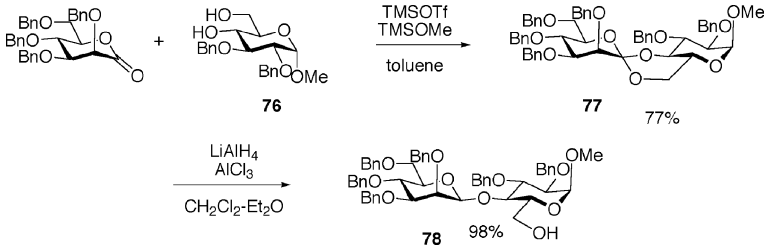
4.2 Reduction of the Anomeric Position

Reductions at anomeric positions, both by ionic and radical mechanisms, deliver hydrogen from the axial direction. Kahne prepared the hemithio orthoester **75** from thiolactone and subjected it to tin hydride reduction, which resulted in predominant formation of the β-glycoside [116] (*Scheme 40*).

A similar concept was applied for the synthesis of 2-deoxy-β-glycoside where Barton reductive decarboxylation was utilized as the key transformation [117].



Scheme 40



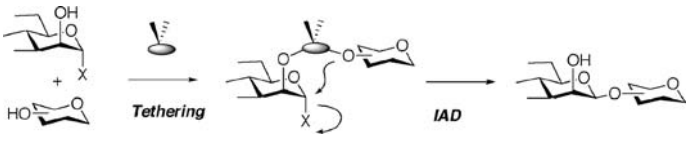
Scheme 41

Iimori et al. reported the metal hydride reduction of glycosylidene acetals (anomeric orthoesters), which constitutes an efficient synthetic strategy well-suited for the β-Man1→4Glc (and probably β-Man1→4GlcNAc) linkage (*Scheme 41*). The required compound **77** was prepared from the lactone by treatment with TMSOTf and TMSOMe in the presence of diol **76** [118,119]. Reductive opening of the orthoester was effected by $LiAlH_4$-$AlCl_3$ to afford **78** almost quantitatively. The reaction was remarkably stereo-and regioselective, and the formation of either the corresponding α-isomer or the 1→6-linked disaccharide was not detected [120,121].

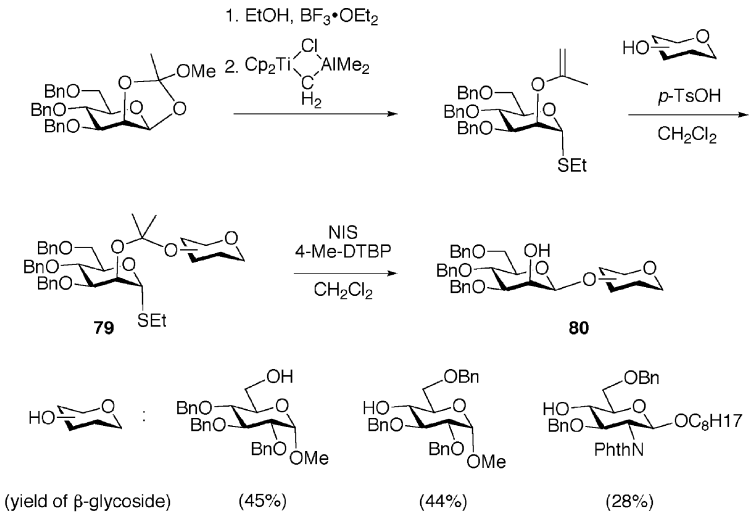
4.3 Intramolecular Glycosylation

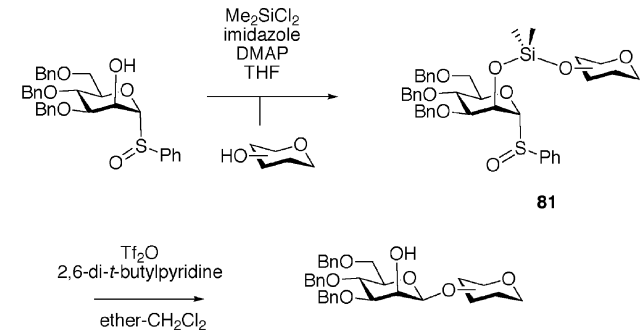
Among the various types of intramolecular glycoside bond formation [122], a strategy called intramolecular aglycon delivery (IAD) which was first proposed by Barresi and Hindsgaul [123] has been demonstrated to be well suited for β-manno glycosylation. Because of the stereochemical constraint, this approach should give the β-*manno*-glycoside without any stereochemical ambiguity (*Scheme 42*). The authors prepared the mixed isopropylidene acetal **79** from the corresponding isopropenyl ether and alcohol. Subsequent treatment with NIS gave the β-mannoside **80** [123,124,125] (*Scheme 43*). Shortly after Hindsgaul's report, Stork and coworkers reported the use of the silaketal-like intermediate **81** for the same purpose [126,127] (*Scheme 43*).

More recently, Fairbanks et al. explored 2-*O*-isopropenyl and 2-*O*-1-(4-methoxyphenyl)vinyl ether **83**, which are obtainable from **82** [128,129,130] (*Scheme 44*). They also reported the

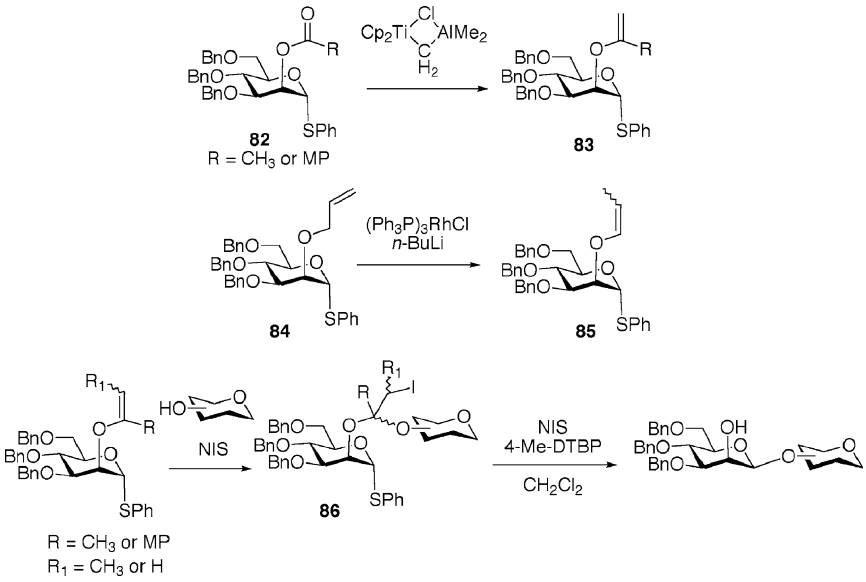


Scheme 42





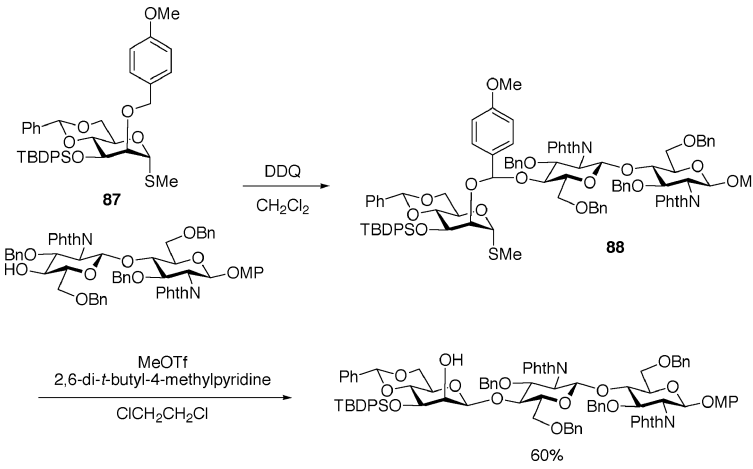
Scheme 43



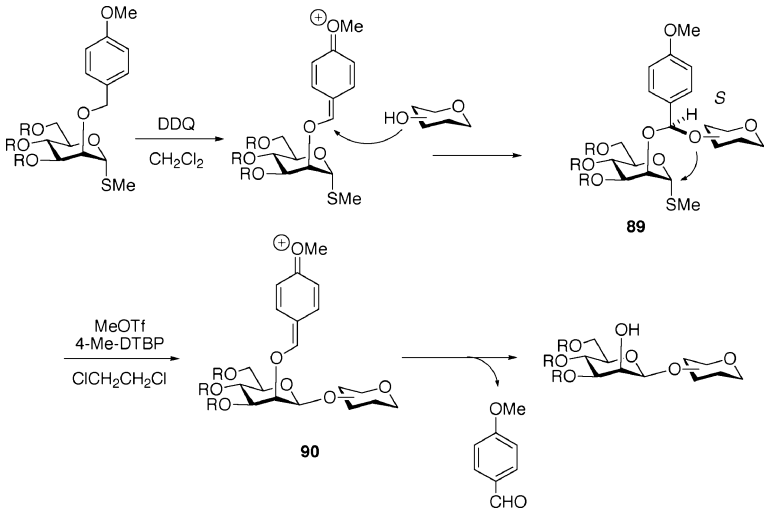
Scheme 44

use of vinyl and propenyl ether (**85**) [131,132], which were prepared by Ir-catalyzed transvinylation and [131] isomerization of allyl ether **84**, respectively. The mixed acetals **86** were synthesized from the vinyl derivatives by the iodoetherification with NIS.

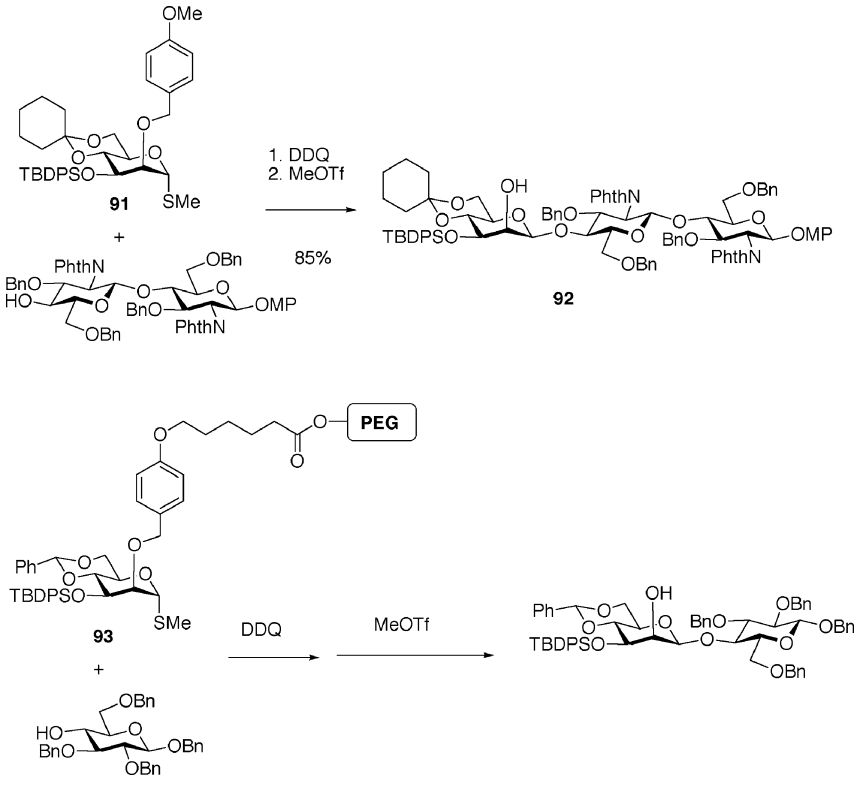
Ito and Ogawa developed an alternative type of IAD, in which the mannosyl donor equipped with a *p*-methoxybenzyl (PMB) group at the C2 position, compound **87**, was used as a donor [133] (*Scheme 45*). Treatment of **87** with the aglycon in the presence of DDQ



Scheme 45



Scheme 46



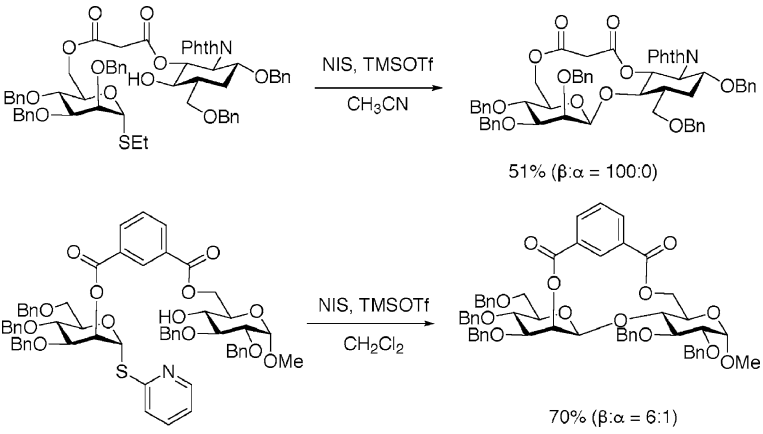
Scheme 47

afforded the mixed acetal **88**. Subsequent activation of the mannose anomeric position with the MeOTf-triggered IAD to afford the β-mannoside as a single stereoisomer in 60% yield. The stereochemistry of the mixed acetal **89** was assigned to be *S* based on NMR and computational analyses [134]. The mechanistic studies with monitoring of the reaction by NMR suggested that the non-hydrolytic pathway that converts the metastable intermediate **90** to product was operative [135] (*Scheme 46*). This PMB-assisted IAD strategy was easily applicable to the condensation of oligosaccharide fragments and a convergent synthesis of the core structure found in Asn-linked oligosaccharide was achieved in a fully stereocontrolled manner [136,137,138].

The efficiency of the PMB-assisted β-mannosylation protocol was enhanced (*Scheme 47*), when the 4,6-*O*-cyclohexylidene group was introduced. For example, compound **91** gave trisaccharide **92** in 85% yield [139]. PMB-assisted IAD has been shown to be highly practical for the construction of complex-type [140,141,142,143] as well as high mannose-type *N*-glycans [144,145,146,147].

In addition, a polymer-supported version of the intramolecular aglycon delivery was explored [148]. In this system, mannosyl thioglycoside **93** bound to polyethylene glycol (PEG) via a *p*-alkoxybenzyl linker was subjected to the two-step sequence and the resultant β-*manno*-glycoside is specifically released into the non-polymeric phase, while most of the by-products remain bound to the polymer.

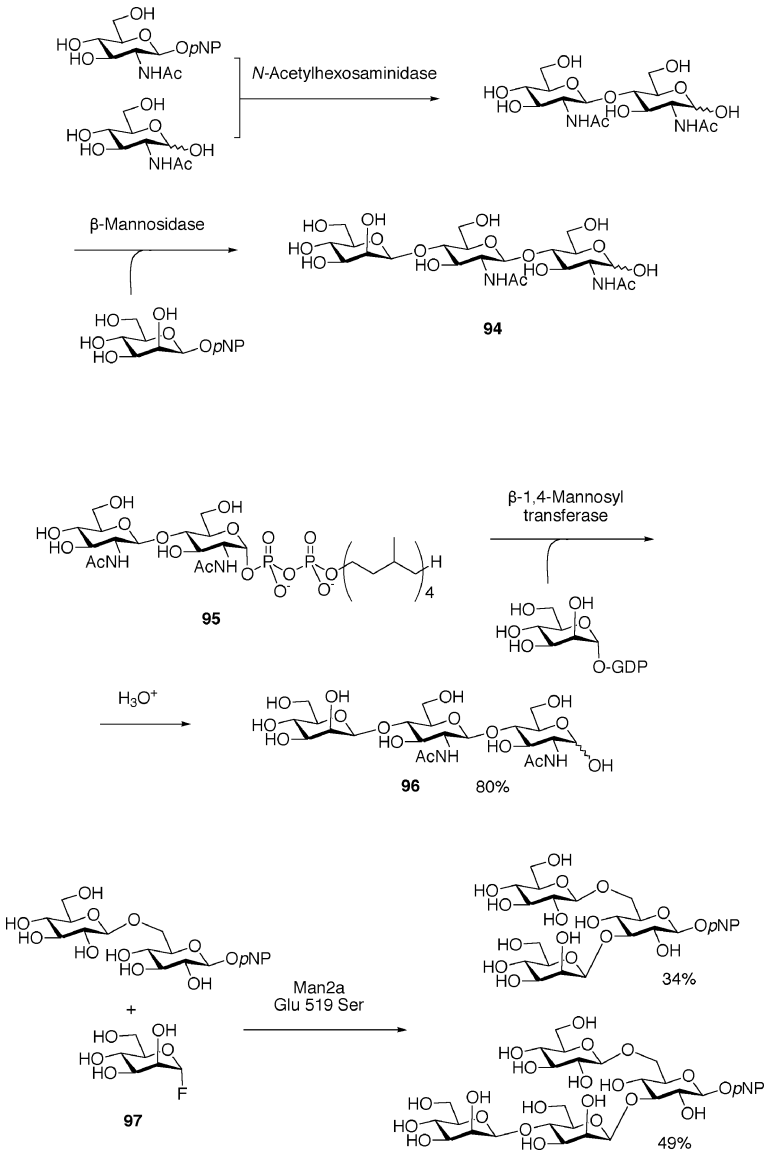
Other types of bridged strategy were developed with promise. For example, Ziegler [149,150] reported the use of a diester linker that connected the donor and the acceptor components (*Scheme 48*). A related strategy was developed by Schmidt [151].



Scheme 48

4.4 Enzymatic Synthesis of β-Manno Glycoside

Enzymatic glycosylations are rapidly attaining practical utility in complex oligosaccharide synthesis [152,153,154]. Recently, Crout and coworkers developed a highly efficient synthesis



Scheme 49

of β-Man1→4-β-GlcNAc1→4GlcNAc, a core trisaccharide of Asn-linked glycans, by using β-mannosidase [155]. Thus, enzymatically prepared chitobiose was treated with β-mannosidase from *A. oryzae*, in the presence of *p*-nitrophenyl mannoside as a glycosyl donor to afford trisaccharide **94** in 26% yield (*Scheme 49*). Since no protection/deprotection is required in the whole sequence, this procedure should be highly valuable for routine preparation of β-Man1→4GlcNAc-containing oligosaccharides.

On the other hand, an efficient expression system of recombinant yeast β1→4-mannosyl transferase in its soluble form was developed by Flitsch and coworkers [156]. Using this enzyme preparation, they performed milligram-scale β-mannosyltransferase-catalyzed glycosylation. It should be noted that easily accessible phytanol [157] carrying chitobiose **95** can be used successfully as an acceptor substrate in place of chitobiosyl dolichol phosphate (*Scheme 49*). After acidic cleavage of the glycosyl phosphodiester linkage, the β-mannosyl chitobiose **96** was isolated in 80% overall yield [156]. For larger-scale preparations, a GDP-mannose regeneration system [158], which was established for α1→2-mannosyl transferase catalyzed glycosylation, may well be applied.

The glycosynthase methodology has been successfully extended to the enzymatic synthesis of β-mannoside. The Glc519Ser mutant of the retaining β-mannosidase (Man2a) proved to afford a catalytic conversion of the various acceptors with the α-mannosyl fluoride **97** as a readily accessible donor [159] (*Scheme 49*). The chitobiose and GlcNAc derivatives, however, would not function as the acceptor.

5 Conclusion

As discussed in this chapter, a number of elegant approaches have been investigated to solve the problem of β-*manno*-glycoside synthesis. In particular, the early improvements in direct glycosylation [42,43,44,45,47,62], glycosylation-inversion [93,94,95,99,101,102,103,104,105] alkylative glycosylation of 1,2-stannylene acetal [114,115], reductive manipulation of orthoester [118,120], intramolecular aglycon delivery [123,124,125,126,127,133,136,137,138,139,148] and enzymatic glycosylation [154,155] are quite dramatic. Recent progress and promising results from a variety of strategies in the last decade, especially in direct glycosylation [46,52,53,54,65,68,73,75,76,81] and intramolecular aglycon delivery [128,131,132,143,147], suggest that practically the requirements for β-mannoside production will be more easily satisfied. By using these methods, β-mannosylation of a wide range of acceptor substrates can be performed with nearly complete stereochemical control.

Abstract

Chemical construction of a α-glycoside of sialic acid is a demanding subject due to the structural disadvantages of sialic acid: the carboxylate group at C1, the deoxy moiety adjacent to the anomeric center, and the glycerol branch from C6. This chapter will provide an overview of sialic acid chemistry and show how the disadvantages can be surmounted and it will also cover the cutting-edge methodology used for α-selective sialylation. In this chapter, the forty-year history of sialylation is compartmentalized into three periods. The first period represents the use of 2-halogeno sialy donors. The second period covers the use of C3-appended sialyl donors and a set of thioglycoside donors, including also the acetonitrile effect, and third is the period of C5-modified sialy donors. While following this division, the chemistry of α-selective sialylation is discussed, and some examples of the stereoselective syntheses of sialyl oligosaccharides are described. Furthermore, the synthesis of the homopolymer of sialic acid and artificial sialyl *S*- and *C*-glycosides is discussed.

Keywords

Sialylation; Glycosylation; Stereoselectivity; Glycosyl donor; Glycosyl acceptor; Sialic acid; Neuraminic acid; Solvent effect; Auxiliary

1 Introduction

The sialic acids are a large family of mono-saccharides derived from 3-deoxy-non-2-ulosonic acid. The three major sialic acids found in nature are *N*-acetyl (Neu5Ac) **1** and *N*-glycolyl (Neu5Gc) **2** derivatives of neuraminic acid (5-amino-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-ulosonic acid) and KDN (3-deoxy-D-*glycero*-D-*galacto*-non-2-ulosonic acid) **3** (● *Fig. 1*) [1,2,3].

The original discovery of sialic acids by Klenk and Blix dates back to the 1930s. Blix isolated sialic acid from submaxillary mucin, named after the Greek word sialos (*saliva*), and Klenk isolated the neuraminic acid derivative from brain glycolipids (neuro + amine + acid). Until the discovery of KDN by Inoue from fish eggs, sialic acid had been defined as neuraminic acid and its derivatives. To date the remarkable structural diversity of sialic acids in nature is well known with the family comprising over 50 structurally distinct compounds and it is also known that the occurrence of sialic acid is limited to the deuterostome lineage of animals (vertebrates and a few higher invertebrates such as starfish) and certain types of bacteria [2,3]. Neu5Ac is biosynthesized via condensation of ManNAc-6-P with pyruvate, while KDN is biosynthesized via condensation of Man-6-P with pyruvate. Furthermore, the α-carbon of the *N*-acetyl group within CMP-Neu5Ac is oxidized to produce CMP-NeuGc catalyzed by CMP-Neu5Ac hydrolase. The hydroxyls of these backbone compounds of "sialic acids" can be further modified by acetylation, lactylation, phospholylation, sulfonation, or methylation [2,3].

Within glycan chains conjugated with lipid or protein scaffolds, sialic acids typically occupy the distal end of glycan chains through α-(2–6) and/or α-(2–3)-linkage with galactose, *N*-acetyl-galactosamine, glucose, or *N*-acetyl-glucosamine, and through α-(2–8), α-(2–9), or α-(2–4)-linkages with another neuraminic acid residue, forming disialic residues. Moreover, homopolymers of sialic acid through α-(2–8) or α-(2–9)-linkage are also formed in nature. CMP-sialic acid **4** is only an exception of the molecule where anomeric configuration of sialic acid is β (● *Fig. 2*) [3]. Unusually, the hydroxyl of the glycolyl moiety of Neu5Gc is glycosylated with other Neu5Gc in sequence, thereby forming a linear polymer of Neu5Gc [4].

Because of the outmost positioning, sialic acid can participate in carbohydrate–protein interaction that mediates a variety of important biological processes such as cell growth, cell differentiation, cell adhesion, cellular immune response, fertilization, oncogenesis, viral infection, and so on. Therefore one can imagine that the elucidation of key biological roles of sialic acid will provide clear insight into dynamism of carbohydrate-mediated biological processes and diseases.

Figure 2
β-Glycoside of sialic acid in nature

In this context, the production of a large quantity of fine sialo-glycans and its conjugates with lipid or protein (peptide) has been a critical subject.

α-Glycoside of sialic acid can be synthesized by the reaction of oxocarbenium ion generated from a sialic acid donor with the hydroxyl of the glycosyl partner. However, the issue of coupling yield and stereoselectivity is much more complicated by the special structural features of sialic acid. First, the electron-withdrawing carboxyl group on the anomeric center makes the tertiary oxocarbenium ion intermediate unstable and susceptible to 2,3-elimination in collaboration with its 3-deoxy structure. Second, because of the deoxy structure, no neighboring functionality at the C3 position is available, assisting with the formation of the alternative thermodynamically more stable β-glycoside. Also the glycerol moiety branching from the C6 position is probably steric hindrance to the anomeric carbon. Therefore, the difficulty of α-sialylation has been centered on the carbohydrate chemistry as well as that of β-mannosylation [5,6].

Back in 1965, Meindl and Tuppy published the paper "Über synthetische Ketoside der *N*-acetyl-D-neuraminsäure"; to our knowledge, it is the first report on sialoside synthesis [7]. In 1971, Khorlin was the first to synthesize the interlinkage between Neu5Ac and glucose or galactose [8]. They prepared a 2-chloro derivative of Neu5Ac as a glycosyl donor, which was reacted with glycosyl acceptors in the presence of Ag_2CO_3 in $CHCl_3$.

Since the outset of the history of sialylation reaction, a huge number of literatures on the synthesis of α-sialoside have been published [9,10,11,12]. In view of type of sialyl donors used in the glycosylation, the 40-years history can be roughly divided into three periods as shown in *Fig. 3*.

The 2-halogeno donor is placed at the origin of the first period from the 1960s to the early 1980s. At the beginning of the second period (the middle of the 1980s), the stream was divided into two branches: one is the lineage of the thioglycoside donor and the other is the C3-appended donor. A thioglycoside derivative of Neu5Ac turned out to be effective for α-selective glycosidation with the assistance of the nitrile solvent effect, and the leaving group was replaced with other varieties. On the other hand, the C3-appended donor incorporates a neighboring functionality at the C3 position in order to direct the α-selective coupling, being independent

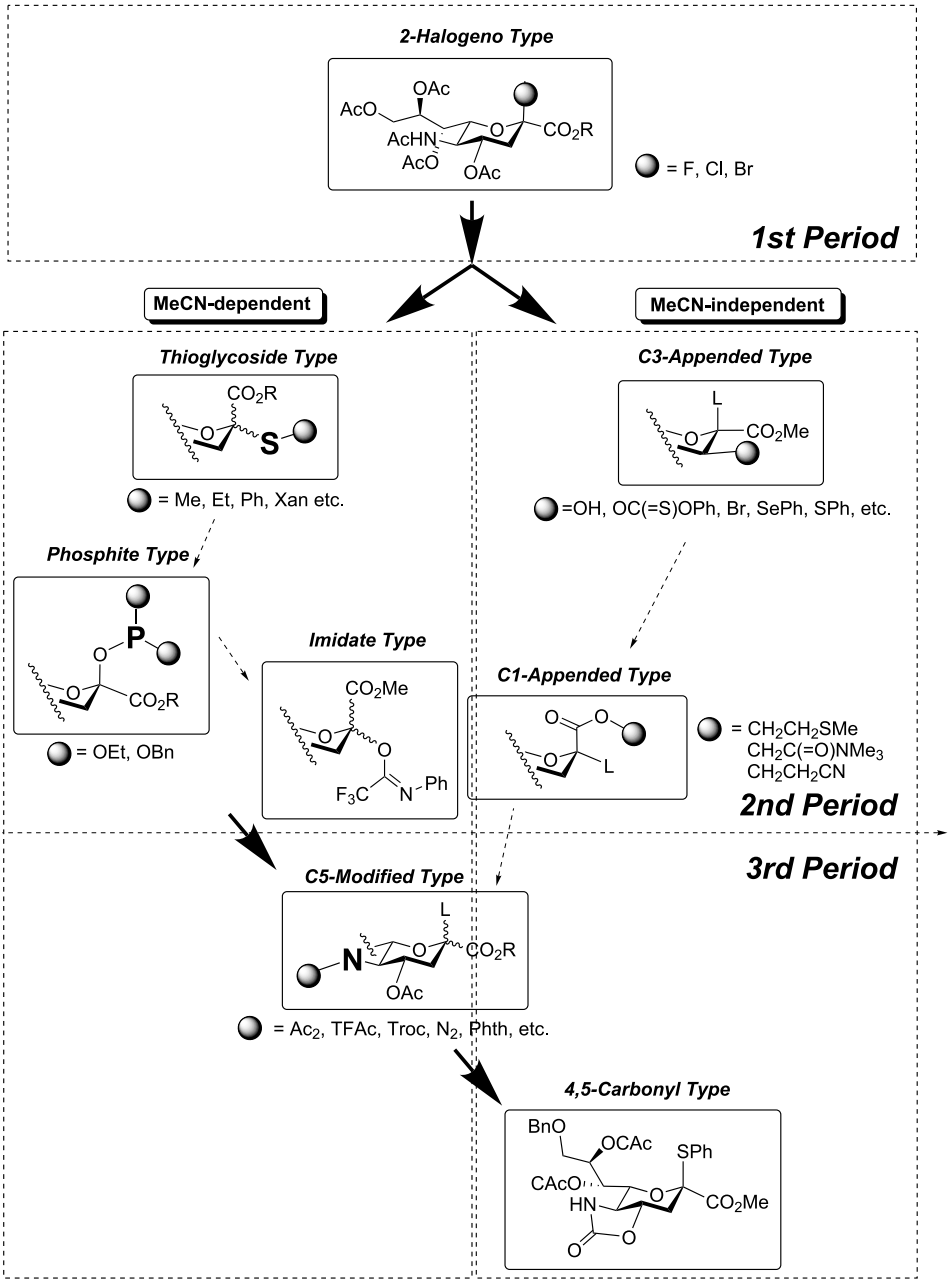

Figure 3
Division of the history

of the solvent effect. The principle was also applied to the design of the C1-appended type of donors.

In 1996, a new type of thioglycoside donor, the *N*,*N*-diacetyl sialyl donor, was devised by Boons and co-workers. This is the beginning of the third period. The *N*,*N*-diacetyl sialyl donor was followed by other analogous C5-modified sialyl donors. Very recently, Tanaka and his co-workers have developed the 5-*N*-4-*O*-oxazolidinone sialyl donor, which can provide α-sialoside without assistance of the nitrile solvent effect despite the absence of an auxiliary at the C3 or C1 positions.

This chapter will outline the chemistry of sialylation and give examples of effective sialylation and the synthesis of complicated sialyl oligosaccharides.

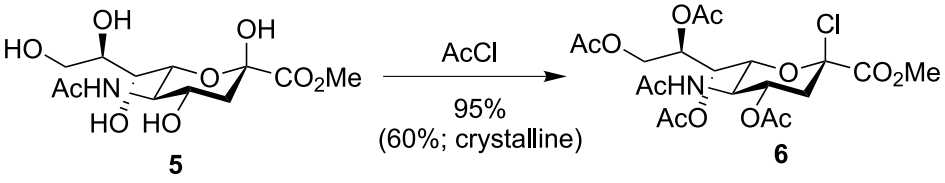
2 The First Period

2.1 2-Chloro Sialyl Donor

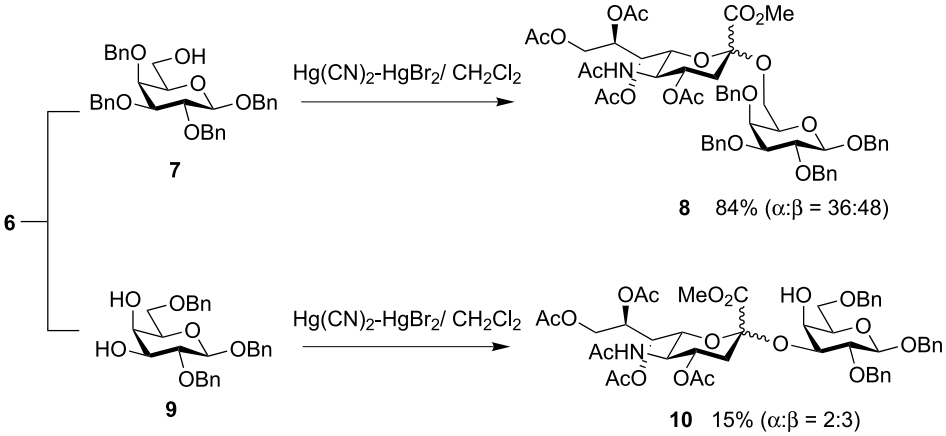
The 2-halogeno derivative of Neu5Ac was first used for the preparation of α-sialosides with the combination of a Koenigs–Knorr type activation system. The 2-chloro derivative has been more widely utilized until the emergence of a second generation of sialyl donor in the 1980s. The 2-chloro derivative is readily available from the methyl ester of Neu5Ac by the action of $TiCl_4$ [13], HCl/AcCl [14,15], AcCl/MeOH [16], or AcCl [17]. For example, the reaction of methyl ester **5** with AcCl produces 2-chloride **6** in 95% yield, the crystalline form of which is stable for several weeks when stored in a freezer (*Scheme 1*) [17]. There are a lot of methods available for the activation of the 2-chloride donor; Ag_2CO_3 (Koenigs–Knorr method) [7,8], $Hg(CN)_2$-$HgBr_2$ (Helferich modification) [7,13], insoluble silver salts (silver polymaleate [18], silver salicylate [19], silver zeolite [20], or silver mercaptoethanesulfonate [21]), soft Lewis acids (AgOTf [22,23], $Sn(OTf)_2$ [23] etc) or I_2 [24].

The stereoselectivity and yield of glycosylation varies to a wide extent, depending on the structure of the glycosylation partner and solvent. As shown in *Scheme 2*, the 2-chloride donor **6** was coupled with the primary hydroxyl of galactoside **7** in 84% yield ($\alpha/\beta = 36/48$), while with the secondary C3 hydroxyl of **9** the yield of α-glycoside was extremely diminished (15%, $\alpha/\beta = 2/3$) [13,25].

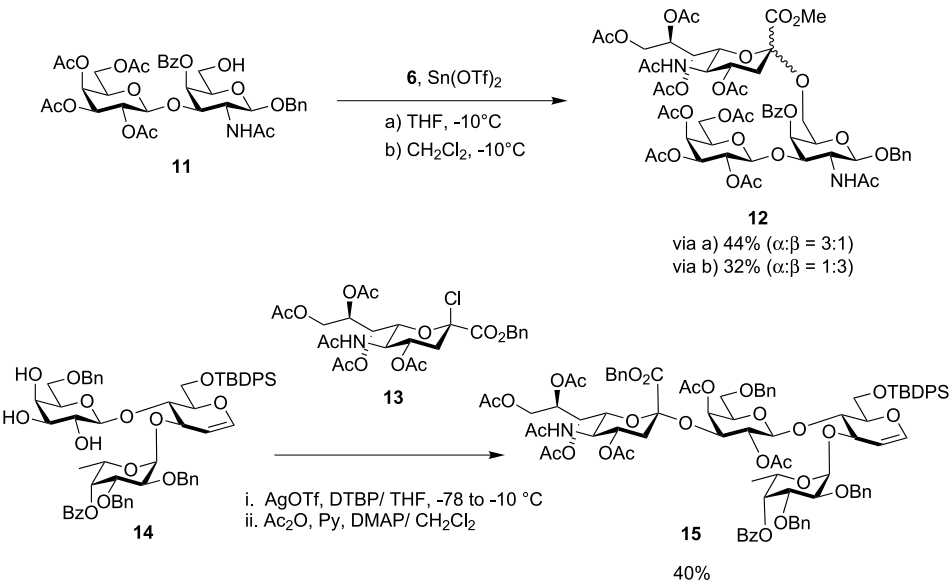
Auge and co-workers have found that the use of THF as a reaction solvent enhances the α-selectivity during the coupling reaction of **6** and disaccharide acceptor **11** effected by $Sn(OTf)_2$ (*Scheme 3*) [23]. This "THF solvent effect" was also successfully applied to the delivery of sialyl Lewis X tetrasaccharide by Danishefski's group; donor **13** was regioselec-



Scheme 1



Scheme 2

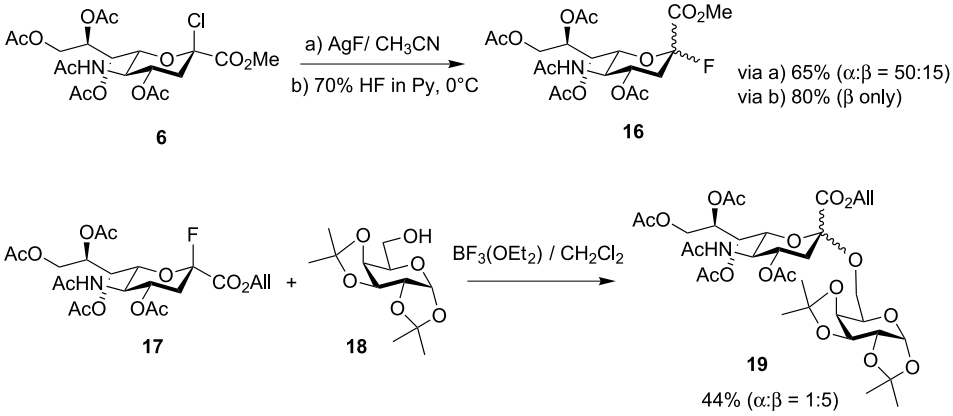


Scheme 3

tively glycosidated with the C3 hydroxyl group of trisaccharide acceptor **14** in the presence of AgOTf and DTBP at −78 to −10 °C, and the subsequent acetylation gave **15** in 40% yield [26].

2.2 2-Bromo and Fluoro Sialyl Donors

The 2-bromo derivative of Neu5Ac is also accessible from the corresponding 2-*O*-acetyl derivative by treatment with $TiBr_4$ or other procedures [13,16]. However, the high reactivity of the 2-bromo derivative causes preferential formation of the 2,3-en byproduct during condensation, and is also prone to decomposition during storage in a freezer. On the other hand, 2-fluoro derivative **16**, which can be prepared from the 2-chloro derivative **6** by the reaction with AgF in MeCN or 70% HF in pyridine, is more stable than 2-chloride and 2-bromide [27]. However, 2-fluoro donor **17**, upon activation by $BF_3(OEt_2)$, was glycosidated with galactosyl acceptor **18** to produce the β-sialyl outcome preferentially (● *Scheme 4*) [28].



■ **Scheme 4**

3 The Second Period

As mentioned above, α-anomeric selectivity during the glycosidation of 2-halogeno type donors lies in the medium range. In the late 1980s, the respective groups of Goto and Hasegawa both provided breakthroughs in relation to α-selective sialylation. Goto's group incorporated an equatorial hydroxyl at the C3 position (*trans* to α-glycoside) of Neu5Ac, which was anticipated to show nucleophilic participation with the contiguous anomeric carbon during condensation, directing α-sialoside formation. In the laboratory of Hasegawa's group, the methylthioglycoside of Neu5Ac was synthesized for the first time, and they have attempted the glycosidation of the 2-methylsulfenyl donor in MeCN. Fortunately, their attempts have resulted in novel effective α-sialylation methods.

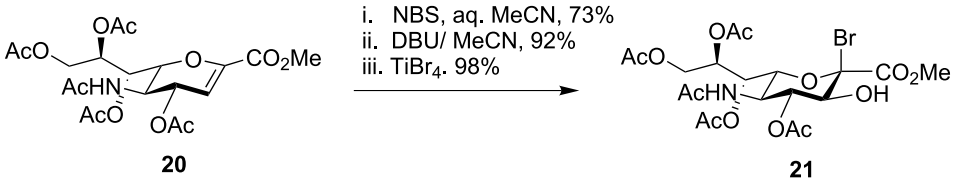
3.1 C3-Appended Sialyl Donors

Goto's group first synthesized the 2-bromo-3-hydroxy derivative of Neu5Ac **21** from the corresponding 2,3-en derivative **20** via bromohydrination, epoxidation, and 2-bromination (*Scheme 5*) [29].

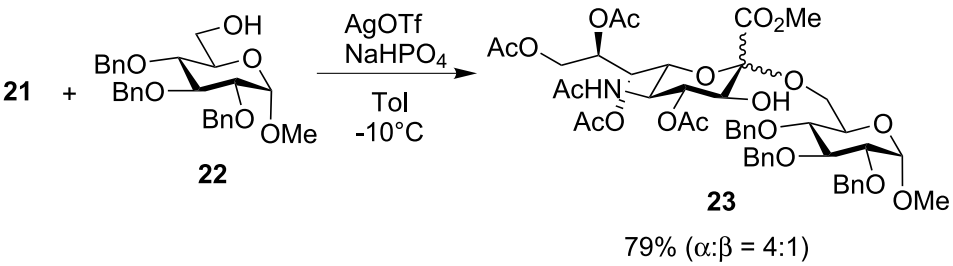
The initial glycosidation of the 3-hydroxy derivative **21** with glucosyl acceptor **22** in the presence of AgOTf and $NaHPO_4$ in toluene afforded Neu5Ac-α-(2–6)-Glc disaccharide **23** in 63% yield accompanied with a β-isomer (16%) (*Scheme 6*) [29,30].

This result suggests that the higher stereoselectivity is endowed with nucleophilic participation of the C3 auxiliary, and the high yield of the coupling is due to the prevention of 2,3-elimination also by the presence of the C3 hydroxyl (*Fig. 4*).

On the basis of this result, the C3 hydroxyl was replaced with phenylselenyl, phenysulfenyl, phenoxythiocarbonyl groups or bromine, and the C2 bromine was also replaced with fluorine, chlorine, or the diethylphosphite group. Schmidt's group demonstrated that, when the C3



Scheme 5



Scheme 6

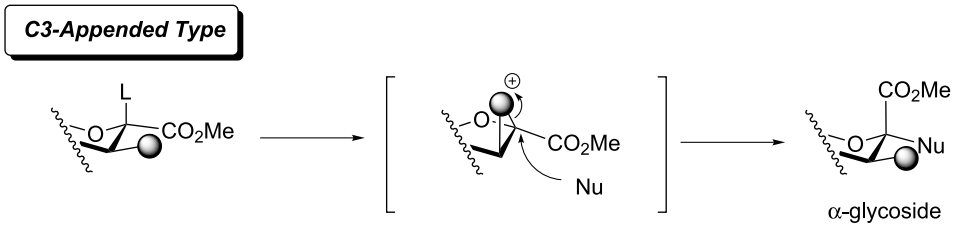


Figure 4
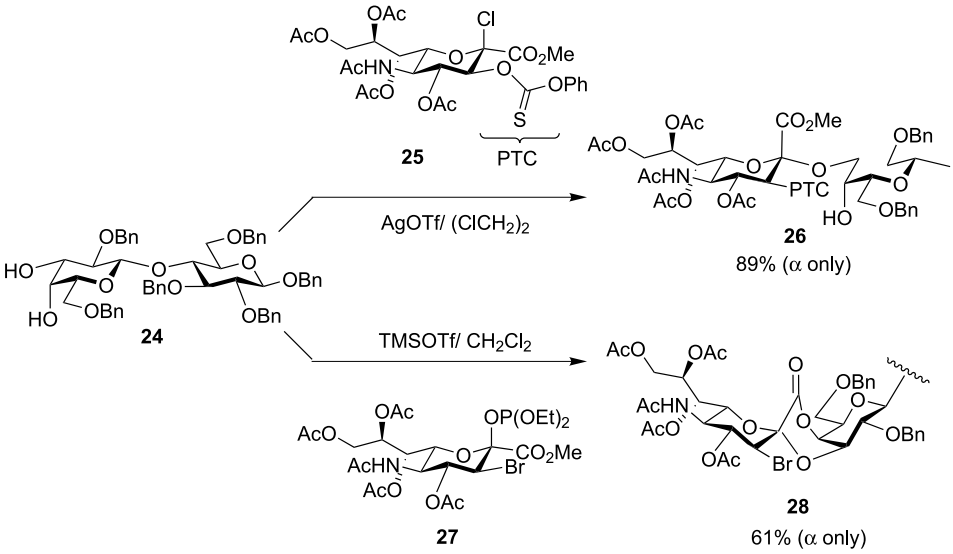
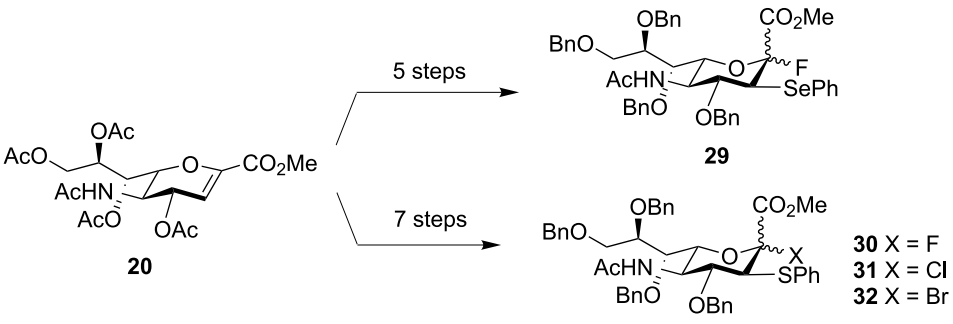
Neighboring participation of C3 auxiliary to direct α-sialylation

hydroxyl was masked with a phenoxythiocarbonyl group in the 2-chloro analog of **21**, the corresponding donor **25** was incorporated at the secondary C3′ hydroxyl of lactosyl acceptor **24** to produce **26** in high yield as a single stereoisomer (*Scheme 7*) [31]. Schmidt's group also reported that 2-phosphite-3-bromide derivative **27** served as an effective glycosyl donor for α-sialylation in TMSOTf-catalyzed glycosidation with **24**, producing 2′,4- lactonated trisaccharide **28** in 61% yield [31].

Phenylselenyl and phenylsulfenyl groups are expected to direct α-sialylation more effectively via predictable episelenium or episulfenium ion intermediates, due to their high nucleophilicity. Ogawa and Ito first developed the 3-phenylselenyl derivative of Neu5Ac **29** having fluorine as a leaving group, which was prepared from 2,3-en compound **20** through the reaction sequence in five steps (*Scheme 8*) [32].



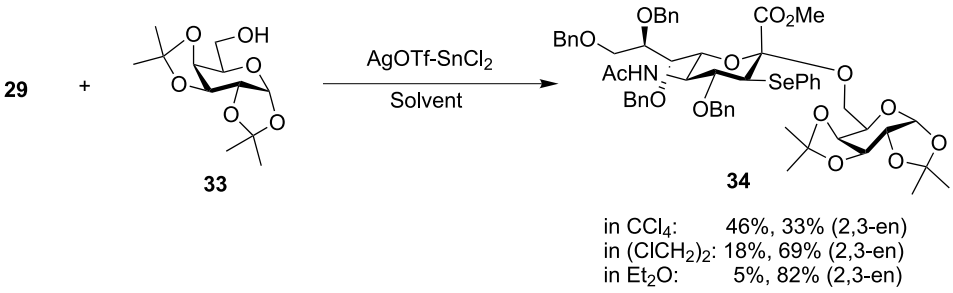
Scheme 7



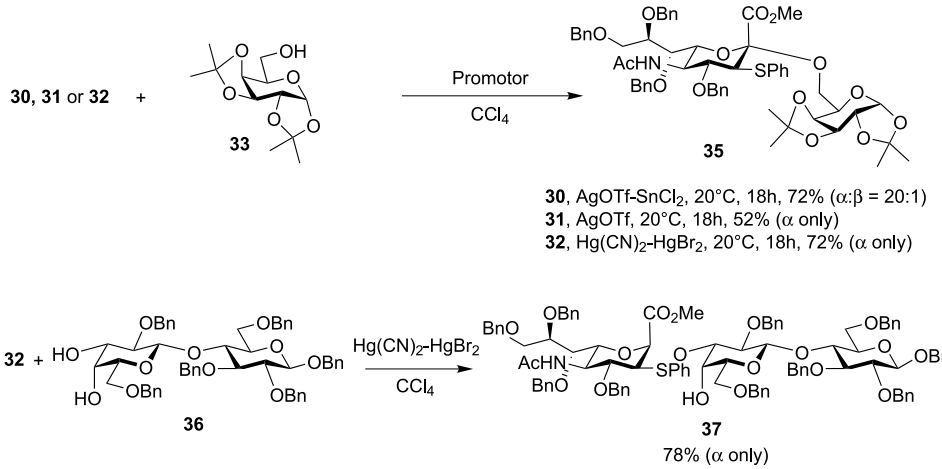
Scheme 8

The coupling reaction with diacetone galactosyl acceptor **33** and the donor **29** was examined in various solvents (Scheme 9) [32]. In all solvents the reaction constantly provided perfect α-selectivity, whereas the coupling yield differed greatly. The best result was obtained when the reaction was carried out in CCl_4 to produce **34** in 46% yield, which was accompanied with the competitive formation of 2,3-en derivative (33%).

This issue was resolved by the replacement of the phenylselenyl group with the phenylsulfenyl group. Among the 3-phenylsulfenyl sialyl donors (**30**, **31**, and **32**) having fluorine, chlorine, and bromine as leaving groups, the 2-bromo derivative **32** turned out to be superior to others (Scheme 10) [33]. The glycan part of ganglioside GM3 **37** was produced by the reaction of **32** with the 3′,4′-dihydroxy lactosyl acceptor **36** in 78% yield, α-exclusively.



Scheme 9



Scheme 10

3.2 C1-Appended Sialyl Donors

Incorporation of an auxiliary at the C1 position, which is anticipated to show long-range participation with the β-face of the anomeric center as depicted in ❯ *Fig. 5*, was originally examined by Takahashi and co-workers. They incorporated the 2-methylthioethyl group through an ester linkage at the C1 position of 2,4,7,8,9-penta-*O*-acetyl derivative **38**, and the 2-acetoxy group was substituted with the methylsulfenyl group (❯ *Scheme 11*) [34]. Similarly, Gin's group synthesized *N*,*N*-dimethylglycolylamide ester derivatives **40** and **41** from **38** [35,36]. Ito's group showed that the cyanoethyl ester derivative **43** was also readily accessible from 2-methylester derivatives **42** via demethylation with high nucleophilic Ph_3SiSH in the presence of Cs_2CO_3 and DTBC, and DCC-mediated dehydrative coupling with 1-cyanoethanol in one pot [37].

In the case of the use of 1-methylthioethyl derivative **39**, 1,2-dimethoxyethane as the solvent was critical for α-selectivity. The optimized coupling with 3,4-diol galactosyl acceptor **44** by iodonium promotion produced disaccharide **45** in the yield of 21% with high anomeric selectivity (❯ *Scheme 12*) [34]. The 2-dimethyl glycolylamide functionality also directed α-selectivity during coupling reaction in CH_2Cl_2. The best result was obtained when 2-hydroxy derivative **41** was activated by the action of (*p*-nitrophenyl)phenyl sulfoxide and Tf_2O in CH_2Cl_2 at −78 °C in the presence of galactose derivative **46**, producing disaccharide **47** in 57% yield [36].

On the other hand, the use of 1-cyanoethyl ester derivative **43** for the glycosylation of **48** resulted in β-exclusive formation of Neu5Ac-(2–6)-Glc sequence **49** in high yield, while in MeCN the production of α-glycoside was preferred [37].

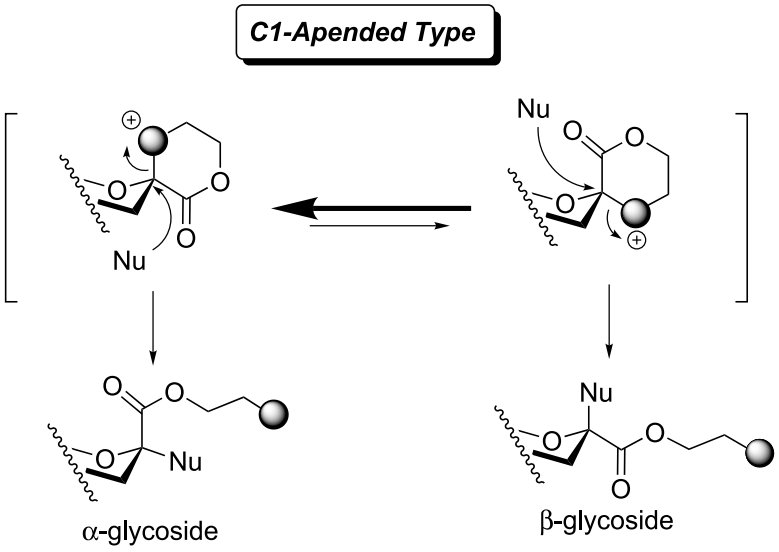


Figure 5
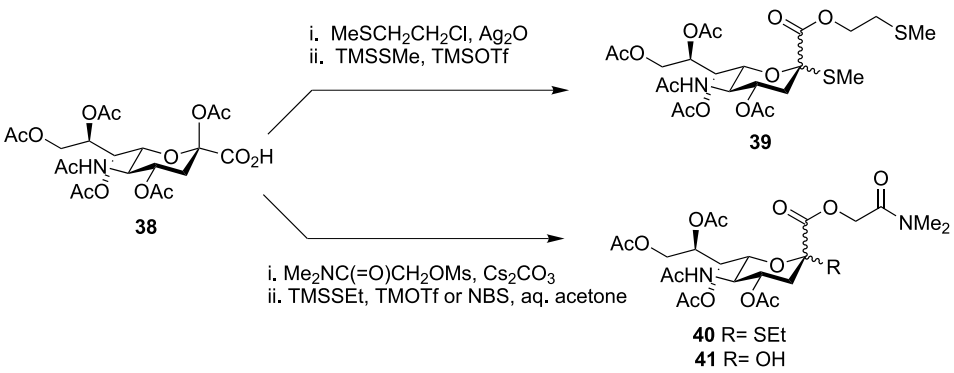
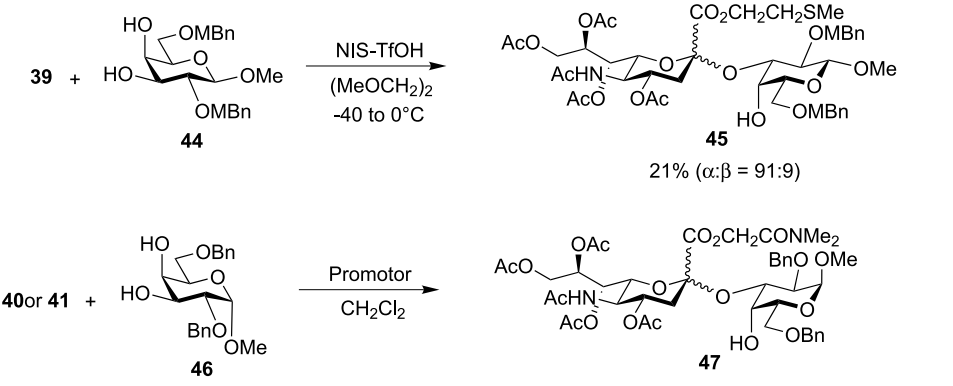
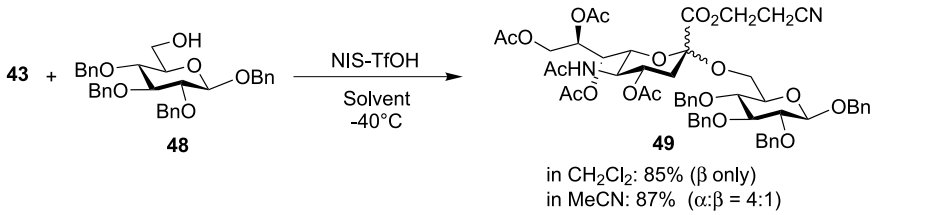
Long-range participation of C1 auxiliary to direct α-sialylation



Scheme 11



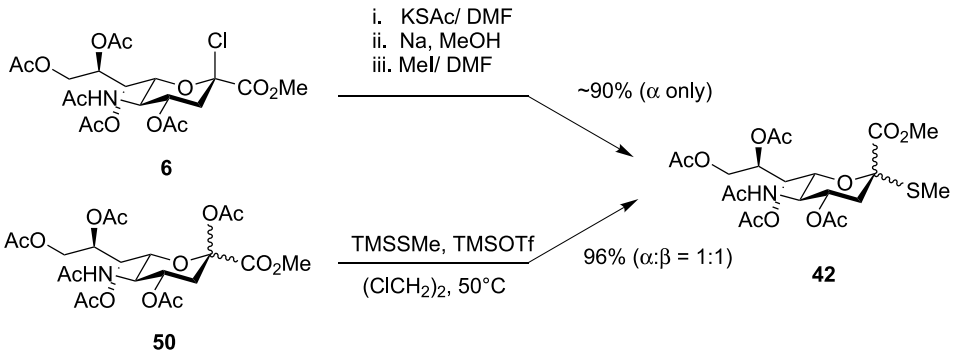


Scheme 12

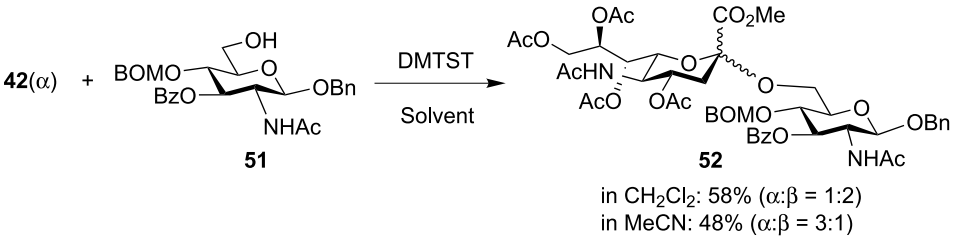
3.3 2-Thioglycoside Sialyl Donors

The 2-α-methylsulfenyl derivative of Neu5Ac **42** was originally synthesized from the corresponding 2-β-chloro derivative **6** through the reaction sequence in three steps: nucleophilic substitution by KSAc, de-*S*-acetylation by NaOMe, and methylation of the resulting sodium salt of glycosyl thiolate with MeI (*Scheme 13*) [38]. The treatment of 2-acetoxy derivative **50** with TMSSMe and TMSOTf also produced **42** in high yield as a mixture of stereoisomers [39]. The methyl group was further replaced with many other groups such as ethyl [40], phenyl [40], substituted phenyl [41,42], (ethoxy)dithiocarbonyl [40], phenyltetrazoyl [43], benzooxazoyl [44], benzothiazoyl [45], benzimidazoyl [45], thiazoyl [44], and lauryl [46] groups. These relatives can also be prepared by the S_N2-like replacement of the 2-chloride with the corresponding thiolate anion, or by the Lewis acid-catalyzed replacement of the 2-acetoxy group with the corresponding thiol reagent.

In the first paper on the glycosidation of the methylthio donor written by Hasegawa's group, **42** was reacted with the C6 hydroxyl of glucosamine derivative **23** upon the activation by DMTST in CH_2Cl_2 or MeCN (*Scheme 14*) [38]. As a result, glycosylation in MeCN proved α-selective to yield Neu5Ac-(2–6)-GlcNAc disaccharide **52** in 48% yield as a mixture of α- and β-isomers ($\alpha/\beta = 3/1$), whereas in CH_2Cl_2 disaccharide was β-preferentially produced in 58% yield ($\alpha/\beta = 1/2$). This result indicated that nitrile solvent assistance can effectively direct the formation of α-glycoside of sialic acid.



Scheme 13



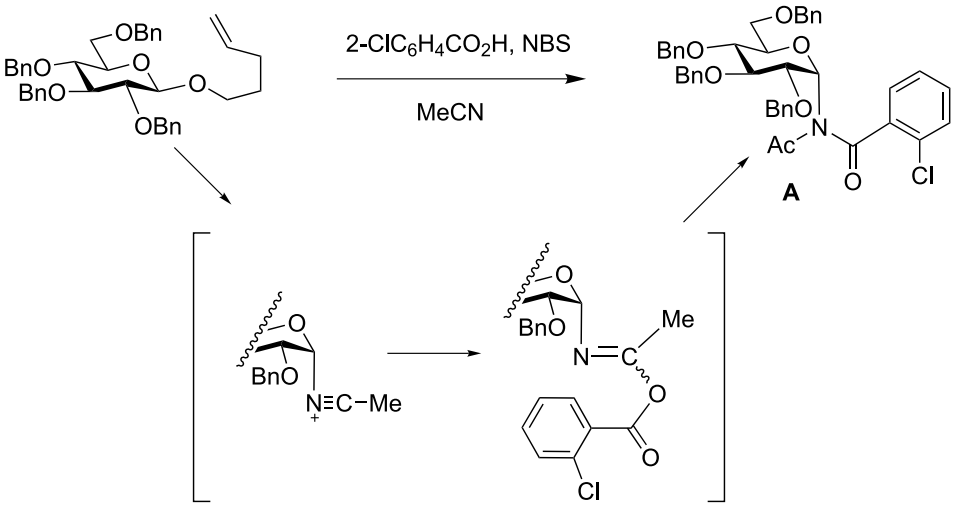
Scheme 14

3.3.1 Acetonitrile Participation in Sialylation

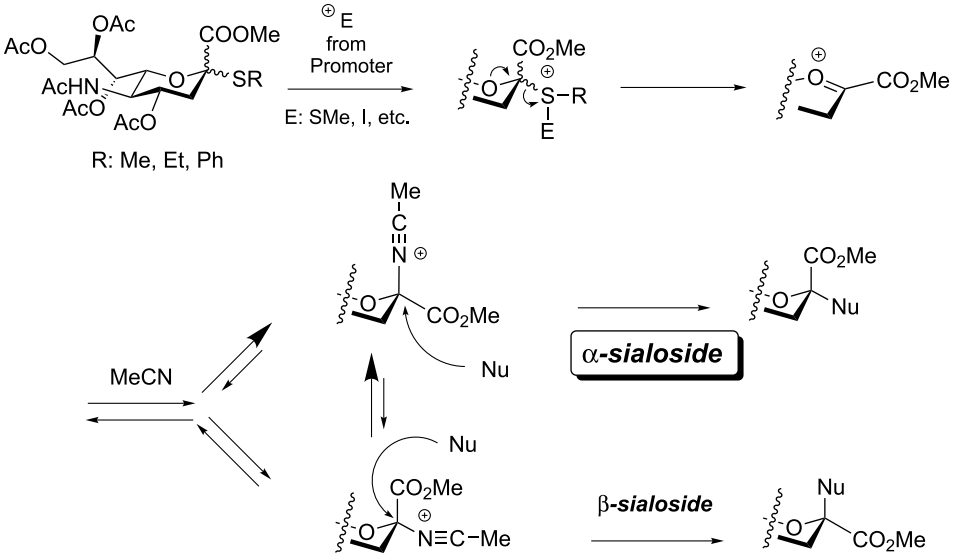
It has been reported that acetonitrile participation directs equatorial glycoside formation during the condensation of a glycosyl donor having non-participating functionality adjacent to the anomeric carbon [47,48,49, 50]. To account for this phenomenon, the intermediacy of the axial-oriented nitrilium ion was advocated by Pavia et al. [51] and Lemieux and Ratcliffe [52]. In contrast, Sinay and Pougny [53] and Schmidt and Michel [54] proposed the β-counterpart because of the so-called reverse anomeric effect [55]. In 1990, Ratcliffe and Fraiser-Reid successfully quenched the nitrilium intermediacy with 2-chlorobenzoic acid to convert into imide (**A**), and determined its α-configuration by NMR spectroscopy (● *Scheme 15*) [56], and later the absence of the reverse anomeric effect was concluded by Perrin's group [57,58]. On the basis of this evidence, the α-selective sialylation in MeCN can be rationalized by the following plausible mechanism (● *Scheme 16*) [59].

A thiophilic electrophile (+SMe) from DMTST reacts with a lone pair on sulfur to afford a cationic sulfonium species, which is an excellent leaving group. Because of the participation of a lone pair on the ring oxygen, the C–S bond is cleaved, forming an oxocarbenium ion intermediate, with which MeCN reacts to form an axial-oriented nitrilium intermediate under kinetic control. This then undergoes S_N2 nucleophilic substitution with a hydroxyl of the glycosyl accepter to yield α-sialoside.

Since other thiophilic activation systems (DMTST [48], NIS-TfOH [60,61], PhSeOTf [62], NBS-Bu_4NOTf or Ph_2IOTf [63], MeSBr-AgOTf [64]) are also compatible with the acetonitrile assistance, the combined use of a thioglycoside donor and acetonitrile (or other nitrile solvents) became a powerful option for α-sialoside synthesis, being parallel with C3-appended donors.



● **Scheme 15**



Scheme 16

3.3.2 Thioglycosides and their Relatives

As mentioned above, 2-methylthioglycoside derivative **42** can be activated by DMTST, NIS-TfOH, PhSeOTf, NBS-Bu_4NOTf, or MeSBr-AgOTf. Among the promoter systems, the excellent affinity of DMTST and NIS-TfOH was exemplified by a large number of successful α-sialylations with the assistance of MeCN [65,66,67,68,69,70]. It is of note that DMTST was preferred for the sialylation with the primary hydroxyl group of a sugar acceptor while the NIS-TfOH system was preferred for the secondary hydroxyl (*Scheme 17*) [59]. As shown in *Fig. 6*, the 2-methylthio derivative was successfully used for the glycosylation of hydroxyl within large oligosaccharide acceptor **57** [71].

2-Phenylsulfenyl derivative **58** is easily accessible from the corresponding 2-chloro derivative **6** or 2-acetoxy derivative **50** (*Scheme 18*) [40,42].

Because the glycosyl donor property of **58** is comparable to that of 2-methylsulfenyl derivative **42**, the use of costly **42** was replaced with the inexpensive **58** in recent examples. Usually, the iodonium promoter system provides better yield and α-selectivity for the glycosidation of a 2-phenylsulfenyl donor. The examples are shown in *Scheme 19*. The direct sialylation of the primary hydroxyl of trisaccharide **61** with sialyl donor **58**, which was promoted by NIS-TfOH in MeCN, gave tetrasaccharide in 90% yield as an anomeric mixture ($\alpha/\beta = 74/16$) [72]. Furthermore, 2-phenylsulfenyl donor **58**, upon activation by NIS-TMSOTf, was incorporated into the hindered secondary hydroxyl within tetrasaccharide **62** in 40% as α-glycoside [73] (*Fig. 7*). The phenylthioglycoside derivatives of α-(2–8)-linked dimeric, trimeric, and tetrameric sialic acid as glycosyl donors were also effectively applied to the synthesis of the oligo-sialyl glycoconjugates [74,75,76,77], for example, ganglioside GQ1b [78] and GT3 [79].

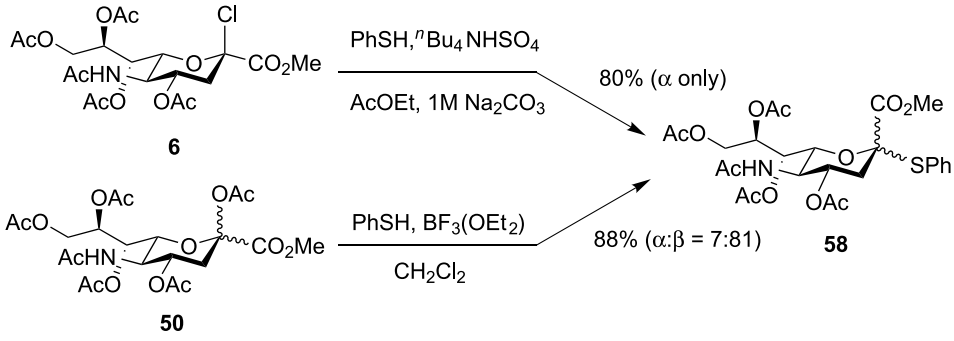
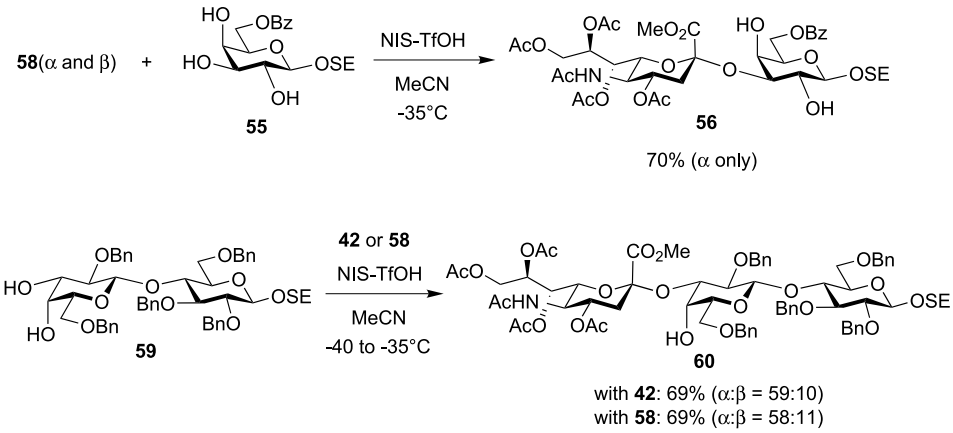


Scheme 18



Scheme 19

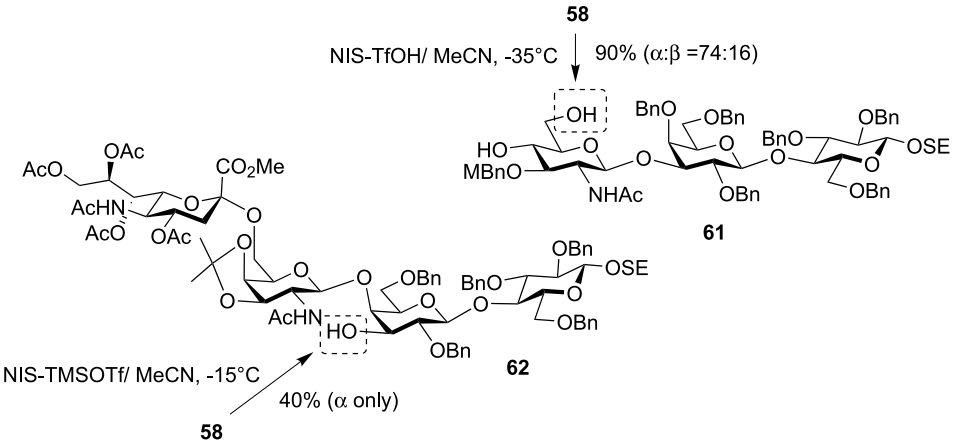


Figure 7
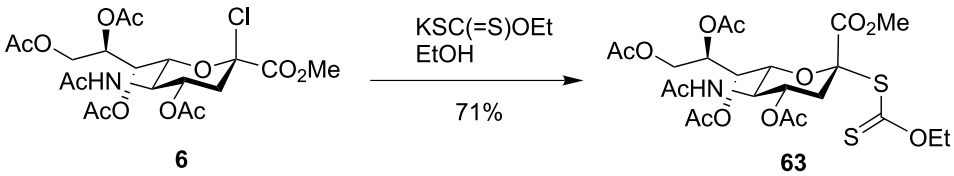
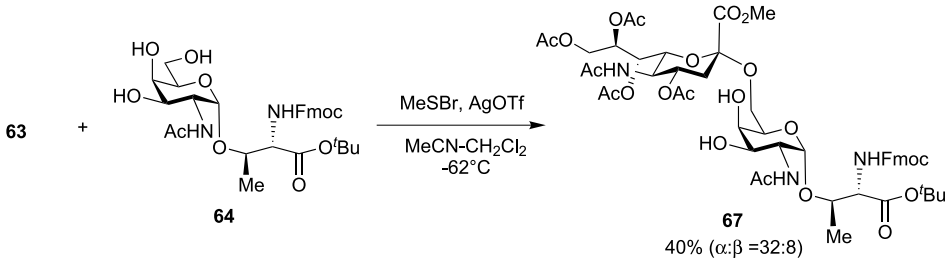
Sialylation of oligosaccharide acceptors with sialyl donor 58

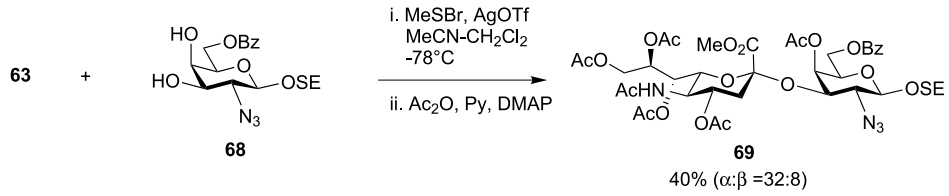
A 2-(ethoxy)dithiocarbonate (xanthate) derivative of Neu5Ac **63** has been synthesized from the 2-chloro derivative **6** by reaction with potassium ethoxydithiocarbonate in EtOH (*Scheme 20*) [40]. This compound was obtained in a stable crystalline form, which has a good shelf-life.

The 2-xanthate derivative can also be activated by DMTST and NIS-TfOH in MeCN, but the coupling yield and α-selectivity were moderate in many cases. This problem has been solved by the introduction of MeSOTf as a glycosylation promoter by Bilberg and Lönn, which can be generated in situ by the reaction of methylsulfenyl bromide with AgOTf



Scheme 20





Scheme 21

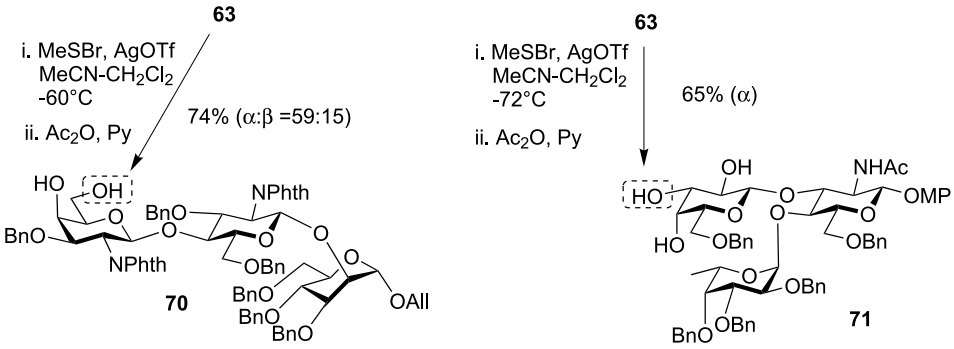


Figure 8
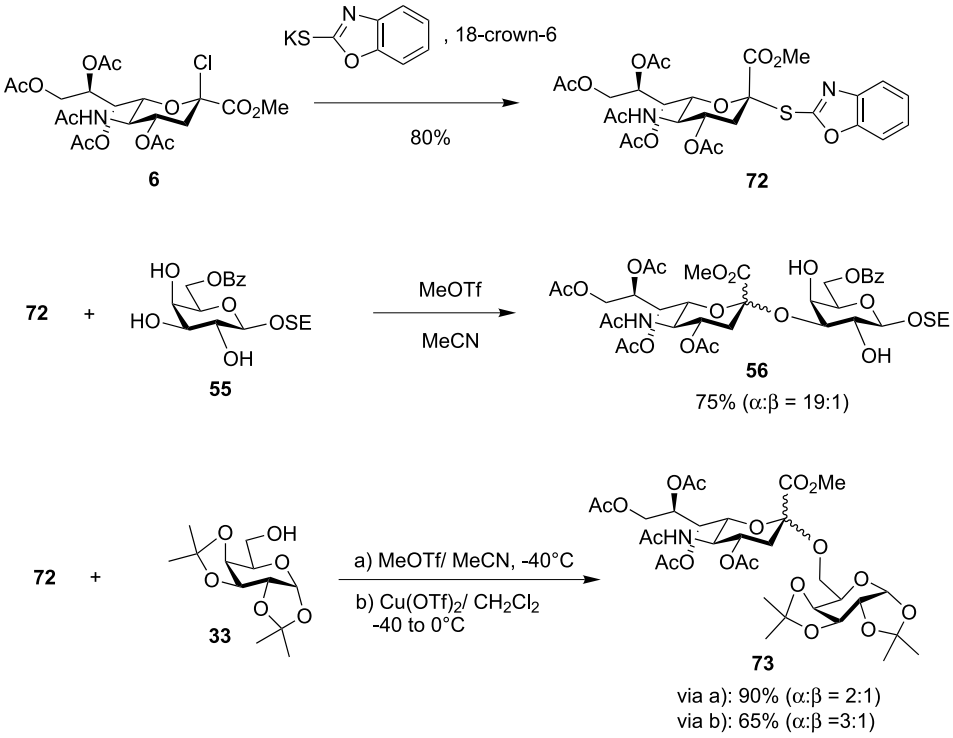
Sialylation of trisaccharide acceptors with sialyl donor 63

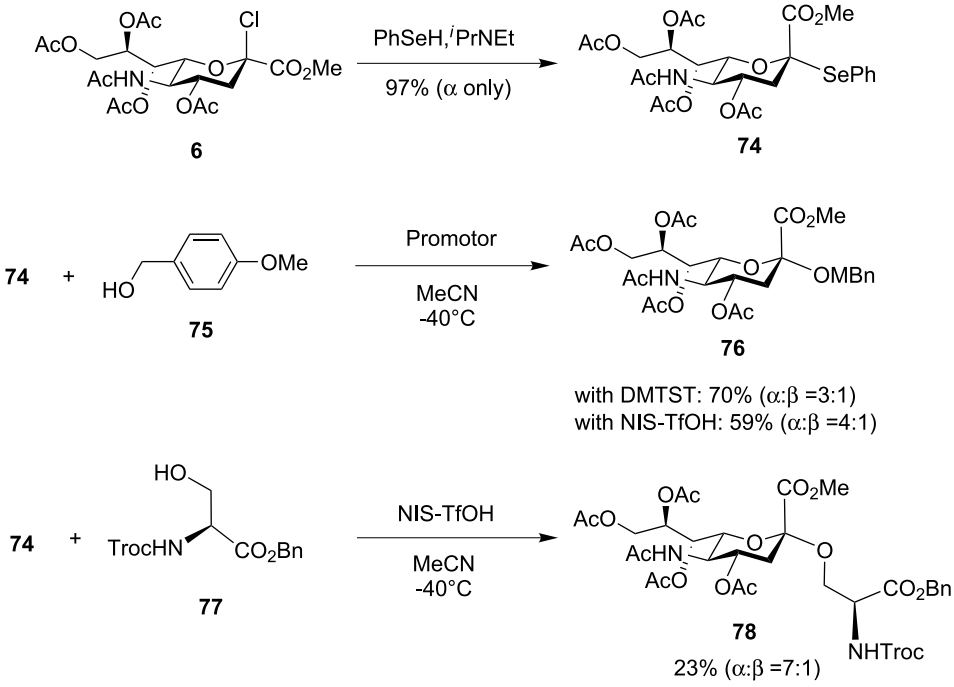


Scheme 22

(*Scheme 21*) [80,81,82]. Bilberg and Lönn also found the significance of solvent for glycoside formation; the use of a mixture of MeCN-CH_2Cl_2 (3/2) afforded the best result. The optimized activation system extended the usage of 2-xanthate derivative **63** to the assembly of a variety of sialyl oligosaccharides as shown in *Fig. 8* [83,84].

Recently, De Meo and Parker introduced 2-benzooxazoylsulfenyl (SBox) derivative **72** [44]. The compound was straightforwardly prepared by the treatment of the 2-chloride derivative **6** with potassium 2-mercaptobenzoxazolate and 18-crown-6 in acetone in 80% yield (*Scheme 22*). For the activation of the 2-SBox donor **72**, MeOTf proved to be the best option. Glycosylation of the donor **72** with 6-*O*-benzoyl-galactosyl acceptor **73** in MeCN at −40 °C yielded α-(2–3)-sialyl galactoside **56** in 71% yield, α-selectively. However, with the more reactive primary hydroxyl group of galactose acceptor **33**, the glycosidation was less α-selective (90%, $\alpha/\beta = 2/1$). Interestingly, when this coupling was promoted by $Cu(OTf)_2$ in CH_2Cl_2 at −40 °C to 0 °C, α-selectivity was improved ($\alpha/\beta = 3/1$).

The 2-phenylselenyl derivative of Neu5Ac **74**, which can be prepared by the treatment of 2-β-chloride **6** with selenophenol and Hünig's base, was also introduced as a glycosyl donor [85]. This compound can be activated by DMTST or NIS-TfOH in MeCN at −40 °C to afford α-sialoside. In general, the yield and α-selectivity were not constantly high (*Scheme 23*).



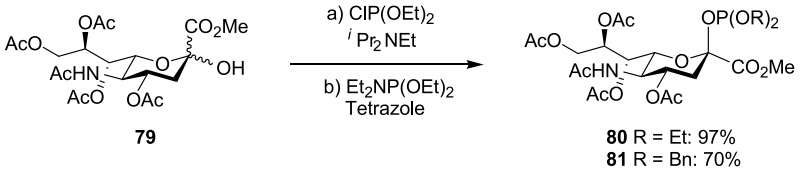
Scheme 23

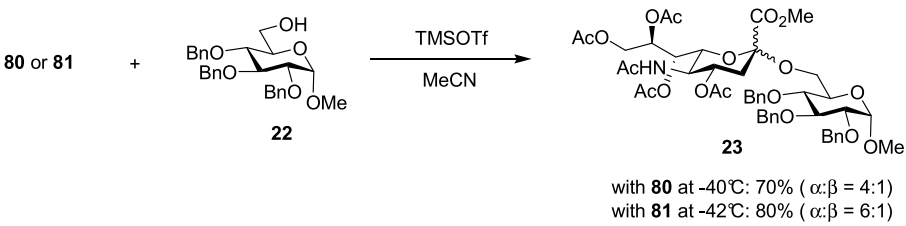
3.4 2-Phosphite and 2-Imidate Sialyl Donors

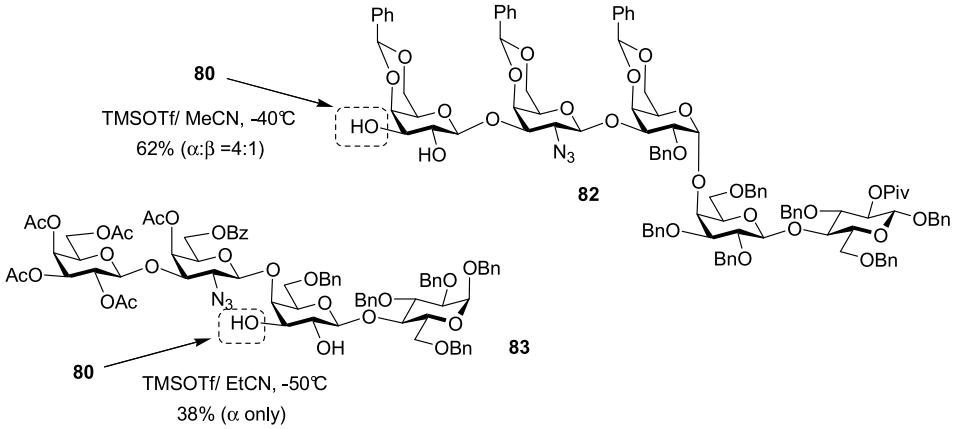
3.4.1 2-Phosphite Derivatives

Schmidt and Wong have developed 2-diethyl and 2-dibenzyl phosphite derivatives of Neu5Ac **80** [86] and **81** [87], individually. Both of the 2-phosphite derivatives can be prepared from a 2-hydroxy derivative of Neu5Ac **79** by the reaction with $ClP(OEt)_2$ in the presence of Hünig's base, and by the reaction of *N*,*N*-diethyl phosphoro amidite and tetrazole, respectively (*Scheme 24*).

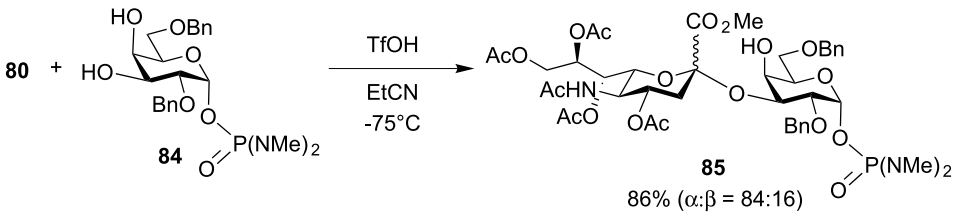
Because of the fact that *N*,*N*-diethyl phosphoro amidite is not commercially available, there is limited application of dibenzyl phophite **81** to oligosaccharide synthesis. On the other hand, the power of diethyl phophite **80** as a useful alternative to the other Neu5Ac donors was exemplified by its incorporation within many linear and convergent syntheses of the complicated sialyl oligosaccharides. The glycosidation of 2-phosphite derivative **80** can be catalyzed by 10 to 20 mol % of acid [TMSOTf, $Sn(OTf)_2$, etc]. This feature has allowed design of synthetic strategies that involve the use of acid-labile protecting groups within glycosylation units [88,89]. Moreover, Hashimoto's group performed, within the synthesis of ganglioside GM3, the orthogonal coupling of 2-diethyl phosphite of Neu5Ac **80** with 1-phosphoroamidite galactose derivative **84** by using TfOH as a glycosylation catalyst (*Scheme 25*) [90].







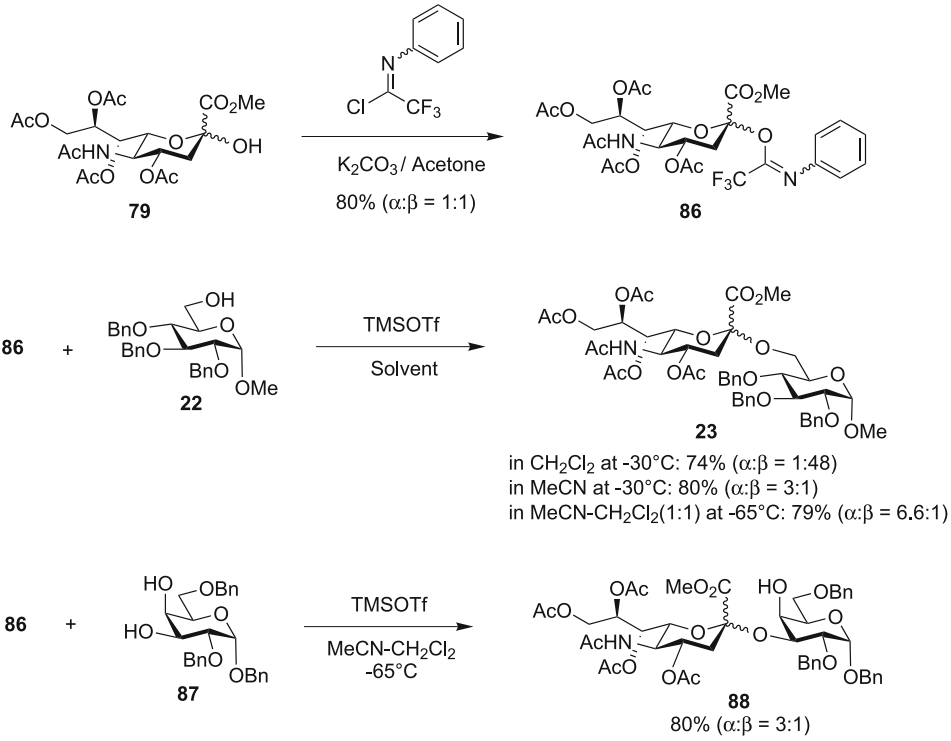
Scheme 24



Scheme 25

3.4.2 2-Imidate Derivative

It is known that the attractive trichloroacetimidate glycosyl donor invented by Schmidt's group [91] can not be incorporated into sialylation, mostly due to the poor stability of the corresponding 2-trichloroacetimidate derivative. Recently, Yu's group successfully incorporated a 2-trifluoroacetimidate derivative of Neu5Ac into α-sialoside synthesis [92]. The reaction of a 2-hydroxy derivative of Neu5Ac **79** with *N*-phenyltrifluoroacetimidoyl chloride and K_2CO_3 in acetone produced the corresponding 2-trifluoroacetimidate derivative **86** in 80% yield as a mixture of α- and β-isomers (α/β = 1/1) (*Scheme 26*). In the coupling reaction with the C6 hydroxyl of glucosyl acceptor **22**, the use of a mixture of MeCN-CH_2Cl_2 (1/1) as solvent provided high α-selectivity, thereby yielding disaccharide **23** in 79% yield as a stereo mixture (α/β = 6.6/1). The efficacy of 2-trifluoroacetimidate derivative **86** as a sialyl donor was also demonstrated by conducting the glycosylation of 3,4-diol galactosyl acceptor **87** in MeCN again, producing disaccharide **88** in 80% yield as a stereo mixture (α/β = 3/1).



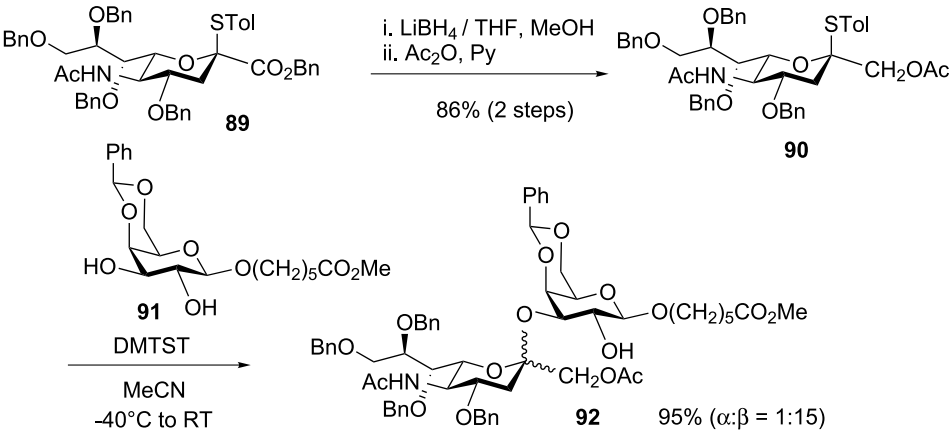
Scheme 26

4 The Third Period

Looking at the array of Neu5Ac donors mentioned above, it is of note that the type of leaving group, its activation system, and solvent dominantly affect the reactivity of the glycosyl donor in terms of the efficiency of glycosidation and the α-anomeric selectivity. Furthermore, it is known that the feasibility of glycosidation depends on the unpredictable "match-mismatch" relationship between coupling partners. This issue makes sialyl glycan synthesis much more complicated. In this context, many researchers are still eager to develop a universal method for α-sialylation.

4.1 Effect of Reduction of the C1 Carbonyl Group on the Sialy Donor

In work on nitrile solvent-dependent α-sialylation, the importance of the C1 carbonyl group for α-selectivity was suggested by Wong's group [93]. Thus, they converted the carbonyl group of Neu5Ac derivative **89** into a hydroxymethyl group to obtain the Neu5Ac derivative **90** (*Scheme 27*). The DMTST-promoted glycosylation of the derivative **90** with 4,6-benzylidenated galactosyl acceptor **91** afforded the mixture of α- and β-sialylated products **92** in 90% yield with the ratio of 1/15. Although they also examined glycosylation by altering acceptors and promoters, β-sialosides were preferentially produced in all events.



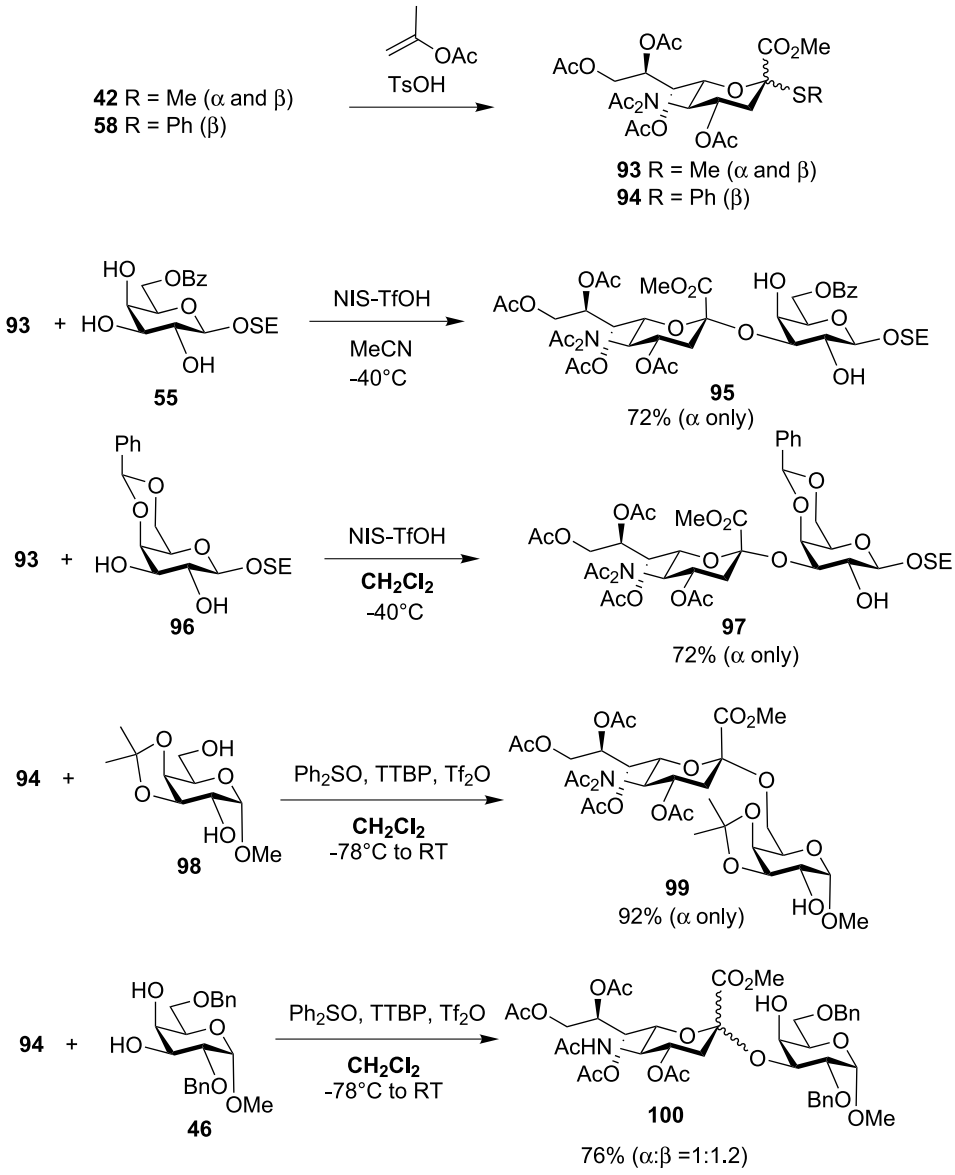
Scheme 27

4.2 C5-Modified Sialyl Donors

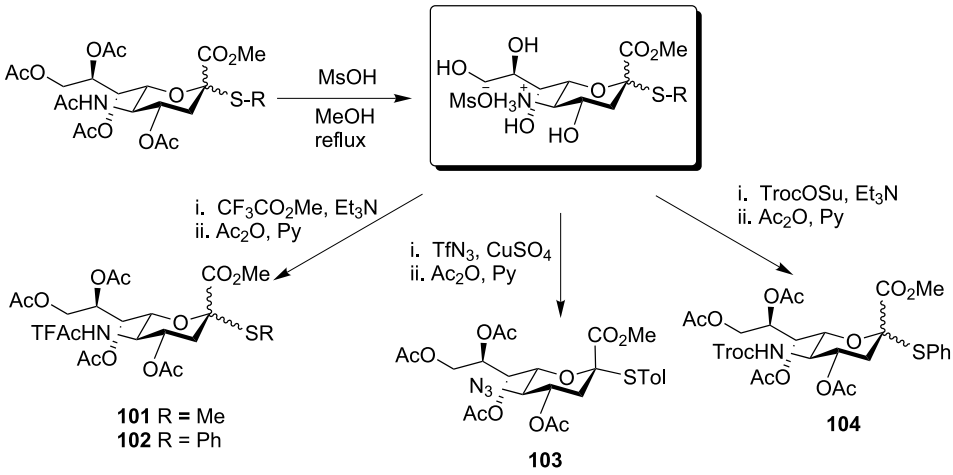
4.2.1 *N,N*-Diacetyl Derivatives

On the other hand, Boons and co-workers demonstrated that the conversion of the C5 *N*-acetyl group into a *N*,*N*-diacetyl group raised the coupling efficiency and α-selectivity during sialylation [94,95].

The initial purpose of the acetylation of the C5 acetamido group is to prevent *N*-methylation in the course of MeOTf-promoted glycosidation using methylthioglycoside of Neu5Ac-α-(2–3)-Gal as a glycosyl donor. Without the acetyl protection, the glycosidation with a glucosyl acceptor produced *N*-acetyl-*N*-methyl trisaccharide in 70% yield. *N*,*N*-Diacetyl



Scheme 28



Scheme 29

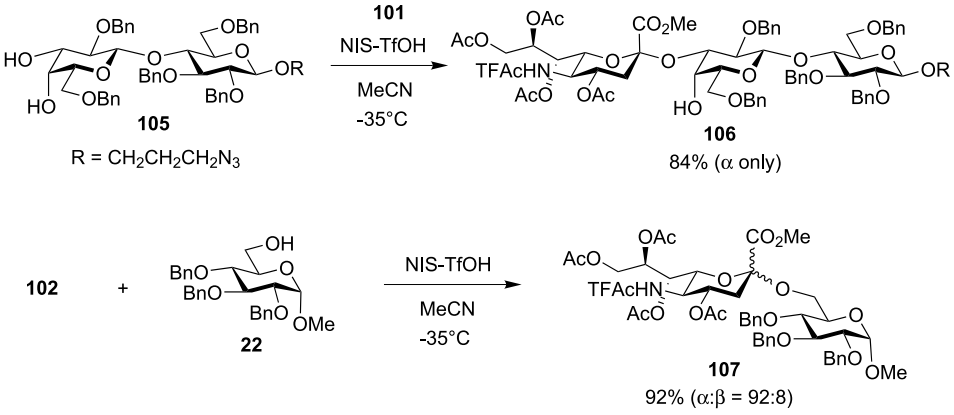
derivative **93** can be prepared by the acid-catalyzed acetylation of the *N*-acetyl derivative **42** with isopropenyl acetate at 65 °C in 99% yield (*Scheme 28*). They found that the glycosidation of the *N*,*N*-diacetyl sialy donor **93** with the suitably protected galactosyl acceptor **55** by activation with NIS-TfOH in MeCN was swift and terminated within 5 min, and the sialyl outcome **95** was produced as a single α-isomer in high yield (72%). More surprisingly, the sialylation of 4,6-benzylidenated galactosyl acceptor **96** in CH_2Cl_2 also exhibited perfect α-selectivity, producing disaccharide **97** in 72% yield. Upon the action by diphenyl sulfoxide, Tf_2O, and TTBP, the 2-phenylsulfenyl derivative **94** was condensed with the C6 hydroxyl of galactose derivative **98** in CH_2Cl_2 to produce α-glycoside **99** solely [96]. However, the α-selectivity differed depending on the structure of the coupling partner.

The new finding of the *remote functionality effect* on the sialyl donor property has given rise to a variety of C5-modified sialyl donors **101**–**104** (*Scheme 29*).

4.2.2 *N*-Trifluoroacetyl Derivatives

Originally, the *N*-trifluoroacetyl (TFAc) derivative of sialic acid was introduced by Bovins and co-workers as a 2-bromide glycosyl donor, which was reacted with benzyl alcohol in the presence of sym-collidine to give a 1/2 mixture of α- and β-glycosides in 30% yield [16]. In our laboratory, the 2-phenylsulfenyl derivative of *N*-TFAc sialic acid has been used for the synthesis of de-*N*-acetyl-6-sulfo-sialyl Lewis X [97]. However, Boons and co-workers were again first to describe the high potential of the *N*-TFAc sialyl donor [98].

The glycosidation of the methylthioglycoside of *N*-TFAc sialic acid derivative **101** with 3′,4′-dihydroxy lactoside derivative **105** in the presence of NIS-TfOH at −35 °C in MeCN produced sole α-sialoside with improved yield (84%), which also terminated within 5 min (*Scheme 30*). Also, 2-phenylsulfenyl derivative **102** exhibited excellent glycosyl donor properties in the coupling reaction with the 6-hydroxy derivative of glucoside **22**, producing disaccharide **107** with high α-selectivity. Furthermore, the highly reactive sialyl donor



Scheme 30

was also successfully applied to the synthesis of α-(2–8)-linked disialic acid (discussed in *Section 5.1.2*).

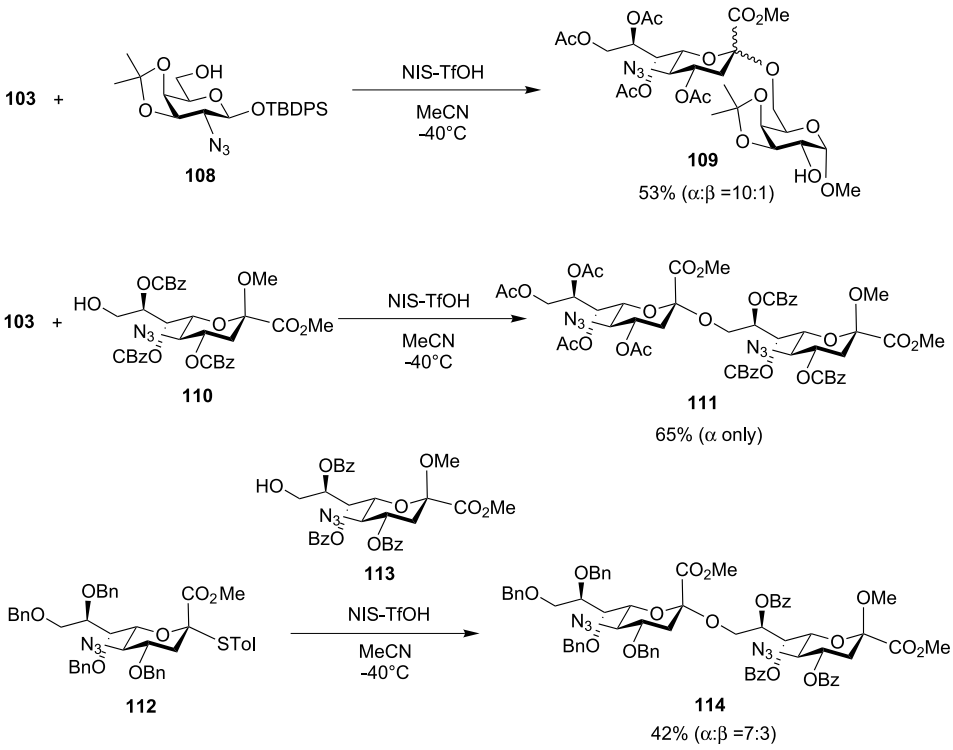
4.2.3 5-Azido Derivatives

It was also reported that the substitution of the C5 acetamido group with an azido group enhances the α-selectivity during sialylation in MeCN, especially with primary sugar hydroxyls [99,100]. The azido group can be introduced at the C5 position by diazo transfer reaction of the corresponding 5-amino derivative with TfN_3 to afford the C5 azido derivative, which was successively acetylated (vide supra) [99]. As shown in *Scheme 31*, the power of the 5-azido donor **103** was successfully applied to the synthesis of α-(2–9)-linked disialic acid, where 9-hydroxy-5-azido derivative **110** served as the glycosylation partner. When the acetyl groups within **103** were replaced with benzyl groups, however, the yield of α-sialyl product was extremely diminished [101].

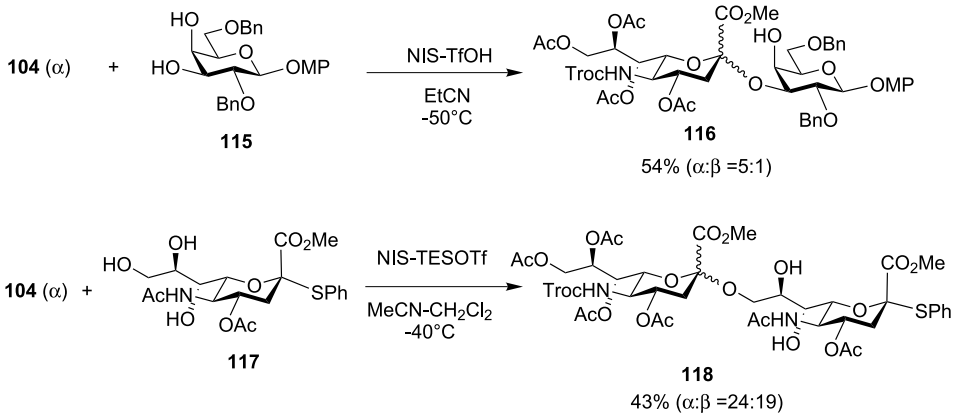
4.2.4 *N*-2,2,2-Trichloroethoxycarbonyl Derivatives

The 2,2,2-trichloroethoxycarbamoyl (*N*-Troc) group at the C5 position also serves as an enhancer of the reactivity of a sialic acid donor during glycosidation. The synthesis of the *N*-Troc phenylthioglycoside donor was first introduced by Wu and co-workers; it was incorporated within the synthesis of a α-(2–5)-linked oligomer of Neu5Gc [102]. There is easy access to *N*-Troc derivative **104** from the corresponding 5-amino derivative as shown in *Scheme 29*. The high potential of α- and β-phenylthioglycoside derivatives **104** were explored by our group [103,104] and Takahashi's group [105,106].

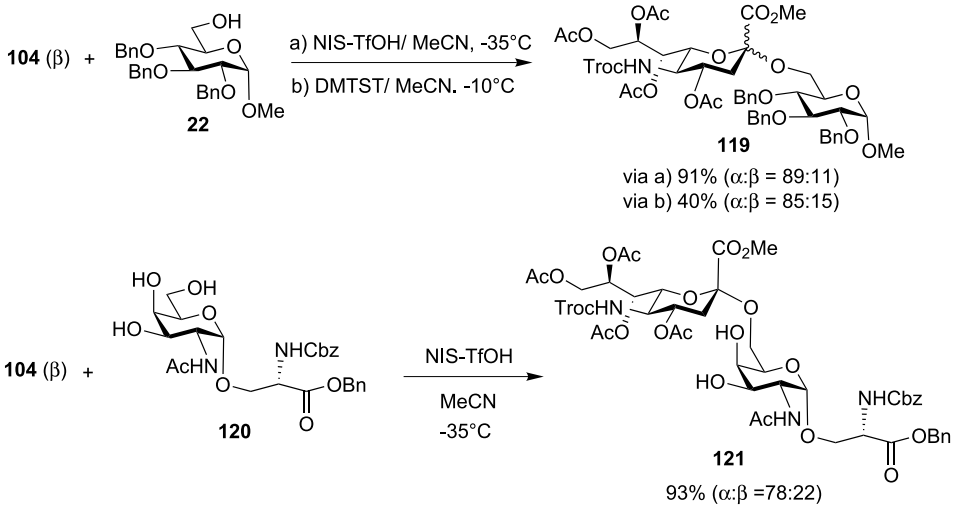
α-Sialylation with the *N*-Troc sialyl donor in MeCN is more effective by comparison with the corresponding *N*-acetyl donor. The glycosylation of 3,4-dihydroxy galactosyl acceptor **115** with *N*-Troc donor **104** in the presence of NIS-TfOH in EtCN at −50 °C terminated within 20 min to produce α-sialoside in 54% yield with β-isomer (10%), whereas the reaction with the *N*-acetyl donor was sluggish at −25 °C in MeCN to afford α-sialoside in 23%



Scheme 31



Scheme 32

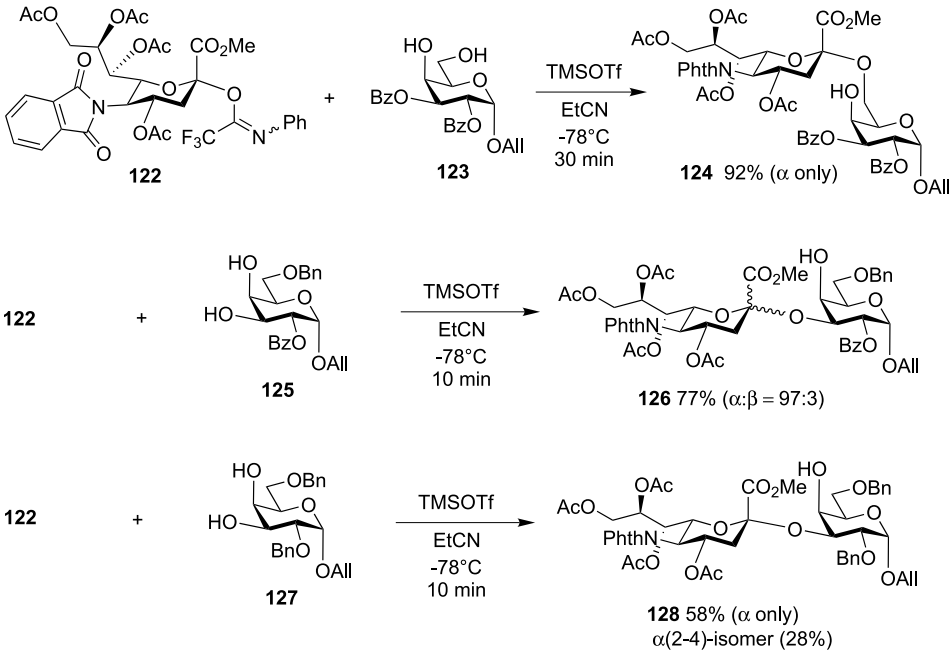


Scheme 33

yield (*Scheme 32*). Because of the distinct difference of the reactivity between *N*-Troc and *N*-acetyl donors, an "armed-disarmed"-like coupling reaction could be performed between the potent phenylthioglycoside of *N*-Troc sialic acid **104** and the less reactive phenylthioglycoside of *N*-acetyl sialic acid **117**, producing (2–9)-linked disialoside **118** in 43% yield ($\alpha/\beta = 24/19$). In Takahashi's group, β-phenylthioglycoside of *N*-Troc sialic acid proved to be a prominent glycosyl donor during work on glycosidation with a variety of C5-functionalized sialyl donors. The NIS-TfOH system has better affinity to the *N*-Troc sialyl donor **104** than DMTST does. An example is shown in *Scheme 33*. Furthermore, in the coupling reaction of *N*-Troc donor **104** and the primary hydroxyl of galactosyl serine derivative **120**, the quantity of molecular sieves (3A) and the concentration of substrates turned out to influence the efficiency of the reaction. Under optimized conditions (molecular sieve 3 Å; 0.5 g mmol^{-1}), the glycosylation of **120** with **104** in MeCN (5 mL mmol^{-1}) fashioned sialyl Tn antigen glycan **121** in 84% yield. They also have incorporated the *N*-Troc donor into a one-pot synthesis of sialyl T antigen frame, successfully.

4.2.5 *N*-Phthaloyl Derivative

Recently, a *N*-phthalimido-2-trifluoroacetimidate derivative of sialic acid **122** has been introduced as an efficient glycosyl donor (*Scheme 34*) [107]. It could be glycosidated with C6 hydroxyl of galactosyl acceptors **123** in MeCN catalyzed by TMSOTf to exclusively produce α-sialyl outcome **124**. Similarly, the glycosidation with *p*-nitrophenyl 2,6-di-*O*-benzylated galactose derivative **125** produced α-sialoside **126** in 72% yield along with a slight quantity of β-isomer. However, when the benzoyl group at the C2 position was replaced with a benzyl group, the sialylation also took place at the C4 hydroxyl to produce **128** (58%) along with $\alpha(2 \rightarrow 4)$-isomer (28%).

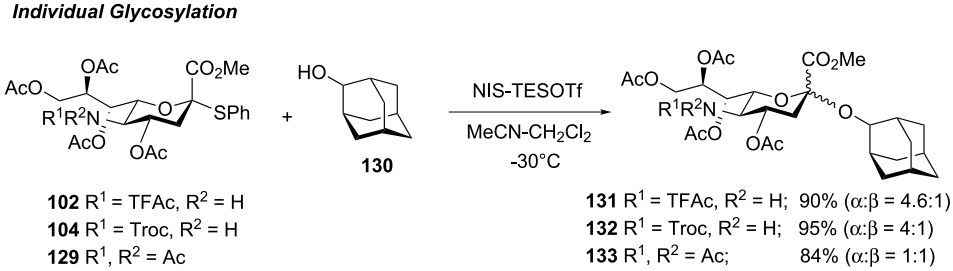


Scheme 34

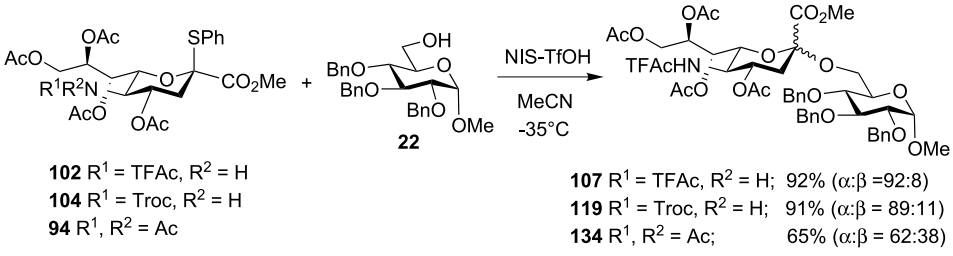
4.2.6 Comparison of Glycosyl Donor Properties

When making a comparison of sialyl donor properties, one should consider that it is difficult to conclude the general order between various sialyl donors in terms of glycosidation efficiency, because the efficiency differs depending on the match-mismatch relationships between glycosyl donor and acceptor. Accordingly, the relationship is related to the relative energy level of the transition state of the substrate complex, which comprises an oxocarbenium ion, acceptor, anionic species derived from the glycosylation promoter (triflate anion, etc), solvent molecule, and so on. Therefore, one can conclude the individual order between sialyl donors in terms of glycosidation efficiency for each reaction system.

In order to compare the glycosylation efficiency of C5-modified sialyl donors, our group has conducted competitive coupling reactions (*Scheme 35*) [103]. The individual glycosylation of *N*,*N*-diacetyl, *N*-TFAc, and *N*-Troc donors (**129**, **102**, and **104**) with 2-adamantanol **130** promoted by NIS-TfOH in MeCN-CH_2Cl_2 (5/1) provided sialyl glycosides **133** (84%, $\alpha/\beta = 1/1$), **131** (90%, $\alpha/\beta = 4.6/1$), **132** (95%, $\alpha/\beta = 4/1$), respectively. In all events, reactions terminated within 10 min. Next, competitive coupling reactions of **102**, **104**, and **129** under similar conditions afforded *N*-Troc sialoside **132** (40%, $\alpha/\beta = 4/1$), *N*,*N*-diacetyl sialoside **133** (22%, $\alpha/\beta = 1/1$), and *N*-TFAc sialoside **131** (15%, $\alpha/\beta = 4/1$). This result suggests the hierarchy of *α-sialylation efficiency* is *N*-Troc donor **104** > *N*-TFAc donor **102** > *N*,*N*-diacetyl donor **122** *in the reaction system*.



Scheme 35



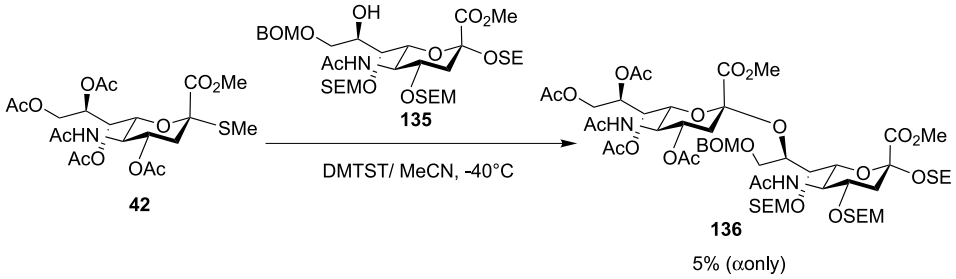
Scheme 36

As depicted in *Scheme 36* [106], the results of glycosylations of the primary hydroxyl of glucosyl acceptor **22** with *N*-Troc, *N*-TFAc, and *N*,*N*-diacetyl sialyl donors (**104**, **102**, and **94**) promoted by NIS-TfOH in MeCN at −35 °C also showed a similar hierarchy of the α-sialylation efficiency between these donors; *N*-Troc sialoside **119** was obtained in 91% ($\alpha/\beta = 89/11$), *N*-TFAc sialoside **107** in 92% ($\alpha/\beta = 92/8$), and *N*,*N*-diacetyl sialoside **134** in 65% yield ($\alpha/\beta = 62/38$), respectively. On the basis of these results, it can be concluded that the efficiency of α-sialylation with a *N*,*N*-diacetyl sialyl donor is less constant than the corresponding *N*-Troc and *N*-TFAc derivatives, depending on the reaction system.

5 Synthesis of an Oligomer of Sialic Acid

5.1 α-(2–8)-Linked Disialic Acid

The synthesis of α-(2–8)-linked disialic acid is complicated because of the remarkably diminished reactivity of the C8 hydroxyl of Neu5Ac. The difficulty was exemplified by the unsuccessful results of the reaction shown in *Scheme 37* [38]. Schmidt has hypothesized that the



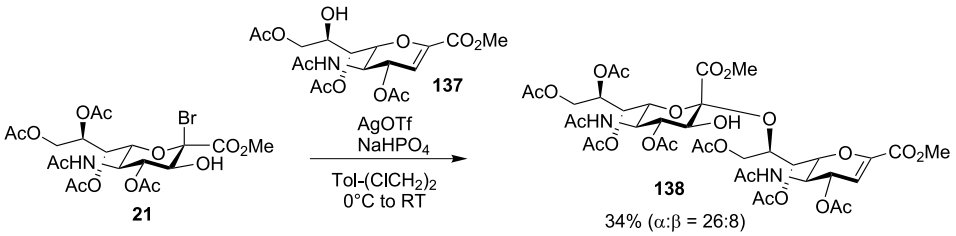
Scheme 37

low nucleophilicity is due to the complicated interaction with the C5 acetamido group, ring oxygen, C1 carboxylate group, or glycosidic C2-OR bond [108,109].

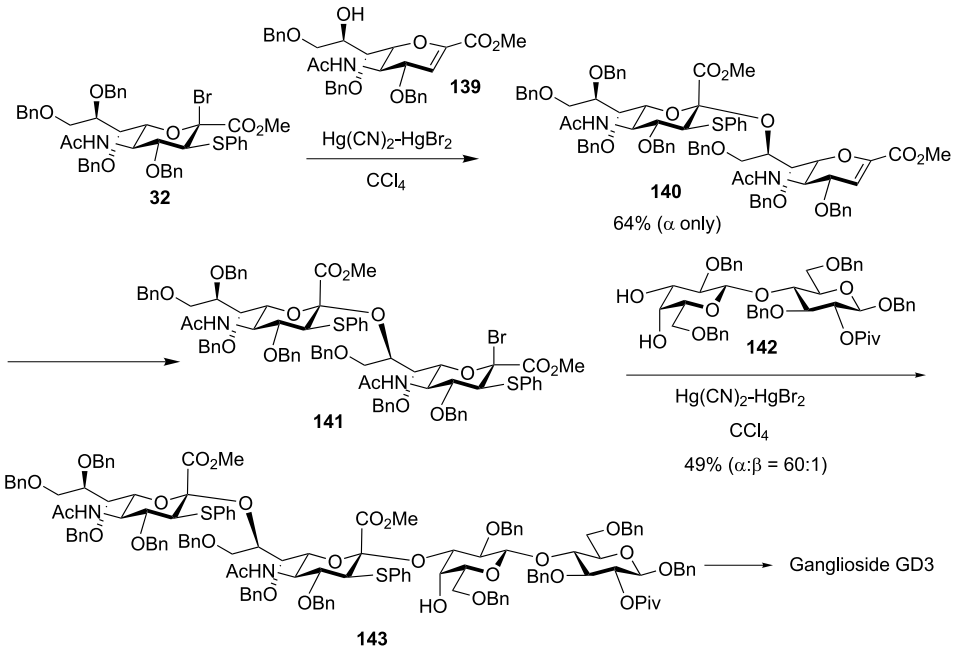
5.1.1 The Use of C3-Appended Sialyl Donors

The first accomplishment of α-(2–8)-disialic acid synthesis came with the combined use of the 3-hydroxy derivative of Neu5Ac **21** and 2,3-en derivative of Neu5Ac **137**, which was expected to prevent the intramolecular hydrogen bonding between the C8 hydroxyl and C1-carboxylate group or C2-OR bond. The coupling reaction was promoted by AgOTf in the presence of $NaHPO_4$ to afford the dimer **138** in 34% yield as a 3/1 mixture of α/β anomers (*Scheme 38*) [110].

Other C3-appended-type donors were also used for the production of α-(2–8)-disialic acid derivatives with the combination of 2,3-en-type glycosyl acceptors [31,111]. Ogawa's group employed the 3-phenylsulfenyl donor **32** and the 4,7,9-tri-*O*-benzylated 2,3-en acceptor **139** in the first total synthesis of ganglioside GD3. The coupling reaction provided single α-isomer of disialic acid **140** in 64% yield. The dimer was further converted to the 3-phenylsulfenyl disialyl derivative **141**, which was glycosidated with C3′ hydroxyl within lactoside derivative **142** in high yield, producing GD3 glycan frame **143** (*Scheme 39*) [110]. The coupling of the C3-appended donor with the Neu5Ac acceptor in $^2C_5$ chair form was also performed by several groups [112,113].



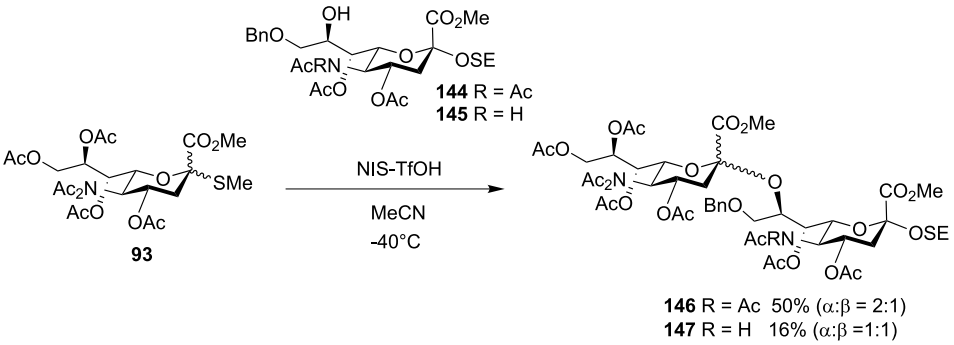
Scheme 38



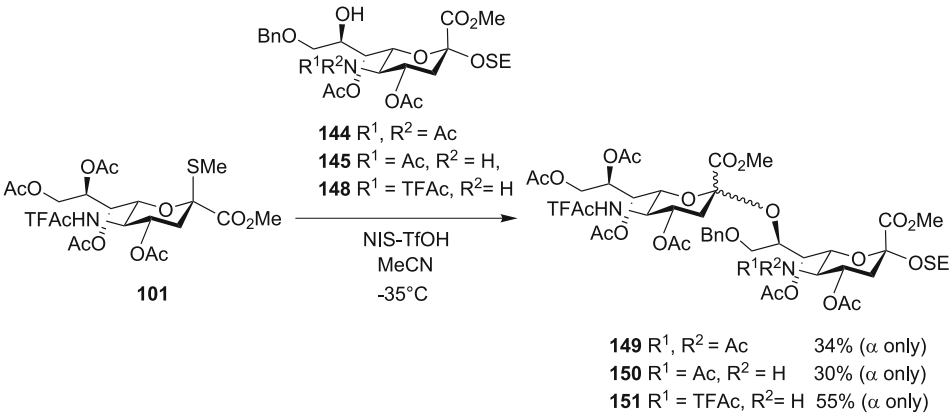
Scheme 39

5.1.2 The Use of C5-Modified Sialyl Units

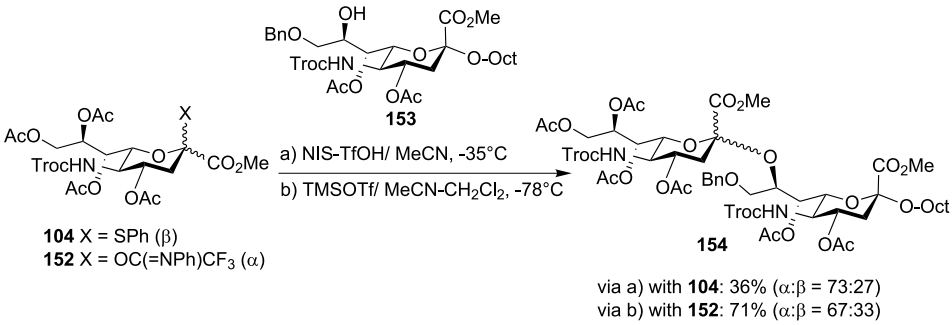
Similar to the reactivity tuning of sialyl donors mentioned above, it was found that the modification of the C5 acetamido group or its substitution by other functionalities also raises the reactivity of the C8 hydroxyl of sialic acid. Boons and co-workers originally synthesized *N*,*N*-diacetyl sialyl acceptor **144**, which was applied to the sialylation with *N*,*N*-diacetyl sialyl donor **93** in MeCN at −40 °C. In comparison to *N*-acetyl sialyl acceptor **145**, the sialylation produced α-(2–8)-disialic acid **146** in raised yield (50%, $\alpha/\beta = 2/1$) (*Scheme 40*) [94,95].



Scheme 40



Scheme 41



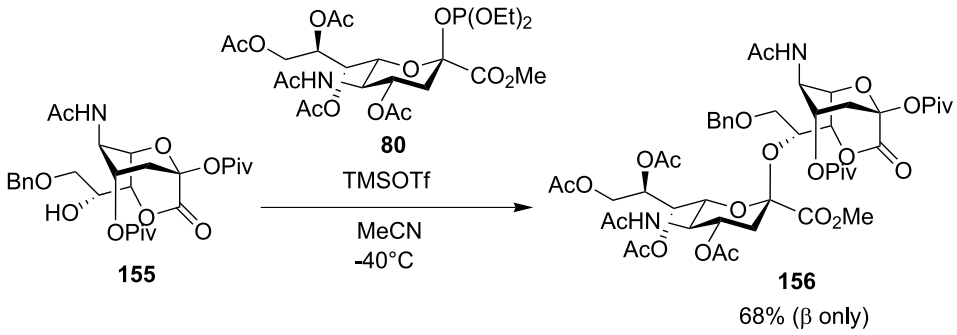
Scheme 42

Boons and co-workers next examined the coupling reaction between *N*-TFAc sialyl donor **101** and acceptor **148** (*Scheme 41*) [98]. As a result, the reaction provided the corresponding dimer **151** in 55% yield as a single isomer. This method enabled the highly stereoselective synthesis of GD3 ganglioside.

Similarly, the coupling reaction between the *N*-Troc sialyl donor and acceptor proved effective. 2-Trifluoroacetimidate-5-*N*-Troc donor **152** was reacted with *N*-Troc sialyl acceptor **153** in the presence of a catalytic amount of TMSOTf at −78 °C in MeCN-CH_2Cl_2 to afford the dimer **154** in 71% yield as a stereo mixture ($\alpha/\beta = 67/33$) (*Scheme 42*) [114].

5.1.3 Conformational Change of the Sialyl Acceptor

In order to prevent the steric hampering of the C5 acetamido group via intramolecular hydrogen bonding, Schmidt's group has converted the $^2C_5$ conformation into $^5C_2$ by making a 1,7-lacton bridge, where the C8 hydroxyl is far from the acetamido group. This improvement of steric circumstance around the C8 hydroxyl resulted in an increase in the yield of glycosylation product, but β-anomer **156** was solely produced (*Scheme 43*) [108].



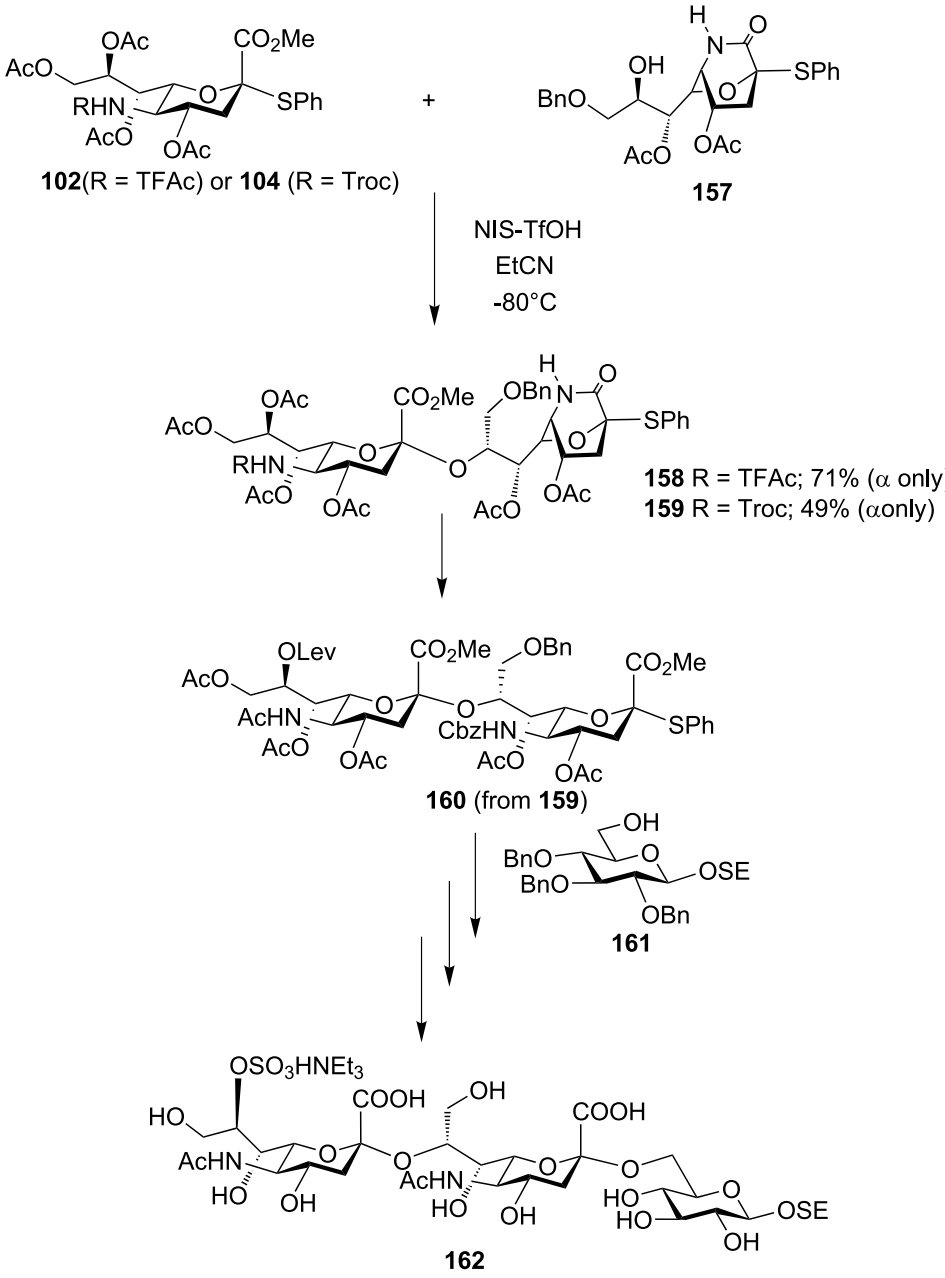
Scheme 43

On the other hand, 1,5-lactamized sialic acid derivative **157**, which was developed by our group, served as an excellent coupling partner for α-sialylation (*Scheme 44*) [115]. Thus, the glycosylation of the C8 hydroxyl of the 1,5-lactamized derivative **157** having a phenylsulfenyl group at C2 with *N*-TFAc and *N*-Troc sialyl donors **102** and **104**, which was promoted by NIS-TfOH in EtCN at −80 °C, delivered α-(2–8)-linked disialic acid **158** and **159** in 71% and 49% yields with complete stereoselectivity, leaving the phenylsulfenyl group at the bridgehead carbon unaffected. For the further glycosidation, the lactam ring was opened to retrieve the $^2C_5$ conformation, and the resulting disialyl donor **160** was enabled to glycosidate with the C6 hydroxyl of glucosyl acceptor **161** to produce the Neu-α-(2–8)-Neu-α-(2–6)-Glc sequence, which led to the glycan structure of Hp-s6 ganglioside **162** having a 8-sulfonyl-Neu5Ac residue.

5.2 α-(2–8)-Linked Oligosialic Acid

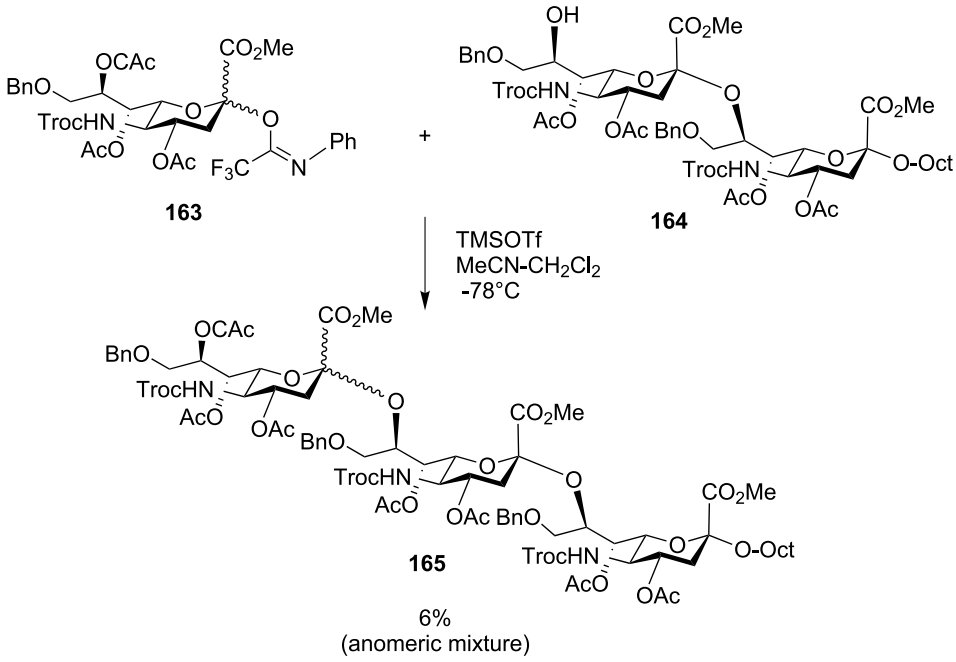
Despite the development of the exquisite methods for α-(2–8)-linked disialic acid synthesis discussed above, the assembly of the α-(2–8)-linked oligomer has been far from a success. Recently, Tanaka disclosed the unpredictable difficulty of the oligomer synthesis. As mentioned above, the coupling of *N*-Troc-protected sialic acid donor and acceptor successfully delivered the dimer of sialic acid. However, the *N*-Troc donor **163** was hardly incorporated into the *N*-Troc disialyl acceptor **164**: the glycosylation produced the stereo mixture of trisialic acid **165** in 6% yield (*Scheme 45*) [114].

On the basis of this lesson, Tanaka has redesigned the strategy of α-(2–8)-linked oligosialic acid synthesis [116]. As shown in *Scheme 46*, the 5-*N*-4-*O*-oxazolidinone moiety was introduced into the sialyl donor and acceptor. Surprisingly, the coupling reaction of the sialy donor **166** and acceptor **167** promoted by NIS-TfOH provided solely α-(2–8)-linked dimer **168** in 86% yield without the assistance of MeCN. Also in the case of glycosylation of the C6 hydroxyl of the glucoside derivative in CH_2Cl_2, α-sialoside was again the sole product. Furthermore, the sialylation of the C8 hydroxyl within the corresponding dimer **169** and trimer **171** acceptors with the 4,5-oxazolidinone sialyl donor **166** proved α-selective and high-yielding. Thereby, the α-(2–8)-linked tetrasialic acid has been synthesized for the first time.



Glycan part of Hp-s6

Scheme 44



Scheme 45

5.3 α-(2–9)-Linked Oligosialic Acid

α-(2–9)-Linkage between sialic acids can be assembled by straightforward chemistry, due to the high reactivity of the C9 primary hydroxyl of Neu5Ac. Initial synthesis has been accomplished by the coupling reaction of the 2-chloro sialyl donor and 9-hydroxy derivative of Neu5Ac in the presence of $Hg(CN)_2$-$HgBr_2$ [117]. To date there have been several reports on α-(2–9)-linked dimer synthesis, where the thioglycoside donor, C3-appended donor, or C5-modified donor was successfully used [95,99,110,116,118]. For a recent example, the assembly of α-(2–9)-linked pentasialic acid by Lin's group is shown in *Scheme 47* [119].

5.4 α-(2–4) and α-(2–5)-Linked Disialic Acid

Recently, various new gangliosides have been isolated from marine animals, some of which have a α-(2–4)-linked disialic acid residue within their glycan structures [120,121]. The construction of the α-(2–4)-linkage is not straightforward, due to the low reactivity of the C4 hydroxyl of Neu5Ac.

An initial attempt of sialylation of the C4 hydroxyl of the Neu5Ac derivative **181** with *N*-Troc sialyl donor **104** in our laboratory resulted in the production of a stereo mixture of disialic acid **182** in less than 10% yield (*Scheme 48*) [115].

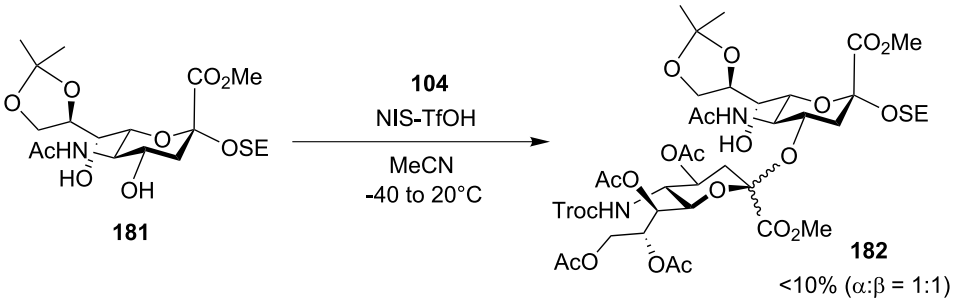
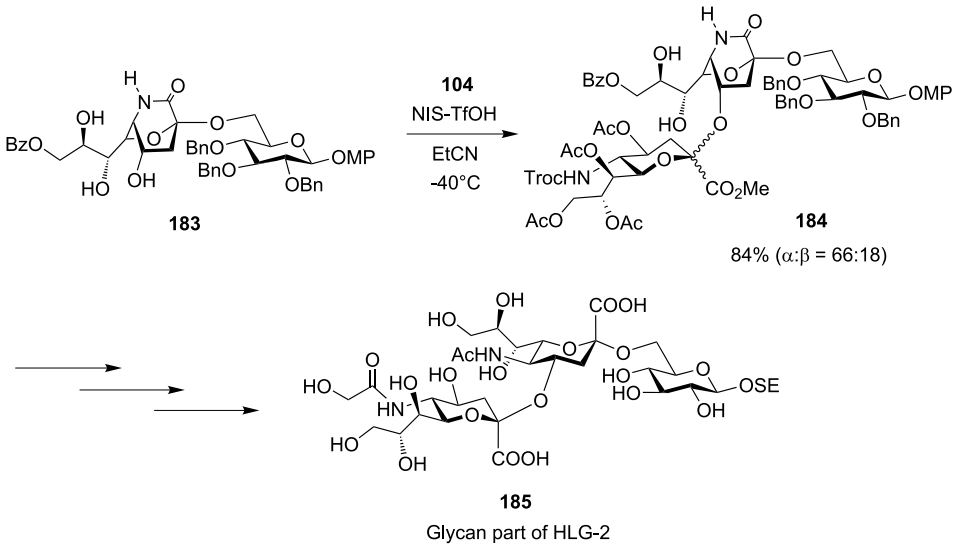
Scheme 47



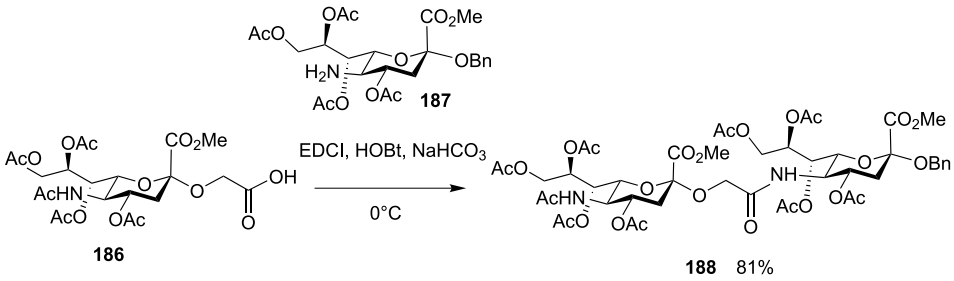
Scheme 48



Scheme 49

The breakthrough again came with the introduction of a 1,5-lactam bridge into the sialic acid acceptor (*Scheme 49*) [115]. The reaction of the 1,5-lactamized sialoside acceptor **183** with *N*-Troc donor **104** gave Neu-α-(2–4)-Neu-α-(2–6)-Glc trisaccharide **184** with improved efficiency (84%, $\alpha/\beta = 66/18$). The trisaccharide was further converted to Neu5Gc-α-(2–4)-Neu5Ac-α-(2–6)-Glc glycan frame **185** of the new ganglioside HLG-2. Taking account of this result, it can be hypothesized that the low reactivity of the C4 hydroxyl of Neu5Ac is probably due to steric hampering by the C5 acetamido group, similar to the case of the C8 hydroxyl.

Recently, *O*-glycolyl-linked oligo-sialic acid was also identified as a component of glycoproteins associated with the egg jelly coat of sea urchins [4]. Wu's group first reported the assembly of α-(2–5)-linked dimeric sialic acid by the condensation of sialyl glycolyl acid derivative **186** with 5-amino-sialic acid **187** in the presence of EDCI and HOBt (*Scheme 50*) [102].

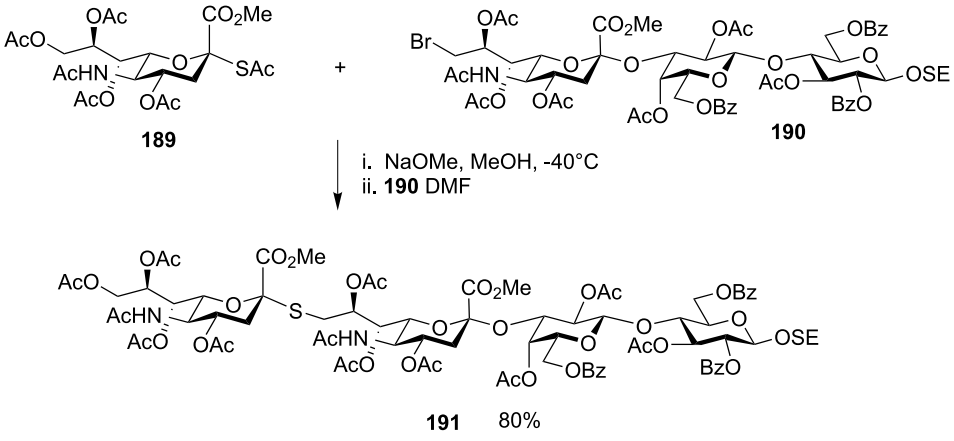


Scheme 50

Moreover, this approach was effective for the synthesis of a α-(2–5)-linked NeuGc oligomer as large as octasaccharide [122]. Other groups also reported the synthesis of the α-(2–5)-linked dimer by similar approaches [123,124].

6 Synthesis of Sialyl *S*- and *C*-Glycosides

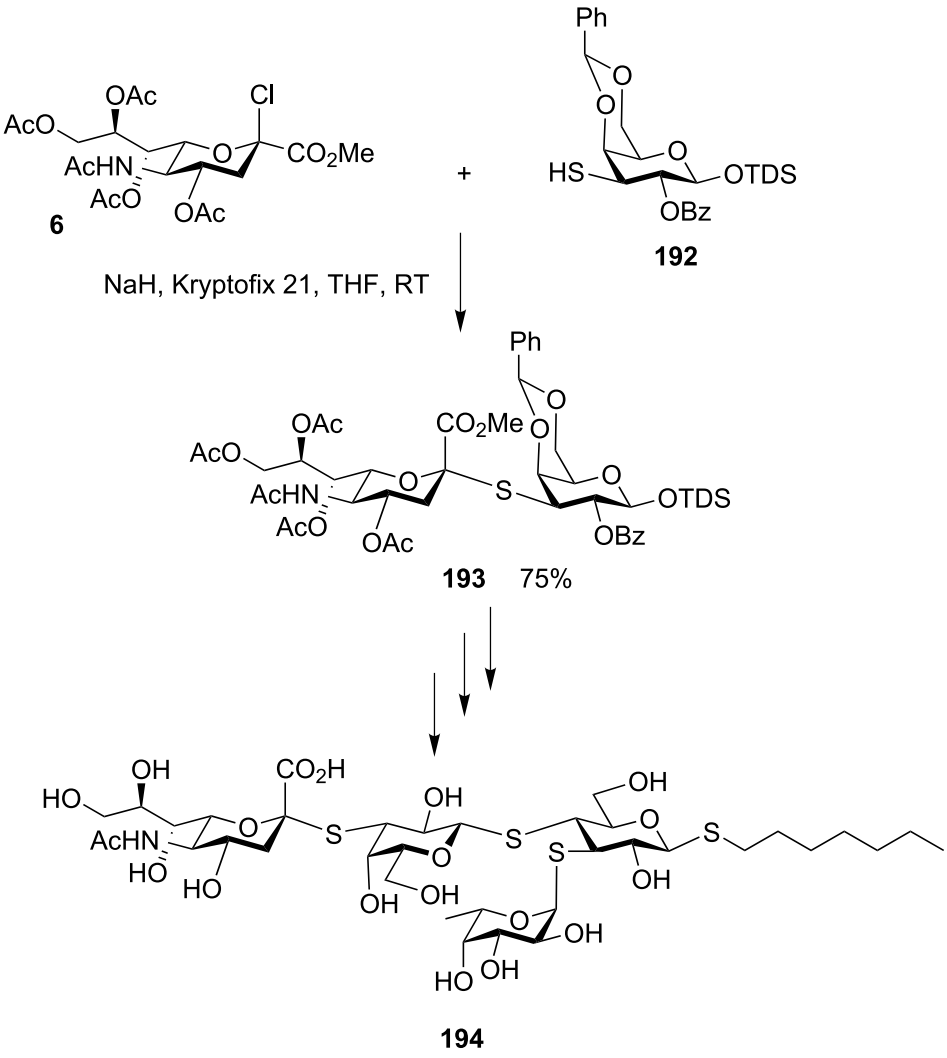
Replacement of the anomeric oxygen of the glycoside bond by sulfur, carbon, or nitrogen is an important technique of carbohydrate mimicking. Such replacement endows the carbohydrate with resistance to enzyme-mediated hydrolysis with the upkeep of the original biological property. *S*- and *C*-linked sialyl glycosides have been targeted for the purpose of the application to biological study, carbohydrate-based drug development, vaccination [125] and so on.



Scheme 51

6.1 *S*-Glycoside

Thioglycoside between sialic acid and other sugars can be synthesized easily by the S_N2 reaction of the glycosylthiolate anion with a halo or alkylsulfonyl sugar counterpart [126]. Mostly, the α-sialyl thiolate anion, which was generated by the treatment of α-thioacetate of Neu5Ac with NaOMe, was subsequently used for the reaction with a secondary halogeno- or alkylsulfonyl-carbon to furnish thioglycoside with complete retention of α-configuration (*Scheme 51*) [127].



Scheme 52

The S_N2 replacement of the 2-β-chloro derivative of Neu5Ac with a thiol group incorporated into the sugar derivative also successfully produces sialyl thioglycoside. In recent examples, the latter approach was incorporated into sialyl thiooligosaccharide synthesis (Scheme 52) [128].

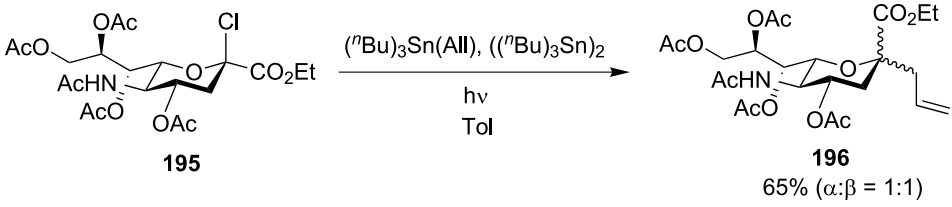
6.2 *C*-Glycosides

Since sialyl *C*-glycoside formation results in a quaternary carbon atom, it is synthetically a difficult subject. In addition, as mentioned earlier, due to the electron-withdrawing carboxylate group, the generation of the carbenium ion is also problematic.

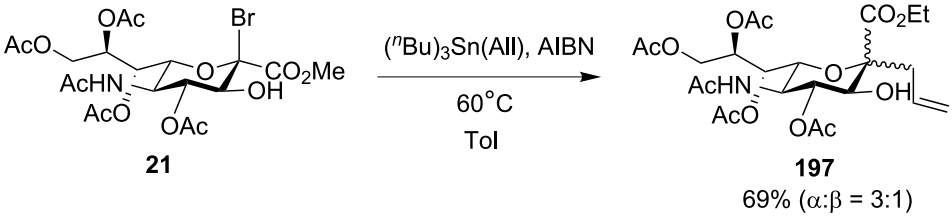
In 1991, the syntheses of sialyl *C*-glycosides were introduced by Bednarski et al., Paulsen et al., and Vasella et al. Bednarski and Paulsen exploited a 2-halogeno derivative of Neu5Ac as a precursor of the anomeric radical, which was anticipated to be stabilized by the "capto-dative effect" of the C1 carboxylate group and ring oxygen. Bednarski reacted the 2-chloro derivative **195** with allyltributyltin and a catalytic amount of bis(tributyltin), and photolized for 18 h to obtain *C*-glycoside **196** as a 1/1 of anomeric mixture in 65% yield (Scheme 53) [129].

To improve the diastereoselectivity of *C*-glycosidation, Paulsen's group exploited 2-bromo-3-hydroxy derivative **21**. As a result, the reaction of **21** with allyltributyltin and AIBN at 60 °C provided **197** (69%), favoring α-glycoside in the ratio of 3/1 (Scheme 54) [130].

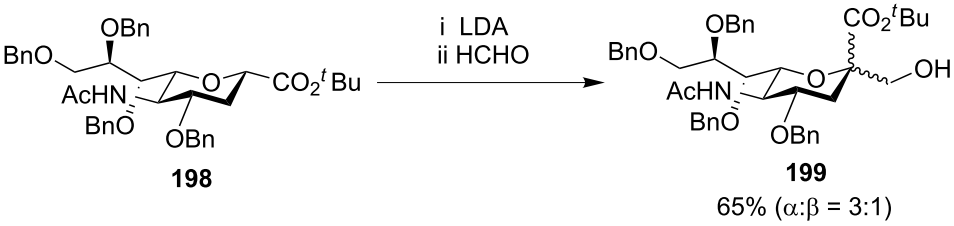
Unlike the radical approaches mentioned above, Vasella exploited a carbanion approach. Thus, the anomeric carbanion was anticipated to be stabilized by the C1-carboxylate group. A 1-deoxy derivative of Neu5Ac **198** was treated with LDA, and the resulting anion was reacted with formaldehyde to produce a 3/1 mixture of α- and β-isomers of 2-hydroxymethyl product **199** (Scheme 55) [131].



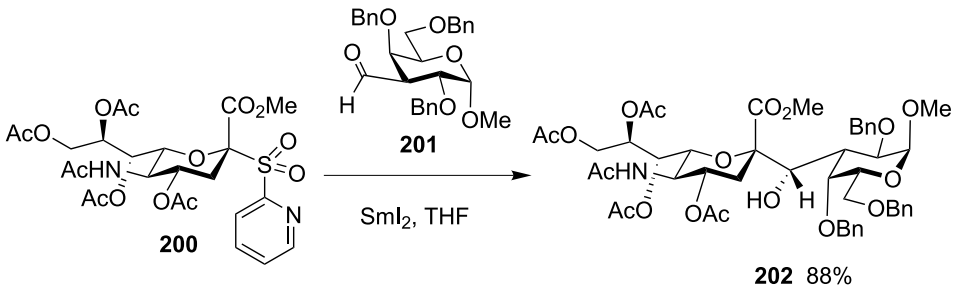
Scheme 53



Scheme 54



Scheme 55



Scheme 56

Also exploiting the anomeric anion approach, Lindhart and co-workers have generated sialyl samarium (III) in situ as an anomeric anion equivalent, which was reacted with carbonyl compounds under Barbier conditions. Thus, a 2-α-pyridyl sulfone derivative of Neu5Ac **200** was reacted with *C*-formyl sugar **201** in the presence of SmI_2 in THF, producing *C*-disaccharide **202** in 88% yield with complete diastereoselectivity (*Scheme 56*) [132]. This approach was successfully applied to the synthesis of *C*-glycoside mimics of biologically relevant sialyl glycans, such as GM3 [133] and sialyl Tn antigen [134]. Later, the 2-sulfone derivative was replaced with 2-pyridylsulfide and 2-acetate derivatives by Beau's group [135,136]. Both derivatives were also capable of serving as precursors for an anomeric anion in samarium-mediated Reformatsky-type coupling reactions, producing *C*-sialyl glycosides. Both approaches developed by Linhart and Beau lead to hydroxymethylene-bridged Neu5Ac-monosaccharide sequences. The hydroxyl group has to be cleaved to complete the replacement of interglycosidic oxygen with carbon.

Schmidt's group has disclosed a different strategy which leads to methylene-bridged *C*-sialoside [137]. They designed a strategy based on the electrophilic cyclization of an open chain precursor of Neu5Ac using phenylselenyl triflate as a cyclization reagent, followed by the generation of the carboxylate moiety and introduction of the nitrogen. This strategy was successfully applied to the synthesis of methylene-bridged Neu5Ac-α-(2–3)-Gal *C*-disaccharide.

7 Closing Remarks

As discussed in this chapter, a large variety of sialic acid donors have been developed, addressing anomeric selectivity during glycosylation. Because of the nucleophilic participation of the auxiliary mounted at C3 with anomeric carbon, the C3-appended derivatives of Neu5Ac have realized nearly complete α-selectivity during the glycosylation of a wide spectrum of glycosyl acceptors. On the other hand, C1-auxiliaries were not generally effective in directing α-selective coupling reactions. The combined use of the nitrile solvent effect and 2-methylsulfenyl, phenylsulfenyl, and xanthate derivatives of Neu5Ac offered facile α-sialylation, the efficacy and practicality of which have been exemplified by a number of syntheses of sialy oligosaccharides. The discovery of a C5 functionality effect on the reactivity of the sialyl donor and sialyl acceptor has brought about the innovation of sialylation chemistry. Furthermore, it has led to the tour de force of the first synthesis of α-(2–8)-linked tetrasialic acid. However, the chemistry underlying the remote functionality effect is yet to be understood.

Abstract

Glycosyltransferases are important biological catalysts in cellular systems generating complex cell surface glycans involved in adhesion and signaling processes. Recent advances in glycoscience have increased the demands to access significant amount of glycans representing the glycome. Glycosyltransferases are now playing a key role for in vitro synthesis of oligosaccharides and the bacterial genome are increasingly utilized for cloning and over expression of active transferases in glycosylation reactions. This chapter highlights the recent progress towards preparative synthesis of oligosaccharides representing terminal sequences of glycoproteins and glycolipids using recombinant transferases. Transferases are also being explored

1 Introduction

Carbohydrates are diverse biological structures that occur naturally in conjugation with proteins (glycoproteins) or lipids (glycolipids) and are involved in different cellular functions. The contribution of glycans in cellular recognition, adhesion, motility, and signaling processes, have been well documented [1,2]. Therefore, abnormalities in biosynthesis or presentation of carbohydrates can effectively lead to functional irregularity and diseased states. However, in almost every instance this pursuit is limited by the unavailability of carbohydrate compounds for in vitro studies, due to the enormous complexity of carbohydrate synthesis.

Extensive efforts have been made to overcome the challenging tasks of carbohydrate synthesis. In a glycosylation reaction, both donors (nucleotide-activated monosaccharides) and acceptors (which receive the activated monosaccharide) contain many similar functional groups that must be differentiated and protected to accomplish a desirable glycosidic bond. The product must then be selectively deprotected for the next round of reactions. The complexity of protecting-group manipulation increases with every additional glycosidic linkage (*Fig. 1*). Furthermore, the two possible isomers concerning the geometry of the anomeric carbon atom of each monosaccharide, i. e. alpha and beta isomers, introduces another level of complication, namely "stereoselectivity," to the field of carbohydrate chemistry. Multiple steps of protection-deprotection, as well as, a careful design of reactions, are required to construct a regio- and stereoselective glycosidic bond in a chemical approach. Thus, traditional organic chemistry with solution phase synthesis is not well-suited with difficulties involved in carbohydrate synthesis [3,4]. Because of this problem, there is currently no single step-wise synthetic approach that is applicable to the synthesis of all oligosaccharides or even, just the 15 million possible tetrasaccharides that can be assembled from the nine common monosaccharides found in humans. Nonetheless, in the past few decades, the work of many research groups has started to open up new paths to oligosaccharide and glycoconjugate synthesis. Coupling techniques with

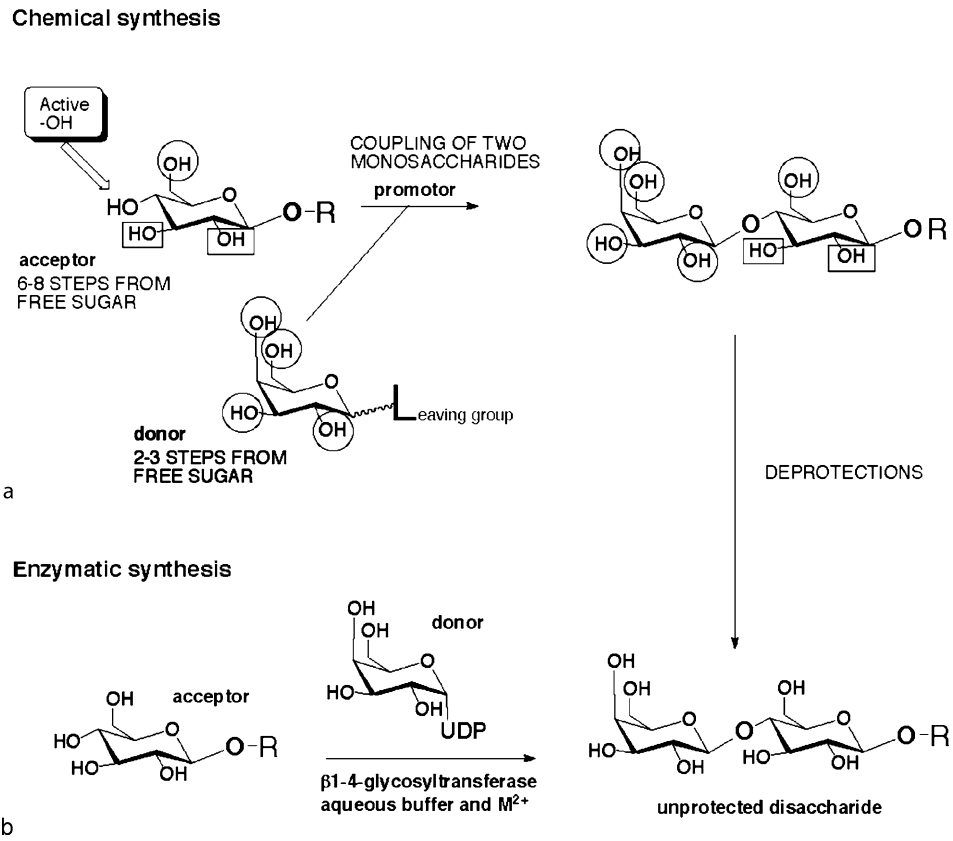

Figure 1
Generalization of chemical and enzymatic synthesis of a carbohydrate disaccharide

better yields and stereoselectivity have been worked out, and new protecting group chemistries have also become available. Alternatives to traditional chemical synthesis, such as solid-phase synthesis and one-pot reactivity based glycosylations [5,6,7] and synthetic automations [5] have been developed to prevail over the synthetic constraints. These elegant methods dramatically shorten and simplify chemical synthesis and, although with differing degrees of difficulty, make it possible to synthesize essentially any glycosidic linkage. Despite such improvements, the construction of a defined glycosidic bond is still one of the most time consuming and challenging tasks facing synthetic chemists, organic synthesis is not realistic for the large-scale pharmaceutical preparations [8].

A practical alternative to traditional, non-biological, organic synthesis is the utility of enzymes as catalysts for oligosaccharide synthesis in chemoenzymatic methods. Through the use of enzymes, the impractical, or sometimes impossible, synthetic manipulations of complex carbohydrates can be performed in an environmentally benign manner. The enzymes can be used as the sole catalyst in a reaction, in combination with other enzymes, or with non-biological reagents. The chiral nature of enzymes results in the formation of defined stereo- and regio

specific products with remarkable rate acceleration of the reaction (typically 10^5 to 10^8). Most enzymes operate at room temperature, under neutral aqueous conditions, and in the absence of substrate functional-group protection. The application of enzymes in carbohydrate synthesis offers promising opportunities for the development of industrial, chemical, and pharmaceutical processes [9,10].

In this chapter, we discuss the recent developments in glycosyltransferase (GT) preparations and their use in chemoenzymatic synthesis of oligosaccharides. Special attention will be given to the practical preparative strategy of the multi-step synthesis of complex carbohydrates using a "tool box" of functional recombinant enzymes developed in different expression systems. A library of glycans with representative structures found on glycoproteins and glycolipids have been generated in preparative scale and enabled distribution of these useful compounds to multiple users in the community to be used towards advancing the field of glycomics (http://www.functionalglycomics.com).

2 Oligosaccharide Synthesis with Enzymes

The coupling of monosaccharides to form oligosaccharides via specific, glycosidic linkages can be catalyzed by glycosidases or GTs [10].

2.1 Glycosidases

Glycosidases, enzymes that in vivo function to cleave oligosaccharides and polysaccharides via glycosyl transfer to water, can form glycosidic linkages under conditions in which a carbohydrate hydroxyl moiety acts as a more efficient nucleophile than water. Glycosidases were used well ahead of GTs for the preparative synthesis of sugars and are, most frequently, used to synthesize oligosaccarides via "transglycosylation" [11] and condensation [12]. Glycosidases are stable, easy to isolate and generally, more available than GTs. Glycosidases, however, have suffered from two major drawbacks: poor regio-selectivities and low chemical yields for the construction of glycosidic bonds. The low production yield is due to the fact that the glycosidases promote not only glycosylation, but also the reverse reaction, namely, hydrolysis of the resulting product. Efforts have been made to circumvent the limitations of glycosidases by mutagenizing methods that abolish glycosyl hydrolase activity and create novel catalysts, such as "glycosylsynthases" [13] (see also Chap. 5.9).

2.2 Glycosyltransferases

GTs, on the other hand, offer the significant advantages of increased yield and specificity relative to glycosidase-based syntheses. They do so, however, at the expense of limited substrate specificity, relatively high cost of the glycosyl nucleotide donor, and limited enzyme availability. GTs are responsible for the biosynthesis of oligosaccharides and are divided into two classes according to the type of glycosyl donor they accept. One group follows the Leloir pathway, which is the utilization of activated glycosyl esters of nucleoside mono- or diphosphates as glycosyl donors. This group was named after the Argentinean biochemist that discovered and investigated its properties and functions. The other group, the non-Leloir transferases typically

uses glycosyl phosphates as glycosyl donors (i. e. monosaccharides). Non-Leloir transferases have been used preferentially in synthesizing nucleosides and nucleoside analogs, but also in a variety of oligosaccharides and polysaccharides [14]. Leloir-type GTs, generally known as GTs, are responsible for the synthesis of most *N*- and *O*-linked glycoproteins and glycoconjugates in mammals and display higher stereo- and regioselectivities than both the glycosidase and their glycosyl phosphate-transferring relatives. The activated nucleotide-monosaccharides (glycosyl donors) are the substrates for the GTs in mammals. Each glycosyl donor is accepted by various GTs mediating the transfer of the glycosyl group onto different acceptors. In vivo, these enzymes are generally specific for the given glycosyl donor, the type of linkage to be formed, the structure of the acceptor and a specific hydroxyl group of the acceptor. Such observed specificity is required to permit the synthesis of information-containing biomolecules without a template. Nevertheless, GTs display some flexibility with respect to their substrate requirements under in vitro conditions, i. e. when the substrates are provided in high concentration.

Utilizing GTs in the chemo-enzymatic synthesis of oligosaccharides has in the past, been limited by different restriction factors such as: availability of the enzymes, availability of the activated monosaccharide building blocks, inhibition of glycosylation pathway by the released nucleotide phosphate and the enzyme substrate specificity. To overcome the inhibition effects of by-products and consumption of expensive sugar-nucleotides, elegant sugar-nucleotide regeneration systems have been explored but have shown limited use due to it's rather complex compositions [15].

GTs have been utilized in different contexts to synthesize oligosaccharide moieties on natural glycoconjugates, glycoconjugate mimetics and a variety of un-natural aglycons and analogs. The use of isolated enzymes or engineered whole cells allows the synthesis of oligosaccharides in both, in vitro and in vivo methods. GTs have been mostly utilized as catalysts in aqueous solution reactions ranging from milligram to kilogram scale reactions [16,17]. In order to take advantage of these biocatalysts for preparative synthesis of oligosaccharides two prerequisites have to be fulfilled: the recombinant GTs and the sugar nucleotides have to be available in preparative scales.

Advances in molecular biology have unquestionably diminished most of the restrictions in enzymatic synthesis. Flourishing cloning and isolating GTs from different sources, particularly bacteria [18,19,20], constructing mutated and fusion enzymes [21] with more favorable properties for synthesis than their parent proteins, as well as, bacterial engineering [22], have continuously broadened the GTs utilization in carbohydrate synthesis.

2.2.1 Recombinant Glycosyltransferase Expression

Over 200 GTs appear to exist in mammalian tissues [23]. Extraction and purification of GTs from tissues are neither practical, nor responsive to the demands of large amounts of the enzymes required for enzyme characterization or oligosaccaride synthesis. Since the first GT gene, β4-galactosyltransferase (β4Gal-T), which was cloned two decades ago [24,25], many GT genes from different natural sources have been cloned and most of these enzymes are shown to be suitable for oligosaccharide synthesis [23,26]. In addition, these enzymes have been used for non-natural substrates to synthesize versatile oligosaccharide analogs on a preparative scale for drug discovery in glycobiology research [27,28]. A wide variety

of expression systems, such as bacterial, yeast, insect and mammalian—each with its own advantages and disadvantages—have been used to produce sufficient amounts of GTs for enzymatic characterization and oligosaccharide synthesis. However, large-scale production of eukaryotic enzymes for industrial purposes is still a challenge facing the researchers in the field. Bacterial expression has the advantage of being simple to manipulate, but the disadvantage of lacking the eukaryotic post-translational machinery. This often results in the desired protein being locked in inclusion bodies. Nevertheless, some mammalian GTs have been successfully expressed in *Euscheria coli* and refolded to generate active protein [29,30,31,32]. Insect systems, such as sf-9 and High five, and mammalian systems, such as Chinese hamster ovary (CHO) and monkey and (COS) celllines have been most widely used for expression of GTs; the examples are too numerous to count. However, background endogenous activities, as well as the more complex nature of the laboratory tasks, hamper the large-scale production of mammalian enzymes in these systems. Fungi and yeasts have the advantage of being simpler to cultivate than mammalian cells, while still being eukaryotic. Large-scale expression of GTs was successfully reported in *Aspergillus niger* and yeast species such as the budding yeast *Saccharomyces cerevisiae* and the methylotrophic yeast *Pichia pastoris* [33,34,35]. GT expressions in yeast have been very successful. Recent genetic manipulations of yeast have led to constructing transformed yeast cells that produce GTs that either remain anchored to the cell surface so that the intact yeast cells are being used as an enzyme source [36,37], or are secreted into the culture. The whole yeast cells, used as an enzyme source, can easily be separated from the reaction products and can be used repetitively which makes the technique favorable and attractive.

A large collaborative effort was launched within the Consortium for Functional Glycomics (CFG) to centralize many of the cloned and expressed GTs and over expressing them as active enzymes. These enzymes are expressed as referenced in *Table 1* and continuously being explored for preparative synthesis of oligosaccharides and glycoconjugates as described below.

2.2.2 Sugar Nucleotide Generation Systems

Although several of the recombinant enzymes are readily available for synthesis, their corresponding sugar-nucleotides are not accessible as reagents and are very expensive. These drawbacks were recognized early by Wong and co-workers who introduced the in-situ full cycle regeneration system for sugar-nucleotides [38,39] (*Fig. 2*). Recently, Wang and co-workers extended the concept of sugar-nucleotide generation using the bacterial biosynthetic pathway [40]. Despite these improvements, the full-cycle regeneration approach has not been widely applicable due to its rather complex layout. Therefore, synthesis of milligram amounts of oligosaccharides that utilize stoichiometric amounts of commercial sugar-nucleotides have generally been the preferred choice in many laboratories. Several examples of the synthesis of neo-glycoproteins and glycolipids of well-defined carbohydrate structures have also been recorded in the literature [9,41,42,43,44]. However, with an increasing academic and pharmaceutical interest in the glycomics arena an urgent need for the accessibility of glycoconjugates has been recognized and this reflects the attention given to the large-scale synthesis of this group of compounds.

Recent advances in cloning and recombinant expression of bacterial GTs and their accessory enzymes such as sugar-nucleotide synthases have enabled further scale-up synthesis of

oligosaccharides [20,45]. Several of these sugar-nucleotide synthases and other aldolases can efficiently generate the donor substrates from inexpensive precursors in bulk quantities. For example, utilizing rat UDP-*N*-acetylglucosamine-4′epimerase (GalNAcE) that converts less expensive UDP-GlcNAc to UDP-GalNAc in-situ has drastically reduced the cost of multi-gram synthesis of galactosides [46]. Moreover, the accessory enzyme can also be conveniently combined into one-pot reactions without the need of a full re-cycling system all performed in scaleable amounts (*Fig. 3*).

3 Enzymatic Glycosylation in Solution

Enzymatic synthesis of oligosaccharides can be performed with the general procedure as follows: Reaction mixtures containing acceptor substrates (20–50 mM) and the corresponding sugar-nucleotide donor substrate (1–3 mole equivalents) are dissolved in an enzyme specific buffer including additives (see *Table 1* for details). Reaction is initiated by adding enzymes (typically 1–5 Units / mmole acceptor) to the reaction mixture after which it is slowly agitated at room temperature or 37 °C for 24–48 h. Ion exchange and size exclusion chromatography are the common procedures for product isolation. However, serious purification problems can be encountered when scaling up to multi-gram reactions. Additives, such as nucleotide sugars, buffer salts, and crude enzymes are among the factors that interfere with efficient purification with conventional chromatographic techniques used at the mg-scale. In general, the selected

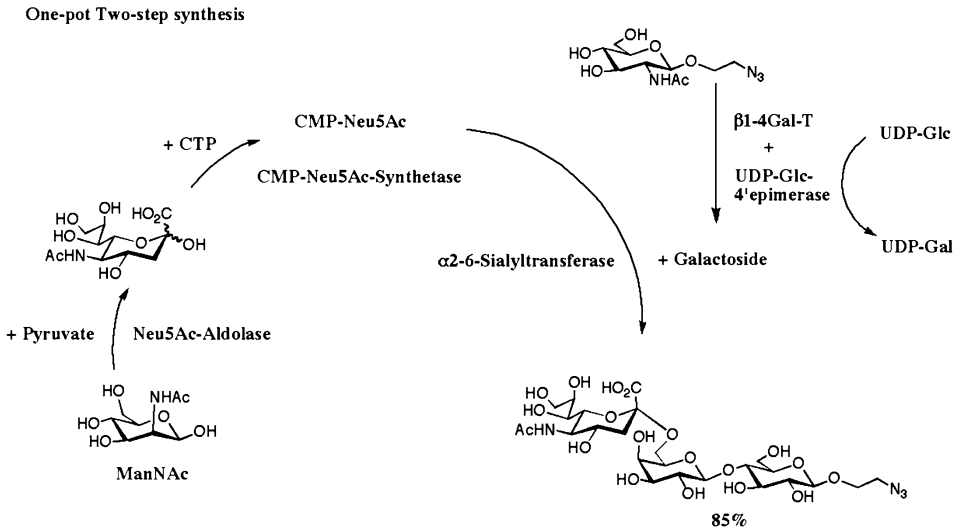

Figure 3
Enzymatic synthesis using partial in-situ generation of sugar nucleotides

isolation strategy depends on the scale and the compounds being prepared. Typical yields are 50–90% with a purity of 90–95% [47]. Various oligosaccharide sequences representing terminal structures of *N*-glycans [48,49] and glycolipids [46,50] have been successfully synthesized in gram-scales, using the simplified one-pot approach.

3.1 Poly-*N*-Acetyllactosamine Synthesis

Poly-*N*-acetyllactosamine (pLN), a unique carbohydrate structure composed of *N*-acetyllactosamine (LN) repeats, is known to represent the backbone of many glycan structures that participate in different cell functions [51,52] as well as being a tumor-associated antigen [53,54,55,56]. pLNs are present in two forms of linkages, Galβ1-3GlcNAc and Galβ1- 4GlcNAc, which constitute the type I pLN and type II pLN, respectively. Because of the practical limitations, most of these structures are not available by isolation. Therefore, the preparation of lactosamine derivatives is crucial for studying their structures and precise interactions with other biomolecules. Numerous chemical syntheses, including chemoenzymatic efforts [57,58,59,60] for pLN have been developed [61,62,63,64,65]. Recently, we further improved the synthesis of pLNs by taking advantage of the relaxed substrate specificity of the recombinant bacterial enzymes β1,4-galactosyltransferase (β4GalT) (entry h, *Table 1*) and β1,3-*N*-acetylglucosaminyltransferase (β3GlcNAcT) (entry a, *Table 1*) [66,67] which, by concerted action, generated repeating LN units. A similar strategy was used, albeit utilizing a β1,3galactosyltransferase (GalT-5) (entry e, *Table 1*) to make type 1 structures. These structures were further modified with different recombinant fucosyltransferases (FUTs) and sialyltransferases (STs) to obtain a diverse collection of pLN derivatives (*Fig. 4* and *Fig. 5*) [49]. Type 1 and type 2 pLN repeats are seen either separately each in one chain,

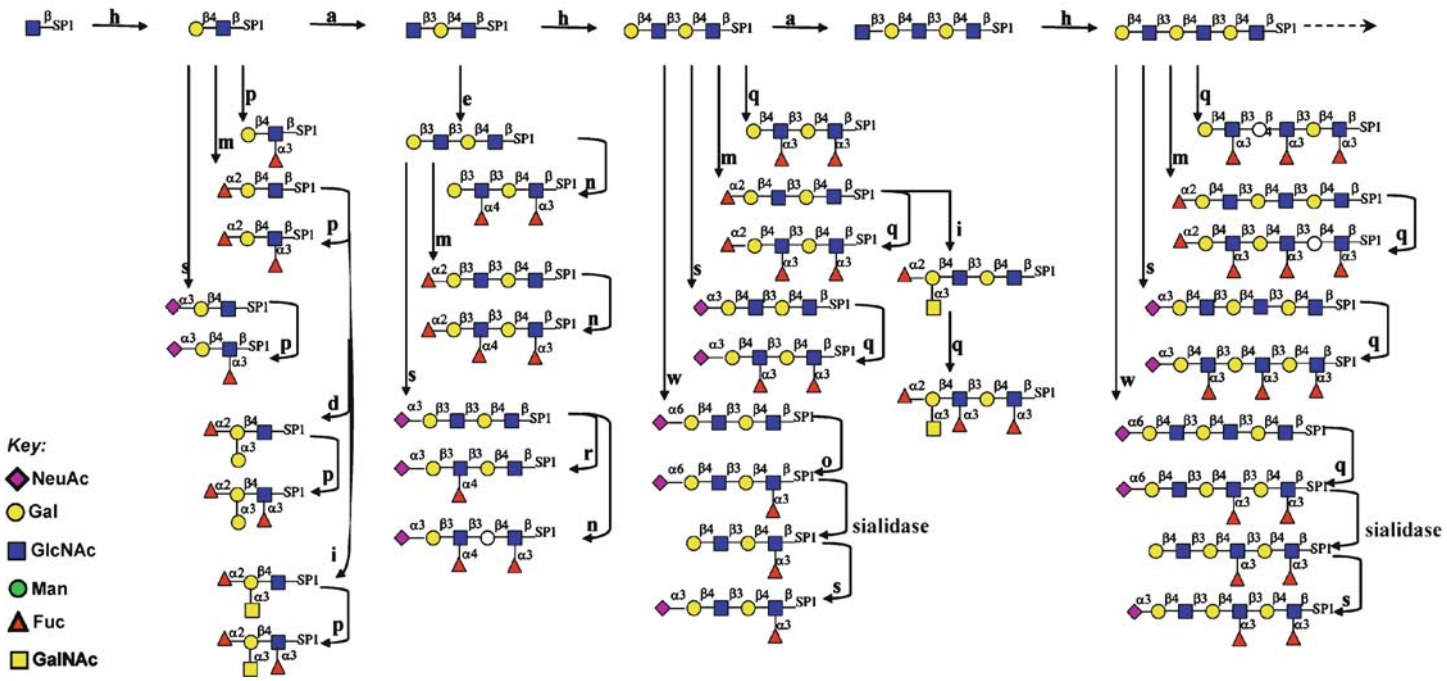

Figure 4
Enzymatic synthesis of poly-*N*-acetyllactosamines of type 2 chains

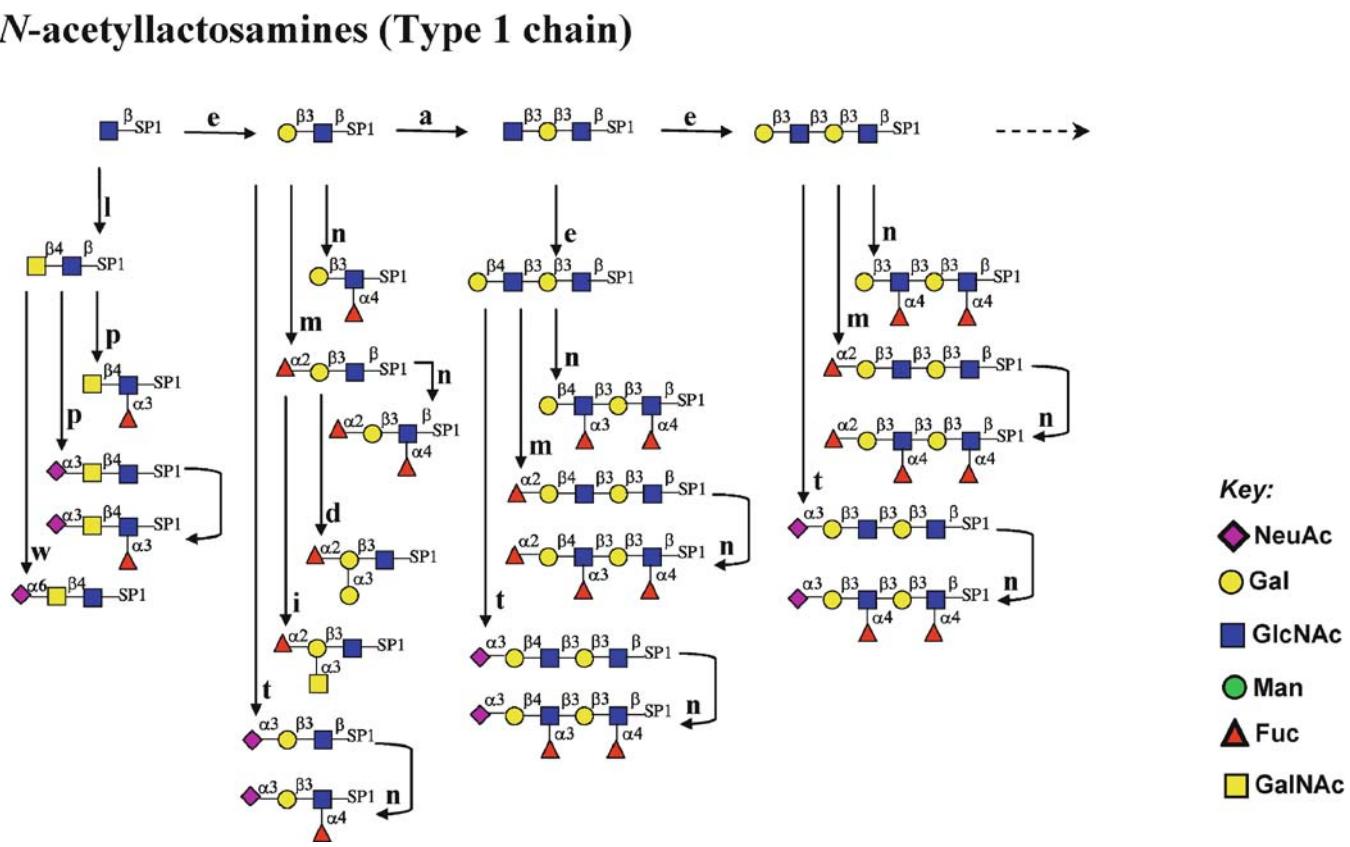

Figure 5
Enzymatic synthesis of poly-*N*-acetyllactosamines of type 1 chains

or in combination within the same pLN chain. A wide array of sialylated and/or fucosylated derivatives of type 1, type 2, and combinations of both types are found in nature.

3.2 Ganglioside Mimetic Synthesis

Gangliosides are diverse sets of sialylated glycolipids that are integral components of most cell membranes, and particularly abundant in neuronal tissues. They are implicated as tumor-associated antigens; active immunization with gangliosides has been shown to suppress melanoma growth [68,69,70,71,72,73]. Several elegant chemical approaches for ganglioside synthesis have been reported over decades by various groups [74,75,76]. The crucial step to synthesize the gangliosides is the introduction of multiple units of sialic acids onto these structures. The enzymatic approach in generating multi-sialylated glycans has significantly facilitated the time demanding and tedious procedures of ganglioside synthesis [46]. A key enzyme in this reaction is the bifunctional α-(2→3/8)-sialyltransferase (α3/8SiaT) [77,78] that incorporates multiple sialic acid units onto glycans (poly-sialic acidk). The number of the sialic acid units is regulated by the controlled supply of the sugar nucleotide donor, CMP-Neu5Ac. By using a chemoenzymatic approach, a series of ganglioside mimetics, built on a chemically made 2-azidoethyl lactoside, utilizing a combination of relevant enzymes, were synthesized (*Fig. 6*) [46].

3.3 Globo-Series of Glycolipid Synthesis

The P blood group antigens are glycan structures displayed by membrane-associated glycosphingolipids present on red blood cells and on other tissues [79,80]. The P1 antigen is formed by the addition of a galactose in an α1,4-linkage to the paragloboside by the P1 α1,4galactosyltransferase, forming the pentasaccharide Galα1–4Galβ1–4GlcNAcβ1–3Galβ1–4Glc [81]. The physiological functions of the P blood group antigens are not known, but these molecules have been implicated in the pathophysiology of urinary tract infections and parvovirus infections (*Fig. 7*) [82].
Using a recombinant fusion construct of the key enzyme α1,4galactosyltransferase-GalE [81] (entry g) and a β1,3-*N*-acetylgalactosaminyltransferase [83] (entry j *Table 1*), in combination with the recombinant GalNAc epimerase (entry y *Table 1*) [46] we generated various structures of the globoside series (published at http://www.functionalglycomics.org).

3.4 *O*-Linked Glycans Synthesis

The most common *O*-linked carbohydrates are based on core structures represented by the Tn-(GalNAcα1–1Thr/Ser) and T- (Galβ1–3GalNAcα1–1Thr/Ser)-antigens (*Fig. 8*). Sialylated versions of these *O*-antigens are expressed at low levels by many normal tissues, but become highly expressed in many types of human malignancies including colon, breast, pancreas, ovary, stomach, and lung adenocarcinomas, as well as, myelogenous leukemias [84,85,86]. *O*-glycans based on the Core-2 epitope (Galβ1–3[GlcNAcβ1–6]GalNAcα1–1Thr/Ser), on the other hand, are expressed in normal tissues. Synthesis of various compounds of *O*-linked structures using the key enzymes of human core-2-β1–6GlcNAcT (C2GnT), chicken GalNAcα2–

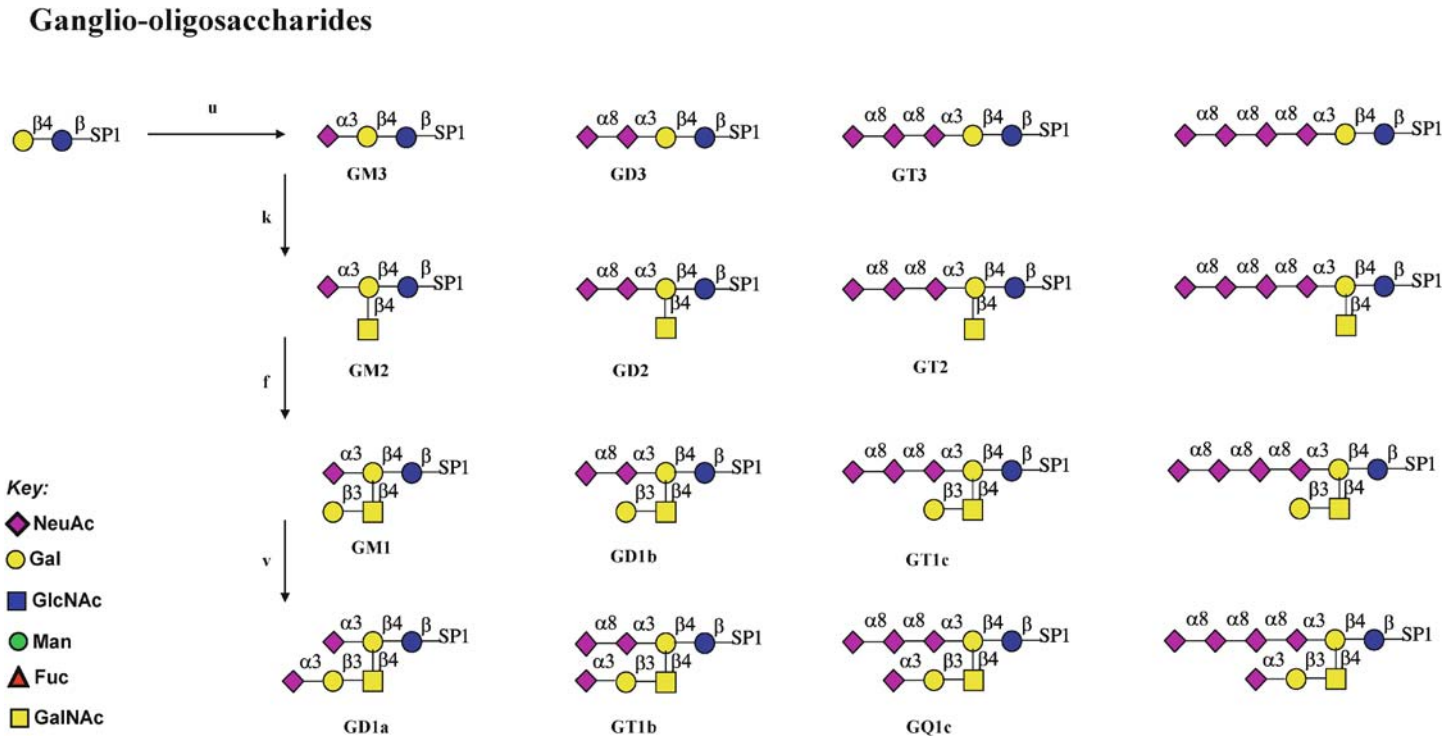

Figure 6
Enzymatic synthesis of ganglio-oligosaccharides

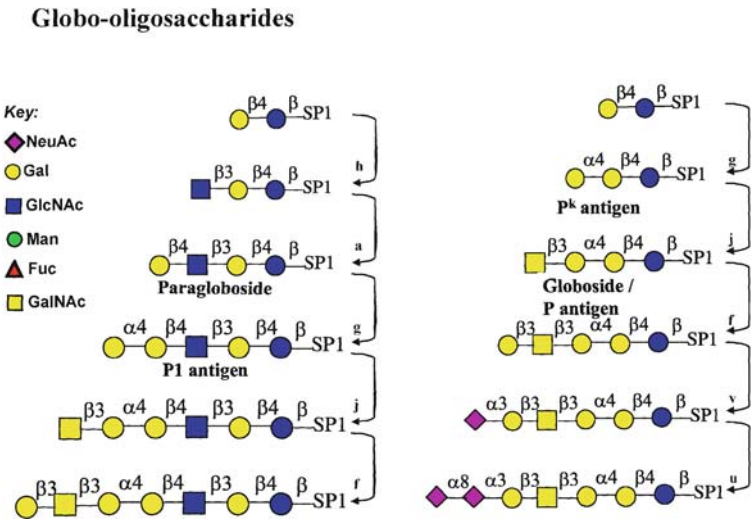

Figure 7
Enzymatic synthesis of globo-oligosaccharides

6-sialyltrasferase (chST6GalNAc-I), and pig Galα2–3-sialyltrasferase (ST3Gal-I) on the threonine-containing aglycon acceptors (*Fig. 8*) have been accomplished [87] (also published at http://www.functionalglycomics.com). Recently, elegant enzymatic elongations of peptides using recombinant polypeptide *N*-acetylgalactosaminyltransferases [88,89,90] were performed and demonstrate the power of enzymes for a fully enzymatic executed synthesis of complex *O*-linked glycoproteins with well-defined carbohydrate structures.

3.5 α-1,4-*N*-Acetylglucosamine-Capped Glycan Synthesis

Glycoproteins carrying GlcNAcα1,4Galβ-R at non-reducing terminals are defined structures of particular interest, they are found on the class III gastrointestinal mucins. Class III mucins exist in deeper portions of the mucosa and are secreted from the gastrointestinal gland mucous cells, including mucous neck cells, cardiac gland cells, and pyloric gland cells [91]. *Helicobacter pylori* rarely colonize the deeper portions of gastric mucosa, where the gland mucous cells produce mucins having terminal α1,4-*N*-acetylglucosamine (α1,4-GlcNAc) attached to *O*-glycans. It has been proposed that α1,4-GlcNAc-capped *O*-glycans have protective properties against *H. pylori*. Thus, the unique *O*-glycans in gastric mucin appeared to function as a natural antibiotic, protecting the host from H. *pylori* infection [92].

The human α1,4-*N*-acetylglucosaminyltransferase, which has been cloned [91] and overexpressed in stable CHO cell lines, was used for preparative synthesis. This enzyme catalyzes the transfer of GlcNAc, with an α-linkage to C4 of the non-reducing terminal galactose in beta linkage, α1,4-GlcNAc-capped sequences of *N*- and *O*-glycans were synthesized in milligram amounts (published at http://www.functionalglycomics.com).

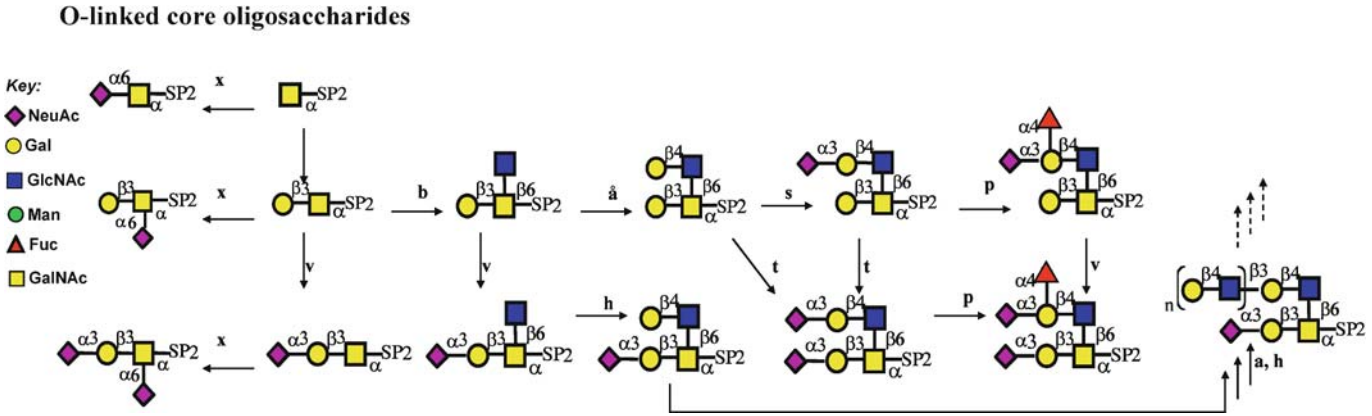

Figure 8
Enzymatic synthesis of *O*-glycans

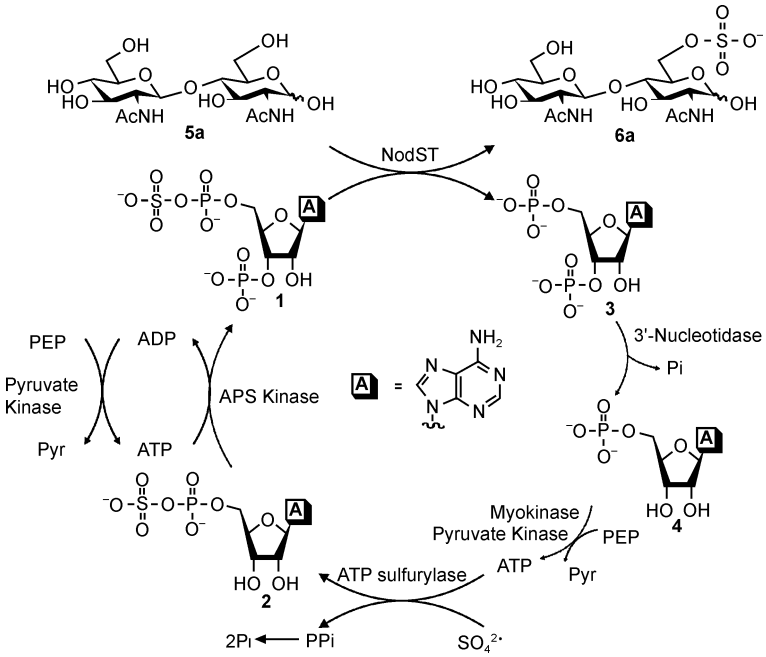

Figure 9
Multi-enzyme PAPS regeneration (from reference [39] with permission from publisher)

3.6 Synthesis of Sulfated Glycans

Sulfated glycans have generated interest due to their roles in specific cell signaling and biological functions both in normal and disease processes. Just as the kinases that mediate the diverse phosphorylation events within the cytosol have received great attention in recent years, the Golgy-associated sulfotransferases that impart specific sulfation modifications are now stimulating considerable interest [93,94,95]. Sulfated oligosaccharides can be chemically synthesized and followed by enzymatic elongations [96,97,98]. A number of sulfated disaccharides of Galβ1–3GlcNAc, Galβ1–4GlcNAc and Galb1–4Glc, sulfated at various positions, were chemically synthesized and further elongated by enzymatic approach with ST and FUT [99] from *Table 1* (see http://www.functionalglycomics.com). In addition, sulfotransferases of Keratan Sulfate 6-*O*-galactosylsulfotrasferase (KSGal6ST) [100,101] and corneal 6-*O*-glucosaminylsulfotransferase (GlcNAc6ST) [102] are promising enzymes for sulfation of poly-LacNAc derivatives. However, the preparative enzymatic sulfation is untenable because of the high cost and instability of phospho adenosin phospho sulfate (PAPS), which is the universal donor of sulfate for most sulfotransferases. Furthermore, the released PAP (3′-phosphoadenosine-5′-phosphate), from the PAPS desulfation in sulfotransferase reactions, is a potent inhibitor of the sulfotransferase activity. To overcome the PAPS limitations in enzymatic sulfation with sulfotransferases, different PAPS regenerating methods have been developed (*Fig. 9*) [39].

3.7 Synthesis of *N*-Linked Glycans

Isolation and purification of natural glycans is complicated and tedious. Nevertheless, it is important to include them in existing and future glycan libraries. Several recent reports demonstrate that isolated or chemically synthesized [103,104] *N*-glycans can be efficiently modified with various glycosyltransferases [105,106,107,108]. The accumulated enzyme library at the CFG (● *Table 1*) is being used for modifications of *N*-glycans as exemplified in ● *Fig. 10* (http://www.functionalglycomics.com).

4 Enzymatic Glycosylation on Solid-Phase

Enzymatic solution-phase synthesis still requires several tedious chromatographic purifications between the enzymatic elongation steps. Enzymatic elongation of oligosaccharides on a solid-phase support was first successfully demonstrated on a controlled-pore glass [109], which has helped avoid the tedious purification process. The key issue in the solid-phase strategy is to establish a proper solid-phase support that is compatible with both organic and aqueous solvents and swells well in an aqueous buffer, so that the enzymes could access the substrates easily. The strategy also requires a proper linker to anchor the oligosaccharide, and the linker should be selectively cleavable to release the product (● *Fig. 11*) [110]. The tetrasaccharide sialyl-Lewis^x was synthesized on an agarose matrix in three consecutive enzymatic steps, followed by a final size exclusion chromatography purification step in 57% yield [111].
A combined solid- and soluble-phase synthesis was used in the preparation of PSGL-1 *N*-terminal glycopeptide that contains a sulfated tyrosine and an α-*O*-linked sialyl Lewis^X structure [112]. In this method, a glycopeptide with a short disaccharide was assembled by conventional solid-phase peptide synthesis. After the glycopeptide was sulfated and deprotected, the resultant free glycopeptide was treated with a series of glycosyltransferases including β-1,4-galactosyltransferase, α-2,3-sialyltransferase, and α-1,3-fucosyltransferase in the presence of corresponding glycosyl donors to afford the target glycopeptide. The product of each enzymatic reaction was purified by size exclusion and ion-exchange columns.

5 Immobilized Glycosyltransferases

The use of immobilized glycosyltransferases for synthesis offers the advantage to use the same enzyme molecule over a long (● *Fig. 12*) period of time. The extent of the reaction can be controlled and there are automation capabilities as well for continuous operations. Auge and co-workers pioneered this multi-enzyme immobilization technique and demonstrated efficient synthesis of blood group I epitopes [113]. Similar work was also reported for both immobilization of enzymes [114] and whole enzyme producing cells [40]. The enzyme-displayed yeast cell technique using *S. cerevisiae* has been used to immobilize enzymes on the same cell surface to promote one-pot sequential synthesis of oligosaccharides [115]. Sequential synthesis of sLe^X by co-expressing catalytic domains of two mammalian glycosyltransferases (α2,3 sialylT and α1,3 fucosylT VII) fused with yeast cell wall proteins was achieved [116]. In attempts to elucidate the functions of sugar chains as bioactive substances, as well as, advancing the techniques for glycan synthesis and carbohydrate analysis, the National Institute of

Chemoenzymatic solid-phase oligosaccharide synthesis

Advanced Industrial Science and Technology in Japan has recently launched a project titled "Construction of a glycogene library" [117]. This program aims at identifying and cloning all the possible human glyco genes, particularly glycosyltransferases. The enzyme-displayed yeast cell technique has been employed to develop a library of enzymes expressed on the yeast cell wall [23,118] (*Fig. 13*).

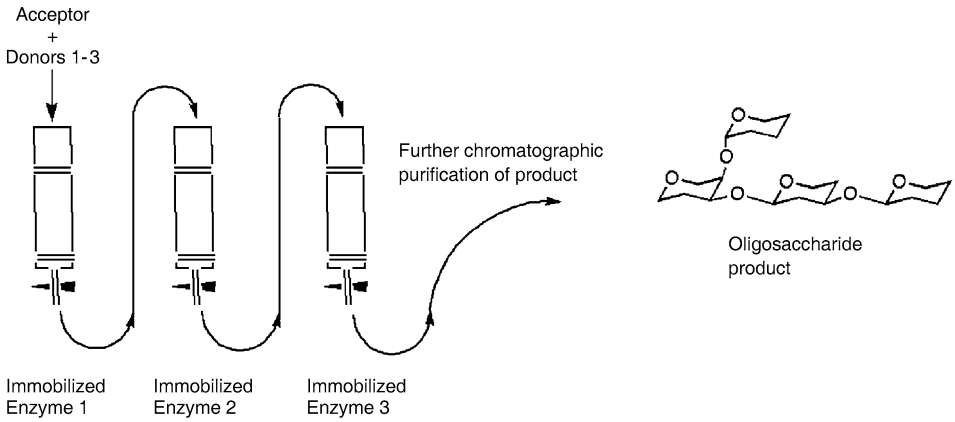

Figure 12
A serial-sequence of immobilized glycosyltransferases for oligosaccharide production

6 In-situ Glycosylation Using Engineered Bacteria

A very elegant and innovative approach for large-scale production of oligosaccharides was developed by Koizumi and co-workers. Expensive sugar-nucleotides were regenerated in-situ by coupling metabolically engineered *E. coli* bacteria [119,120,121]. Starting from inexpensive and industrially available precursors, the microorganisms produce high levels of nucleoside 5′-triphosphates and thereby, overcome the drawbacks of enzymatic methods that require expensive phosphophenolpyruvate and nucleoside 5-phosphates. Multi-gram scale synthesis of di- and trisaccharides such as LacNAc, globi-triose, and sialyllactose have been accomplished [22,122].

7 Future Outlook

Sugar-chain engineering is one of the key techniques of biotechnology. As knowledge of their physiological roles increases, research on carbohydrate-based therapeutics will continue to accelerate and draw more attention to oligosaccharide synthesis. Once viewed as a hydrophilic heterogeneous nuisance to be removed from cell surfaces or secreted proteins of interest, oligosaccharides are now being synthesized on proteins and displayed on different platforms to mimic the repertoire of the cell surface glycans.

Continuous improvement of chemoenzymatic glycan synthesis is imperative. The combined efforts of the recent development of chemical advances and the exploration of new and more flexible GTs will continue to make advances towards synthesis of the glycome. Some of the GTs show remarkable flexibility and broad tolerance towards non-natural residues of the acceptor substrates and the sugar nucleotide donors. For example, the replacement by aromatic or heteroaromatic moieties, charged residues, sulfonamides or bulky polar monosaccharides, are well tolerated by enzymes and offers an efficient approach to the creation of oligosaccharide analog libraries that can be used in drug developments by designing enzyme inhibitors and ligand antagonists [123]. Although an increasing number of glycosyltransferases are commercially available, they are still prohibitively expensive, particularly for synthesis on a preparative scale. Nonetheless, glycosyltransferases have shown promise as reagents for solid phase synthesis that may facilitate the development of automated solid-phase glycan synthesis, similar to what has revolutionalized the protein and nucleic acid era.

The cutting-edge technique, known as glycan array technology, has emerged as a new set of tools to facilitate the studies of carbohydrate–protein interactions [124]. A principle challenge in cell biology is to define the paradigm of carbohydrate protein interactions in many biological processes. Glycan array technology offers a solution to the high-throughput analysis and profiling of carbohydrate-related interactions, as well as, the identification of optimal

sugar ligands and inhibitors [125,126]. Expanding the glycan array with synthetic oligosaccharide structures that represent the complete pattern of the natural glycans is a focus for the future.

University of Hamburg, 20146 Hamburg, Germany
joachim.thiem@chemie.uni-hamburg.de

Abstract

Chemoenzymatic applications of glycosidases and glycosynthases employing transglycosylation reactions are outlined. Addressed are the absolute stereospecificity as well as the generally poor regioselectivity of glycohydrolases. A dominant part of this chapter is concerned with the use of exo-glycosidases. Manifold reactions with different activated galactopyranosides are reported for the synthesis of a variety of terminally β-galactosylated oligosaccharides. By choice of the appropriate enzyme also the regiochemistry can be largely controlled. Some preparative transformations are reported for α-fucosidases, β-mannosidases, β-*N*-acetylhexosaminidases and—quite important—α-sialidases. Another part of this chapter describes the favorite use of *trans*-sialidases for important novel synthetic endeavors. Further, the chemistry with endo-glycosidases, in particular with regard to glycoprotein construction is mentioned. The last section briefly reports on recent excellent results employing glycosynthases for construction of complex heterooligosaccharides.

MAG myelin-associated glycoprotein
MPEG polyethyleneglycole ω-monomethylether
TSia *trans*-sialidase

1 Introduction

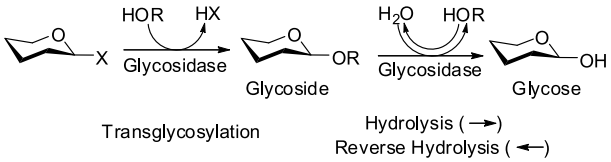
The chemoenzymatic assembly of complex oligosaccharides and glycoconjugates enjoys the application of all enzymes involved in carbohydrate metabolism and catabolism. In comparison to chemical glycosylation enzymatic glycosylation is of advantage in several cases, such as

- Unreliable chemical procedures for glycosylation.
- Harsh methods leading to decomposition and generally low yields.
- The wrong anomers are formed by chemical glycosylation, e. g. 1,2-*trans*-glycosides instead of the desired α-galactopyranosides or β-mannopyranosides.
- Heavy metal catalysts are employed, which is not acceptable for products with potential use in the pharmaceutical area or in nutrition due to toxicity and high price.

Most prominent is the use of glycosyltransferases in synthesis (cf. Chap. 5.8), however, the appropriate application of "glycosylhydrolases" (glycosidases) in the synthetic direction is of considerable interest. This subject has been of growing interest for preparative carbohydrate chemistry for about the last 15 years and thus has been reviewed several times [1,2,3,4,5,6,7,8,9,10,11,12].

2 Exo-Glycosidases

Exo-Glycosidases are involved in the trimming processes of glycoprotein biosynthesis [13]. In general, they are used to cleave the terminal non-reducing saccharide unit of an oligosaccharide (Gly-OR), and do show a high specificity for that unit. As to the interglycosidic linkage they are less specific, and the aglycon (R) may even vary widely. Thus, an activated intermediate will be formed and with water hydrolysis will occur. The process can be inverted and then reverse hydrolysis may be used to synthesize lower oligosaccharides. This is a thermodynamically controlled reaction which is favored, for example, by increase of concentration of the starting materials (Gly-OH and ROH) or enhanced temperature.



Scheme 1

Alternatively, transglycosylation may be employed which requires an activated glycosyl donor component (Gly-X) carrying a good anomeric leaving group (X). In this case, a kinetically controlled product formation is at hand, and in order to minimize the competing hydrolytic cleavage before equilibrium is reached the reactions should be quenched at the maximum of product formation. Generally, yields in transglycosylation are considerably higher than in reverse hydrolysis, and therefore the former is largely preferred (*Scheme 1*).

Glycosidases are low-priced enzymes, and they also require cheap donor substrates. They are quite robust to handle and show absolute stereoselectivity in their substrate recognition. The main drawbacks for their use in glycoside synthesis are generally low yields and little regioselectivity. This can be partly controlled by choice of the appropriate glycosidase with more pronounced regioselectivity or transglycosylations by dosing of reactants and use of co-solvents.

Another eminent advantage of using glycosidases in glycosylation is their good stereoselectivity. These enzymes are considered to be "retaining enzymes." There are, however, a few exceptions of inverting glycosidases which lead to products with an inverted anomeric configuration by using glycosyl fluorides or, for example, glycosyl pyridinium ions.

In contrast to glycosyltransferases, glycosidases are able to glycosylate many "xeno-substrates" with primary or secondary hydroxy groups. Even though the activity of water as acceptor in the reaction mixture is usually one to two orders higher than the activity of the alcohol to be glycosylated, the yields of the glycosides are often much higher than would be expected from simple thermodynamic calculations. This is considered to be caused by the enhanced affinity of the alcoholic substrates compared to water for binding to the "aglycon site" of the glycosidase. A possible influence of the groups adjacent to the respective hydroxy group is often speculated, and electron-rich moieties such as double bonds in the allylic position, conjugated systems of double bonds, aromatic or heteroaromatic systems generally support glycosylation. Aliphatic alcohols are also suitable acceptors for glycosyl moieties transferred by glycosidases. Amphiphatic properties and the presence of nitrogen in the acceptor molecule usually enhance transglycosylation yields.

A broad variety of substrates were efficiently glycosylated by glycosidases such as aliphatic and alicyclic alcohols [14], phenols, oximes, steroids and terpenes [15], amino acids [16], alkaloids [17] and many other substances.

The substrate to be glycosylated by a glycosidase should be at least partly soluble in water. The solubility can be enhanced by addition of water-miscible solvents, for example, acetonitrile, dimethylformamide, dimethylsulfoxide, dioxane, or *tert*-butyl alcohol. Concentrations of co-solvents up to 30% are usually well tolerated by most glycosidases. In contrast to lipases, lowering the water activity by co-solvents usually does not increase yields, the improved solubility of the acceptor and of the donor is the only decisive factor. There are, however, examples

of lowering the water activity by, for example, addition of various salts [18] that improved the glycosylation yields.

There are few examples of enzymatic glycosylation of simple alcohols in biphasic systems with organic solvents or by polyethyleneglycol-modified glycosidases in organic solvents [19]. In general glycosidases show rather poor regioselectivities, and with respect to their original biofunction this is expected. Nevertheless, many exhibit preferential cleavage of distinct glycosidic linkages and thus the corresponding transglycosylation effects. Should the acceptor substrate present more than one hydroxyl group for glycosylation the formation of several isomers should be encountered. Often the regioselectivity can be estimated or even predicted; for example, in hexopyranose acceptor substrates the affinity of hydroxyl groups is roughly 6-OH≫4-OH∼3-OH>2-OH resembling also the chemical reactivity of a nucleophilic OH-group.

There are reports that indicate that a change of configuration at the anomeric center should influence the regioselectivity [20,21], however, other subtle changes may be similarly effective. Quite often the regioselectivity is comparable for transglycosylation reactions and hydrolysis of the corresponding interglycosidic linkage. In many cases this could be demonstrated unequivocally by rational selection of the appropriate glycosidase as will be outlined below.

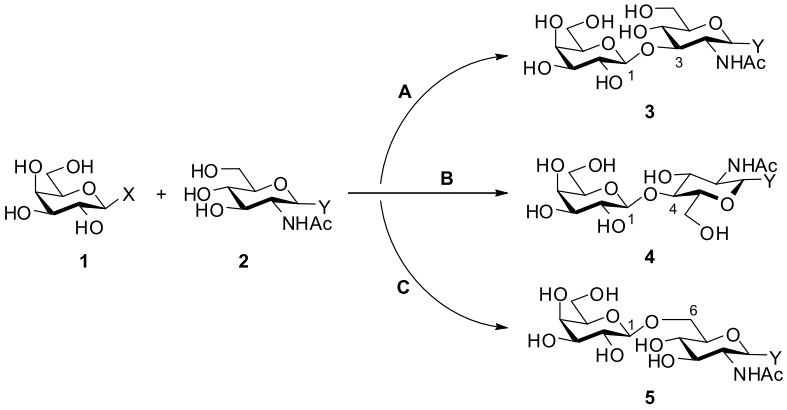
The stereoselectivity of glycosidases is always complete concerning the anomerity at the donor substrate site. In addition, many studies were performed to employ the chiral discrimination of these enzymes (as frequently used for lipases, esterases, etc.) regarding stereogenic centers in the aglyconic site. Both in the cleavage mode and also in transglycosylation such effects could be demonstrated [13,22,23,24], but will not be in the focus of this discussion.

2.1 β-Galactosidases

The availability and their easy handling has made β-galactosidases a preferred choice in preparative enzymatic glycoside synthesis often in positive competition to classical synthetic protocols. Employing as donor substrates galactopyranosyl derivatives **1** with various β-positioned leaving groups X and a suitable acceptor substrate, for example, the *N*-acetyl-glucopyranosyl component **2** with different anomeric functions Y, was shown to lead to the appropriate transglycosylation products **3**–**5**. Dependent on the β-galactosidase β,1–3-(**3**),β,1–4-(**4**, *N*-acetyllactosamine) or β,1–6-linked β-galactopyranosyl-*N*-acetylglucopyranosyl components (**5**) could be obtained. Advantageous for the formation of **3** were β-galactosidases from *Streptococcus* sp. or bovine testes [25], **4** could be favorably obtained employing β-galactosidase from *Bacillus circulans*, and **5** could be made using β-galactosidases from *Aspergillus oryzae*, *Penicillium multicolor*, *Kluyveromyces lactis*, and *Escherichia coli* [21] (Scheme 2).

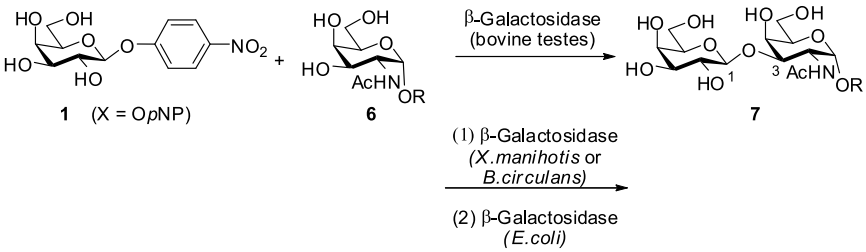
2.1.1 β,1–3-Galactosidases

En route to modified sialylated Thomsen–Friedenreich antigen components the core disaccharide motif Galβ1–3GalNAc needed to be easily accessible and thus β,1–3-galactosidase from bovine testes was employed [26,27]. A considerable number of GalNAc α-glycosides **6** could be transgalactosylated with **1** (X = *p*NP) to give the desired disaccharide derivatives **7** in 15–40% yield [25,28,29]. In more recent studies modifications could be employed to furnish yields up to 70% [30,31]. If β-galactosidases of *Xantomonas manihotis* (Xm) [32] or



Scheme 2

recombinant *Bacillus circulans* (bgaC-gene, Bc) [33] were employed for the same reaction in addition to **7** the corresponding regioisomeric Galβ1–6GalNAc derivative was formed [ratio 10 : 1 (with Xm) and 3 : 2 (with Bc)]. By in situ hydrolytic cleavage of the latter with β-galactosidase (*E. coli*) [26] the overall yields of **7** were 15–20% (with Xm) and about 30% (with Bc), respectively [30,31] (Scheme 3).



Scheme 3

Further acceptor modifications in these galactosylations were studied. Thus, 2-deoxy-galactose and *N*-acetylgalactose structures were recognized by all these galactosidases and gave the corresponding disaccharides in 20–70% yield [30]. With *N*-acetyl-chitobiose and -chitotriose β,1–3- and β,1–4-galactosylation (ratio 1 : 1) were reported [34]. Treatment of food saccharides such as sucrose (**8**), lactose, isomalt, isomaltulose, isomelezitose (**10**), raffinose (**12**), and 1-kestose (**14**) with lactose as donor substrate and β-galactosidase (bovine testes) furnished the terminally β,1–3-galactosylated-tri- to tetrasaccharides (**9**, **11**, **13**, and **15**) in 10–15% yield. The reactions could also be run on the 30–40 gram-scale and gave products in about 20% yield [30] (Scheme 4).

Modifications of donor substrates were also of interest. Generally, aromatic β-galactopyranosides were employed with good yields and easy UV-survey of the reaction due to the phenolic leaving group. Among them *o*- and *p*-nitrophenyl galactopyranosides represent standard donors, and also methylumbelliferyl as well as resorufinyl β-D-galactopyranosides were

Scheme 4

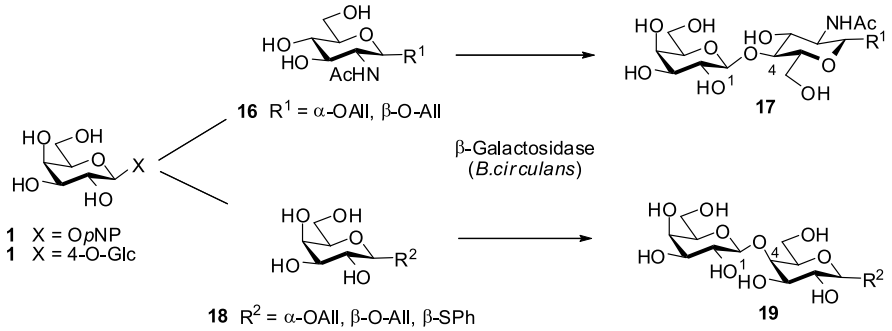
reported to be good donors. Often their solubility in aqueous–organic solvent mixtures causes problems. In a recent study [36] 16 aromatic and heteroaromatic β-galactopyranosides of type **1** were prepared. Their β,1–3-galactosylation potential for allyl *N*-acetyl-α-D-galactopyranoside was studied employing galactosidase from bovine testes to give the corresponding disaccharides in 10–75% yield. The solubility was also tackled in experiments studying various galactosides, however, *p*NP-β-D-Galp (**1**) was superior to lactose and was again much better than both lactulose and lactitol in donor substrate efficiency (about 30 : 10 : 2 : 1) [35].

2.1.2 β,1–4-Galactosidases

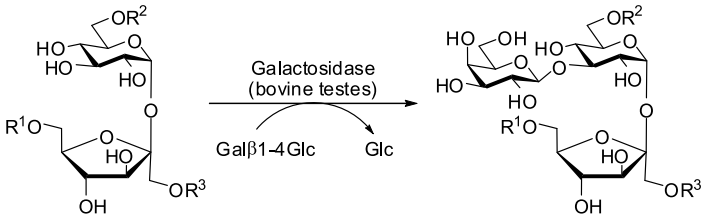
Early on, there were reports on the preparative use of β-galactosidase from *B. circulans* for the synthesis of β,1–4-galactosylated components [37]. This enzyme is commercially available under the name "Biolacta®", Lactase (EC 3.2.1.23) [38]. Biolacta is a quite stable enzyme ($t_{1/2}$ = 226 h at 22 °C and pH 7.0) that allows for an easy transfer reaction between pH 5.0–9.5 and up to 55 °C [38]. Its activity for transglycosylation in aqueous solvent mixtures was determined, and it showed considerable tolerance to several organic solvents. The activity in 30% aqueous organic solvent mixtures at pH 7.0 and 30 °C was measured after one hour and gave: DMSO (85%), acetone (70%), DMF (67%), dioxane (59%), and acetonitrile (12%) [39]. Studies toward the transglycosylation synthesis of *N*-acetyl-lactosamine and derivatives were of particular interest and performed by several groups [40,41,42]. As demonstrated [42] *p*NP-galactopyranoside (**1**, X = O*p*NP) was superior to lactose, and with α- as well as β-allyl *N*-acetyl-glucosaminide (**16**) the *N*-acetyllactosaminides could be obtained in up to 60% yield in acetonitrile/aqueous phosphate buffer. Correspondingly, with several α- and β-galactopyranosides (**18**) the appropriate Galβ1–4Gal disaccharides **19** could be synthesized in 50–70% yield (*Scheme 5*).

There was also interest in potential novel food additives that could be formed by β,1–4-galactosylation of natural oligosaccharides [43]. Compared to the results with β,1–3-galactosylation [35, see above] sucrose (**8**) and 1-kestose (**14**) were cleanly β,1–4 galactosylated at the 4 position of the incorporated glucopyranose residue to give the trisaccharide ("lactosucrose") **20** and the tetrasaccharide **21** in 20–30% yield (*Scheme 6*).

In contrast, both isomelezitose (**10**) and raffinose (**12**) gave rise to the formation of two isomeric tetrasaccharides. For **10** both available glucopyranose units were β,1–4-galactosylated



Scheme 5



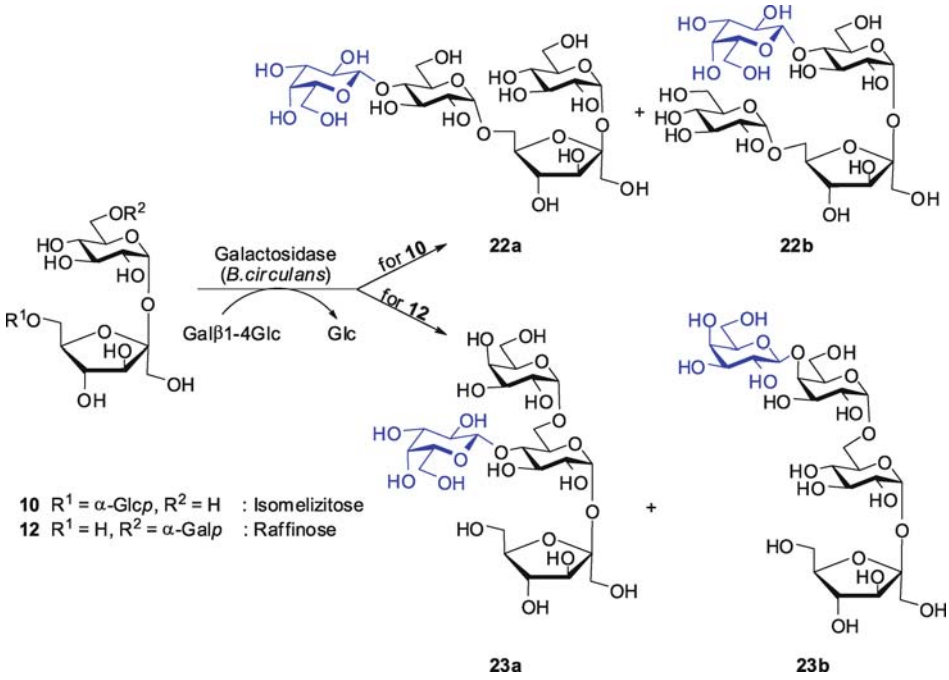
8 $R^1 = R^2 = R^3 = H$: Sucrose — **9**
10 $R^1 = \alpha$-Glc*p*, $R^2 = R^3 = H$: Isomelizitose — **11**
12 $R^1 = R^3 = H$, $R^2 = \alpha$-Gal*p* : Raffinose — **13**
14 $R^1 = R^2 = H$, $R^3 = \beta$-Fru*f* : 1-Kestose — **15**

Scheme 6

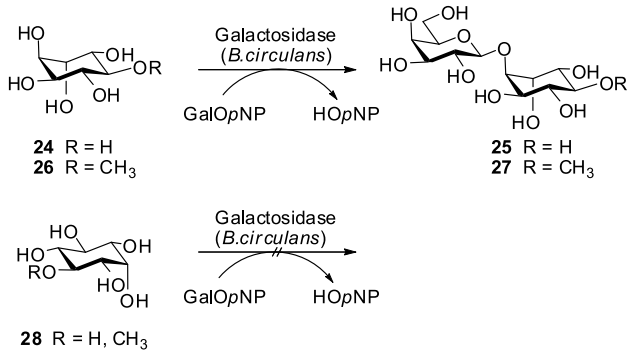
to give **22a** and **22b** (ratio 1 : 1, 21%), and for raffinose the β,1–4-galactosylation of the glucose residue gave **23a**, and that of the terminal galactopyranose ring led to **23b** (ratio 4 : 3, 38%) (*Scheme 7*).

Modifications of gluco-, galacto-, *N*-acetyl-gluco-, and *N*-acetyl-galacto-configured acceptor structures have been extensively studied. Generally, in the *gluco*-, equatorial-, and in the *galacto*-components the axial 4-hydroxy groups are galactosylated. With regard to the anomeric function, there were apparently no restrictions because alkyl- and aryl(thio)glycosides as well as *N*-acyl-glycosylamines could be employed [39,40,41,44,45,46,47,48]. Interestingly, galactosylation of inisitols could be also effected. Treatment of 1D-chiroinositol (**24**) as well as of 1D-pinitol (**26**) under standard conditions led to the galactosylated species **25** and **27**, respectively, in 45% yield. Apparently, these acceptors structures seem to resemble galactopyranose acceptors. In contrast, the isomers 1L-chiroinositol (**28**, R = H) and 1L-quebrachitol (**29**, R = CH_3) which rather resemble mannopyranose structures were not galactosylated [49] (*Scheme 8*).

Some recent work checked donor modifications in *B. circulans*-catalyzed galactosylations of allyl α-*N*-acetyl-hexosaminides (**30**) [50,51]. Whereas the 6-azido or 6-mesyloxy-galactopyranosides (**29** with R = CH_2N_3 or CH_2OMs) were not recognized, the 6-amino component

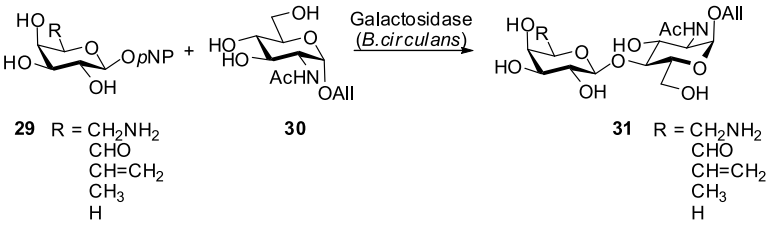


Scheme 7



Scheme 8

(**29**, R = CH_2NH_2) could be reacted to give the modified LacNAc glycoside structure **31** (R = CH_2NH_2). Reaction of the aldehyde **29** (R = CHO) to give **31** (R = CHO, 70% yield) could be confirmed [52] but surprisingly even the 6,7-olefin structure **29** (R = $CH{=}CH_2$) could be readily glycosylated to give the disaccharide **31** (R = $CH{=}CH_2$) in 30% yield. Also the 6-deoxy-galactopyranoside **29** (R = CH_3) acted as a quite good donor substrate to give the disaccharide **31** (R = CH_3) in 76% yield. In contrast, the configurationally corresponding L-arabino derivative **29** (R = H) showed only a transfer yield of 13% **31** (R = H) (*Scheme 9*).



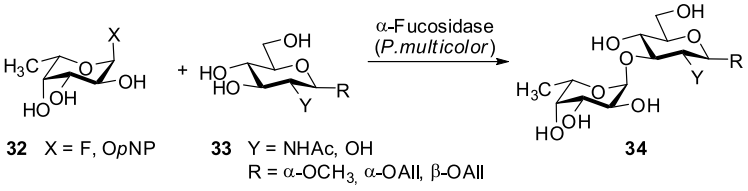
Scheme 9

2.1.3 β,1–6-Galactosidases

β-Galactosidases of *Aspergillus oryzae*, *Penicillium multicolor*, *Kluyveromyces lactis*, and *Escherichia coli* were reported to form β,1–6-linkages [21]. Employment of β-galactosidase of *Xantomonas manihotis* and recombinant *Bacillus circulans* (bga C gene) also gave considerable amounts of β,1–6-linked disaccharides [30].

2.2 α-Fucosidases

Fucosylated oligosaccharide structures associated with an array of biological recognition events represent important synthetic targets. α-L-Fucoside-fucohydrolases (EC 3.2.1.51) were isolated from prokaryotic and eukaryotic sources, namely bacteria and moulds, mollusks, plants, and mammals with different substrate specificities. Whereas many α-fucosidases are useful in oligosaccharide analysis only some of them could be used for synthetic purposes. Transglycosylation activities were observed by α-fucosidases from porcine liver [53,54], bovine kidney [55] and bovine testes [56], from *Aspergillus niger* [57], *Corynebacterium* sp., Ampullaria, and *Penicillium multicolor* [58,59], and from *Alcaligenes* sp. [54]. Recently, the enzyme from *P. multicolor* could be used to synthesize a disaccharide portion of Lewis x [60] employing either α-L-fucopyranosyl fluoride (**32**, X = F) or fucopyranoside (**32**, X = O*p*NP) as donor substrates. With α- and β-methyl or allyl glycosides of both *N*-acetyl-glucosamine (**33**, Y = NHAc) and glucose (**33**, Y = OH) the corresponding α,1–3-linked derivatives **34** (Y = NHAC, OH, R = α-OCH_3, α-*O*-All, β-OAll) were obtained in 10–40% yield (*Scheme 10*).



Scheme 10

2.3 β-Mannosidases

The conventional synthesis of 1,2-*cis*-configured glycosides is considerably demanding, and thus alternative approaches to β-mannopyranosides would be of interest. Whereas there are several reports on β-mannosidases (EC 3.2.1.25) with regard to their biochemistry and purification [e. g., 61], only β-mannosidase from guinea pig liver was used in transglycosylation to give disaccharides in low yields [62]. Later studies with a β-mannosidase from snail viscera and *p*NP β-D-Man*p* as donor substrates also gave minor yields of β,1–3- and β,1–4-linked mannobiosides [63,64]. Noteworthy may be the advantageous application of the complex of glycosidases from *Aspergillus oryzae* which contains a number of glycosidases (β-galactosidase, β-glucosidase, β-mannosidase, β-*N*-acetyl-glucosaminidase, β-*N*-acetyl-galactosaminidase) [65,66] for the preparation of β-mannosylated derivative [63,64].

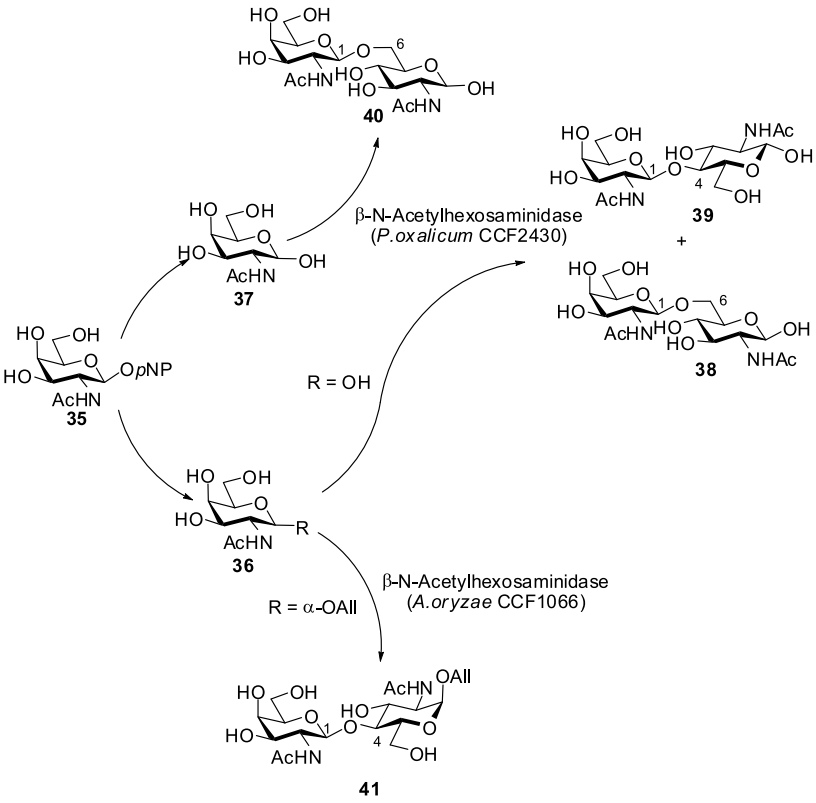
2.4 β-*N*-Acetylhexosaminidases

These enzymes (EC 3.2.1.52) show affinity for both β-GlcNAc and β-GalNAc moieties and thus both are hydrolyzed. Early reports proved them to transfer GlcNAc [67,68,69,70] and GalNAc [69,70] units to glucose-terminated oligosaccharides giving β,1–4- as well as β,1–6-linkages. Also, the transfer of GalNAc onto a β-GalNAc unit afforded GalNAcβ1–6-GalNAc [71]. Employing a β-*N*-acetylhexosaminidase from *P. oxalicum* CCF 2430 and *p*NPGalNAc (**35**) on *N*-acetyl-glucosamine (**36**, R = OH) gave both the regioisomeric glycosylation products GalNAcβ1–4GlcNAc (**38**) and GalNAcβ1–6GlcNAc (**39**) in 27% and 19% yield, respectively. With *N*-acetylgalactosamine (**37**), however, the same reaction gave exclusively the GalNAcβ1–6GalNAc disaccharide **40** in 87% yield. Further experiments used the same donor **35** with α-allyl *N*-acetyl-glucosaminide (**36**, R = α-OAll) and β-*N*-acetylhexosaminidase from *A. oryzae* OCF 1066 which gave only the disaccharide GalNAcβ1–4GlcNAcαOAll (**41**) in 78% yield [72] (*Scheme 11*).

In addition to transglycosylation sometimes selective degradation of oligosaccharides may be the method of choice to arrive at complex target structures. A recent convincing example started with an asparagine-linked biantennary complex-type sialylundecasaccharide **42** isolated from egg yolk. Mild acid hydrolysis gave a mixture of Asn-oligosaccharides which were FMOC-protected at Asn to allow for HPLC purification. Successive treatment with β-galactosidase and β-*N*-acetylhexosaminidase gave a collection of *N*-linked glycans such as the penta- (**45**) and the isomeric octasaccharides **43** and **44** which could be further used in solid-phase glycopeptides synthesis [73] (*Scheme 12*).

2.5 α-Sialidases

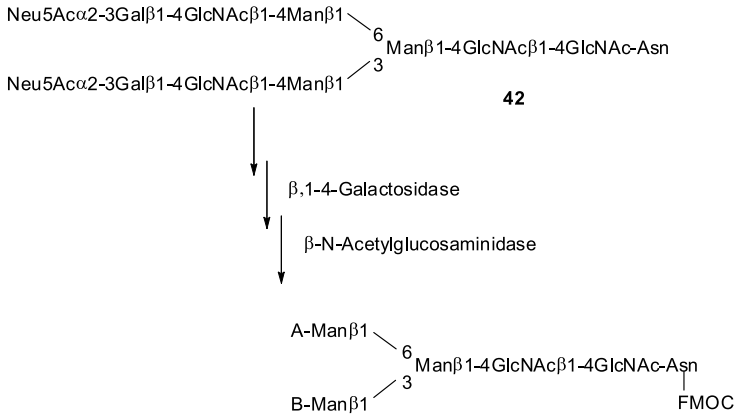
Neuraminic acid (Neu5Ac) is the major constituent in a variety of glycoconjugates such as glycoproteins, gangliosides, and oligosaccharides occurring in higher animals, viruses, bacteria, protozoa, and pathogenic fungi. The crucial role of sialylation in regulation of cellular and molecular recognition in biological systems associated with the variation in the glycosylation pattern of cell surface glycoconjugates led to particular interest in the synthesis of (mostly terminally) sialylated components. In addition to many studies using the difficult



Scheme 11

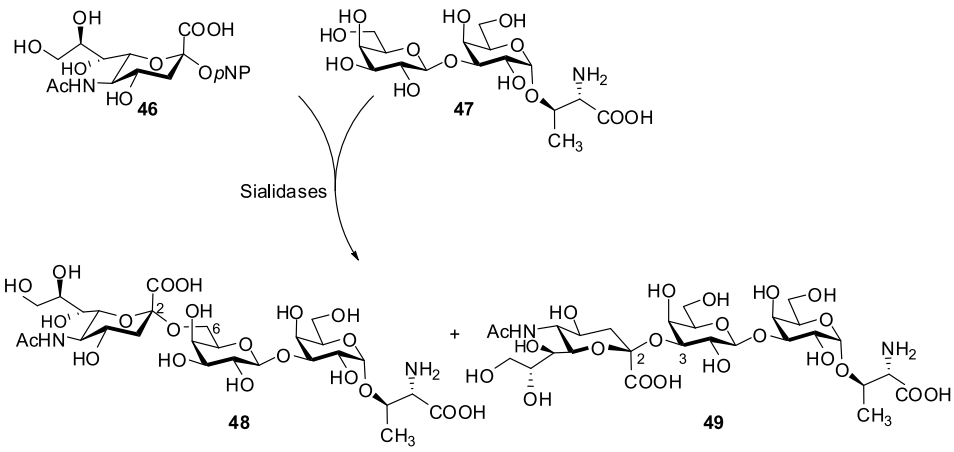
to access and handle sialyltransferases (cf. e. g. [25] for a combined hydrolase-transferase approach) there are some reports employing sialidases [74,75,76]. A comprehensive study revealed the synthetic potential of various sialidases in the preparation of sialylated Thomsen–Friedenreich (T) antigen structures [77]. Treatment of Neu5Ac*p*NP (**46**) with the α-threonin disaccharide glycoside **47** and several sialidases gave both the regioisomeric α,2–6- (**48**) and the α,2–3-linked trisaccharide derivatives (**49**) in varying amounts. Application of sialidases from *Vibrio cholerea* and *Chlostridium perfringens* gave virtually exclusively (> 99%) the α,2–6-amino acid trisaccharide **48**. On the other hand sialidase from *Salmonella typhimurium* (86–99%) and Newcastle disease virus sialidase (> 99%) showed almost exclusively the formation of the α,2–3- sialylated structure **49**. Generally, the yields ranged from about 10–25% which required subsequent selective hydrolytic glycosidase cleavages of the non-desired side product and separations (*Scheme 13*).

An extension of this method could be shown by employing MPEG polymer-supported acceptor glycoside structures. Again these could be sialylated with **46** in solution-phase giving about 15–25% yield. These sialylated polymer-bond components did not undergo glycosidic cleavage, however, the excess donor substrates did on subsequent treatment with β-galactosidase



43 A = Neu5Acα2-3Galβ1-4GlcNAcβ1-4, B = 0
44 B = Neu5Acα2-3Galβ1-4GlcNAcβ1-4, A = 0
45 A = B = 0

Scheme 12



Scheme 13

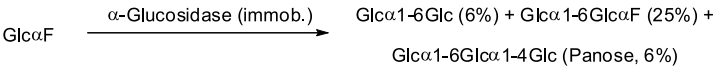
(*E. coli*) and *β-N*-acetylhexosaminidase (*A. oryzae*), and thus a facile separation and purification approach could be established [78].

2.6 Further Glycosidases

Biochemical studies constantly report and characterize novel glycosidases, and with time their fortunate stereochemistry and their easy access become attractive for chemoenzymat-

ic work. Well established are α-mannosylations employing α-mannosidase from jack bean. With *p*-nitrophenyl α-D-mannopyranoside ergot alkaloids could be successfully α-mannosylated [79,80]. The recently reported α-mannosidase from *Candida albicans* [81] still awaits synthetic application. Also α-L-rhamnosidases could be used in rhamnosylation of deoxy mannojirimycin [82]. A Galactosylation and change of the regioselectivity of the original enzyme was reported [83].

Early on [84,85] it could be demonstrated that glycosyl fluorides were excellent donor substrates for glycosidases [86]. In an example immobilized α-glucosidase (EC 3.2.1.20) could be used for self transfer of α-glucopyranosyl fluoride to give isomaltose (6%), α-isomaltosyl fluoride (25%), and the trisaccharide panose (6%) [87] (● *Scheme 14*).



● Scheme 14

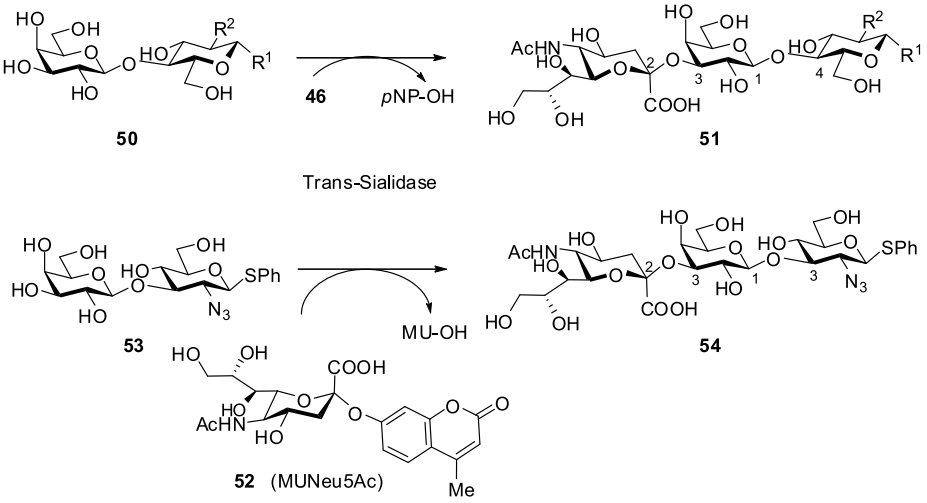
Besides glycosidases recognizing hexopyranose structures recently there were reports on the chemoenzymatic use of an α-L-arabinofuranosidase which could be also used to synthesize β-D-galacto-furanosides [88].

A quite interesting area with considerable application potential opens up with enzymes obtained from extremophiles [89]. First reports on properties and functions described a novel α-glucosidase from the acidophilic archaeon *Ferroplasma acidiphilium* strain Y [90] and two β-glucosidases from a thermo-tolerant yeast *Pichia etchellsii* [91].

There are a number of valuable reports on the use of further glycosidases in chemoenzymatic studies which due to spatial restrictions had to be omitted from this review.

3 *trans*-Sialidase

The pathogen responsible for Chagas disease is *Trypanosoma cruzi*. This upon infection expresses a *trans*-sialidase (TSia) that catalyzes transfer of terminal Neu5Ac of the host's sialoglycoconjugates onto its own surface mucins and thus masks its own epitopes to prevent degradation by the host's natural killer cells [92,93,94]. On the basis of its primary structure TSia belongs to the glycosidase family 33 which also includes multiple bacterial sialidases [95]; kinetic and crystallographic studies of the closely related TSia from *T. brucei* provided information on the binding pocket and the mechanism [96,97,98]. The easy handling of TSia and the excellent stereoselectivity in transferring Neu5Ac from various donors in α,2–3-linkages to galactose-terminated oligosaccharides was recognized and synthetically used [99,100,101,102,103]. Some recent extensions of this approach allowed us to synthesize an array of sialylated structures associated with T-antigen determinant components as well as Neu5Ac-terminated oligosaccharide motifs for binding of the myelin-associated glycoprotein (MAG) [104,105,106]. Treatment of various lactose and *N*-acetyllactosamine structures **50** (R^1 = SPh, R^2 = N_3; R^1 = R^2 = OH; R^1 = OAll, R^2 = OH; R^1 = OMe, R^2 = NHAc) with *p*-nitrophenyl sialylate **46** and *trans*-sialidase gave the corresponding trisaccharides **51** in 30–60% yield. Correspondingly, the β,1–3-linked isolactosamine precursor **53** could be reacted with muraminyl sialylate **52** to give **54** in 30% yield [107] (● *Scheme 15*).

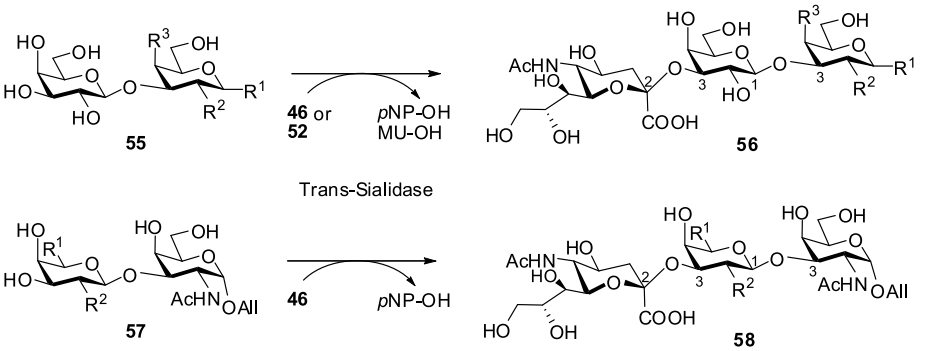


50 51 52 (MUNeu5Ac) 53 54

Scheme 15

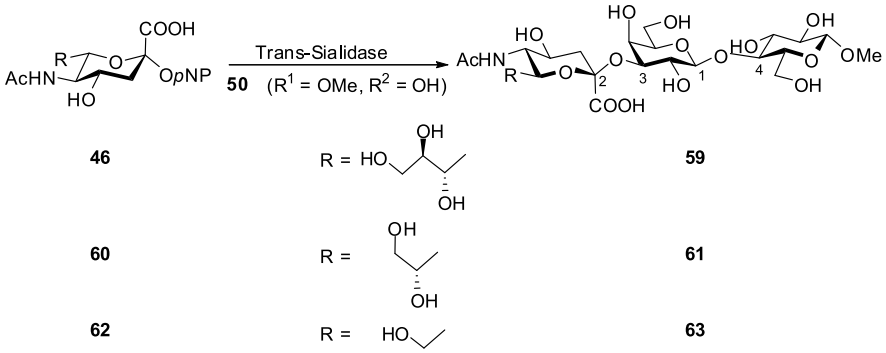
Further transformations were done with β1–3-galactobiose structure **55**. Here Galβ1–3-GalNAcαThr and Galβ1–3GalNAcαSer (**55**, $R^1 = \alpha$Thr or αSer, $R^2 = NHAc$, $R^3 = OH$) could be used as acceptor structures and also 2-deoxy ($R^2 = H$) and 2-azido ($R^2 = N_3$) were α,2–3-sialylated with TSia and **46** or **52** as donors to give the modified trisaccharides **56** in 30–50% yield [105,106]. In the LacNAc derivatives **57** the terminal galactose unit which directly accepts the sialyl residue, could be modified. 2-Deoxy-galactose-(**57**, $R^1 = H$, $R^2 = CH_2OH$) and also the D-fucose-(**57**, $R^1 = OH$, $R^2 = CH_3$) and the L-arabinose-(**57**, $R^1 = OH$, $R^2 = H$) terminated disaccharides were nicely sialylated to give the corresponding derivatives **58** (30–50% yield) [106] (*Scheme 16*).

In recent studies modified donor substrates were obtained from *p*NPNeu5Ac **46** by selective oxidative cleavage. Dependant on the ratio of compound **46**:oxidant the octose (**60**,



55 56 57 58

Scheme 16

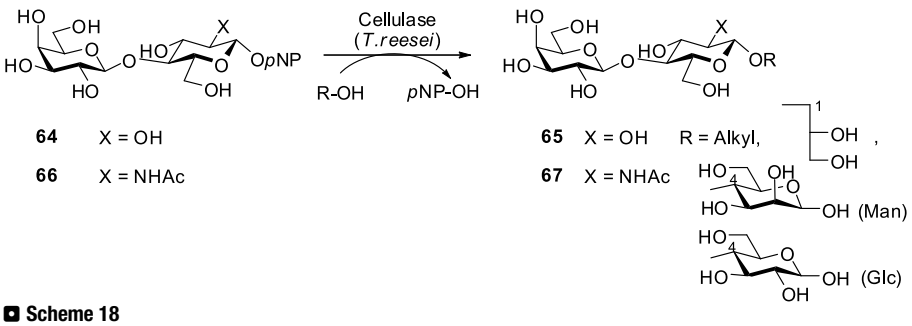


Scheme 17

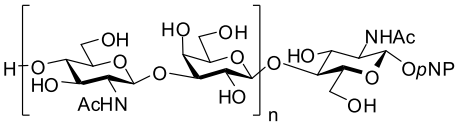
*p*NPOct5Ac) or the heptose (**62**, *p*NPHep5Ac) donor substrates were obtained in high yields. Surprisingly, their transfer onto methyl β-lactoside (**50**) under TSia catalysis did not show any problems; in fact, the yields of the octose (**61**) or heptose analog of neuraminic acid carrying trisaccharides (**63**) were identical to the original derivative **59**, that is 55–65% yield. Apparently, *trans*-sialidase will easily recognize these modified structures. In contrast, STD-NMR studies showed that only the original trisaccharide **59** is a well-binding substrate for MAG and the analogous structures **61** and **63** are not [107] (*Scheme 17*).

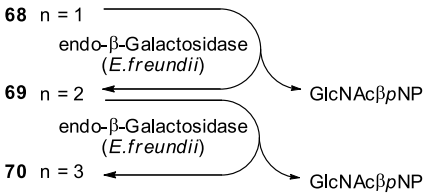
4 Endo-Glycosidases

In oligosaccharides or glycoconjugates internal glycosidic linkages are cleaved by endo-glycosidases, and under kinetic control their transglycosylation activity is favored. Some of them could be employed in preparative approaches [108,109,110], and recently the commercially available cellulas from *Trichoderma reesei* was shown to transfer entire lactose or lactosamine units employing the corresponding *p*-nitrophenyl β-glycosides **64** or **65**. With aliphatic alcohols as well as lower di- and triols yields of **65** and **67** in the range of 1–20% were obtained. However, with mannose or glucose LacNAcβ*p*NP (**66**) gave the corresponding β1–4-linked trisaccharides **67** in 13 and 9% yield, respectively [111] (*Scheme 18*).

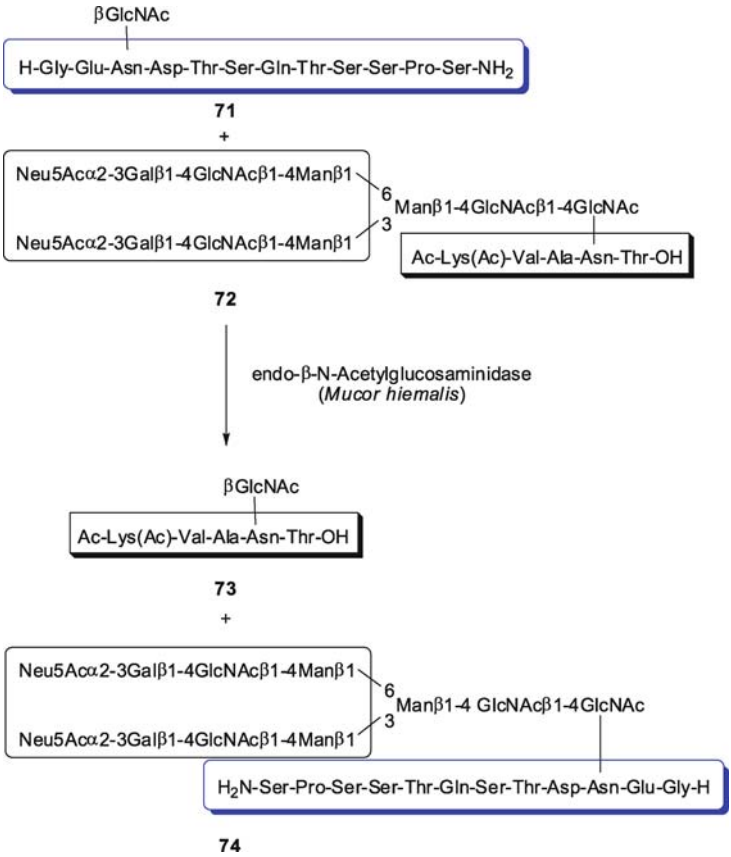


Scheme 18





Scheme 19



Scheme 20

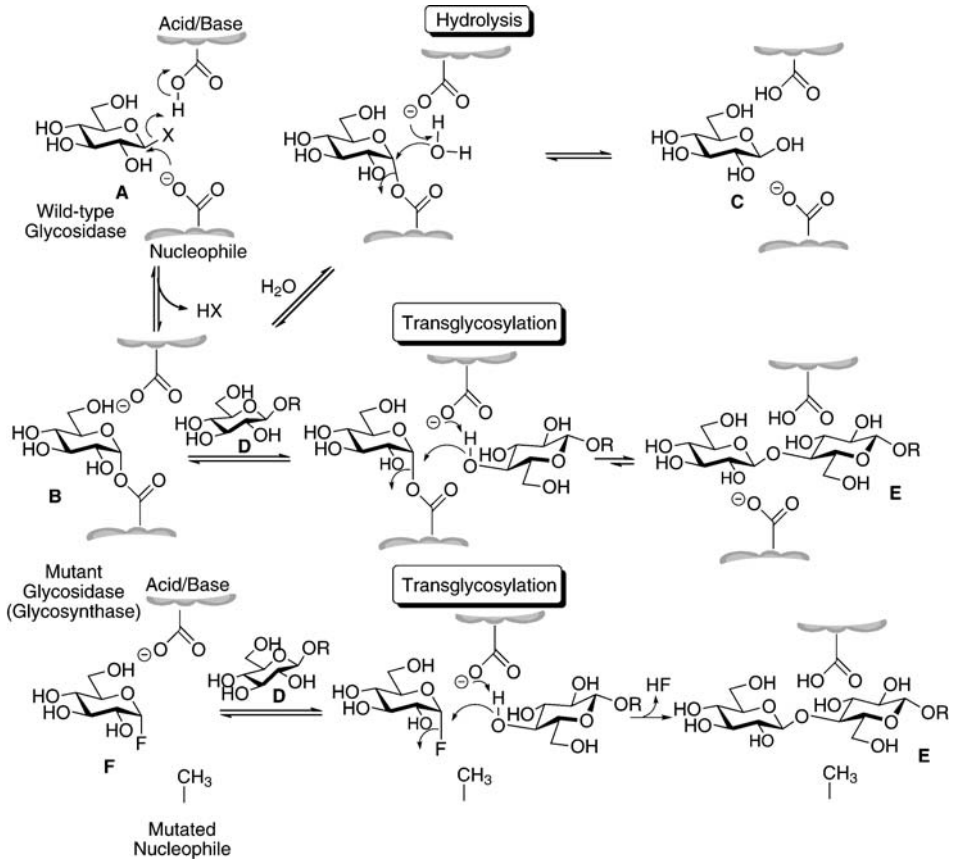
An interesting self-transglycosylation could be observed with endo β-galactosidase from *E. freudii* employing the *p*-nitrophenyl β-glycoside of the trisaccharide **68** (n = 1) in high concentration. Chain elongations to give regio- and stereoselectively the pentasaccharide **69** (n = 2) and also the heptasaccharide **70** (n = 3) in about 10% were observed with GlcNAcβ*p*NP as the leaving group [112,113] (● *Scheme 19*).

Endo-β-*N*-acetylglucosaminidase from *Mucor hiemalis* (endo-M) shows transglycosylation activity with a number of different substrates. It could be used to transfer high-mannose, hybrid-type, as well as complex-type oligosaccharides and thus glycopeptides became available [114]. Employing this enzyme for the transfer of a complex-type oligosaccharide chain in **72** from the GlcNAc-CD52 (**71**) gave the GlcNAc peptide **73** and the complex-type CD52 target structure **74** [115] (● *Scheme 20*).

5 Glycosynthases

A quantum leap in using glycosidases for preparative oligosaccharide synthesis came along with the introduction of glycosynthases by Withers et al. [116]. As elaborated for retaining glycosidases the problem of product hydrolysis in transglycosylation could be solved by bioengineering of suitable mutants. Thus, the active-site catalytic nucleophile was removed and replaced by a non-nucleophilic amino acid side chain. As depicted in ● *Scheme 21* hydrolysis and transglycosylation for a wild-type retaining β-glycosidase (in this depiction a retaining β-glucosidase) led to hydrolysis and transglycosylation products. It is generally accepted that the donor substrate **A** reacts with the nucleophilic amino acid to give the glycosyl-enzyme intermediate **B**. This on treatment with water involving a proton transfer to the acid–base amino acid and subsequent release of the nucleophilic amino acid yields the hydrolysis product **C**. In transglycosylation the acceptor substrate **D** is transformed correspondingly to give the disaccharide product **E**. Mutant glycosidases fold apparently in the same way as the wild-type enzymes, however, devoid of a nucleophilic site they cannot form the intermediate **B**, and thus hydrolysis does not occur. However, if a donor substrate with opposite anomeric configuration is offered like in the glycosyl fluoride **F** with a small leaving group the mutant glycosidase, the glycosynthase, will recognize it as an analogue of the covalent glycosyl-enzyme intermediate **B**. Thus, employing the same transglycosylation mechanism as for the wild-type enzyme the acceptor sugar is transferred to give again the disaccharide **E**. Since these mutant enzymes cannot display hydrolytic activity the yields are generally excellent (● *Scheme 21*).

Within recent years a considerable number of glycosynthases have been described both from exo- as well as from endo-glycosidase and the subject was also reviewed several times [114,117,118,119,120]. In the original work a well-known β-glucosidase Abg from *Agrobacterium* sp. was studied. Mutation of the nucleophilic amino acid E358 from glutamate to alanine could be achieved. Condensation of α-glucosyl fluoride (**75**) with several acceptor glucopyranosides such as the *o*-nitrophenyl β-glucopyranoside **76** or the 2,4-dinitrophenyl β-2-deoxy-2-fluoro-glucopyranoside (**77**) gave transglycosylation yields of di- to tetrasaccharides **78a**–**c** and **79a**–**c**, respectively, in 76–84% overall yield [116] (● *Scheme 22*). Another glycosynthase could be employed by the same group [121] and transgalactosylation was effected with galactopyranosyl fluoride (**80**) to the PGA-resin-bound glucopentapeptide **81** to give cleanly the corresponding resin-bound lactosylpentapeptide **82**. In this study



Scheme 21

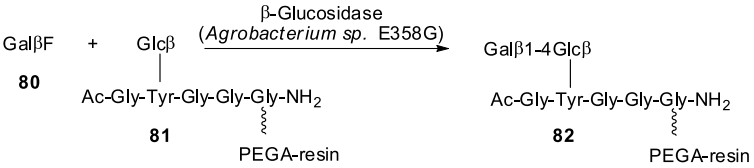
79a-c n = 1-3, X = F, R = *op*N_2P

Scheme 22



Scheme 23

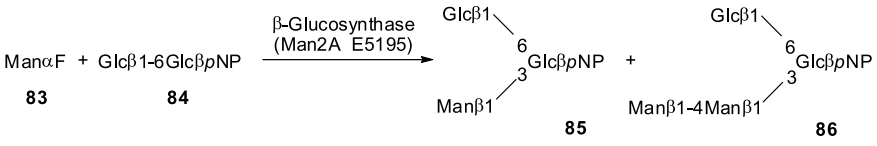
the use of solid phase PEGA resin bound acceptor structures in glycopeptide synthesis with glycosynthases could be demonstrated (*Scheme 23*).

As mentioned above β-mannosylation is an often realized structural feature in natural glycoconjugates and oligosaccharides, yet the chemical formation of β-mannopyranosides remains a challenging issue. Consequently, β-mannosyl-transferases were successfully employed, but too demanding for preparative purposes. In contrast, β-mannosylations using β-mannosidases could be performed only in poor yields. Now the present approach demonstrated convincingly the mutation of a retaining β-mannosidase from *C. fini* (Man2A) [122]. This mannosynthase catalyzed the β-mannosylation of several acceptor structures. Treatment of β-mannopyranosyl fluoride (**83**) with the *p*-nitrophenyl β-glycoside of gentiobiose (Glcβ1–6GlcβpNP) catalyzed by this glycosynthase afforded a mixture of tri- (**85**) and tetrasaccharides (**86**) with mono- as well as dimannosylation in 34% **85**) and 49% (**86**) yield, respectively. Whereas the first β-mannosylation in both products goes to the 3-position of the gentiobioside, the second mannosylation occurs at the site of the *manno*-unit and results in a Manβ1–4 Man substructure as in **86** (*Scheme 24*).

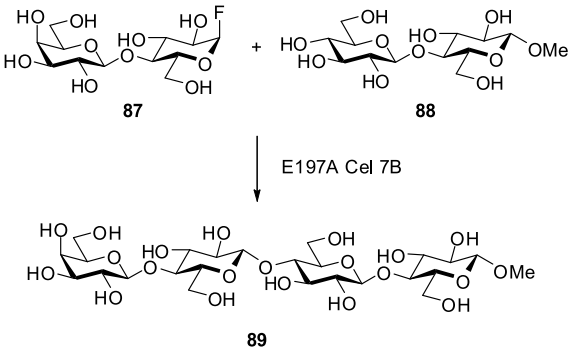
Glycosynthases could also be obtained from retaining endo-glycosidases. The first one was the endo-acting 1,3–1,4-β-glucanase of *Bacillus licheniformis*, in which the nucleophilic amino acid E134 was substituted with alanine. This enzyme could accept laminaribiosyl fluoride (Glcβ1–3GlcαF) as the donor substrate and glycosylate glucosides, cellobiosides as well as laminaribiosides in excellent yields [123].

The endo-glycosynthase obtained from the E197A mutant of the retaining cellulose Cel7B of *Humicola insolens* could be employed to transfer α-cellobiosyl fluoride (**87**) to methyl β-cellobioside (**88**) to afford the cellotetraoside **89** in virtually quantitative yield [124] (*Scheme 25*).

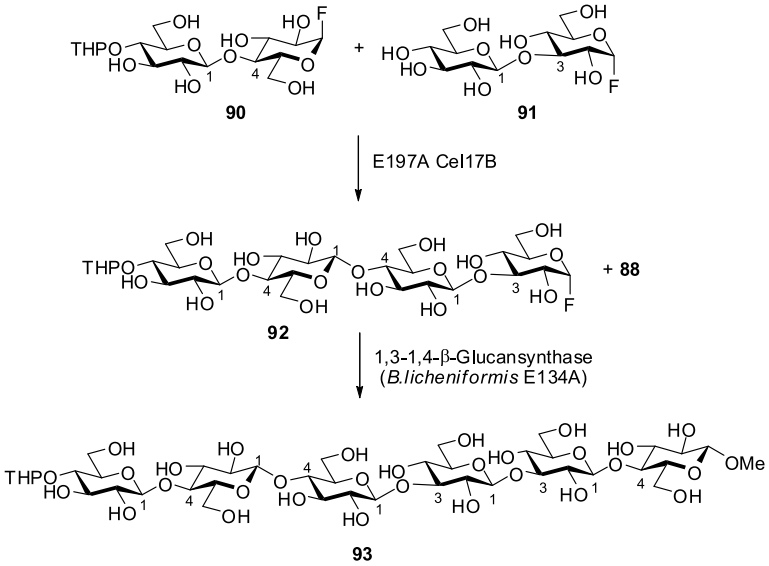
Another quite impressive example was reported by collaboration of the same Spanish-French scientists. In a tandem-type glycosylation using the aforementioned endo-glycosynthases, the α-cellobiosyl fluoride with a 4′-tetrahydropyran protection **90** was transglycosylated to the acceptor disaccharide α-laminaribiosyl fluoride **91** employing the mutant cellulose to give the tetrasaccharide **92**. Its further use as a donor structure with the mutant 1,3–1,4-β-glucanase and the acceptor cellobioside **88** gave the β,1–4- and β,1–3-linked hexasaccharide glucan **93** stere-



Scheme 24



Scheme 25



Scheme 26

oselectively and in excellent yield [125] (*Scheme 26*). An excellent resource for structural data of glycohydrolases as well as glycosytransferases and other carbohydrate active enzymes can be found in the database of Carbohydrate-Active enZymes [CAZy].

Part 6
Complex Polysaccharides

6.1 Polysaccharides: Occurrence, Significance, and Properties

James N. BeMiller
Department of Food Science, Whistler Center for Carbohydrate Research, Purdue University, West Lafayette, IN 47907–2009, USA
bemiller@purdue.edu

Abstract

Polysaccharides are present in all living organisms where they carry out one or more of their diverse functions. While there is no specific category or definition of a complex polysaccharide, most are structurally complex. Polysaccharides contain 1–5 different monosaccharide (sugar) units. The different sugar units may have different anomeric configurations and/or be joined by different glycosidic linkages. Polysaccharides may be linear or branched. Branches may be short saccharide units on a linear backbone or the molecule may have a branch-on-

Chapter-DOI 10-1007/978-3-540-30429-6_34:

branch structure; in either case, the branches may be isolated or clustered. Polysaccharides may contain non-carbohydrate groups. Esters or cyclic acetal groups, when present, can be removed by appropriate treatments. All polysaccharides are polydisperse, i. e., are present in a range of molecular weights rather than having a single molecular weight. Most are polymolecular, i. e., differ in fine structure from molecule to molecule. So most polysaccharides can be said to be structurally complex. They may be attached to protein molecules or to other polysaccharide molecules. They are solvated by water. Most dissolve in aqueous systems, especially if they are alkaline. Polysaccharides can be depolymerized by acids and heat, specific enzymes, and high pH systems following oxidation. Their hydroxyl groups can be esterified (acylated), etherified (alkylated), and oxidized. Amino groups can be acylated (and deacylated). Carboxyl groups can be converted into esters, amides, and amines. Structural modification makes the molecules even more complex and polymolecular and, perhaps, polydisperse.

1 Introduction

Polysaccharides [1], as the name implies, are polymers of saccharide units, i. e., polymers whose monomer units are simple aldose and/or ketose sugars (monosaccharides). The average number of monosaccharide units in polysaccharides varies from about 20 (although it is usually at least 100) to perhaps 10 million. The number of different monosaccharide units found in polysaccharides is not known with any certainty; more than 100 have been identified. Most are hexoses, but pentoses are not uncommon; eight- and nine-carbon-atom sugars are less common, but found. The monosaccharide units are in either five-membered (furanosyl) or six-membered (pyranosyl) ring forms, most often the latter. These units are joined together in a head-to-tail fashion by glycosidic linkages (*Fig. 1*).

Polysaccharides may be linear or branched. There are numerous branched structures, including structures with only a few, very long branches; linear structures with short branches regularly spaced, irregularly spaced, or in clusters; and branch-on-branch structures with branches clustered or positioned to produce bush-like structures with or without decoration with short branches [2,3]. Each polysaccharide has one, and only one, reducing end, which is the end terminating in a hemiacetal (or carbonyl) group (*Fig. 1*). Each branch generates an additional non-reducing end, which consists of a glycosyl unit which is attached to another through

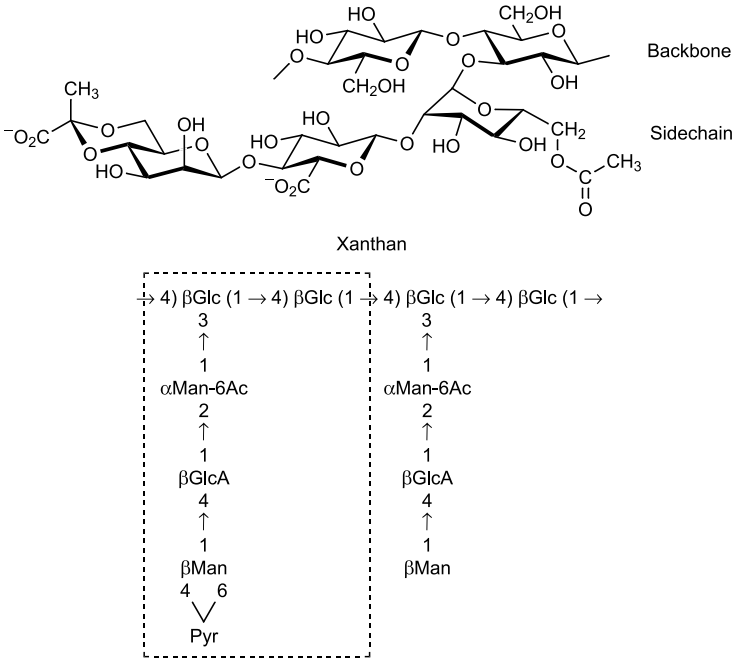

Figure 1

Structure of the pentasaccharide repeating unit of xanthan, a commercial exopolysaccharide produced by *Xanthomonas campestris* (Chap. 6.4). The main chain has the structure of cellulose, i. e., it has a repeating unit of cellobiose. The trisaccharide side chain has, at its non-reducing end, a β-D-mannopyranosyl unit (β-Man*p*) with pyruvic acid attached as a 4,6-cyclic acetal. (About one-half of these terminal mannosyl units in the polysaccharide have these 4,6-*O*-pyruvyl groups.) This non-reducing end unit is linked (1→4) to a β-D-glucuronopyranosyl unit (β-Glc*p*A), which is linked (1→2) to a 6-*O*-acetyl-α-D-mannopyranosyl unit (α-Man*p*6Ac), which in turn is linked (1→3) to a β-D-glucopyranosyl unit of the main chain. The terminal glucosyl unit on the far right of the main chain as the structure is written will have a terminal hydroxyl group, making the structure a hemiacetal. As a result, the ring can easily and rapidly open to an acyclic aldehydo form. This is the reducing end of the polysaccharide. The opposite end on the far left terminates with addition of a hydrogen atom. This is the non-reducing end of the main chain. Inside the box of the shorthand designation (bottom) is a pyruvylated pentasaccharide building block unit which is identical to the upper structure; outside the box is a non-pyruvylated repeating unit. [Reprinted by permission from Whistler RL, BeMiller JN (1997) Carbohydrate chemistry for food scientists. American Association of Cereal Chemists, St. Paul, MN]

its anomeric hydroxyl group but which has no glycosyl unit attached to it, making it a chain end (the terminal unit of the trisaccharide side-chain in *Fig. 1*). Therefore, a polysaccharide molecule may have many non-reducing ends. In terms of mass, linear polysaccharides are the most abundant, because they are structural components of higher plants and marine algae. However, there are many more branched polysaccharides than linear ones. (See Chap. 6.2, Chap. 6.4, and Chap. 6.5 for additional polysaccharides and additional information about polysaccharides not presented in this chapter.)

Polysaccharides may contain, in addition to monosaccharide units, ester, ether, and/or cyclic acetal moieties (*Fig. 2*).

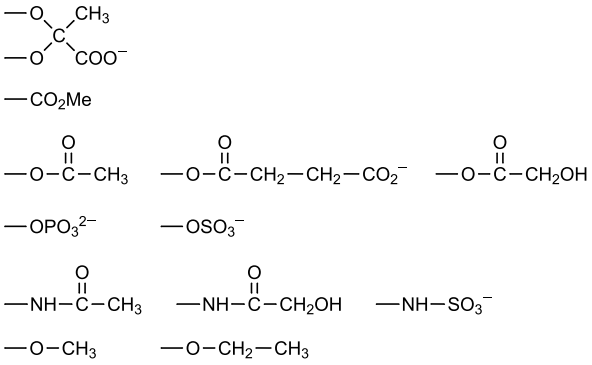

Figure 2
Some on-carbohydrate functional groups that may be part of the structure of a polysaccharide

Ester groups include acetate, glycolate, succinate, sulfate, and phosphate groups on the polysaccharide's hydroxyl groups. Methyl and ethyl ether groups may be present. Pyruvic acid may be present as a cyclic acetal. In those polysaccharides containing amino sugars, the amino groups are usually not free, but present as amido groups, with the acid moiety contributed by acetic, glycolic, or sulfuric acid. In polysaccharides containing uronic acid units (sugar units with a carboxylic acid group in place of the hydroxymethyl group), the carboxylic acid functions may be present as methyl esters.

Glycan is the formal generic term for a polysaccharide. For example, a xylan is a polysaccharide made up primarily of D-xylopyranosyl units (it may contain minor amounts of other sugars and still be called a xylan); a β-glucan is constructed of β-D-glucopyranosyl units; an arabinoxylan has L-arabinose and D-xylose as its monomeric units; a glucuronoxylomannan consists of D-glucuronic acid, D-xylose, and D-mannose; etc. If the polysaccharide has a backbone structure, it is the latter part of the name, e. g., galactomannans have a main mannan chain to which are attached D-galactopyranosyl units; the same is true of arabinoxylans. In a few cases, the anomeric configuration is used with the name. An example is the family of β-glucans, whose name indicates that they are made up of β-D-glucopyranosyl units (although so is cellulose) and distinguishes them from α-glycans (amylose, amylopectin, glycogen, and others). Polysaccharides/glycans that were named before there were systematic names do not follow either of these rules; examples are cellulose, amylose, pectin, glycogen, hyaluronic acid, heparin, and alginic acid. The term glycan, often misused, is restricted to polymers of simple sugars, i. e., to chains of more than 20 saccharide/ glycosyl units.

Polysaccharides may be attached to proteins, in which case they are known as protein-polysaccharides, when they originate from plants, or proteoglycans, when they originate from animals. Polysaccharides may also contain lipid components. Lipopolysaccharides and other mycobacterial constituents are covered in Chap. 6.5 and Chap. 7.

Many bacteria produce polysaccharides and either incorporate them in cell walls, incorporate them in capsules, or excrete them into the growth medium. When they are components of a capsule (capsular polysaccharides) or dissolve in the extracellular medium, they are known as exopolysaccharides.

Great structural diversity is found in the polysaccharides of both plants and microorganisms. Because their synthesis does not involve a template molecule (Chap. 6.4), polysaccharides are polydisperse, i. e., molecules of a specific polysaccharide from a single source are present in a range of molecular weights. In addition, the degree of polydispersity, the average molecular weight, and the range of molecular weights in a polysaccharide preparation vary from source to source. Most polysaccharides are also polymolecular, i. e., their fine structures vary from molecule to molecule. With the exception of cellulose and a few other plant polysaccharides, only bacterial polysaccharides have repeating-unit structures. Structures of other polysaccharides, and even of bacterial polysaccharides with regard to non-carbohydrate components, can vary between taxa and with growth conditions of the plant or microorganism and even between tissues of the same plant. As a result of the attributes described above and the fact that the structures of polysaccharides, whether of plant, algal, or microbial origin, vary with variations in the growth conditions of the source organism, the structures of most polysaccharides can be described as "complex". However, there is no specific category or definition of "complex carbohydrates", and a nutritionist would interpret the term differently than would a carbohydrate/polysaccharide chemist.

Polysaccharides are present in most living organisms. In fact, polysaccharides comprise about 70% of the dry weight of the total biomass. (Probably, at least 90% of all carbohydrate in nature occurs in polysaccharides.) They serve a variety of functions, not all of which are known. They are most abundant in higher plants:

1. as structural components of primary and secondary cell walls and in the middle lamella,
2. as reserve food materials in leaves, seeds, stems, roots, tubers, rhizomes, and other tissues,
3. as exudates of unknown function, and
4. as extractable material of unknown function.

They are cell-wall constituents, non-cell-wall constituents, and storage materials in algae. In microorganisms, they may be cellular or extracellular constituents. The polysaccharide chitin is a structural component in the exoskeletons of crustaceans and insects. The greatest amount of polysaccharides is found in plant cell walls (higher plants, algae, and fungi).

There is no ideal system of polysaccharide classification [3]. The best system should be that based on chemical structure. However, because of their polymolecularity, which limits descriptions to statistical structures in many cases, and the great variety of structures, classifying polysaccharides in this way has limitations. Combinations of the following categories are used [3]:

1. Branching:
    - unbranched,
    - linear with short branches or side units
        - regularly spaced,
        - irregularly spaced, or
        - clustered,
    - highly branched (branch-on-branch) structures;

2. Different kinds of monomer units:
   - one (homoglycan),
   - two (diheteroglycan),
   - three (triheteroglycan),
   - four (tetraheteroglycan),
   - five (pentaheteroglycan);
3. Charge:
   - neutral,
   - anionic (acidic),
   - cationic.

Specific-sugars and linkage types may then be used within each of these general groups. There may also be variability in any non-carbohydrate constituents. Polysaccharides used industrially are most often classified by source. Polysaccharides may also be categorized by function, the major two being structural and energy storage. However, especially in plants, it is not always clear whether a polysaccharide has a structural or a reserve role or both and, in both plants and animals, their functions are not always clearly and completely understood.

2 Animal Polysaccharides

2.1 Glycosaminoglycans

As their name implies, glycosaminoglycans are polysaccharides that contain amino sugars (specifically 2-amino-2-deoxy sugar units). Glycosaminoglycans are non-reserve polysaccharides that are usually covalently bound to proteins to form the proteoglycans of mammalian tissues [4]. Proteoglycans have different overall structures, but generally consist of a large number of polysaccharide chains attached to a polypeptide backbone to form structures that, in some cases, may resemble the brush part of a bottle brush (*Fig. 3*). About 90% of these structures are carbohydrate. There are considerable species-to-species and tissue-to-tissue differences in structures of the overall proteoglycan and the individual components. Most, but not all, proteoglycans are found in extracellular matrices of connective and certain other tissues, where they form a macromolecular framework.
Proteoglycans as a group contain three types of linkages attaching the reducing end of the polysaccharide chain to the core protein:

1. the GlcNAc-Asn (2-acetamido-2-deoxy-D-glucopyranosylasparagine) glycosylamine linkage as part of the core pentasaccharide unit found in many glycoproteins (Chap. 8) attaches keratan sulfate I to the core protein;
2. the GlcNAc-Ser(Thr) (2-acetamido-2-deoxy-D-glucopyranosylserine (or threonine) glycosidic linkage attaches keratan sulfate II to the core protein;
3. the Xyl-Ser (D-xylopyranosylserine) glycosidic linkage attaches chondroitin sulfates, dermatan sulfate, heparan sulfate, and heparin to the core protein.

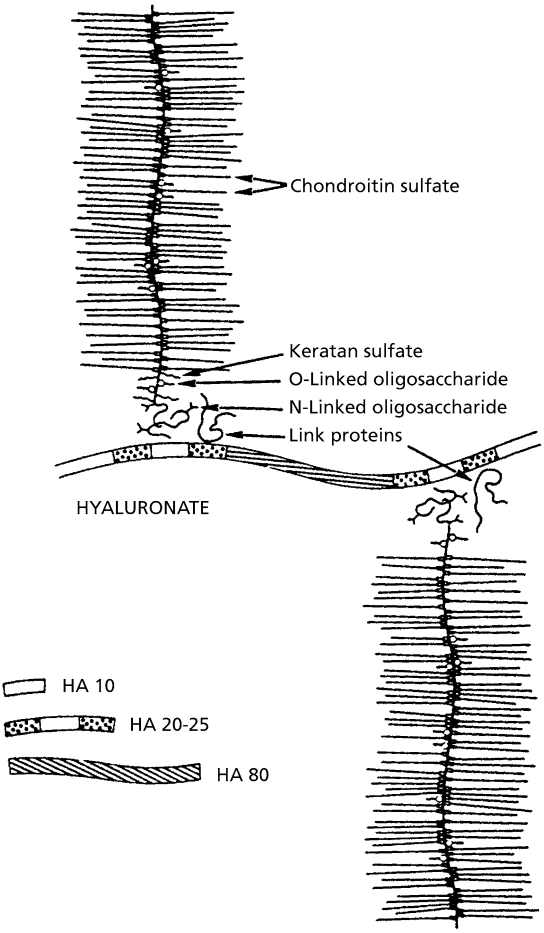

Figure 3
Proteoglycan aggregate of cartilage, consisting of a hyaluronic acid (hyaluronate, HA) chain to which proteoglycan molecules are bound non-covalently. [Reprinted by permission from reference [4, Fig. 15]

With these polysaccharides, the linkage is
$\rightarrow 4)\beta$Glc*p*A$(1\rightarrow 3)\beta$Gal*p*$(1\rightarrow 3)\beta$Gal*p*$(1\rightarrow 4)\beta$Xyl*p*$(1\rightarrow$Ser [4].
The proteoglycan molecules bind non-covalently to a decasaccharide segment of the hyaluronic acid (hyaluronate, HA) via a specific binding region, which is at one end of the protein core. Next to the HA-binding region is a segment that contains both *N*- and *O*-linked oligosaccharides and keratan sulfate. Finally, a more extended part of the core is heavily substituted with chondroitin sulfate chains plus scattered keratan sulfate molecules and oligosaccharides. The binding of proteoglycans to hyaluronate is stabilized by link proteins, which bind non-covalently, both to the hyaluronate chain and to the globular portion of the proteoglycan core. There

are ca. 40 hyaluronate disaccharide repeating units between each proteoglycan unit. The size of the aggregate depends on the size of the hyaluronate chain. Because the latter may comprise as many as 5000 disaccharide repeating units and the proteoglycan molecules are about 100 monosaccharide units apart, one hyaluronate chain may accommodate up to 100 proteoglycan chains [4].

Chondroitin sulfates have disaccharide repeating units of D-glucuronic acid and 2-acetamido-2-deoxy-D-galactose (*N*-acetylgalactosamine), viz, →4)βGlc*p*A(1→3)βGal*p*NAc(1→. Chondroitin 4-sulfate has a sulfate half-ester group on O4 of most GalNAc units; chondroitin 6-sulfate has a sulfate half-ester group on O6 of most GalNAc units. A single chondroitin sulfate molecule, however, can consist of both types of disaccharide units, and certain cells produce chondroitin 4,6-disulfate in which GalNAc units are doubly esterified. Linkage to the core protein has been previously described. Proteoglycans containing chondroitin sulfates are present in a wide variety of mammalian tissues. As much as 10% of the wet weight of cartilage and intervertebral disc tissue may be chondroitin sulfate. Chondroitin sulfates usually comprise at least 75% of the polysaccharides of cartilage; the proteoglycans of non-cartilaginous tissues contain higher proportions of dermatan sulfate. Chondroitin sulfate occurs as part of the proteoglycan stored in mast cell granules [4].

Structurally, dermatan sulfate is similar to the chondroitin sulfates, the difference being that, in dermatan sulfate, some of the D-glucuronic acid units are replaced by L-iduronic acid units, L-iduronic acid being the C5 epimer of D-glucuronic acid and always the primary uronic acid in dermatan sulfate. As with other polysaccharides of this family, dermatan sulfate is composed of various sulfated disaccharide units, the predominant ones in the case of dermatan sulfate being →4)αL-Ido*p*A(1→3)βGal*p*NAc(4-SO_3^-)-(1→, →4)βGlc*p*A(1→3)βGal*p*NAc(4-SO_3^-)-(1→, and →4)βGlc*p*A(1→3)βGal*p*NAc(6-SO_3^-)-(1→, with lesser amounts of →4)αL-Ido*p*A(2-SO_3^-)-(1→3)βGal*p*NAc(4-SO_3^-)-(1→ and →4)αL-Ido*p*A(2-SO_3^-)-(1→3)βGal*p*NAc(1→. Proteoglycans with dermatan sulfate chains are generally present, in concentrations of a few percent of the organic material, in fibrous connective tissue, in the cornea of some species, and in certain fibrous cartilages [4].

Keratan sulfate, which has a relatively low degree of sulfation, is composed of repeating units of *N*-acetyllactosamine, →3)βGal*p*(1→4)βGlc*p*NAc(1→. Sulfate half-ester groups are present on some of both monosaccharide units. As previously stated, keratan sulfate I and keratan sulfate II differ in the type of linkage to the core protein. Keratan sulfate I occurs in cornea, erythroid cell lines, and embryonic liver and lung tissue. Keratan sulfate II, which always occurs together with chondroitin sulfate in proteoglycans, is present in skeletal tissues such as bone, cartilage, and nucleus pulposus. In cartilage, a few keratan sulfate chains are clustered at one end of the core protein (*Fig. 3*); the remainder of the protein core is heavily substituted with chondroitin sulfate with some keratan sulfate chains scattered among them [4].

Heparan sulfate is the generic name for a family of glycosaminoglycans. The disaccharide unit of heparan sulfate contains either βGlc*p*A or αL-Ido*p*A linked to either αGlc*p*NAc or αGlc*p*NSO_3^-, all glycosidic linkages being (1→4). Not only do individual members of the family differ in chain structure, they differ in amounts of sulfate groups, which may be present on N2 and/or O6 of a 2-amino-2-deoxy-α-D-glucopyranosyl unit (α-D-glucosaminyl unit) and/or the O2 position of an α-L-idopyranosyluronic unit. Heparan sulfate proteoglycans are cell-surface components of many cell types [4].

Heparin has the same general structure as heparan sulfate. Heparin proteoglycan is found exclusively in granules of mast cells [4]. Heparin itself, which is obtained by degradation of the native proteoglycan, is a potent anticoagulant. Chondroitin 4,6-disulfate is also stored in mast cell granules.

Hyaluronic acid/hyaluronate is the only glycosaminoglycan that does not occur naturally as a proteoglycan. Hyaluronic acid has a disaccharide repeating unit of $\rightarrow 4)\beta$Glc*p*A$(1\rightarrow 3)\beta$Glc*p*NAc$(1\rightarrow$. It is widely distributed in mammalian tissues, viz, in synovial fluid, vitreous humor, and a variety of connective tissues and is synthesized by many bacteria. In cartilage, very large hyaluronic acid molecules form the backbones of aggregates of multiple proteoglycan molecules (*Fig. 3*), as each cartilage proteoglycan molecule contains a hyaluronate-binding region [4]. Free hyaluronic acid is found in synovial fluid and vitreous humor and in tissues with a high content of water such as skin.

As with other biopolymers, structures of the glycosaminoglycans, the proteoglycans of which they are a part, and the complexes of hyaluronic acid plus proteoglycans (*Fig. 3*) determine their physicochemical properties, which are very much related to their biological roles/functions. X-ray fiber diffraction and molecular modeling has shown that glycosaminoglycans can adopt several alternative chain conformations, but in general, the nature of the glycosidic linkages and their charged nature leads them to be in the form of extended helices [5]. When bound to a core protein molecule, the negative electrostatic charges also cause the extended chains to repel each other, leading to their ability to occupy very large hydrated domains. Because a proteoglycan of cartilage may have as many as 10,000 negative charges, the tissue has a great capacity to resist compressive forces that would force the like charges closer together. Proteoglycans also serve as a network for holding cations.

2.2 Chitin

Another structural polysaccharide of animals is chitin, which is also found in the cell walls of certain fungi [6]. Chitin is related to cellulose in that the structures are identical with replacement of the hydroxyl group at C2 of the β-D-glucopyranosyl units of cellulose with an acetamido group, i. e., chitin is a polymer of $(1\rightarrow 4)$-linked 2-acetamido-2-deoxy-β-D-glucopyranosyl (*N*-acetyl-β-D-glucosaminyl) units, although chitin is usually incompletely *N*-acetylated. Technically, chitin is a glycosaminoglycan because it contains an aminosugar as a monomer unit, but the term glycosaminoglycan is almost always restricted to those acidic/anionic mammalian polysaccharides discussed above, with the insoluble, somewhat cationic chitin being considered separately.

Like cellulose (*Sect. 3.1*), chitin imparts mechanical strength. Both chitin and cellulose form fibrils. Chitin fibrils are structural elements in the exoskeletons of insects and crustaceans. Fungal cell walls, which often contain 80–90% (dry-weight basis, db) polysaccharide, have been categorized into eight types by polysaccharide composition:

- cellulose-glycogen,
- cellulose-β-glucan,
- cellulose-chitin,
- chitosan-chitin,
- chitin-β-glucan (the most common),

- mannan-β-glucan,
- mannan-chitin,
- galactosaminoglycan-chitin.

The primary cell-wall component of many species is chitin. At least in fungal cell walls and probably elsewhere, chitin occurs as part of a proteoglycan.

2.3 Glycogen

Glycogen is a storage form of carbohydrate in many organisms. It is ubiquitous in mammals, especially in muscle and liver tissue, fish, mollusks, insects, other animals, bacteria, and fungi

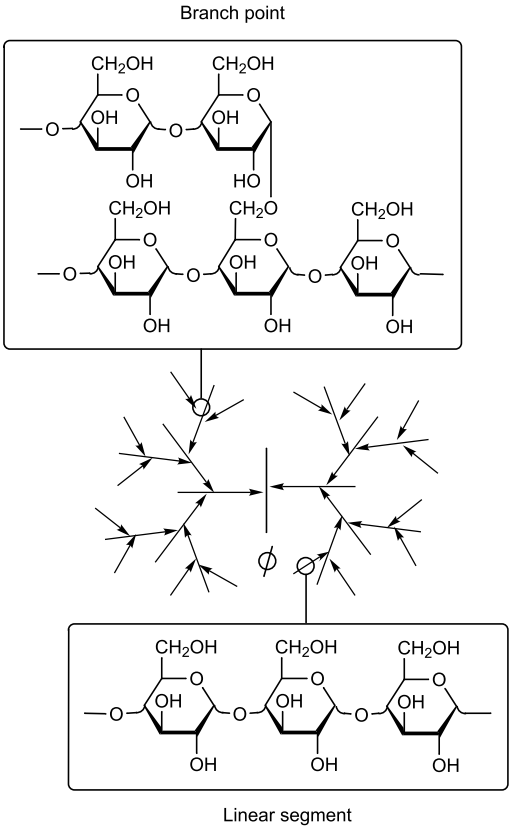

Figure 4
A schematic representation of a glycogen molecule with all but the innermost four tiers removed (see text), showing the linking of the α-D-glucopyranosyl units (in the Haworth representation) in the linear chains and at the branch points (arrowheads) and the overall arrangement of the chains according to Whelan and coworkers [8]. Φ represents the reducing end where the polysaccharide is attached to the protein primer. [Reprinted by permission from BeMiller JN (1986) Glycogen In: Mark-Bikales-Overberger-Menges: Encyclopedia of Polymer Science and Engineering, 2nd edn, vol 6. Wiley, New York]

and exists in different forms and amounts in different organisms. A related polysaccharide, phytoglycogen, which is also related to starch amylopectin, is found in some plants. The structure of the glycogen molecule is that of a tiered, branch-on-branch, bush-like structure, in which chains of (1→4)-linked α-D-glucopyranosyl units are joined by α-D-(1→6) linkages (*Fig. 4*) [7,8].

Because of its function to provide an energy source for muscle and to maintain blood sugar levels (liver), animal glycogen is always in a dynamic state. Its molecular weight, therefore, may vary from less than 1×10^6 to perhaps 2×10^9 (>6200 to at least 10^7 D-glucosyl units) depending upon the tissue of origin, the hormonal and nutritional state of the animal, and the presence or absence of disease. Even temperature, time of day, and season can affect the amount and nature of glycogen in some organisms. In any organism, at any time, the glycogen in a given tissue will be quite polydisperse, i. e., will vary considerably with regards to molecular weight/size. The highly tiered, branch-on-branch structure with approximately 50% of the D-glucosyl units in external chains gives a glycogen molecule up to tens of thousands non-reducing ends from which D-glucose 1-phosphate can be released quickly and rapidly by the action of phosphorylase when required. Glycogen in mammalian tissue occurs as single spherical (β) particles and as aggregates of as many as 100 β particles (α particles) [7].

Glycogen synthesis begins on glycogenin, a self-glucosylating protein that remains as a covalently bound part of the glycogen molecule [9,10,11]. Glycogen from certain sources contain small amounts of D-glucosamine (2-amino-2-deoxy-D-glucose) [12] and phosphate mono- and diester groups [13,14].

3 Higher Plant Cell-Wall Polysaccharides

Differences in compositions of the cell walls of higher plants occur within phyla, classes, families, and genera of higher plants, with location within a given plant (because different cells have different functions and exist in different environments), and with stage of development [15]. Nevertheless, some general features can be described. Polysaccharides are the primary constituents of plant cell walls.

3.1 Cellulose

Cellulose is the principal component of the cell walls of higher plants and, therefore, the most abundant organic compound on Earth [16,17,18,19]. Cellulose is also present in brown, red, and green algae and in certain fungi and slime molds and excreted extracellularly by certain bacteria. Even certain animals (truncates and protozoans) synthesize cellulose. Hence, cellulose is synthesized by both plants and animals, but almost exclusively by plants, and by both prokaryotes and eukaryotes (primarily by eukaryotes). The amount of cellulose in a plant varies greatly from species to species. Wood, which is about half cellulose on a dry-weight basis, has the highest percentage of cellulose, except for the fibrous seed hairs of cotton, which are ~90% cellulose. In wood, the majority of cellulose fibrils are found in thickened secondary cell walls where they provide mechanical strength and stability.

Cellulose differs from most other polysaccharides in being a homoglycan with a single type of linkage and in occurring naturally as a partially crystalline, high-molecular-weight poly-

mer with a preponderance of microcrystalline domains. In its native state, cellulose usually exists in the form of strong fibers. Chemically, all celluloses are the same, i. e., all are polymers of β-D-glucopyranosyl units linked (1→4), but these (1,4)-β-glucans differ in physical organization into fibrillar structures from source to source.

3.2 Other Plant Cell-Wall Polysaccharides

In both primary and secondary cell walls, cellulose is mixed with other polysaccharides (◉ *Table 1*) and lignin [20,21,22,23,24,25,26]. Historically, the other polysaccharides have been called hemicelluloses. The term hemicellulose indicates a polysaccharide closely associated with cellulose in cell walls. The relationship is physical, not structural. These polysaccharides are almost always heteroglycans; β-glucans and some polysaccharides that are composed almost exclusively of D-xylose are among the exceptions. Structures of hemicelluloses vary from linear to highly branched and bushlike.

Hemicelluloses have traditionally been defined by extraction procedures, i. e., hemicelluloses are those polysaccharides extracted by alkaline solutions from plant tissues after removal of low-molecular-weight substances with hot aqueous alcohol, removal of waxes and other lipid-soluble substances, delignification, and removal of pectin with an aqueous solution of a calcium ion chelator. The most abundant hemicelluloses in the primary cell walls of dicotyledons are xyloglucans. Xyloglucans have a backbone chain whose chemical structure is identical to that of cellulose. About 75% of the β-D-glucopyranosyl units in that chain are substituted

Table 1
Some cell-wall polysaccharides[a,b]

Higher land plants	*Marine algae*	*Fungi and yeasts*
Cellulose	Algins	Cellulose
Hemicelluloses	Cellulose	Chitin
Arabinoxylans	Galactans	β-Glucans
Galactoglucomannans	Agars	α-Glucans
β-Glucans	Carrageenans	Mannans
Glucomannans	Furcellarans	
Mannans	β-Glucans	
Xylans	L-Fucans	
Xyloglucans	Mannans	
Pectic polysaccharides	Xylans	
Arabinans		
Arabinogalactans		
Galactans		
Galacturonans		
Rhamnogalacturonans		

[a]Other than those of bacteria; [b]Many of these polysaccharides may contain monosaccharide units other than those indicated in the name. For example, xylans often contain uronic acid units, and the polysaccharides named L-fucans may contain, in addition to the principal sugar (L-fucose), D-galactose, D-glucuronic acid, D-mannose, and D-xylose

at O6 with β-D-xylopyranosyl units or oligosaccharide chains terminated at the reducing end (the end attached to the main chain) with a β-D-xylopyranosyl unit. In monocotyledons, the most abundant polysaccharides are branched glucuronoarabinoxylans. These polysaccharides have main chains of (1→4)-linked β-D-xylopyranosyl units, which is the structure of cellulose with the terminal hydroxymethyl group (C6) removed. Attached to the main chains at O2 and/or O3 are units of L-arabinose, D-galactose, or D-glucuronic acid. Both xyloglucans and glucuronoarabinoxylans are cross-linked via substituents attached via ester or ether bonds and may be linked to other cell wall components, viz., lignin, in the same way.

The predominant hemicelluloses in secondary cell walls of both monocotyledons and dicotyledons are xylans. These polysaccharides have a xylan main chain that is decorated with 4-*O*-methyl-D-glucopyranosyluronic acid, D-glucopyranosyluronic acid, L-arabinofuranosyl, and/or L-arabinopyranosyl units. These related polysaccharides are usually acetylated to various degrees. Gymnosperms contain glucomannans, also acetylated, as the principal secondary cell-wall hemicellulose [26].

Pectic substances, another family of polysaccharides (*Table 1*), are located in middle lamellae and primary cell walls. Their structures can be complex, with more than one type of polysaccharide chain in a single molecule [21]. For example, arabinogalactan chains are attached to poly(α-D-galactopyranosyluronic acid) chains in native pectins (rhamnogalacturonans). (Arabinogalactans also commonly occur in protein-polysaccharide structures.) The primary structural units of rhamnogalacturonans are α-D-galacturonopyranosyluronic acid units. Ten other monosaccharide units have been found in rhamnogalacturonans, including the rare sugars D-apiose, L-aceric acid, and 3-deoxy-D-*lyxo*-2-heptulosaric acid and a sugar usually associated with bacterial polysaccharides, 3-deoxy-D-*manno*-2-octulosonic acid (Kdo) [26]. Pectic substances comprise 1–4% of woody tissue. Biotechnology is being used to modify plant pectins.

The polysaccharides found in cell walls are specific to specific cell types. Most flowering plants have type-I cell walls. These walls have a cellulose-xyloglucan interlocking framework (~50% of the wall mass) embedded in a matrix of pectic polysaccharides [(~30%; rhamnogalacturonan I plus lesser amounts of partially methyl-esterified poly(D-galacturonic acids) (galacturonans)]. Grasses have type-II cell walls. The characteristic components of these walls are cellulose, glucuronoarabinoxylans, galacturonans, and mixed-linkage β-glucans/(1,3:1,4-β-glucans) [27].

Multicellular algae must be tough and flexible. Holding the plant upright is not a requirement as it is with land plants, which are too brittle for aquatic existence. Structural polysaccharides of algae vary greatly between phyla. Included as cell-wall components of algae are alginates, sulfated galactans (carrageenans, agars, etc.), glucans, fructans, xylans, mannans, cellulose, pectic substances, and other polysaccharides [28].

3.3 Plant Cell-Wall Polysaccharides that Have a Reserve Function

Plant cell walls are the source of the greatest quantity of polysaccharides. Some cell-wall-associated polysaccharides may serve storage functions in addition to or rather than structural functions. Such polysaccharides include the β-glucans [29,30], mannans [31], galactans [28], and arabinogalactans [23].

β-Glucans occur in cereal seeds from which they can be extracted [29,30]. Some are (1→3)-linked β-glucans. Barley endosperm cell walls contain ~75% of this type, some of which may be covalently bound in some way. (1→3)-Linked β-glucans are also found in many other monocots, especially in oat and other Graminae. Another group of β-glucans in the grasses, known as mixed-linkage β-glucans, contains polysaccharides with both (1→3) and (1→4) linkages.

4 Energy-Reserve Polysaccharides of Plants

Some polysaccharides provide a reserve energy supply for tissues and organisms (● *Table 2*). One polysaccharide that serves in this role, glycogen, is discussed in ● *Sect. 2.3*. Starch is the principal carbohydrate energy-storage substance of higher plants [32,33,34] and, after cellulose, the second most abundant carbohydrate end-product of photosynthesis. Starch is not only a reserve substance of many higher plants, it is an energy source for animals that feed on them. All higher plants produce starch sometime during their lifetime. Starch is found in leaves, where it serves as a transient D-glucose storage material, and in seeds (especially those of cereal grains), fruits, roots, rhizomes, stems, tubers, and trunks for long-term storage. Starches provide at least 70% of human caloric intake on a worldwide basis.

Starch is unique among carbohydrates in that it occurs in discrete particles called granules. Starch granules are relatively dense and insoluble. Most starch granules contain two polymers: an essentially linear polysaccharide called amylose and a highly branched polysaccharide called amylopectin. Each starch from each plant source and tissue is unique in terms of granule morphology, composition, polysaccharide structures, and behavioral characteristics. Several mutant variants of starch are known; two of them, waxy maize and high-amylose (amylose extender) maize, are major commercial products.

Other energy-storage polysaccharides include inulin and other fructans in roots, tubers, stems, and algae [35]; galactomannans in legume seeds [36, ● Chap. 6.4]; mannans [31]; glucomannans [31]; starch-like polysaccharides (floridean starch), fructans, and β-glucans of algae [37]; and α- and β-glucans of fungi [37].

It is not always clear whether cell-wall polysaccharides have a structural or reserve function because some, for example, the β-glucans of cereal grains, may have dual roles. However, it is likely that the β-glucans and other hemicelluloses in cell walls of tissues other than those in

Table 2

Xyloglucans				

[a]Starch- and glycogen-like polymers

seeds function as structural components. During germination, seed components, including in some cases β-glucans, are used for energy and carbon sources for synthesis.
(1→3)-Linked β-glucans are cell-wall constituents of bacteria, blue-green and other algae, fungi, yeasts, and lichens [30]. Some of this class of polysaccharides in cell walls of some bacteria and some fungi are (1→3), (1→6)-β-glucans which have a (1→3)-linked main chain to which are attached β-D-glucopyranosyl and, in some cases, gentiobiosyl units via (1→6) linkages. Other β-glucans, other than cellulose, contain other linkages, e. g., all (1→6), all (1→2), and other mixed linkages [30].

5 Bacterial Polysaccharides

Bacterial cell walls contain a structural material called peptidoglycan or murein. This substance is composed of glycosaminoglycan chains cross-linked with peptides to form a three-dimensional network [38,39,40]. The glycosaminoglycan chains are composed of a disaccharide repeating unit in which one member is a 2-acetamido-2-deoxy-β-D-glucopyranosyl unit and the other is usually an *N*-acetylmuramic acid (a 2-acetamido-2-deoxy-β-D-glucopyranosyl unit etherified at O3 with D-lactic acid) unit. (Modifications of *N*-acetylmuramic acid are rare, but do occur.) Therefore, the glycan has the structure of chitin with alternating glycosyl units possessing a lactic acid ether group. Bacterial cell walls may also contain non-polysaccharide carbohydrate polymers (teichoic acids and teichuronic acids). In these polymers, alditols, monosaccharides, or oligosaccharides are joined by phosphodiester linkages. Teichoic and teichuronic acids are linked covalently to the peptidoglycan in the cell wall via a phosphodiester bond.
Some carbohydrate-containing polymers are components of capsules or are secreted into the culture medium. As stated by Kenne and Lindberg [41], structural variation in such bacterial polysaccharides is almost unlimited and unusual sugars are not uncommon. The overwhelming majority of bacterial polysaccharides are heteroglycans composed of oligosaccharide repeating units. A majority is also antigenic and responsible for the specific immunological properties of one type, one species, or one group of bacteria. Bacterial cell-wall polysaccharides, i. e., the lipopolysaccharides and other mycobacterial cell-wall polysaccharides, are described in Chap. 6.5 and Chap. 7.
Bacterial exopolysaccharides (extracellular polysaccharides) include those that are made from sucrose, viz., dextrans and fructans. Dextrans are branched α-glucans containing (1→3) and/or (1→6) and occasionally (1→2) linkages. Fructans contain β-D-fructofuranosyl units linked (2→6) or (2→1).

6 Fungal and Yeast Cell-Wall Polysaccharides

In addition to chitin (*Sect. 2.2*), yeast cell walls may contain a (1→3)-β-glucan, a (1→6)-β-glucan, various mannans, or a galactan. Other cell-wall components of certain fungi are rhamnomannans, glucomannans, galactomannans, xylomannans, glucuronoxylomannans, and other polysaccharides [42].

7 Physical Properties

Because the structures of polysaccharides vary widely, their physical properties vary. This section mentions in a cursory way two common properties: (1) that of being water-soluble or hydratable and (2) that of forming intermolecular associations. Neither is a universal property of polysaccharides. Polysaccharides that are unbranched (or only very slightly branched) and unsubstituted homopolymers with a single type of linkage (generally 1→3 or 1→4) are insoluble in water at temperatures up to 100 °C because of their ability to form intermolecular hydrogen bonds over much of their lengths; examples are cellulose, mannan, and crystalline amylose. Some polysaccharides that, while slightly branched or substituted, but which have significant chain segments that are unbranched may be soluble only in hot water or high-pH solutions; examples are locust bean (carob) gum, some xylans, and certain arabinoxylans (Chap. 6.4). Modification or derivatization of only a few hydroxyl groups on an insoluble polysaccharide appears to be sufficient to diminish intermolecular hydrogen bonding and provide water solubility. Polysaccharide molecules or bundles of molecules that can associate with other polymer molecules or bundles of molecules over only a short portion of their lengths will form three-dimensional networks and gel the aqueous system in which they are present (Chap. 6.4). In some cases, these associations involve hydrogen bonding between hydroxyl groups of portions of adjacent chains. Some polysaccharides will form gels by themselves; others require the presence of other substances to form a gel. Many commercial water-soluble polysaccharides will gel aqueous systems (Chap. 6.4). The physiological function of certain natural "complex polysaccharides" as described in *Sect. 2.1* requires them to form a gel matrix. Polysaccharides cannot be dissolved under conditions in which they would form a gel.

8 Structural Analysis

There are generally six aspects of determining the structure of a polysaccharide: (1) determination of the monosaccharide composition, (2) determination of linkages to the various monosaccharide constituents, (3) determination of the sequence of monosaccharide units, (4) determination of anomeric configurations, (5) determination of the presence and location of any substituent (ester, ether, cyclic acetal) groups, (6) determination of average molecular weight and degree of polydispersity. Determination of the monosaccharide composition begins with acid-catalyzed hydrolysis under conditions determined experimentally to give both maximum depolymerization and minimum destruction of the sugars [43]. Released monosaccharides are then determined both qualitatively and quantitatively by HPLC [44], usually by using high-performance anion-exchange chromatography and pulsed amperometric detection (HPAEC-PAD).

Linkages of most polysaccharides have been determined by methylation analysis, which can provide information about the linkage site, ring size, and the nature of the monosaccharide unit [45]. Methylation analysis determines the position(s) of linkage(s) to each monomer unit. It does not give information about the sequence of the units or their anomeric configuration(s). To provide information about the monosaccharide sequence(s), the polysaccharide may be partially depolymerized using enzyme- or acid-catalyzed hydrolysis or methanolysis to gener-

ate oligosaccharides, whose structures are then determined. One approach to determining the structure (other than anomeric configurations) of an oligosaccharide is via use of MALDI-TOF mass spectroscopy [46]. A technique that provides both linkage analysis and anomeric configurations of the monomer units is that known as reductive cleavage analysis [46]. Oxidative techniques can also provide structural information [46].

Combinations of methylation, various degradative techniques, and various ^{1}H and ^{13}C NMR spectroscopic techniques are used to characterize polysaccharides, except for molecular weight and degree of polydisperity. Ten selected examples are given in references [47,48,49,50,51,52,53,54,55,56]. Average molecular weights and molecular weight ranges are determined by high- or medium-angle laser light scattering (MALLS) analysis of the eluate. Mass spectrometric techniques are commonly used to sequence structures of the oligosaccharide portions of glycolipids and glycoproteins [57,58]. Mass spectrometry can be combined with other techniques in the structural analysis of polysaccharides [46,59,60].

Mishnick and co-workers have developed several techniques for determining the positions of substitutions on monosaccharide units and distribution of substituents along derivatized polysaccharide chains, primarily cellulose derivatives. Examples are found in references [61,62,63,64,65,66,67,68,69,70]. An important method involves perdeuteromethylation followed by partial acid-catalyzed hydrolysis, then reductive amination with propylamine, and finally permethylation to yield completely *O*- and *N*-alkylated charged oligosaccharides that are analyzed by MALDI-TOF-MS [68,70]. Statistical methods are then applied.

8.1 Molecular Conformations

Molecular conformations [71,72] and associations can be determined by CP-MAS-^{13}C-NMR and two-dimensional NMR methods [73], but the primary means of determining molecular conformations has been X-ray fiber diffraction analysis coupled with molecular modeling as practiced by Chandraskeran and co-workers. Examples are found in references [74,75,76,77,78,79,80,81,82,83,84]. The technique has also been used to study polysaccharide-polysaccharide interactions [85]. Recently, powder diffraction data has been used to determine a molecular conformation [86]. Modeling alone has been used to predict possible conformations [87].

9 Reactions of Polysaccharides

Although polysaccharide molecules may contain a variety of functional groups, including amino groups (especially in bacterial polysaccharides), carboxyl groups (in polysaccharides containing uronic acids and succinate half ester and pyruvyl cyclic acetal groups), and various organic and inorganic ester and amide and ether groups (*Sect. 1*), the primary reactions of polysaccharides involve hydroxyl groups. Reactions resulting in cleavage of glycosidic bonds are also important. Selected examples of the former and of non-hydroxyl group reactions are presented below.

9.1 Esterifications

Esterifications (acylations) with organic acids can be effected in two ways. One is to use a highly reactive reagent such as the acylpyridinium ion (e. g., acetic anhydride or acetyl chloride in pyridine), often with a tertiary amine for neutralization of the generated acid [88], or with an acid anhydride in an aqueous alkaline system. Commercially, organic esters are made in an aqueous alkaline medium using acid anhydrides. Starch is acetylated with acetic anhydride to a low-DS for the purpose of making a stabilized product [89] (Transesterification using vinyl acetate is used in countries in which acetic anhydride cannot be possessed [89].) Reaction with a difunctional reagent (acetic adipic mixed anhydride) is used to strengthen starch granules via cross-linking [90].

Practiced with cellulose is acylation to the extent that the molecules are soluble in organic solvents. The product is often thermoplastic. These products include cellulose triacetate, cellulose 2,3-diacetate (acetate rayon), cellulose acetate butyrate, cellulose acetate phthalate, and cellulose acetate propionate.

Inorganic esters, viz., the sulfate half ester and phosphate esters, are also produced. Sulfate half esters can be made using sulfur trioxide and a tertiary amine [91,92,93]. An example of the latter is sulfation by SO_3-trimethylamine in DMF. Sulfation of dermatan sulfate using this method resulted in initial substitution on the O6 of the 2-acetamido-2-deoxy-β-D-galactopyranosyl 4-sulfate units to produce the 4,6-disulfate. When this initial step was about 50% complete, sulfation occurred about equally on O2 and O3 of the α-L-idopyranosyluronic acid units, producing a product with β-GalNAc 4,6-disulfate, αLIdoA 2-SO_4, αLIdoA 3-SO_4, and αL-IdoA 2,3-disulfate units [94]. There are other regioselective approaches for polysaccharide functionalization by sulfation [95].

The reverse of sulfation is desulfation, which can be effected under mild enzymic conditions [96]. Similarly, enzymic depolymerization, closely guarded by trade secrets, is routinely used in the production of heparin-derived drugs.

Sulfate groups are also easily removed by aqueous acid with S–O bond scission so that the configuration of the carbohydrate is fully retained. The general order for desulfation is O6 > O2 > O2 [97].

Cyclic sulfates can be prepared from cyclic but not acyclic carbohydrate units by reaction with sulfuryl chloride in pyridine [98] or phenyl chlorosulfate and sodium hydride [99]. The reactivity of cyclic sulfates is quite similar to that of epoxides. Thus, they can be used to form fluoro or azido derivatives of polysaccharides by highly regiospecific approaches, usually, but not always, leading to *trans*-diaxial products from which the sulfate can be easily removed by mild, acid-catalyzed hydrolysis [100,101].

Both monostarch and distarch phosphate esters are commercial starch derivatives [90,102].

9.2 Etherifications

Etherifications (alkylations) are carried out for two reasons: structural analysis (*Sect. 8.1*) and to change the nature (properties) of the polysaccharide (Chap. 6.4). The basic reaction used is the classical Williamson ether synthesis, i. e., some of the hydroxyl groups on the polysaccharide are converted into the alkoxy form, then these molecules are reacted with

molecules with leaving groups, i. e., epoxides or alkyl or aryl halides [103,104,105]. In addition to the common water-soluble derivatives, called gums, described in Chap. 6.4, sulfoethyl, sulfopropyl, diethylaminoethyl, and other ether derivatives are made commercially as chromatography media.

Fundamentally, any reaction of a low-MW alcohol to produce an ester or ether can be done with a polysaccharide. Many derivatives have been made, including those made with difunctional reagents for the purpose of cross-linking molecules [101]. Only a few have been commercialized. Highly substituted ethylcellulose, a thermoplastic substance with organic solvent solubility, is made commercially.

9.3 *N*-Acylation of Aminopolysaccharides

Selective *N*-acylation of a number of aminopolysaccharides and glycosamino-glycuronans depends on the basicity of the nitrogen atom present in the polysaccharide chain [106] and they can be efficiently acylated using anhydrides in organic media [107]. Various free aminochitosan fractions, for example, can be quantitatively acylated at ambient temperature within a short period of time. The high efficiency of the above reaction can be attributed to the increased basicity of the amino function during the reaction. *N*-Alkylations are effected in a similar manner.

9.4 Oxidations

Partial oxidations [104,105] of polysaccharides is commonly done, both during structural analysis and to modify their properties. Oxidation introduces both carbonyl and carboxylate functions at different positions, and especially in alkaline systems, can result in chain cleavage, i. e., depolymerization [108]. Oxidation using sodium hypochlorite by itself [109] or in combination with sodium bromide [110] is practiced in the starch industry, both to introduce specific properties into the product and for depolymerization. This oxidation is non-specific.

Vicinal diol functions are oxidized with a high degree of specificity using periodic acid. Dialdehyde polysaccharides are formed [111,112].

Selective oxidation of primary hydroxyl groups can be achieved with 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) and hypobromite or hypochlorite at pH 10.5–11. A 98% selectivity was observed for starch, and selectivity of over 90% for inulin [113].

Another selective method for primary hydroxyl group oxidation is the oxidation by dinitrogen tetraoxide in the gas phase or dissolved in carbon tetrachloride [114]. When this reaction is applied to cellulose, formation of a high yield of D-glucuronic acid units incorporated into the cellulose chain results [115]. Selective oxidation of the primary hydroxyl group was increased to 88% by using phosphoric acid and sodium nitrite to generate the dinitrogen tetraoxide.

Other selective oxidation methods include the combination of dimethyl sulfoxide/acetic anhydride [116] and oxygen (using Adams catalyst) [117]. The specific combination of chromium trioxide/perchloric acid [118] was extremely effective for the selective oxidation of the primary hydroxyl groups of chitosan, producing a polymer made up entirely of 2-amino-2-deoxy-D-glucuronic acid units. An interesting mechanism explaining the formation of this product was proposed. The mechanism is based on the quaternization of the primary amino group

prior to oxidation and formation of a bulky ammonium perchlorate group, thus providing the required protection of the hydroxyl group at C3.
Selective oxidation of amylose at C3 has been achieved with dimethyl sulfoxide/phosphorus pentaoxide [119]. In contrast, the oxidation of unprotected cellulose with dimethyl sulfoxide/acetic anhydride [120] or dicyclohexylcarbodiimide/dimethyl sulfoxide [121] produced a product containing modified β-D-glucopyranosyl units – some with a carbonyl function at C2, some with a carbonyl function at C3, and some with carbonyl functions at both C2 and C3 [122].

9.5 Reactivity of Carboxyl and Carbonyl Groups of Polysaccharides

Carboxylic acid-containing polysaccharides can be easily functionalized by reactions such as esterification, amination, or amidation. Industrial esterification of polyuronides, including alginic acid (Chap. 6.4), in aqueous medium can be easily accomplished by reaction with ethylene, propylene, butylene, and pentylene oxides in 50–80% yield [123].
Amination can be achieved by reductive amination of carboxyl groups using sodium cyanoborohydride [124]. By this method, 2-amino-2-deoxy functionalized amylose and cellulose have been produced. Reductive amination can also be applied to the synthesis of other amino derivatives of various oxidized polysaccharides such us xanthan [125] or alginic acid and galactomannans [126].

Chapter-DOI 10-1007/978-3-540-30429-6_35:

Abstract

Starch is a very important and widely distributed natural product, occurring in the leaves of green plants, seeds, fruits, stems, roots, and tubers. It serves as the chemical storage form of the energy of the sun and is the primary source of energy for the organisms on the Earth. Starch is composed of two kinds of polysaccharides, amylose and amylopectin, exclusively composed of D-glucose residues with α-(1→4) linkages in a linear amylose and α-(1→4) linkages and ~5% α-(1→6) branch linkages in amylopectin, both combined in a water-insoluble granule that is partially crystalline and whose size, shape, and morphology are dependent on its biological source. The properties, isolation, fractionation, enzymatic degradation, biosynthesis, chemical modification, and specific methods of analysis of starch are presented.

Keywords

Amylose; Amylopectin; Granules; Crystallinity; Hydrogen bonding; Hydrophobic bonding; Isolation; Fractionation; Gelatinization; Solubilization

Abbreviations

ADPGlc	adenosine diphosphate glucose
α-Glc-1-P	α-D-glucopyranosyl-1-phosphate
avg. d.p.	average degree of polymerization
CGTase	cyclomaltodextrin glucanyltransferase
d.s.	degree of substitution
DMSO	dimethyl sulfoxide
EDTA	ethylene diamine tetraacetic acid
FACE	fluorescence-assisted capillary electrophoresis
P_i	inorganic phosphate
PPO	2,5-diphenyloxazole
POPOP	1,4-bis-2-(5-phenyloxazoly)benzene
TEMPO	2,2,6,6-tetramethyl-1-piperidine oxoammonium ion
UDP-Glc	uridine diphosphate–glucose

1 Introduction, History, Development, and Uses

Starch is an abundant, naturally occurring polysaccharide, rivaling cellulose in the amount found on the Earth. It is found in the leaves of all green plants and in the seeds, fruits, stems,

roots, and tubers of most plants. Starch results as an end-product of photosynthesis and serves as the chemical storage form of the energy of the sun on the Earth. A high percentage of the energy available to non-photosynthetic organisms comes from starch, which is found in the principal food crops of the world: wheat, potatoes, rice, maize, barley, rye, beans, peas, sorghum, tapioca (or cassava), sweet potatoes, avocados, arrowroot, taro, bananas, mango, pineapple, sago (palm starch) and so forth.

It is estimated that 60–70% of the caloric intake by humans comes from starch. As such, starch has been of great importance in the evolution of organisms and especially for humans, where it also has had a role in the evolution of culture. Besides being used as an essential food, wheat starch was used to give body and the ability to hold ink to papyrus, a thin bark that was the earliest material used for writing (~4000 B.C.), especially in Egypt. When paper was developed in China, around 100 A.D., starch was also used to give body to the paper and to hold ink on the paper and it continues today to be used to size paper. The Romans (~100 B.C.) used starch to whiten cloth and to powder hair, and about 300 A.D., it was widely used to stiffen cloth and was often mixed with dyes to color the cloth. Colored starches (especially yellow and red) were also used as cosmetics.

Starch is one of three major biorenewable materials found on the Earth, sucrose and cellulose being the other two. Of the three, starch is today the most important because of its relative abundance and its relative ease of isolation in a highly pure form, which is relatively easily solubilized and enzymatically hydrolyzed to glucose and/or different maltodextrin products, or chemically modified. It, therefore, is a biorenewable, natural product that finds many industrial uses, such as the formation of glucose syrups, high-fructose syrups, maltodextrins with a wide range of average molecular weights, cyclomaltodextrins, D-glucitol (D-sorbitol) and the formation of ethanol, acetic acid, D-lactic acid, and other organic compounds by fermentation.

2 Isolation of Starch Granules

Because of the water-insolubility of starch granules, they are relatively easy to isolate from their plant sources. The source, for example seeds from maize, wheat, barley, rice, beans, and so forth are first steeped in water for 10–15 h at 50 °C. Steeping softens the outer parts of the seeds so the starch inside can be more easily obtained. The steep water often contains 1.63 g of sodium hydrogen sulfite per liter to remove protein. In some cases, the sulfite is omitted to retain the protein and give a starch as it more closely exists in the plant. The steeped material is then ground, milled, or blended to give a white insoluble suspension of starch that is filtered one time through six layers of cheese cloth and a second time through eight layers, to remove fibrous non-starch substances. The starch is allowed to settle and the water is poured off and fresh water is added and the starch is washed two or three times in this manner. The starch is then centrifuged or filtered and allowed to air dry at 20 °C. It is then lightly pounded into a fine powder.

If the starch is to be isolated from a tuber, stem or rhizome, the plant materials are washed and peeled and then cut into 1-cm pieces, placed in water, and blended. The resulting starch suspension is then obtained in a similar manner, as described above, beginning with filtering through the cheese cloth.

3 Chemical Composition of Starch

Most starches are composed of two kinds of polysaccharides, a linear α-(1→4) linked glucan, called amylose, and an α-(1→4) linked glucan with 4.2 to 5.9% α-(1→6) branch linkages, called amylopectin. See *Fig. 1* for the chemical structure of a segment of amylose and a segment of amylopectin and *Table 1* for the percent branching in amylopectin for several different starches.

The ratio of amylose to amylopectin also varies, depending on the source of the starch; it ranges from 17 to 70% amylose and a corresponding 83 to 30% amylopectin. See *Table 2* for a list of different starches and their composition of amylose and amylopectin. Usually amylopectin is present as the major component, with a common ratio of 1:3 or ~25% amylose and ~75% amylopectin. There are mutants, however, such as, waxy barley, waxy maize, waxy rice, waxy potato, and waxy sorghum that are 100% amylopectin and there are the high-amylose starches,

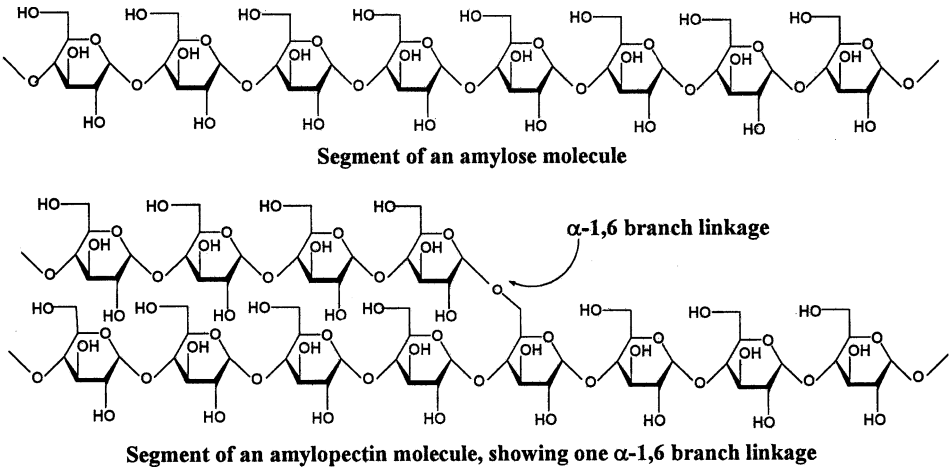

Figure 1
The structures of segments of amylose and amylopectin

Table 1
Percent branching of amylopectin from different starches

Amylopectins	% Branching[a]
Maize	4.2
Potato	4.5
Wheat	4.8
Barley	5.0
Oats	5.2
Waxy maize	5.9

[a]The avg. % branching was calculated from the avg. chain length determined by the enzymatic method [177]

Table 2
Composition of starch granules from ten plant sources

Starch	Amylose[a] (%)	Amylopectin[a] (%)	Lipid[b] (%)	Protein[b] (%)	Phosphate[b] (%)
Maize	25	75	0.80	0.35	0.090
Waxy maize	0	100	0.20	0.25	0.024
Amylomaize-5	53	47	0.70	0.30	0.090
Amylomaize-7	70	30	0.75	0.30	0.060
Potato	22	78	0.01	0.10	0.210
Wheat	23	77	0.90	0.40	0.180

Shoti	30	70	0.01	0.20	0.630

[a]The percent amylose and amylopectin were determined by precipitating the amylose with 1-butanol and then precipitating the amylopectin with two volumes of ethanol; the butanol-1 was removed and both were dehydrated by trituration with acetone several times and ethanol, followed by drying under vacuum at 40 °C, and weighed.
[b]From Ref. [178]

such as, amylomaize-5, with 53% amylose and 47% amylopectin, amylomaize-7, with 70% amylose and 30% amylopectin, and wrinkled pea with 66% amylose and 34% amylopectin.
The molecular weights of the two polysaccharides also vary, depending on the source of the starch. Amylose is much lower than amylopectin and both polysaccharides exist as a distribution of molecular weights, so that the determined molecular weight is an average. Amylomaize-7 amylose has an average degree of polymerization (avg. d.p.) of ~400 glucose residues or a number average molecular weight of ~64,800 Da; potato amylose has an avg. d.p. of ~1,000 glucose residues or a number average molecular weight of ~162,000 Da; and wheat amylose has an avg. d.p., of ~4,000 glucose residues or a number average molecular weight of 648,000 Da. Amylopectin is a much larger molecule, having number average molecular weights of 1×10^6 to 5×10^8 Da. The polydispersity of the sizes of the amylose component is lower than the amylopectin component.
It has been determined that for a starch granule of 15 μm diameter and a mass of 2.65×10^{-9} g, containing 25% amylose, with an avg. d.p. of 1,000 and 75% amylopectin, with an avg. d.p. of 100,000, there would be 2.5×10^9 molecules of amylose and 7.4×10^7 molecules of amylopectin in a granule [1].
Two minor carbohydrate components have been found in starch granules. The first is a water-soluble amylose that is slightly branched ~0.5 to ~2.0% [2,3,4]. The second is a very highly branched componentfound in 12 varieties of starch granules that were isolated and examined for their structure and properties and most probably occur in all starches. They ranged in amounts from 0.51% (w/w) in amylomaize-7 starch to 8.4% (w/w) in rice starch. They had relatively high molecular weights, 2.47 kDa for amylomaize-7 starch to 5.75 kDa for waxy maize starch, and a high degree of α-(1→6) branching, ranging from 15.6% for rice starch to 41.4% for shoti starch [5].
In addition to these major carbohydrate components, starch granules also contain minor non-carbohydrate components: lipids from 0.01 to 0.80% (w/w); proteins, from 0.10 to 0.40% (w/w); and phosphate 0.09 to 0.63% (w/w). See *Table 2* for the compositions of ten types

of starch granules. The lipids are primarily found in the cereal starches: maize, waxy maize, amylomaize-5, amylomaize-7, rice, wheat, barley, rye, and so forth; and the phosphate in these starches are part of the phospholipids. The phosphate in the tuber starches, canna, potato, shoti and others, is attached to the primary alcohol of the glucose residues in amylopectin. At least some of the protein, if not all of it, is the enzymes, starch synthases and starch branching enzymes that were responsible for the biosynthesis of the starch in the granule (see *Sect. 8*). In addition to the composition mentioned above, starch granules at equilibrium with their environment (20 °C) and humidity (40–50%) will absorb water and contain 10–15% (w/w) water of hydration. When starch granules are suspended in water, they swell to a limited extent and adsorb water to ~30% (w/w).

4 Occurrence of Starch as Water-Insoluble Granules

All starches are stored in plants as water-insoluble particles or granules in the chloroplasts in leaves and in amyloplasts in other plant tissues. The granules are relatively dense particles of compact molecules, with semi-crystalline properties. They were first observed in the early eighteenth century by van Leeuwenhoek, using his newly invented microscope. In the middle of the nineteenth century, Nägeli [6] described differences in the size and shapes of starch granules from various plant sources. In 1913, Reichert [7] published a book containing hundreds of photomicrographs of starch granules from widely different plant sources. In 1994, Jane et al. [8] published a comparative anthology of scanning electron micrographs of starch granules from 54 plant sources, showing widely different sizes of large (100 μm) to very small (0.2 μm) granules and different morphologies, such as smooth, oval, and spherical shapes, round pancake shapes with varying thicknesses, flat thin plates or lenticular-shaped disks, and irregularly shaped polygons whose edges have varying degrees of sharpness. Canna bulb starch granules are very large (60 × 100 μm) and potato starch granules are also large (20 × 75 μm). Many of the starches from the cereal grains, such as maize, waxy maize, oats, and sorghum are smaller (15–25 μm), with the exception of rice starch granules, which are quite small (3–5 μm). The cereal starches have irregular polygonal shapes, with a number of faces that have relatively sharp edges. Starches from beans and peas have smooth oval granules, with 10–45 μm diameters. They often are accompanied by an indentation in the center or at the end of the granule. There are some starches that are extremely small, such as the granules from Chinese taro (1–4 μm), amaranth (0.5–2 μm), and parsnip (1–3 μm); they generally have polygonal shapes, with sharp edges, similar to the cereal starches, but much smaller. Most leaf starches are very small, biconvex granules of ~1 μm in diameter. *Figure 2* illustrates these differences by pictures of scanning electron micrographs of nine starch granules with varying sizes and morphologies.

4.1 Structure of the Starch Granules

Starch granules also have varying degrees of crystallinity, as shown by X-ray powder pattern diffractions. Three distinct X-ray patterns have been observed, A-, B-, and *C*-patterns [9,10]. The A-patterns are characteristic of cereal grain starches, such as maize, waxy

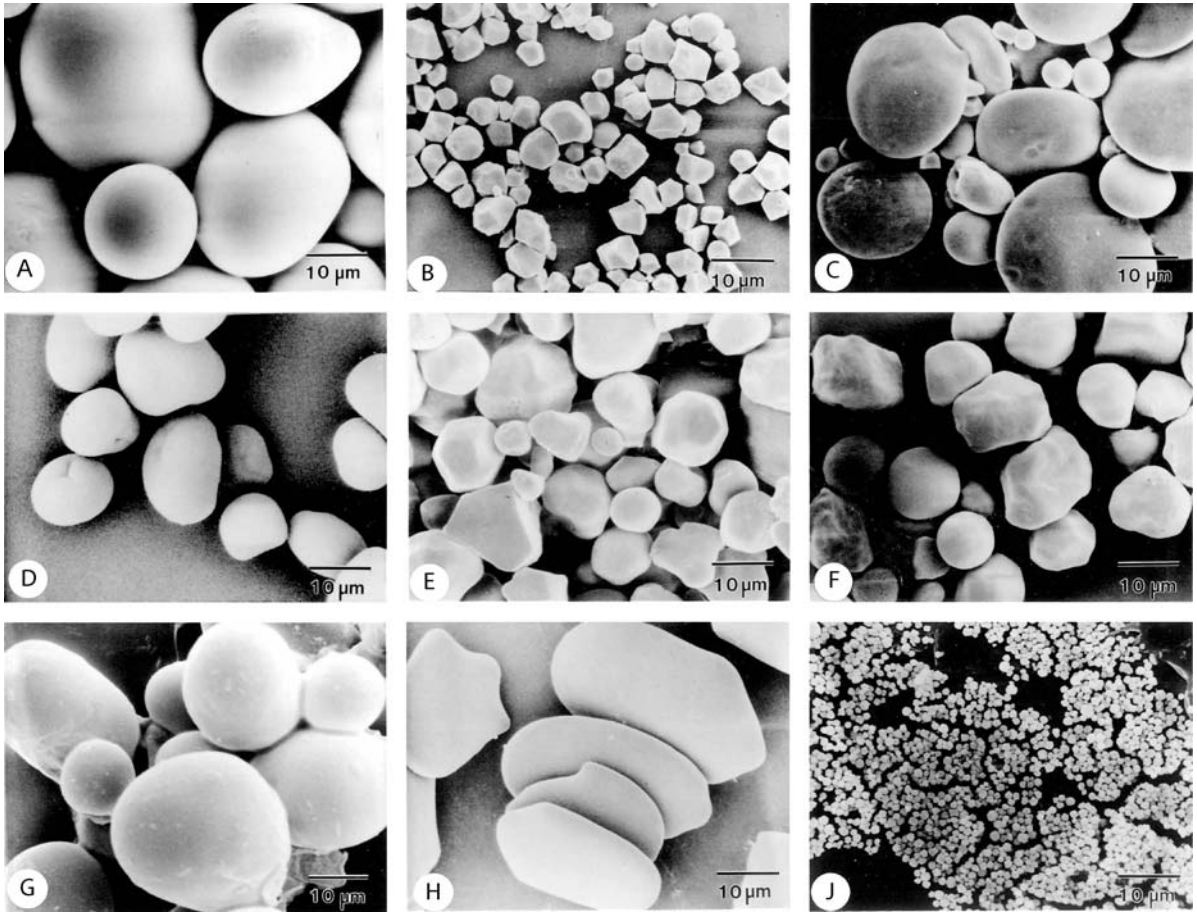

Figure 2
Scanning electron micrographs of starch granules from nine different botanical sources: A, potato; B, rice; C, wheat; D, mung bean; E, maize; F, waxy maize; G, tapioca; H, shoti; J, leaf starch. Magnification 1500X for each starch

maize, wheat, and rice. The B-patterns are characteristic of tuber, fruit, and stem starches, such as canna, potato, sago, banana starches and the mutant maize starches, amylomaize-5 and amylomaize-7 [9,10]. *C*-type patterns found in roots, beans, and peas are intermediate between A- and B-types [10,11]. Tapioca starch gives a typical *C*-type X-ray pattern. It has now been shown that *C*-type starch granules have a central core with a B-type structure, surrounded by an A-type structure [12].

When B- and *C*-type native starches are heat-moisture treated, 30 °C for B-type and ~50 °C for *C*-type, they are converted into A-type X-ray patterns [13,14,15,16]. Conversion of A-type starches into other crystalline forms only occurs when the original structure is completely destroyed and it is then allowed to recrystallize [17].

The interpretation of the X-ray diffraction patterns of starch granules and the significance of the A- and B-types of granules are problematic. There are differences in the ultrastructures of starch granules from different plant sources [18]. This was reinforced by a study of the kinetics and products of the reaction of glucoamylase with seven native starch granules in which three distinct categories were obtained: waxy maize starch was the most susceptible; barley, maize, and tapioca starches were intermediate; and amylomaize-7, shoti, and potato starches were quite resistant [19].

A general model for the crystalline parts of the starch granule has developed as a spherocrystalline assembly of disk-shaped amylopectin molecules [20] that are radially directed with the non-reducing-ends of the chains directed toward the surface of the granule [21,22]. The amylose chains in the cereal starches exist as lipid complexes that are left-handed extended helices, arranged tangentially in the granule. For non-complexed amylose chains in the cereal starches and in other starches, the amylose chains exist as both single and double helices [23,24]. In the granule, the chains of the amylopectin molecules can be considered as two-dimensional molecules that stack on top of each other, along with amylose chains, to make a three-dimensional micelle, giving radially oriented crystallites 9 nm in size. These units of both crystalline and amorphous phases form a network, extending throughout the granule in repeating units that are a common structural feature for all starches [25]. The amylose and amylopectin molecules form hydrogen bonds and hydrophobic bonds, both intermolecularly and intramolecularly, to varying degrees that hold the molecules together, giving a water-insoluble granule. The arrangement and quantity of these bonds in the granules gives rise to the differences in granule properties (degrees of crystallinity, types of X-ray diffraction patterns, gelatinization temperature, and susceptibility to enzyme hydrolysis [19,26,27]) found in starches from different plant sources. The α-(1→6) branch linkages in amylopectin are believed to occur in the amorphous regions of the granule. The branch linkages of amylopectin are clustered, with several chains of 15–20 glucose residues from the cluster, intertwined into double helices, contributing to the crystallinity [17,21].

4.2 Growth Rings in Starch Granules

Growth rings are readily seen in the large tuber starch granules, such as potato or canna starches, by optical microscopy. Growth rings are particularly apparent by scanning electron microscopy of granules that have been treated with acid or α-amylases [9]. ❯ *Figure 3* is a scanning electron micrograph of a potato starch granule that has been treated with *Bacillus*

Figure 3
Scanning electron micrograph of potato starch granule treated with *Bacillus amyloliquefaciens* α-amylase, showing growth rings of the crystalline α-amylase resistant starch in the granule

amyloliquefaciens α-amylase. During treatment with α-amylase, the amorphous layers in the granule are hydrolyzed and the crystalline layers remain intact. These so-called growth rings most likely originate during different phases of the biosynthesis of starch granules in which the deposition of crystalline layers of starch alternates with an amorphous layer of starch. These layers most probably are produced by fluctuations in the rate and/or mode of starch deposition during biosynthesis. Potato and canna starch granules show the growth rings the best when they are fully hydrated. When the starch granules are dried, the growth rings disappear [28].

4.3 Gelatinization of Starch Granules and the Solubilization of the Starch

The first step in the utilization of starch often involves the disruption of the granule, although by no means is this always the case (see *Sect. 9* on the chemical modification of starch granules). Disruption of starch granules can be accomplished by heating a suspension of starch granules in water, either by boiling the water (100 °C) or by autoclaving the suspension under pressure at 121 °C.

Starch granules swell when heated in water and have a "gelatinization temperature" that is characteristic of their source. When this temperature is reached, the swollen granules loose their birefringence, as evidenced by the loss of the "polarization cross" that can be observed with a polarizing microscope. The granules, however, still have a certain amount of structural integrity, but as the temperature is increased further, they continue to swell and eventually burst, releasing the amylose and amylopectin molecules, along with the minor components,

Table 3
Water solubility of seven native starches by autoclaving 220 mg in 10 mL at 121 °C for 20 min

Starches	Solubility (mg/mL)
Waxy maize	18.7
Tapioca	17.4
Potato	12.4
Maize	12.4
Rice	7.9
Amylomaize-7	5.5
Wheat	5.2

From Ref. [32]

into the aqueous solution. The heating process promotes increased motion of the molecules in the granule, eventually breaking the hydrogen and hydrophobic bonds between the molecules in the crystalline regions of the granule, which become hydrated and are released into the water. Cold, chemical methods of solubilization of starch can also be used, such as alkali (1 M NaOH) and dimethyl sulfoxide (DMSO) that gelatinize starch granules at low temperatures (20 °C). Gelatinization and the consequent solubilization of starch granules in DMSO occurs by a very different path from gelatinization in boiling water or autoclaving. Starch granules do not swell in DMSO as they do in boiling water [29,30], instead the granules slowly dissolve in anhydrous DMSO by fragmentation of the interior of the granules into smaller and smaller pieces. The addition of water to DMSO, however, greatly increases the rate of gelatinization and alters the pathway, which is different from gelatinization in anhydrous DMSO. Potato and canna starches retain their shape and birefringence during dissolution in aqueous DMSO and fragmentation does not occur. Instead the starch is peeled from the surface of the granules, with large pieces of starch gel adhering to the smooth surfaces of the ungelatinized portions of the granule [31]. When water is added, the DMSO breaks hydrogen bonds of the starch molecules at the surface of the granule and the water hydrates and gelatinizes the starch molecules at the surface, peeling the starch from the granules in layers [32].

Another method of chemically gelatinizing starch granules is by the use of relatively high concentrations of salt solutions to produce swelling and dissolution [33]; 4-M $CaCl_2$ has been used to gelatinize potato starch granules [34] and 13-M LiCl to gelatinize the starch from the surface of maize starch granules [35]. A method has been developed in which the surfaces of eight starch granules were peeled under controlled conditions, using aqueous-DMSO to give slow, gradual peeling from the surface of the granules in 8–10 h by selecting the amount of water from 5 to 15% (v/v) and the temperature from 0–15 °C [36].

There is evidence from two sources that the gelatinization process does not completely disrupt the hydrogen and hydrophobic bonds between the starch molecules, even though they are dissolved in the water. The first is the significant and greatly different activities of a single kind of α-amylase hydrolyzing solubilized starch from different plant sources [26]. The second is the differences that are observed in the water-solubility of starches from different plant sources and from acid/alcohol modified starches [32]. The maximum water solubilities for seven common starches are given in *Table 3*.

5 Fractionation of Starch into Amylose and Amylopectin

Early methods in 1940 for fractionating starch involved the leaching of an amylose component from swollen starch granules with hot water [37,38,39,40]. Starch granules (1–2% w/v) were successively treated with 70 °C water and the linear amylose component was obtained. This extraction, however, was found to be incomplete [41] and only the low molecular weight amylose was extracted. A few years later, the amylose and amylopectin components were completely separated by first solubilizing the starch granules in boiling water and selectively precipitating the amylose from the solution by 1-butanol [41,42]. This 1-butanol complex was crystalline, giving a V-type X-ray pattern [43]. After the removal of the 1-butanol-amylose precipitate by centrifugation, the amylopectin component was precipitated from the supernatant with two volumes of anhydrous ethanol. The 1-butanol can be removed from the amylose and the two components can be dehydrated by being treated several times with anhydrous acetone and once with anhydrous ethanol, followed by drying under vacuum at 40 °C to give dry powders. It is emphasized that the lipids complexed in the granules of the cereal starches must first be removed by defatting with methanol, ethanol, or 2-methoxyethanol (methyl cellosolve) extraction before solubilizing the granule and removing the amylose by adding an organic complexing agent [44], otherwise the removal of the amylose in these starches is incomplete.

Another organic compound that forms a complex with amylose is thymol, which also has been used to separate amylose from amylopectin [45]. Thymol is added to a starch solution as a 10% (w/v) solution in ethanol. Besides 1-butanol and thymol, many other organic compounds have been found to form complexes with amylose and give precipitates [46]. A list of organic compounds that form complexes with amylose and a list of those that do not form a complex and precipitate amylose are given in *Table 4*.

6 Properties of Amylose and Amylopectin

It has been known for almost 200 years that starch gives a deep blue color when a solution of potassium iodide and iodine is added [47]. More than a century later it was suggested that the complex consisted of a helical polysaccharide, with triiodide in the center of the helix [48]. Using flow dichroism, it was demonstrated that the triiodide was stacked in a linear structure, as required for the helical model [49]. Another study of the optical properties of crystals of the amylose-triiodide complex showed it to be consistent with a helical structure [50] and X-ray diffraction showed the triiodide complex gave the dimensions of a unit-cell of a helix with six glucose residues per turn [51]. This confirmed a helical structure for the amylose complex with triiodide that predated the helical models proposed by Pauling for polypeptides [52] and the double helical model for DNA by Watson and Crick [53] by 10 years.

The amylose-organic compound complexes give a particular kind of X-ray pattern that is called a "V-pattern" [54,55,56]. Amylose complexed with 1-butanol or 1-hexanol forms helices with six glucose residues per turn of the helix; branched chains or halogenated alkanes, such as tert-butyl alcohol (2-methyl-2-propanol) and tetrachloroethane form helices with seven glucose residues per turn of the helix [46,57,58,59], and bulkier molecules, such as 1-naphthol and thymol form helices with eight glucose residues per turn of the helix [60]. The length of the

mesitylene	

From Ref. [46]

helical chain that is folded back and forth, however, remains at 10 nm for all of the complexing agents.

α-Amylases hydrolyze the amorphous, folding areas on the surfaces of the lamella of packed helices, with the formation of resistant amylodextrin helical complexes of different degrees of polymerization (d.p.) values that are dependent on the number of glucose residues per turn of the helix: 1-butanol complex (six glucose residues per turn) gave d.p. 75 ± 4, tert-butyl alcohol and 1,1,2,2-tetrachloroethane (seven glucose residues per turn) gave d.p. 90 ± 3, and 1-naphthol (eight glucose residues per turn) gave d.p. 123 ± 2 [61]. See *Fig. 4* for the formation of these amylodextrin complexes by α-amylase hydrolysis of the surface of the folded amylose-organic complex.

The reason that amylose forms a complex with the organic molecules is that it is a relatively long, linear molecule, whose structural features inside the helix are hydrophobic, allowing hydrophobic bonding with the organic molecules, whereas amylopectin chains are much short-

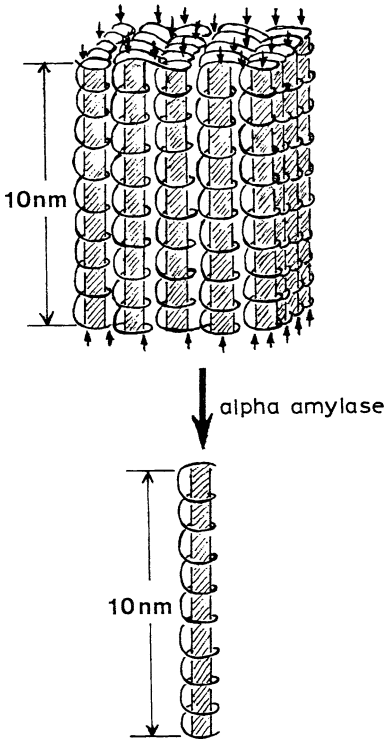

Figure 4
Alpha-amylase hydrolysis of the organic molecule (1-butanol, tetrachloroethane, or 1-naphthol) amylose complexes of the lamella-crystalline material in which the α-amylase hydrolysis takes place at the tops and bottoms (*arrows*) of the complexes, giving a resistant amylose-complex fragment of approximately the same size with avg. d.p. values of 108, 122, and 169, respectively, for the three organic complexes. From ref. [61], by permission of the authors and the publisher, Elsevier Press

er because of branching and do not form a sufficient length of helical complex with organic compounds that can give the lamella crystalline complexes, thus, allowing amylose to be separated from amylopectin.

It is the amylose component of starch that gives the blue color when KI/I_2 solution is added. To study the iodine-iodide color of amyloses of different d.p. values, maltodextrin-amylose molecules, with various avg. d.p. values from 6 to 568 were prepared by Bailey and Whelan [62], using phosphorylase, α-D-glucopyranosyl-1-phosphate, and maltohexaose. The colors of the various sized maltodextrins (1 mg) were observed when 10:1 (w/w) KI/I_2 solution was added. The first color to be observed was faint red for avg. d.p. 12; a red-purple color was observed for avg. d.p. 31; a purple color was observed for avg. d.p. 40; and a blue color was observed for avg. d.p. 45. The increase in the "blue value" was linear as a function of avg. d.p. up to $\sim$ avg. d.p. 60; the absorbance at 645 nm then slowly increased and reached a maximum at avg. d.p. of 400. The intensity of the iodine/iodide color in the low molecular weight range was dependent on the concentration of the iodine. When the concentration of the iodine was increased 10-fold, the intensity was increased 50% [62].

Amylose in a water solution is thought to behave as a random coil that has some helical character [63]. The random coiled amylose moves randomly in the aqueous solution with helices constantly being formed and deformed, giving a dynamic structure. An aqueous solution of amylose, 2 mg mL^{-1} or more is unstable and comes out of solution (retrogrades), as an insoluble precipitate, at a rate that is dependent on the concentration. At a concentration of 1 mg mL^{-1}, however, this same amylose does not retrograde and stays in solution indefinitely.

Acid hydrolysis of retrograded amylose (avg. d.p. 1,000) gives a resistant fragment with an avg. d.p. of 32 [61]. Hydrolysis of the retrograded amylose by human salivary α-amylase and porcine pancreatic α-amylase also gives a resistant fragment of avg. d.p. of 43, and hydrolysis by *Bacillus amyloliquefaciens* α-amylase gives a resistant fragment of avg. d.p. of 50 [61]. A structure for retrograded amylose was proposed in which crystalline double helical chains of 32 glucose residues of ~10 nm lengths are interspersed with amorphous regions to give resistant double helical structures. When the retrograded amylose is acid hydrolyzed for prolonged periods, most of the α-(1→4) glycosidic linkages in the amorphous regions are hydrolyzed, leaving the double helical, crystalline regions of 32 glucose residues. When the retrograded amylose, however, is hydrolyzed by α-amylases, they cannot hydrolyze the α-(1→4) glycosidic linkages close to the crystalline regions because of the numbers of their substrate-subsites, leaving stubs of glucose residues on the ends of the retrograded amylose chains, giving larger fragments than acid hydrolysis. Porcine pancreatic α-amylase has five subsites and human salivary α-amylase has six subsites, giving a chain with ~10–11 more glucose residues, 32 + 11, or 43 glucose residues, and *B. amyloliquefaciens* α-amylase has nine subsites, giving a chain with 18 more glucose residues than acid hydrolysis, nine glucose residues on each end, giving a total of 32 + 18 or 50 glucose residues [61].

Amylopectin acts very differently in aqueous solution. Even though it is 3- to 5-orders of magnitude larger than amylose, it is much more water soluble. This is primarily due to the presence of ~5% α-(1→6) branch linkages in the amylopectin molecule. The branch linkages of 50 for every 1,000 linkages give an average chain length of 20 glucose residues per chain. Because of the branching, the amylopectin chains are, thus, relatively short and, therefore, cannot line up in solution to give intermolecular double helices of sufficient length and they, hence, do not give a significant mixture of crystalline and amorphous regions in solution that retrograde. This then is the reason why amylopectin is much more soluble and stable in an aqueous solution than is amylose.

The amylopectin molecules are not compact or spherical as are glycogen molecules, which have 10–12% α-(1→6) branch linkages, randomly distributed. Amylopectin has relatively high viscosity, indicating an elongated structure. Electron microscopy, X-ray diffraction, chemical, and enzymological studies have shown that amylopectin has its branch linkages clustered at ~70 Å intervals [64]. Amylopectin molecules are ~100–150 Å in width and ~2,000–4,000 Å in length. Further, there is a regular alternation of elongated α-(1→4) linked chains and clustered α-(1→6) branch linkages that gives the 70 Å periodicity of the clustered branch linkages [64]. The amylopectin molecules can be considered to be two-dimensional, with the third dimension coming from stacking of the molecules through the formation of intermolecular hydrogen and hydrophobic bonds in the water-insoluble granule and also partially when in an aqueous solution [26,32]. See *Fig. 5* for a schematic drawing of amylopectin and its clustered branches and its branched chains.

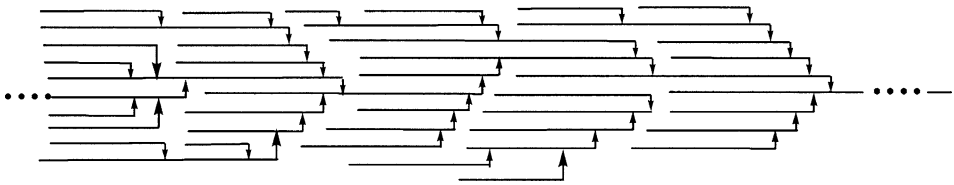

Figure 5
Schematic picture (looking from the top down) on a segment of amylopectin, showing the clustering of the α-(1→6) branch linkages in a repeating sequence

As was mentioned previously, the crystalline regions in the starch granules are primarily made up of amylopectin molecules, but with the amorphous regions being made up of the clustered branch linkages of amylopectin. The amylose molecule has one reducing-end and one non-reducing-end, and the amylopectin molecule also has one reducing-end, but many non-reducing-ends due to the branching.

Retrograded and dehydrated amylose is very water insoluble. It can, however, be put into an aqueous solution by first dissolving ~100 mg in 1 mL of DMSO by stirring and if necessary gently warming to 40–50 °C. After the amylose is completely dissolved in the DMSO, a thick clear gel-like solution is obtained. This gel can then be very slowly diluted with water, while stirring, to give the desired concentration of amylose in water. Amylopectin is readily dissolved in boiling water to give solutions of 2 to 5% (w/v).

7 Enzymatic Degradation of Starch

Several different kinds of enzymes degrade starch to give different kinds of products.

7.1 Endo-Acting Alpha-Amylase Hydrolysis of Solubilized Starch

The major category of enzymes that hydrolyze the α-(1→4) linkages of starch is the α-amylases. These enzymes are ubiquitous and are produced by bacteria, fungi, plants, and animals. In mammals, there are two specific sources, the salivary glands that secrete the enzyme into the mouth and the pancreas that secretes the enzyme into the small intestine. The α-amylases are endo-acting enzymes that attack the interior parts of the polymeric starch chains, producing a rapid drop in viscosity and a rapid change in the iodine-iodide color; because of these properties, they are sometimes called liquefying enzymes. When α-amylases encounter a starch chain and hydrolyze an α-(1→4) linkage, they also produce low molecular weight maltodextrins by a process called multiple attack on one of the two chains that were initially cleaved [65,66]. A common misconception about the action of α-amylases is that they act randomly, but this is not true. The major maltodextrin products that are formed are of specific sizes and depend on the particular biological source of the α-amylase and they, therefore, do not act randomly.

Human salivary and porcine pancreatic α-amylases primarily produce maltose, maltotriose, maltotetraose [67,68], and several kinds of α-(1→6) branched maltodextrins, ranging in size from four to seven glucose residues [69,70]. An even more common misconception about the

action of α-amylases is that glucose is the major product. Glucose, in fact, is only a very minor product, being produced by a slow secondary hydrolysis of the primary maltodextrin products. For example, salivary and pancreatic α-amylases slowly hydrolyzes maltotetraose to two molecules of maltose, the primary reaction; they also more slowly hydrolyze maltotetraose to give glucose and maltotriose and they hydrolyze maltotriose even more slowly to glucose and maltose; and they do not hydrolyze maltose at all [67,68].

A common bacterial α-amylase is excreted by *Bacillus subtilis* (whose name later was changed to *B. amyloliquefaciens*). It primarily produces maltotriose, maltohexaose, and maltoheptaose as the major products [71]. It also only produces glucose from a slow secondary hydrolysis of the primary maltodextrin products; it very slowly hydrolyzes maltohexaose to glucose and maltopentaose; it slowly hydrolyzes maltoheptaose to maltose and maltopentaose, and it slowly hydrolyzes maltoheptaose to maltohexaose and glucose; maltopentaose and smaller maltodextrins are not hydrolyzed [71]. Another α-amylase that is very similar to *B. amyloliquefaciens* α-amylase is the plant enzyme, barley malt α-amylase [72]. The bacterial α-amylase from *B. licheniformis*gives high yields (33%) of maltopentaose as a primary product [73]. It has a high temperature optimum of 70 °C and a broad pH optimum from 5 to 8, with significant activity in the alkaline pH range of 9–10 [74].

7.2 Exo-Acting Beta-Amylase and Glucoamylase Hydrolysis of Solubilized Starch

Starch exo-acting enzymes act exclusively at the non-reducing-ends of starch chains to form maltodextrin or glucose products. A primary exo-acting amylase is beta-amylase that is almost exclusively found in plants. The major β-amylases that have been studied are from sweet potato, barley, and soy beans [75]. β-Amylases catalyze the hydrolysis of the penultimate glycosidic bond at the non-reducing-ends of starch chains, forming β-maltose. Amylose is completely hydrolyzed; hydrolysis of amylopectin, however, only gives 55% β-maltose because the action of the enzyme is blocked by the α-(1→6) branch linkages that β-amylase cannot hydrolyze. This limitation leaves ~45% of a high molecular weight limit dextrin that contains all of the branch linkages of the original amylopectin molecules at the non-reducing-ends of the limit dextrins [76]. The first β-amylase from a source other than plants was reported from *B. polymyxa* [77]. It acted identically to the plant β-amylases. An α-amylase was reported from *Streptomyces* sp. that is an endo-acting enzyme, but produced 75–80% α-maltose [78].

Glucoamylase is another exo-acting enzyme that hydrolyzes the first glycosidic linkage at the non-reducing-ends of starch chains to give β-D-glucose. Many fungi, such as *Aspergillus niger*, *A. awamori*, *Rhizopus delemar*, and *R. niveus* elaborate glucoamylases [79,80,81,82,83]. In contrast to other types of amylases, glucoamylase can hydrolyze both α-(1→4) and α-(1→6) glycosidic linkages, although at different rates, with the α-(1→4) linkages being hydrolyzed ~600-times faster than the α-(1→6) linkages. But because of the hydrolysis of the α-(1→6) branch linkages, glucoamylases can completely hydrolyze all of the starch to β-D-glucose.

Another exo-acting starch-degrading enzyme is phosphorylase. It is produced by many plants and may be a primary enzyme involved in starch degradation in plants, although many plants

also have α- and β-amylases. Phosphorylase, however, is not a hydrolase and catalyzes the reaction between the α-(1→4) linkage of the terminal glucose residue at the non-reducing-ends of starch chains and inorganic phosphate to give α-D-glucose-1-phosphate [84]. Phosphorylase, like β-amylase, is unable to by-pass α-(1→6) branch linkages. It does not even remove all of the glucose residues close to the branch linkages and stops four glucose residues from the branch point on the two chains. Another enzyme, starch debranching enzyme, is required to hydrolyze the α-(1→6) branch linkages for further cleavage of the α-(1→4) linkages by phosphorylase.

Pseudomonas stutzeri produces an enzyme that forms maltotetraose from the non-reducing-ends of starch chains and, like β-amylase, cannot bypass the α-(1→6) branch linkages of amylopectin [85]. It gives 42% (w/w) α-maltotetraose and 58% limit dextrin. A similar exo-acting amylase is elaborated by *Aerobacter aerogenes* (*syn*: *Klebsiella pneumoniae* subsp. *aerogenes*; *Enterobacter aerogenes*) and exclusively forms maltohexaose from starch [86,87].

Another exo-acting starch enzyme forms cyclomaltodextrins. The enzyme is not a hydrolase, but a glucanyltransferase and is called cyclomaltodextrin glucanyltransferase (CGTase). The C4–OH group of the non-reducing glucose residue of starch chains is made to attack C1 of the sixth, seventh, and eighth α-(1→4) glycosidic bonds from the non-reducing-end to form cyclic, non-reducing α-(1→4) linked maltodextrins, containing six, seven, and eight glucose residues, respectively. Several different enzymes of this type are elaborated by different species of bacteria. The first CGTase to be isolated was from *Bacillus macerans*and it primarily forms cyclomaltohexaose, with smaller amounts of cyclomaltoheptaose and cyclomaltooctaose [88]. CGTases are also elaborated by *B. megaterium* [89] and *B. circulans* [90] that primarily form cyclomaltoheptaose, and a *Brevibacterium* sp. CGTase that primarily forms cyclomaltooctaose [91].

Isoamylases that exclusively hydrolyze the α-(1→6) branch linkages of starch were first recognized in plants and first isolated from broad beans [92]. A bacterial isoamylase was obtained from the culturing of *Pseudomonas amyloderamosa* [93,94,95,96] and has found wide use in studying the structure of amylopectin and related polysaccharides [97].

A new exo-acting enzyme, a starch lyase, has been discovered in red seaweeds and fungi. It removes glucose residues at the non-reducing-ends of starch chains and converts them into 1,5-anhydro-D–fructopyranose units. This product has been found to be an antioxidant and a new and versatile chiral building block for the formation of fine chemicals [98,99].

7.3 Reaction of Enzymes with Starch Granules

Starch granules generally have been thought to be resistant to hydrolysis by amylases [100], although as early as 1879 [101], they were reported to be digested by amylases. Ten percent hydrolysis by α-amylases of starch granules were reported [102]. In a study of the hydrolysis of starch granules by α-amylases from four sources (malt, fungi, bacteria, and pancreas), it was found that there were differences, with pancreatic α-amylase being the most effective, followed by malt, bacterial, and fungal α-amylases [103]. The activity of *B. subtilis* var. *amyloliquefaciens* varied according to the type of starch [104], with waxy maize being the most susceptible and high amylose starch (amylomaize-7 starch) the least susceptible.

The hydrolysis of starch granules by *R. niveus* glucoamylase also varied with the type of starch [105]. Reactions of glucoamylase on wheat and corn (maize) starch granules were followed visually by scanning electron microscopy and chemically by the determination of the amount of glucose released [106]. The scanning electron microscopy showed that wheat starch granules were attacked along the equatorial groove of the pancake-shaped granules and that extensive reaction with maize starch granules produced a Swiss-cheese appearance with many deep holes into the granules [106].

A systematic study of the kinetics of glucoamylase was made using seven kinds of starch granules, and it was found that they divided into three groups: waxy maize starch, which was the most susceptible, being converted with 200 units into 98% glucose in 32 h; barley, maize, and tapioca starches were intermediate, being converted into 82, 77, and 75% glucose, respectively, in 32 h of reaction; and the third group of amylomaize-7, shoti, and potato starches, which were the least susceptible, being converted into 21, 15, and 13%, respectively, in 32 h [107].

Scanning electron microscopy showed that when the starch granules in the first two categories were converted into ~50% glucose, there were numerous deep holes formed into the granules (see *Fig. 6*). Higher degrees of conversion showed that the remaining granules were hollow shells, with the interior parts hydrolyzed. It was concluded that glucoamylase enters the gran-

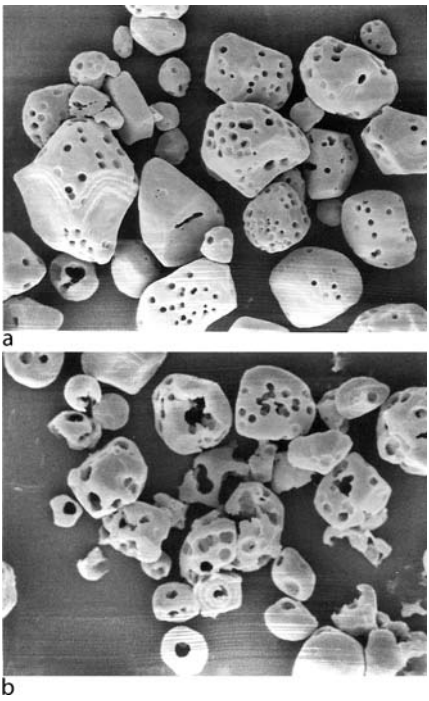

Figure 6
Scanning electron micrographs of maize starch granules that have been reacted with *Aspergillus niger* glucoamylase. A, 50 mg mL^{-1} starch granules, 20 IU mL^{-1} glucoamylase at 37 °C for 32 h; B, 50 mg mL^{-1} starch granules, 100 IU mL^{-1} glucoamylase at 37 °C for 32 h

ule and catalyzed reactions inside the granule [106,107]. The granules of the least susceptible starches in the third group did not show much change in the granule morphology, except for some minor pitting of the surface.

When the starches in the third group from potato, shoti, and amylomaize-7 were heated in water to their onset gelatinization temperatures of 60, 70, and 90 °C, respectively, for 0.5, 1, 2, and 4 h, the granules increased in size ~2–3 fold and birefringence was lost. Glucoamylase hydrolysis of potato and amylomaize-7 gelatinized starches was significantly increased after heating, from 13 to 86.6% for potato starch and from 21 to 45% for amylomaize-7 starch. The glucoamylase hydrolysis of shoti starch, however, only increased slightly from 14.7 to 21.1%, after being heated for 4 h. The results after 4 h of heating of shoti starch granules were only slightly higher than the results after 0.5 h [108].

Two of the three starches that were quite resistant to glucoamylase hydrolysis, amylomaize-7 and shoti starches, gave the highest percent reaction with the α-(1→6) debranching enzyme, *Ps. amyloderamosa* isoamylase of 11.9 and 11.5%, respectively [109]. Waxy maize, maize, and barley starches were intermediate in their susceptibility to isoamylase hydrolysis, giving 7.8, 7.3, and 6.2%, respectively.

Heating at the gelatinization temperatures of the starch granules for 1 h significantly increased the reaction with isoamylase: potato starch increased from 3.7 to 56%; amylomaize-7 starch increased from 11.9 to 36%; waxy maize starch was increased from 7.8 to 36%; and shoti starch was increased from 11.6 to 22%.

When gelatinized waxy maize starch was hydrolyzed 36% with isoamylase, only 16% of the hydrolyzed chains remained inside the granule. When 40% (v/v) ethanol was added to the waxy maize reaction digest, however, 44% of the isoamylase hydrolyzed chains remained inside the granule, and when 80% (v/v) ethanol was added, 100% of the hydrolyzed chains remained inside the granule [109]. With an 80% ethanol concentration, 100% of the isoamylase hydrolyzed chains also remained inside the granules for potato and shoti starches, and 98% of the isoamylase hydrolyzed chains remained inside the granules for amylomaize-7 starch for a total percent isoamylase hydrolysis of 41, 10, and 13%, respectively [109].

An in situ method has also been developed to retain 100% of the glucose inside the granule by reacting it with glucoamylase in a minimal amount of water, 50 mg of starch in 1.0 mL of buffer, containing glucoamylase [110]. This was called the "solid-granule" reaction system. The buffer, with glucoamylase, completely enters the granules and reaction takes place inside the granules. Although eventually the concentration of glucose produced in the granules is relatively high, only a very low amount (< 0.01%) of reversion products (maltose, isomaltose, nigerose) were formed. Using a sealed vessel, it was possible to convert waxy maize starch granules into 51% glucose, all inside the granules. The amount of starch conversion was proportional to the number of non-reducing ends. It was possible to control the percent conversion by heating the reaction vessel at different times for 20 min at 110–120 °C to inactivate the glucoamylase and thereby control the amount of glucose produced to give 10, 20, 30, 40, and 50% hydrolysis. The granules with 20% or more glucose have a sweet taste [110].

A similar reaction was conducted with cyclomaltodextrin glucanyltransferase (CGTase) reacting with waxy maize starch granules in a minimal aqueous environment. The yield was disappointing, giving only 1.3% (w/w) cyclomaltodextrins inside the granules. This could be increased to 3.4%, with 100% retention of cyclomaltodextrin inside the granule by adding a combination of CGTase and isoamylase to the solid-granule reaction system [111].

In general, the rates of reaction of enzymes with native starch granules is 3- to 4-orders of magnitude slower than they are with solubilized starch. The reaction of starch granules with enzymes is one method of modifying and altering the structure of starch granules. See *Sect. 9* for chemical methods of modifying starch granules. It also is important to recognize that a single enzyme, reacting with starch granules from different plant sources or with solubilized starches from different plant sources will have significantly different activities on the different starches [26]. Furthermore, this activity can be greatly increased and the enzyme stabilized, by the addition of 0.04% (w/v) polyethylene glycol [26], as a specific-sized polyethylene glycol will give the maximum enzyme activity for a specific enzyme, however, the activities will still remain significantly different on the different starches [112].

8 Biosynthesis of Starch

Starch is biosynthesized in plant organelles. In leaf or transitory starch, the organelles are chloroplasts and in storage starch in seeds, tubers, stems, and roots, the organelles are amyloplasts. The process of starch biosynthesis is divided, for convenience of discussion, into three steps: (1) initiation, (2) elongation, and (3) termination, and for amylopectin, a fourth step, branching.

Starch chains were the first polysaccharides to have a mechanism proposed for their biosynthesis. This was in 1940 and was based on the studies of Hanes on the action of potato phosphorylase [113]. Hanes proposed that potato phosphorylase transferred glucose from α-D-glucopyranosyl-1-phosphate (α-Glc-1-P) to the non-reducing ends of the starch chains and maltodextrins to give elongation of the starch chains. For starch biosynthesis by phosphorylase, it was recognized that the synthesis required a primer molecule that was either amylose, amylopectin, or a maltodextrin with a minimum of three glucose residues [114,115]. Phosphorylase is an enzyme that catalyzes a reaction that is reversible. The reaction can be either degradative or synthetic, depending on the starting substrates. It is degradative, if it is inorganic phosphate (P_i) or synthetic if it is α-Glc-1-P, as shown in the following reaction:

$$\underset{\text{starchchain}}{P_i + G-G-G-G-G-\cdots} \xrightarrow[\text{synthetic}]{\text{degradative}} \underset{\alpha\text{-Glc-1-P}}{G-P} + \underset{\text{degraded starchchain (putative primer)}}{G-G-G-G-\cdots} \qquad (1)$$

The synthetic reaction of the putative primer chain, however, only will occur when the ratio of P_i to α-Glc-1-P is less than the equilibrium value, which is 10.8 at pH 5, 6.7 at pH 6, and 3.1 at pH 7.0 [116]. These ratios are not obtained in vivo, as the concentration of P_i is 20- to 40-fold higher than the concentration of α-Glc-1-P [117,118] so that the in vivo conditions greatly favor degradation by phosphorylase, rather than synthesis.

Because a degraded starch chain is the product of the degradation reaction, the synthetic phosphorylase catalyzed reaction would require a starch chain or a maltodextrin chain to be a substrate in the synthetic reaction, as shown above. This was the origin for the primer required reaction for starch biosynthesis from the non-reducing-end of the primer, and it has pretty much been retained for 60 years [119,120,121].

In 1960, some 20 years after the phosphorylase experiments, it was found that UDP-Glc and ADPGlc were the high-energy glucosyl donors for the biosynthesis of starch chains, rather than α-Glc-1-P, and that active starch synthesizing enzymes, starch synthase and starch branching enzyme were entrapped inside the starch granules [122,123]. When ADP-[^{14}C]Glc was incubated with starch granules, ^{14}C-labeled glucose was incorporated into the starch in the granules. When this labeled starch was reacted with the exo-acting beta-amylase, ^{14}C-labeled maltose was obtained and it was assumed that the glucose from ADPGlc was, therefore, being added to the non-reducing-ends of starch primers [122,123,124]. This experiment has been widely considered as proof that starch is biosynthesized by the addition of glucose from ADPGlc to the non-reducing-ends of starch primer chains. This conclusion, however, is not necessarily correct in that if starch chains were synthesized from the reducing-end de novo, independent of a primer, the synthesized starch chains would have every glucose residue labeled when the starch granules were reacted with ADP-[^{14}C]Glc and reaction of this chain with beta-amylase would also give ^{14}C-labeled maltose.

Because of these problems and the lack of definitive experiments supporting the mechanism of starch chain elongation, Mukerjea and Robyt carried out a number of experiments to test the non-reducing-end, primer mechanism [125,126]. The first series of experiments was the pulsing of starch granules from eight different plant sources with ADP-[^{14}C]Glc and the chasing of the pulsed starch granules with non-labeled ADPGlc [125]. The pulsed starch granules gave starch chains that on reduction with $NaBH_4$ gave ^{14}C-labeled D-glucitol. The chased starch gave a significant decrease of ^{14}C-labeled D-glucitol. These experiments indicated that the starch chains were being elongated by the addition of glucose to the reducing-end and not to the non-reducing end, because if the glucose was being added to the non-reducing-end of a primer, it would be impossible to obtain any ^{14}C-labeled D-glucitol and further it would also be impossible to chase the label from the D-glucitol. In addition, it was found that both labeled-amylose and labeled-amylopectin components were synthesized and that a significant amount of starch was synthesized: maize starch had an avg. labeled d.p. of 827, waxy maize 436, taro 462, rice 467, wheat 476, and potato 524. There was also evidence that covalent intermediates were formed with the starch synthase during synthesis [125].

A two-site insertion mechanism for starch biosynthesis from the reducing-end was proposed, as shown in *Fig. 7*. The initiation step occurs with the glycosylation of the two sites, with the two nucleophilic X-groups attacking C1 of the glucose residues of ADPGlc. Polymerization proceeds by the C4–OH group of one of the covalently linked glucose residues attacking the C1 group of the other, displacing the X-group, which attacks C1 of another ADPGlc. The C4-OH of this glucose residue then attacks the C1 of the maltosyl unit, which is transferred to the glucose residue, freeing the other X-group, which makes an attack onto the glucose residue of another ADPGlc. This process continues, going back and forth between the two X-groups, giving the polymerization of the starch chain by addition of glucose from ADPGlc to the reducing-end of the growing chain. The starch chain is extruded from the active site of starch synthase. The elongation of the chain is eventually terminated by hydrolysis of the chain from the active site.

In the second set of experiments by Mukerjea and Robyt, the effect of adding the putative primers to the reaction of ADP-[^{14}C]Glc was studied with three kinds of starch granules from maize, wheat, and rice [126]. The reactions were examined in the absence and presence of increasing concentrations of maltose (G2), maltotriose (G3), and maltodextrin (d.p. 12). All

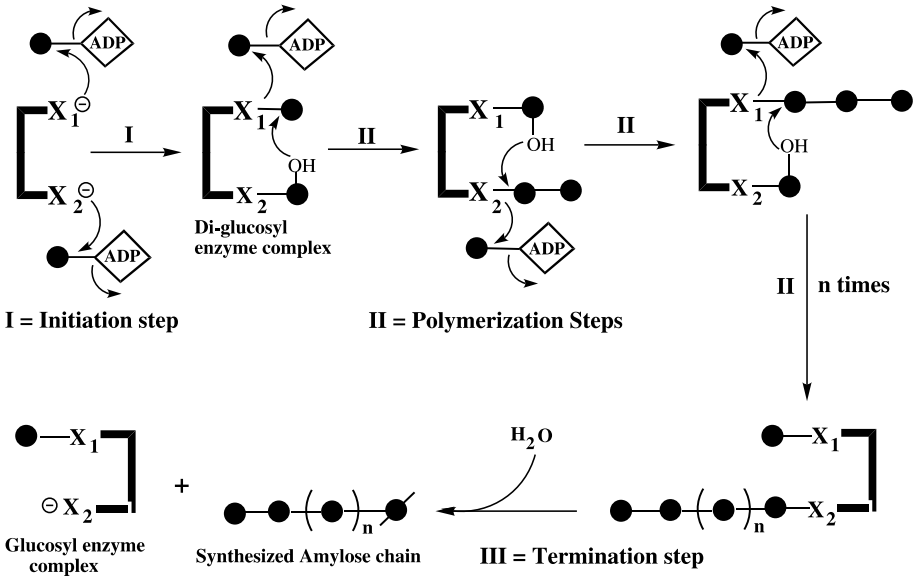

Figure 7

Proposed mechanism for the elongation of starch chains by starch synthase, showing the initiation step (I) and the polymerization steps (II) in which D-glucopyranose residues (*circles*) are added to the active site groups (X^-) from ADPGlc and inserted between X and the reducing-end of a growing glucan chain by a transglycosylation reaction to give a polymer of α-(1→4) linked D-glucopyranose residues. The polymerization is terminated (III) when water enters the active-site and hydrolyzes the X-acetal linkage of a reducing-end glucose residue attached to the starch chain. The mechanism gives a primer free elongation of the starch chain from the reducing-end. The *dark circles* are glucose residues and the *dark circle with a line through it* is a free hemi-acetal, reducing-end glucose residue

of the added putative primers were found to inhibit starch synthesis in increasing amounts, as the concentrations of the maltodextrins were increased, rather than stimulating synthesis, as would be expected for primers [126].

The putative primers did undergo a reaction. The major product in the presence of G2 was G3, with exponentially decreasing amounts of G4–G12; in the presence of G3, the major product was G4, with exponentially decreasing amounts of G5–G12. Further, the addition of glucose was to the non-reducing end of the putative primers. It was concluded that the putative primers were undergoing an alternate reaction in which they were acceptors that released glucose from the active site of starch synthase, with the glucose being added to C4–OH of their non-reducing-ends. This was confirmed by adding the acceptors to pulsed starch granules and observing the release of ^{14}C-label from the granules in the absence of ADPGlc [126]. This study showed that primers are not involved in starch biosynthesis and in fact their presence inhibited starch biosynthesis.

Leloir and co-workers [122,123,124] and Frydman and Cardini [127] also found that the incubation of starch granules with maltodextrins and UDPGlc or ADPGlc exclusively transferred glucose to the non-reducing-ends of maltose, maltotriose, and maltotetraose primarily to give

the next higher homologues, but they concluded that this was due to the primer non-reducing-end mechanism and did not recognize that starch synthesis was inhibited. This transfer of glucose to the non-reducing-end of carbohydrates is a well-known reaction in the synthesis of dextran by dextransucrase when low molecular carbohydrates are added to the reaction digest, glucose is transferred to C6–OH of the non-reducing-ends of the carbohydrates [128,129]. The carbohydrates are acceptors that inhibit dextran synthesis [129] just as the putative primers in starch biosynthesis accepted glucose and inhibited starch biosynthesis [126].

The third set of experiments by Mukerjea and Robyt involved two reactions with three varieties of starch granules from maize, wheat, and rice. In reaction I, the granules were reacted with 1-mM ADP-[^{14}C]Glc and in reaction II, a portion of the granules from reaction I was reacted with 1-mM nonlabeled ADPGlc [130]. The starch granules from the two reactions were solubilized and reacted with the exo-acting enzymes, glucoamylase and beta-amylase to an extent of 50% or less of the ^{14}C-label. The amounts of ^{14}C-labeled products from the two enzymes, respectively, were nearly equal for reaction I and reaction II. If the addition of glucose had been to the non-reducing-ends of primers, reaction II would not have given any labeled products. These results confirm that the elongation of the starch chain is the addition of glucose to the reducing-end by a de novo reaction and not by the addition of glucose to the non-reducing-end of a primer [130].

It must be emphasized that the mechanism of starch biosynthesis does not require a preformed starch chain primer or a maltodextrin chain primer and the starch chains begin de novo by forming covalent di-glucosyl intermediates from ADPGlc with starch synthase that proceed to synthesize amylose chains by adding glucose to the reducing-end of a growing chain, essentially by a transferase reaction of the enzyme covalently linked starch chain to the enzyme covalently linked glucose (see ❯ *Fig. 7*).

To produce amylopectin, it is necessary to have a starch branching enzyme that is capable of introducing the α-(1→6) branch linkages into the linear amylose molecules synthesized by starch synthase. Such an enzyme (Q-enzyme) was first identified in potatoes [131] and then in broad beans [132]. The potato Q-enzyme has been isolated and purified and the properties determined [133]. Q-enzyme is a glucanyltransferase and cleaves an α-(1→4) linkage of an amylose chain, and then transfers the chain to the C6–OH of another amylose-chain, rather than being transferred and attached to the residual part of the cleaved chain [134]. It was shown that water is not involved in these branching reactions [133].

There remain a number of important questions as to how branching enzymes convert the synthesized amylose chains into amylopectin and how the branch linkages appear in clusters in amylopectin, with a repeat distance of 70 Å. Another question is how starch granules are initiated and formed and how the percentages of amylose and amylopectin molecules are in a constant ratio that is specific for the particular plant source of the starch (see ❯ *Table 2*).

A logical assumption that can be surmised is that the enzymes that are found entrapped in the starch granules have most likely been responsible for the synthesis of the starch molecules in the granules. It has been hypothesized that starch synthase might exist both as a single enzyme and as a multi-enzyme complex of several starch synthases and branching enzymes. In the former case, amylose would be produced, and in the latter case, the multi-enzyme complex could produce amylopectin [135,136].

9 Chemical Modification of Starch

The chemical and physical properties of starch can be significantly altered by chemical modifications.

9.1 Acid Modifications of Starch Granules

One of the first reported modifications of starch granules was the treatment with aqueous acid in which there was hydrolysis of some or all of the glycosidic linkages. Obviously the molecular size of the polysaccharide molecules is decreased by acid hydrolysis. In 1874, Nägeli reported the treatment of native starch granules with 15% (w/v) sulfuric acid for one month at ~20 °C. An acid-resistant material resulted that was insoluble, but when isolated it could be solubilized in hot water [137]. This resistant material was called Nägeli Amylodextrin. It has an avg. d.p. of 24–30 and was fractionated by gel permeation chromatography to give three fractions [138]. Fraction I had the highest molecular weight and consisted of a mixture of branched maltodextrins with two or more branches per molecule. Fraction II, with a d.p. of ~ 25, primarily had a single branch linkage, with the branch located close to the reducing end [138]. Fraction III was linear with an avg. d.p. of 13 [138]. With continued acid hydrolysis, Fraction I disappears and Fractions II and III are better resolved on Sephadex G-50.

A soluble starch of much higher molecular weight than the Nägeli Amylodextrin was prepared by treating a suspension of starch granules with 7.5% (w/v) HCl for 1 week at 22–24 °C, or 3 days at 40 °C, followed by washing the granules free of acid [139]. The method is called the Lintner Procedure and is usually performed on potato starch granules. The Lintner Procedure is the method still used today to produce commercial soluble starch. The product is not completely water soluble and is polydisperse, with a relatively high reducing-value. The amylose component of Lintner soluble starch has an avg. d.p. of 340 and the amylopectin component has an avg. d.p. of 603, with a wide distribution of d.p. values [140].

Another method was reported in 1919 for obtaining soluble starch by refluxing the starch granules in 95% ethanol, containing 0.2–1.6% (w/v) HCl for 6–15 min [141]. The product is called Small's soluble starch. It is soluble (10 mg ml^{-1}) in hot water and has a low reducing value due to the formation of ethyl-glycosides at the hydrolytic points.

In 1987, Ma and Robyt reported the modification of starch granules by treating them with 0.36% (w/v) HCl in anhydrous methanol, ethanol, 2-propanol, and 1-butanol at 65 °C for 1 h. The starch granule was maintained, but the molecular sizes of the starch molecules progressively decreased in the different alcohols, as the number of carbons in the alcohols increased [140]. The molecular size distribution was greatly narrowed for these acid-hydrolyzed starches and the amylose component completely disappeared in the starch granules modified in 2-propanol and 1-butanol. The starch granules modified in 1-butanol also became quite soft. It was also found that acid hydrolysis was occurring inside the granules where there was 10–15% (w/w) water and the amount of acid also increased inside the granules as the size of the alcohols increased [140].

Fox and Robyt reported the kinetics of the acid-alcohol modifications by determining the avg. d.p. vs. time of reaction of the starch granules with 0.36 and 6.0% (w/v) HCl at 25 °C [142]. The kinetics showed that the avg. d.p. values dropped rapidly in the first 10 h and then leveled

off, becoming constant at ~30 h, d.p. values decreasing as the size of the alcohols increased and as the concentration of the acid increased. The avg. d.p. values varied from a high of 1717 to a low of 19, depending on the kind of alcohol and the acid concentration. The products represented new kinds of acid-hydrolyzed limit dextrins, with a relatively narrow distribution and widely different avg. d.p. values, and different proportions of amylose and amylopectin.

The acid hydrolysis of starch granules in the four alcohols was also studied as a variation of temperature from 5 to 65 °C, acid concentration from 0.36 to 5.0% (w/v), and in the concentration of the starch granules [143]. The avg. d.p. values of the limit dextrins were dependent on all three parameters: first, the acid concentration and the temperature, of which combinations can be obtained to give limit dextrins with avg. d.p. values ranging from 1800 to 12 for the starch granules. In addition, the concentration of the starch granules was inversely proportional to the avg. d.p. values. This latter result confirmed that the mechanism of the hydrolysis of the glycosidic bond was taking place by the water inside the granules, because as the concentration of the starch granules increased, the concentration of the acid decreased inside the granules, due to the fact that there were more granules.

The acid hydrolysis of potato starch granules was studied using mixtures of two alcohols, methanol and 2-propanol from 90:10 to 10:90 in 10% (v/v) intervals [144]. The avg. d.p. of the different modified starches leveled off in 48–72 h of reaction at 20 °C. The results gave a family of 11 curves, starting with 100% methanol and ending with 100% 2-propanol, all with different limiting avg. d.p. values. As the concentration of 2-propanol was increased and methanol decreased, the plots of avg. d.p. of the limit dextrins vs. the ratios of the two alcohols resembled titration curves, with different plateaus, in which the d.p. of the limit dextrin changed very slowly, or not at all. These plots were characteristic and dependent on the types of alcohols, the volume ratios of the two alcohols in the mixture, and the kind of starch [144]. It was proposed that the different ratios of the two alcohols produced the exposure of different glycosidic linkages to acid hydrolysis by converting different crystalline regions in the granule into amorphous regions that became susceptible to acid hydrolysis.

Another type of acid-modified starch is "thin-boiling" starches. Thin-boiling starches are produced by mild hydrolysis with 0.1–0.2% (w/v) HCl at 45–50 °C [145]. The treatment weakens the forces, holding the starch molecules together in the granule to give a starch that is more easily solubilized and has decreased viscosity. In the production of thin-boiling starches, the viscosity is monitored and the process is stopped when a particular desired viscosity is attained. The thin-boiling starches are widely used in the food industries to improve the appearance (clarity), stability, and texture of the food products in soups, sauces, dressings, bakery products, dairy products, and confectioneries.

9.2 Chemical Modification of the Starch Molecules in the Granules

The majority of the D-glucopyranose residues in starch granules have three hydroxyl groups, one each at C-2, C-3, and C-6, which can be modified. The amount of modification is called the "degree of substitution" (d.s.). If all three of the hydroxyl groups on all of the glucose residues are modified, the d.s. = 3; if two are modified, the d.s. = 2; and if only one is modified, the d.s. = 1; if one hydroxyl group out of every ten glucose residues is modified, the d.s. = 0.1, and so forth.

Three general kinds of modifications can be obtained: oxidation, esterification, and etherification to enhance hydrophilic character, to introduce hydrophobic character, to introduce positive or negative charges, to cross-link the starch chains, and to introduce color to the starch. The purposes for the modifications is varied, for example, to lower the gelatinization temperature, to decrease or prevent retrogradation, that is to decrease or prevent precipitation from solution, to enhance gelatinization, to increase the hydration of the starch molecules, to impart increased thickening and gelling properties, to increase binding of other molecules to starch, and to impart film-forming properties.

The function of modified starch is dependent on a number of things: the kind of starch (plant source), the amylose to amylopectin ratio, the nature of the substituents that are added, the degree of substitution, whether it is premodified by acid hydrolysis, and whether the starch is granular or gelatinized.

9.2.1 Oxidation of Starch

Alkaline hypochlorite is the most common method of oxidizing starch granules. The reaction is the oxidation of the secondary alcohols to ketones and the primary alcohol to a carboxyl group [146,147,148]. Alkaline hypochlorite oxidation is sometimes used to produce thin-boiling starches instead of acid hydrolysis.

Primary alcohol groups can be exclusively oxidized to aldehyde groups with pyridinium dichromate [149,150] and to carboxyl groups with the 2,2,6,6-tetramethyl-1-piperidine oxoammonium ion (TEMPO) [151]. The aldehydes can then be reduced to primary alcohols by reaction with NaB^3H_4 [150,152], giving radiolabeled ^{3}H-starch and the carboxyl group can be inverted by the action of *Azotobacter vinlandii* poly-β-D-mannuronic acid C-5-epimerase to give L-iduronic acid [153].

Vicinal alcohol groups, the 2,3-glycol structure of starch, can be oxidized by periodic acid or periodate to cleave the carbon–carbon bond and oxidize the two carbons to produce two aldehyde groups at C-2 and C-3 [154,155]. The product is called "dialdehyde starch." There are, however, very few actual aldehyde groups present. The main products are hydrated aldehyde groups and intra- and inter-molecular hemiacetals [154,156,157]. The amount of oxidation can be controlled by the amount of periodate used. The resulting "aldehydes" can react with alcohols, amines, hydrazines, and hydrazides to give additional modification products. Chlorous acid will oxidize the "aldehyde groups" to polycarboxylic acid polymers [154].

9.2.2 Formation of Ester Derivatives

Common starch esters include the acetates. High d.s. starch acetates have been formed by using acetic anhydride with either sodium acetate or pyridine catalysts at 90–100 °C [158,159,160]. The major use of starch acetates have been in the study of the structures of amylose and amylopectin after acid hydrolysis. Acetylation of granular starch in aqueous suspension by acetic anhydride at pH 10–11 is used to produce low d.s. starch acetates that are primarily used for the stabilization of their viscosity and for their water-soluble clarity. The acetylation decreases the hydrophilic character and increases the hydrophobic character of starch. The major uses of starch acetates is in the paper industry for surface sizing to give improved print quality, uniform porosity, surface strength, and resistance to various solvents [161].

The solubility of starch acetates depends on the d.s. and the d.p. Starch acetates of 10–15% are soluble in water at 50–100 °C and are insoluble in organic solvents. Starch acetates of 40% or more are soluble in aromatic hydrocarbons and halogenated aliphatic hydrocarbons.

Starch esters formed by reaction of acid chlorides give a wider range in the kinds of esters that can be synthesized. In particular, reaction of oxalyl dichloride gives an ester with a free carboxylate group; reaction with succinyl dichloride also gives an ester with a free carboxylate group, but in addition can give intra- and inter-molecular cross-linking of the starch chains; adipyl dichloride gives the same kind of reactions, but with greater potential for intermolecular cross-linking due to its larger size.

Starch granules have been cross-linked with phosphate by the reaction of an aqueous alkaline (pH 8–12) suspension reaction with phosphorus oxychloride [161]. Trimetaphosphate has also been used to produce phosphate cross-linkages. These reactions are primarily with the C-6–OH groups and only a minimal number with the C-3–OH groups [162]. Starch phospho esters can be obtained by phosphorylation with sodium triphosphate at pH of 8.5 [163].

The esterification of starch with p-toleunesulfonyl (tosyl) chloride in pyridine gives partial 6-*O*-tosyl starch [164,165]. This ester can be replaced by a number of nucleophilic groups, such as iodide to give 6-deoxy-6-iodo starch that in turn can be reduced with $NaBH_4$ to give partial 6-deoxy-starch or azide groups that on reduction give partial 6-amino-6-deoxy starch [166,167].

9.2.3 Formation of Ether Derivatives

Ethers are formed with the alcohol groups of starch when alkyl halides or epoxides are added to an alkaline suspension of starch granules. The starch ethers that are produced are frequently water-soluble. Methyl or ethyl ethers can be formed by the reaction of starch at pH 10 with methyl or ethyl chlorides at 70–120 °C to give d.s. values of 1.2–2.3 [168]. A common ether is the formation of 6-*O*-carboxymethyl starch by the reaction of 2-chloroacetic acid with alkaline starch [169]. Carboxymethyl starch is a water-soluble starch that is used as an emulsifier and thickening agent and provides stability against heat damage and amylase degradation.

Hydroxy ethers of starch are prepared by reaction of alkaline starch with epoxides, such as ethylene oxide and propylene oxide. The reaction is usually run on a 40–45% (w/v) suspension of starch granules in water under strong alkaline conditions (0.1–0.2-M NaOH) at 40–50 °C, under nitrogen. The hydroxy ethyl starches are primarily used as binders for pigmented coatings and as surface sizing agents in paper manufacturing. Hydroxypropyl starches are of importance in food applications, where they are used as an edible, water-soluble film coating [161]. The formation of hydroxyalkyl derivatives increases their water solubility and decreases or prevents retrogradation of the starch chains. Ethylene oxide and propylene oxide do undergo “chaining reactions” in which they keep adding to the newly generated hydroxyl groups to give a chain of hydroxy alkyl ethers. This chaining reaction can be reduced or eliminated by conducting the reaction in the presence of methyl or ethyl chloride, which cap the newly formed hydroxyl groups, preventing further additions.

Starches can be chemically dyed by reacting a procion dye with 2,4,6-trichloro-triazine or 2,4-dichloro-triazine, followed by reaction with alkaline starch [170,171]. A chloro group on the triazine ring of the dye derivative is replaced by a starch hydroxyl group to form a stable

ether linkage between the dye and the starch. Various colors of chlorotriazine dyes are available: Cibacron Blue, Procion Brilliant Blue, Procion Brilliant Red, Procion Brown, Procion Green, and Procion Yellow.

10 Analytical Methods in Starch Chemistry

10.1 Iodine/Iodide Colors

The formation of a blue-purple color by the interaction of starch and its components with iodine/iodide is a very characteristic and unique property of starch. The blue color that is observed is due to the amylose component and has a maximum absorbance at 645 nm. The other major component, amylopectin, gives a red-purple or maroon color, with a maximum absorbance at 490 nm. The ability of starch and its major components to give this iodine/iodide color provides a method for specifically detecting very low amounts of starch from as little as 1 μg mL^{-1}. This property of starch is unique in that no other polysaccharide reacts with iodine/iodide to give a color and it hence provides a specific qualitative method for detecting starch and its components. It also provides a very sensitive method for detecting the cleavage of the α-(1→4) glycosidic linkages produced by enzymatic and chemical degradations, as the color rapidly changes as the molecular size of the starch decreases [62].

The method: the iodine reagent to obtain the blue color of starch contains 0.2% (w/v) iodine in a 2.0% (w/v) potassium iodide solution [172]. Usually a solution with 10-times this concentration is prepared and then diluted 1→10 immediately before use. The analysis is carried out by the addition of 25 μL of the diluted iodine/iodide reagent to 50 μL of each sample in a microtiter plate well and the absorbance is measured at 600–620 nm, using a microtiter plate colorimeter. The starch triiodide blue color is most stable under acidic conditions (pH 1–2) and will not form under alkaline conditions (pH 8 and higher).

It should be emphasized that the reaction to give the "blue color" is the reaction of starch with triiodide and higher complexes and not with iodine. The quantitative use of the starch-triiodide color is problematic. As indicated, its most useful application is the qualitative identification of starch. An example is the identification of starch fractions from gel-permeation chromatography [140,142] and the detection of the cleavage of the α-(1→4) glycosidic linkages of starch by enzymatic or chemical degradation reactions, which gives a decrease and eventually a change in the color [65].

10.2 The Reducing Value

The reducing value, as the name implies, is the quantitative or qualitative measurement of the specific aldehyde or hemiacetal ends of the amylose and amylopectin molecules or the ends of their degradation products. There are several methods that might be used, such as the alkaline Somoygi–Nelson method [173] or the ferricyanide/ferrocyanide/cyanide method [174]. However, for amylose and amylopectin, there is only one reducing-end group per molecule, most of the reducing-value methods are not sensitive enough to determine the reducing-end of the starch macromolecules. In the last 15 years, however, a very sensitive, micro-method has been developed that can quantitatively measure the reducing-ends of the

starch macromolecules when the starch is in concentrations of 1–9 mg mL^{-1} [175]. The method can also be used to measure the reducing value of smaller oligosaccharides, as well. It involves the copper-bicinchoninate reagent as the oxidizing reagent that oxidizes the aldehyde and itself becomes reduced to give a purple color whose absorbance can be measured at 560 nm [175].

Two reagents are involved: Solution A consists of 97.1 mg of disodium 2,2′-bicinchoninate dissolved in 45 mL of water containing 3.2 g of sodium carbonate monohydrate and 1.2 g of sodium bicarbonate, with the final volume made to 50 mL with water. Solution B consists of 62 mg of copper sulfate pentahydrate and 63 mg of L-serine dissolved in 45 mL of water, with a final volume of 50 mL. The working reagent is prepared daily by mixing equal volumes of Solution A and B. Reducing carbohydrate standards consist of 1–20 μg mL^{-1}.

The reducing value is determined by adding 100 μL of the reducing carbohydrate to 100 μL of the working reagent to the wells of a 96-sample microtiter plate. The plate is covered with Saran wrap or some other method to seal the plate and prevent evaporation of the sample and reagent when the plate is heated in a water bath at 80 °C for 35 min. The plate is then cooled for 15 min and the absorbance is measured at 560 nm. Triplicate analyses are usually performed for each sample and for the maltose standards, along with a water blank [175].

It is important to use maltose or an equivalent disaccharide, such as isomaltose, cellobiose, nigerose, and so forth as standards, as glucose gives over-oxidation for all of the reducing-value methods and cannot be used, unless glucose is the only carbohydrate reducing compound that is being measured. The substituted di- and higher-oligosaccharides do not give over-oxidation for most reducing value reagents, with the exception of the 3,5-dinitrosalicylic acid method [176].

10.3 Determination of the Total Amount of Glucose-Carbohydrate in a Sample

The total amount of starch in a solution of pure starch can be measured, using the phenol-sulfuric acid micro method [175]. The procedure consists of adding 25 μL of sample (containing 10–200 μg of gluco-carbohydrate mL^{-1}) and 25 μL of 5% (w/v) phenol to the wells of a microtiter plate. Appropriate standards of glucose or maltose (10–200 μg mL^{-1}) are used, along with a water blank. This should be done in triplicate. The plate is then placed into a bed of ice and 125 μL of concentrated sulfuric acid is added to each well, containing sample and phenol. The plate is again mixed at slow speed on a vortex mixer for 30 sec and then incubated in a water bath at 80 °C for 30 min and cooled, and the absorbance is measured at 492 nm.

10.4 Specific Determination of Starch When in the Presence of Other Carbohydrates, Using the Glucoamylase/Glucose Oxidase Method

The solution containing starch (~1 g or less) in 100 mL of pyridinium acetate (pH 5.2) is hydrolyzed by 20 IU of glucoamylase (where IU equals the amount of enzyme that will produce 1 μmole of glucose at pH 5.2 and 37 °C in 1 min). The reaction is allowed to proceed at 37 °C for ~5 h. These conditions should specifically hydrolyze 1 g of starch completely to

glucose. The glucose is then specifically and quantitatively determined by the micro glucose oxidase method [175].

For the glucose oxidase determination of glucose, there are two solutions: Solution A consists of 7.5 mg of glucose oxidase and 0.75 mg of peroxidase (Sigma Chemical Co., St. Louis, MO, USA) which is dissolved in 12.5 mL of tris-phosphate-glycerol buffer (18.1 g of tris and 28.3 g of sodium dihydrogen phosphate dihydrate dissolved in 100 mL of water plus 100 mL of glycerol, diluted to 250 mL with water). Solution B consists of 50 mg of o-dianisidine dissolved in 250 mL of the buffer described for Solution A above. The working reagent consists of equal volumes of Solutions A and B, prepared fresh daily. Solution A is stable for 1 week stored at 4 °C.

The analysis: 50 µL of sample containing 10–100 µg mL^{-1} is added to 200 µL of the working glucose oxidase reagent in a micro titer plate. Each sample is analyzed in triplicate and a blank is prepared with water. The plate is briefly mixed for 30 sec on a vortex plate mixer; 50 µL of concentrated HCl is added to each sample well and the absorbance is measured at 490–500 nm [175].

10.5 Determination of the Average Degree of Polymerization of Starch Fractions

The number of glucose residues in a starch component or fraction is termed the "degree of polymerization" or d.p. The determination of the avg. d.p. is based on the counting of the number of molecules in a given weight of starch. A method of counting the number of molecules in a given sample is the reducing value as described in *Sect. 10.2*, using copper bicinchonate that "counts" the aldehyde/hemiacetal groups. The weight of the starch fraction can be obtained by using either the phenol-sulfuric acid method (*Sect. 10.3*) or the glucoamylase/glucose oxidase method (*Sect. 10.4*). The avg. d.p. is calculated by the following formula:

$$\text{avg. d.p.} = \frac{\text{total weight of starch (µg ofglucose)}}{\text{reducing value of starch (as µg of maltose)}} \times 1.9 \qquad (2)$$

The factor 1.9 is the quotient of the (molecular weight of maltose) / (molecular weight of glucose) or 342 / 180.

10.6 Determination of the Degree of Branching of Starch Fractions

A branched starch fraction whose degree of branching or percent of branching is to be determined, first has the avg. d.p. determined (*Sect. 10.5*). Then a sample of the branched compound is dissolved in 20-mM acetate buffer (pH 4.8). Then 40 mIU of isoamylase per 50 µg (where 1 IU = 1 µmole of α-(1→6) branch linkage is hydrolyzed per min by the enzyme). The isoamylase must be free of α-amylase and glucosidase activities and can be obtained from Megazyme International [Wicklow, Ireland]. After reaction with isoamylase, the avg. d.p. is determined as per *Sect. 10.5* The percent branching is then computed from the following:

$$\%\ \text{branching} = \frac{\text{avg. d.p. after debranching withisoamylase}}{\text{avg. d.p. before debranching}} \times 100 \qquad (3)$$

The average chain length of the branched chains in the starch fraction can then be calculated by the following:

$$\text{avg. chain length} = \frac{1}{\%\ \text{branching}} \times 100 \tag{4}$$

If a sample has 5% branching, the avg. chain length would be $(1/5) \times 100 = 20$ glucose residues. The individual maltodextrin chains can be separated and further analyzed by fluorescence-assisted capillary electrophoresis (FACE), (see Sect. 15.3 in Chap. 1.2).

10.7 Measurement of Amylase Activity on Starch and Related Substrates

Amylases, both α- and β-, hydrolyze the α-(1→4) glycosidic linkages of starch to give reducing maltodextrin products that can be measured by using the micro copper-bicinchoninate reducing value method (*Sect. 10.2*). Starch (1.5 mL of 0.5% w/v) is prepared in 25 mM of a buffer with the optimum pH of the α- or β-amylase, containing 1.0 mM for α-amylases; this is incubated for 10 min at the optimum temperature of the enzyme. The reaction is started by the addition of 25–50 µL of the enzyme to the starch solution. Aliquots of 150 µL are taken every 5 min for 30 min and added to 300 µL of 50 mM NaOH, which gives a pH of 12.5 and stops the reaction. The reducing value is measured, using the copper-bicinchoninate method in which 100 µL of the stopped reaction is added to 100 µL of the working reagent in triplicate in a 96-well microtiter plate. Similar amounts (100 µL) of maltose standards from 2.0–20.0 µg are added to 100 µL of the working reagent in triplicate. The plate is covered with Saran wrap to prevent evaporation and the plate is heated at 80 °C for 35 min, cooled, and the absorbance measured at 560 nm. Dilutions of the enzyme in the reaction mixture and the stopping reagent are used to determine the amount of reducing maltose produced by the α-amylase and this is determined for each time point. The average of the triplicate measurements are obtained and a plot of µg of maltose produced versus the time of the reaction is prepared and the slope of the linear part of the line determined, which gives the µg of maltose produced per min. This is converted into µmoles of α-(1→4) bonds hydrolyzed per min by dividing by the molecular weight of maltose (342), which gives the number of International Units of α- or β-amylase [175].

10.8 Measurement of the Activity of Starch Synthase

Starch synthase catalyzes the synthesis of amylose. It can be measured in starch granules, where the enzyme is entrapped or it can be measured in a solution obtained in a plant extract.

10.8.1 Measurement of Starch Synthase Activity in Starch Granules

Starch granules (100 mg) are suspended in 1.0 mL of 0.1-mM EDTA and 4-mM glycine buffer (pH 8.4). The reaction is initiated by adding 20-mM (0.2 µCi) ADP-[^{14}C]Glc and allowed to react for 1 h. The reaction is terminated by centrifuging and washing the granules 5-times with 1 mL of water to obtain background radioactivity. This removes the unreacted ADP-[^{14}C]Glc from the granules and terminates the reaction. The granules are then treated 3-times with 1 mL of anhydrous acetone to remove water. Small amounts of residual acetone are removed

from the granules by pulling a vacuum for 1 min. The acetone-dried starch is weighed and the amount of ^{14}C-glucose incorporated into the starch is determined by heterogeneous liquid scintillation counting by putting the granules in 10 mL of toluene scintillation cocktail [5.0 g PPO and 0.1 g POPOP in 1.0 L of toluene] and counting in a liquid scintillation spectrometer. The sample is counted for 10 min or 10,000 cpm, whichever comes first. The activity of the enzyme is nmoles of glucose incorporated into starch per h per 100 mg of starch granules [125].

10.8.2 Measurement of Soluble Starch Synthase Activity in a Plant Extract

Plant extract (25 µL) is added to 75 µL of 0.1-mM EDTA and 4-mM glycine buffer (pH 8.4), containing 20-mM (0.05 µCi) ADP-[^{14}C]Glc. The digest is incubated at 37 °C for 30min. An aliquot (25 µL) is then added to (1.5 × 1.5 cm) Whatman 3-mm paper and placed into 150 mL of methanol and stirred for 10 min. The washing is repeated two more times and the paper is then dried under a heat lamp. A blank is prepared with the 20-mM (0.05 µCi) ADP-[^{14}C]Glc by adding 25 µL of water instead of plant extract and then putting 25 µL onto the Whatman 3-mm paper and washing the paper 3-times with 150 mL of methanol. The dried papers are added to 10 mL of toluene liquid scintillation cocktail and counted by heterogeneous liquid scintillation counting. The blank value is subtracted from the sample value to obtain the amount of ^{14}C-glucose incorporated into starch.

10.9 Measurement of the Activity of Starch Branching Enzyme

The formation of amylopectin occurs through the action of starch branching enzyme on maltodextrins and/or amylose to form the α-(1→6) branch linkage. Amylose or maltodextrins can be used as the substrates, but the amylose must be at a concentration of 1 mg/mL or less, as higher concentrations leads to the precipitation (retrogradation) of amylose from solution.
The assay described here uses amylose. Amylose (10 mg) is dissolved in 1.0-mL dimethylsulfoxide by stirring on a hot plate and gently warming to 40–50 °C. After the amylose has been solubilized, the dimethylsulfoxide-amylose solution is slowly diluted with 0.1-mM EDTA and 4-mM glycine buffer (pH 8.4) to 10.0 mL. The solution containing starch branching enzyme (100 µL) is added to 200 µL of the amylose solution and incubated at 37 °C for 30 min. The reaction digest is heated in a boiling water bath for 5 min, cooled, and 200 µL added to 200 µL isoamylase (250 mIU) and incubated 30 min at 37 °C. The isoamylase reaction digest (100 µL) is added in triplicate to 100 µL of the working reagent of the copper-bicinchoninate and the reducing value determined, using maltose as a standard (see *Sect. 10.2* for the reagent and the procedure). The activity of the starch branching enzyme is the number of α-(1→6) bonds formed, which in this assay would be the µmoles of maltose determined $\text{min}^{-1} \times 1.9$.

6.3 Cellulose and Associated Heteropolysaccharides

Wolfgang G. Glasser
Dept. Wood Science and Forest Products, Virginia Tech,
Blacksburg, VA 24061, USA
wglasser@vt.edu

Abstract

Polysaccharides constitute a class of polymers in which the elemental composition (i. e., O/C ratio) has been reduced from that of carbon dioxide to that of carbon monoxide plus hydrogen. The resulting structural diversity is employed by plants to support the life-sustaining functions of energy storage, structural support, and moisture management. Whereas cellulose is the plant's premiere structural support molecule, the associated heteropolysaccharides ("hemicelluloses") serve to provide for moisture sorption, fracture toughness, and storage energy. This variety of function is achieved by molecular manipulations resulting in strict regularity and uniformity on one hand, and careful tailoring of irregularity capable of preventing crystallization on the other. Synthetic structure manipulation strategies (i. e., derivatizations) employ

1 Introduction

Carbohydrates, substances having the general composition of C_x $(H_2O)_x$, are central to planet Earth's survival and sustainability. Carbohydrates result from the solar energy-driven reduction of carbon dioxide by photosynthesis. Photosynthesis generates both carbohydrate matter (solids) and oxygen (gas). The reduction of carbon dioxide to carbohydrates and oxygen (plus water) requires 112 kcal/mol of CO_2 [1].

Carbohydrates include a large variety of different molecules and materials, different in composition, size, and function. The chemistry of C_x $(H_2O)_x$-molecules (i. e., carbohydrates) is extremely complex in terms of its molecular and stereo-chemical diversity. This complexity has been the subject of numerous texts [2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25].

The process of photosynthesis is central to the planet's survival. Without photosynthesis and without solar energy-collecting plant life, planet Earth would soon turn into a planet with an environment not unlike that of Mars, a planet which is described as having had water on its surface in the past. Water and plant life are central to Earth's ecology; and carbohydrates are central to plants.

The life-sustaining function of carbohydrates necessitates that they meet three general requirements: (A) carbohydrates must serve as **stored energy**, materials that are capable of readily releasing energy by degradation; (B) carbohydrates must serve for **structural support**, materials that provide mechanical strength to individual cells as well as plant tissues; and (C) carbohydrates must provide plants with the ability to manage **moisture**, materials that control the water household over a wide range of physical properties and physiological needs, materials capable of immobilizing water and controlling water's rheological properties. The purposes of **energy storage**, **structural support**, and **gel formation** are all central to life as we recognize it; and they are all addressed by carbohydrates.

For carbohydrates to meet these requirements, diversity is needed on both the molecular and the size-level. Only large carbohydrate molecules, **polysaccharides**, can provide the wide spectrum of storage, structural, and gel-forming abilities required by nature. Meeting these requirements has made it necessary for plants to produce polysaccharides that can be classified as **linear**, **branched**, and **crosslinked** polymers, as well as **homo-** and **heteropolymers** in accordance with terminology in common use in the polymer community (◉ *Fig. 1*) [26]. Nature has found need to adopt all different kinds of macromolecular architectures in pursuit of the three different functions of carbohydrates.

Cellulose ranks first among the strength-building polysaccharides in abundance. It is most prevalent in wood fibers where it helps trees gain the strength necessary to lift crowns (i. e., solar energy-collecting devices) above ground level. However, cellulose is not exclusive to trees or even plants in general. A very pure form of cellulose is present in the seed hairs (*trichomes*) of the cotton and several other plants; in soft and hard bast fibers from the stems

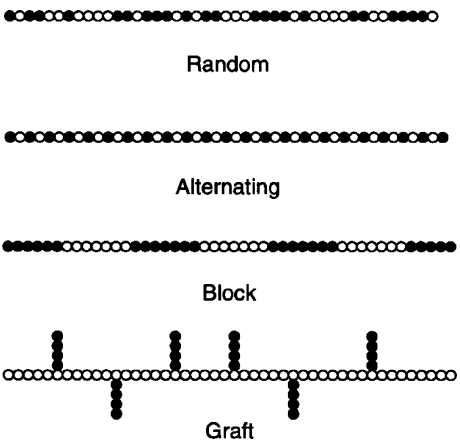

Figure 1
Common structures of heteropolymers with two types of repeat units

of such plants as hemp, ramie, flax, sisal, banana, pineapple, etc.; and cellulose is also produced by a variety of bacteria (esp. *Acetobacter xylinium*), algae (such as *Valonia ventricosa*), and even marine organisms (*Tunicatae*). The algal cellulose from *V. ventricosa* is of interest because of its large and highly oriented crystallites; and bacterial cellulose has become a commercial product for material, nutritional, and medicinal applications (such as *Cellulon* by Weyerhaeuser; *PrimaCel* by NutraSweet Kelco; and *Biofilm*, a skin-substitute) [12,13,27,28]. Whereas these different sources of cellulose differ in a wide range of characteristics and properties, they all consist of one form of a linear homopolysaccharide whose structural characteristics have been studied for the better part of almost two centuries. Most of this research has focused on wood-based cellulose generated by industrial delignification (pulping) processes. It is estimated that the total amount of cellulose grown and degraded annually on Earth is about $5–10 \times 10^{10}$ t [12]. Other estimates put the annual plant synthesis rate at $10^{11}–10^{12}$ t [18]. This compares to an annual pulp production (for paper and board) of about 200×10^{6} t worldwide [29].

2 Formation and Structure

2.1 Chemical Structure

Cellulose is a linear homopolymer of β-(1 → 4)-linked D-anhydroglucopyranose monomeric repeat units (AGU). Since every second glucose unit is sterically rotated by about 180 °C with respect to its neighbors, it can be considered a syndiotactic homopolymer of glucose or an isotactic homopolymer of cellobiose units (● *Fig. 2*) [18]. Arguments can be presented in favor of either viewpoint, cellulose as polymer of monomeric glucose or dimeric cellobiose units.

Each monomeric repeat unit possesses three hydroxyl (OH–) groups, in positions C-2, C-3, and C-6 of the pyranose unit. The homopolymer is asymmetric having two distinct end-units a **nonreducing** and a **reducing** end. The nonreducing end features an additional OH-group in position C-4, and the reducing end has carbonyl (reducing) functionality.

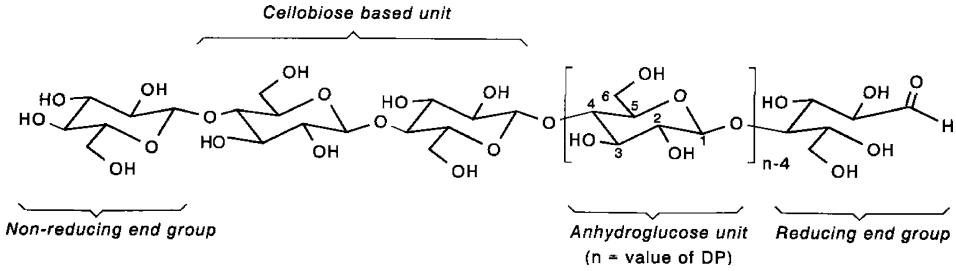

Figure 2
Chemical structure of cellulose indicating two different endgroups and repeat units in two optional interpretations, cellobiose, or anhydroglucopyranose. The rotation of every second anhydroglucose unit creates a syndiotactic linear poly[anhydroglucose]-molecule, called *cellulose* [18]

Table 1
Average degrees of polymerization (DP) of celluloses of different origin

Type of cellulose	DP	Molecular weight (g mol^{-1})
Cotton	7,000–14,000	1,125,000–2,250,000
Flax	8,000	1,300,000
Bacterial cellulose	2,700	500,000
Wood pulp	2,500–3,300	400,000–600,000
α-Cellulose	800–1100	130,000–180,000
Regenerated cellulose	250–500	40,000–80,000
Microcrystalline cellulose	100–200	15,000–30,000

Source: H. Krässig et al., 2004 [13].

The size of cellulose molecules is consistently expressed as **degree of polymerization** (DP), which expresses size in terms of the number of AGUs per individual chain. In natural state, cellulose is thought to be a homopolysaccharide with relative size-uniformity (**monodisperse**) consisting of somewhere around 14×10^3 glucose units (*Table 1*) [30,31,32]. This size, however, is limited to cellulose in intact plant tissues because its isolation always results in molecular degradation. Commercially available celluloses range in size from DP of 100 to 12,000 (for cotton) in relation to their method of isolation (*Table 1*) [13].
The asymmetric nature of cellulose molecules, with a distinctive carbonyl group at one end, is sometimes used for the determination of molecular mass by **end group determination**. More common methods of molecular weight determination, however, employ viscosimetry. Whereas the highly hydroxylated nature of cellulose serves as an almost ideal qualification for water solubility, its strict molecular regularity, linearity, and uniformity also qualify it for crystallinity. Water solubility is limited to DP < 6, and typical polymer properties arise already at DP 30 [14]. Sincecrystallization is spontaneous and exothermic, preventing it requires the introduction of irregularity, branching and/or diverse functionalization. This principal rule of polymer chemistry is adopted by nature when nonstructural, gel-forming polysaccharides are needed. The transition from structural to gel-forming and nutritional (storage energy) purposes is accomplished by nature strictly on the basis of variation in chemical structure [33].

2.2 Physical Structure

All molecules regardless of physical state (gas, liquid, or solid) wish to undergo Brownian motion. This desire results in such observations as gas pressure varying with temperature; solution behaviors (and viscosity) varying in relation to temperature and solvent parameters; and solids changing properties in relation to glass transition temperatures (T_g) and melting points (T_m). Resistance to motion originates from intra- and intermolecular interactions, and this relates to rotational freedom and unfreedom of polymer chains. A widely used illustration of the rotational freedom phenomenon is the *energy contour map* (*Fig. 3*) [3,16]. Energy contour maps are constructed on the basis of dynamic molecular modeling experiments. The models determine energy parameters involved in the rotation of two neighboring repeat units around the common interunit bond. When two adjacent anhydroglucose units are rotated with

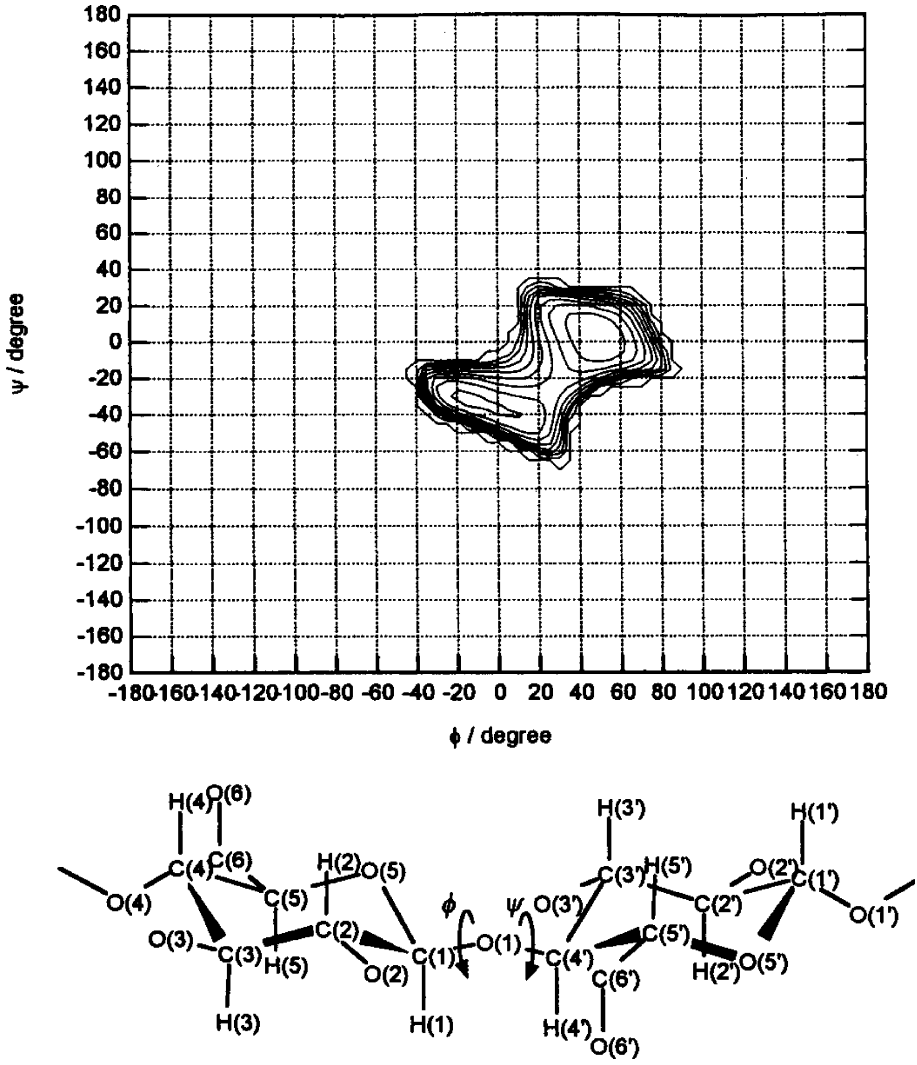

Figure 3

The *2-D energy contour map* illustrating the potential energy barriers to rotation around two dihedral angles, Φ and Ψ, of cellobiose. (Adopted from Kajiwara and Miyamoto [34])

respect to each other around the connecting glycosidic ether bond, certain conformations meet positions of higher and lower potential energy. The most stable conformations are characterized by a low energy state. When rotation is plotted as bond angles vs. stored energy, a three-dimensional energy profile is created that identifies positions of high and low energy states in a manner similar to a topographical map (*Fig. 3*).

With cellulose, the region of angular orientation that produces the lowest point on the energy contour map is narrow and well defined. Any distortion out of the most relaxed position involves significant energy input. Several positions of relaxed state are identified on the ener-

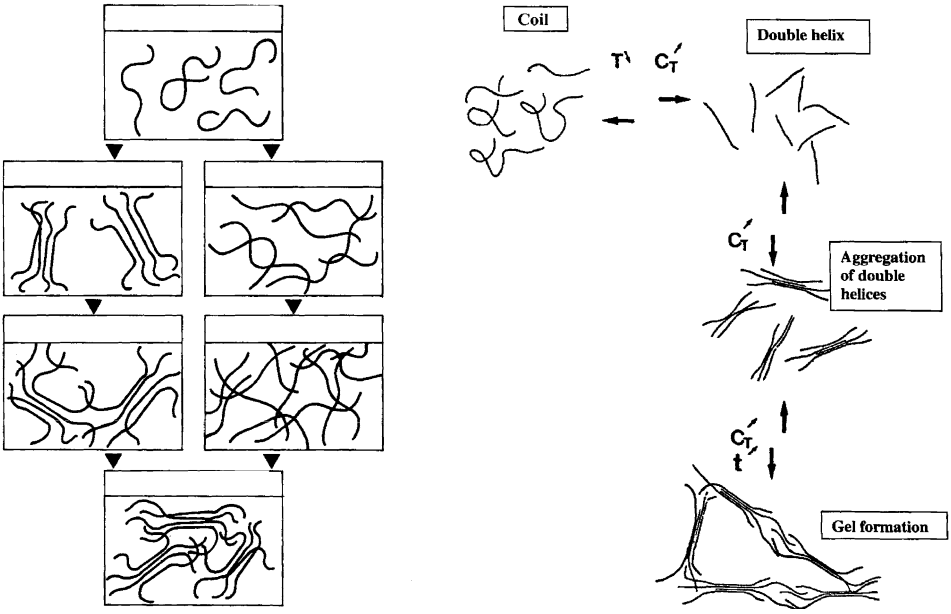

Figure 4
Organization of cellulose (left) and κ-carrageenan molecules (right) during desolvation. The figure illustrates the possible paths to the formation of solid structures: early formation of organized structures in solution (left side) leading to liquid crystalline structures of rigid-type molecules, and desolvation without organization (right) leading to a largely amorphous structure (left, according to Schurz, [35]). And gel formation by the aggregation of helices (right, according to Rinaudo, [33])

gy contour map for cellotriose (◉ *Fig. 3*). The consequence of this contour is the identification of several preferred conformations (in solution) and several lesser stable ones. The more pronounced an energy gradient is with regard to intermolecular rotation, the more rigid is a molecule in solution. The steeper the energy gradient, the stiffer is the molecule and the faster will it organize into a conformation of order when desolvated (◉ *Fig. 4*). This perspective suggests that order can be gained already in solution, and this phenomenon is known as *liquid crystallinity*. Cellulose exhibits distinct signs of liquid crystallinity [12].

In the case of cellulose, intramolecular order produces a helix with a two fold screw axis [4]. The particular helical arrangement of single cellulose molecules represents an extremely extended conformation, i. e., a helix with high pitch (◉ *Fig. 5*), that serves cellulose well for building stiffness and tensile strength in solid state. Hydrogen bonds play a pivotal role in achieving this helical organization.

In solid state, cellulose exists in mostly crystalline state. This state has been the subject of extensive studies for at least 100 years, and several important aspects need to be pointed out at the onset. Crystallinity is neither *uniform* (options exist) nor *static* (crystallinity can be lost as well as gained in relation to molecular mobility), nor is it *permanent* (conditions have been identified under which transitions of order take place). Cellulose crystallinity manifests itself through the existence of distinctive X-ray diffraction patterns. These patterns allow the determination of the overall dimensions of *unit cells* which are spatial units that represent the

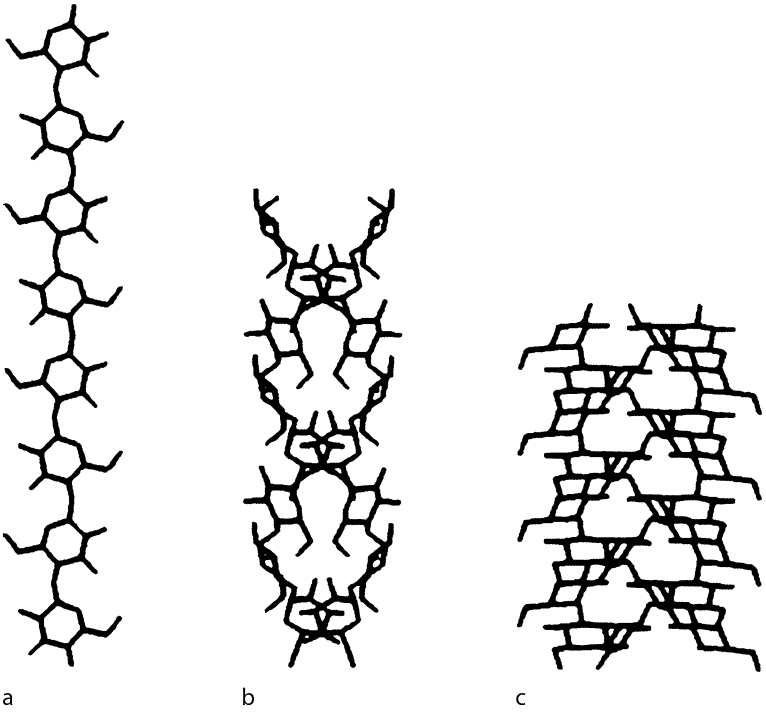

Figure 5
Three potential helical structures of polysaccharides. (a) Single helix with twofold screw axis (cellulose); (b) double helix (amylose); and (c) triple helix (β, 1–3 glucan) (according to Rees [4]). The particular structure depends largely on the constraints imposed by hydrogen-bonds and rotational freedoms around the glycosidic intermonomer bonds (i. e., *Fig. 3*, energy barriers to rotation)

smallest part of the crystal that can reproduce the entire crystal by translations of its contents along its edges [36]. Unit cell dimensions reflect the molecular arrangement of cellulose chains in the crystal. Cellulose crystallinity has most often been illustrated by use of the Meyer Misch monoclinic unit cell (*Fig. 6*), which has variably been revised since its first publication in 1938 [37]. The monoclinic unit cell is based on the understanding that hydrogen (H)-bonds exist intramolecularly between the H-atom of the OH group in position C-3 (i. e., O(3)H) and the oxygen-atom of the C-5 position (O5) of the adjacent unit in the same cellulose chain. Additional H-bonds exist between the O(6) of one glucose residue and the O(2)H of the adjacent unit. Since this H-bonding pattern results in every glucose unit of a cellulose chain being rotated by 180 °C with respect to its neighbor, a stable 2-fold screw axis is formed. The formation of intermolecular H-bonds between adjacent cellulose chains (in the O–B plane of *Fig. 7*) involves the position O(3) on one, and O(6)H on the adjacent unit. This arrangement results in the formation of a flat sheet. In crystallites, sheets are staggered on top of each other whereby cellulose chains are shifted from their respective neighbors. There appear to be no H-bonds between layers of sheets, but sheets are bonded to each other via Van der Waals bonds (hydrophobic interactions) [40].

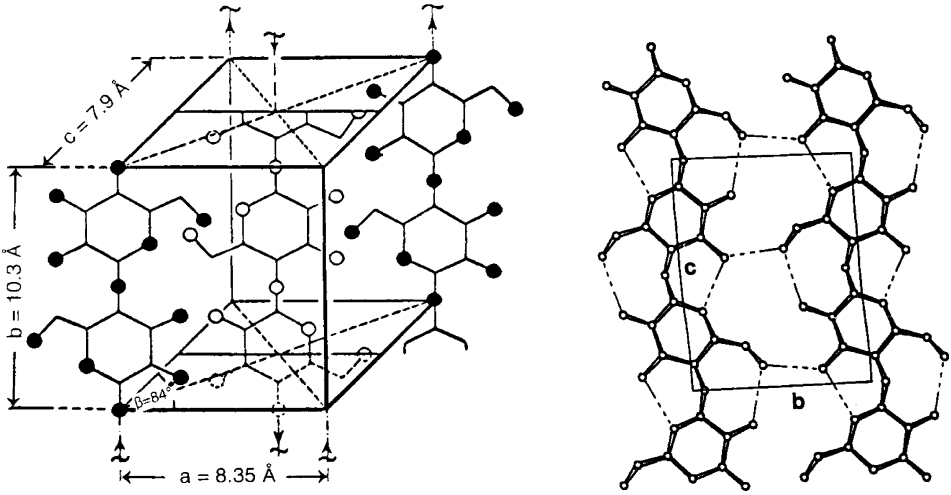

Figure 6
Monoclinic unit cell of *cellulose I* according to the model by Meyer and Misch [37], which shows the antiparallel orientation of adjacent chains (left); and the hydrogen-bonding network of two adjacent cellulose chains forming a sheet-like structure according to Gardner and Blackwell [38]

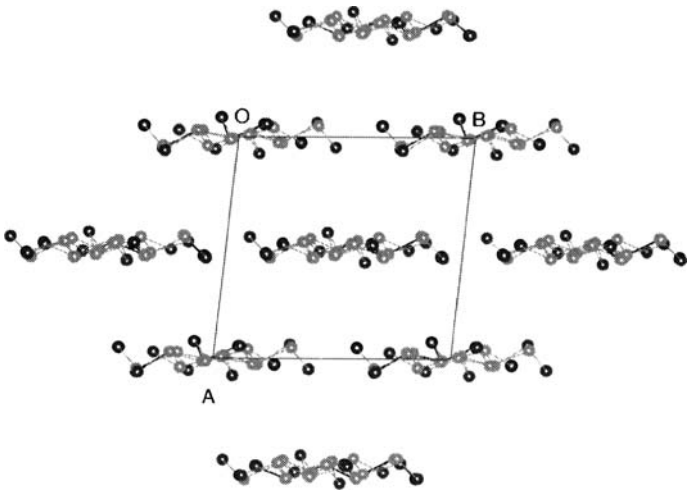

Figure 7
Segment of a crystal structure of cellulose I_β illustrating the relationship between unit cell and crystal structure. Hydrogen bonds (not shown) are in the direction of O to B creating sheets of aligned chains. (Adopted from Horii and Wada [39])

Cellulose crystallinity is not uniform. A simple experiment of immersing cellulose in cold concentrated alkali, a process used for enhancing the dye-absorbing quality of cotton fabrics called *mercerization*, was found already in the 1930s on the basis of X-ray diffraction to produce a cellulosic *allomorph* with different unit cell dimensions [13,14]. This was given the

Table 2
Unit cell dimensions for different cellulose polymorphs (in nm)

	a	b	c	β (degree)
Cellulose I	0.821	1.030	0.790	83.3
Cellulose II	0.802	1.036	0.903	62.8
Cellulose III	0.774	1.030	0.990	58.0
Cellulose IV	0.812	1.030	0.799	90.0

For unit cell definitions, see *Fig. 6*.

designation *cellulose II* in contrast to the native cellulose state, which was designated *cellulose I*. While cellulose II has the same types of hydrogen bonds, it is apparent that it is composed of antiparallel chains whereas cellulose I possesses parallel chains. Since new hydrogen bonds between the corner and center chains are formed during the transformation from I to II, cellulose II is the more stable crystalline configuration compared to cellulose I. Virtually all regenerated cellulose (regenerated from solution) exists in cellulose II-form [15].

In addition to the recognition of two significantly different cellulose allomorphs, cellulose I and II, several other crystalline arrangements have been identified (*Table 2* [15]). These evolve from treatment with strongly hydrogen-bonding, swelling agents, such as liquid ammonia (*cellulose III*) and treatment with glycerol at high temperatures (260 °C), which produces *cellulose IV*.

Whereas cellulose I had always been considered to consist of a uniform monoclinic crystal structure, evidence surfaced in the 1950s that cast doubt on this hypothesis. On the basis of mostly ^{13}C-NMR evidence, it was established in the 1980's that cellulose I exists in two separate and distinct subclasses, designated *cellulose* I_α and I_β. The more stable I_β-form (by 8.7 kJ mol^{-1} for cellobiose) predominates in plant celluloses, whereas I_α is more prevalent in some bacterial celluloses (*Valonia* sp.). Its unit cell is described as a 1-chain triclinic arrangement that has been reviewed recently [40]. Whereas crystal transformation from cellulose I to II involves treatment with highly concentrated solutions of alkali or regeneration from solution, crystal transformation from Cellulose I_α to I_β was found to be possible by annealing at high temperatures with saturated steam; annealing at high temperature in alkaline solution; or regeneration of cellulose from cellulose triacetate or from cellulose III crystal state [40]. The ease of transition of cellulose I_α to I_β, and of cellulose I to II, illustrates how the crystal structure of cellulose is dynamic and in some cases transient. Examples of these transitions have been described elsewhere [12,13,13,14,15,16].

Unit cells are the smallest repeatable spatial units within crystallites. A crystallite contains multiple unit cells in parallel arrangement giving rise to crystalline strands or *elementary fibrils* (*Fig. 8*). These fibrils are quoted with cross-sectional dimensions of 2.5 to 4 and 12–14 nm in length. In cotton they can have dimensions of 10 to 40 × 50–60 nm. Elementary fibrils aggregate to form microfibrils.

The formation of crystalline microfibrils has been elucidated using the bacterium *Acetobacter xylinum* as cellulose producing model. It appears that individual cellulose chains are "extruded" at multiple cellulose-synthesizing sites located in the cytoplasmatic membrane of the organism. Cellulose synthesis produces 12 to 16 cellulose chains into the surrounding medium

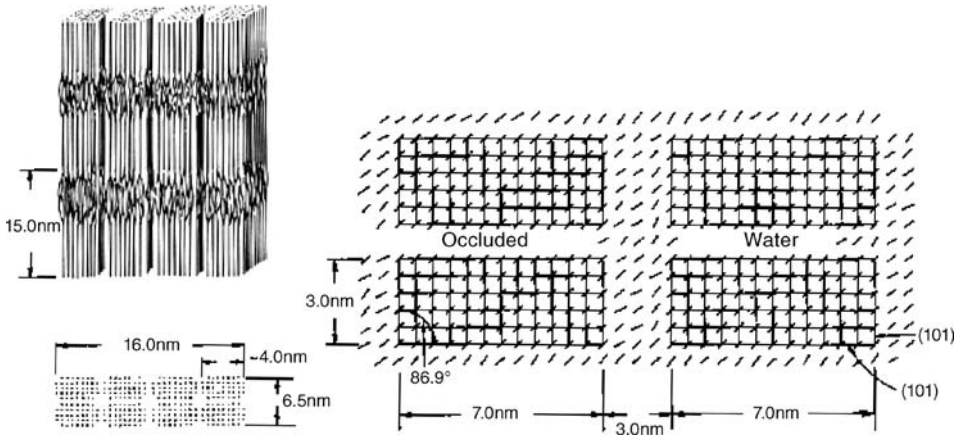

Figure 8
The architecture of elementary and microfibrils of cellulose illustrating the mixture of crystalline and amorphous (*paracrystalline*) phases. (After Kreaessig et al. [13])

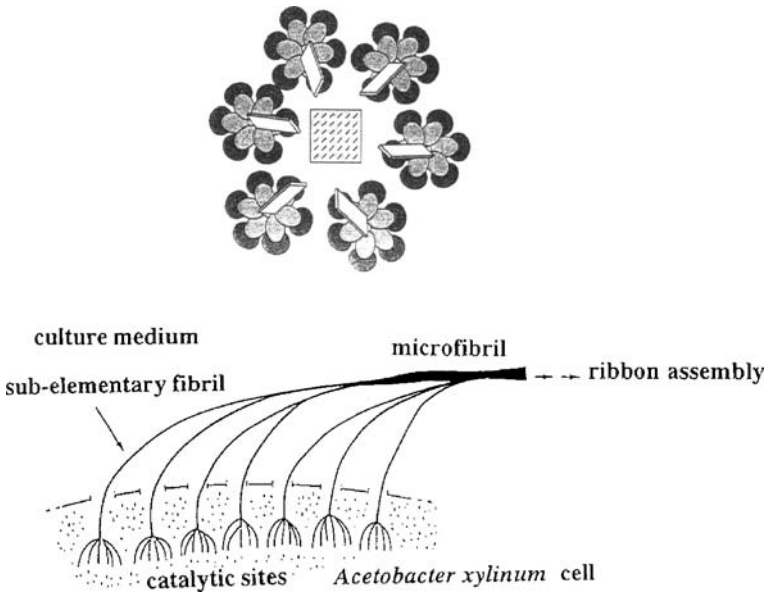

Figure 9

where they form sub elementary fibrils with cross sectional dimensions of about 1.5 nm. These fibrils aggregate with each other to form microfibrils that combine to form ribbon assemblies with diameters of 40 to 60 nm. The molecular biology and biosynthesis of cellulose formation has recently been reviewed [41]. A schematic model is given in ❯ *Fig. 9*.

2.3 Properties

The transition from crystalline to melt state, which is normal for crystalline polymers, is not observed with cellulose under normal conditions. It appears that the secondary bonds giving rise to the crystalline state are too strong and too numerous to be broken by a rise in temperature. Thermal degradation (beginning at ca. 180 °C) precedes melting under atmospheric pressure conditions. Nevertheless, a plastic deformation interpreted as melting has recently been reported for cellulose fibers exposed to laser radiation in a highly confined (pressurized) space [43]. The fracture surface of a thermoplastically deformed cellulose disc is shown in *Fig. 10*.

Parallel observations are made for solution behavior where interaction with conventional solvents fails to result in dissolution. Solvents with extremely high hydrogen bonding capability, or the reduction of H-bonds by derivatization, are required to allow crystalline cellulose to dissolve or to melt.

Cellulose is soluble in several *derivatizing* and *nonderivatizing* solvents [20,44,45,46]. These, in general, are solvents that modify OH-groups covalently or that form strong secondary bonds

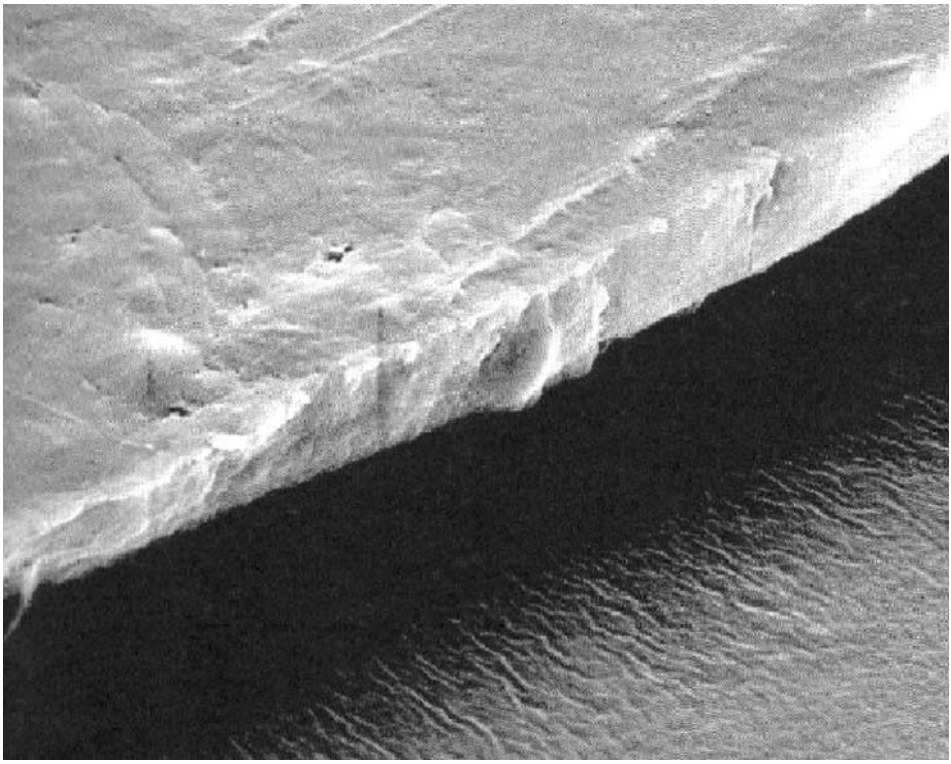

Figure 10

Table 3
List of common aqueous cellulose solvents and their major applications

Solvent designation	Composition (of solvent or cellulose derivative)	Application[a]
Cuoxam (Schweizer's reagent)	Copper (II) tetra ammonium hydroxide	Viscosity molecular weight
Cuen	Copper (II) ethylenediamine hydroxide	Viscosity molecular weight
Cadoxen	Cadmium ethylene-diamine hydroxide	Viscosity molecular weight
Acetone or ethyl- or butyl acetate	Cellulose trinitrate	Viscosity molecular weight and molecular weight distribution
Acetone, THF, or dioxane	Cellulose tricarbanilate	Molecular weight distribution

[a]Viscosity molecular weight is calculated using the Mark–Houwink–Sakurada (MHS) equation of $[\eta] = K_m M_v^a$, where η is intrinsic viscosity, M_v is viscosity molecular weight, a is the MHS exponential factor (material and system-specific, between 0.9 and 1.0 for metal complex-based solvents), and K_m is a constant. Molecular weight distributions result from GPC experiments.

with OH-groups, respectively. A list of the most common aqueous solvent systems is given in *Table 3*.

Among the best-known nonderivatizing solvent systems is a combination between copper, alkali, and ammonia termed **Schweizer's reagent**. Solutions of cuprammonium hydroxide have been used for both analytical and industrial cellulose dissolution. Regenerated fibers with silk-like appearance and dialysis membrane have been (and partially continue to be) industrial products on the basis of cellulose dissolution in cuprammonium hydroxide. The success of this solvent is based on the ability of copper and ammonia to complex with the glycol functionality of cellulose as shown in *Fig. 11*. Because of the potential side reactions (oxidation and crosslinking, "Norman" compound formation), alternatives to both ammonia as well as copper have been developed. "Cuen" and "cadoxen" are related formulations based on the use of ethylene diamine and cadmium, respectively. The various combinations of alkali, ammonia,

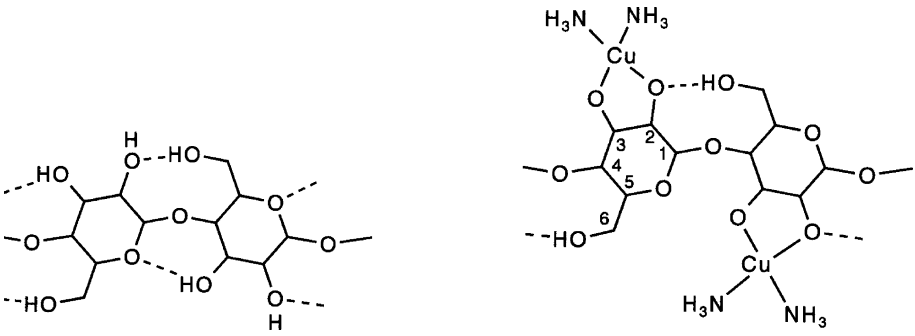

Figure 11

and copper or cadmium continue to form the basis for numerous molecular weight determination methods for cellulose. The commerce of cellulose-rich (chemical) pulp relies heavily on molecular weight determinations using any one of these combinations (*Table 3*).
Advances of the past three decades, however, have produced alternatives to the heavy metal-based cellulose solvents. Prominent among them are dimethylacetamide/LiCl (DMAc/LiCl); N,MMN-O hydrate (NMMO); tetrabutylammonium fluoride/DMSO (TBAF/DMSO); and potassium thiocyanate/DMSO [48]. While many of these solvents have gained significant popularity among laboratory chemists, only the amine oxide solvent, N,MMNO, has achieved industrial practicality. This will be discussed in the section on regenerated cellulose fibers.
Several other important physical properties of cellulose are given in *Table 4*.

2.4 Sources

Cellulose is the primary component of the cell walls of all major plants (Table 5). As cellulose content varies in relation to its source, so does the method of isolation.

Whereas cotton represents the purest form of cellulose, wood contributes the vast majority of it. Depending on end use, paper, board or chemical grade, wood conversion to some type of cellulose-rich fiber amounts to about 200×10^6 t/a a worldwide [29]. This compares to about 15×10^6 t/a cotton [13]. Only a minor amount, ca. 7×10^6 t/a, of high-purity cellulose is used for chemical purposes, mainly regenerated fibers (viscose rayon, lyocell) and derivatives (esters, ethers). Smaller amounts are also used for hydrocolloids [microcrystalline cellulose (MCC)].

Qualification of different cellulose sources for the various end use applications is determined on the basis of purity, molecular size, and *α-cellulose content*. α-cellulose refers to the portion of cellulose insoluble in 18% aqueous sodium hydroxide. Whereas the content of noncellulosic polysaccharides has proven to be a hindrance to the clarity of cellulose esters (determined as *haze* in otherwise clear films), α-cellulose content is important for the spinnability of cellulose solutions into regenerated fibers, and for viscosity characteristics of cellulose ethers. Molecular weights play an important role in various cellulose ethers.

The isolation of cellulose from wood may employ any one of several process options [13,15,16]. Chemical wood pulp may be derived by delignification using acidic solutions of sulfur

dioxide (*sulfite pulp*) or alkaline solutions most commonly containing sodium sulfide (*kraft* or *sulfate pulp*). An option based on the use of organic solvents (ethanol/water, *organosolv pulp*) has been practiced in Canada in the past. All process types may be applied to softwoods and hardwoods.

Commercial trade in chemical celluloses is assisted by the definition of standard methods of analysis. Extensive collections of quality-defining protocols have been assembled by ISO, the International Standards Organization; ASTM, the American Society for Testing Materials; TAPPI, the Technical Association of the Pulp and Paper Industry (of USA); DIN (German Industrial Norms); and many others.

3 Heteropolysaccharides ("Hemicelluloses")

3.1 Occurrence and Structure

The pure homopolysaccharide cellulose exists in nature at best only in the seed hairs of some plants (such as cotton). Whereas cellulose-producing viable cells always produce a pure, uncontaminated form of polymer, most cellulose generated exists as part of a multiphase composite material (wood and other lignocellulosic plant materials). Most cellulosic natural materials contain pure cellulose only on the nano-level where it interfaces with a variety of other molecules that contribute properties complementary to the pure homopolysaccharide. Whereas cellulose is well qualified to add mechanical strength to biological structures, it is limited by its high degree of crystallinity, which results in brittleness, low failure strain, and low ability to interact with other molecules. Yet the materials of nature typically have needs that transcend structural reinforcement. Control over such material properties as ductility, viscoelasticity, impact resistance (at all levels of temperature and humidity), biological degradability and digestibility, water retention, etc., all requires a level of variation in chemical structure that cannot be achieved with a highly ordered, crystalline homopolysaccharide alone. Since virtually all linear homopolymers crystallize, both biological organisms as well as synthetic organic chemists have learned to limit crystallinity by limiting order via structural variability. In plants, interfering with, and reducing, molecular regularity has been achieved by the introduction of several types of *different repeat units* into the polysaccharide chains, so as to create copolymers consisting of different sugar units; by introducing *branches* and *side groups*; and by introducing *derivatizing substituents* that interfere with crystallization and hydrogen bond formation. Nature uses all three different strategies for tailoring physical properties to the structural needs of a living plant.

Hemicelluloses represent a class of noncellulosic polysaccharides that is associated with cellulose in plant cell walls [56]. The term hemicelluloses was first used by Schulze in 1887 in the belief that *(hemi- or half)-celluloses* were perhaps components that were on the way of becoming cellulose; a term meant to distinguish this group of noncellulosic polysaccharides from that which makes up the cell wall structure. It has long been recognized that the term is unfortunate and misleading, and that *polyoses* or *heteropolysaccharides* are better descriptors [57]. However, "hemicelluloses" is an often-used designation for the noncellulosic heteropolysaccharide components in plants. The latter term shall be used in this text.

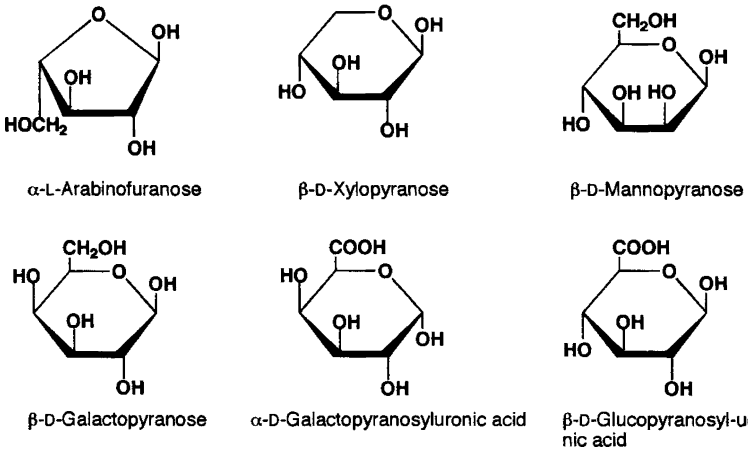

Figure 12
Most important monosaccharide units of plant heteropolysaccharides associated with cellulose (excl. β-D-glucopyranose)

It is the heteropolysaccharides of plants that bestow cellulosic composites with the ability to absorb impact, the ability to absorb moisture, and the ability to create pores in the form of free volume in amorphous (disordered or *para-crystalline*) materials [58,59]. Modification by reducing molecular regularity has the additional benefit of creating a transition from a focus on mechanical (structural) functions to an emphasis on energy storage and gel formation. Reduction in order translates into ease of hydrolysis, enzyme accessibility, rate of nutrient release for decay organisms, water absorption and swelling. Reduction in order is achieved by the introduction of monosaccharide units, and of bond types, which differ from those of cellulose. The principal monosaccharides involved in the heteropolysaccharides of plants are shown in *Fig. 12*.

Heteropolysaccharides are classified into five primary classes, xylans, glucomannans, arabinans, galactans, and glucans (*Table 6*) [60]. With few exceptions, heteropolysaccharides consist of linear homo- or copolymers with variable degrees of branching (usually by single monosaccharidic branches) and with occasional (3–13 wt.%) replacement of OH groups by *O*-acetyl groups.

Whereas cellulose contributes 40 to 60% by weight to plant mass, the balance is divided between primarily lignin and heteropolysaccharides (see *Table 5*). This division varies with plant source. The most prominent group of heteropolysaccharides in hardwoods and annual plants are the *xylans* (*Fig. 13*). Xylans have a backbone that consists of anhydro-D-xylopyranose units that are linked in β, $1 \rightarrow 4$ manner [60,61]. This gives xylan backbones the same structure as cellulose with the exception of the C-6 methylol group on the pyranose units. Pure and unbranched xylan therefore also crystallizes [63]. However, in plant tissues, xylans are heavily branched with 4-*O*-methyl-D-glucuronic acid and/or L-arabinose units. Many xylans also have a high degree of acetylation. It is known that low degrees of acetylation promote solubility in water.

Table 6
Classification of noncellulosic heteropolysaccharides

Polysaccharide type	Monosaccharide units present	Linkage types	Monosaccharide present in branches	Heteropolysaccharide designation
Xylan	D-Xyl *p*	β , 1 → 4	L-Ara *f*, 4–O-Methyl-D-Glu A *p*	Arabinoxylan, Glucuronoxylan Arabinoglucurono xylan
Glucomannan	D-Man *p* D-Glu *p*	β , 1 → 4	D-Gal *p*	Glucomannan, Galactoglucomannan
Arabinan	L-Ara *f*	α , 1 → 5	L-Ara *f*, D-Gal *p*	Arabinan
Galactan	D-Gal *p*	β , 1 → 4 and/or β, 1 → 3	L-Ara *f*, D-Gal *p* D-Glu A *p*	Arabinogalactan (2 types)
Glucan	D-Glu *p*	β , 1 → 4 or β, 1 → 3	D-Xyl *p*, D-Gal *p*, D-Ara *f* None	Xyloglucans β-Glucans

Source: Tenkanen [61]

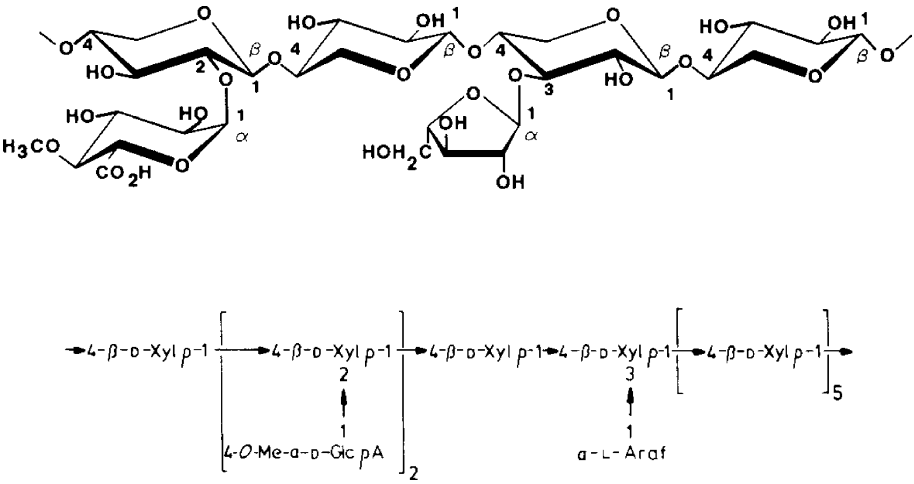

Figure 13
Schematic structure of arabinoglucuronoxylan (without acetyl groups). The formula below gives the abbreviation with some quantitative detail. (Taken from Sjostrom [16])

The second most abundant group of heteropolysaccharides are the *glucomannans* [60,61]. Glucomannans consist of a linear copolymer chain made up of glucose and mannose units in different ratios (although mostly favoring mannose). Glucomannans are also β,1 → 4-linked, and they occasionally carry single galactose side chains. Glucomannans are typical of soft-

wood species. Arabinans, galactans and glucans are present in various plant tissues to lesser extents.

3.2 Isolation

Heteropolysaccharides are not present in pure form although they often represent 20–30% of cell wall mass. Their chemical structures and some of their physical properties resemble those of the natural gums, although they are typically of modest molecular size (DP in the range of 50 to 200). They are also closely associated with pectins [58]. In woody plant tissues, heteropolysaccharides are typically connected to lignin via a variety of covalent bonds. This combination of two polymer classes with widely different chemical and physical properties, and with a molecular architecture resembling that of block copolymers, is responsible for the insolubility of both polymer components. In contrast to cellulose heteropolysaccharides are easier to dissolve in alkali or DMSO. Heteropolysaccharides are usually isolated from lignified plant tissues by pretreatment procedures that aim at removal of extractives, pectins, and lignin so as to produce a *holocellulose* that represents the combination of cellulose and heteropolysaccharides [62]. Holocellulose is subject to fractionation by (mostly) alkali extraction. The subject of heteropolysaccharide isolation from holocellulose has recently experienced a renaissance since the heteropolysaccharide fraction represents a significant mass fraction of plants [60,63]. Heteropolysaccharides as well as lignin both resist dissolution without depolymerization. Only the hydrolysis of covalent bonds existing between and within lignin and heteropolysaccharides will result in effective delignification or carbohydrate removal. This is why most heteropolysaccharide isolation protocols begin with the preparation of holocellulose. This involves various degrees of lignin extraction and/or lignin degradation (with strong, lignin-specific oxidants, alkali, and/or organic solvents) followed by heteropolysaccharide extraction using usually aqueous alkali.

Heteropolysaccharides are, in general, highly desirable components of paper-grade pulps while they are not tolerated in *dissolving-grade* pulps used for the production of regenerated cellulose products and cellulose derivatives. A vast body of literature exists on the effects of hemicelluloses on the papermaking process.

Although abundant in nature, and although several opportunities have been identified [64], heteropolysaccharides have largely escaped industrial exploitation. Exceptions are the conversion of pentoses into furfural (for temperature-resistant foundry resins) by acid hydrolysis; the fermentation of pentoses into single cell protein (*Torula yeast*); the catalytic reduction of xylose to xylitol, a dietary sweetener; and the use of larch (*Larix* sp.)-specific arabinogalactan extracts as dispersants in printing inks.

4 Microcrystalline Cellulose, Nanocrystals and Cellulose Whiskers

Being composed of linear chains of a highly crystalline polysaccharide, linked by β, $1 \rightarrow 4$, D-anhydroglucopyranose bonds that are hydrolyzed with relative ease, cellulose has long been the subject of partial acid hydrolysis to mixtures of hydrocolloid particles [65]. Hydrolysis of the disordered (paracrystalline) regions of cellulose liberates highly crystalline particles with dimensions in the 50 to 100 μm range. When dissolved in a suitable cellulose solvent, these par-

ticles represent materials with molecular weights corresponding to DPs in the range between 50 and 400 depending on cellulose source. Since these molecular weights are determined by the hydrolysis of the amorphous regions existing between crystalline areas, they received the term *level off DP* (LODP).

The discovery that cellulose is capable of forming a stable colloidal suspension of microcrystallites if this hydrolysis is carried out with a nonpeptizing acid (such as HCl) followed by mechanical disintegration led to the introduction of a commercial *microcrystalline cellulose* product under the trade name AVICEL (FMC Corp., Philadelphia, PA) [66,67,68]. The successful production of MCC requires hydrolysis and sufficient mechanical disruption of a $>5\%$ aqueous suspension to allow the liberation of monocrystals in stable gel-form. Since its introduction in 1961 [66], MCC has been recognized for its unique rheological properties, which distinguish it as a gel with stable viscosity at ambient as well as elevated temperatures. Its smooth texture produces a favorable mouthfeel that, in turn, has helped MCC capture markets in the food industry. Its viscosity properties have helped MCC to find entrance into such applications ranging from ceramics to food to cosmetics and to pharmaceuticals (*Table 7*). In comparison to gels produced using hydrophilic macromolecules, such as natural gums, MCC does not form rubbery gels upon exposure to the air. Following dialysis and spray drying, MCC forms flowable powders of micron-sized particles that are widely accepted in tableting operations because of their excellent compression properties. Annual production figures of 550×10^3 t/a by the FMC Corp. have been reported in the literature [68].

Continued hydrolysis of MCC with sulfuric acid was found to lead to the separation of nanosized crystals, variably referred to as whiskers, monocrystals, nanocrystals, cellulose crystallites, etc., which represent the crystalline phase of cellulose [69,70,71]. Depending on source, these crystallites have dimensions of 5 to 15 nm in diameter and 200 to 1000 nm in length. Their aspect ratio (i. e., length divided by diameter) may vary from nearly 1 to >100 [71]. It is apparent that MCC consists of agglomerations of whiskers (*Fig. 14*). The retention of sulfate groups on whisker surfaces helps in the formation of stable dispersions in water. Whiskers are reported to have mechanical moduli of about 130 GPa, and this corresponds closely to values calculated for cellulose crystallites [71]. Cellulose whiskers have attracted significant attention as reinforcing agents in composites.

(From Dufresne et al. [71] and Kraessig et al. [13])

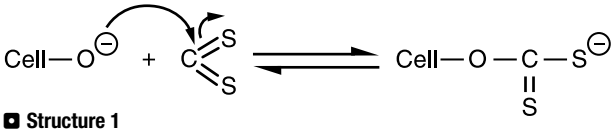
5 Cellulose Regenerates

Cellulose is soluble in a wide range of solvents from which it can be regenerated in unadulterated (crystalline) form [13]. This is accomplished in either fiber (especially staple fiber) form, in filament form or in any other form (sheets or films, sponges, etc.). Cellulose solvents are divided into *derivatizing* and *nonderivatizing* solvent systems [73]. The principle of deriva-

tizing solvents involves the formation of transient cellulose derivatives that have substituent groups that are covalently attached and that can easily be removed during the regeneration step. Nonderivatizing solvents, by contrast, are those solvents that are capable of dissolving cellulose on the basis of intermolecular interaction alone. However, the delineation is less precise when it comes to solvent systems that form strong secondary interactions. Three types of cellulose regeneration technologies are currently in industrial practice, and these are the *viscose rayon process* (derivatizing), the *lyocell process* (nonderivatizing) and the *cuprammonium hydroxide process* (nonderivatizing). Other cellulose fibers of commercial significance are cellulose acetate (CA with DS circa. 2.5) and cellulose triacetate (CTA with DS nearly 3.0) fibers and filaments. However, these do not qualify as cellulose regenerates as they retain their substituent groups.

The oldest and most widely practiced cellulose regeneration technology of the derivatizing solvent-type is the ***viscose rayon*** process. It is based, in part, on the discovery in 1857 by Cross, Bevin, and Beadle of the dissolution of sulfidized cellulose in alkali. Viscose fibers are by far the most important cellulose regenerates, amounting to an annual fiber production of 2.5×10^6 t worldwide [13,74].

The viscose rayon process (◉ *Fig. 15*) follows a process flow diagram that distinguishes several steps. Cellulose (usually in sheet form) is alkalized with 20% aqueous alkali and *ripened* to a reduced DP of approximately 300. This may be accomplished in continuous or discontinuous operations. The ripened alkalized cellulose is then subjected to a chemical modification with carbon disulfide (CS_2) in a *xanthation* step. Cellulose xanthate requires a DS of 0.5–0.6, amounting to the use of 150–400 kg of CS_2 per ton of fiber. Xanthation occurs on all three available OH-groups, but with predominance of C-2 and C-6. Following reaction with CS_2, the cellulose xanthate is dissolved in alkali to yield a sticky, honey-colored solution with 7–12% cellulose xanthate and 5–8% alkali. This solution is filtered and deaerated before it is spun (through spinnerets) into a precipitation bath containing sulfuric acid and zinc salts. The chemistry of the complex process is illustrated by the following equation.



Structure 1

Complexity, environmental difficulties (especially with CS_2 regeneration) and overall slow processing conditions (compared to melt-spun synthetic fibers) catalyzed the search for alternative cellulose regeneration processes.

The ***lyocell process*** is based on the regeneration of cellulose from a true (underivatized) solvated molecular state. The solvent, N, methyl morpholine-*N*-oxide (NMMO)-hydrate, dissolves cellulose on the basis of its strong hydrogen bonding capacity. NMMO is a substance with a melting point of 80 °C that can be fully recovered in the process. American Enka developed the process in 1976, and it is presently commercially operated by Accordis (formerly Courtaulds) with operations in Mobile, Alabama, USA, and Grimsby, United Kingdom (70×10^3 t/a) and in Heiligenkreuz, Austria (Lenzing, AG). Most operations generate staple fibers for textiles that are marketed under the trade name *Tencel*®; no filaments are produced as yet [13,74].

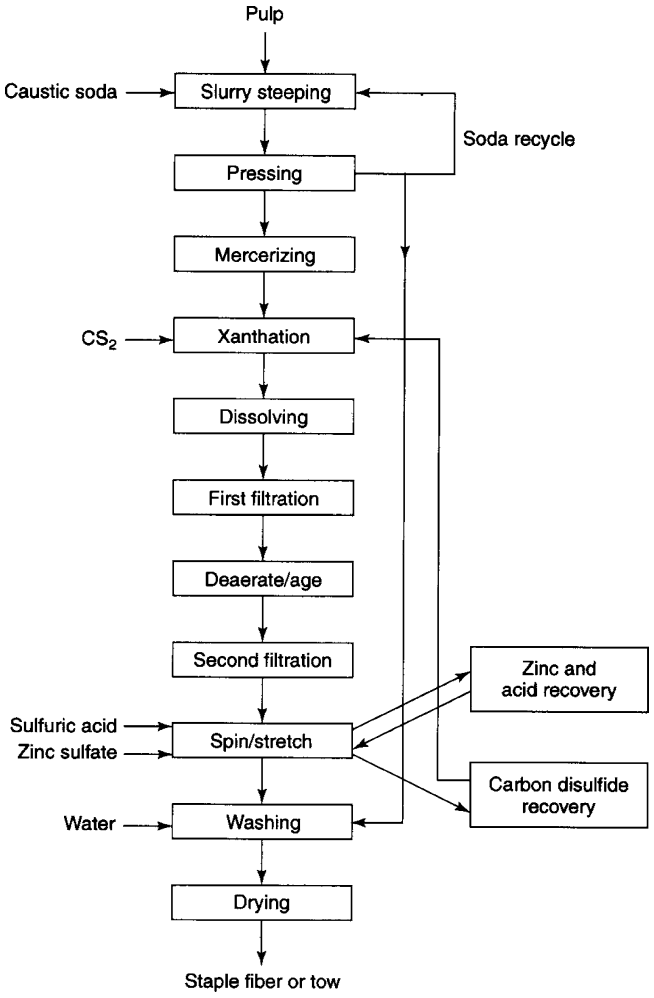


Figure 15
Process diagram of the *viscose rayon* process (Adopted from Woodings [74])

The process of cellulose regeneration in the form of lyocell fibers is significantly simpler than that of the viscose rayon process. It is illustrated in *Fig. 16*. A solution containing 14% cellulose, 10% water, and 76% NMMO plus stabilizers is extruded at a temperature slightly above 100 °C into an aqueous NMMO-bath from which cellulose is precipitated [74,75]. The extrusion has been described as a melt-spinning process that has recently made it possible to manufacture cellulosic self-bonded meltblown nonwovens as well [76].

The third type of cellulose regenerate with commercial significance operates on the basis of ***cuprammonium hydroxide*** (Schweizer's reagent). The process had significance for fibers in the first half of the 20th century, but it started to decline in the 1960s due to insurmountable obstacles in the recovery of copper ions. The main producer of cuprammonium fibers

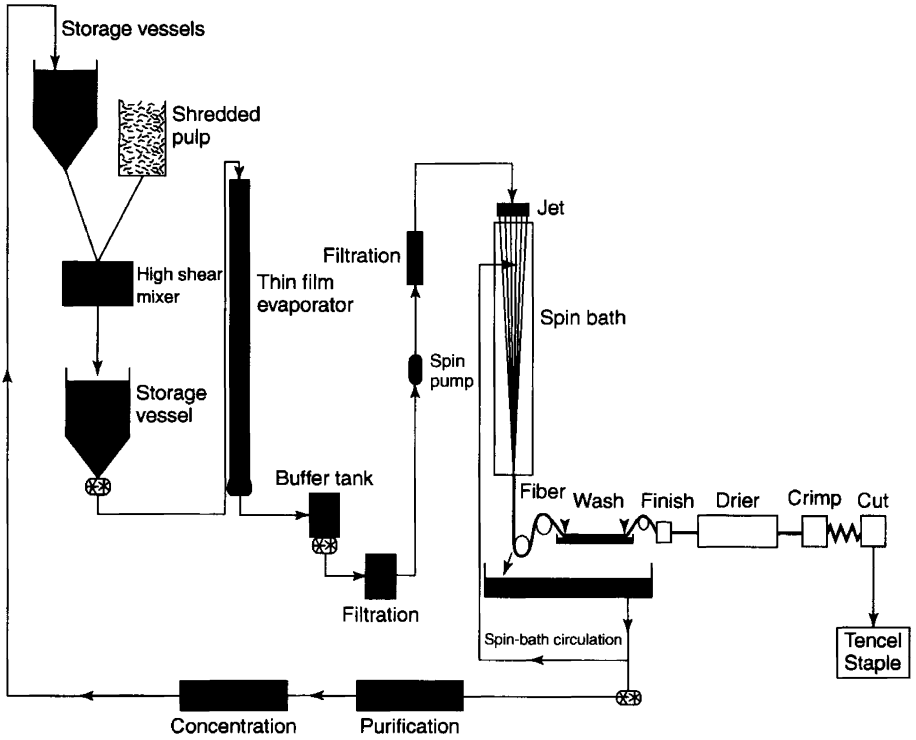

Figure 16
Regenerating cellulose in the form of lyocell fibers from a solution in NMMO according to the *Tencel* Process by Accordis (From Woodings [74])

(Bemberg AG of Germany) shifted the production to that of hemodialysis membranes in the form of flat sheets and hollow fibers. The membrane products are known under the name *Cuprophan* and are produced by *Membrana*, a division of AKZO Nobel Fibres [13,75].
The spinning of *cuprammonium* hydroxide fibers involved solutions of 4–11% cellulose, 4–6% Cu, and 6–10% NH_3. Solution viscosities were 200 Pa × s at 20 °C.
Cuprammonium fibers were popular for their superior fiber feel and their silk-like appearance, which are based on the extreme fineness of the filaments.
Alternatives to alkaline solutions of carbon disulfide are combinations of formaldehyde and DMSO; various alkyl silanes, and urea and alkali. The latter is currently being promoted for industrial applications. It is known under the term *carbamate process*. The carbamate process has advantages over the viscose rayon process while being able to use the same process technology.

6 Cellulose Derivatives

Cellulose derivatization has the purpose of (a) *reshaping* cellulose from its original cotton or wood fiber form; (b) *modifying* its chemical and/or physical properties (such as solution,

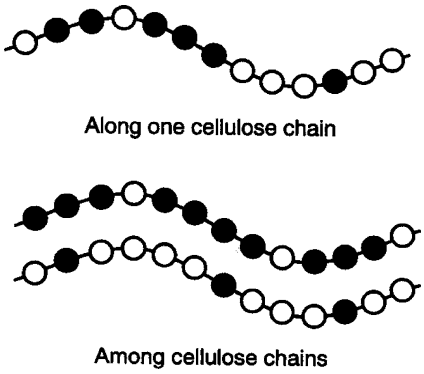

Figure 17
Schematic illustration of the possible distribution of substituents in cellulose derivatives with variation along single chains or among adjacent chains. The resulting *block-like* architecture of the former and the corresponding *over-* and *under*-derivatization of the latter both potentially restrict thermal and solubility properties of the derivatives

thermal, or physiological behaviors); or (c) making cellulose amenable to *analysis* by a specific analytical methodology, such as molecular weight or chemical structure determination.

Since the cellulose molecule is virtually monofunctional in terms of aliphatic hydroxyl groups, derivatization reactions target predominantly *substitutions* of OH-groups. In addition to substitution reactions, *oxidations*, at the reducing end group, at the C-6 methylol group, or at the glycolic group (C–C cleavage between C-2 and C-3 with formation of a dialdehyde), also play a role. A third type of reaction involves *hydrolytic depolymerization*.

The important class of *derivatization by substitution* is measured in terms of the degree of substitution, DS, which may range between 0 and a maximum of 3.

The introduction of substituents is rarely uniform in practice. In most cases, modification reactions occur preferentially in the most accessible regions of the molecule or at the most reactive OH-groups (◉ *Fig. 17*). The three OH groups are not entirely equivalent, as they differ in accessibility within the crystalline organization as well as in their relative reactivity. The reaction sequence usually progresses from C-6 (most accessible and reactive), to C-2 and C-3. In addition to variations in the pattern of substitution within an AGU repeat unit, differences are encountered along the chain (◉ *Fig. 17*). Since most reactions with cellulose begin as heterogeneous reactions, diffusion and accessibility limitations play an important role in the progression of the reaction. The mixture of crystalline and disordered regions within cellulose produces a more rapid derivatization within the amorphous phase, and this results in *blockiness* whereby regions of high DS neighbor regions of unsubstitution. The resulting irregularities tend to influence thermal properties and solution behaviors. Blockiness is prevented either by conducting derivatization reactions in homogeneous phase (i. e., in solution state); or by completing derivatizations to a high DS followed by substituent removal under homogeneous conditions.

Only reactions in homogeneous phase, in dilute solution, can be expected to minimize variations within and between cellulose derivative molecules.

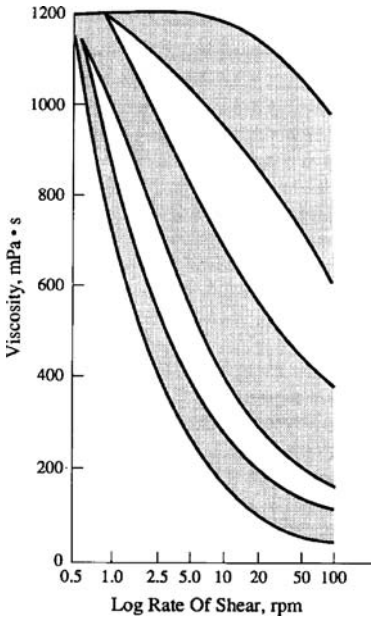

Figure 18
Relationship between viscosity and shear rate. The reduction in viscosity with rising shear rate describes the degree of *shear thinning*, an important material characteristic of water-soluble polysaccharides. The mouthfeel of foods becomes less slimy with increasing shear thinning behavior. (Adopted from Szczesniak and Farkas [77])

The chemical structure of cellulose ethers is typically described on the basis of total product hydrolysis and analysis of the resulting monosaccharide derivative units. The yield of mono-, di- and tri-substituted glucose units, and the distribution of substituents between the hydroxyl groups in positions C-2, C-3, and C-6, represents distinguishing molecular features. The determination of degrees of substitution (DS) and molar substitutions (MS), representing the number of substituent equivalents per anhydroglucose unit, widely dictate rheological and other properties. Additional analytical methods describing the properties of cellulose ethers involve viscosity measurements. Cellulose ethers may be both thixotropic and pseudoplastic (*shear thinning*) as is illustrated in *Fig. 18*.

Since cellulose and cellulose derivatives have found wide acceptance in the cosmetic, pharmaceutical and medical industries, much work is currently focusing on highly selective modification of cellulose ethers (as well as cellulose esters) for highly targeted controlled release characteristics. Interaction with water, and interaction with a variety of co-substrates under conditions varying in temperature, ionic strength, pH, etc., has opened avenues for the use of cellulose ethers in drug delivery. This field has recently been reviewed [78,79].

The two primary categories of cellulose derivatives, *cellulose esters* and *cellulose ethers*, which dominate the markets for cellulose derivatives (*Table 8*), have somewhat different raw material requirements. Whereas both types of modification technologies prefer to start with chemical cellulose of high α-cellulose content, ethers give preference to molecular weight considerations while esters are sensitive to impurities. This is a consequence of the predom-

Table 8
Estimated cellulosic materials markets excl. paper pulp and textiles (in tons/a worldwide)

Chemical pulp		4.4×10^6

Cellulose esters	Nitrates	$150–200 \times 10^3$
	Phosphates	Insignificant
	Sulfates	Insignificant
	Acetate and mixed acetates	850×10^3
Cellulose ethers	Carboxymethyl	230×10^3
	Methyl and hydroxyalkylmethyl	120×10^3
	Hydroxyethyl	60×10^3
	Hydroxypropyl	10×10^3

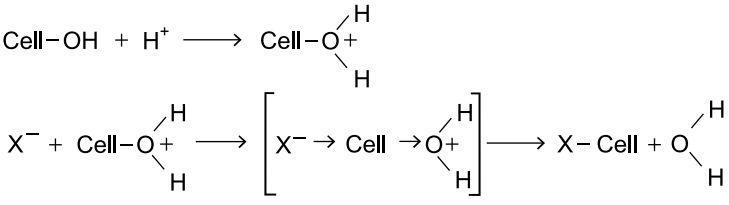
[1] Estimated based on the assumption that FMC has between 50 and 100% of world market.

inant application of both types: Whereas ethers find their greatest use in connection with the modification of aqueous solution viscosities (*rheology modifiers*), esters are often used for structural purposes where visual appearance and clarity matter most.

6.1 Cellulose Esters

Cellulose esters are used primarily in structural applications, such as films, fibers, coatings, etc. Since they are processed in solution or in melt state, their resistance to flow (i. e., melt viscosity) represents a distinct handicap. Commercial cellulose esters are all generated by heterogeneous modification reaction [80,81,82,83,84]. However, reactions in homogeneous phase (with various solvents) are increasing in number and variety, and they have recently been reviewed by Heinze et al. [82]. Cellulose esters are usually classified as *inorganic* and *organic* esters.

In general, all esters are based on the stepwise formation of oxonium ions followed by their nucleophilic substitution with an acid residue and the elimination of water (*Structure 2*). Because this substitution reaction reverses in the presence of water, water removal by binding



Structure 2

or other means is required. Esterification proceeds in heterogeneous phase, and derivatization does not necessarily destroy the fiber structure.

6.1.1 Inorganic Esters

Inorganic cellulose esters are formed with nitric, sulfuric, and phosphoric acid [13,80,85]. Of greatest commercial significance are the *cellulose nitrates* (sometimes erroneously designated *nitrocellulose*), which have first been described in 1832 by H. Braconot. Cellulose nitrates are formed by treating cotton (or chemical cellulose) with mixtures of nitric and sulfuric acid. Their ready inflammability has given them the name *gun cotton*. When A. Nobel discovered that mixtures of nitroglycerine and cellulose nitrate form a stable form of an explosive mixture known as *blasting gelatin* in 1875, this discovery, and the development of smokeless gun powder, changed human history forever.

Cellulose nitrates were used as base films in early photography, where they were plasticized with camphor and other substances. The frequent fires experienced with early motion pictures, which were produced using cellulose nitrate as basis, are still responsible for the stringent fire code regulations in today's movie theaters.

Cellulose nitrate continues to be used in fine lacquers and automotive coatings. The nitrates are easy to produce, and simple mixtures with other polymers and plasticizers are readily formulated. Their use depends on the DS, which is determined via nitrogen content. The target-DS is adjusted via the water content maintained in the reaction mixture (› *Fig. 19*). Cellulose nitrates of low DS (10.9 to 11.7% nitrogen) provide for solubility in a range of organic solvents, and derivatives with high DS are used for gun cotton.

Cellulose nitrates are often used for the determination of molecular weights and weight distributions of cellulose on analytical scale.

Cellulose sulfates are appealing water soluble polymers even at low DS. Cellulose sulfation, however, is complicated by serious chain degradative side reactions. Cellulose sulfation has been carried out using chlorosulfonic acid, sulfuric acid, or sulfur trioxide. At low degrees of substitution (DS 0.2 to 0.3), cellulose sulfates are used in oil well drilling, foodstuffs, cosmetics, and pharmaceuticals. The preparation of cellulose sulfates for symplex capsules can

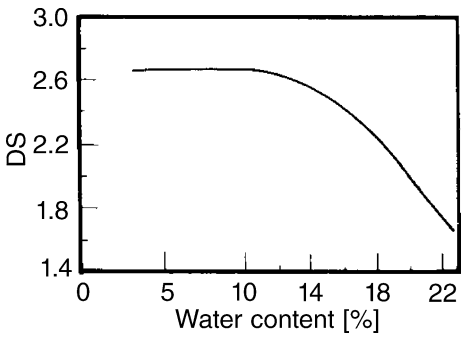


Figure 19
Relationship between DS and water content during cellulose nitration with HNO_3 and H_2SO_3. (From Klemm et al. [18])

be accomplished using cellulose acetate (DS 2.5) in DMSO-solution with SO_3-pyridine or SO_3-DMF. The sulfate substituents survive the ensuing deacetylation with NaOH. Interest in medical and pharmaceutical applications of cellulose sulfates is increasing lately [79,81].
Cellulose phosphate can be prepared by converting cellulose with molten H_3PO_4 and urea at 120 °C. The derivative with DS 0.3 to 0.4 has a high water retention value and is used in the textile industry for flame retardancy, as thickeners, and for membranes targeted for hemodialysis [79,86].

6.1.2 Organic Esters

Cellulose can be esterified with almost any organic acid [81,82,84]. Whereas this is possible in principle with both alkyl chlorides and carboxylic anhydrides, commercial practice has focused on the anhydride option. Although many esters have been described in the literature, industrially manufactured organic esters are prepared only with aliphatic fatty acids with between 2 and 4 carbon atoms in length (i. e., acetates to butyrates, CA to CB). Exceptions are some mixed esters with phthalic acid, which are used for enteric coatings in pharmaceutical applications; and a novel carboxymethyl cellulose acetate butyrate (CMCAB), which is used in water-borne coatings applications [81,84].
Cellulose esters have been known for 150 years [83,85]. However, their utility was not fully appreciated until after a significant industrial breakthrough (credited to G. W. Miles) revealed the well-soluble cellulose diacetate in 1904. Whereas the initial applications of cellulose diacetate focused on replacing the highly flammable cellulose nitrates used in airplane coatings during World War I, there was increasing demand for cellulose acetates throughout the first half of the 20th century. Principal applications for cellulose acetates were in the textile fiber business; in cigarette filter tows; in plastics; and in films and coatings. Applications for cellulose esters in specialty markets, such as LCD flat screens and controlled release agents, continue to be developed today [81,83].
A recent monograph on cellulose acetates lists more than ten acetate manufacturers worldwide (*Table 9*) [83]. The industrial process distinguishes several process steps (*Fig. 20*).

Table 9

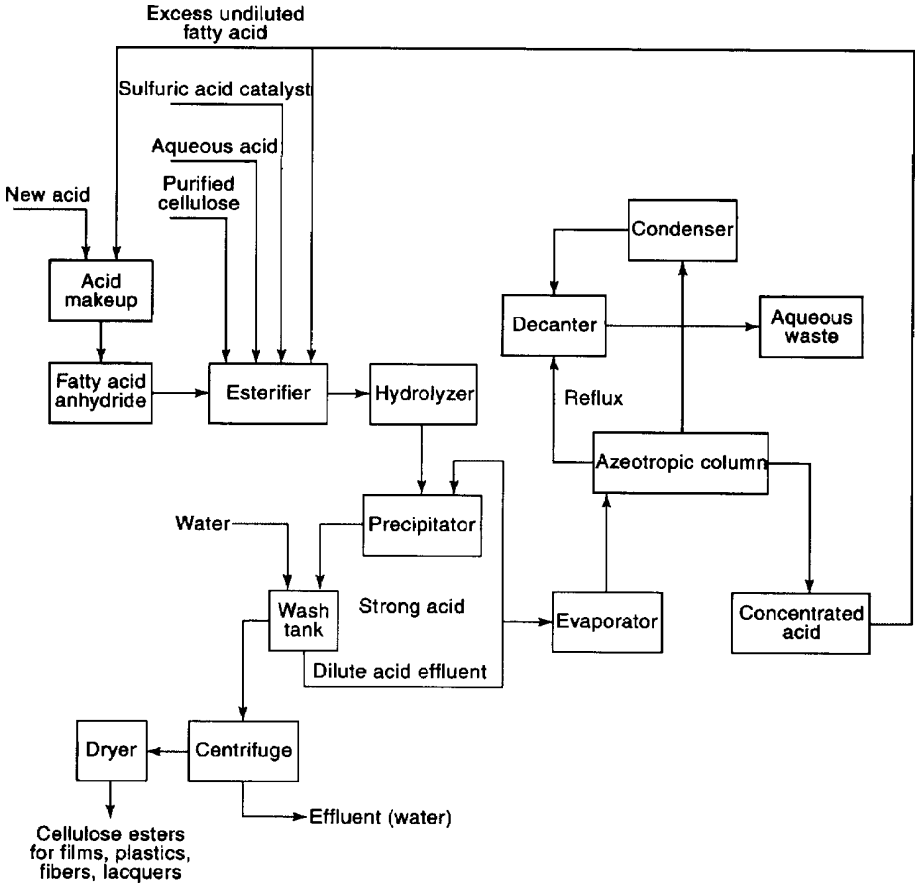

Figure 20
Flow diagram of cellulose ester (acetates, CA, and mixed acetates with propionic or butyric acids, CAP or CAB) production. Note the introduction of water via dilute acid serves the purpose of reducing DS and raising solubility in organic solvents. (Adopted from Edgar [87])

Pretreatment/activation involves swelling mostly chemical pulp fibers with glacial acetic acid and 4–7% moisture (on cellulose basis). Activation ensures uniform acetylation.
Esterification involves the treatment of preactivated cellulose with a mixture of acetic acid and acetic anhydride at a consistency of about 10%. The acetic anhydride content of the mixture is approximately 25%, and this amounts to a 10–40% excess over stoichiometric requirement. The reaction proceeds at 50 °C. ***Hydrolysis*** refers to a process step in which the DS of the esterification product is reduced from its level of > 2.9 to a level between 2.3 to 2.7 by the addition of 5 to 10% water. The temperature during hydrolysis is maintained at 40 to 80 °C. The consequence of hydrolysis is a uniform release of acetyl groups from the cellulose backbone so as to assure uniform solubility. ***Precipitation*** involves either the addition of the acetylation mixture into water or dilute acetic acid to produce a *flake* product, or the addition of water

Table 10
Solubility characteristics of commercial cellulose acetates in relation to DS (expressed in the form of acetic acid content). (Adapted from Balser et al. as quoted in Rustemeyer [83])

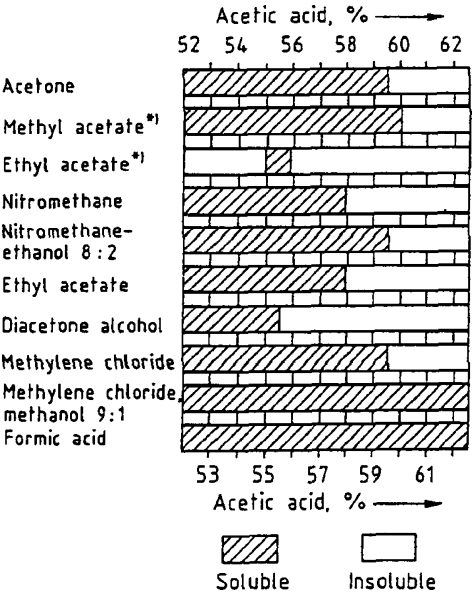

Table 11
Cellulose acetate solubility

DS	Acetyl content (%)	Soluble in
2.8–3.0	43–44.8	Methylene chloride
2.2–2.7	37–42	Acetone
1.2–1.8	24–32	Methoxyethanol
0.6–0.9	14–19	Water

into an ester mixture under stirring to generate a powderous product. Critical performance measures for cellulose acetate and mixed acetates involve solution behavior (including water dispersibility), thermal properties, and controlled release characteristics.

Cellulose ester solubility varies widely. Cellulose acetates with uniform substituent distribution are soluble in several organic solvents and these range from cellosolves (ethylene glycol ethers) to acetone and methyl chloride (*Table 10* and *Table 11*). Whereas the cellulose triacetate with >60% acetic acid content is barely soluble in chloroform or methylene chloride/methanol, a cellulose acetate with a DS of 0.6 to 0.9 (14 to 19% acetyl content) is fully soluble in water (*Table 11*). Important thermal properties depend largely on type and pattern of substitution (*Table 12*). Whereas cellulose acetates are not melt processible without the addition of large amounts of plasticizer, cellulose mixed acetates with propionyl or butyryl groups, CAP and CAB, have lower melting points depending on the degree of fatty acid substi-

Table 12

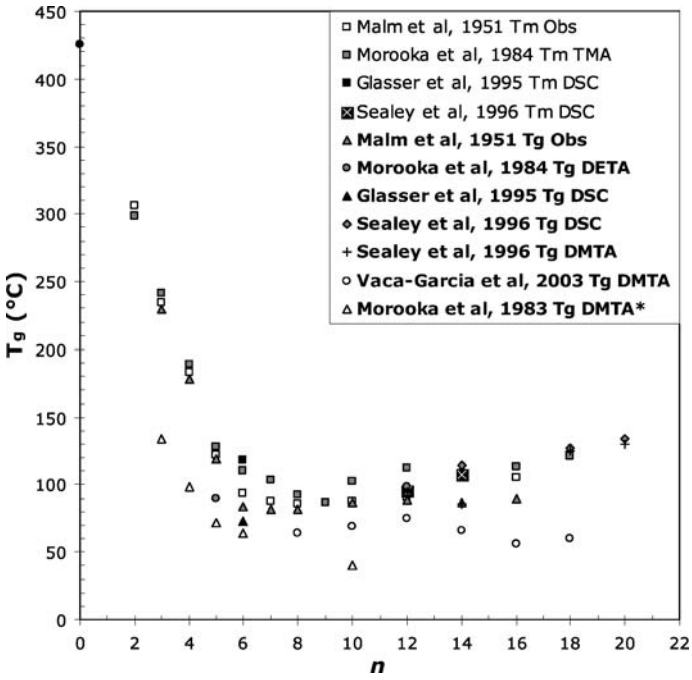

Figure 21
Relationship between apparent glass transition temperature (referred to frequently by different designations) and size of alkanoate substituents in C-atoms (*n*) of cellulose triesters. Data obtained from Malm et al. [90], Morooka et al. [91,92], Glasser et al. [93], Sealey et al. [94], Edgar et al. [88], Vaca-Garcia et al. [89]

tution. This has recently been evaluated for cellulose triesters including fatty and waxy esters (*Fig. 21*) [88,89].

Extensive research into the thermal properties of long-chain cellulose esters (LCCE) has produced an understanding of the melt- and flow properties of fully as well as partially substituted derivatives. It is apparent that T_g declines quickly to between 50 and 150 C as acyl chain length exceeds that of butyrate (*Fig. 21*).

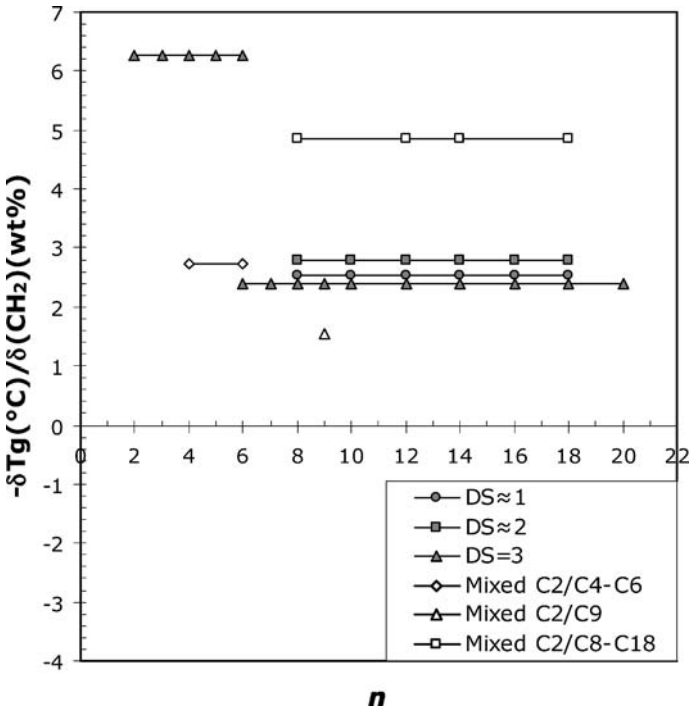

Figure 22
Relationship between the average reduction in apparent glass transition temperature per weight percent methylene, i. e., $\partial T_g/\partial(CH_2)$ (wt.%)-parameter, and alkanoate substituent size (n) for the different data sets of Fig. 21. (Corrected for liquid crystalline-phase content of cellulose esters with $n > 6$). (Adopted from work by Vaca-Garcia et al. [89])

A comparison of the extensive data sets available for LCCEs has recently produced the recognition that the thermal characteristics of cellulose esters are the result of an internal plasticization by methylene groups, for the most part (*Fig. 22*). Whereas the highest plasticization effect is observed for C2 to C6 triesters, most LCCEs with substituents greater than hexanoate experience a plasticization effect of ca. 2.5° C/CH_2(wt.%). Plasticization with methylene groups is reduced by the presence of OH-groups, and by the formation of liquid crystalline phases [89].
Controlled release applications for a variety of cellulose esters have recently been summarized by Marchessault et al. [86] as well as by Edger [79].

6.2 Cellulose Ethers

The formation of cellulose ethers aims, in general, at permanent and irrevocable disruption of crystallinity, and at controlling viscosity properties of aqueous solutions (i. e., *rheology modification*). Since "stiffening water" and gel formation are primary targets for many natural polysaccharides (in gums as well as body fluids), cellulose ethers aim to achieve solutions with

high viscosity at low solids content. This is why cellulose ether manufacturers prefer cotton over wood pulp, which has a lower degree of polymerization.

$$\text{Cell–}\overline{\underline{O}}\text{H} + \text{Na}^{+}\text{OH}^{-} \rightarrow \text{Cell–}\overline{\underline{O}}|^{-}\ \text{Na}^{+} + \text{H}_2\text{O}$$

$$\text{Cell–}\overline{\underline{O}}|^{-}\ \text{Na}^{+} + \overset{\delta+}{\text{CH}_3}\text{–}\overset{\delta-}{\text{Cl}} \rightarrow \text{Cell–}\overline{\underline{O}}\text{–CH}_3 + \text{Na}^{+}\text{Cl}^{-}$$

Structure 3

Cellulose ethers are generally formed by *alkalizing* high purity cellulose fibers in suspension, under conditions involving high alkalinity and low water content [95]. Industrial cellulose (*Structure 3*) ether reactions all involve heterogeneous conditions in organic solvent suspension. Low temperatures help preserve molecular weight. Much recent work has focused on the differences in properties between homo- vs. heterogeneously prepared cellulose ethers [46]. Homogeneous reactions, in general, produce derivatives with a more uniform distribution of substituents along the backbone of cellulose, and they allow a wider range of degree of modification. However, homogenous cellulose modification chemistry is not practiced commercially at present.

Cellulose ethers are formed from alkalized cellulose in (a) a typical Williamson synthesis using alkyl halides; (b) using ring opening reactions with oxiranes; or (c) by reaction with vinyl compounds. Cellulose ethers with industrial significance include various alkyl ethers (ca. 100,000 tons per year), hydroxyalkyl ethers (ca. 50,000 tons per year), and carboxymethylethers (ca. 300,000 tons per year) (see *Table 8*). These products are used as thickeners and dispersants in agriculture and food products, as well as in ceramics, cements, textiles, pharmaceuticals, cosmetics, paints, and detergents (*Table 13*). Four major cellulose ether categories are distinguished, and these include carboxymethyl cellulose (CMC); methylcellulose and hydroxyethyl methyl cellulose (HAMC); hydroxyethyl cellulose, also with varying degrees of hydrophobic substitution; and hydroxypropyl cellulose (HPC) (*Table 13*).

Cellulose ethers swell or are colloidally soluble. They all raise viscosity and have specific rheology profiles (see *Fig. 18*). Many cellulose ethers are surface-active, and they reduce the surface activity of water by about 20 to 25% depending on type. Cellulose ethers are generally compatible with other hydrocolloids and many other substances. The field has recently been reviewed by Majewicz et al. [95]. The primary manufacturers of industrial cellulose ethers are listed in *Table 14*.

There are three distinguishing characteristics of cellulose ethers, and these relate to the behavior during dissolution; the structure and rheological properties of the solutions; and the ability to interact and blend with other solids. These behaviors depend on a variety of molecular features including type of substituents, number of substituents, distribution of substituents, and molecular mass. Most cellulose ethers are *pseudoplastic* or *shear thinning*, meaning that they exhibit reduced viscosity under conditions of applied shear (*Fig. 18*). Many of the cellulose ethers also coagulate with temperature rising: they are thermally reversible gels and flocculate

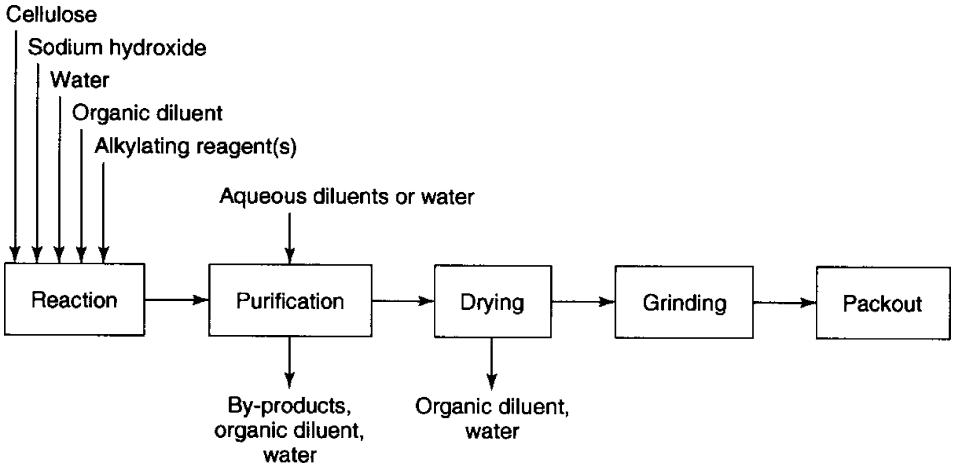

Figure 23
Process flow diagram for the manufacture of cellulose ethers. (Adapted from Majewicz et al.,95 2003)

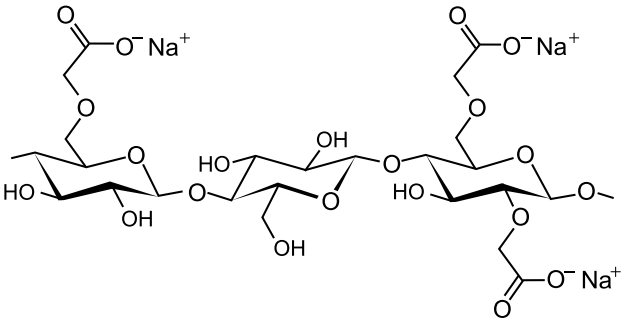
when heated. When derivatized with substituents that are capable of secondary substitution (i. e., hydroxyalkyl ethers and related derivatives), ethers may be formed in which the number of substituent moles/AGU exceeds the DS. This is expressed as number of derivatizing moles / AGU (i. e., *molar substitution* MS) in distinction of degree of substitution, DS. If MS exceeds DS, side chains or branches are formed on the cellulose backbone. Such branches have a significant influence on solubility and rheology.

The production of cellulose ethers proceeds in two major steps, *activation* by pretreatment with alkali followed by *reaction*.

The *activation* treatment involves steeping cellulose (cotton or pulp fibers in sheet form) with cold 15 to 20% aqueous alkali for several hours. This *alkali cellulose* is subsequently reacted with reagents that consume alkali (Williamson synthesis); or alternatively in reactions in which alkali serves as catalyst (alkoxylation). Reactions are carried out between room temperature and 110 °C. Following reaction, cellulose ethers in solid fiber form (by virtue of being suspended in a small polar solvent such as isopropanol) are washed with aqueous alcohol, dried, and powdered by granulation (◉ *Fig. 23*).

Specific products include the following:

Carboxylmethyl cellulose (◉ *Scheme 1*) is produced in many grades by many manufacturers owing to its various end use applications as well as simple reaction protocol. CMC is used in detergents, paper coatings, drilling mud additives in oil well drilling, cosmetics and pharmaceuticals (as fat free ointments for example) and in food products (soups, ketchups, etc.).



◘ Scheme 1
Structural scheme of carboxymethyl cellulose

Methyl cellulose and *hydroxyalky methyl cellulose* manufacture involves in part Williamson synthesis with methyl chloride and alkoxylation. The various ethers are used primarily in building materials and in industrial applications (◉ *Table 13*). Higher grades with greater purities consist of modified vegetable gums, and they find uses in controlled release applications in pharmaceuticals, and in food products and cosmetics where they serve as emulsifiers and texture agents.

Hydroxyethyl cellulose (◉ *Fig. 24*) is a nonflocculating, nonionic cellulose ether that has side chain extensions expressed in MS/DS-ratios of about 1.5 to 3.5. HECs are used in latex paints owing to their excellent interaction ability with solids.

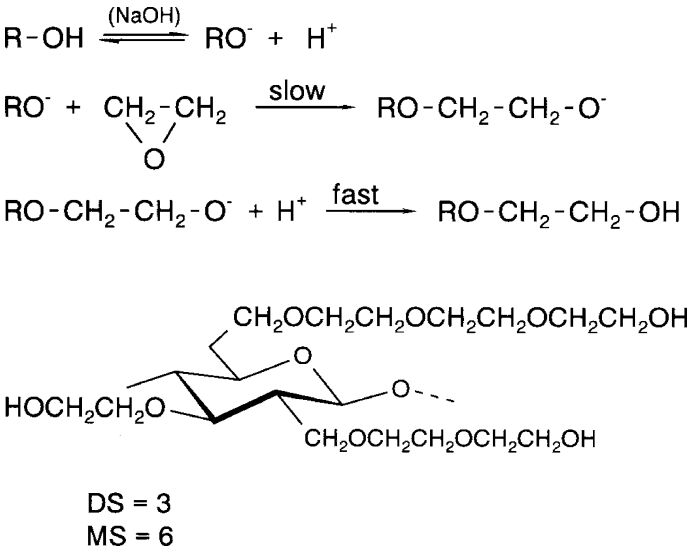


Figure 24
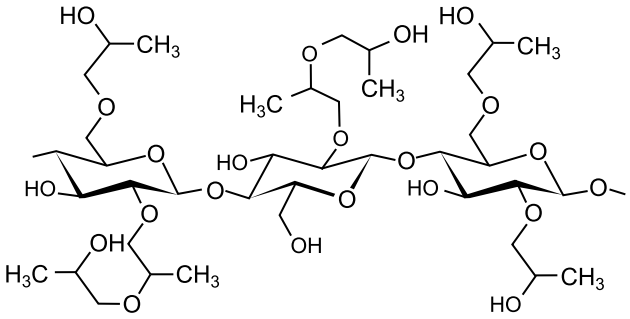
Reaction and chemical structure of hydroxyethyl cellulose with a (hypothetical) DS of 3 and an MS of 6 (for illustration of DS and MS, only). Commercial HEC products have an MS between 1.8 and 3.5. (From Klemm et al., [18])



Scheme 2
Structural scheme of hydroxypropyl cellulose

Hydroxypropyl cellulose (Scheme 2) may either be swellable in water or may dissolve, and it is thermoplastic. HPC is used in the pharmaceutical industry and in cosmetics. It coagulates at temperatures above around 40 to 50 °C. It forms liquid crystalline solutions.

7 Conclusions

Plant polysaccharides are highly energy-efficient polymers serving nature in three vital capacities: energy storage, structural support, and water management. Plants control functional char-

acteristics via molecular structures. Whereas cellulose is a highly regular, organized molecule giving rise to a variety of crystalline formations, heteropolysaccharides ("hemicelluloses") gain their energy-release and gel-formation (i. e., rheological) function by careful control of irregularity. The abundant availability of cellulose has invited industrial efforts to modify functions via chemical derivatization. Cellulose derivatives are available that are thermoplastically processible as well as water-soluble. Numerous chemical modification strategies are available for tailoring mechanical, thermal, and solubility characteristics to desired end-uses.

Abstract

In the context of carbohydrates, gums are usually considered to be non-starch, water-soluble polysaccharides with commercial importance. When used as ingredients in processed foods, they may be called hydrocolloids. Gums are used because of the functionalities they impart to whatever system or product into which they are incorporated. As with other polymers, their chemical structures, together with the nature of the aqueous environment surrounding the molecules (pH, types and concentrations of salts or other solutes, temperature, shear, etc.) determines the shapes of the molecules; the chemical nature and shapes of the molecules determines the gum's physiochemical properties, and their physicochemical properties determines their functionalities. All gums have one similar property, i. e., the ability to thicken water and aqueous systems, but they may impart different rheological properties to the systems they thicken. Certain gums provide certain functionalities better than do other gums.

Keywords

Gums; Hydrocolloids

Abbreviations

CMC	carboxymethylcellulose
Gal	D-galactosyl units
β**Glc*p***	β-D-glucopyranosyl units
β**Glc*p*A**	β-D-glucuronopyranosyl units
α**LGul*p*A**	α-L-guluronopyranosyl units
HEC	hydroxyethylcellulose
HM	high-methoxyl
HPMC	hydroxypropylmethylcellulose
LBG	locust bean (carob) gum
LM	low-methoxyl
Man	D-mannosyl units
β**Man*p***	β-D-mannopyranosyl units
β**Man*p*A**	β-D-mannuronopyranosyl units
MC	methylcellulose
MW	molecular weight
NSP	non-starch polysaccharides
PES	processed Euchema seaweed
PGA	propylene glycol alginate
PNG	Philippine natural grade
α**LRha*p***	α-L-rhamnopyranosyl units

1 Introduction

There is no chemical category of gums (or mucilages, a term once used to describe substances that produce slimy or tacky aqueous dispersions, which are properties manifested by many types of water-soluble plant, animal, and microbial polysaccharides, including starches and modified starches). The term gum is an umbrella term common to several different fields with different definitions in each field. As applied to water-soluble substances, it refers to water-soluble, non-starch polysaccharides (NSP), both those that are natural and those that are made from natural NSP by structural modification. In general, they have the ability to produce highly viscous aqueous solutions at low concentrations, but there are exceptions to this principal. Gum arabic and "low viscosity grades" of certain gums are the most notable exceptions; they require rather high concentrations to produce highly viscous aqueous solutions. The starch polysaccharides (amylose and amylopectin), although they and their derivatives are water-soluble, are not considered to be gums, but rather starches are put in a separate category. Those water-soluble polysaccharides (other than those from starches) that are used industrially are often called industrial gums. A few years ago, some in the food industry developed an aversion to referring to food ingredients as gums and started calling food gums hydrocolloids, even though many of them have gum in their name, so names such as guar gum appear on the ingredient

labels of food products. The term hydrocolloid is appropriate because many gums, at least those of higher molecular weights, do not form true solutions. Rather, they form dispersions of hydrated polymer molecules whose particle sizes are in the colloid range. The hydrocolloid category may also include proteins used as food ingredients, especially gelatin, which like the carbohydrate polymer hydrocolloids, is used as a stabilizer in foods. The terms gum and hydrocolloid generally imply commercial importance, as there is nothing else that distinguishes them from many other water-soluble polysaccharides; but again, this is not always true. There are water-soluble polysaccharides that have gum in their name, e. g., corn fiber gum, but are not produced and sold as commodities. There are others that are not produced as isolated substances but are useful as part of the natural matrix in which they occur; examples are the β-glucan known as oat gum and psyllium seed gum. Still, others, such as the arabinoxylans of wheat flour, have a considerable impact on the system (dough) in which the flour is used, but the material (in this case the flour) is used because it contains starch and gluten, not because it contains water-soluble NSP. Yet others, like the aloe polysaccharides, while commercially useful, are probably not thought of as gums. This chapter presents a brief synopsis of those gums/hydrocolloids used in food and/or non-food applications. Additional information can be found elsewhere. An elementary presentation can be found in reference [1]. More in depth presentations are available in references [2,3,4,5,6,7,8,9,10,11,12,13].

2 Classification

It is usually helpful for discussions of the properties of substances, to classify them. However, there is no especially useful way to classify gums [14]. They are usually classified according to source, but that is not useful, even as an indication of relative cost, except that those from bacterial sources, i. e., produced by fermentation processes, are more expensive on a per unit weight basis. But even that can be misleading because it is not the cost per unit weight, but the cost of the amount required to give the desired functionality that should be compared; for at least in some cases, gums can be interchanged. Gum sources are algae, higher plants, microorgan-

Table 1
Sources of common gums

Source		Gums
Marine algae		Agars, alginates, carrageenans, furcellaran
Higher plants	Extracts	Larch arabinogalactan, pectins
	Seeds	Guar gum, locust bean (carob) gum, tara gum
	Tubers and roots	Inulin, konjac glucomannans
	Exudates	Gum arabics
Microorganisms		Curdlan, dextrans, gellans, xanthans
Cellulosics (by chemical modification)		Carboxymethylhydroxyethylcelluloses, cetylhydroxyethylcelluloses, ethylhydroxyethylcelluloses, hydroxyethylcelluloses, hydroxyethylmethylcelluloses, hydroxypropylcelluloses, hydroxypropylmethylcelluloses, methylcelluloses

isms, and derivatives of cellulose (◉ *Table 1*). (There is one synthetic water-soluble polymer, polydextrose, made by reacting D-glucose and sorbitol in the presence of citric acid, that has the properties, of a low-viscosity gum, but which is not usually considered to be a gum.) There have been attempts to classify food gums as to whether they are used as thickeners and stabilizers or to form gels, but there is overlap in these properties. In fact, no classification system is effective because of the multiple properties of most gums. It would probably be most desirable to classify gums based on their structures (◉ *Table 2*). But here again, there are difficulties with a classification system based on structure for two reasons: (a) in one sense, most gums have similar structures; (b) in another sense, in most cases the structure of a given gum is sufficiently unique that it needs to be placed in a category by itself. Most of the commercially important hydrocolloids/industrial gums are linear polymer molecules with short side groups that either occur naturally or are introduced by chemical derivatization. When they occur naturally, they may be either saccharide units or functional groups (most often an organic or inorganic ester group). Ester and ether derivatives can be made chemically. Whether the side group is a saccharide unit or an ester or ether group, such groups are called "side chains", even though the longest is a trisaccharide unit. Exceptions to this general structure of linear polymers with short side chains are gum arabic, which has a highly branched, branch-on-branch structure, and curdlan, which is an unsubstituted linear molecule. Gellan and konjac mannan may be deacylated to give mostly unsubstituted linear molecules. Most, if not all, linear polysaccharides exist in some sort of helical shape.

All polysaccharide gum preparations are polydisperse, i. e., they contain populations of molecules with a range of molecular weights. All algal and higher plant polysaccharides are polymolecular, i. e., the fine structures of the molecules vary from molecule to molecule. (There are a few exceptions, most notably cellulose in this context. Cellulose molecules are composed of a single type of monomer unit joined by a single type of linkage (◉ Chap. 6.3), so there is no opportunity for variation in chemical structure.) Bacterial polysaccharides/gums (curdlan, gellans, xanthans) have constant repeating-unit structures, but they can have some degree of polymolecularity due to differences in attached ester (gellans, xanthans) and/or cyclical acetal (xanthans) groups. Bacterial polysaccharide preparations can also differ from each other depending on the strain of the organism and the culture conditions (medium, temperature, etc.) used to produce them. Therefore, only statistical structures can be determined and presented for the gums discussed here. Details of structures can be found elsewhere. This chapter emphasizes the characteristics of the principal polysaccharides called gums that place them in that category of substances, but the presentation is cursory.

◘ Table 2
General structures of some common gums

Overall structure	Gums
Linear, unbranched molecules	Alginates, carrageenans, curdlan, inulin, pectins
Linear molecules with short branches (side chains)	Gellans, guar gum, konjac, glucomannans, larch arabinogalactan, locust bean (carob) gum, tara gum, xanthans, all cellulosics
Branch-on-branch (bush-like) molecules	Gum arabics

3 General Properties

This section outlines the general properties of gums. Each gum has unique properties; those will be discussed under the discussion of that particular gum.

Gums are available as dry powders. Because polysaccharides possess a strong affinity for water and hydrate readily, gum particles take up water, swell, and usually undergo partial or complete dissolution when they are added to an aqueous system. As alluded to, a common property of gums is their ability to gel and/or thicken aqueous systems, but the rheological properties of the gels and/or viscous solutions made with gums varies with the gum used, its viscosity grade, its concentration, other components of the system, and temperature. The systems into which they are incorporated become viscoelastic. Another general property of gums, therefore, is their ability to change the flow properties of liquid products and the deformation properties of semisolid products, even though they are usually used in low concentrations (<0.5%), indicating their great ability to produce viscosity and/or to form gels [15,16,17,18,19,20,21]. The increase in viscosity with an increase in concentration of a gum is not linear, except at maybe very low concentrations. Rather viscosity increases geometrically with increases in gum concentration.

A common property of gums that form gels is their ability to form junction zones, either by themselves or in combination with another water-soluble polymer (polysaccharide or protein). A junction zone is an association of two or more polymer molecules over a portion of their lengths. The molecules can be held together in a junction zone by hydrogen bonding, ionic cross-bridges, or hydrophobic associations. When gum molecules form intermolecular associations with other polymer molecules over more than one portion of their lengths, a three-dimensional network entrapping water and whatever is dissolved in it, i. e., a gel, is formed.

In order to thicken or gel aqueous systems, gums must be soluble, which is why that is part of their definition. They are water-soluble because they are polyhydroxy substances. As a result, another common property is their ability to bind and hold water (to different degrees). Yet another common property, and a property of all polysaccharides, is their susceptibility to acid- and enzyme-catalyzed hydrolysis (to varying degrees). The extent of hydrolysis of their glycosidic linkages, i. e., the extent of depolymerization, in an acidic environment is a function of the structure of the polysaccharide (its monomer units and the types of linkages), acid concentration (pH), temperature, and time at that temperature and pH. Gums, like other polysaccharides, are also subject to enzyme-catalyzed hydrolysis. This process is controlled by the specificity of the enzyme, pH, temperature, time, and the presence of any required co-factors, such as metal ions. Required enzymes usually come from bacterial or fungal sources, but some may be of plant origin. They are generally specific for a gum or, in a few cases, the polysaccharides in a family of closely related gums such as the galactomannans.

Not to be forgotten aspects of gums are the facts that they are abundant and obtained from a variety of replenishable sources. They are obtained from marine algae (seaweeds), higher plants (as extracts and exudates), microorganisms (via fermentation), and from cellulose (from forest products) (❯ *Table 1*). They are amenable to chemical and biochemical modification via reactions of their hydroxyl groups and hydrolysis of their glycosidic linkages. They have a variety of structures (❯ *Table 2*). They are non-toxic and biodegradable. As mentioned, the terms gum and hydrocolloid usually, but not always, imply commercial importance. Some applications of gums are given in ❯ *Table 3*.

Table 3
Some applications of gums

Product category in which gums are used	Examples
Construction Materials	In tape joint compounds; in gypsum spray plaster; in ceramic tile adhesives, grouts, and mortars; in cement mortars, stuccos, and plasters; in concrete; as wallpaper adhesive; as a ceramic processing aid; as a thickener for latex paint
Consumer products	As absorbents, as binders, in detergents to encapsulate
Food products	As thickeners, to provide specific rheology, to form gels, to inhibit syneresis, to stabilize emulsions, to stabilize suspensions, to emulsify, to bind/hold water, to form films and coatings, to inhibit crystallization, to improve texture/mouthfeel, as processing aids, as whipping agents, to stabilize foams, as extrusion aids, as binders, to stabilize proteins, to encapsulate, to flocculate
Health care, medical, and pharmaceutical applications	In controlled-release products; as tablet and capsule binders, tablet and capsule excipients, wound healing materials, and blood volume expanders; and for constipation and diarrhea treatment
Mining operations	As flotation agents and suppressants
Personal care and cosmetic products	In hand lotions (as emollients/demulcents), in toothpaste, in cosmetics, in shampoo and hair conditioning formulations
Petroleum production	In drilling muds, cementing fluids, hydraulic fracturing fluids, workover fluids, completion fluids, pipeline cleaning fluids, and enhanced recovery fluids
Textiles	In printing pastes, as a warp size
Other	In suspension polymerization, as binders for fertilizers and pesticides, in tire sealants, in de-icing fluids

4 Specific Gums

4.1 Xanthans

Xanthan [22,23,24,25,26,27,28], known commercially as xanthan gum, is a high-molecular-weight bacterial polysaccharide produced in fermentation vats by the microorganism *Xanthomonas campestris*. It is a non-gelling polysaccharide that imparts unique rheological properties to its solutions. It is a linear polymer with a backbone structure identical to that of cellulose (*Sect. 4.3*). On every other D-glucopyranosyl unit of its main-chain backbone is a trisaccharide unit containing, from the reducing end outward, an α-D-mannopyranosyl 6-acetate unit, a β-D-glucuronopyranosyl unit, and a β-D-mannopyranosyl unit at the non-reducing end. Some of the non-reducing end units are terminated with a 4,6-*O*-pyruvyl cyclic acetal group. Xanthan molecules have the shape of a five-fold helix, rather than the two-fold helical shape of cellulose. They often are in the form of double helices and bundles of double helices. Xanthan undergoes a conformational transition as the properties of the solvent are altered. An ordered helical conformation is stabilized by high ionic strength and/or low temperature. Determined average MW values for xanthan range from 3×10^5 to 7.5×10^6 or greater, an indication of the ability of xanthan molecules to aggregate.

Xanthan molecules behave as rather rigid, linear molecules, and the stiffness of its molecules gives it unique properties. The actual properties of xanthan preparations can vary with the strain of the organism used and the conditions of fermentation, so not all xanthan products are identical. In addition, xanthan preparations are available in the following types: different particle sizes, different viscosity grades, transparent (clear-solution) types (devoid of the usual inactivated bacterial cells), salt/brine-tolerant types, easily dispersible types, rapidly hydrating types, delayed-hydrating types, smooth-flow types (reduced pseudoplasticity), types with greater suspending power, dust-free types (granular mesh), and cellulase-free types.

Xanthan forms the most pseudoplastic (instantaneous, reversible shear thinning) solutions of all the gums. This property is due to the stiffness of its molecules and/or intermolecular associations of two or more molecules. In plots of viscosity vs. concentration, there is a Newtonian (non-pseudoplastic) plateau at very low shear rates, which at least, makes its solutions appear to have a yield value (a yield value being the force required to initiate flow). As a result, xanthan is an excellent stabilizer for suspensions and emulsions.

The viscosities of solutions of xanthan, unlike those of all other water-soluble polymers, do not decrease as the temperature is raised. They are unaffected by temperature between 0 °C and 100 °C. And even though it is an anionic polymer, its solution viscosity is not affected by pH or most salts, i. e., although ionic, it behaves as if it were a neutral gum. Xanthan interacts synergistically with guar gum and locust bean gum (both galactomannans) (*Sect. 4.2*). An increase in solution viscosity results from its interaction with guar gum. Heat-reversible gelation results from its interaction with locust bean gum.

4.2 Galactomannans

Commercial gums that are in the galactomannan family of polysacharrides are guar gum, locust bean (carob) gum, and tara gum [29,30,31,32,33,34]. All are linear polymers with single-unit branches. The backbone chain of all three gums is composed of (1→4)-linked β-D-manopyranosyl units, a structure identical to that of cellulose, with the exception of the configuration of C2 of the monomeric units. A mannan of this type is highly crystalline and even more insoluble than is cellulose, but the branch units on the galactomannans give the gums water solubility. The branch units are α-D-galactopyranosyl units attached to *O*-6 positions of main-chain β-D-mannopyranosyl units. The differences between the different galactomannans are in the percentages and distributions of the branch units. The polysaccharide of guar gum (guaran) has a Gal : Man ratio of ~0.49–0.67 : 1 and a somewhat random distribution of the side units. The galactomannan of locust bean gum (LBG) has fewer branch units (Gal : Man = ~0.19–0.35 : 1) and a clustered arrangement of the branch units. Locust bean gum has stretches of ~80 unsubstituted D-mannopyranosyl units alternating with sections of ~50 units in which most of the main-chain units have an α-D-galactopyranosyl side-chain unit glycosidically attached to their *O*-6 positions. Because of the difference in structures, guar gum and LBG have somewhat different physical properties, even though both are galactomannans and are composed of long, somewhat rigid chains that provide high solution viscosity. (Reported average MW values for guaran are $1–2 \times 10^6$ and for the polysaccharide of LBG $3–4 \times 10^5$.) Because guaran has its galactosyl units fairly evenly placed along the chain, there are few locations on the chains that are suitable for intermolecular associations. However,

molecules of LBG, with their stretches of unsubstituted backbone units, can hydrogen bond with each other. This structural difference makes locust bean gum less soluble than is guar gum. Guar gum is rather soluble in cold water, but heating of dispersions of LBG in water to a temperature of at least 80 °C is required for its complete dissolution.

The unsubstituted backbone stretches of LBG can also hydrogen bond to xanthan (◉ *Sect. 4.1*) and κ-Carrageenan (◉ *Sect. 4.8*) helices, producing a three-dimensional network and forming rigid gels. In the case of xanthan and LBG, neither forms gels by itself, but their combination can result in rigid gels. Rigid gels can also be formed by the LBG-κ-carrageenan combination. (κ-Carrageenan itself is a gel-forming gum.)

Tara gum is used in much less quantities than are the other two galactomannans. Its structure is intermediate between those of the other two galactomannans with a Gal : Man ratio of ~0.33 : 1 (closer to that of LBG than to that of guar gum). Fenugreek galactomannan has a Gal : Man ratio of ~1 : 1. There are also other galactomannans, such as those of species of *Cassia*, *Crotalaria*, *Indigofera*, and *Sesbania* (all of the Leguminosae family), some of which find commercial use, primarily in India.

In no case is one of these galactomannans available and used as a pure polysaccharide. Rather they are the ground endosperm of the seeds of the plant from which they are obtained. As a result, the commercial gums also contain fiber, protein, ash, and other constituents. As already indicated, the polysaccharide present in guar gum is called guaran. Chemical names have not been given to the other galactomannans.

Guar gum is derivatized to modify its properties and functionalities. Available derivatives include the hydroxypropyl ether, the carboxymethyl ether, a cationic ether, a mixed hydroxypropyl cationic ether, the phosphate ester, and a mixed phosphate ester and cationic ether (amphoteric product).

4.3 Derivatives of Cellulose

Cellulose (◉ Chap. 6.1 and ◉ Chap. 6.3) is a high-molecular-weight, linear, insoluble polymer of repeating β-D-glucopyranosyl units in the $^4C_1$ conformation joined by (1→4) glycosidic linkages. The (1→4) linkages joining the β-D-glucopyranosyl units of cellulose molecules are equatorial → equatorial linkages, which gives the molecules a flat, ribbon-like structure in which each glucopyranosyl unit in the chain is turned upside down as compared to the units preceding and following it. This flat, linear structure enables cellulose molecules to associate with each other via hydrogen bonding over extended regions, forming polycrystalline, fibrous bundles. Crystalline regions are separated by amorphous regions. Cellulose is insoluble because, in order for it to dissolve, most of its multitude of hydrogen bonds would have to be released at once. Cellulose can, however, through derivatization, be converted into water-soluble gums. All cellulose derivatives that are gums are linear polymer molecules with chemically introduced ether groups as side units. Commercial cellulose derivatives are only partially etherified.

To make water-soluble derivatives of cellulose, purified wood pulp or cotton linters are treated with a solution of sodium hydroxide (18%) to produce the alkoxy form of cellulose, called alkali cellulose. In alkali cellulose, some of the hydroxyl groups exist as $-O^-$ and some as –OH. The alkali cellulose is nucleophilic and is reacted with a reagent containing a leaving

group to produce an ether linkage [35,36,37,38,39,40,41,42,43,44]. Detailed structural analyses (relative derivatization of O2, O3, and O6 and average distribution of substituent ether groups along the polymer chain) have been carried out for some cellulose derivatives.

4.3.1 Neutral Cellulose Derivatives

The primary neutral, water-soluble cellulose derivatives are hydroxyethylcelluloses (HEC), methylcelluloses (MC), and hydroxypropylmethylcelluloses (HPMC). To introduce hydroxyethyl ether groups (–O–CH_2–CH_2–OH), alkali cellulose is reacted with ethylene oxide. To introduce hydroxypropyl ether groups (–O–CH_2–CH_2OH–CH_3), alkali cellulose is reacted with propylene oxide. To introduce methyl ether groups (–O–CH_3), alkali cellulose is reacted with methyl chloride. Other water-soluble, neutral gums made commercially from cellulose are cetylhydroxyethylcelluloses, ethylhydroxyethylcelluloses, hydroxyethylmethylcelluloses, and hydroxypropylcelluloses. All cellulose derivatives are families of products. Different products within each family can be made by varying the amount of derivatization (with each group if products are doubly substituted), the order of reagent addition if two reagents are used, the regularity of distribution of substituent groups, average molecular weights of products (giving different viscosity grades), and the physical nature of the products. All products in these families of products are water soluble to different degrees. They are soluble because the ether group protrusions along the polymer chains prevent the intermolecular associations characteristic of native cellulose. While a few added ether groups spread along the chains enhance water solubility, they also decrease chain hydration by replacing water-binding hydroxyl groups with less polar ether groups, hydroxyethylcelluloses being the least affected. In products like the methylcelluloses and hydroxypropylmethylcelluloses, the ether groups restrict hydration of the chains to the point that they are on the borderline of water solubility. When aqueous solutions of these products are heated, the water molecules hydrating the polymer dissociate from the chain and hydration is decreased sufficiently that intermolecular associations increase (probably via van der Waals interactions) and gelation occurs. Lowering the temperature of the gel allows the molecules to rehydrate and redissolve, so the thermogelation is reversible. Because of non-polar groups, MC, HPMC, hydroxypropylcelluloses, cetylhydroxyethylcelluloses, ethylhydroxyethylcelluloses, and hydroxyethylmethylcelluloses are somewhat surface active and absorb at air–water and oil–water interfaces.

4.3.2 Anionic Cellulose Derivatives

The only anionic group added to cellulose is the carboxymethyl (–O–CH_2–CO_2^-) ether group. To introduce the carboxymethyl group, alkali cellulose is reacted with chloroacetic acid. (The carboxymethyl ether is also the ether of glycolic acid.) Also prepared commercially is carboxymethylhydroxyethylcellulose.

The ionic charge on the molecules makes them hydrate and dissolve rapidly. Electrostatic repulsion of the carboxylate groups causes the molecules of carboxymethylcellulose (CMC) and its hydroxyethyl ether derivative to repel each other and to be somewhat extended. As a result, solutions of CMC tend to be both highly viscous and stable.

Different products can be made by manipulating the same variables listed for the neutral cellulose derivatives.

4.4 Alginates

Alginates (algins) are polysaccharides extracted from brown marine algae [45,46,47,48,49,50]. They are salts (most often the sodium salt) of poly(uronic acids). As a result, they have a carboxylate group on every monomer unit of their structures. They are composed of two monomer units: β-D-mannuronopyranosyl units (βMan*p*A) and α-L-guluronopyranosyl units (αLGul*p*A), both linked (1→4). The αLGul*p*A : βMan*p*A ratio in alginates from different seaweed sources ranges from ~0.5 : 1.0 to ~2.5 : 1.0.

The monomer units in alginates are arranged so as to give the molecules a block copolymer structure. In an alginate polymer, there are stretches of only βMan*p*A units, stretches of only αLGul*p*A units, and stretches where the two monomer units alternate. Segments containing only βMan*p*A units, because the units are in the $^4C_1$ conformation and joined in (1→4) equatorial-equatorial linkages, are flat and ribbon-like. Segments containing only αLGul*p*A units, because the units are in the $^1C_4$ conformation and joined by (1→4) axial-axial linkages, have a pleated (corrugated) structure. Different percentages of the different block segments cause alginates from different seaweed sources (harvested in different regions of the world) to have different properties.

Solutions of sodium alginates are highly viscous. The calcium salt of alginates is insoluble. Insolubility results from interactions between calcium ions and the poly(αLGulA) regions of molecules. Calcium ions bind together stretches of poly(αLGulA) segments to form what is known as a junction zone. The result is a three-dimensional polymer network and a gel. The strength of the gel depends on the content of poly(αLGulA) regions in the alginate used and the concentration of calcium ions. Alginates with a greater content of poly(αLGulA) regions produce gels of higher strength.

The free carboxylic acid form of the polymer is alginic acid. Reaction of alginic acid with propylene oxide produces the propylene glycol ester. Commercial propylene glycol alginates are partial esters (50–85% of the carboxyl groups esterified). Solutions of propylene glycol alginates (PGA) are much less sensitive to low pH and polyvalent cations, including calcium ions, than are solutions of non-esterified alginates, because the esterified carboxyl groups cannot ionize. Also, the propylene glycol group introduces a protrusion that prevents the close association of chains. Therefore, PGA solutions are stable. The somewhat hydrophobic propylene glycol groups also give the molecule mild interfacial activity, i. e., foaming, emulsifying, and emulsion-stabilizing properties. Propylene glycol alginate is used when stability to acid, non-reactivity with calcium ions, or its surface activity is desired.

4.5 Pectins

Commercial pectins are partially esterified (methyl ester) polymers composed primarily of α-D-galacturonopyranosyl units linked (1→4) [51,52,53,54,55,56,57,58,59]. The native molecules present in the cell walls and intercellular layers of all land plants (Chap. 6.1), from which commercial pectins are obtained, are more complex molecules that are converted into the partially methyl esterified poly(α-D-galactopyranosyluronic acids) during extraction with acid. Commercial pectin is obtained from citrus peel and apple pomace. Generally, the highest quality pectin is obtained from lemon and lime peel.

The compositions and properties of pectins vary with source, the processes used during preparation, and any subsequent treatments. During extraction with mild acid, some hydrolytic depolymerization and hydrolysis of methyl ester groups occurs. The term pectin denotes a family of compounds. The term pectin is usually used in a generic sense to designate those water-soluble poly(galacturonoglycan) preparations of varying methyl ester contents and degrees of neutralization that are capable of forming gels. (Pectins produce little viscosity and, while they find some use as milk protein stabilizers, are not used as thickeners.) In all natural pectins, some of the carboxyl groups are in the methyl ester form. Depending on the manufacturing conditions, the remaining free carboxylic acid groups may be partly or fully neutralized, i. e., partly or fully present as sodium, potassium, or ammonium carboxylate groups. Typically, they are present in the sodium salt form.

By definition, preparations in which more than 50% of the carboxyl groups are in the methyl ester form ($-COOCH_3$) are classified as high-methoxyl (HM) pectins; the remainder of the carboxyl groups will be present as a mixture of free acid (–COOH) and salt (e. g., $-COO^-Na^+$) forms. Preparations in which less than 50% of the carboxyl groups are in the methyl ester form are called low-methoxyl (LM) pectins. Treatment of a pectin preparation with ammonia (often dissolved in methanol) converts some of the methyl ester groups into carboxamide ($-CONH_2$) groups (15–25%). In the process, a low-methoxyl (LM) pectin (by definition) is formed. These products are known as amidated LM pectins.

The principal and key feature of all pectin molecules is a linear chain of (1→4)-linked α-D-galactopyranosyluronic acid units. Neutral sugars, primarily L-rhamnosyl units, are also present. In citrus and apple pectins, the α-L-rhamnopyranosyl units are inserted into the polysaccharide chain at rather regular intervals. The inserted rhamnopyranosyl units may provide the necessary irregularities in the structure required to limit the size of the junction zones and effect gelation (as opposed to precipitation/complete insolubility). At least some pectins contain covalently attached, highly branched arabinogalactan chains and/or short side chains composed of D-xylosyl units. The presence of side chains may also be a factor that limits the extent of chain association. Pectins from some sources, such as sunflower heads, have acetate ester groups at O2 of the main-chain monomer units. These acetyl units hinder intermolecular associations and gel formation.

Junction zones are, therefore, formed between regular, unsubstituted pectin chains when the negative charges on the carboxylate groups are removed (addition of acid), hydration of the molecules is reduced (by addition of a cosolute, almost always sugar, to a solution of HM-pectin), and/or when polymer chains are bridged by calcium ions.

HM pectin solutions gel when sufficient acid and sugar is present. As the pH of a pectin solution is lowered, the highly hydrated and charged carboxylate groups are converted into uncharged, only slightly hydrated, carboxylic acid groups. As a result of losing some of their charge and hydration, the polymer molecules can now associate over a portion of their length, forming junction zones and a network of polymer chains that entraps the aqueous solution of solute molecules. Junction zone formation is assisted by the presence of a high concentration (~65%, at least 55%) of soluble solids (most often sugar), which competes with the pectin molecules for the water molecules and reduces hydration of the chains, allowing them to interact with one another.

LM pectin solutions gel only in the presence of divalent cations (only calcium ion is used in food applications, and almost all pectin is used as a food ingredient) which crosslink the poly-

mer chains. Increasing the concentration of divalent cations increases the gelling temperature and gel strength.

4.6 Gellans

Gellan [26,28,60,61,62,63], known commercially as gellan gum, is an extracellular, anionic polysaccharide produced by the bacterium *Sphingomonas elodea*, making it a fermentation gum. The gellan molecule is linear and is composed of β-D-glucopyranosyl, β-D-glucuronopyranosyl, and α-L-rhamnopyranosyl units in a molar ratio of 2:1:1. Native gellan (also called high-acyl gellan) contains two ester groups, an acetyl group at O6 and a glyceryl group at O2, on one of the two (the same) β-D-glucuronopyranosyl units. On average, there is one glycerate ester group per tetrasaccharide repeat unit and one acetate ester group for every two repeat units.

Some gellan is de-esterified by treatment with alkali. Removal of the acyl groups has a dramatic effect on the properties of the gel produced. The de-esterified form is known as low-acyl gellan. Its tetrasaccharide repeat unit structure is $\rightarrow$4)-αLRha*p*-(1$\rightarrow$3)- βGlc*p*-(1$\rightarrow$4)-βGlc*p*A-(1$\rightarrow$4)- βGlc*p*-(1$\rightarrow$, so one out of four monomer units is a uronic acid unit. Both high- and low-acyl gellans have average molecular weights of $1–2 \times 10^6$.

Three basic forms of gum are available: high-acyl (native), low-acyl clarified, and low-acyl unclarified. Blending of high- and low-acyl types results in products with intermediate properties.

Gellan can gel aqueous systems. It forms gels with both monovalent and divalent cations, divalent cations (Ca^{2+}) being about 10 times more effective. Gels can be formed with as little as 0.05% gum (99.95% water). Gelation is often effected by cooling a hot solution containing the required cation. Shearing during cooling of a hot gellan solution prevents the normal gelation mechanism from occurring and produces a smooth, homogeneous, thixotropic fluid (a pourable gel) that stabilizes emulsions and suspensions very effectively because of its high yield value. Gentle agitation of a weak gellan gel will also disrupt the gel structure and turn the gel into a smooth, pourable, thixotropic fluid with excellent emulsion and suspension stabilizing properties.

The low-acyl types of gellan form firm, brittle, non-elastic gels (with textures similar to those of gels made with agar and κ-carrageenan) (➤ *Sect. 4.8*). The high-acyl (native) type forms soft, elastic, non-brittle gels (with textures similar to those made with mixtures of xanthan and locust bean gum) (➤ *Sect. 4.1* and ➤ *Sect. 4.2*). A range of intermediate gel textures can be achieved by mixing the two basic types of gellan.

4.7 Gum Arabic

Gum arabic, also known as gum acacia [64,65,66], is another gum that is ionic because of the presence of uronic acid units. The structure of the most important polysaccharide of gum arabic is that of a highly branched, branch-on-branch (bushlike), anionic polymer that is attached to a polypeptide. The structure is not only complex, but variable. What is harvested as, and called, gum arabic is a heterogeneous material, but generally consists of two primary fractions. One, which accounts for about 70% of the gum, is composed of polysaccharide molecules with

little or no protein. The other fraction contains molecules of higher molecular weight that have protein as an integral part of their structures and is the functional component of gum arabic. The protein-polysaccharide fraction is itself heterogeneous with respect to protein content. The polysaccharide structures are covalently attached to the protein component via linkage to hydroxyproline and, perhaps, serine units, the two predominant amino acids in the polypeptide. The overall protein content is about 2 wt%, but fractions may contain as much as 25% protein. Some glycoprotein is also present.

Detailed analyses have been carried out on a number of gum arabic preparations. These analyses include composition, i. e., ratios of the various fractions, and structural analysis of the polysaccharide component. Both those polysaccharide components attached to protein molecules and those that are not are acidic arabinogalactans with the following approximate composition: D-galactose, 44%; L-arabinose, 24%; D-glucuronic acid, 14.5%; L-rhamnose, 13%; 4-*O*-methyl-D-glucuronic acid, 1.5%. They contain chains of (1→3)-linked β-D-galactopyranosyl units having two- to four-unit side chains consisting of (1→3)-linked β-D-galactopyranosyl units joined by (1→6)-linkages. Both the main chain and the numerous side chains have attached α-L-arabinofuranosyl, α-L-rhamnopyranosyl, β-D-glucuronopyranosyl, and 4-*O*-methyl-β-D-glucuronopyranosyl units. The uronic units occur most often as non-reducing end-units.

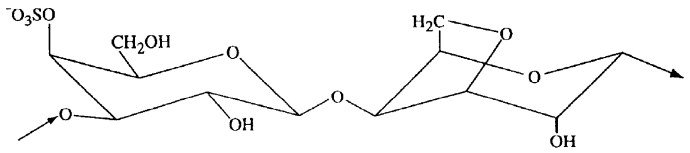
The unique structure of gum arabic, i. e., the anionic, highly branched, very compact structure of its polysaccharide component and its multiple attachments to a hydrophobic polypeptide, give it unique properties. Among its unique properties is the fact that even though it has a very high molecular weight, high concentrations in water produce only low viscosity; 40% concentrations are about as viscous as a thin sugar syrup, and solutions of 50% concentration can be made. So gum arabic is used for its properties other than thickening aqueous systems. It is used for its interfacial activity and for its compatibility with high concentrations of soluble solids (sugar). It does form gels at concentrations greater than 50%.

Gum arabic is an exudate of acacia trees, of which there are many species distributed over tropical and subtropical regions. The most important growing area for species that give the best gum is in Sudan. Purified, spray-dried forms of gum arabic are commonly used.

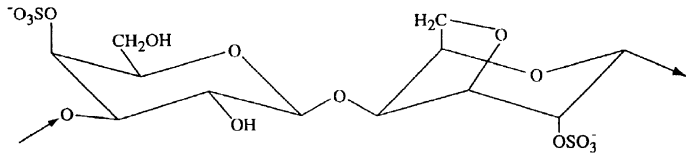
There are other exudate gums that were gums of commerce in ancient times and used up to about World War II that are used in only very small amounts today. They are gum karaya, gum ghatti, and gum tragacanth [64,65,66,67].

4.8 Carrageenans and Related Gums

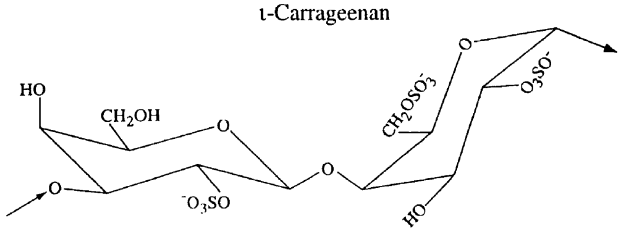
There is one large family of algal polysaccharides (the carrageenans and related polysaccharides [68,69,70,71,72,73]) that are acidic (anionic) because they contain sulfate half-ester groups. The term carrageenan denotes a group of sulfated galactans extracted from red marine algae (seaweeds) with dilute alkaline solutions. The sodium salt of a carrageenan is normally produced. Carrageenan polysaccharide molecules are linear chains of D-galactopyranosyl units joined by alternating (1→3)-α-D- and (1→4)-β-D-glycosidic linkages, with most sugar units having one or two sulfate half-ester groups esterified to O2 and/or O6. Their sulfate contents range from 15 to 40%. Units often contain a 3,6-anhydro ring. The principal structures are termed kappa (κ), iota (ι), and lambda (λ) carrageenans (❯ *Fig. 1*). Carrageenans, as



κ-Carrageenan



ι-Carrageenan



λ-Carrageenan

Figure 1
The predominant repeating unit structures in the three basic types of carrageenan

extracted, are mixtures of non-homogeneous polysaccharides. The disaccharide units shown in Figure 1 represent the predominate building block of each type, but are not repeated throughout the entire chain. Commercial carrageenan products have average molecular weights in the range 10^5–10^6.

Carrageenan products, of which a large number are usually available from a single supplier for different specific applications, contain different proportions of the three main behavioral types (kappa, iota, and lambda) produced by starting with mixtures of red seaweed species. Other substances, such as potassium ions and sugar (for standardization), may be added to the obtained powder to produce the commercial product.

Carrageenan products dissolve in water to form highly viscous solutions. The viscosity is quite stable over a wide range of pH values because the sulfate half-ester groups are always ionized, even under strongly acidic conditions, giving the molecules a negative charge. However, carrageenans undergo rather facile depolymerization in hot acidic solutions.

Segments of molecules of κ- and ι-type carrageenans exist as double helices of parallel chains. In the presence of potassium or calcium ions, thermoreversible gels form upon cooling a hot solution containing double-helical segments. Gelation can occur in water at concentrations as low as 0.5%. When κ-type carrageenan solutions are cooled in the presence of potassium ions,

a stiff, brittle gel results. Potassium and calcium ions together produce a high gel strength. Gels made with κ-type carrageenans are the strongest of the carrageenan gels. These gels tend to synerese as junction zones within the structure grow in length.

Iota-type carrageenans are a little more soluble than are kappa-types, but again, only the sodium salt form is soluble in cold water. Iota types gel best with calcium ions. The resulting gel is soft and resilient, has good freeze-thaw stability, and does not synerese, presumably because ι-type carrageenans are more hydrophilic and form fewer junction zones than do κ-type carrageenans.

During cooling of hot solutions of κ- or ι-type carrageenans, gelation occurs because the linear molecules are unable to form continuous double helices due to the presence of structural irregularities. The linear helical portions then associate to form a three-dimensional network in the presence of the appropriate cation. All salts of lambda-type carrageenans are soluble and non-gelling.

Under conditions in which double-helical segments are present, carrageenan molecules, particularly those of the kappa type, form junction zones with the unsubstituted segments of LBG (*Sect. 4.2*) to produce rigid brittle gels. This gelation occurs at a concentration one-third that needed to form a pure κ-type carrageenan gel. The synergistic effect between a κ-type carrageenan and LBG produces gels with greater elasticity and gel strength, and with less syneresis than occurs with gels made with potassium kappa-carrageenate alone. This combination is often used in food products.

A useful property of carrageenans is their reactivity with proteins, particularly those of milk [74]. Kappa-type carrageenans complex with kappa-casein micelles of milk, forming a weak, thixotropic, pourable gel. The thickening effect of κ-type carrageenans in milk is 5–10 times greater than it is in water.

Carrageenans are most often used because of their ability to form gels. They will form gels with both milk and water. Mixtures of carrageenan types are used to provide a wide range of products that are standardized with various amounts of sucrose, glucose (dextrose), buffer salts, or gelling aids, such as potassium chloride. The available commercial products form a variety of gels: gels that are clear or turbid, rigid or elastic, tough or tender, heat-stable or thermally reversible, and do or do not undergo syneresis. Carrageenan gels do not require refrigeration because they do not melt at room temperature. They are freeze-thaw stable.

Also prepared and used is an alkali-modified seaweed flour that has been called processed Euchema seaweed (PES), Philippine natural grade (PNG) carrageenan, semi-refined carrageenan, and alternatively refined carrageenan [71]; but is now often called carrageenan like the extracted carrageenan. To prepare semi-refined carrageenan, a red seaweed (usually a *Euchema* sp.) is treated with a solution of potassium hydroxide. Because the potassium salts of the kappa types of carrageenans found in these seaweeds are insoluble, the carrageenan molecules are not solubilized and not extracted out. Primarily low-molecular-weight soluble components are removed from the seaweed fronds during this treatment. The remaining seaweed is dried and ground to a powder. Semi-refined carrageenan is, therefore, a composite material that contains not only the molecules of carrageenan that would be extracted with dilute sodium hydroxide, but also other cell-wall materials.

Carrageenans are used in food products and toothpaste. The two other gums, agar [75,76,77,78,79] and furcellaran (also called Danish agar) [80], are also extracted from red seaweeds. Agar, whose structure is somewhat different than those of the carrageenans and furcellaran, is pri-

marily used to make media for growing microorganisms, although some is used in foods. Small amounts of furcellaran are used in processed milk products.

4.9 Cationic Gums

There are no natural cationic gums. The one that comes closest is chitosan [81,82,83,84,85,86]. Chitosan is largely deacetylated chitin. Chitin (Chap. 6.1) is a linear polymer of (1→4)-linked 2-acetamido-2-deoxy-β-D-glucopyranosyl (*N*-acetyl-β-D-glucosaminyl) units, i. e., a structure like that of cellulose, but with an acetamido (–NH–CO–CH_3) group on C2 of the monomer units in place of the hydroxyl group of cellulose. Chitosan, which is mostly deacetylated, has more amino (–NH_2) groups than acetamido groups along the polymer molecule. Chitosan, which is primarily obtained from crab and lobster shells using a hot, concentrated solution of sodium hydroxide, is soluble only in acidic solutions which convert the amino group to the ammonium ion (–NH_3^+) form. Carboxymethylchitosan is amphoteric. Chitosan can also be obtained from the mycelia of certain fungi. Little chitosan is used commercially.
One cationic gum (cationic guar gum) is produced by etherfication with a cationic reagent, viz., 1-chloro-2-hydroxy-3-trimethylammoniumpropane. In an alkaline solution, the reagent is converted to 3-trimethylammoniumpropylene oxide, which reacts with the guar gum.

4.10 Fermentation Gums other than Xanthans and Gellans

Curdlan is a bacterial polysaccharide made by *Agrobacterium biovar* [87,88,89]. It is a linear (1→3)-β-glucan (MW ~73,000) that forms a triple helix. Curdlan is insoluble in cold water. When aqueous dispersions of curdlan are heated, two types of gels form. First curdlan dissolves. When the solution reaches 55–66 °C, then is cooled, a reversible gel forms. The gel melts when held at about 60 °C. When the thermoreversible gel is heated to a temperature above 80 °C, an irreversible gel forms. Heating to higher temperatures results in stronger irreversible gels. Transition temperatures are a function of concentration.
Dextrans [90,91] are a group of bacterial polysaccharides composed of α-D-glucopyranosyl units. Their linkages are mainly (1→6); they also contain (1→3) linkages as branch points. Native dextrans are usually of very high molecular weight (at least 10^7), but lower molecular weight types are commercially available. They are not used as thickeners or gel formers. They are used as blood volume expanders, to make beads (via crosslinking) for size-exclusion chromatography, to complex iron ions for animal nutrition supplements, in the preparation of X-ray film, and in the Bayer process for aluminum refining.
A polysaccharide with the commercial name Diutan is highly pseudoplastic and proposed for use as a rheology modifier in concretes, grouts, and mortars. Diutan has the same backbone structure as gellan, but has a disaccharide side unit [28].
Another polysaccharide also has the same backbone structure as gellan, but has a single monosaccharide side on the backbone [28]. It is known commercially as welan. Welan was originally proposed as a thickener for oil well drilling fluids. It is now used in de-icing fluids, as a pigment suspending agent for concrete, and as a tire sealant.
Pullulan [92] is produced in cultures of *Aureobasidium* sp., *A. pullulans* being primarily used. Its structure is that of α-maltotriosyl units linked (1→6); a few (~6.6%) α-maltotetraosyl units

are present. Depending on the bacterial strains used and the conditions or times of fermentation, molecular weights of from 10^3 to more than 10^6 can be obtained. Pullulan dissolves in water, forming stable, low-viscosity, non-gelling solutions. It is useful for preparing water-soluble films.

Succinoglycan [89] produced by a strain of *Alcaligenes faecalis* contains D-glucopyranosyl and D-galactopyranosyl units in a 7 : 1 molar ratio, succinic acid ester groups, and pyruvyl cylic acetal groups at the end of a tetrasaccharide side unit that is found on every fourth unit of the main chain. The β-D-glucopyranosyl units of the main chain are joined by (1→4) and (1→3) linkages in a 3 : 1 ratio, making it a mixed-linkage β-glucan. The side units are linked (1→6) to the main chain.

4.11 Other Plant Gums

There are other water-soluble polysaccharides that have some economic importance, but are generally not employed as isolated substances. Many are beneficial because of the physiological effects they produce upon consumption rather than the physical properties they impart to aqueous systems. Some are presented here in alphabetical order.

Aloe polysaccharides [93] are obtained from the fleshy leaves of *Aloe* sp. Crude preparations of Aloe polysaccharides are especially used in cosmetic and pharmaceutical preparations to be applied to the skin, but have other uses as well.

Cereal brans contain a polysaccharide of a class called beta-glucans [94,95]. (Cellulose is a β-glucan, but unlike cellulose, the polysaccharides called β-glucans contain entirely or partly (1→3) linkages.) β-Glucan is the major non-starch polysaccharide in oat and barley brans. Oat bran [96] is the principal source. Oat β-glucan is a linear chain of β-glucopyranosyl units, about 70% of which are linked (1→4) and about 30% (1→3). Such (1→4, 1→3)-β-glucans are known as mixed-linkage β-glucans. They can be extracted with hot water, which may occur during cooking, eg., in the preparation of oatmeal. Oat and barley bran are added to certain food products like breads. The value of oat β-glucan, which has been called oat gum, especially lies in its effectiveness in reducing serum cholesterol and providing the other health benefits of soluble dietary fiber, but the health benefits imparted by soluble dietary fiber polysaccharides (reducing postprandial serum glucose levels and the accompanying insulin response and protecting against hypertension, stroke, cardiovascular disease, and type-2 diabetes) vary in degree from gum to gum. A negative side to β-glucans is that they cause problems in the brewing industry. They increase wort viscosity and decrease the rate of wort filtration, beer clarity, and stability.

Inulin [97,98,99,100] is the only commercial, water-soluble polysaccharide containing D-fructose, a ketose. It is a linear molecule of β-D-fructofuranosyl units linked (2→1). It is much smaller than other gums with chain lengths of only 15–22 units and is much more easily depolymerized under acidic conditions because its monomer units are in the furanosyl ring form. It is obtained mostly from roots of the chicory plant. Because of its small molecular size, hot solutions are relatively non-viscous even at concentrations of 50%. When hot solutions of > 25% concentration are cooled, a particulate gel forms. Inulin is used for its health benefits, viz, as a prebiotic.

Konjac glucomannan (also known by other names) [97,101,102] is a mostly linear, but slightly branched polymer containing β-D-mannopyranosyl units and β-D-glucopyranosyl units, with all inter-unit linkages being (1→4). The βMan*p* : βGlc*p* ratio varies from ∼1.5 : 1 to ∼2.0 : 1, depending on the source. The two units are randomly distributed within the polymer chains. Its molecular weight is $\sim 10^6$. Preparations contain 0.05–0.17 acetyl (acetate ester) groups per monomer unit. Konjac glucomannan molecules are rather acid stable (as compared to other polysaccharides). It forms strong, elastic, thermoreversible gels when used in combination with κ-carrageenan (*Sect. 4.8*) or xanthan (*Sect. 4.1*). Heat-stable gels are formed from deacetylated products. The gum is obtained from tubers of *Amorphallus konjac* (known by various local names) grown primarily in mountainous or hilly regions of Southeast Asia. Konjac glucomannan finds little use outside of Asia.

A low-viscosity gum, an arabinogalactan, is extracted from wood chips of *Latrix* sp. This substance, known both as larch gum and Larch arabinogalactan [66], consists of a backbone chain of (1→3)-linked β-D-galactopyranosyl units, each of which bears a side-chain substituent attached to O6. Most of the side chains are β-galactobiosyl (disaccharide) units. Other side units are β-L-arabinopyranosyl-(1→3)-α-L-arabinofuranosyl units or simply α-L-arabinofuranosyl units. Its molecular weight ranges from ∼16,000 to ∼100,000. Its solubility is high, and solutions with concentrations as high as 60% are fluid. Larch arabinogalactan is marketed as a prebiotic and a stimulator of the immune system.

Cereal flours contain polysaccharides that are classified as hemicelluloses (Chap. 6.1), but which, when they come from cereal flour, are called pentosans. Pentosans are mostly arabinoxylans and are divided into two classes: water soluble and water insoluble. Their structure is that of a main chain of (1→4)-linked β-D-xylopyranosyl units to which are attached short side units, mostly monosaccharide units and mostly L-arabinosyl units. Two side units may be on the same backbone unit, i. e., a backbone unit may be doubly branched. The water-soluble molecules have more side units than do the water-insoluble molecules. The molecules also contain ferulic acid ester groups. Of primary interest are wheat flour arabinoxylans because of their water-absorbing and water-binding capacities. Especially do arabinoxylan molecules crosslinked by oxidative coupling of the ferulic acid ester groups have high water-holding capacity. Even though they are present in very small amounts, arabinoxylans significantly affect distribution of water between bread dough constituents, the rheological properties of both the dough and the finished product, gas retention in the baked product, and texture of the baked product.

Arabinogalactans are also polysaccharide components of wheat flour. Arabinogalactans in wheat flour are attached to protein molecules and thus are part of the structures of arabinogalactan-protein molecules. Like the arabinoxylans, there are variations in both amounts and structures of water-extractable arabinogalactan-protein molecules in wheat flours.

Psyllium gum (gum psyllium) can be extracted from psyllium seed husks (hulls) [93]. The husks themselves are incorporated into products sold to prevent constipation and to a few food products as a source of dietary fiber. The gum is extracted when water or milk is added to these products.

Many other polysaccharides have been investigated as gums, but have not reached the status of commercial viability. Among these are polysaccharides from chia seeds [93], corn hull (corn fiber), flaxseed [93], okra [93], and tamarind seeds [93] (used in India).

Yet other water-soluble polysaccharides are used commercially but are not referred to as gums. They include the chondroiton sulfates (animal) (Chap. 6.1), hyaluronic acid (animal and bacterial) (Chap. 6.1), and polydextrose (synthetic).

Abstract

Bacterial cells are surrounded by a variety of cell-surface structures that allow them to thrive in extreme environments. Components of the cell envelope and extracellular matrix are responsible for providing the cells with structural support, mediating intercellular communication, allowing the cells to move or to adhere to surfaces, protecting the cells from attack by antibiotics or the immune system, and facilitating the uptake of nutrients. Some of the most important cell wall components are polysaccharide structures. This review discusses the occurrence, structure, function, and biosynthesis of the most prevalent bacterial cell surface polysaccharides: peptidoglycan, lipopolysaccharide, arabinogalactan, and lipoarabinomannan, and capsular and extracellular polysaccharides. The roles of these polysaccharides in medicine, both as drug targets and as therapeutic agents, are also described.

Keywords

Cell wall; Peptidoglycan; Lipopolysaccharide; Arabinogalactan; Lipoarabinomannan; Capsular polysaccharides; Extracellular polysaccharides

Abbreviations

ACP	acyl carrier protein
AG	arabinogalactan
AraLAM	uncapped LAM
CPS	capsular polysaccharide
EPS	exocellular polysaccharide
GFP	green fluorescence protein
HMW	high molecular weight
IM	inner membrane
LAM	lipoarabinomannan
LM	lipomannan
LMW	low molecular weight
LPS	lipopolysaccharide
mAGP	mycolyl-arabinogalactan-peptidoglycan complex
ManLAM	mannose-capped LAM
MGT	monofunctional glycosyltransferase
OM	outer membrane
OMP	outer membrane protein
PBP	penicillin-binding protein
PGT	peptidoglycan glycosyltransferase
PI	phospho-inositol
PILAM	inositol phosphate-capped LAM
PIM	phosphatidylinositol mannoside
PMB	polymyxin B
TPase	transpeptidase
Dab	2,4-diaminobutyric acid
DAP	2,6-diaminopimelic acid
***m*DAP**	*meso*-2,6-diaminobutyric acid
HyDAP	*meso*-2,6-diamino-3-hydroxypimelic acid
Hyg	*threo-P*-hydroxyglutamic acid
HyLys	hydroxylysine
Orn	ornithine
f	furanose
p	pyranose
P	phosphate
PP	pyrophosphate
PEtN	2-aminoethyl phosphate
Ara	arabinose
Col	L-colitose
Fru	fructose
Fuc	fucose
FucNAc	*N*-acetylfucosamine
Gal	D-galactose
GalA	galacturonic acid

GalN	2-amino-2-deoxy-galactose
GalNAc	*N*-acetylgalactosamine
GalNAcA	*N*-acetylgalacturonic acid
Glc	D-glucose
GlcA	glucuronic acid
GlcN	2-amino-2-deoxy-glucose
GlcNAc	*N*-acetylglucosamine
Hep	L-glycero-D-*manno*-heptose
Kdo	2-keto-3-deoxyoctonate
Man	mannose
ManNAc	*N*-acetylmannosamine
MurNAc	*N*-acetylmuramic acid
NAG	*N*-acetyl-D-glucosamine
NAM	*N*-acetyl-D-muramic acid
Neu5Ac	5-*N*-acetyl-D-neuraminic acid
Qui	quinovose
QuiNAc	*N*-acetylquinovosamine
Rha	rhamnose
Rib	ribulose

1 Introduction

Bacteria have evolved over the last three billon years to occupy such diverse niches as υ deep sea vents and the GI tracts of multicellular organisms as different as nematodes and humans. Some, such as the mycobacteria that cause tuberculosis and leprosy, have even evolved to live inside other cells. Accordingly, different bacterial species produce wildly different cell-surface structures adapted to life in these diverse environs. Bacterial cell surface architecture is complex, and the assorted cell surface structures perform a host of important functions. They play structural roles, providing the cells with mechanical support and controlling cell shape. They form permeability barriers, controlling entry of molecules into the cells and protecting the bacteria from antibiotics. They also mediate interactions between cells, facilitating intercellular adhesion and invasion of host tissue, and allowing bacteria to evade the immune system. Several of the most important cell surface components contain saccharide structures, and these are the subjects of this review.

In most bacteria, the cytoplasmic membrane is surrounded by a cell wall containing layers of a crosslinked carbohydrate polymer called peptidoglycan [1]. Peptidoglycan is the major structural component of the cell wall and is essential for protecting bacteria from osmotic lysis. Disruption of the peptidoglycan layers causes the cell to burst. The structure and biosynthesis of peptidoglycan are remarkably conserved across bacterial species, making it a very attractive antibiotic target [2]. In fact, peptidoglycan biosynthesis is the target of several clinically important antibiotics, including the penicillins and vancomycin.

Other cell-surface structures, although less well conserved than peptidoglycan, typify broad groups of bacteria. For example, most bacteria can be divided into two groups that possess different general surface architectures, termed “Gram-positive” and “Gram-negative” (❯ *Fig. 1*).

Figure 1
Bacterial cell envelope architecture

This classification is based on a staining technique developed in 1884 by a Danish doctor, Hans Christian Gram. Gram observed that some bacteria (Gram-positive) were able to retain crystal violet dye, while others (Gram-negative) were not. This differential behavior hints at one major difference in the two types of cell envelopes: while both types of bacteria have a hydrophilic cell wall made of peptidoglycan, the thickness of the peptidoglycan layers range from less than 10 nM in Gram-negative cells to up to 80 nM in Gram-positive organisms [3]. The crystal violet dye diffuses through the thin peptidoglycan layers of Gram-negative bacteria and can be washed out, but is retained in the thicker matrix of Gram-positive organisms [4]. Perhaps to compensate for their thinner, and thus more fragile, peptidoglycan matrix, Gram-negative bacteria possess an outer membrane that blocks the passage of many different types of molecules into the periplasmic space that contains the peptidoglycan layers [5]. *E. coli* and many other Gram-negative bacteria are able to thrive in the human intestine because their outer membranes exclude bile salts and other toxic molecules. The outer membrane also acts as a barrier to many antibiotics, so some classes of drugs that are very effective against Gram-positive infections are virtually useless against Gram-negative pathogens. In addition to *E. coli*, some of the better-known Gram-negative pathogens include *Vibrio cholerae*, *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Pseudomonas aeruginosa*, and *Hemophilus influenzae*.

The outer membrane is an unusual structure consisting of an asymmetric lipid bilayer, with an inner leaflet containing phospholipids and an outer leaflet composed of lipopolysaccharide (LPS) [6]. LPS is a complex glucosamine-based glycolipid composed of three parts: the membrane anchor lipid A, a short core oligosaccharide and a highly variable *O*-antigen polysaccharide [5]. Lipid A, also referred to as "endotoxin," stimulates the innate immune response, promoting the release of pro-inflammatory cytokines and thereby producing some of the dramatic symptoms seen with systemic Gram-negative infections, including fever and sepsis [7]. Gram-negative *O*-antigen usually produces a strong antibody response, which can confer protection against subsequent infection [8]. For some Gram-negative pathogens, vaccine strategies employing synthetic polysaccharides mimicking fragments of *O*-antigen have been investigated for protective effects [9]; however, since most pathogenic species synthesize an impressive array of *O*-antigen structures (*E. coli*, for example, synthesizes more than 150 different types) [10], the immune protection conferred by infection or vaccination with one type of *O*-antigen may not confer protection against bacteria of the same species possessing different *O*-antigen structures. Other distinguishing features of the Gram-negative outer membrane include lipoproteins and integral membrane proteins (outer membrane proteins or OMPs) that are embedded in the outer membrane [11,12]. Some OMPs function as channels that allow the cell to take in nutrients and excrete waste products. Others are enzymes, or serve as adhesins. In addition to LPS, the outer membrane can also include other glycolipids such as enterobacterial common antigen, a structure specific to the Enterobacteriaceae including *E. coli* [13,14]. The outer membrane is also the attachment site for surface organelles, such as pili, which are involved in adhesion and allow bacteria to colonize cells or environmental surfaces [15].

The cell walls of Gram-positive bacteria, including the pathogens *S. aureus*, *Bacillus anthracis*, *Streptococcus pneumoniae*, *and Enterococcus faecalis* contain thick layers of peptidoglycan. The peptidoglycan layers serve as both a protective barrier and as a scaffold for the attachment of secondary cell wall polymers and surface proteins. Surface proteins include hydrolytic enzymes involved in peptidoglycan turnover, as well as structures such as pili

and adhesin/invasin proteins that help bacteria colonize surfaces and invade host tissue [16]. Important secondary cell wall polymers include the polyanionic wall teichoic acids (WTAs) and teichuronic acids, which are covalently linked to the peptidoglycan layers, and lipoteichoic acids (LTAs), which are anchored in the cytoplasmic membrane and extend through the cell wall into extracellular space [17,18]. Both WTAs and LTAs are involved in virulence in pathogenic organisms. LTAs, like lipid A, stimulate innate immunity; WTAs have been shown to mediate processes such as adhesion, biofilm formation, and antibiotic resistance [18]. Lipoteichoic acids also serve as the attachment site for a number of the surface proteins, including enzymes that hydrolyze peptidoglycan.

A subset of Gram-positive bacteria possess a cell envelope that differs markedly from other Gram-positive bacteria. These microorganisms, collectively classified as Corynebacterineae or mycolata, include notorious human pathogens such as *Mycobacterium tuberculosis*, *Corynebacterium diphtheriae*, and *Mycobacterium leprae*. Other Corynebacteria are industrially important for the production of amino acids [19]. The Corynebacterineae have a multilayered cell wall comprised of peptidoglycan covalently attached through a disaccharide linker to an arabinogalactan polysaccharide, which is tethered at its other end to long-chain beta-hydroxy fatty acids called mycolic acids [20,21]. The mycolic acids are perpendicular to the plane of the membrane, forming a thick lipid barrier functionally similar to the Gram-negative outer membrane.

Mycobacterial infections are particularly difficult to treat because most antibiotics cannot penetrate the densely mycolylated cell walls [22]. Cell wall biosynthesis inhibitors are usually administered in combination with drugs that have intracellular targets, so that the latter can get through the cell wall. For example, the standard regimen for TB treatment involves two months of the transcription inhibitor rifampicin delivered with the mycolic acid biosynthesis inhibitors pyrazinamide and isoniazid, followed by another six months of isoniazid and rifampicin [23].

In addition to the cell envelope structures described above, many Gram-negative and Gram-positive bacteria produce polysaccharide structures called capsular antigens. These include capsular polysaccharides, which are attached to the outer membrane of Gram-negative bacteria or the peptidoglycan layers of Gram-positive cells to form an outer protective layer called the ‘capsule’, and extracellular polysaccharides, which are excreted into the extracellular space [24]. The capsule can perform a variety of roles. For example, some pathogenic bacterial strains construct capsules that mimic mammalian cell surfaces to avoid detection by the immune system [25]. Many capsular polysaccharides, however are highly immunogenic, and have been used to produce vaccines against a number of bacteria including *Neisseria meningitidis* and *Streptococcus pneumoniae* [26]. Extracellular polysaccharides are an important component of biofilms, multicellular cooperative bacterial communities. Biofilms are more resistant to antibiotics and immune attack than free-swimming bacteria, and biofilm formation is implicated in the establishment of persistent infections by several common human pathogens [27].

This review will address the structure and biosynthesis of important microbial cell wall polysaccharides, as well as chemical syntheses of these structures, and their roles in human diseases and disease treatments. The document is divided into sections discussing bacterial peptidoglycan, the Gram-negative outer membrane, corynebacterial cell wall components, and capsular antigens.

2 Peptidoglycan

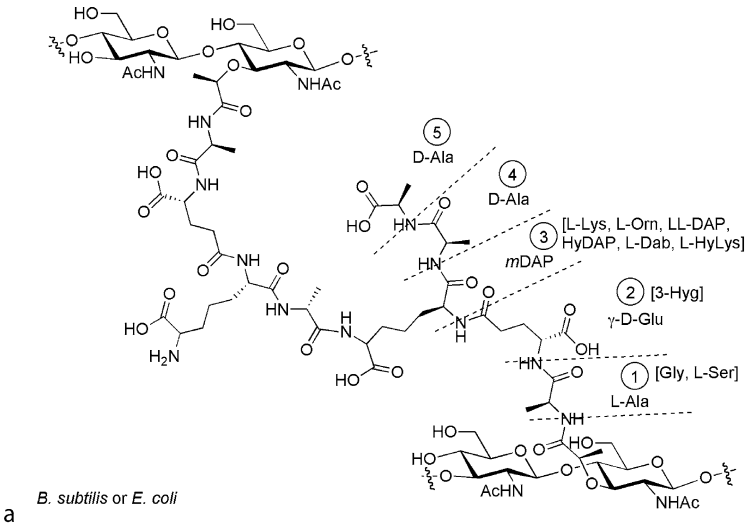
2.1 The Peptidoglycan Monomer Unit

2.1.1 Structure of the Peptidoglycan Monomer Unit

Peptidoglycan is constructed from monomers containing an *N*-acetylglucosamine-β(1,4)-*N*-acetylmuramic acid (NAG-NAM) disaccharide. The C3 position of *N*-acetyl-muramic acid (MurNAc) is modified with a peptide sidechain. The chemical composition of peptidoglycan polysaccharide was first described in the early 1960s using a method involving enzymatic degradation of cell wall extracts and subsequent chromatographic separation [28,29]. Shortly thereafter, Weidel and coworkers and Ghuysen and coworkers published methods for determining the amino acid sequence of the peptide side chain [30,31]. Both groups used enzymatic degradation of cell wall extracts to isolate peptide fragments for chemical structure determination.

Since the execution of these early experiments, the structure of peptidoglycan from many different bacteria has been determined. The structure of the NAG-NAM disaccharide is highly conserved among most bacteria. A notable variation occurs among mycobacteria, where the muramic acid is predominantly *N*-glycolylated rather than *N*-acetylated [32]. 1,6-anhydro MurNAc is also found at the end of the peptidoglycan strands in *E. coli* and other Gram-negative bacteria. Other possible modifications include acetylation or phosphorylation of the muramyl 6′ hydroxyl group, and occasional absence of an *N*-acetyl group or peptide chain.

In contrast with the disaccharide, the peptide chain shows a great deal of interspecies variation [33]. The general peptide chain composition and variations are shown in ❯ *Fig. 2*. The peptide is connected to the lactyl group of muramic acid through its N terminus, and consists of alternating D and L amino acids. D amino acids are not metabolized in eukaryotes, and their only known uses are in peptidoglycan and some prokaryotic secondary metabolites. The first and second amino acids in the chain are usually L-Ala and D-Glu, respectively. The most variation occurs at position 3, which usually contains a diamino acid involved in crossbridge formation as shown in ❯ *Fig. 2*. Meso-diaminopimelic acid (*m*DAP) occurs most frequently, and is found in most Gram-negative bacteria, but L-Lys is also commonly found, and occurs for example, in *S. aureus*. Position 4 is usually a D-Ala, connected by a crossbridge to another peptide chain. If no crossbridge is formed, this residue may either be stripped off (resulting in a tripeptide) or remain substituted by another D-Ala (resulting in a pentapeptide); mature peptidoglycan in most organisms contains primarily a mixture of tri- and tetrapeptides. The composition of the crossbridges is also species-specific [33]. The peptide chains are connected either directly as seen in *E. coli* and *B. subtilis*, or through an interpeptide bridge such as the pentaglycine bridge seen in *S. aureus*, (L-Ala)$_2$ seen in *Enterococcus faecalis* or L-Ser-L-Ala seen in *S. pneumoniae*. Representative structures are shown in ❯ *Fig. 2*. Other variations occur, including cross-links between two *m*DAP residues. The crossbridge variations can confer resistance to beta-lactam antibiotics [34,35,36]. The polypeptide chain variations have been reviewed extensively by Schleifer and Kandler [33].



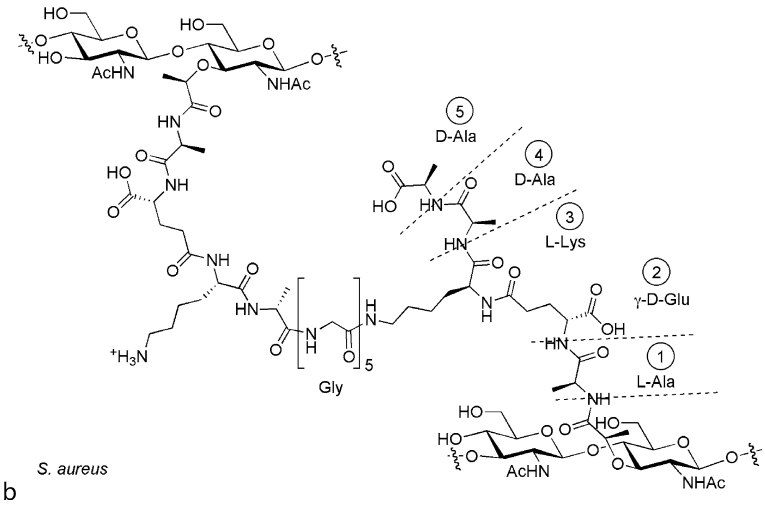


Figure 2
Structure of peptidoglycan. a) A segment of crosslinked peptidoglycan, showing the common variations in peptide chain composition and the direct crosslinking seen in *E. coli* and *B. subtilis*. b) A fragment of *S. aureus* peptidoglycan, showing the pentaglycine bridge

2.1.2 Biosynthesis of the Peptidoglycan Monomer Unit

Peptidoglycan monomers are assembled on a carrier lipid anchored in the cytoplasmic membrane, and then flipped across the membrane for incorporation into peptidoglycan. The intracellular synthesis of the peptidoglycan momomers is well understood (*Fig. 3*) [37]. The peptidoglycan monomers are made from the common cellular building block UDP-GlcNAc

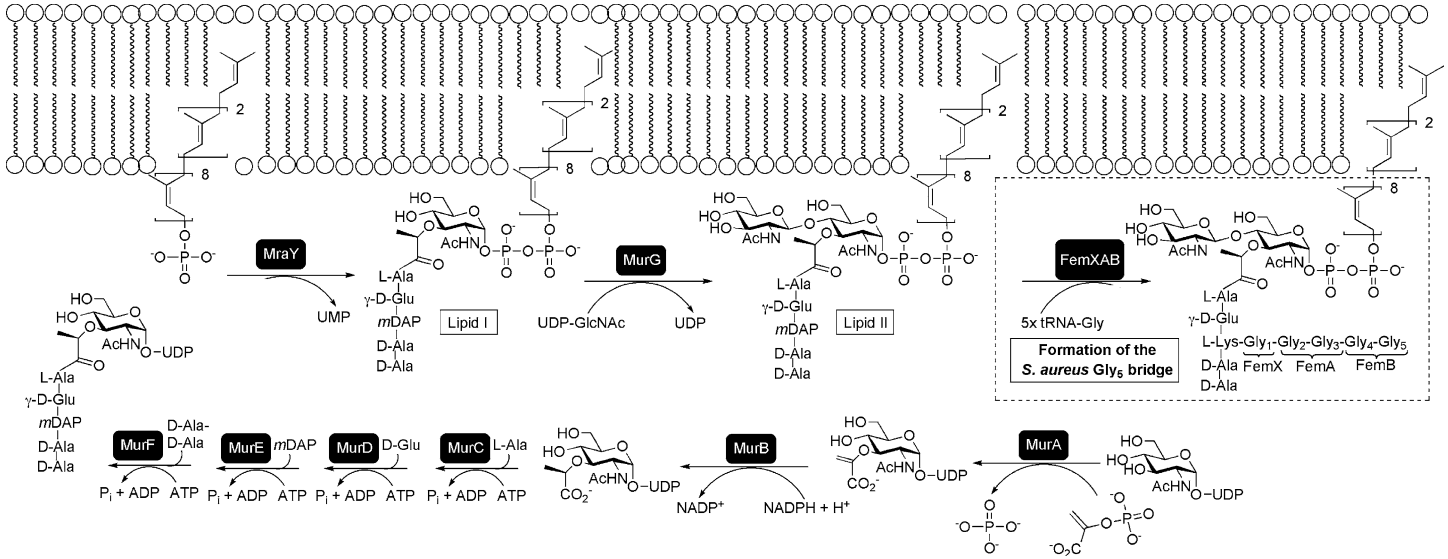

Figure 3
The intracellular steps of peptidoglycan biosynthesis

by the enzymes MurA-G and MraY. Briefly, MurA transfers an enolpyruvyl group to the 3-hydroxyl of UDP-GlcNAc. MurB then reduces the enolpyruvyl group to a lactyl group. The amino acid ligases MurC, D, and E then sequentially catalyze the addition of L-Alanine, D-glutamic acid, and *m*DAP or L-Lysine to the lactyl chain. MurF catalyzes addition of the terminal D-Ala-D-Ala dipeptide, completing the peptide chain. The MurC, D, E and F ligases all catalyze peptide bond formation in an ATP-dependent fashion. MraY transfers phospho-MurNAc-pentapeptide from UDP-MurNAc-pentapeptide to an undecaprenyl phosphate carrier lipid anchored in the cytoplasmic membrane, forming the first membrane linked intermediate (Lipid I). Finally, MurG catalyzes the transfer of GlcNAc from UDP-GlcNAc to C4 of MurNAc, forming GlcNAc-MurNAc-pp-undecaprenyl (Lipid II). Though most bacteria utilize undecaprenyl phosphate as a carrier lipid, the Corynebacterineae instead use decaprenyl phosphate (see ❯ *Section 4*). Lipid I and II intermediates from *Mycobacterium smegmatis* were recently isolated and analyzed, and found to contain decaprenyl rather than undecaprenyl carrier lipid chains [38].

The Lipid I and II building blocks may be further elaborated by many other enzymes that modify the sugars or amino acid chains. Branched peptides are added to the Lipid I and II peptide chains either by enzymes that act in an ATP-dependent fashion similar to the MurC-F ligases [39], or by enzymes that add amino acid residues from aminoacyl tRNA intermediates, such as the *S. aureus* enzymes FemA, FemB and FemX , which form the pentaglycine bridge (❯ *Fig. 3*) [36], and the *S. pneumoniae* enzymes FemM and FemN, which form an L-Ser-L-Ala or L-Ala-L-Ala dipeptide bridge [34,35]. Lipid II is also the substrate for the sortase enzymes that catalyze the attachment of surface proteins for incorporation into peptidoglycan [40].

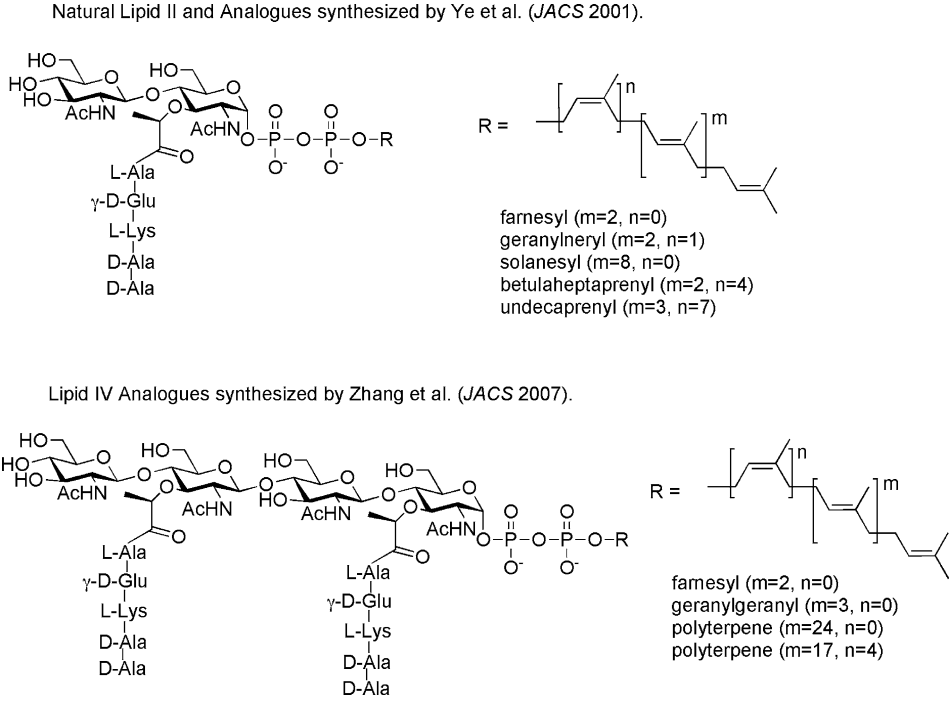
By 2001, mechanistic characterization had been completed for MurA-G from *E. coli*, and crystal structures had been obtained for all of these enzymes except MurC [41,42,43,44,45,46,47,48]. For a detailed discussion of the work completed on this pathway prior to 2000, see the review by van Heijenoort [37]. Since then, *E. coli* MurC and MurG have been crystallized [47,48,49], and homologues of the Mur enzymes from other bacteria have been purified and characterized as well. MraY has also now been purified and characterized [50], a significant accomplishment because this enzyme is an integral membrane protein with many hydrophobic segments, making it particularly hard to purify in significant quantities. However, there is still no crystal structure for this enzyme.

2.1.3 Chemical Synthesis of the Peptidoglycan Monomer Unit

Interest in the synthesis of Lipids I and II was motivated by difficulties in isolating these compounds from natural sources. These intermediates are present in only small amounts in bacterial cells, and the 55-carbon undecaprenyl membrane anchor of the natural compounds aggregates extensively, limiting their aqueous solubility [51,52]. The limited availability of Lipids I and II impeded characterization of MurG and downstream enzymes in the peptidoglycan biosynthetic pathway that use these lipid-linked compounds as substrates. Some characterization of these enzymes was accomplished using assays that measured incorporation of radioactivity from labeled precursors onto uncharacterized membrane acceptors [53], but these assays were not sufficient for detailed mechanistic investigations of individual enzymes. Guan et al. have recently reported a procedure for extracting natural Lipid II from *E. coli* in quantities sufficient for mass spectrometry [54], but extraxtion of larger quantities remains impracticable.

Lipid I and analogues thereof have been prepared using both chemical and enzymatic approaches. In 1997, Auger et al. reported a semi-synthetic approach to a Lipid I analogue containing an unnatural lipid chain that involved enzymatic degradation of UDP-MurNAc-pentapeptide to the corresponding anomeric phosphate followed by coupling to a heptaprenyl lipid phosphate [55]. Almost simultaneously, Men et al. reported the total chemical synthesis of a Lipid I analogue containing a citronellyl carbon chain (◉ *Fig. 4*) [56]. Both the heptaprenyl and citronellyl lipids were found to serve as substrates for *E. coli* MurG, despite substantial changes to the length and structure of the lipid chain. In 2001, two chemical syntheses of undecaprenyl Lipid I were reported [57,58]. Ye et al. synthesized undecaprenyl Lipid I and a range of analogues containing different lipids, and these compounds were tested as substrates for MurG [58]. Substrate analogs containing shorter lipids were shown to be better substrates than the 55-carbon lipid for in vitro studies of MurG, probably as a result of limited solubility of the C_{55} compound [59]. Substrate analogs with short lipid chains were subsequently used to develop several activity assays for MurG, which facilitated the mechanistic and structural characterization of this enzyme [48,60,61].

Syntheses of undecaprenyl Lipid II have also been developed. Ye et. al. took a chemo-enzymatic approach, converting chemically synthesized Lipid I to Lipid II using purified *E. coli* MurG [58]. Since MurG utilizes substrates containing a variety of lipid chains, this route has been used successfully to prepare a range of Lipid II analogues. Two fully chemical routes



◘ Figure 4
Synthetic Lipid II and Lipid IV

to the synthesis of Lipid II have also been developed [62,63,64]. In principle, the chemical approach allows the preparation of wider range of substrate analogues than the chemo-enzymatic route, but extensive protecting group manipulations are required to make the GlcNAc-MurNAc glycosidic linkage. In the chemical literature, the structures of undecaprenyl Lipids I and II are commonly drawn incorrectly, showing 7 *cis* and 3 *trans* isoprene units (and a terminal isoprene). The natural undecaprenyl chain is biosynthesized from farnesyl pyrophosphate, and contains instead 8 *cis* and 2 *trans* isoprene units (see *Fig. 3*) [65,66].

An addition enzymatic synthesis of Lipid II has been reported by Breukink et al., in which the UDP-GlcNAc, UDP-MurNAc pentapeptide, and prenyl phosphate substrates are incubated with bacterial membrane preparations containing MraY and MurG [67]. This method has been used to prepare natural Lipid II, as well as analogues containing polyprenyl chains of varying length. The development of multiple routes to Lipids I and II has made these compounds readily available, facilitating the characterization of the peptidoglycan biosynthetic enzymes as well as screens for inhibitors.

2.2 The Peptidoglycan Matrix

2.2.1 Structure of the Peptidoglycan Matrix

Bacterial peptidoglycan has a mesh-like structure consisting of linear glycan chains connected by peptide crossbridges. As mentioned in *Sect. 2.1.1*, the structure of the glycan is remarkably conserved between bacterial species, and consists of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid residues (or in mycobacteria, *N*-glycolylmuramic acid) connected through $\beta(1,4)$ glycosidic linkages [33]. In Gram-negative bacteria, the glycan chains terminate in 1,6-anhydro MurNAc [68]. The peptidoglycan of a given bacterium contains a distribution of chain lengths, with both long and short chains. Glycan chain length distributions are typically measured by isolating bacterial sacculi, using an amidase to break the crosslinks between the glycan strands, and then evaluating the length distribution by separating the strands using C18 chromatography [69]. Using this method, *E. coli* glycan strands were found to have an average length of 21 and a maximum length of 80 disaccharide units, with ~70% of the chains averaging 8.9 disaccharide units, and 30% averaging 45.1 units [69,70]. This method yielded slightly shorter chain lengths for several *S. aureus* strains, with 85–95.5% of the glycans having a calculated average length of 6 disaccharide units, and the remaining 4.5–15% having lengths longer than 23–26 disaccharides [71]. The average chain lengths for a number of bacteria have also been determined using methods that involve reduction of the reducing termini with $NaBH_4$ followed by hydrolysis of the glycans using acid or muramidase, separation of the muropeptides by chromatography, and quantification of the reducing ends. This method cannot be used for *E. coli* because the reducing termini are capped with 1,6-anhydro-MurNAc, but similar methods for chain length analysis have been used where the non-reducing termini are derivatized enzymatically with D-galactose, or the amount of 1,6-anhydro-MurNAc is determined directly. These methods have been used to analyze glycan chains for a handful of bacterial species, and the chain lengths have been found to depend on the bacterial species as well as the growth conditions. Chains from different species were found to average between 10 and 65 disaccharide units, and for a given organism different lengths were calculated when it was grown as rods or spheres [31]. For *E. coli*, different average chain

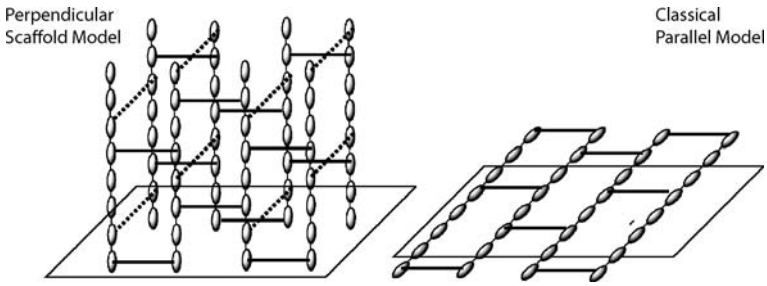


Figure 5
Models for the 3-dimensional arrangement of peptidoglycan

lengths (between ~18 and 33 disaccharide units) were obtained in different media, and in exponential and stationary phase growth [70]. Despite the existence of several different methods for chain length determination, the actual lengths are still subject to much debate. Different analytical methods can yield wildly different estimates of chain length. For example, longer average glycan chain lengths were estimated for *E. coli* strains using the galactose derivatization method (35–50 disaccharides) [72] than by 1,6-anhydro-MurNAc quantification (18–33 disaccharides) [70], and slightly longer average chain lengths (12–16 disaccharide units) were estimated for *S. aureus* using derivitization and digestion than by C18 chromatography of intact chains [31]. For *Bacillus* strains, average chain lengths of 45–140 disaccharides have been determined, with the length estimate varying two-fold depending on the method used for calculation [73]. Differences in measured chain lengths may also be a function of how the sacculi are prepared, since lytic transglycosylases may degrade the glycan chains during sample processing. In addition, the average lengths of glycan chains may vary as a function of their position within the matrix. These factors complicate interpretation of data concerning average chain lengths and variations thereof between organisms.

The degree of crosslinking also varies between bacterial species. In Gram-negative organisms the percentage of crosslinked peptides has been estimated as 40–50% [68,74], while in Gram-positives it is generally higher. For example, in Staphylococci including *S. aureus*, 80–90% of the peptides are crosslinked [75,76]. Gram-positive cells also contain considerably more peptidoglycan than Gram-negatives. The Gram-positive cell wall contains a thick layer of peptidoglycan that accounts for 90% of the weight of the cell wall, and 50% of the weight of the cell. Electron micrographs show the peptidoglycan to be 20–80 nm thick [3]. In contrast, Gram-negative bacteria contain only a thin layer of peptidoglycan surrounding the cytoplasmic membrane, and only 15–20% of the cell wall is peptidoglycan. The thickness of *E. coli* peptidoglycan has been determined using several techniques, including cryotransmission electron microscopy [77], small-angle neutron scattering [78], and atomic force microscopy [79]. All three techniques indicate a maximum thickness of 6 or 7 nm, and neutron scattering suggests a non-uniform peptidoglycan layer, where 75 to 80% of the surface is 2.5 nm thick and the remaining 20 to 25% is about 7 nm thick [78].

Despite the large amount of data available on the physical characteristics and chemical composition of peptidoglycan, the three-dimensional structure of the peptidoglycan matrix is unknown. Computer simulations have been used to produce structural models using experi-

mental data on the conformations of glycan chains, the lengths of the glycan chains, and the degree of crosslinking [70]. The cell wall has classically been pictured with the glycan chains arranged parallel to the membrane. Different models have predicted that the glycan chains are either regularly arranged or randomly coiled, depending on the parameters and constraints used in model construction [70,80]. An alternate "scaffold model", recently proposed by Dmitriev et al., contends that the glycan strands are oriented perpendicular to the membrane [81,82]. These two models are shown in ❯ *Fig. 5*. Dmitriev et al. use computer models of *E. coli* and *S. aureus* peptidoglycan to argue that perpendicular glycan strands would yield a cell wall with elastic properties and porosity more consistent with the observed properties of peptidoglycan. They also contend that the scaffold model more easily explains the synthesis of new peptidoglycan.

Arguments have subsequently been launched both for and against the scaffold model. Notable contributors to this debate include Meroueh et al. [83], who synthesized a tetrasaccharide fragment of peptidoglycan (corresponding to two monomer units), and obtained a solution NMR structure of the fragment. Structural constraints obtained from this model were then used to build a computational 3D model of peptidoglycan in accordance with the scaffold model. Meroueh et al. argue that their model demonstrates the plausibility of the scaffold model because the sizes of the pores in their peptodoglycan model are in accordance with the pore sizes of 50 to 500 Å seen in atomic force microscopic imaging of *S. aureus*.

Arguments against the scaffold model have been reviewed by Vollmer and Holtje [70]. Perhaps the most compelling arguments involve the estimated lengths of the glycan strands. In constructing their models, Dmitriev et al. assume glycan chains that average 8–12 disaccharides in length, much shorter than most of the measurements reported for *E. coli*. These longer glycan chains isolated from *E. coli* would far exceed the estimated width of the *E. coli* peptidoglycan layer, making vertical chain orientation unlikely.

2.2.2 Synthesis of the Peptidoglycan Matrix

Lipid II monomers are assembled into peptidoglycan on the outer face of the cytoplasmic membrane as shown in ❯ *Fig. 6*. The transport of the Lipid II monomers from the inner face to the outer face of the membrane is presumed to involve a transporter protein, but neither the gene nor the protein involved has been identified. The lipid II units are incorporated into peptidoglycan by peptidoglycan glycosyltransferases (PGTs) that form $\beta(1–4)$ glycosidic linkages between the disaccharide units, and transpeptidase (TPase) enzymes that catalyze formation of the peptide cross-bridges [84]. These reactions are believed to occur sequentially, with glycan chain formation preceding crosslinking [85,86]. Bifunctional enzymes that catalyze both transglycosylation and transpeptidation are thought to be responsible for the majority of peptidoglycan biosynthesis [87]. These enzymes have been dubbed "penicillin binding proteins" (PBPs) because they were first identified by their ability to bind radiolabeled penicillin. Bacteria typically contain several high molecular weight (HMW) PBPs, some of which ("Class A") have active PGT domains, and some of which ("Class B") contain only vestigial PGT domains in addition to the active TPase domains [88]. There are also several low molecular weight (LMW) PBPs that have only endopeptidase or carboxypeptidase activities. Some bacterial strains also contain monofunctional peptidoglycan glycosyltransferases (MGTs), which lack TPase domains [89,90,91].

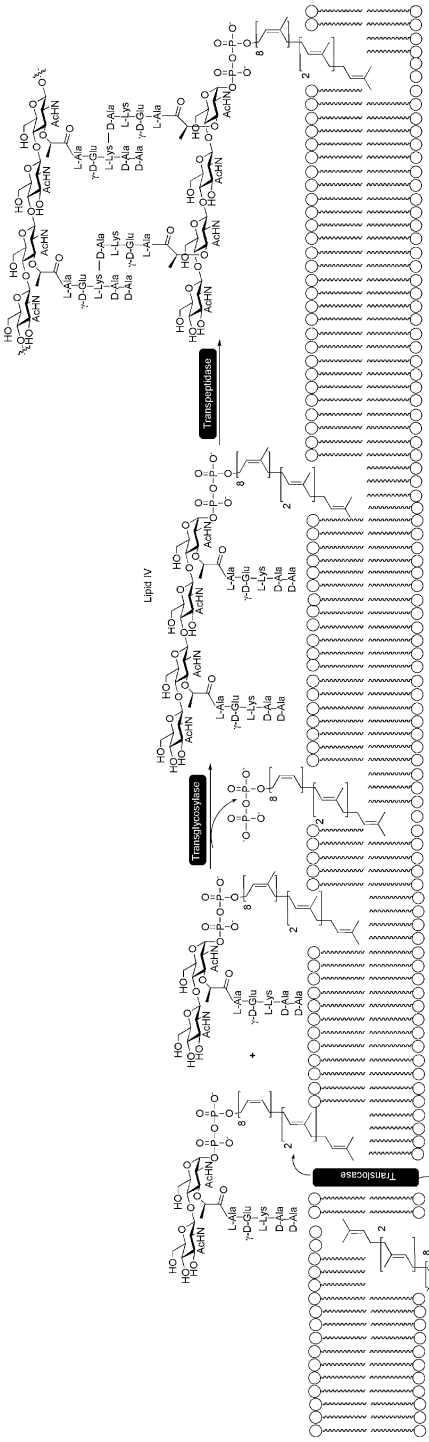

Figure 6
Extracellular steps of peptidoglycan biosynthesis

Most bacteria contain many PBPs, and it is thought that different enzymes play different roles in cell growth and division [33]. For example, *E. coli* contains twelve different PBPs and one monofunctional glycosyltransferase (MGT) [92,93,94,95]. From knock-out studies, two of the HMW PBPs have been shown to play important roles in cell elongation and cell division [94]. *E. coli* also contains four LMW PBPs that are thought to be important for cell shape [96]. Most LMW PBPs have carboxypeptidase rather than transpeptidase activity. Rather than crosslights forming, they moderate the amount of cross-linking found in the cell wall by cleaving the peptide chains, usually at the D-Ala-D-Ala terminal peptide bond. Other bacteria contain different numbers of these enzymes. For example, *S. aureus* contains four different PBPs, as well as two MGTs [97]. Different numbers and types of PBPs and MGTs may be required to maintain the cell sizes and shapes of different bacterial species.

The process of cell wall assembly has proven difficult to unravel. The roles of individual enzymes are largely unknown. Many of the PBPs have been knocked-out in an attempt to determine their specific functions, but these studies have yielded limited information, presumably because the enzymes have redundant functions so that when one enzyme is knocked out, another one can functionally compensate. *E. coli* cells, for example, remain viable even after the inactivation of at least 8 of the 12 PBPs present in this organism [94]. Moreover, it is not clear how cell wall synthesis is coordinated with the processes of cell growth and cell division. To grow and divide, bacteria must break specific bonds in existing peptidoglycan while simultaneously inserting new material so that the integrity of the cell wall is not compromised. This requires coordinating the action of the enzymes that make peptidoglycan with the muramidases, glucosaminidases, amidases, endopeptidases, and carboxypeptidases that specifically hydrolyze the bonds in existing peptidoglycan [92].

2.2.3 The Coordination of Peptidoglycan Biosynthesis

Researchers have used a number of different experimental approaches in an attempt to understand the spatial and temporal organization of cell wall synthesis. In general, experiments have been designed to either identify enzyme complexes, track the cellular localization of individual enzymes or label newly synthesized peptidoglycan. This work has been recently reviewed by Scheffers and Pinho [98].

Several techniques have established the association of enzymes in peptidoglycan assembly and degradation. In vivo crosslinking experiments in bacteria including *E. coli*, *B. subtilis*, and *H. influenzae* have shown that the PBPs are organized into several multienzyme complexes [99,100,101]. Data from co-immunoprecipitation studies support this conclusion [102], and affinity chromatography has additionally shown that the PBPs interact with peptidoglycan hydrolases [103,104,105].

The localization of different PBPs and peptidoglycan hydrolases in several bacterial species has been determined using immunofluorescence and, more recently, using GFP-fusions [106, 107,108,109,110]. From these studies, it appears that in coccoid bacteria cell wall synthesis occurs mainly at the septum, while in rod-shaped bacteria different PBPs are localized to sites of cell division and peripheral cell wall synthesis. Furthermore, the localization of the enzymes seems to be dependent on both interactions with other enzymes and with substrate [98]. These visualization techniques have also helped explain the apparent functional redundancy of the PBPs. For example, in *S. pneumoniae*, different PBPs are specifically localized to sites of

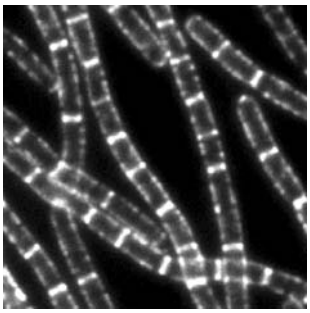

Figure 7
***B. subtilis* cells stained with fluorescent ramoplanin**

septal and peripheral peptidoglycan synthesis. However, if one of the PBPs is knocked out, a different PBP from the same class will compensate by taking over the normal localization of the missing enzyme [111].

A complimentary approach to determining localization of the peptidoglycan machinery is to determine the location of newly synthesized peptidoglycan. Early experiments sought to do this with pulse-chase experiments, to watch time-dependent incorporation of labeled precursors [112,113,114]. More recently, fluorescence microscopy has been used to image peptidoglycan synthesis in Gram-positive bacteria by using fluorescent analogs of certain antibiotics to label extracellular peptidoglycan precursors. This method was first demonstrated by Daniel and Errington, who used fluorescent vancomycin to suggest that peptidoglycan is synthesized in a helical pattern along the walls of *B. subtilis* cells [115]. Vancomycin recognizes the terminal D-Ala-D-Ala in the peptapeptide chain of Lipid II and un-crosslinked peptidoglycan (see ❯ *Sect. 2.3*). Tiyanont et al. subsequently used a fluorescent analog of the antibiotic ramoplanin to assess the roles of specific cytoskeletal proteins in directing the helical pattern of peptidoglycan synthesis (❯ *Fig. 7*)[116].

2.2.4 Kinetic and Structural Studies of the PBP Enzymes

Structural and mechanistic investigations of the PBPs face the same obstacles described in ❯ *Sect. 2.1.2* and ❯ *Sect. 2.1.3* for MurG and MraY. The PBPs are anchored to the membrane by a hydrophobic transmembrane domain, making them difficult to solubilize in active form, and the initial substrate of these enzymes is the membrane-anchored Lipid II produced by MurG. The LMW PBPs and the class B HMW PBPs have proven much easier to study than the class A HMW bifunctional enzymes. Soluble, active constructs of LMW and class B enzymes have been obtained in a straightforward manner by removal of the transmembrane domains. Moreover, many of these enzymes were found to accept structurally simple substrates, facilitating kinetic analysis of hydrolysis. For example, kinetic studies of the class B enzyme *Streptococcus pneumoniae* PBP2x employed a soluble form of the enzyme with a deleted transmembrane domain, and the thioester substrate *N*-benzoyl-D-Ala-thioacetic acid [117]. Mechanistic studies have now been completed for several LMW and class B PBPs, and a number of crystal structures have been solved for these enzymes, including co-complexes with beta-lactam antibiotics [117,118,119,120,121,122,123,124,125].

Kinetic and structural studies on class A PBPs were slower to emerge due to difficulties in obtaining soluble, active constructs. The first demonstration of PGT activity was reported by the Strominger laboratory in the 1960s [126], but no biochemical characterization of any PGT domains appeared for decades. Kinetic studies of the PGT domains were made possible by the development of preparative routes to Lipid II and analogs, discussed in Sect. 2.1.3. Studies with PBP1b, the major PGT in *E. coli* have shown that this enzyme has more stringent requirements than MurG for the lipid substrate, but compounds with shorter lipid chains still make better substrates for in vitro assays of enzyme activity than the natural undecaprenyl Lipid II substrate [58]. Kinetic characterization has now been reported for several PGTs [127,128,129,130,131,132].

The first crystal structures for the transpeptidase domains of class A PBPs were published in 2005 and 2006 [133,134,135]. Until very recently, there were no crystal structures for any PGT domains. However, in 2007 Yuan et al. reported the 2.1 Å crystal structure of the isolated PGT domain of *Aquifex aeolicus* PBP1A [136]. Simultaneously, Lovering et al. reported a 2.9 Å structures of *S. aureus* PBP2 containing both the PGT and TP domains. A 2.8 Å complex of the *S. aureus* enzyme bound to moenomycin was also reported [137]. Based on these crystal structures and additional biochemical information, each of these groups independently proposed a mechanism for glycan polymerization where lipid II acts as the glycosyl acceptor, and the growing polymer chain is the glycosyl donor. These structures have contributed significantly to the development of a mechanistic picture for peptidoglycan assembly.

2.2.5 Chemical Synthesis of Peptidoglycan Polymer

Access to discrete sections of polymeric peptidoglycan would facilitate studies of both the structure and enzymology of peptidoglycan assembly. As discussed in Sect. 2.2.1, the three-dimensional structure of peptidoglycan is not known. Structural studies have been hindered by difficulties obtaining pure samples for structural studies. As a step toward solving this problem, Meroueh et al. synthesized a tetrasaccharide fragment of peptidoglycan (corresponding to two monomer units), and obtained a solution NMR structure for this compound [83].

Discrete, polymeric peptidoglycan fragments are also needed for studying the PGTs. In the first coupling cycle, two molecules of Lipid II are condensed to form a tetrasaccharide, "Lipid IV", which is elongated to form polymer in subsequent coupling cycles. Access to polymeric substrates like Lipid IV is thus necessary for mechanistic studies of the PGTs and for characterization of inhibitors. Toward this end, Zhang et al. recently reported the synthesis of heptaprenyl Lipid IV (Fig. 4) [138]. Reaction of this substrate with several PGTs was demonstrated.

There have also been some studies addressing the assembly of three-dimensional peptidoglycan. The peptidoglycan cross-bridges of *Staphylococcus aureus*, *Enterococcus faecalis*, and *Enterococcus faecium* consist of the sequences Gly_5, L-Ala_2, and D-Asx, respectively. In one study, the *fmhB*, *femA*, and *femB* genes of *S. aureus* were expressed in *E. faecalis*, leading to the formation of Lipid II with mosaic side chains [139]. It was found that the *E. faecalis* PBPs were able use these chains for peptidoglycan cross-linking.

2.3 Medicine

Peptidoglycan biosynthesis is an important antibiotic target, and there is continuing interest in the development of new antibacterial drugs that target this pathway [2]. Several features make peptidoglycan synthesis a particularly attractive drug target. Peptidoglycan is essential in all bacteria, its structure and biosynthesis are highly conserved, and it contains structures like D-amino acids and *N*-acetylmuramic acid that are not produced by eukaryotes. Drugs that target peptidoglycan biosynthesis therefore have the potential to work against a wide range of bacteria while having few side effects in humans. Many existing classes of antibiotics, including the clinically important penicillins and glycopeptides, target peptidoglycan biosynthesis.

Most of the steps in the peptidoglycan biosynthetic pathway are targeted by one or more natural product inhibitors. Natural products targeting the intracellular steps of peptidoglycan have been reviewed by Bugg and Walsh (see *Fig. 9*) [140]. A few of these are in clinical use, including the broad-spectrum antibiotics D-cycloserine and phosphomycin (*Fig. 8*). D-cycloserine is a cyclic analog of D-alanine that targets alanine racemase and D-Ala-D-Ala ligase. Cycloserine is often administered with other drugs for treatment of TB. Phosphomycin, which is commonly used for treatment of urinary tract infections, inhibits MurA by binding irreversibly to enzyme. Bacitracin, which is used as a topical antibiotic, binds to the undecaprenyl carrier lipid on the outside of the cell membrane, preventing it from being recycled.

Several classes of natural products inhibit MraY, and though none of these are used commercially as antibiotics, there is much interest in developing them for clinical use. Research efforts toward this end, including structure-activity studies and mechanistic investigations, have been recently reviewed [141,142,143]. Several families of nucleoside antibiotics targeting MraY show promise for clinical development, including the caprazamicins, which showed activity against a mouse TB model [144], and the mureidomycins, which protected a mouse model from *P. aeruginosa* infection (*Fig. 8*) [145].

The PBPs, which are located outside the cytoplasmic membrane, may make especially attractive antibiotic targets. This extracellular location is advantageous because potential antibiotics aren't limited to structural types that can penetrate the cell membrane, and there are fewer mechanisms by which resistance can develop to compounds that inhibit extracellular targets. Furthermore, there are no human homologues of these enzymes, decreasing the likelihood of inhibitor toxicity.

PBP inhibitors can be grouped into two classes: substrate binders, which recognize structural elements in Lipid II or nascent peptidoglycan, and enzyme binders, which inhibit transglycosylation or transpeptidation by binding directly to the enzymes. Most of the inhibitors that target the PGTs are substrate binders. These include the glycopeptides vancomycin and teicoplanin, which bind to the terminal D-Ala-D-Ala in the pentapeptide chain of Lipid II or un-crosslinked peptidoglycan [146], lantibiotics such as nisin and mersacidin, which are believed to recognize the diphospho-sugar portion of Lipid II [67,147,148], and the lipoglycodepsipeptide antibiotics ramoplanin and enduracidin, which also recognize the diphospho-sugar portion of Lipid II (*Fig. 9*) [149,150].

Substrate binders are attractive as drugs because resistance to them tends to develop relatively slowly, and many hit more than one cellular target. For example, vancomycin acts by binding to D-Ala-D-Ala, blocking both the transglycosylation and transpeptidation reactions. Certain analogs of vancomycin are also thought to inhibit transglycosylation by binding to

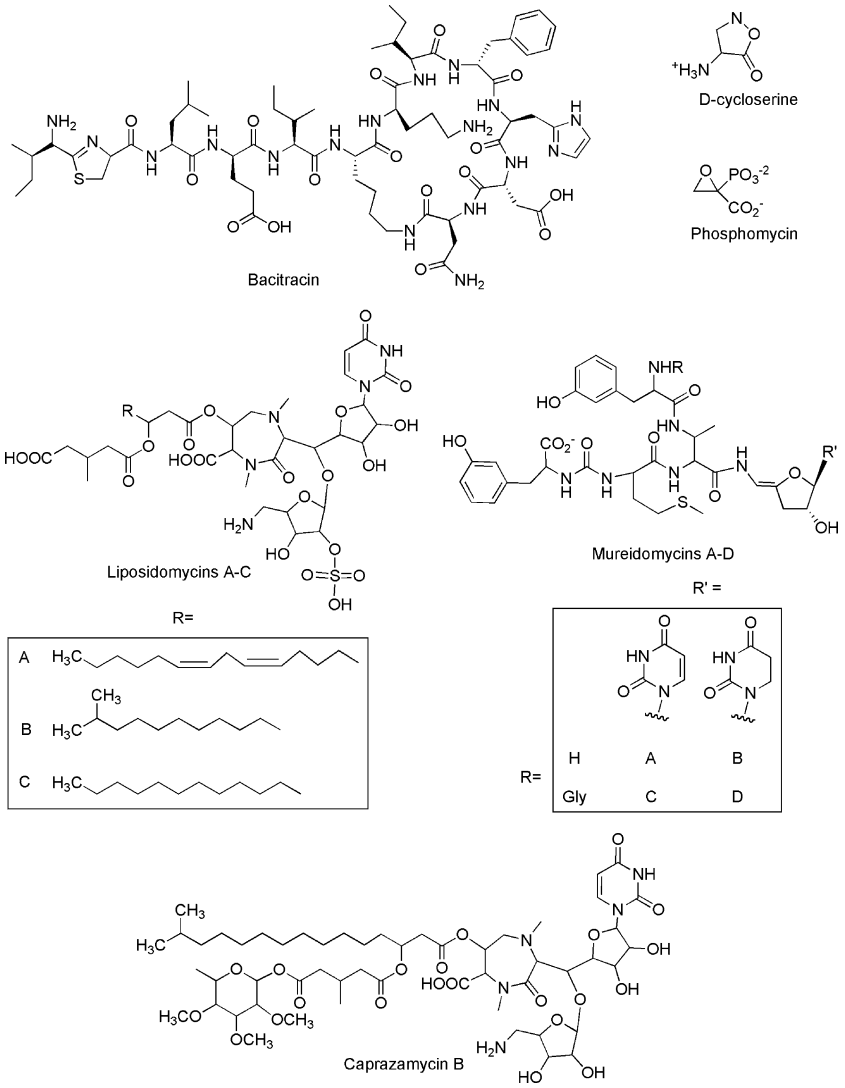

Figure 8
Antibiotics targeting the intracellular steps of peptidoglycan biosynthesis

the enzyme in addition to the substrate [151,152]. Nisin also uses multiple mechanisms: it is thought to block transglycosylation by binding to Lipid II, and to form pores in the bacterial membrane [148,153]. Some of these substrate binders are used clinically; vancomycin and teicoplanin have been in clinical use for many years, and ramoplanin is in clinical trials. Some lantibiotics are also being investigated for possible clinical development [148,149]. Substrate binders do have a few drawbacks: they tend to be large and polar, so they are generally only effective against Gram-positive bacteria because they are unable to penetrate the Gram-

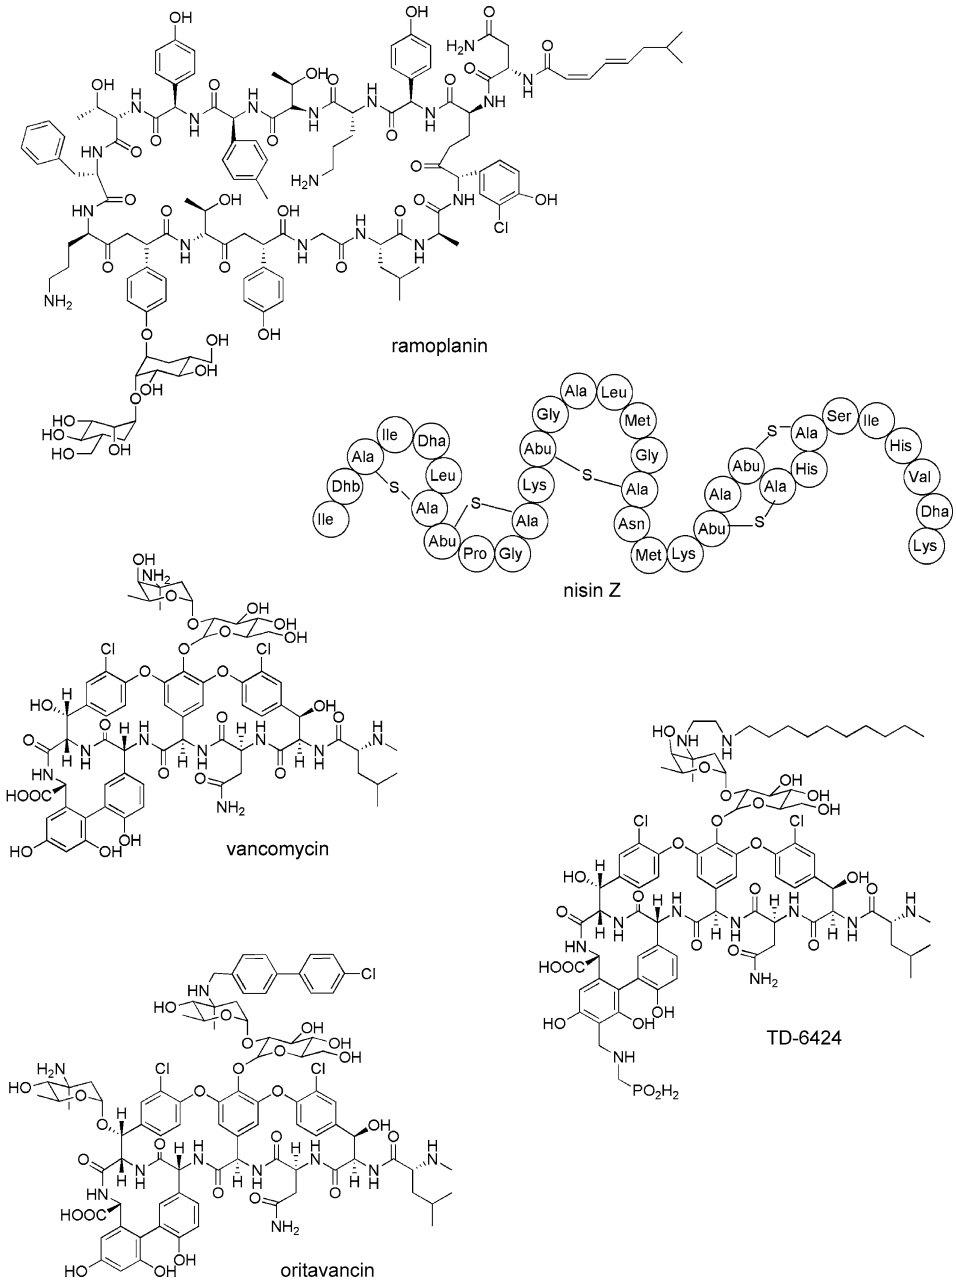

Figure 9
Substrate-binding antibiotics targeting transglycosylation and transpeptidation

negative outer membrane (see *Section 3*). They also require parenteral administration for systemic use because they are poorly absorbed when administered orally. The syntheses and modes of action of PGT inhibitors, including teicoplanin, ramoplanin, and nisin, have been reviewed by Welzel [154]. Synthetic routes to vancomycin have been reviewed by Nicolaou and Snyder [155].

There is only one family of antibiotics known to bind directly to the PGTs, the moenomycins [156]. The most prominent of these is moenomycin A, shown in *Fig. 10*. Moenomycin A is extremely potent, with minimum inhibitory concentrations (MICs) in the range of 0.01 to 0.1 μg mL^{-1} [152], but it is not currently used in humans because of undesirable properties that include a long half-life, toxicity, and poor oral bioavailability. Studies of the moenomycins are aimed at unraveling structure-function relationships in order to design derivatives with more favorable properties. Much work in this area has been carried out by Welzel and coworkers, who have identified features of the molecule that are important for bioactivity and for target interactions. They have suggested that moenomycin is a substrate mimic, though because methods to dissect the peptidoglycan glycosyltransferase mechanism are still lacking, the actual mode of inhibition is unknown. The total synthesis of moenomycin was recently completed, and synthetic methods have been developed to access moenomycin derivatives [157,158]. The gene cluster for moenomycin has also recently been identified, and a subset of these genes have been cloned and heterologously expressed to produce a moenomycin precursor [159]. With the availability of chemical and enzymatic routes to moenomycin derivatives, as well as crystal structures of the PGTs, it should be possible to dissect the mechanism of moenomycin and to develop new antibiotics that target the PGT enzymes.

The transpeptidase enzymes are targeted by the most widely used of all antimicrobial classes, the β-lactams (*Fig. 11*). β-lactams inhibit by binding irreversibly to the enzyme active site. Many different structural classes exist, including the penicillins, cephalosporins, cephamycins, carbapenems, monobactams, and monocarbams [160]. These drugs are widely used because they are highly effective and safe, and many derivatives are available. The original β-lactams were effective only against Gram-positive pathogens, but many years of development have produced drugs that have activity against Gram-negative strains, as well as some broad-spectrum antibiotics. There are two major resistance mechanisms against these drugs: production of β-lactamases that hydrolyze the drugs and production of altered PBPs that do not bind the drugs [161,162]. The latter type of resistance is seen in methicillin resistant *S. aureus* (MRSA). MRSA infections have become a major problem in hospitals, prompting great concern. Historically, the former type of resistance has been circumvented by administering β-lactams in combination with β-lactamase inhibitors. New β-lactams and β-lactamase inhibitors are continuously designed as new β-lactamases continue to emerge [163]. There are not yet any β-lactams in clinical use that can overcome MRSA-type resistance, but a cephalosporin with high affinity for the β-lactam resistant PBP expressed in MRSA, PBP2a, is entering phase III trials (ceftobiprole, *Fig. 11*) [164].

Efforts to design design new inhibitors of the PGTs have focused on making derivatives of known inhibitors. Boger and co-workers have developed a synthetic route to the ramoplanin aglycone, and have made a set of analogues with which to study the mechanism of action of this molecule [165,166,167]. Hydrophobic substituents appended to glycopeptides have been found to increase activity against resistant microorganisms, and there is some evidence that these compounds, in addition to binding peptidoglycan precursors, can also interact with

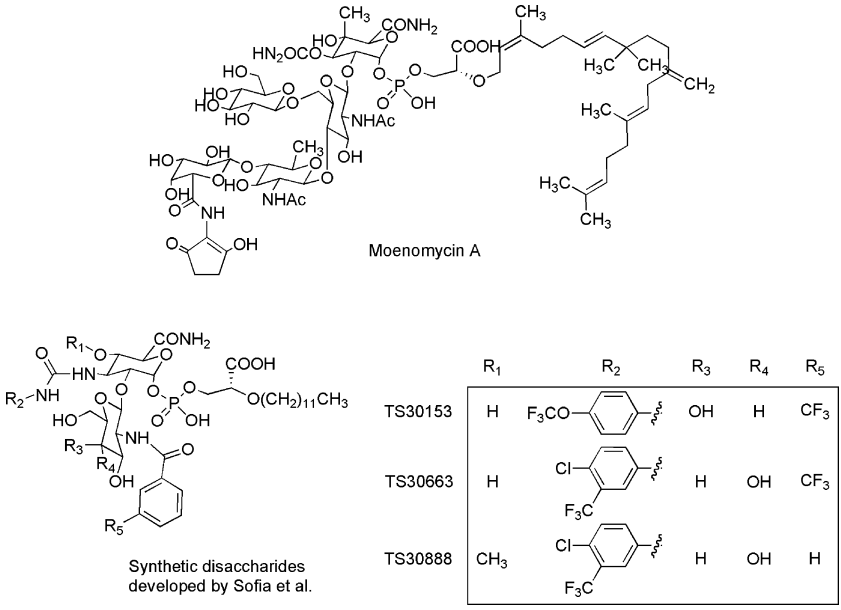

Figure 10
Moenomycin and bioactive disaccharide analogs developed by Sofia et al. [174]

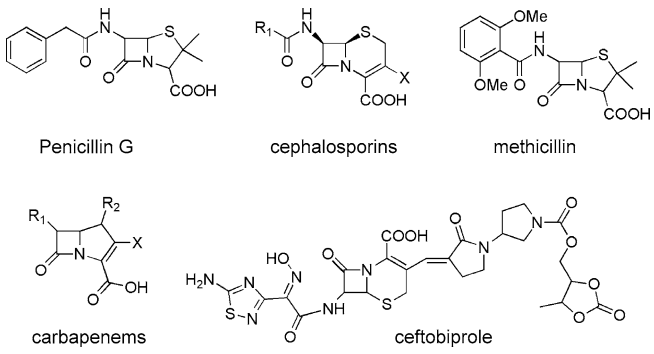

Figure 11
Beta-lactams. Ceftobiprole shows promising activity against MRSA, and is in phase III clinical trials [369]

the PGTs [146]. Four glycopeptide derivatives with hydrophobic substituents are currently in clinical trials: dalbavancin, oritavancin, TD-6424 and telavancin (*Fig. 9*) [146,168]. Several groups are also exploring the use of glycopeptide biosynthetic enzymes for the production of novel derivatives [168,169,170,171,172].

In addition to the aforementioned studies of substrate binding antibiotics, there have been efforts to design inhibitors that bind to the enzyme. These inhibitors have been patterned on either moenomycin or Lipid II, which are among the few compounds known to bind directly to PGTs. For example, Sofia et al. developed a combinatorial library approach to

synthesize disaccharide analogues of moenomycin [173]. 1300 analogs were prepared and tested, and some compounds with activity approaching that of moenomycin were identified (◉ *Fig. 10*) [174,175]. These compounds exhibited interesting differences in in vivo activity against different microorganisms, suggesting structural and functional differences in the PGTs expressed within and among bacteria. It is possible that the various inhibitors targeted different subsets of PGTs. This finding would not be unprecedented: β-lactam antibiotics are known to display differential activities against different PBPs. If moenomycin analogues are similarly able to discriminate amongst PGTs, they could be useful tools to dissect the functions of the different enzymes that participate in cell wall assembly. Two other recent papers describing modest PGT inhibitors based on moenomycin and Lipid II analogs have been reported [176,177].

2.4 High-Throughput Screens

There are ongoing efforts to develop screens for identification of peptidoglycan biosynthesis inhibitors. Many pathway enzymes have no known inhibitors, and identification of small molecules that target these enzymes would provide a starting point for drug design. There is also interest in identifying new classes of inhibitors that hit validated targets, such as non-β-lactamase inhibitors of the transpeptidases. Over the years, many different screens have been used for inhibitor identification. The history of peptidoglycan drug discovery has been recently reviewed by Silver [2].

Most of the in vitro screens used for inhibitor identification have been multi-target screens where several pathway enzymes were incubated together with starting materials, and inhibition of any of the enzymes is measured as a decrease in product formation. These types of assays are efficient because they allow simultaneous screening of multiple targets. Inhibitors of MurA and MurC have successfully been identified in this manner [178,179].

One potential drawback to multi-target screens is that they are unable to distinguish between different modes of inhibition, so are equally likely to identify substrate binders and enzyme binders. The latter are specifically needed to help unravel enzymatic mechanism. Affinity screens can be used to identify compounds that bind to the enzyme. This type of screen has been successfully used to identify inhibitors of MurF that were subsequently used to obtain a crystal structure to aid in drug design [180,181]. A slightly different approach is a displacement screen, which selects for inhibitors that compete with the substrate for binding. This method has been used successfully to identify small-molecule inhibitors of MurG [182,183].

3 The Gram-Negative Outer Membrane

3.1 The Outer Membrane as a Permeability Barrier

The outer membrane (OM) is an asymmetric lipid bilayer, with an inner leaflet composed of phospholipids and an outer leaflet composed of lipopolysaccharide (◉ *Fig. 1*) [6]. The phospholipid composition of the inner leaflet of the OM of *E. coli* is similar to that of the inner membrane: predominantly phosphatidylethanolamine, with smaller amounts of phosphatidyl-

glycerol and cardiolipin [184]. In addition to LPS, the outer membrane also contains lipoproteins and integral OM β-barrel proteins (OMPs). *E. coli* has at least 90 lipoproteins, which protrude into the periplasm and are anchored to the inner leaflet of the outer membrane by their lipid tails [12]. The OMPs adopt a barrel-shape using antiparallel β-strands to span the OM. Many of the OMPs serve as channels that allow essential hydrophilic nutrients to diffuse across the OM [11]. There are also OMPs that function as enzymes. In addition to the components mentioned above, the OM also contains other types of lipid-linked polysaccharides, such as enterobacterial common antigen [13,14]. The OM is also the attachment site for surface organelles, such as pili, which play an important role in pathogenesis [15]. The OM serves as a permeability barrier that prevents toxic compounds, including detergents and antibiotics, from entering the cell [5]. The existence of this barrier enables *E. coli* and other *Enterobacteriaceae* to live in the human intestine, where there are high concentrations of bile salts. It also makes Gram-negative bacteria resistant to many antibiotics [185].

3.1.1 Structure of LPS

The structure of LPS is can be divided into three parts: the membrane anchored disaccharide lipid A, a short core oligosaccharide bearing multiple phosphoryl groups, and the structurally diverse *O*-antigen polysaccharide [7]. LPS has been best studied in the *Enterobacteriaceae*. Lipid A is the most highly conserved part of LPS. Lipid A typically consists of a β-(1′,6) linked glucosamine disaccharide that is phosphorylated at the 1 and 4′ positions of the disaccharide. The lipid A of *E. coli* and *S. enterica* is acylated by four (*R*)-3-hydroxymyristic acids at the 2, 3, 2′, and 3′ positions, and the fatty acids on the non-reducing glucosamine are further acylated on their hydroxyl groups (*Fig. 12a*). Lipid A is important for the structural integrity of the outer membrane, and a 30% reduction in lipid A renders *E. coli* hypersensitive to antibiotics. The acyl chains attached to lipid A are all unsaturated, allowing them to pack tightly together, and resulting in the very low fluidity (and thus low permeability) of the outer membrane. Lipid A is also responsible for inducing Gram-negative septic shock, and so is often referred to as ‘endotoxin’ [7]. The basic lipid A structure described above may be modified

in response to environmental signals. For example, the charge may be altered by capping the lipid A phosphates with aminoarabinose or 2-aminoethylphosphate, which provides protection against cationic peptides.

The structures of the core oligosaccharides of many different bacteria have been determined [7]. The inner core, which is linked to lipid A, is more highly conserved than the outer core. The inner core is made up of 3-deoxy-D-*manno*-octulosonic acid (Kdo) and, in most bacteria, L-glycero-D-*manno*-heptose (Hep). The minimal structure of LPS required for the survival of *E. coli* is commonly thought to consist of the lipid A and attached Kdo residues [186,187]. However, Meredith et al. recently reported isolation of a viable mutant of *E. coli* devoid of Kdo, with an outer membrane composed of the tetra-acylated lipid A precursor [188]. There are five known core structures for *E. coli* (● *Fig. 12b*), which differ in the outer core. These structures are composed predominantly of α-glucose and α-galactose. The R1 core type is seen most commonly in clinical isolates. One core type predominates among the *Salmonella* (● *Fig. 12b*). The sugars of the inner core are commonly phosphorylated [189]. In *E. coli* and *S. enterica* these phosphoryl substituents are known to be critical for outer membrane stability, and it is thought that adjacent LPS molecules are linked together through divalent cations bound to the phosphoryl groups.

O-antigens are polysaccharides composed of repeating oligosaccharide units. The structures of the repeating units exhibit remarkable diversity in the type, linkage, and substitution of component sugars. More than 170 different *O*-antigens have been identified in *E. coli* [10], and approximately 60 different *O*-antigens are characterized for *S. enterica* [190]. The *O*-antigen structures of *E. coli* have been compiled into a searchable database, available on the web at http://www.casper.organ.su.se/ECODAB/ [191]. A few representative structures are shown in ● *Fig. 13*. The *O*-antigen polymers are usually between one and forty repeating units in length. *O*-antigens are known to play important roles in pathogenesis, by helping the bacteria evade immune attacks from the host and colonize host tissue [192]. *Helicobacter pylori*, for example, evades immune detection by synthesizing *O*-antigens that mimic the Lewis blood group antigens of the host [192]. Mucosal pathogens such as *Neisseria*, *Haemophilus*, and *Bordatella* have LPS lacking *O*-antigen chains. Instead, they synthesize shorter, more highly branched LPS structures referred to as lipooligosaccharides (LOS) (● *Fig. 13*). For more information about LOS structures, see the review by Preston et al. [193]. Pathogenic *Neisseria* and *Haemophilus* species synthesize LOS that mimic human glycolipids and glycosphingolipids. These structures have been shown to be important for both evading the immune system and for adhering to and invading human cells [194,195]. *Campylobacter jejuni* LOS mimic human gangliosides, and it is suspected that development of antibodies against these LOS in individuals infected with *C. jejuni* may lead to GBS, an autoimmune disease that attacks nerve cells [196].

3.1.2 The Outer Membrane as a Permeability Barrier

The OM serves an important barrier function, protecting Gram-negative bacteria against hydrophobic dyes and detergents, as well as hydrophobic antibiotics such as the macrolides, novobiocins, rifamycins, actinomycin D, and fusidic acid that are effective against Gram-positives [185]. The OM is much less permeable than the phospholipid bilayer of the IM because the LPS fatty acyl chains are tightly packed, resulting in low fluidity [5]. The tight

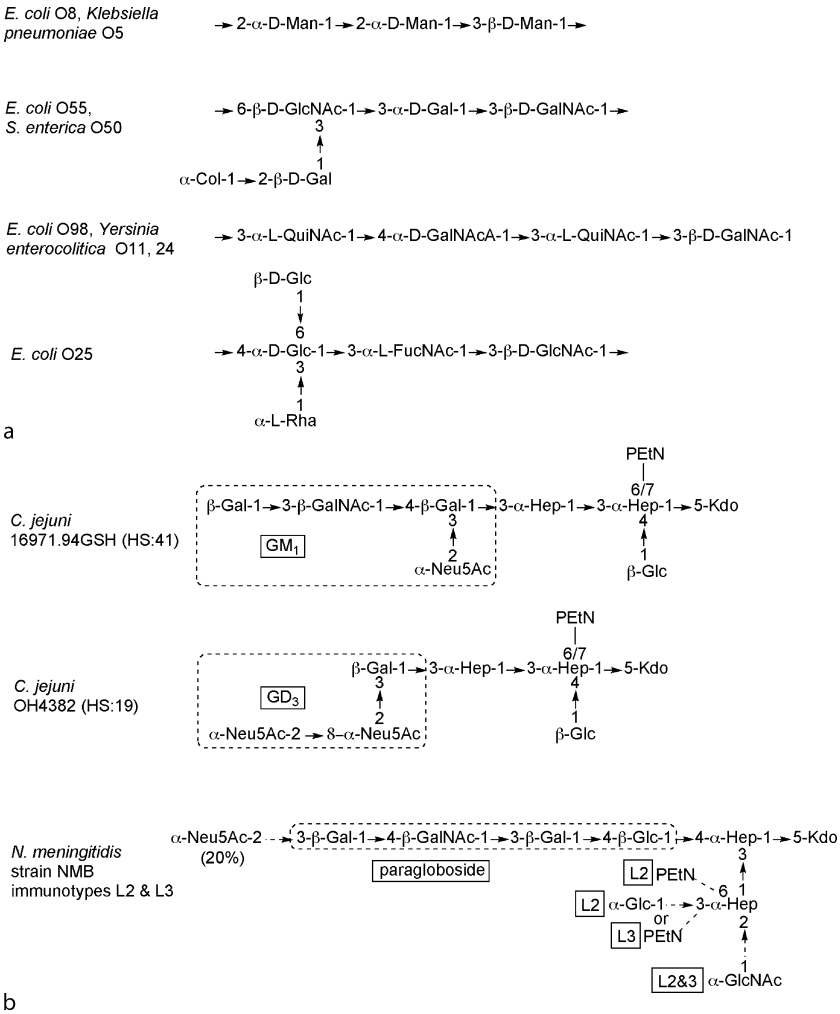

Figure 13

These structures are identical or nearly identical to the *O*-antigens from other bacteria, where noted. b) Lipooligosaccharide structures from *C. jejuni* and *N. meningitidis*. Structures corresponding to the human GM_1 and GD_3 gangliosides and paragloboside antigen are noted

packing is a result of several factors. There is a strong hydrophobic interaction between LPS molecules because LPS has a higher number of fatty acyl chains per molecule than normal glycerophospholipids, and the acyl chains are all saturated. LPS also contains a large number of H-bond donor and acceptor groups both in the sugar and in the lipid part of the molecule, and extensive H-bonds between LPS molecules stabilize the packing of the LPS leaflet and prevent the partitioning of hydrophobic molecules into the outer membrane.

In addition, divalent cations are recruited to neutralize the negatively charged groups in the inner core and lipid A regions, preventing electrostatic repulsion between LPS molecules. Chelators such as EDTA, which remove divalent cations from the cell surface, can cause

a "deep rough" phenotype characterized by hypersensitivity to detergents and antibiotics, and leakage of periplasmic proteins into the culture medium [197]. *E. coli* cells treated with EDTA release about half of their LPS into the medium [198]. Polycations, such as polymyxin B, also disrupt the OM (See ❯ *Sect. 3.4.1*) [199]. Polymyxin B binds to lipid A, primarily through electrostatic interactions.

3.2 Biosynthesis

The components of the outer membrane are synthesized inside the cell, and then transported across the inner membrane and periplasm to the outer membrane for assembly. The assembly process must be coordinated such that the structural integrity of the outer membrane is preserved. The intracellular biosynthesis of cell envelope components is well understood and is the subject of several reviews [7,200].

3.2.1 LPS Biosynthesis

The biosynthesis of lipid A was elucidated largely by work done by the Raetz group. Lipid A-Kdo_2 is synthesized from UDP-GlcNAc by a series of nine enzymes, as shown in ❯ *Fig. 14* [7,201]. Most of these enzymes have been characterized to some degree, and there are crystal structures for several. Inhibition of any of the first seven steps in lipid A biosynthesis results on cell death. Addition of the Kdo sugars necessarily precedes addition of the acyloxy groups in *E. coli* and *S. enterica*, but this not necessary for other Gram-negatives, such as *P. aeruginosa* [7,201]. The unusual Kdo sugar is added from a CMP-Kdo donor, for which the biosynthetic pathway has been determined [186]. The acyloxy groups attached by the final two acyltransferases are not essential, but are important for the biological effects exerted by endotoxin. LpxL and LpxM mutants constructed in pathogens including *E. coli*, *H. influenzae*, and *Salmonella* exhibit decreased virulence and provoke less of an inflammatory response [201]. Such mutants are being explored for use in vaccines [202,203].

After assembly of lipid A-Kdo, a series of glycosyltransferases attaches the core sugars from nucleotide-sugar donors [7]. For *E. coli*, all of the glycosyl and phosphoryl transferase genes involved in the synthesis of the R1 core have been characterized [204,205]. Homologs of the heptosyltransferases responsible for transferring the conserved inner core Hep residues from ADP-Hep have been identified in many bacteria, and most of the enzymes that form the unusual ADP-Hep donor are now known [7,206]. *E. coli* and *S. enterica* strains missing one or both core Hep residues exhibit a "deep rough" phenotype, characterized by hypersensitivity to hydrophobic detergents and antibiotics, and release of periplasmic enzymes from the cell [5,185]. Phosphorylation of the Hep residues was likewise shown to be important for antibiotic and detergent resistance. An *S. enterica* mutant lacking both phosphates was completely non-virulent, and in *P. aeruginosa* this mutant was non-viable [207,208].

The completed lipid A-core oligosaccharide structure is transported across the plasma membrane by the ATP-dependent transporter MsbA. In vitro experiments with *E. coli* MsbA suggest that the ATPase recognizes only fully hexaacylated Kdo_2-lipid A, but the transporter appears to be slightly less selective in vivo [209]. Crystal structures have been reported for MsbA homologues from *E. coli* and *Vibrio cholera* [210,211,212]. However, these structures

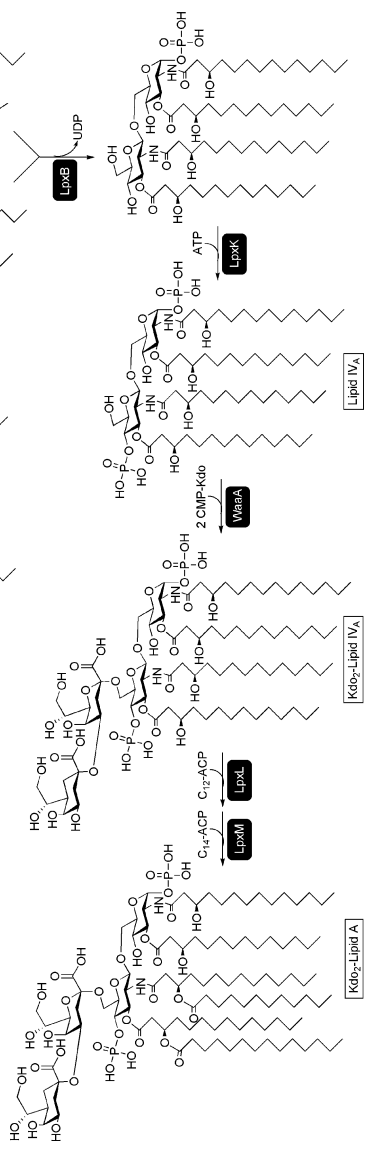

Figure 14
Biosynthesis of Kdo_2-lipidA

were incorrect due to an error in data processing, and were later retracted [213]. MsbA is expected to be structurally homologous to other ABC transporters for which structures exist, including the bacterial multidrug transporter Sav1866 [214].

O-antigens are synthesized on undecaprenyl phosphate carrier lipids anchored in the plasma membrane. There are three different mechanisms for chain assembly [7]. In the Wzy-dependent pathway, individual *O*-antigen repeat units are synthesized on carrier lipids, then flipped across the membrane to the periplasm by Wzx, and polymerized by Wzy. Chain length is regulated by Wzz. The Wxy pathway is also used in capsular polysaccharide biosynthesis (see ❯ *Sect. 5.2.1*). In the ABC transporter-dependent pathway, the entire *O*-antigen chain is synthesized on the cytoplasmic face of the membrane and then flipped to the periplasm by an ABC transporter which comprises Wzm and Wzt. There is also a third, synthase-dependent pathway, where *O*-antigen synthesis occurs concurrently with export [215].

The first step in chain synthesis for each of these pathways involves attachment of an initial sugar residue to the undecaprenyl membrane anchor. This step is relatively highly conserved; all initiating enzymes thus far identified are homologues of either *E. coli* WecA, which adds GlcNAc-1-P to the anchor [216,217], or *S. enterica* WbaP, which attaches Gal-1-P to the carrier lipid [218]. The chain is then elongated by a series of glycosyltransferases utilizing nucleotide-sugar donors [219], and exported by one of the mechanisms described above. The completed *O*-antigen is attached to the lipid A–core at the periplasmic face of the membrane by WaaL ligase. The WaaL proteins from different organisms have low sequence homology, but can functionally compensate for each other and are expected to have similar structures [220,221,222].

As mentioned in ❯ *Sect. 3.1.1*, the lipid A and the core oligosaccharides can undergo structural modifications in response to environmental signals [7]. Modifications of lipid A usually entail removal or modification of the phosphates and fatty acyl chains (❯ *Fig. 15*). Modifications occur at both early and late stages of OM biosynthesis. In *E. coli* grown at low tem-

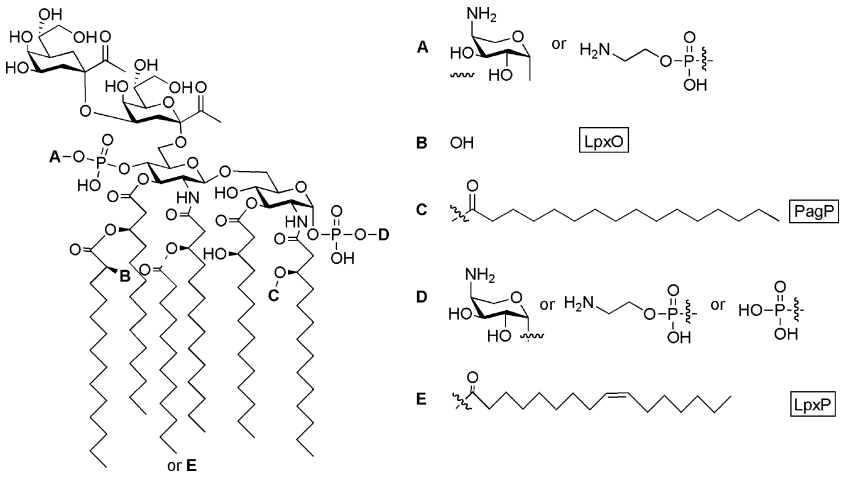

Figure 15
Possible modifications of lipid A in *E. coli* and *S. enterica*

peratures, the biosynthesis of lipid A uses the alternate acyltransferase LpxP, which incorporates an unsaturated palmitoleoyl group into the lipid A chains in place of the saturated acyl group added by LpxL. The unsaturated chains maintain membrane fluidity at low temperatures. A common phosphate modification is the addition of 4-amino-4-deoxy-L-arabinose to lipid A, which confers increased resistance to antimicrobial peptides by altering the charge on lipid A. This occurs at the outer surface of the inner membrane. Lipid A can also be modified after incorporation into the OM. For example, lipid A can be heptaacylated by transfer of palmitate from glycerophospholipids to lipid A by the OM enzyme PagP [223,224]. The extra acyl chain may be needed to increase resistance against the host's immune system during certain stages of infection. The genes and enzymes responsible for many such modifications are known, as are the regulatory pathways that control these modifications [7,201]. These are all potential targets for therapeutic intervention.

3.2.2 LPS Export and Assembly

The transport of these components and their incorporation into the outer membrane are subjects of ongoing research. After the *O*-polysaccharide is ligated to the lipid A-core at the periplasmic side of the inner membrane [225], LPS is somehow targeted across the periplasm to the OM. How this occurs is still not well understood [226]. "Zones of adhesion" or "Bayer's Patches" have been observed where the IM is thought to contact the OM [227], and it has been proposed that the OM components reach the OM via these membrane contact sites, without traveling through the periplasm [228]. Consistent with this model, EM shows newly synthesized LPS at regions of membrane adhesion [229].

Recent publications have shed some light on how the LPS components are assembled. Wu et al. recently identified a complex of proteins in *E. coli* that is responsible for assembly of lipopolysaccharide [230]. Two genes, *lptA* and *lptB*, were also recently proposed to be involved in the transport of LPS from the IM to the OM of *E. coli* [231].

3.3 Chemical Synthesis

Lipid A was first synthesized by Imoto et al. in the mid 1980s [232,233], and the synthetic compound was found to possess all endotoxic activity of LPS. Many derivatives of Lipid A were subsequently synthesized in order to tease apart the importance of different structural elements for endotoxic activity. These investigations have been recently reviewed [234,235]. The tetraacylated lipid A precursor (lipid IV_A, ❯ *Fig. 14*) was found to compete with lipid A for binding to macrophages, but to have endotoxic activity 10^7 less than that of lipid A [235], with the result that it acts as a lipid A antagonist in human cells. In contrast, synthetic Re LPS (Kdo_2-lipid A, ❯ *Fig. 14*) was found to have enhanced immunostimulatory ability compared with lipid A.

Oligosaccharide mimics of the *O*-antigens of many bacterial pathogens, including *E. coli* [236], *Helicobacter pylori* [237], *Shigella flexneri* [238,239] and *Vibrio cholerae* [240,241] have been synthesized and evaluated for use in antibacterial vaccines (❯ *Fig. 16*).

3.4 Medicine

One of the major problems associated with Gram-negative infections is septic shock, which results from an overly vigorous immune response launched as a reaction to LPS recognition. During bacterial death or division, endotoxins are released into the blood stream, where the lipid A moiety is recognized by a circulating protein called the lipopolysaccharide binding protein (LBP) [242]. The LPS-LPB complex binds to the CD14 receptor on the surface of myeloid cells, which subsequently forms an activated complex with the soluble receptor MD-2 and the transmembrane signaling receptor Toll-like receptor-4 (TLR4) [243]. Activation of the receptor cluster results in an inflammatory cascade and the production of reactive oxygen species, which may eventually lead to multiple organ failure. Septic shock can thus result in death even if the bacterial infection is successfully controlled. There is therefore much interest in designing therapeutics that would prevent septic shock by neutralizing LPS.

3.4.1 Drugs that Neutralize LPS

Attempts to design therapeutics for LPS neutralization have largely focused on designing analogs of the naturally occurring molecules that bind LPS. Many cationic peptides with antimicrobial activity also neutralize LPS. These peptides penetrate the Gram-negative cell wall by binding to the cation binding sites on LPS or neutralizing the charge over a patch of the OM, resulting in defects in the LPS. The structures of several of these peptides are shown in ❯ *Fig. 17*. These include Polymyxin B, magainin, cecropin, the bactenecins, gramicidin S, and the defensins. Efforts toward peptide-based endotoxin neutralization have been recently reviewed [244].

The gold standard for anti-endotoxin peptides is Polymyxin B (PMB), a small cyclic lipopeptide (❯ *Fig. 17*). It neutralizes LPS very efficiently, and has been shown to employ a two-step binding process where it first attaches to the LPS by electrostatic interactions and then inserts its acyl chain into the lipid layer. PMB is used only topically because it is neurotoxic. However, there have been many attempts to design analogs with lower toxicity [245,246,247]. Synthetic anti-endotoxin peptides (SAEP) based on Polymyxin B have been engineered to have low toxicity while retaining the in vitro and in vivo detoxification ability of PMB. Furthermore,

Figure 17
Peptide antibiotics that neutralize LPS

a vaccine against *Neisseria meningitidis* LPS which uses purified LPS from pathogenic strains detoxified by complexation to SAEP has entered Phase I clinical trials.
Some bactenecin derivatives have also shown good activity in vitro and in vivo. In particular, the proline-rich synthetic bactenecin Bac7(1–35) proved to be as effective as PMB at reducing plasma endotoxin levels and decreasing mortality in endotoxin-challenged rats [248]. Some success has also been achieved with derivatives of cecropin, which binds lipid A, and magainin, which inserts itself into the OM as an alpha-helix, disrupting the arrangement of fatty acid chains. Hybrids of cecropin and the potent anti-microbial peptide mellitin have been shown to bind LPS and inhibit cytokine production as well as PMB, and novel analogs of magainin with improved amphiphilicity have exhibited affinities for LPS close to that of PMB [244].
Other synthetic LPS binding peptides have been based on fragments of larger proteins that bind LPS, such as serum amyloid P component (SAP), human neutrophil bactericidal/permeability-increasing protein (BPI), Limulus anti-LPS factor (LALF), lactoferrin, and histones [244]. BPI is an extracellular endotoxin receptor that neutralizes LPS in vivo by binding to it and forming large aggregates. Several synthetic peptides derived from BPI have shown good microbicidal and LPS neutralizing activity, and a recombinant protein derived from BPI provided protection meningococcal sepsis in a Phase III clinical trial [249]. Peptides derived from SAP and lactoferrin have also shown good in vitro and in vivo activity.

3.4.2 Antibacterial Vaccines

A common method used in vaccine development is to link polysaccharide antigens to immunogenic peptide "adjuvants" such as tetanus or diphtheria toxoid. Vaccination with such glycoconjugates results in the activation of T-cell dependent immunological memory. LPS-based glycoconjugate vaccines are currently in various stages of development for several bacteria, including *E. coli*, *Francisella tularensis*, *Pseudomonas aeruginosa*, *Salmonella*, *Shigella*, and *Vibrio cholerae* [26].
There is still no LPS-based vaccine in clinical use, but a *Shigella* vaccine based on detoxified LPS from *Shigella sonnei* was used in a trial by the Israeli Army several years ago, with the result that the infection rate was reduced by 75% in the vaccinated group [250]. A vaccine against *E. coli* using detoxified *E. coli* J5 lipopolysaccharide complexed to an group B meningococcal outer membrane protein (OMP) has also fared well in Phase I clinical trials [251]. Several synthetic derivatives of LPS components have also shown promise as vaccine candidates, including a synthetic triacylated lipid A derivative [252] and oligosaccharide mimics of an *O*-antigen from *Shigella flexneri* [239].

3.4.3 LPS in Cancer Treatment

LPS has well-documented antitumor effects, and cancer treatments employing LPS have been in development for quite some time [253]. The first cancer treatment investigations using LPS were clinical trials performed by Coley in 1898 [254]. Lipid A was shown to be responsible for the antitumor activity of LPS, and trials in animal models of cancer have generally shown that administration of lipid A increases survival and slows tumor growth. The mechanisms by which lipid A exerts its antitumor effects have largely been elucidated [253], though an in-depth discussion is beyond the scope of this review. Briefly, lipid A activates signaling cascades

in the host, leading to the production of cytokines that are either cytotoxic or stimulate the immune system. LPS and lipid A have been tested in Phase I and II clinical trials in cancer patients, and both were found to cause disease stabilization and cytokine production [253]. Lipid A has also been mixed with tumor cell homogenates or cell-surface antigens to create vaccines targeted to particular tumors. In these vaccine preparations, the lipid A acts as an adjuvant to promote the development of an immune response to the tumor antigens. Phase I and II trials with adjuvant vaccines look promising, and antitumor effects are correlated with an antibody response or with cell-mediated cytotoxicity [253].

Thus, the potent immunostimulatory ability of LPS results not only in its severe toxicity, but also in its potential utility as a therapeutic agent. The interactions between LPS and the immune system are complex, and there is continued research aimed at unraveling the signaling pathways responsible for the inflammatory and anti-tumor properties of LPS.

4 Cell Wall Components in the Corynebacterineae

The Corynebacterineae, or mycolata, are a subset of actinomycetes including the genera *Corynebacterium*, *Dietzia*, *Rhodococcus*, *Gordonia*, *Mycobacterium*, *Nocardia*, *Skermania*, *Tsukamurella*, *Turicella and Williamsia*. The best-known members of this group are the notorious pathogens *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and *Corynebacterium diphtheriae*, the causative agents of tuberculosis, leprosy and diphtheria, respectively. Though they are Gram-positive, lacking an outer membrane, they possess a multi-layered cell wall containing an outer lipid bilayer that is functionally similar to the Gram-negative outer membrane. This bilayer structure is very dense in some species, creating an almost impenetrable barrier. For pathogens such as *Mycobacterium tuberculosis*, and *Mycobacterium leprae*, the result is a cell wall that is impermeable to many antibiotics, making infections caused by these organisms particularly difficult to treat [22]. Many other mycolata, including species belonging to the *Corynebacterium*, *Mycobacterium*, and *Nocardia* genera, cause infections primarily in immunocompromised individuals but are equally resistant to drug treatment.

In the previous edition of this book, Todd Lowary exhaustively reviewed what was known to date about the structure, function and biosynthesis of the mycobacterial cell wall polysaccharides, as well as chemical syntheses of substrates and inhibitors for the biosynthetic enzymes [21]. Cell wall biosynthesis remains better studied in mycobacteria than in the other mycolata because of the obvious medical significance of these bacteria. The purpose of this section is therefore to highlight more recent developments in the study of the mycobacterial cell wall, and to describe some of the variation in cell wall structure seen among different genera within the mycolata.

4.1 Structure of the Mycobacterial Cell Wall Polysaccharides

The basic structure of the mycobacterial cell wall is shown in ❯ *Fig. 1* (❯ *Sect. 1*). The major component of the cell wall is the mycolyl-arabinogalactan-peptidoglycan (mAGP) complex [21]. This consists of an inner peptidoglycan layer attached through a linker unit to an arabinogalactan polysaccharide, which is in turn esterified to mycolic acids. The mycolic acids are branched hydroxy fatty acids that form the inner leaflet of the lipid bilayer. The outer leaflet

is made up of free glycolipids and phospholipids, which also fill any gaps in the inner leaflet. These are the subject of several reviews, and will not be discussed here [20,255]. In addition to mAGP, the mycobacterial cell wall contains several other distinctive polysaccharide components, including lipoarabinomannan (LAM) and lipomannan (LM), glycolipids that are anchored in the cytoplasmic membrane and extend through the cell wall. LAM is the major antigenic component of the mycobacterial cell wall.

4.1.1 Arabinogalactan

The structure of mycobacterial AG has been elucidated by fragmentation using either enzymatic digestion or acid hydrolysis, followed by mass spectrometry (*Fig. 18*) [256]. The arabinogalactan is covalently bound to peptidoglycan through a phosphodisaccharide linker, α-L-Rha*p*-(1→3)-D-GlcNAc-P. This linker unit is highly conserved among all the mycolata. The linear galactan chain, which contains approximately 30 β-D-galactofuranose (Gal*f*) residues with alternating β-(1→5)- and β-(1→6)-linkages, is attached to the linker through C-4 of rhamnose. Approximately three arabinofuranose (Ara*f*) chains are attached to each Gal*f* chain through α(1→5) linkages to C5 of the β(1→6) linked Gal*f* residues. The arabinan chain is composed of α(1→5) linked D-Ara*f* residues with (1→3) linked α-D-Ara*f* branches. The non-reducing terminus of each arabinan is decorated with a [β-D-Ara*f*-(1→2)-α-D-Ara*f*]$_{2-}$3,5-α-D-Ara*f*-(1→5)-α-D-Ara*f* motif. Mycolic acids are anchored to both the terminal β-Ara*f* and the penultimate 2-α-Ara*f*.

The non-reducing terminal regions of the arabinan chains have been described for a number of bacteria. Because of the methods used for digestion, however, the structure of the remainder of the AG complex, including the location of branch points and the locations and types of modifications, remains largely speculative. Recently, a more detailed structural model of mycobacterial arabinan was obtained by digestion with an arabinase able to release large oligoarabinosyl fragments from AG, followed by advanced tandem mass spectrometry [256]. This study confirmed the presence of the Ara_{22} structural motif shown in *Fig. 18a*, and identified a galactosamine substituent on the C2 position of a portion of the internal 3,5-branched Ara residue of the AG of *M. tuberculosis.*

The arabinogalactan structures of other mycolata have been studied in less detail than that of the mycobacteria, but differences are apparent in both the saccharide linkages and in the composition of the non-reducing terminus. The arabinogalactan of *C. diphtheriae* contains roughly the same linkages as that of *M. tuberculosis*, but lacks 3,5-linked Ara*f* residues, suggesting an unbranched arabinan [257]. The AG of *C. diphtheriae* AG also contains a significant amount of mannose, which may form a mannose cap on the arabinan domain. Rhodococcal galactan differs from that of mycobacteria in that it contains (1→3) and (1→2) linkages in addition to (1→5) and (1→6) linkages [258]. The AG chains can also contain a variety of terminal motifs, including a branched tri-arabionsyl unit and an unbranched (1→5) linked linear terminus, and termini capped with mannose residues. Rhodococcal AG may also contain fewer than three arabinans per galactan.

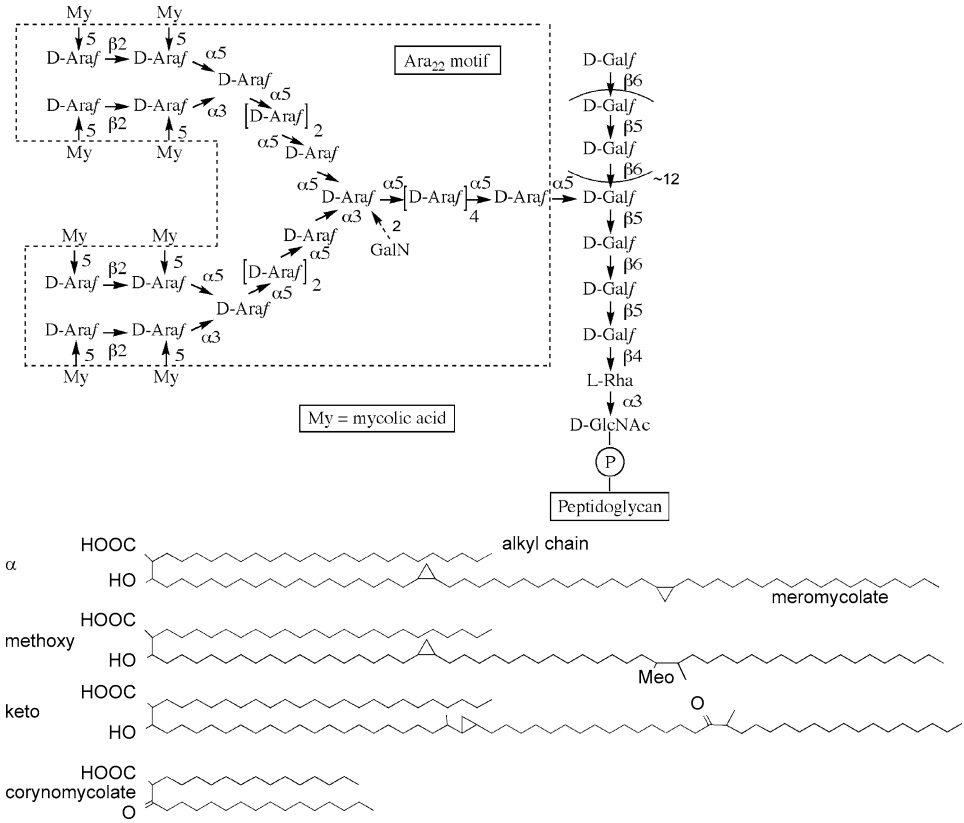

Figure 18
a) Structure of arabinogalactan from *M. tuberculosis*. b) Structures of mycolic acids from *M. tuberculosis*, and a corynomycolic acid

4.1.2 Mycolic Acids

Mycolic acids are α-alkyl branched, β-hydroxy long-chain fatty acids. The alkyl chain is considerably shorter than the main meromycolate chain. The mycolic acids of different bacterial species differ in both the length and structure of the long meromycolate [259]. The mycolic acids from mycobacteria contain 60–90 carbons, and are longer than those from the other mycolata. *Mycobacterium tuberculosis* contains three structural classes of mycolic acids, as shown in ❯ *Fig. 18b* [259]. The α-mycolic acid is the most abundant, with only 10–15% each of the methoxy- and keto-mycolic acids. The cyclopropyl groups of α-mycolic acid are in the *cis, cis* configuration, with variations in the length of the terminal alkyl group and the number of methylene groups between the cyclopropane rings and the carboxyl group. Methoxy- and keto-mycolic acids can contain either *cis*- or *trans*-cyclopropane rings. Corynebacterial corynomycolic acids (❯ *Fig. 18b*) are simple and short, containing only 22–38 carbons [260]. Rhodococcal mycolic acids contain 30–54 carbons, and like their mycobacterial counterparts

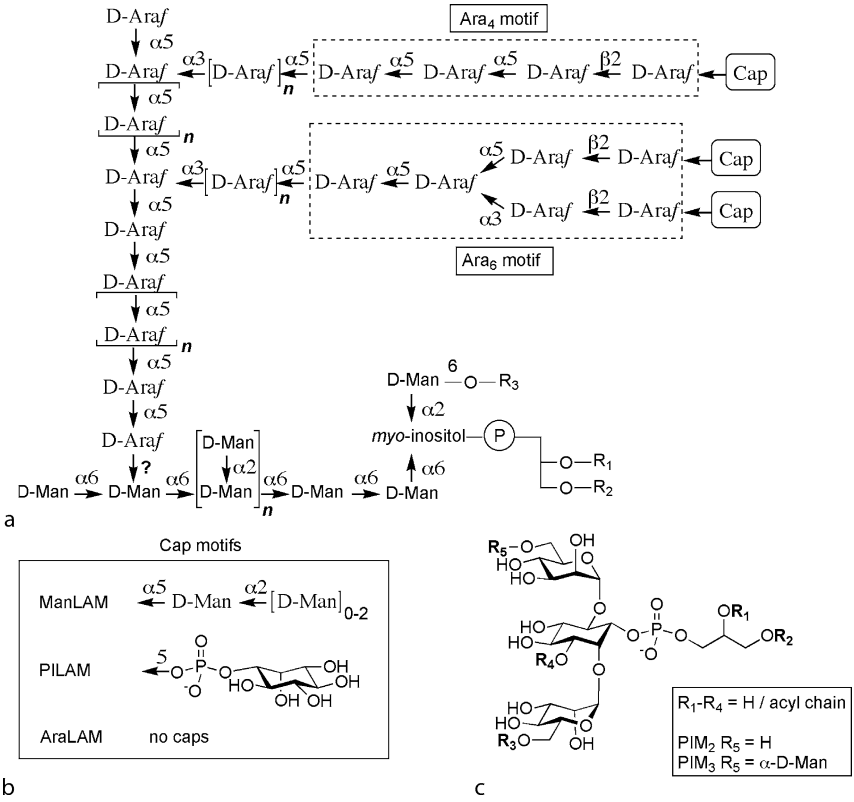

Figure 19

a) Structure of mycobacterial LAM, showing the Ara_4 and Ara_6 terminal arabinan motifs. b) LAM caps. c) Structure of the MPI anchor. The four potential sites of fatty acid attachment are shown

contain a short alkyl chain and a longer meromycolate chain. The rhodococcal meromycolate is unsaturated with up to four double bonds [258,261].

4.1.3 Lipoarabinomannan and Related Lipoglycans

The mycobacterial cell wall contains the essential lipoglycan structures lipoarabinomannan, lipomannan, and phosphatidyl-*myo*-inositol-mannosides (PIMs) [262]. These molecules are attached to the cytoplasmic membrane and extend through the cell wall into the extracellular environment (*Fig. 1*). PIMs, LMs, and LAMs are attached to the cytoplasmic membrane by a conserved anchor, which consists of an sn-glycero-3-phospho-(1-D-*myo*-inositol), with a single α-D-Man*p* linked at C2 of the *myo*-inositol (*Fig. 19c*). The mannan core is attached to C6 of the *myo*-inositol unit. There are four potential sites of fatty acid attachment on the anchor: both free hydroxyls of the glycerol unit, C6 of the Man*p* linked to C2 of *myo*-inositol and C3 of the *myo*-inositol. The fatty acids are most commonly palmitic and tuberculostearic (10-methyl-octadecanoic) acids, and less frequently, stearic acid. Other fatty acids are seen in

some mycobacteria. There is a lot of variation in the number, identity and location of the fatty acids. Different mycobacteria possess different characteristic fatty acid acylation patterns, and these have been determined for a number of species using ^{31}P NMR [262].

In PIMs, 1–6 mannoses are attached to the anchor. In LMs and LAMs, this chain is extended into a 20–25 residue mannan containing a linear chain of α(1,6)-linked Man*p* units, with single Man*p* units attached at C-2 in many species, including *M. tuberculosis* and *M. leprae* (● *Fig. 19a*) [263,264]. In LAMs, the mannan is linked to arabinan chains similar to those in AG, containing a linear $\alpha(1\rightarrow5)$-linked Ara*f* substituted at C3 of some residues with arabinan branches. The arabinan branches contain terminal linear tetra-Ara*f* and branched hexa-Ara*f* motifs (● *Fig. 19a*) [262]. Each LAM contains about 50–80 Ara*f* residues, though the number and length of arabinan chains attached to each mannan is uncertain [263]. The LAMs of many pathogenic species including *M. tuberculosis*, *M. leprae*, *M. avium*, and *M. kansasii* are capped with capped with one, two or three αMan*p* units (● *Fig. 19b*). The mannose capped LAMs (ManLAMs) are important for several aspects of infection (see ● *Sect. 4.4.3*). LAMs of many non-pathogenic strains, in contrast, are capped with inositol phosphate, and these PILAMs are highly inflammatory [264].

LAM-like lipoglycans have been identified in several non-mycobacterial strains, including members of the *Rhodococcus*, *Corynebacterium*, and *Gordonia* genera. These molecules all possess α(1,6)-Man*p* backbones, attached either to a few arabinose residues, or to longer arabinan chains [262]. The immunogenic properties of these LAMs are not well studied, but the LAM from the equine pathogen *Rhodococcus equi* was shown to induce a strong pro-inflammatory response.

4.2 Biosynthesis of Cell Wall Polysaccharides in Mycolata

In the past few years, much has been learned about the biosynthesis of cell wall components in mycolata. Credit for this recent surge of information belongs largely to bacterial genome sequencing projects. Before 2001, only one complete genome sequence, from a *M. tuberculosis* strain, was available for any of the mycolata. Since that time, complete genome sequences have been reported for several additional mycobacterial species including *M. leprae* and several corynebacterial species including *C. diphtheriae*, as well as species belonging to the *Nocardia* and *Rhodococcus* genera.

This section will summarize what is known about the biosynthesis of arabinogalactan and lipoarabinomannan. For a more comprehensive discussion of how glycan assembly is coordinated, and the glycosyltransferases involved, the reader is referred to a recent review by Berg et al. [265].

4.2.1 Biosynthesis of Donor Sugars

The AG and LAM polysaccharides contain unusual sugars, notably D-Ara*f*, D-Gal*f* and Rha. The biosynthetic pathways for the sugar donors thus hold potential as targets for anti-tuberculosis drugs. The glycosylation reactions in the early steps of AG and LAM biosynthesis utilize NDP-sugar donors, while those in the later stages use sugars linked to decaprenyl-phosphate. For most of the nucleotide-sugar donors in *M. tuberculosis*, the biosynthetic pathways have

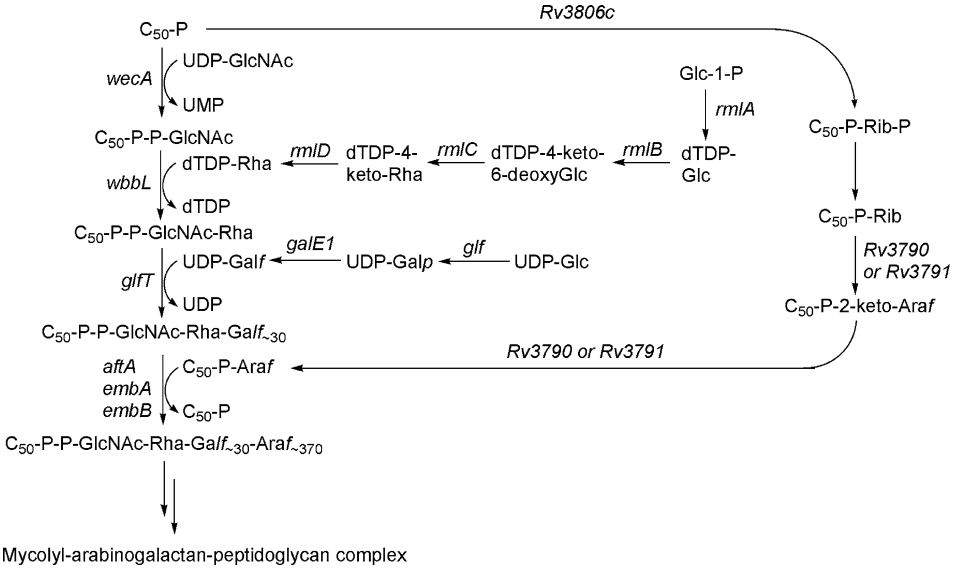

Figure 20
Biosynthesis of arabinogalactan. Biosynthetic genes are indicated, where known

been characterized or the genes involved have been annotated based on homology to other bacteria (*Fig. 20*) [265]. The Rml enzymes responsible for synthesis of dTDP-Rha have been identified and expressed in *E. coli*. The biosynthetic pathways for the polyprenyl-based sugar donors have also been largely characterized [265]. The mannosyltransferase involved in the synthesis of β-D-mannosyl-1-monophosphoryl-decaprenol (C_{50}-P-Man) was identified by homology with eukaryotic dolichol monophosphomannose (DPM) synthase (*Fig. 21*), and subsequently characterized [266]. β-D-arabinofuranosyl-1-monophosphoryl-decaprenol (C_{50}-P-Ara*f*) is the only known donor of Ara*f* in mycobacteria. C_{50}-P-Ara*f* is formed in an unusual process by epimerization of decaprenylphosphoryl ribose (*Fig. 20*), and the enzymes responsible for this process have been purified [267].

4.2.2 Biosynthesis of Arabinogalactan

Information about the biosynthesis of arabinogalactan was originally obtained in the laboratory of Patrick Brennan, in a series of studies where mycobacterial membrane preparations were incubated with radiolabeled sugar donors [32,265]. The biosynthesis was found to proceed in a stepwise fashion as shown in *Fig. 20*, with UDP-GlcNAc, dTDP-Rha, UDP-Gal*p* and C_{50}-P-Ara*f* sequentially incorporated into polymeric glycolipid product. The entire AG polymer is assembled on a decaprenyl membrane anchor. The enzyme responsible for initial attachment of GlcNAc to decaprenyl-P has not been characterized, though a candidate gene has been identified by homology to the gene for WecA, a GlcNAc phosphotransferase involved in lps enterobacterial common antigen synthesis in *E. coli* (see *Sect. 3.2.1*). The linkage unit is completed by transfer of Rha from dTDP-Rha by the enzyme WbbL [268]. Synthesis of the galactan is thought to involve at least two glycosyltransferases. The enzyme Rv3782 was

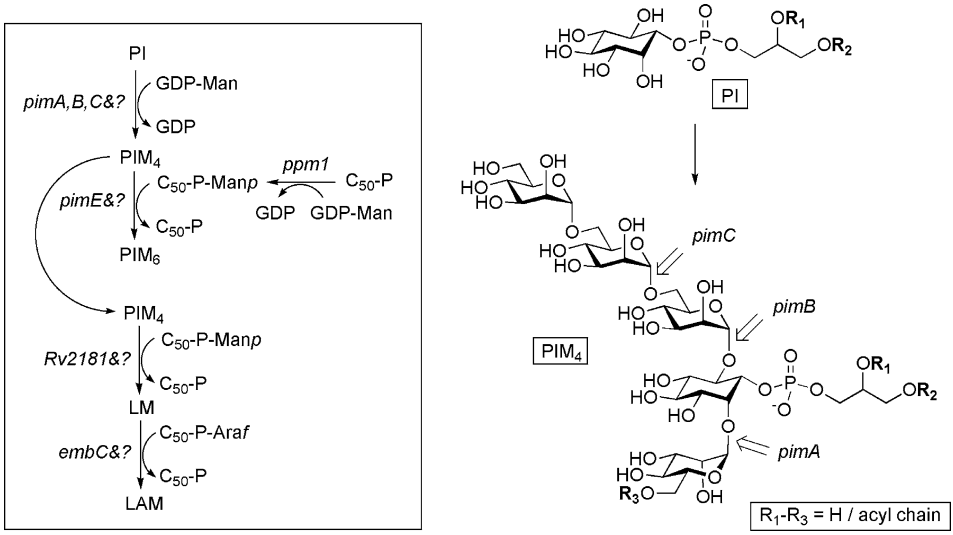

Figure 21
Biosynthesis of PIMs, LMs, and LAMs

shown to initiate galactan synthesis by formation of the Gal*f*-β (1→4)-Rha linkage to the rhamnose [269]. Synthesis of the main galactan chain is catalyzed by the bifunctional enzyme GlfT, which forms both the (1→5) and (1→6) glycosidic linkages [270].
Synthesis of the arabinan domain of AG is less well characterized, but several of the arabinosyltransferases involved have been identified and characterized to different degrees. AftA, which has been purified, was shown in an in vitro assay to add the first Ara*f* residue to the galactan domain of AG [271]. Two proteins, EmbA and EmbB were shown to be to be necessary for formation of the branched Ara_6 motif, as absence of either protein either in vivo or in vitro resulted in a linear glycan (lacking branching at the 3 position of the 3,5-linked Ara*f*) [272]. However, the exact roles of these proteins in glycan formation are unknown.

4.2.3 Biosynthesis of the Mycolic Acids

Mycolic acids are synthesized inside the cell, and then transferred to trehalose-6-phosphate to yield trehalose monomycolate (TMM), which is thought to be moved outside the cell through an ABC transporter. The mycolic acids are then attached to the arabinogalactan complex by a mycolyltransferase. The intracellular synthesis of the mycolic acids in *M. tuberculosis* is fairly well understood, and the mycolyltransferase responsible for peptidoglycan attachment has been identified. The intermediate processing steps, however, remain speculative. Synthesis of the mycolic acids has been recently reviewed by Takayama et al. [273], and will not be discussed in detail here.

4.2.4 Biosynthesis of LAM

LAM, LM, and the PIMs are thought to share a biosynthetic pathway, where PIM_4 is the last common intermediate, and can be extended to either PIM_6 or LM/ LAM (*Fig. 21*) [274].

The first step in the pathway is the synthesis of PI from CDP-diacylglycerol and *myo*-inositol by PgsA (Rv2612c) [275]. *Myo*-inositol is uncommon in prokaryotes, but inositol phosphates and inositol-containing phosphoglycans are important in eukaryotic signaling pathways. The mycobacterial enzymes responsible for *myo*-inositol biosynthesis have been characterized [276,277].

PI is elaborated by a series of mannosyltransferases to make $PIMs_{1-6}$ (*Fig. 21*). Inhibition studies with amphomycin suggest that the first three enzymes that synthesize PIM_1 through PIM_3 use GDP-Man as the glycosyl donor, while those that make $PIMs_{4-6}$ use C_{50}-P-Man [265]. The genes *pimA*, *pimB*, and *pimC* were found encode mannosyltransferases that sequentially attach the first three mannose residues to form $Pims_{1-3}$. While *pimA* is essential, *pimB* and *pimC* are neither essential nor required for PIM/ LM/ LAM synthesis, suggesting the presence of other mannosyltransferases with PimB and PimC activities [265]. Understanding of the biosynthetic pathway after PIM_3 is somewhat vague, but three C_{50}-P-Man-dependent mannosyltransferase genes have been partially characterized: *pimE*, necessary for conversion of PIM_4 to PIM_5 or PIM_6 [278], Rv2181, which attaches α(1,2)-linked Man*P* to the LM backbone [274], and Rv1635c, which attaches the first mannose residue in the cap of ManLAM [279]. An arabinosyltransferase, *embC*, necessary for the synthesis of the LAM arabinan chains, has also been identified [280]. For a more detailed description of LAM biosynthesis, see the review by Nigou et al. [262].

4.3 Chemical Syntheses

4.3.1 Synthesis of Small Oligosaccharides

The enzymes involved in AG and LAM biosynthesis are potential targets for novel therapeutic agents, and there is a lot of interest in developing tools with which to study them. Small polysaccharide analogs of AG and LAM have been explored as potential substrates and inhibitors with which to study the enzymes, and some of these compounds have shown antimicrobial activity. Several groups have demonstrated the utility of small synthetic arabinofuranosyl oligosaccharides as substrates for mycobacterial arabinosyltransferases [281,282,283], and arabinosyltransferase assays using synthetic substrates have been used to probe the functions of several arabinosyltransferases [284]. Synthetic disaccharides have likewise been employed to probe the substrate specificity of mannosyltransferases (*Fig. 22d*) [285] and galactofuranosyltransferase [270].

Disaccharides have also been synthesized as potential cell wall biosynthesis inhibitors, including analogs of the arabinogalactan linkage disaccharide (*Fig. 22e*) [286], and small lipid disaccharides containing arabinose and galactose [287]. Some of these have exhibited moderate in vitro activity against TB.

4.3.2 Synthesis of Larger AG and LAM Fragments

The synthesis of AG or LAM arabinan is complicated by the presence of β-linked arabinofuranosyl moieties. The beta-linkage is difficult to construct because the substituents at C1 and C2 are *cis*. Sterics favor formation of the *trans*-glycoside, and neighboring group participa-

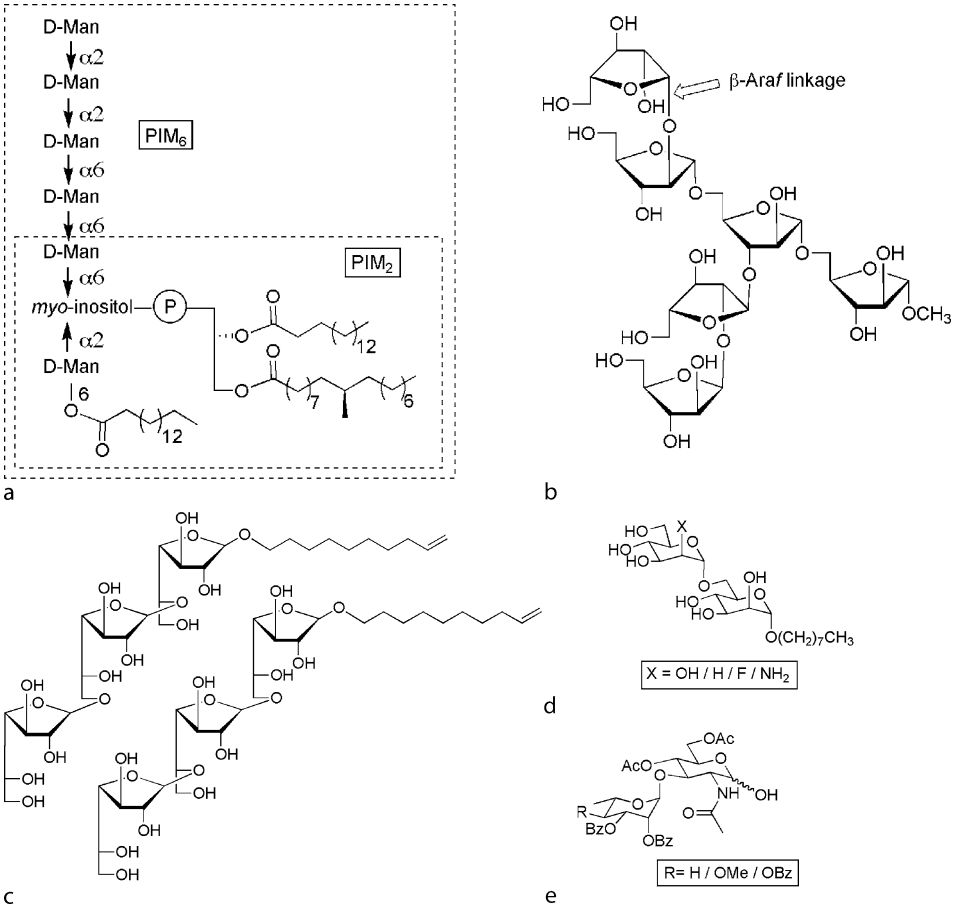

Figure 22
Synthetic disaccharide and oligosaccharide fragments of AG and LAM discussed in the text

tion by a C2 protecting group cannot be used to direct cis-glycosidic bond formation. Much work on arabinan synthesis has been carried out by the Lowary group, and they have explored the use of 2,3-anhydrosugar thioglycosides and sulfoxides for stereoselective construction of β-arabinofuranosyl linkages [288]. Using an epoxide protecting group at C2 and C3, they are able to achieve stereoselective formation of the β-glycosidic bond. Subsequent nucleophilic opening of the epoxide ring gives the arabinofuranoside as the major product. They have used this methodology to construct the arabinofuranosyl hexasaccharide motif (*Fig. 22b*), which is found in AG and LAM.

The synthesis of oligosaccharides containing Gal*f* residues has also been explored. An assay employing synthetic dec-9-enyl glycolipid acceptors was used to elucidate the function of glfT, the bifunctional UDP-galactofuranosyltransferase in galactan biosynthesis [289], and the synthesis of two dec-9-enyl trisaccharide fragments of galactan has been reported (*Fig. 22c*) [290].

Synthetic routes to PIM analogs have also been developed, and the Seeberger group recently reported the first total synthesis of PIM_2 and PIM_6 (*Fig. 22a*) [291]. Shortly thereafter, Ainge et al. reported the first synthesis of PIM_4, and demonstrated that synthetic PIM_2 and PIM_4 were immunogenic, enhancing interferon-gamma production in a transgenic mouse model [292].

4.4 Medicine

4.4.1 Pathogenic Mycolata

Among corynebacterineae, the most notorious human pathogens are *Mycobacterium tuberculosis*, *Corynebacterium diphtheriae* and *Mycobacterium leprae*. Leprosy is no longer considered a major public health problem. Leprosy has been brought under control thanks to free-multi-drug therapy provided by the WHO since 1995, and in 2006 only 200,000 cases were reported worldwide [293]. Diphtheria is now rare in the United States, thanks to rigorous vaccination. However, it continues to be a problem in other parts of the world. Notably, there was a large diphtheria epidemic in the former Soviet Union in the early 1990s, with upwards of 10,000 cases reported [294]. Tuberculosis has proven harder to control than leprosy and diphtheria, and remains a global concern. According to the WHO, approximately a third of the world's population is infected with TB, and more than 8 million people worldwide develop active TB each year [295]. In 2005, the CDC reported 14,097 cases of active TB in the United States [296], and an additional 10 to 15 million people in the US are estimated to have latent TB.

In addition to the three discussed above, there are a number of other pathogens within the mycolata. Infections by non-TB mycobacteria including *M. avium-intracellulare*, *M. marinum* *M. ulcerans*, and *M. kansasii* are rarely seen in healthy individuals, but are common sources of skin infections and lung disease in AIDS patients [297]. In addition, there are increasing reports of human infections caused by multidrug-resistant non-diphtheria Corynebacteria, especially in immunocompromised patients [298,299].

4.4.2 Current TB Treatments

The drug regimens currently used for TB infection require at least 6 months of treatment with multiple drugs, typically a combination of rifampicin, isoniazid, ethambutol, and pyrazinamide [23]. Rifampicin inhibits transcription, while these other drugs target the synthesis of mycobacterial cell wall structures (see *Sect. 4.4.4* and *Fig. 23*). These treatment regimens are harsh, and rifampicin, isoniazid, and pyrazinamide can all cause hepatitis [300]. Treatment is also complicated by the prevalence of TB among HIV-positive individuals. Rifampicin and other rifamycins accelerate the metabolism of many of the protease inhibitors and reverse transcriptase inhibitors used in HIV treatment, leading to sub-therapeutic levels of the HIV drugs [23]. TB is becoming increasingly resistant to the drugs currently used in treatment. In 2005, the CDC reported that 7.3 percent of tuberculosis cases in the US were resistant to isoniazid, and 1.0 percent were resistant to both isoniazid and rifampin [296]. According to the WHO, between 1999 and 2003 10.2% of new TB cases showed resistance to at least one of the

first-line TB drugs, and 4.3% of all TB cases worldwide were multidrug-resistant (MDR-TB), showing resistance to at least isoniazid and rifampicin [295]. Unfortunately, no new anti-TB medications with novel mechanisms of actions have been developed since the introduction of rifampicin in 1966.

There is also a vaccine for TB, the BCG vaccine, made from live attenuated *M. bovis* [301]. The WHO recommends vaccination of infants in parts of the world where TB is common. However, BCG does not protect adults very well against TB, and people who have received the vaccine may show a false positive reaction on the TB skin test. Because of these limitations, BCG is rarely used in the US [302].

4.4.3 Roles of Polysaccharide Structures in Infection and Disease Progression

M. tuberculosis bacteria persist in the harsh environment of the host's alveolar macrophages. These bacteria are able to survive by downregulating the host's immune response. Specifically, *M. tuberculosis* prevents activation of the infected macrophages. Macrophage activation would lead to production of pro-inflammatory cytokines, such as IL-12, IL-18 and tumor necrosis factor α (TNF-α), and to production of interferon-γ producing T cells, allowing the host to combat the infection [303]. Both the LAMs and the mycolic acids of *M. tuberculosis* are able to modulate the host's immune response.

ManLAM and PILAM seem to have opposite effects on the immune response [262,264]. ManLAM was shown to inhibit macrophage activation, the production of the pro-inflammatory cytokines IL-12 and TNF-α and, *M. tuberculosis* -induced macrophage apoptosis. PILAM, in contrast, induces the release of pro-inflammatory cytokines. By suppressing the immune response, ManLAM thus promotes survival of pathogenic mycobacteria, while PILAM promotes killing of non-pathogenic mycobacteria. ManLAM and PILAM were also shown to interact with different cell-surface receptors on phagocytic cells [262,264].

Mycolic acid structure is also important for virulence. Deletion of the proximal cyclopropane ring of the α-mycolate leads to significantly decreased growth in a mouse model of TB infection, as does deletion of the methoxy- and keto-mycolates. Deletion of keto-mycolates was also shown to result in restricted growth in macrophages [273,304].

4.4.4 LAMs and mAG as Drug Targets

Several currently used TB drugs target the biosynthesis of the unique mycobacterial cell wall structures (*Fig. 23*). Ethambutol is an arabinosyltransferase inhibitor [305], and mycolic acid synthesis is targeted by several commonly used antituberculosis drugs, including isoniazid, ethionamide, isoxyl, thiolactomycin, and triclosan. In addition, pyrazinamide was shown to inhibit the synthesis of mycolic acid precursors [306].

There have been efforts to target new inhibitors to most of the steps in AG and LAM biosynthesis, including synthesis of the decaprenylphosphoarabinose and UDP-Gal*f* donor sugars, and the construction of the arabinan and galactan chains. The approaches taken to design inhibitors of LAM and AG biosynthesis were reviewed by Lowary in 2003 [307]. Thus far, the most successful novel inhibitors have been directed at the proven drug targets: the arabinosyltransferases and the mycolic acids. Efforts to synthesize analogs of the diamine antibiotic ethambutol as arabinosyltransferase inhibitors produced SQ109 (*Fig. 23*), which was found

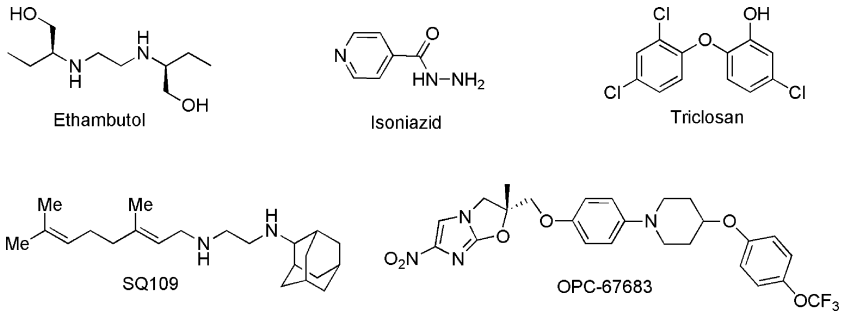

Figure 23
TB drugs that inhibit the arabinosyltransferases or mycolic acid synthesis

to be more effective than ethambutol in treating a mouse model of TB [308]. In addition, screens have been used to identify new structural classes of inhibitors. One promising compound identified in this manner is the nitro-dihydro-imidazooxazole OPC-67683 (*Fig. 23*), recently reported to be a novel highly active inhibitor of mycolic acid biosynthesis [309]. This compound was found to be highly potent against TB, including MDR-TB, with an MIC range of 0.006–0.024 μg mL^{-1}. In combination therapy with rifampicin and pyrazinamide, this compound showed improved efficacy in a mouse model of TB when compared to the standard regimen of rifampicin, isoniazid, ethambutol, and pyrazinamide. Furthermore, the drug was reported to have no effect on liver function.

Thus, though mycobacterial infections are difficult to treat under even the best of circumstances using currently available drugs, novel antibiotics targeting the biosynthesis of the unique mycobacterial cell wall structures show promise for clinical development. Further characterization of the enzymes involved in the biosynthesis of cell wall structures will facilitate the development of such antibiotics. Furthermore, studies of the cell wall biosynthetic pathways will likely uncover new potential targets for drug design efforts.

5 Capsular Antigens

Capsular antigens comprise both capsular polysaccharides, which are attached to the bacterial cell surface, and exocellular polysaccharides, which are excreted into the bacterial environment. These two types of polysaccharides have similar structures and properties [24]. Capsular polysaccharides (CPS) are the major constituents of the extracellular capsule layers that encase many bacteria. The capsules serve as an extra layer of defense and protect the enclosed cells from dehydration. Exocellular polysaccharides form a slime that surrounds the producing cells. They are a crucial component of biofilms, which contribute substantially to the severity and persistence of bacterial infections (see *Sect. 5.4.3*) [310]. Capsular antigens are produced by both Gram-negative and Gram-positive bacteria. Most capsular antigens are highly immunogenic, and vaccination with them produces high antibody titer [311]. Antibodies interact with immunodeterminants (epitopes) of capsular antigens, and bacteria are commonly classified into serotypes possessing different immunodeterminant groups. The capsules of pathogenic

organisms are frequently used for vaccine development [26]. This section will describe the structure and synthesis of capsular polysaccharides from some common pathogens, and discuss their use in vaccines.

5.1 Structure

5.1.1 Capsular Antigen Structure

The structures of capsular antigens are very diverse. The polysaccharides are composed of repeating units, which can be either homo- or heteropolymers containing either branched or unbranched chains (*Fig. 24*) [24]. The chains contain a range of sugars, and can also be substituted with both organic and inorganic molecules. For example, the capsules of pneumococci are built from glucose, galactose, rhamnose, and glucuronic acid and various glycosamines (in particular, *N*-acetyl derivatives of D-glucosamine, D-galactosamine, D-mannosamine, D-fucosamine and 2,4-diamino-2,4,6-trideoxy-D-galactose). In addition, some pneumococcal capsular antigens show structural similarities to teichoic acids, containing residues of ribitol phosphate and glycerol phosphate, and many contain pyruvate residues. Several groups of streptococcal polysaccharides contain hyaluronic acid, while the chains of another group contain terminal sialic acid residues. The *E. coli* capsular antigens can be divided into four groups that share general structural features and biosynthesis [312]. Groups 1 and 4 are acidic polysaccharides resembling *O*-antigens. Group 2 and 3 capsules are found in *E. coli* isolates that cause extraintestinal infections. The structures are diverse, and some contain phosphate residues in their backbone structures, while others resemble vertebrate glycoconjugates. See *Fig. 24*. *S. pneumoniae* and *E. coli* each possess more than 80 different CPS. For an overview of capsular antigen structures, the reader is referred to a recent review by Ovodov [24].

5.1.2 Capsule Structure

Capsular polysaccharides are covalently linked to the cell surface, forming a highly hydrated protective barrier around the cell. In Gram-negative bacteria, CPS are thought to be attached to either phospholipid or lipid A (*Fig. 25*). The *E. coli* capsular antigens of groups 1 and 4 are both found in two forms: either linked to a Lipid A core (K_{LPS}), or as a high molecular weight capsular antigen with an unknown mode of attachment, while groups 2 and 3 are attached to the OM through a diacylglycerolphosphate anchor [312]. The CPS of many Gram-positive pathogens, including *Staphylococcus aureus* [9], *Streptococcus pneumoniae* [313], and group B *Streptococcus* [314], are covalently linked to peptidoglycan (*Fig. 25*). The mode of attachment is not well-documented, but in group B *Streptococcus* the CPS is attached through a phospodiester bind to a linker oligosaccharide, which is in turn attached to the GlcNAc residues in peptidoglycan (*Fig. 25*) [314]. In some Gram-positives, including one serotype of *S. pneumoniae*, CPS may be membrane-associated rather than covalently attached [315].

5.1.3 Biofilm Structure

A biofilm is a community of microorganisms that settles on a surface and is covered by an exopolymer matrix. Cells in biofilms are slow-growing, and exhibit clear phenotypic differences from free-living planktonic cells. Biofilm structure is both complex and dynamic, and

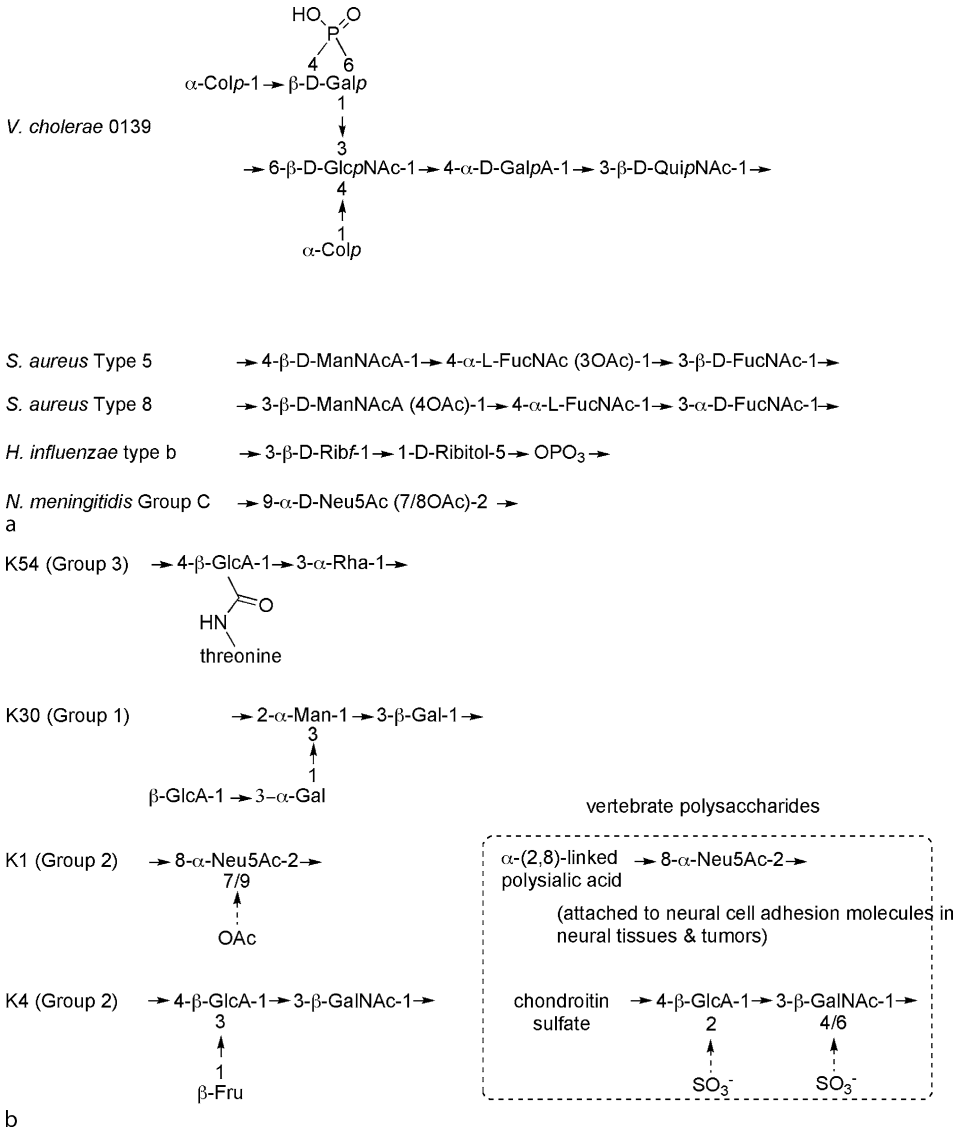

Figure 24
Capsular antigen structures. a) Some CPS currently used in vaccines. *S. aureus* type 5 and 8 are the CPs in StaphVAX [355]. b) Some *E. coli* capsular antigens. For structures that mimic vertebrate glycoconjugates, the corresponding human structures are shown

the composition of biofilms varies greatly depending on the bacterial species as well as on the growth conditions. Biofilm composition and architecture has been reviewed by Sutherland [316]. The cells are encased in a webbing made of exocellular polysaccharides (EPS), and production of EPS is essential for construction of the biofilm matrix [317]. Different bac-

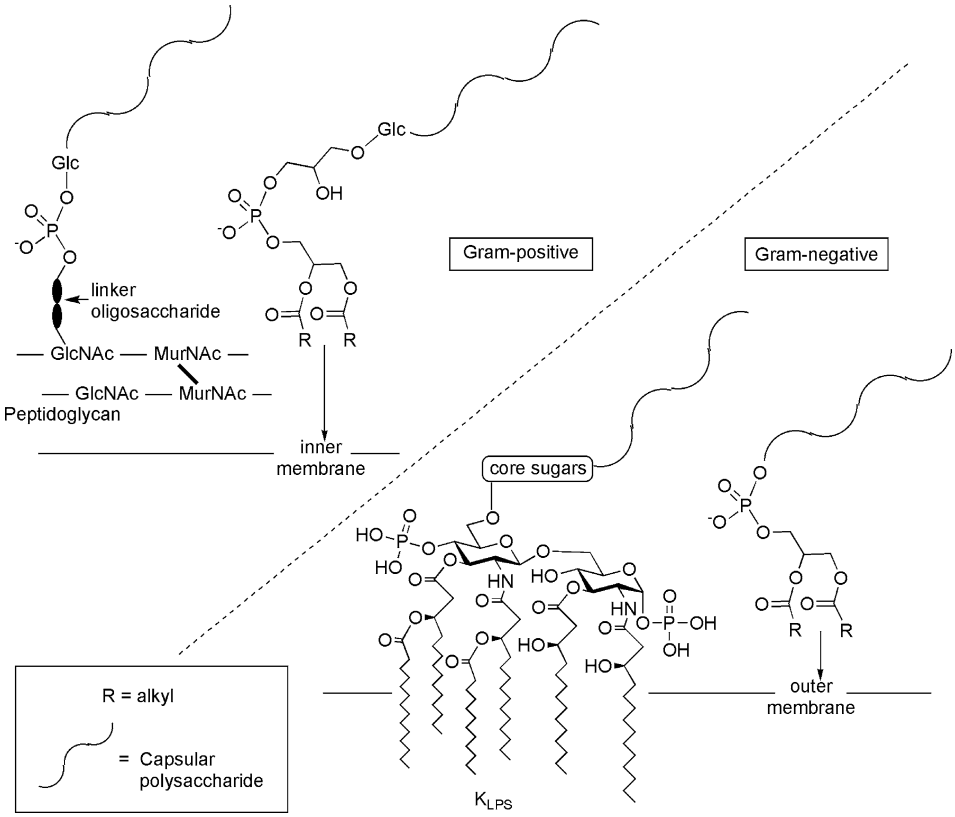

Figure 25
Attachment of capsular polysaccharides to the cell surface. Gram-negative CPS are attached to the outer membrane while Gram-positive CPS are attached to peptidoglycan or anchored in the inner membrane

teria produce a variety of EPS structures, but cellulose and β(1,6)-linked *N*-acetylglucosamine are the most common biofilm components of many bacteria [318]. Cellulose, for example, is a crucial component of biofilms for *Salmonella typhimurium*, *Escherichia coli*, and many other bacteria. β(1,6)-linked *N*-acetylglucosamine (PNAG, also called PIA) is the main component of biofilms produced by most *Staphylococcus epidermidis* and *Staphylococcus aureus* strains, and is thought to be produced by other bacteria including *E. coli* and *Yersinia pestis*. *E. coli* biofilms also commonly contain the extracellular polysaccharide colonic acid.

In addition to extracellular polysaccharides, biofilms contain proteins, DNA and RNA, as well as peptidoglycan, lipids, phospholipids and other cell components. Some of these materials are secreted by the bacteria, while others are products from cell lysis, or environmental material [316,319]. Biofilms are highly hydrated, and up to 97% of the biofilm can be made of water [320]. Confocal scanning laser microscopy has shown that cells within biofilms are aggregated into microcolonies separated by channels that allow the passage of nutrients and waste products [316].

5.2 Biosynthesis

Each polysaccharide structure is synthesized by a distinct set of enzymes, and the biosyntheses of the individual structures will not be discussed here. The biosynthetic gene clusters for many different capsular and extracellular polysaccharides are known, and many of the enzymes involved have been characterized. For a general review of the genetics and biochemistry of CPS production, the reader is referred to a review by Roberts [321]. There are also many excellent reviews discussing capsule formation in individual bacteria, including *H. influenzae* [322], *S. Aureus* [323], *E. coli* [312], and pathogenic streptococci [324,325].

5.2.1 Conserved Features of Capsular Antigen Biosynthesis

Despite the diversity of capsular antigen structures, the genes involved in CPS assembly and export in a number of different bacteria share a high degree of homology, suggesting that the export and assembly processes are conserved. Two different pathways have been described for the assembly and export of CPS in *E. coli*: the Wzy-dependent pathway and the ABC transporter-dependent pathway (*Fig. 26*). Other bacteria are expected to utilize similar pathways based on the presence of homologous gene clusters [321,326,327]. The Wzy-dependent pathway, for example, has been studied in Gram-positive bacteria including streptococci [328], staphylococci and lactococci [329]. The *E. coli* pathways were recently reviewed by Whitfield [312].

E. coli capsule groups 1 and 4 are exported and assembled via the Wzy-dependent pathway, which is also used for LPS biosynthesis (see *Sect. 3.2.1*) [312]. Individual CPS repeat units are assembled on an undeacprenyl phosphate carrier lipid by the sequential action of several glycosyltransferases. The lipid-linked repeat units are then thought to be flipped across the plasma membrane by Wzx, and polymerized by Wzy. New units are added to the reducing end of the growing polymer. At this point, polymerized products are either transferred from the carrier lipid to lipid A-core acceptor by WaaL ligase (forming K_{LPS}, *Fig. 25*), or incorporated into capsules in a process that depends on Wzc, a tyrosine autokinase located in the plasma membrane, Wzb, a tyrosine phosphatase, and Wza, an outer membrane lipoprotein [312].

Based on EM data and the crystal structure of Wza, the Whitfield and Naismith groups have recently proposed a model in which Wza and Wzc form a complex for CPS export that spans the periplasm [330]. Their model is significant because it provides a mechanism by which CPS may move from the periplasm through the outer membrane. The export processes for macromolecules such as LPS, CPS and OM proteins, and coordination of export and biosynthesis are poorly understood.

E. coli capsule groups 2 and 3 are exported and assembled in a completely different fashion than groups 1 and 4 [14,312]. The CPS is fully assembled in the cytoplasm by addition of new units to the non-reducing terminus by processive glycosyltransferases. The polymer is attached to the cytoplasmic membrane by a diacylglycerolphosphate or diacylglycerolphosphate-Kdo anchor (*Fig. 25*). After polymerization, the chain is exported by an ABC transporter (KpsM and KpsT). The CPS is then thought to be shuttled from the IM to the OM by KpsE and exported by the OM protein KpsD, though the roles of these proteins are speculative. See the recent review by Whitfield for further discussion [312].

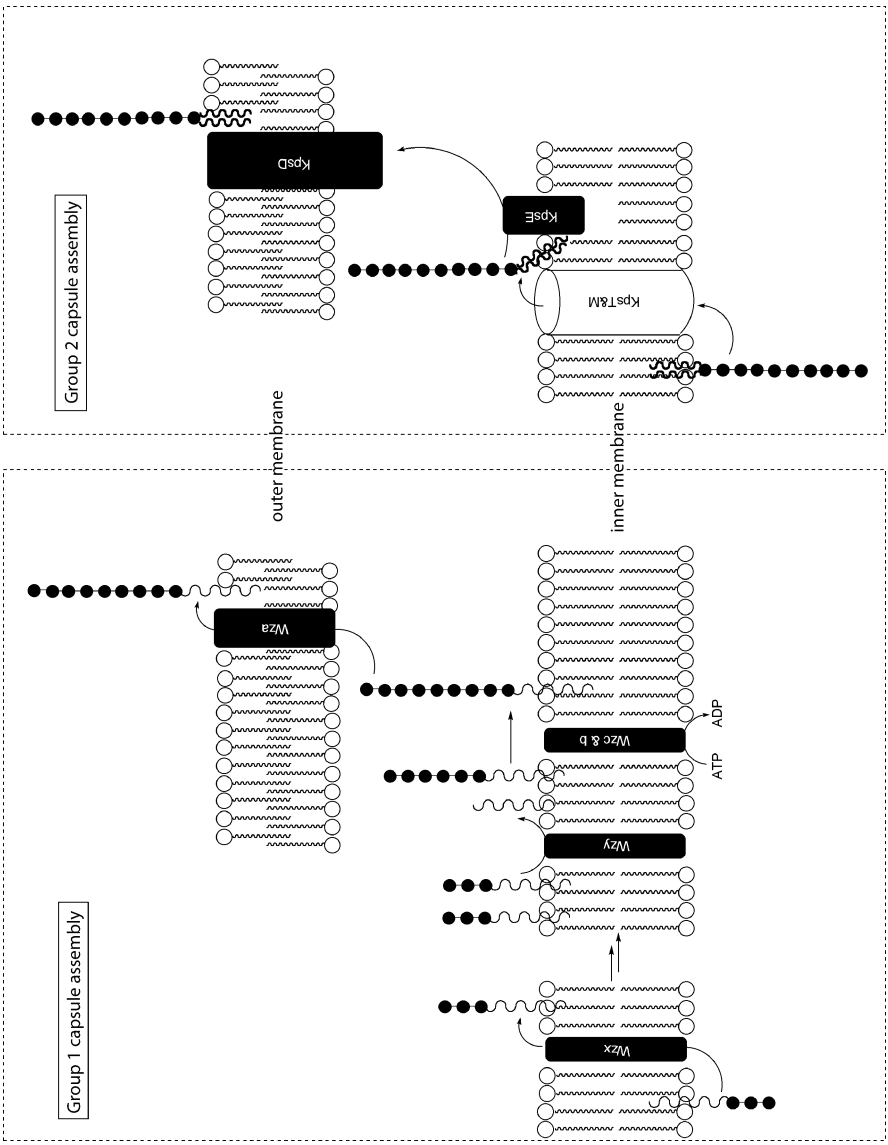

Figure 26
Capsular polysaccharide assembly and export in *E. coli*

5.2.2 Biofilm Assembly

In response to environmental signals, bacteria are able to switch between a free-living planktonic state and one in which they function as part of a multicellular biofilm community. The processes involved in biofilm formation are very complex and not yet well understood. Genetic and molecular approaches to studying biofilm development, as well as the genes and regulatory circuits known to be important for the formation and maturation of biofilms and the return of biofilm microorganisms to planktonic growth have been recently reviewed [331].
Microscopy techniques including confocal laser scanning microscopy and low-temperature scanning electron microscopy have also been used to help unravel the process of biofilm formation. For example, Moscato et al. used microscopy to observe early steps in biofilm formation by *Streptococcus pneumoniae* grown on polystyrene or glass surfaces [332]. Using *S. pneumoniae* mutants deficient in the synthesis of certain cell envelope components, they were then able to determine which of these components were important for biofilm formation.

5.3 Chemical Synthesis

Synthetic investigations of capsular polysaccharides have largely focused on the synthesis of fragments for use in vaccines. Routes have been developed, for example to CPS fragments from pathogenic strains of *N. meningitidis*, *V. cholerae*, *H. influenzae*, *S. pneumoniae*, and group B *Streptococcus* for use in vaccine construction and immunological studies (*Fig. 27*) [333,334,335,336,337,338,339,340].
In addition, a synthetic route was recently reported for β-(1,6)-linked glucosamine oligosaccharides containing up to 11 glucosamine residues, corresponding to fragments of the extracellular polysaccharide poly-*N*-acetylglucosamine, important in biofilm formation in many bacteria (*Fig. 27*) [341].
Lactic acid bacteria are used to produce fermented milk products, and the exopolysaccharides produced by the bacteria influence the texture of the resulting products. More importantly, these exopolysaccharides are thought to have several health benefits. There is evidence they lower cholesterol, modulate the immune system, help prevent colon cancer, and fight ulcers [342,343]. There is thus interest in establishing structure-function relationships for these structures, as well as in metabolic engineering of lactic acid bacteria to produce capsular polysaccharides with the desired properties [342,343].

5.4 Medicine

5.4.1 Roles of Capsular Antigens in Bacterial Infections

Capsular and extracellular polysaccharides are involved in several aspects of cellular behavior that are tied to bacterial survival and virulence [321]. The capsule layer provides a physical barrier that prevents the bacteria from drying out, aiding in survival outside a host. CPS are also involved in colonization and biofilm formation. In some bacteria CPS promote adherence to surfaces, aiding colonization and biofilm formation, while CPS in other bacteria inhibit adhesion and biofilm formation [344].

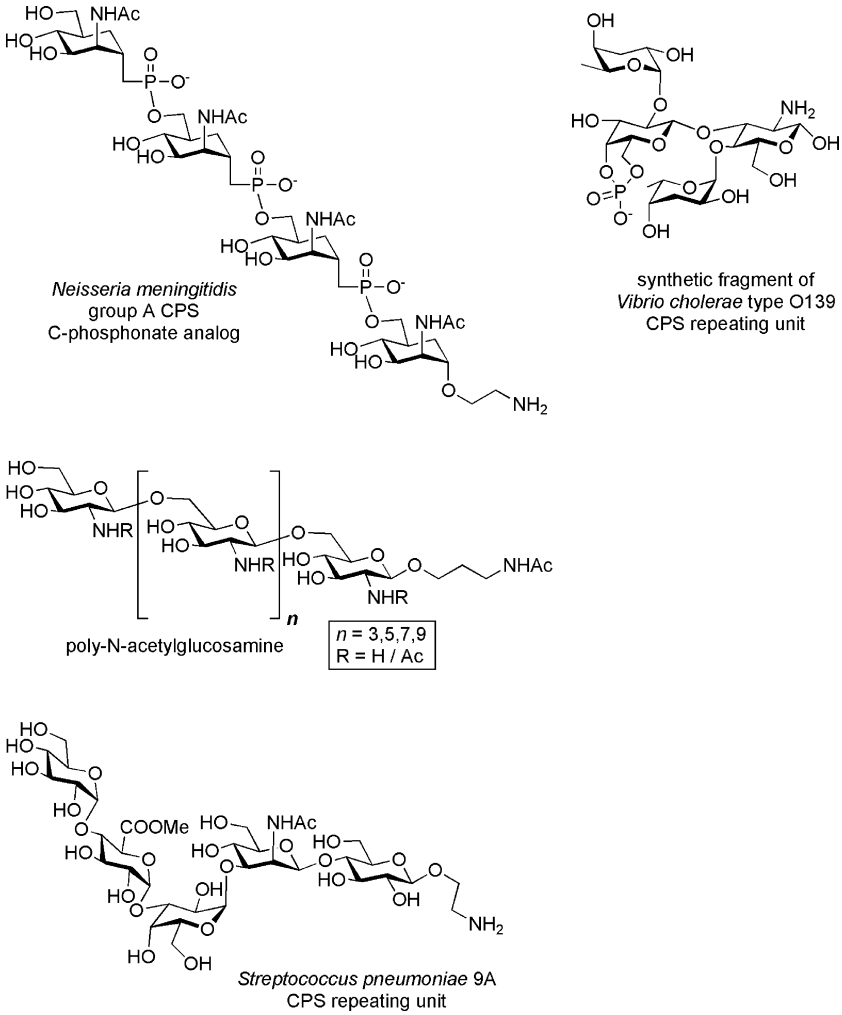

Figure 27
Synthetic capsular polysaccharide structures

Importantly, CPS also help bacteria evade the host's immune system. Following infection by a bacterial pathogen, the host's first lines of defense involve the innate immune system. Highly conserved bacterial structures including peptidoglycan, LPS and lipoteichoic acids are recognized by receptors on macrophages or by soluble pattern recognition molecules, leading to activation of the complement pathway, phagocytosis of the invading bacterial cells, and activation of an inflammatory cascade [345]. Bacterial capsules mask underlying bacterial cell surface structures, preventing recognition by the innate immune system and activation of the complement pathway. Furthermore, bacteria including *E. coli*, *N. meningitidis*, and *Group B Streptococcus* suppress activation of the innate immune system by making capsules containing *N*-acetylneuraminic acid (sialic acid). Vertebrates decorate their cell surfaces with sialic acid

as a mechanism to avoid accidentally killing their own healthy cells. The sialic acid binds complement regulatory proteins, and helps prevent complement activation on the surface of host cells. Bacterial capsules containing sialic acid are thought dampen an innate immune response by several mechanisms, including suppression of complement activation [346,347,348].
In both *S. pneumoniae* and *N. meningitidis*, the thickness of the capsule has been shown to vary at different points in infection. In *Neisseria meninigitidis* decreased capsule production enhances tissue invasion, while increased capsule production is essential for survival in systemic infections [349]. Likewise, studies in pneumococci have suggested that the capsule prevents bacterial adhesion to epithelial cells, as well as to endothelial cells [350,351,352]. Bacteria producing less capsular polysaccharide more efficiently colonize mucosal surfaces, while those producing more capsule are more virulent in systemic infections [350,353].

5.4.2 Anti-Bacterial Vaccines Based on CPS Structures

Most capsular polysaccharides strongly stimulate antibody production, and antibodies raised against particular capsular epitopes have been shown to prevent infection by bacteria possessing these capsules. Capsular polysaccharides are thus commonly used to develop vaccines against both Gram-negative and Gram-positive pathogens. Early vaccines contained just polysaccharides, while more recent formulations are based on glycoconjugates, where the polysaccharide antigens are bound to protein carriers [26]. Glycoconjugate vaccines offer several advantages over polysaccharide vaccines.
Polysaccharides are generally thymus-independent antigens, meaning that they stimulate antibody production by B-cells without the aid of helper T-cells [345]. This type of immune response does not result in the formation of memory B-cells or T-cells. Vaccination with polysaccharides thus provides protection for only a limited amount of time. Moreover, polysaccharide vaccines elicit a poor antibody response in young children and older adults [354]. In glycoconjugate vaccines, the protein carrier stimulates a T cell response. Immunological memory is thus established, and re-vaccination is not usually required (unlike with polysaccharide vaccines, which generally need to be re-administered every 5 years). The antibodies produced with T cell-mediated immunity are also of higher avidity. At present, several CPS vaccines are commonly used, and there are many more in development. For a thorough discussion, the reader is directed to a recent review by Jones [26]. Polysaccharide vaccines are currently used against *Salmonella typhi*, *Neisseria meningitidis* and *Streptococcus pneumoniae*. Glycoconjugate vaccines are licensed for use against *H. influenzae*, *N. meningitidis* and *S. pneumoniae*.
CPS vaccines against other pathogenic bacteria, including enterococcal and streptococcal strains, are in various stages of development and clinical trials. Notably, a vaccine against *S. aureus* called StaphVAX has been tested in Phase 3 clinical trials. StaphVAX is made from the two types of capsular polysaccharides most commonly found in clinical isolates (*Fig. 25*), each bound to recombinant *P. aeruginosa* exotoxin A (as a protein carrier). The vaccine was found to provide some protection from *S. aureus* infection, but only up to 40 weeks after injection [355].
An alternative to polysaccharide or glycoconjugate vaccines involves using peptides that mimic CPS antigens. Methods for obtaining peptide mimics include selection from phage-display libraries and use of anti-idiotype antibodies [354]. Anti-idiotype antibodies are antibodies that mimic the antigen to which they are raised, and are generated during a normal antibody-medi-

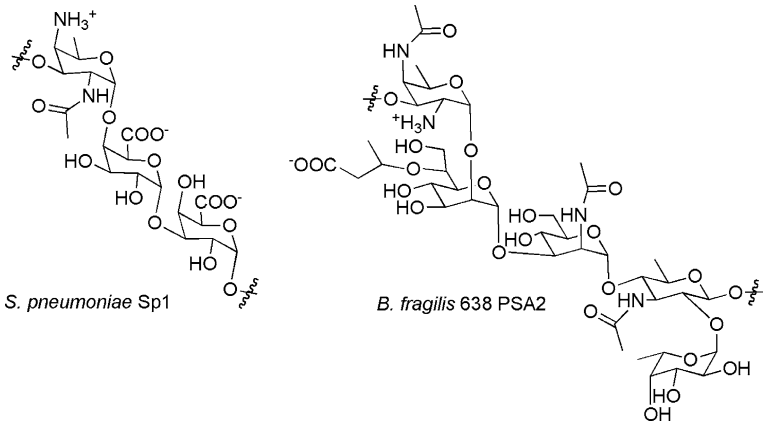

Figure 28
Zwitterionic capsular polysaccharides

ated immune response. Vaccines based on peptide mimics have the advantage of being able to stimulate a T-cell response, but the peptides are often degraded rapidly in vivo. The potential of this vaccine strategy has been demonstrated for bacteria including *Neisseria meningitidis*. Mice immunized with peptides mimicking *N. meningitidis* CPS were subsequently protected against infection by this pathogen [356,357].

While most polysaccharide antigens act in a T-cell independent fashion, zwitterionic polysaccharides have been shown to induce T-cell mediated immunity [358]. Several bacteria produce zwitterionic CPS, which contain both free amine and free carboxyl groups in the repeating unit. These include CPS types 5 and 8 of *Staphylococcus aureus*, PSA from *B. fragilis* and the type 1 *S. pneumoniae* polysaccharide (*Fig. 28*). Vaccination with zwitterionic polysaccharides have been shown to produce T-cell mediated immunity in mice [359], and vaccines based on zwitterionic CPS may be useful for combating several common bacterial pathogens.

5.4.3 Roles of Extracellular Polysaccharides in Bacterial Infections

Extracellular polysaccharides are a crucial component of biofilms. Biofilm formation is increasingly being recognized as an important factor in the transmission and persistence of bacterial infections. According to the CDC, more than 60% of bacterial infections involve biofilms, and these infections are problematic because biofilms are resistant to antibiotic therapies and host immune attack. The basis for the antibiotic resistance of biofilms is not completely understood, but is thought to involve a combination of factors [360]. Within the biofilm sub-populations of cells are living in a variety of different microenvironments, growing at different rates, and expressing different genes, so that some subset of cells is likely to show decreased susceptibility to any given antibiotic. In addition, the biofilm is highly charged, retarding the passage of some charged compounds and antibiotics [361,362].

Biofilms play key roles in several chronic human infections including infectious kidney stones, bacterial endocarditis, and cystic fibrosis lung infections, and the roles of biofilm formation in these diseases have been reviewed [27]. Biofilms also serve as environmental reservoirs for

pathogens. Biofilms can form on a variety of surfaces, and patients have obtained bacterial infections from biofilms persisting, for example, in hospital water lines, dialysis equipment and endoscopes [363]. In 1999, the CDC estimated that up to 270 000 infections may be transmitted by flexible endoscopes each year [364].

Patients with implanted medical devices, including replacement joints, cardiac pacemakers, urinary catheters and dialysis catheters, also commonly develop infections as a result of biofilm formation. A variety of Gram-positive and Gram-negative bacteria have been isolated from colonized devices, and biofilms often contain multiple bacterial species [363]. Strategies being investigated to prevent such infections involve development of infection resistant materials for use in implants [365], and covering medical devices with antimicrobial coatings [366]. Biofilm formation requires the coordinated action of many individual bacteria, and the importance of bacterial quorum sensing in biofilm formation has been demonstrated. For example, knocking out genes involved in quorum sensing in *Pseudomonas aeruginosa* results in reduced virulence [367]. Quorum sensing inhibitors are therefore being explored to prevent biofilm formation [368]. Greater understanding of the bacterial processes involved in biofilm formation will provide insight into better strategies for preventing biofilm-associated infections.

Glycolipids

7.1 Glycolipids: Occurrence, Significance, and Properties

Otto Holst
Structural Biochemistry, Research Center Borstel, 23485 Borstel, Germany
oholst@fz-borstel.de

Abstract

This chapter focuses on the occurrence and the physicochemical properties of glycolipids in Nature. Owing to space limitations, the presented overview must be incomplete, and, thus, mainly publications of the past 15 years are included. However, all review articles cited herein inform the interested reader about earlier work. Although lipopolysaccharides (LPS), lipoarabinomannan (LAM), lipomannan, lipoglycans, and lipoteichoic acids are not understood as glycolipids per definition, their occurrence and properties are also described in this chapter. GPI-anchored lipids is a main topic of ❯ Chap. 7.4.

Keywords

Glycolipids; Diacylglycerol ethers; Diacylglyceryl esters; Sulfated glycolipids; Trehalose-containing lipo-oligosaccharides; Glycopeptidolipids; Phenolic glycolipids; Lipopolysaccharides; Lipoglycans; Lipoteichoic acids

Abbreviations

BHT bacteriohopanetetrol
CAC critical aggregate concentration

1 Introduction

Glycolipids are membrane components and occur in all kingdoms of organisms, i. e., bacteria, plants, and animals including man. They are glycoconjugates and comprise a very heterogeneous group of molecules which possess one or more monosaccharide units linked by a glycosyl linkage to a hydrophobic moiety such as acylglycerol, ceramide, or prenyl phosphate [1]. In general, glycolipids are important factors of membrane stabilization and cell surface rigidization. They also play an important role in a broad variety of biological processes, e. g., in photosynthetic electron transport in plants, in cell-cell communication, in receptor modulation, or in signal transduction.

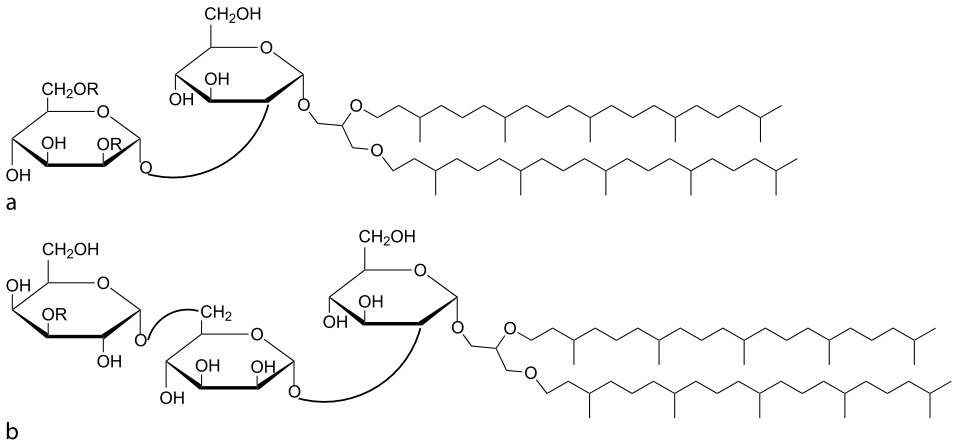
In general, glycolipids are amphiphilic molecules comprising a hydrophilic headgroup and apolar hydrophobic hydrocarbon (acyl) chains. Thus, glycolipids tend to aggregate to clusters in aqueous environments, i. e., to lipid bilayers or membranes. Possible supramolecular arrangements are micellar, lamellar, hexagonal, non-lamellar cubic, and inverted-hexagonal structures [2]. Which of these structures is furnished, is influenced by the primary chemical structure of a molecule and by extrinsic factors like temperature, pH, and the concentration of bivalent ions. Elevated temperature leads to the transition of the gel (β) to the liquid crystalline (α) phase of the acyl chains which occurs at the transition temperature T_c. A major difference between glycolipids and phospholipids results from the strong influence of hydrogen bonds on the phase behavior of the former, which leads to a rather high T_c (providing structural integrity in glycolipid-containing membranes) and to metastable polymorphism.

In cells, a particular composition and the physicochemical properties of the lipid matrix at given ambient conditions represent the basis for a normal functioning [3]. Any disturbance of the composition due, e. g., to different net charges or acylation patterns may result in changes of membrane fluidity/permeability, in phase separation, or in disruption of the lamellar membrane architecture. However, cells are potentially able to overcome such changes in lipid matrix composition by altering it ("homovicious adaptation") [4]. If an adaptation of this type does not take place, severe dysfunction of a cell may occur.

Various means and methodologies have been used to investigate the physicochemical properties of synthetic, semisynthetic, and natural glycolipids, e. g., NMR spectroscopy, X-ray diffraction, electron microscopy, or Fourier-transformed infrared spectroscopy (FTIR). In the following paragraphs, the occurence and physicochemical properties of different biological glycolipid classes and of lipopolysaccharides, lipoteichoic acids, and mycobacterial mycolates are briefly discussed.

2 Prokaryotic Glycolipids

Membrane glycolipids of the family Halobacteriaceae (taxon Archaea, formerly Archaebacteria) represent derivatives of *sn*-2,3-di-*O*-alkylglycerol (where alkyl is in most cases phytanyl, ● *Fig. 1*) [5,6] or its dimer. In quite a few cases, these glycolipids are sulfated in their sugar portion [6]. There is evidence that sulfated glycolipids of this type contribute to the control of the ion permeability of the cytoplasmic membrane. Also, these lipids represent useful taxonomic markers of halophilic bacteria. Recently, a novel glycolipid has been isolated from the purple membranes of *Halobacterium salinarum*, with the structure 3-HSO_3-β-Gal*p*-(1→6)-α-Man*p*-(1→2)-α-Glc*p*-(1→1)-[*sn*-2,3-di-*O*-phytanylglycerol]-6-[phospho-*sn*-2,3-di-*O*-phytanylglycerol] [7]. Later, it could be shown that an increase of this glycolipid is induced by osmotic shock [8].



● Figure 1
Sulfoglycodialkylglycerolipids from the halobacteria, (a) *Natralba asiatica*, and (b) *Halobacterium salinarum* and *Hb. saccharovorum*. *R* = SO_3^-

In cyanobacteria, as in photosynthetic bacteria, glycolipids are constituents of the thylakoid membranes. However, they occur also in the heterocyst [9] which represents a specialized cell for nitrogen reduction, and it is believed that they contribute to minimize the content of oxygen in the cell interior. Of these glycolipids, two groups of glycosides have been described, of which in the assumed predominant one α-Glc*p* (● *Fig. 2*) or α-Gal*p* is linked glycosidically to the primary hydroxy group of linear polyhydroxyalkanes or polyhydroxyketones.

In addition to other diacylglycerol-containing glycolipids described earlier, several acylated sulfoquinovosyl-[6,10] and digalacto-[10] diacylglycerol glycolipids have been isolated from different cyanobacteria and were found to be inhibitors of the reverse transcriptase of human immunodeficiency virus (HIV) type 1 [10].

Sulfoquinovosyldiacylglycerol and digalactodiacylglycerol are prominent glycolipids of plants [6,9] where they occur in the plastids; however, members of both lipid types were also identified as major membrane components of bacteroids of *Bradyrhizobium japonicum* [11,12].

Figure 2
Structures of α-D-glucopyranosides and an α-1-*O*-acyl-D-glucopyranose from heterocysts of cyanobacteria

Bacteroids are the nitrogen-fixing form of these and other bacterial species that live symbiotically in leguminoses. Sulfoquinovosyldiacylglycerol lipids have also been identified in phototrophic and a few other bacterial species [6,13]. Different mono- to pentaglyco(di)acylglycerol lipids have been found in membranes of other bacteria possessing a broad variety of sugars and decorations (e. g., methyl or acetyl groups). Another glycolipid, i. e., α-D-Man*p*-(1→3)-6-*O*-acyl-α-D-Man*p*-(1→3)-*O*-acylglycerol (Fig. 3) has been identified in the Gram-positive, coryneform bacterium *Arthrobacter atrocyaneus* [14], and a similar one (different fatty acids) in *Rothia mucilaginosa* [15]. These lipids are unusual with regard to the monoacyl substitution (at *sn*-1) of glycerol and a second fatty acid that is linked to O6 of the first Man residue. Dimannosyl lipids of Gram-positive bacteria have been known for many years; however, it has mostly not unequivocally been shown whether both of their acyl residues are linked to the glycerol moiety. With regard to sugar acylation, α-D-Gal*p*-(1→6)-β-D-Gal*p*-(1→6)-β-D-Gal*p*NAcyl-(1→2)-α-D-Glc*p*-(1→1)-diacylglycerol has been identified in the thermophilic bacterium *Meiothermus taiwanensis* [16] and novel 6-*O*-acyl-α-D-Glc*p*-(1→3)-α-D-Glc*p*-(1→1)-2-*O*-acyl-3-*O*-alkylglycerol [17]. A novel phosphoglycolipid that was alkylated at its glycerol residue was found in thermophilc *Thermus* and *Meiothermus* species [18]. Other 1,2-diacyl-3-α-D-glycopyranosyl-*sn*-glycerols were found in the Gram-negative budding bacterium *Hyphomonas jannaschina* [19], containing as novel glycolipid 1,2-diacyl-3-α-D-glucuronopyranosyl-*sn*-glycerol taurinamide (Fig. 3) [20], *Streptococcus* sp. [21] and *Spirochaeta aurantia* [22], the latter comprising an oligosaccharide of 13 sugars. A phosphocholine-containing amino-

glycoglycerolipid was isolated from *Mycoplasma fermentans* and its structure characterized (Fig. 3) [23,24]. As a very unusual bacterial glycolipid, cholesteryl 6-*O*-acyl-β-D-galactopyranoside has been isolated from *Borrelia burgdorferi* [25,26]. This molecule developed host immunity during Lyme disease and may be used in diagnosis and vaccination.

Mycobacteria possess three major classes of glycolipids, i. e., trehalose-containing lipooligosaccharides, glyceropeptidolipids (GPL), and phenolic glycolipids [27,28]. Other important cell wall lipoglycans are the lipoarabinomannan (LAM) [29], the lipomannan, and the mycolyl arabinogalactan which is covalently linked to the peptidoglycan [30]. GPL (Fig. 4) are unique to Mycobacteria and are the basis for serotyping in the *M. avium–M. intracellulare* complex. These lipids are also found in other mycobacterial species, e. g., *M. smegmatis* and *M. chelonae*; however, they are not found in species that contain phenolic glycolipids. All

GPL investigated to date possess the disaccharide α-L-Rha*p*-(1→2)-α-L-6-deoxy-Tal*p* that is *O*-glycosidically linked to Thr of the acylated tetrapeptide core. The disaccharide is part of an oligosaccharide, the composition of which is responsible for serospecificity.

α,α-Trehalose-containing lipooligosaccharides (*Fig. 5*) have been found in a variety of mycobacteria, e. g., *M. smegmatis* and *M. kansasii*. These lipids comprise oligosaccharides linked to trehalose which in turn may be di-, tri-, or even tetraacylated at various positions. Trehalose-containing lipids represent another class of mycobacterial glycolipid antigens, also found in other *Actinomycetales* like *Rhodococcus* [31]. Phenolic glycolipids (*Fig. 6*) are found, e. g., in *M. leprae*, in some strains of *M. tuberculosis*, and in *M. bovis*. They consist of a similar aglycone and a variable oligosaccharide that is glycosidically linked to the phenol. Each oligosaccharide represents a specific antigen.

Lipopolysaccharides (LPS, endotoxin) are specific compounds of the Gram-negative cell wall where they occur in the outer leaflet of the outer membrane [32]. They consist of a lipid moiety {the lipid A [33,34] which in general comprises an acylated β-(1→6)-linked amino sugar disaccharide that may be phosphorylated at positions O1 and O4′} which is substituted at O6′ by a polysaccharide that consists of the core region, a heterooligosaccharide that is linked to lipid A [35,36], and the *O*-specific polysaccharide [37,38] that substitutes the core region. LPS of this type are called *S*-form LPS, in distinction to LPS comprising only lipid A and the core region (*R*-form LPS). Both LPS forms can be found in wild-type bacteria. A most general LPS structure is depicted in *Fig. 7*. LPS represent the main surface antigens of Gram-negative bacteria and play an important role in severely infected hosts, i. e., by leading to various pathophysiological reactions such as fever, hypotension, and multi-organ failure.

The characteristic components of the cytoplasmic membrane of Gram-positive bacteria are the amphiphilic macromolecules lipoglycan and lipoteichoic acid [39,40] (*Fig. 8*). Lipoteichoic acids possess in their saccharide chain alditol phosphates as characteristic components, whereas lipoglycans are linear or branched polysaccharides linked to diacylglycerol. These molecules may be further substituted by phosphoglycerol residues. Since lipoteichoic acids and lipoglycans are not found in the same bacterium they are believed to replace each other

functionally. It should be noted that a putative precursor of lipoteichoic acid biosynthesis has been isolated from *Bacillus subtilis* [41].

Hopanoids are pentacyclic triterpenoids that make up a class of essential membrane lipids [42,43,44]. They are believed to represent the most abundant natural products on earth. They occur widespread in Gram-negative and Gram-positive bacteria, where they play an important role in membrane stability and rigidity. In particular, hopanoids are thought to function as surrogates of cholesterol. Some hopanoids represent glycolipids, some examples of which are depicted in ❯ *Fig. 9*.

3 Plant Glycolipids

Plant glycolipids can be grouped in esters of glucose and sucrose, steryl glycosides, glycosphingolipids, and glycosyl diacylglycerols [9], the last of which occur most abundantly.

Because of their occurrence in all forms of plastids, galactosyl- and sulfoquinovosyldiacylglycerols are the major lipid components in plants (● *Fig. 10*). 1,2-Di-*O*-acyl-3-*O*-β-D-galactopyranosyl-*sn*-glycerol is the precursor of higher galactosyl diacylglycerols formed by sequential addition of α-D-Gal*p* residues to O6 of the preceding Gal*p*. These mono- to tetragalactosyl lipids represent the predominant glycosyl diacylglycerols in plants. However, Glc*p* is also found in such plant lipids, e. g., 1,2-di-*O*-acyl-3-*O*-β-D-glucopyranosyl-*sn*-glycerol in rice bran. Other lipids derive from galactosyl diacylglycerols by addition or removal of fatty acids (● *Fig. 10*), including the acylation at O6 of galactosyl residues. A galactolipid containing (15*R*)-hydroxy-(9*Z*),(12*Z*)-octadecadienoic acid (● *Fig. 10*) has been isolated from oat seeds [45].

Plant glycosphingolipids are *N*-acylated sphinganine derivatives (● *Fig. 11*). It is thought that these lipids play a role in signaling events in plants, analogous to the function of sphingosine derivatives in animals (see below). Two types of glycosphingolipids are *differentiated* in plants, i. e., neutral cerebrosides and phytoglycolipids which are inositol-containing derivatives of ceramide 1-phosphate (● *Fig. 12*). There exist β-D-Man*p* and β-D-Glc*p* monoglycerol ceramides, and it is mainly the latter derivative that is used for chain elongation of up to four sugar residues (● *Fig. 11*). A galactosylceramide which is rather unusual in plants was found in the red alga *Corrallina pilulifera* [46]. However, oligo-α-mannose-type glycans have also been identified, i. e. in *Candida albicans* [47] and *Aspergillus nidulans* [48]. In addition, such glycans have also been found in some basidiomycetes, however, most investigated species contained β-Gal*p* and α-Fuc*p* residues linked to *O*-6 of the Man in the general structure α-D-Man*p*-2Ins1-[PO_4]-Cer [49]. The most abundant amide-linked fatty acids are C_{14}–C_{26} (*R*)-2-hydroxy fatty acids, and in a few cases 2,3-dihydroxy fatty acids have been identified. In plants, a variety of sterol derivatives are also found, e. g., steryl glycosides which possess up to five linearly linked glycosyl residues, and others, like the saponins, that may possess branched carbohydrate moieties. In the former derivatives, the glycosyl residues are linked to the OH group at C3 of ring A (compare with ● *Fig. 13*). A huge variety of glycosyl residues has been identified in steryl glycosides, including β-D-Glc*p*, β-D-Glc*p*A, β-D-Gal*p*, α-D-Rib*f*, and others. Furthermore, there exist acylated derivatives, which usually carry a fatty acid (e. g., C_{16} or C_{18}) at C6 of Glcp; however, other acyl derivatives have also been identified occasionally. Steryl biosides that originate from steryl glycosides via further glycosylation are also frequently observed. Their acylated derivatives, however, occur only in rare cases.

Esters of glucose and sucrose have been identified as viscous exudates in *Solanaceae* species in amounts of up to 25% of the plant dry mass. In the first group, di- to penta-*O*-acyl-α- and -β-D-glucopyranoses occur, containing acetyl and (branched) acyl chains of up to C_{12} without any general acylation pattern. In sucrose esters, generally the Glc residue is higher, even fully, acylated than the fructose residue. A novel oxo-phytodienoic acid-containing galactolipid (● *Fig. 14*) has been identified in *Arabidopsis thaliana* [50], as well as a novel class of oxylipins, namely *sn*1-*O*-(12-oxophytodienol)-*sn*2-*O*-(hexadecatrienoyl)-monogalactosyl diglyceride [51].

4 Animal Glycolipids

In animal tissues, glycolipids are important constituents of the plasma membrane. They play a significant role in cell-cell communications, cellular differentiation, and proliferation, and also in oncogenesis, as indicated by alterations in their compositions and in glycosyltransferase activities during differentiation and growth of cells.

The most prominent lipid anchor of animal glycolipids is ceramide (*Fig. 15*) which consists of sphingosine that is substituted at its amino group by fatty acids of various chain lengths. Sugars are linked glycosidically to ceramide at the primary hydroxy group of sphingosine. Lipids of this type are called glycosphingolipids. The glycosphingolipids together with sphingomyelin and cholesterol are clustered in microdomains that serve in membrane-linked processes [52,53,54], e. g., signal transduction and internalization of bacteria and viruses.

Glycosphingolipids [55] can be divided in the two groups: neutral and acidic glycosphingolipids. Both comprise mono- or oligosaccharidic sugar moieties. Negative charges in the latter group can be provided by sialic acids, uronic acids, sulfates, phosphates, and phosphonates. Of the neutral glycosphingolipids, galactosylceramide (*Fig. 13*) is the most prominent member in the mammalian brain. This molecule and its sulfated form, i. e., 3-*O*-sulfogalactosylceramide (*Fig. 15*) belong to the dominant and essential glycolipids of the myelin layer of axons [56,57] where they are present in the outer leaflet of the myelin membrane [56], together with cholesterol and sphingomyelin. Less polar glycolipids than GalCer which co-appear with it during myelinogenesis were purified from rat brain. Two structures were identified, i. e. 3-*O*-acetyl-sphingosine-GalCer with non-hydroxy and hydroxy fatty *N*-acylation, respectively [58]. Other varieties, namely plakosides and agelasphins, were isolated from sponges and comprise a bis-hydroxylated ceramide moiety [59].

Higher glycosylated glycosphingolipids are found in all tissues. They are grouped in series, e. g., 'ganglio', 'globo', or 'lacto' in order to distinguish them with regard to structural and functional relationships (*Fig. 15*, *Table 1*). Other higher glycosylated glycosphingolipids were identified in *Schistosoma mansonii* eggs [60], carrying α-Fuc-(1→3)-GalNAc, β-GalNAc-(1→4)-[α-Fuc-(1→3)-GlcNAc], and β-Gal-(1→4)-[α-Fuc-(1→3)-GlcNAc] termini. From the tapeworm *Diphyllobothrium hottai*, ten glycosphingolipids were isolated from adults and four from plerocercoids, comprising mono—tetrasaccharide structures [61]. β-Gal-(1→4)-[α-Fuc-(1→3)]β-Glc-(1→3)-β-Gal-(1→Cer was found only in adults, whereas β-Gal-(1→4)-[α-Fuc-(1→3)]β-Glc-(1→3)-[β-Gal-(1→6)-]β-Gal-(1→Cer was identified in both, adults and plerocercoids. A novel class of fucosylated glycosphingolipids containing polyunsaturated very long chain fatty acids was identified to be essential for spermatogenesis and male fertility in mice [62].

Of the acidic glycosphingolipids, gangliosides are characterized by the presence of one or more sialic acid residues which are linked to O3 or O6 of Gal or GalNAc of the core oligosaccharides [63]. Polysialogangliosides were identified in skate brain [64]. Gangliosides are present in the outer leaflet of the plasma membrane but have also been identified, e. g., in cytosol membranes of some endocrine cells [65]. A broad variety of gangliosides was identified as tumor- and blood-group antigens. Furthermore, gangliosides may also act in autoimmune disorders as autoantigens, e. g., in the Guillain–Barre syndrome and in autoimmune diabetes [65], and there is good evidence that various gangliosides are able to modify the activities of functionally different receptor molecules [66]. In the nervous system, the composition of gangliosides is dif-

ferent in the peripheral nervous system (abundance of the neolacto series, compare *Table 1*) and the central nervous system (abundance of the globo series) [67]. Recently, novel hybrid gangliosides comprising isolacto-, neolacto- and ganglio-core were isolated from the Pacific salmon, *Oncorhynchus keta* [68].

Another group of the acidic glycosphingolipids are the sulfoglycosphingolipids (formerly called 'sulfatides'). This field is comprehensively reviewed in [6]. Most abundant in mammalian tissues is 3-*O*-sulfogalactosylceramide (*Fig. 15*) which occurs, e. g., in human kidney, rat lung, and in the human central and peripheral nervous system. Also, lactosyl II^3-sulfate ceramide is found in mammalian tissues, e. g., in human kidney and liver. Higher glycosylated molecules are present, e. g., in human kidney, and in the rat and human central and peripheral nervous systems.

Glycosphingolipids are also present in invertebrates. Insects contain arthrosides (see *Table 1*) that are structurally similar to gangliosides but contain Man instead of Gal and GlcUA instead of sialic acids [69]. In Drosophila, various zwitterionic and acidic glycosphingolipids were found [70]. Zwitterionic glycosphingolipids have also been identified in worms like *Ascaris suum* [71] or in the Annelida (for references see [71]). Interestingly, a glycosphingolipid with the structure α-D-Gal*p*-(1→2)-Ino-(1→P-Cer was identified in *Ascaris suum* [72] which represents the first 'phytoglycolipid' (see above) that was identified in animals. A highly fucosylated glycosphingolipid with a GlcNAc-(1→3)-GalNAc-(1→4)-Glc-(1→Cer core was identified in eggs of *Schistosoma mansonii* [73]. Also, a broad variety of marine organisms like sponges, starfish, and mollusks possess neutral and phosphorus-containing glycosphingolipids and gangliosides, and sulfoglycosphingolipids, e. g., 3-*O*-sulfogalactosylceramide. This field is excellently reviewed in [46].

Sponges contain also other interesting glycolipids, as was shown in a case study with *Plakortis simplex* [59]. In particular, polyisoprenoid glycolipids like plakopolyprenoside and plaxyloside possessing a C-35 linear polyisoprenoid alcohol as aglycon and a β-Xyl*p*-composed sugar chain were identified, and simplexides, containing a very long chain secondary alcohol (34–37 C-atoms) as lipid moiety, which is hydroxylated in the middle of the chain. This hydroxy group is glycosylated by a Glc*p*-(1→4)-Gal*p* disaccharide.

In protozoa, e. g., *Leishmania* and *Trypanosoma*, glycolipids have been identified that possess a GPI anchor (see Chap. 7.4) [74]. Characteristic for *Leishmania* is lipophosphoglycan [74,75,76,77] which covers the entire surface of the promastigote. The molecule can be divided in four regions, i. e., lipid anchor, core region, repeating units, and cap, the last of which vary in different species.

5 Properties

5.1 Lipopolysaccharides

Like other amphiphilic molecules, LPS aggregate and build up clusters in aqueous solutions. This process occurs only above a critical aggregate concentration (CAC) which has been established for a few lipids, but not, however, for LPS owing to extreme experimental difficulties. Estimations based on comparisons to values of other lipids led to the assumption of a CAC of $< 10^{-10}$ M for hexaacyl-lipid A (*Fig. 16*). For the lipid A precursor IVa (*Fig. 16*) which represents a tetraacyl-lipid A, a CAC of $< 10^{-7}$ has been reported [78].

Since the conformation of a particular LPS molecule depends on the phase state of its hydrocarbon moiety, it is variable and, thus, may exist in a highly ordered gel state or in a less ordered liquid-crystalline state. These states and the changes from one to the other are dependent on the phase-transition temperature and other parameters, like water and ion concentration [79]. The state of order of LPS with a longer saccharide moiety shows a stronger dependence on water and ions than that of LPS with shorter saccharide chains. The addition of cations, e. g., Mg^{2+}, results in the aggregation of LPS due to intermolecular bridging.

Synthetic lipid A analogues were used in FTIR investigations to study possible intermolecular conformations of neighboring molecules [79]. There is good evidence that the bisphosphorylated β-(1→6)-linked GlcN disaccharide backbone of lipid A is inclined (20–40° relative to the membrane normal), thus, the phosphate linked to O1 is reaching to the outside and that at O4′ is buried in the membrane. This model is supported by data from transition temperature measurements and calorimetric experiments. However, it should be noted that other authors reported the reverse conformation with the O4′ phosphate on the surface and the O1 phosphate in the membrane [80,81].

The determination of the relation between the conformation and the supramolecular structure of a given LPS molecule is possible using a simple geometric model described by $S = a_h / a_o$

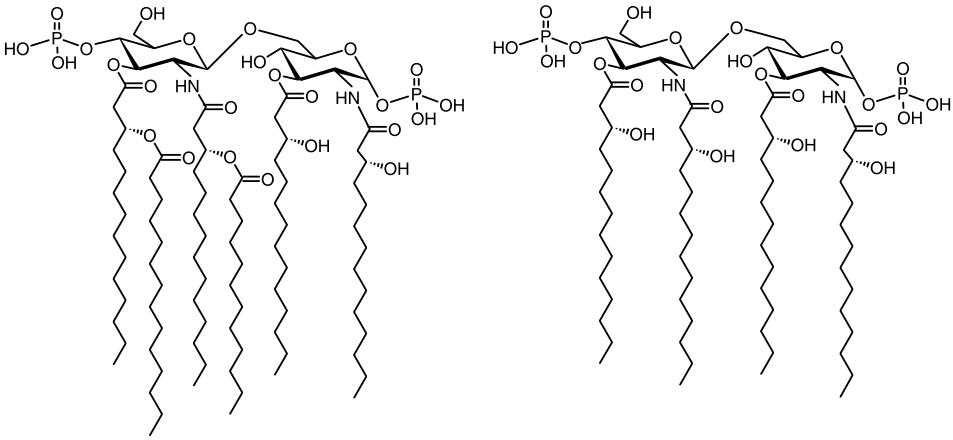

Figure 16
Chemical structures of hexaacyl-lipid A from *Escherichia coli* (left) and precursor IVA from *Escherichia coli* (right)

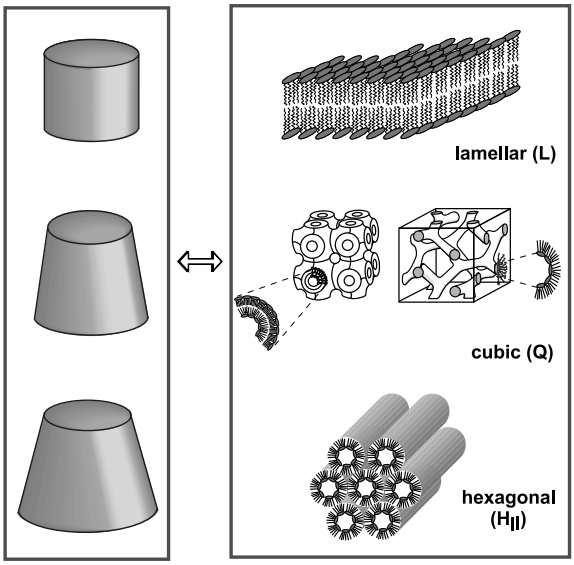

Figure 17
Molecular conformations and supramolecular structures of endotoxins

(*S*, final structure; a_h, effective cross-sectional areas of the hydrophilic region; a_o, effective cross-sectional areas of the hydrophobic region) [82,83]. The value for a_h is strongly influenced by *gauche*-conformers in the acyl chain: their presence (liquid-crystalline state) provokes an increase of a_h, their absence (gel state) a decrease. The presence of ions and variations in the hydration state influence the value for a_o. Furthermore, headgroup charges and/or asymmetric distribution of acyl chains leading to the presence or absence of an axis of the molecule determine the supramolecular structure, the most relevant of which are shown in *Fig. 17*. They are the lamellar, cubic, and hexagonal structures [84]. The phase behavior of LPS and lipid A was shown to depend on the length of the sugar moiety that is present in the molecule [78,83,85,86,87].

It has been well established that the expression of the full biological activity of the lipid A molecule is due to a particular chemical structure, i. e., a bisphosphorylated β-(1→6)-linked Glc*N*-disaccharide that is acylated by 6 fatty acids of chain lengths between C_{10} and C_{16} [88]. Any change in this chemical structure leads to changes of the physical conformation and of the biological properties. Thus, it is a unique lipid A conformation that is responsible for biological activity, a concept that could be verified by comparison of chemical structures of different lipid A and their respective biological activities [89,90,91,92,93,94,95,96,97].

5.2 Lipoteichoic Acids

In distinction to LPS, the critical micellar concentration of various lipoteichoic acids (LTA) has been measured and determined to be in the range of $2.8 \cdot 10^{-7}$ M to $5 \cdot 10^{-6}$ M [98,99], indicating a significantly lower hydrophobicity than for glycerophospholipids which is due to the

large hydrophilic carbohydrate chains [100]. Independent of the different structures of their hydrophilic regions, LTA possess similar spherical micellar structures in aqueous solutions, even over a wide range of temperature [101,102]. It has been determined that LTA of *Streptococcus pneumoniae* furnishes an average micelle of about 150 molecules with a diameter of 22 nm, in which an outer layer of 8.5 nm thickness is built up by the hydrophilic part of the LTA, indicating a highly coiled conformation of this region [102]. Since the effective cross-sectional area of the lipid moieties of LTA is smaller than that of the hydrophilic carbohydrate chains, LTA possess a conical supramolecular structure which does not allow the molecule to form membrane layers. Thus, LTA can only be inserted into a layer of the lamellar phase lipids, and it has been shown that stable membranes formed from membrane lipids and LTA can be obtained [103].

5.3 Mycolates

The structure of the cell envelope of mycobacteria [30,104] is highly complex. Outside the cytoplasma membrane the so-called cell wall skeleton is present, consisting of the three covalently attached polymers, peptidoglycan, arabinogalactan, and mycolic acids. Also present in this skeleton are lipoarabinomannan and lipomannan, and a variety of (glyco)lipids. Mycolic acids are long-chain α-alkyl-β-hydroxyfatty acids that often comprise more than 80 C-atoms and possess functional groups such as *cis*- or *trans*-cyclopropanes, α-methyl methyl ethers, or α-methyl ketones. They are ester-linked to terminal arabinose residues of the arabinogalactan and extend perpendicular to this and the peptidoglycan. Since other lipids (possibly glycolipids) intercalate into the layer of mycolic acids, some kind of bilayer is formed. The mycolic acids furnish the inner leaflet of this bilayer and represent an effective barrier to the penetration of antibiotics and chemotherapeutic agents.

Evidence for this mycolate leaflet has been obtained, among others, by using X-ray diffraction on purified mycobacterial envelopes which gave a strong reflection at 4.2 Å and a rather diffuse reflection at 4.5 Å that were assigned to highly and less ordered fatty acyl chain regions, respectively [105]. Also, the perpendicular orientation of the acyl chains was demonstrated. Such purified mycobacterial cell walls have also been investigated using differential scanning calorimetry in order to examine phase transitions [106]. One important observation was that the lipids of the cell wall possess a melting point above the highest temperature at which the bacteria are viable, and that this is significantly higher than that of other biological membranes. This confirmed the presence of a compact and highly ordered mycolate layer in the cell wall. Further investigations employing electron-spin resonance experiments using spin-labeled fatty acids showed that these enter less ordered regions (more fluid), possibly occupied by the less ordered lipids that build up the outer leaflet of the bilayer and intercalate into the mycolate leaflet. Taken together, evidence is provided that an outer permeability barrier is present in the mycobacterial cell wall, which is constructed as an asymmetric membrane comprising a highly ordered inner (mycolates) and a less ordered outer (lipids) leaflet.

5.4 Hopanoids

Hopanoids are thought to represent surrogates of cholesterol in bacteria, acting as efficient membrane stabilizers. This is supported by the findings that both sterols and hopanoids are

(i) amphiphilic molecules, (ii) possess a rigid, hydrophobic polycyclic skeleton and a polar headgroup, and (iii) possess close conformational similarity, as shown by molecular modeling of cholesterol and bacteriohopanetetrol (BHT) [43,44].
Other proof was obtained from experiments with artificial membranes in which BHT or its glycoside isolated from *Bacillus acidocaldarius* led to a condensation of C16:0 and abolished the clear phase transition between the gel-like and the liquid-crystalline phases. Furthermore, it was found that 40 mol-% of BHT completely suppresses this phase transition in phospholipid bilayers.

5.5 Glycoglycerolipids

Glycoglycerolipids represent one of the major glycolipid classes, and they play important functional roles in furnishing membranes and the maintenance of membrane fluidity as well as in specific lipid-protein interactions [107,108,109] and cell surface recognition. In the latter functions (as well in those of glycosphingolipids), the relation between structure and action is determined by the sequence and conformation of the saccharide chains and, however, influenced by the structures of their lipid moieties and the lipid environment of the whole molecule. Conformational analyses of glucosyldiacylglycerol (Glc-DAG, and glucosyldialkylglycerol) using molecular mechanics indicated that in the membrane only a reduced number of possible conformations appear [110]. Obviously, the saccharide conformation of GlcDAG is in lipid-water systems in the hexagonal phase, owing to a close headgroup packing which is in clear difference to the lamellar arrangement of glycosylceramides.
Model membranes have been used to investigate the influence on membrane structure and function of both polar headgroups and hydrophobic regions of glycolipids, by application of thermodynamic, structural, and spectroscopic methods. With regard to the hydrophobic moiety, the stability of various phases of the lipids was studied with a special focus on length and degree of saturation of the alkyl chains [111]. Investigations using calorimetry showed that size and stereochemistry of the carbohydrate moiety, the anomeric configuration of the glycosidic linkage of the sugar to glycerol, the charge of the lipid moiety, and the stereochemistry of glycerol are essential for transition characteristics. With regard to the hydrophobic moiety, the temperatures for the transitions from lamellar gel to the lamellar liquid crystalline phase ($L_\beta \rightarrow L_\alpha$) and from the lamellar crystalline (L_c) phase to L_α of α-Glc containing DAG increase with the presence of longer acyl chains. On the other hand, the high-temperature transition L_α to non-lamellar phase decreases with increasing chain lengths, e. g., for a di-C18:0 glycerol a direct transition from L_α to the inverted hexagonal liquid crystalline phase is observed [112,113,114,115]. A change from the α- to the β-Glc anomer has some impact on the phase properties. Between the L_c and L_β phases, an additional 'L_c-like' phase is observed. The transition $L_\beta \rightarrow L_\alpha$ is also faster than that for α-glucosides, and the final L_c phase is less stable. Thus, a direct $L_c H_{II}$ transition is not present in the case of β-glucodiacylglycerols, but, instead, two-step $L_c \rightarrow L_\beta \rightarrow H_{II}$ or three-step $L_c \rightarrow L_\beta \rightarrow L_\alpha \rightarrow H_{II}$ transitions have been observed for C20:0/C20:0 and C18:0/C18:0 β-glucodiacylglycerols, respectively. Thermodynamic and NMR data indicate that β-glucodiacylglycerols tend to form inverted non-bilayer phases. Between β-gluco- and β-galactodiacylglycerols, the only difference is the higher stability of the L_c phase of the latter. Although only few data exist in the literature, it seems that mannodiacylglycerols possess a rather simple phase transition behavior, compared to that of

gluco- and galactodiacylglycerols. Glucuronoglycerolipids show a different phase transition behavior, owing to the negative charge of the carboxyl group at C6 of the sugar moiety. As expected, the charge destabilizes the rather ordered gel-phase at low temperature, resulting in a decreased phase transition temperature. At pH values above the pK of the carboxyl group, the lamellar gel phase undergoes a reversible structural change between 40 and 50 °C which is below the melting point at about 69 °C and indicates a disordered bilayer stacking. In di- and trisaccharide diacylglycerols, the introduction of a second or third sugar residue disables these lipids to form non-bilayer structures. Here, the L_α phase represents the final high-temperature phase. It should be noted that a computerized database (LIPDAT) is available which provides the reader with published data on phase behavior of synthetic, semisynthetic, and natural polar lipids [111].

Differential scanning calorimetry, differential scanning densimetry, and small and wide angle X-ray scattering have been used to investigate the polymerization of β-gluco-, β-galacto-, and β-maltodiacylglycerols with varying acyl chain lengths [116]. The aim of the study was to elucidate (i) whether the structural changes occur synchronous with the enthalpy and volume changes and (ii) whether the cooperativity of the transitions is predominantly determined by the geometry of the phase change.

The results show that enthalpy and changes of volume and structure occur in synchrony with the transition temperature. All phase changes may be described under equilibrium conditions as two-state processes. The value for the size of the cooperative unit is the same, independent of the method by which it was determined. The lowest cooperative unit was found during the L_cL_β and L_cL_β transitions (about 37), whereas $L_\beta L_\alpha$ possessed a medium (about 120) and $L_\alpha H_{II}$ a high (several hundreds) number.

The physicochemical properties of a major glycolipid from *Mycoplasma fermentans* [24], namely 6′-*O*-(3″-phosphocholine-2″-amino-1″-phospho-1′,′3″-propanediol)-α-D-glucopyranosyl-(1′→3′)-1,2-diacyl-*sn*-glycerol (MfGl-II), have been characterized [117,118]. Interestingly, the properties of this molecule resembled those of LPS/lipid A, i. e., the $\beta \rightarrow \alpha$ gel-to-liquid crystalline phase transition behaviour of the hydroacarbon chains had a T_c of 30 °C, and a unilamellar/cubic supramolecular structure was identified. At high water contents, MfGl-II formed a L_α phase and isotropic aggregates (vesicles).

5.6 Glycosphingolipids

The LIPDAT data base contains also thermodynamic data that have been published for synthetic, semisynthetic, and natural glycosphingolipids [119]. Of the latter, sphingomyelins, gangliosides, and cerebrosides have been investigated. Natural sphingomyelins undergo mesophase transitions between 20 and 40 °C. On the basis of these and other data and the packing mode of long-chain sphingomyelins, it is thought that these lipids are important for membrane transport. Of the cerebrosides, mainly the monoglycosides have been investigated, some of which possess low-temperature gel phase metastability. A majority of molecules displays unusually high lamellar order to disorder temperatures between 50 and 70 °C, indicating their role in the structural integrity of membranes. The large difference in the gel-to-liquid phase transition temperatures [120] of monoglycosylcerebrosides and phospholipids indicate a phase-separation-induced clustering of the former in membranes, an observation that is indeed of high biological significance (see below). FTIR was used to investigate the transfer of metastable

gluco- and galactocerebrosides to their stable forms [121], and the data led to the conclusion that the presence of an α-OH group in the acyl chain results in a less tightly packed structure, owing to reduced intermolecular hydrogen bonding. These findings were in accord with the reduced enthalpy of the gel-to-liquid crystalline phase transition. Other investigations using bovine brain cerebrosides [122] indicated the presence of two gel states, one of which is in the metastable form. The shift from the metastable to the stable form showed again the formation of hydrogen bonds. The spectra of the metastable and the anhydrous forms were very similar which confirmed the observed identical X-ray diffraction patterns for both forms [124]. In gangliosides, sialic acid residues introduce negative charges to the polar headgroup. The general involvement of gangliosides in the modification of membrane functions is obviously based on their tendency to aggregate. Higher oligosaccharide-containing gangliosides form micelles (critical micellar concentration 10^{-8}–10^{-5} M).

As mentioned above, the different physical properties of sphingolipids and phospholipids in membranes results in clustering of the former, i. e., in microdomain formation [125,126]. This process is furthermore influenced by the differences in the length of the acyl chains which range from 20 to 26 carbon atoms in glycosphingolipids and from 16 to 22 carbon atoms in phospholipids, and by the degree of saturation which occurs more often in the latter class. A model of microdomains (or rafts, in the case where they are associated with GPI-anchored proteins) proposes densely packed glycosphingolipids and cholesterol molecules. Rafts seem to be important in membrane traffic and signal transduction events.

Glycosphingolipids are thought to play important roles in cell recognition and adhesion processes which involve the interaction between the carbohydrate moieties. Thus, saccharide headgroups should possess preferred conformations. In accord with this and as with glycosyldiacylglycerols, the number of possible conformations of glycosphingolipids seems to be reduced by hindrance of the membrane environment, as was measured for glucosylceramide [110]. The orientation of the saccharide chain is furthermore dependent on intrinsic preferences of the saccharide-ceramide linkage. Recently, the adhesion between lactosylceramide-coated bilayers was measured, and it was found that the non-specific van der Waals attraction between the membranes is not increased by the presence of the carbohydrate moiety and, thus, is weak [126]. Therefore, in this case the measured forces can neither be strong enough to overcome intercellular electrostatic repulsion nor be responsible to arrest cells. However, it should be noted that only few such investigations have been performed; thus, this field awaits further clarification.

Acknowledgments

Abstract

Glycolipids, composed of hydrophilic carbohydrate and hydrophobic aliphatic residues, have a wide variety of biological activity. Natural glycolipids are known to be very complex and heterogeneous, and sometimes contain lipophilic contaminants, which cause confusion in the understanding of their original functions in biological process. To investigate their function at the molecular level, structurally defined glycolipids are necessary. A chemical synthetic approach may be the only method to overcome this issue. So far, a lot of synthetic efforts have been devoted in this field. This chapter summarizes syntheses of natural and related glycolipids, sphingoglycolipids, glyceroglycolipids, lipoteichoic acid, mycoloyl arabinan, lipopolysaccharide, glycophosphatidylinositol, etc.

1 Introduction

To date, more than 300 natural glycolipids have been isolated. Structural features of glycolipids are composed of covalently bound mono- or oligosaccharides and lipophilic parts such as alkyl or acyl long chains, which are sometimes modified by additional functional groups such as phosphates, sulfates, glycerols, etc. They work as constituents of the biomembrane, and play significant roles in many biological events such as cell proliferation, cell differentiation, cell recognition, cell adhesion, etc. In addition, some bacterial glycolipids like lipopolysaccharide (LPS) exhibit immunostimulating activity against vertebrates. Recently, structurally unique glycolipids have been isolated and identified from various organisms such as marine sponges, insects, and also in Chinese traditional medicine. These glycolipids exhibit unique bioactivity including anti-tumor and immunostimulating activity.

Evaluation of structure–function relationships and structural assignment of new complex glycolipids have been performed on many glycolipids. Chemical synthesis, which can provide structurally defined molecules, is very important not only for the accurate structural assignment, but also for the precise investigation of their biological functions, since natural glycolipids are usually obtained as inseparable complex mixtures owing to the heterogeneity in the lipid moieties, and may contain lipophilic contaminants.

In this chapter, we reviewed recent works on chemical syntheses of sphingoglycolipids, glyceroglycolipids, bacterial glycolipids such as mycoloyl arabinan partial structure, lipoteichoic acid (LTA), Re-type lipopolysaccharides, glycophosphatidylinositols, and other glycolipids with unique structures.

2 Synthesis of Sphingoglycolipids

Sphingoglycolipids are components of the cell membrane and play a significant role in various biological processes [1,2]. Sphingoglycolipids are composed of at least one monosaccharide residue and long-chain aliphatic components known as ceramides (Cer). A typical structure is illustrated in ❯ *Fig. 1*. They have diverse structural variations on both the ceramide and saccharide residues, and they are classified into many types according to carbohydrate sequence. The representative families are summarized in ❯ *Table 1*. In this section, recent syntheses

regarding sphingosine, gangliosides noting recent progress in sialylation, and cerebroside are described.

2.1 Synthesis of Ceramide

Ceramide is usually composed of an *N*-linked acyl chain and sphingoid. Sphingoid consists of a polar head group and a lipophilic chain. Dihydrosphingosine, sphingosine, and phytosphingosine are known as major sphingoids (see *Fig. 2*). Among them, sphingosine is the most common sphingoid, and a number of synthetic methods have been developed for the syntheses of sphingosine and its protected equivalents, which have been summarized in several reviews [3,4,5,6,7,8,9,10,11,12]. Most of these methods are based on a chiral pool strategy utilizing amino acid (L-serine [13]), carbohydrate (D-glucose [14], D-glucal [15], D-glucosamine [16], D-galactose [17], D-galactal [18], D-xylose [17,19], and D-arabinose [19]), and other chiral sources such as glycidol [20], D-glyceraldehyde [21], D-threose [22], D-tartaric acid [23,24], D-mannitol [25], and so on. An asymmetric strategy via enantioselective aldol reaction [26,27] including aldol reactions with chiral auxiliaries [28], epoxidation [29], alkenylation [30], or *N*-sulfinylaziridination [31] is also effective for the synthesis.
Recently, methods with efficient, simple, versatile, and rapidly accessible routes have been required because sphingosine and its derivatives are potentially useful as a pharmacore. Divergent synthesis of the polar-head group of the sphingosine has been reported [32,33,34]. Hudlicky et al. achieved the synthesis of four stereoisomers (**2**, **3**, **4**, and **5**) of a sphingo-

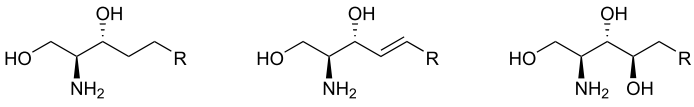

Figure 2
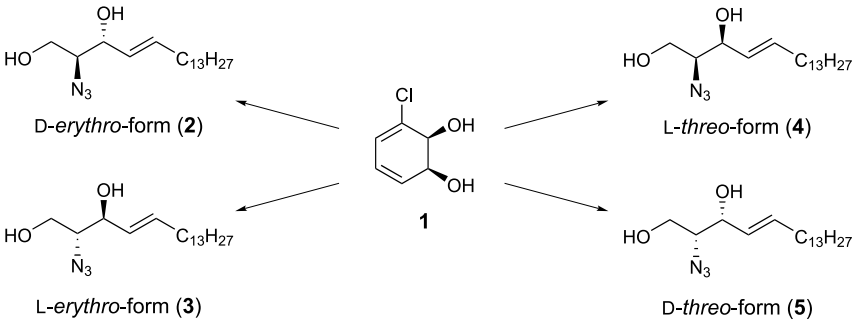
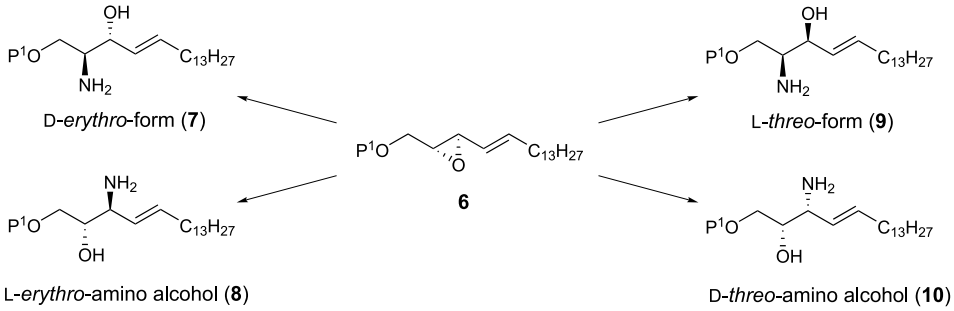
Chemical structure of sphingoids (R = alkyl chain, normally -$C_{13}H_{27}$)



Scheme 1



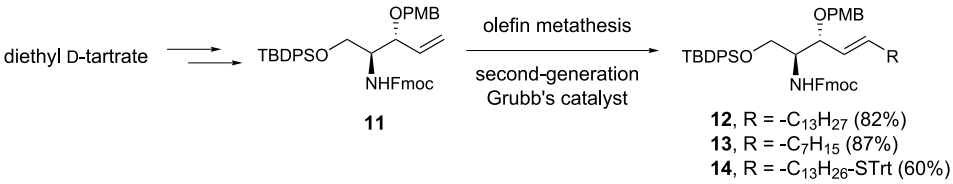
Scheme 2

sine derivative using a chemoenzymatically prepared chiral diol **1** as a starting material [32] (*Scheme 1*). Somfai et al. also successfully synthesized four stereo- and regioisomers (**7**, **8**, **9**, **10**) from chiral epoxide **6** [33] (*Scheme 2*). This method may be more efficient than the former because it can be accessible to the syntheses of the corresponding enantiomers by using *ent*-**6**.

Construction of a lipophilic chain towards divergent synthesis of sphingosine has been performed by cross-metathesis olefination [35,36,37,38]. This strategy is attractive in terms of high *E*-selectivity with good yield in the product formation and the functionality tolerance under metathesis conditions. Basu et al. synthesized sphingosine core building block **11** with an orthogonal protecting group, which was derived from diethyl D-tartrate in several steps. Olefin metathesis of the building block **11** with various alkenes in the presence of Grubbs generation II catalyst [39] gave the corresponding alkenes **12**, **13**, and **14** in good yields [36] (*Scheme 3*).

For synthesis of phytosphingosine [40] and dihydrosphingosine [7], many methods have been reported. These utilized a chiral pool strategy with amino acid or carbohydrate similar to that of sphingosine.

Labeled ceramide derivatives are also important for investigation of its biological behavior. Synthesis of radio-labeled [41,42,43,44,45,46] and fluorescence-labeled [47,48,49,50,51,52,53,54] compounds has been reported.



Scheme 3

2.2 Synthesis of Gangliosides

Gangliosides are generic terms of glycosphingosines containing sialic acid (neuramic acid) and are recognized to possess very important biological functions. Although there are many efforts for synthesizing gangliosides reported in the literature [12], glycosylation with sialic acid (sialylation) is, even now, one of the most important remaining issues for the total synthesis of gangliosides or other compounds containing sialic acid. Efficient methods for sialylation are required. This section deals with recent progress on sialylation and a total synthesis of ganglioside, DSLe^a (disialyl Lewis A).

2.2.1 Glycosylation with Sialic Acid

Sialic acid is regularly located at the non-reducing terminal of glycoconjugates through α-glycosidic bonds. Much effort has been devoted to the synthesis of sialoside [55]. Generally, an α-sialoside is obtained by kinetically controlled α-selective glycosylation. In most cases, the reactions are carried out in a solvent with α-directing effect such as CH_3CN or EtCN [56,57]. The representative glycosyl donors are shown in *Scheme 4*. A glycosyl halide is activated by mercury salt [58]. When secondary hydroxy groups in the acceptor were used for sialylation, the yields were modest. Thioglycosides [59,60,61,62,63,64] and glycosyl phosphates [65,66] afforded α-sialoside in moderate yields with high selectivity. However, when sterically hindered secondary hydroxy groups, such as the 8-OH group of neuramic acid or 3-OH group of galactose, are used in the acceptor, the yields and selectivities are both decreased due to an

-OC(=NPh)CF_3	phthN-	Ac

Scheme 5

undesired elimination in the sialyl donor. Thus, sialylation with 100% α-glycosidic linkage and high yield still remains a significant challenge.

Recently, it was found that the *N*-protecting group of the sialyl donor at the 5-position affected the yield and selectivity of the obtained sialoside (*Scheme 5*). Boons et al. first reported the *N*,*N*-diacetylated sialyl donor in 1998 [67,68]. The *N*,*N*-diacetylated sialyl donor is more reactive than the *N*-acetylated one, giving α-sialoside in good yield. After that, various sialyl donors were prepared, i. e. *N*-trifluoroacetyl [69], *N*-trichloroacetyl [70], azido [71], *N*-2,2,2-

Scheme 6

trichloroethoxy carbonyl [70,72], *N*-fluorenylmethoxy carbonyl [70], *N*,*N*-phthaloyl [73], and 5-*N*,4-*O* carbonyl [74] derivatives. Although the reaction mechanisms of these sialylations is still unclear, it seems that a delocalization of electroproperty and a fixation of dipole moment on the nitrogen atom is important for enhancing reactivity of the sialyl donor. In addition, Yu et al. also reported a *N*-phenyl trifluoroimidate donor [75], which showed a higher reactivity than those previously reported. Thus, α-sialylation is constantly being improved.

A chemoenzymatic sialylation is also an efficient method for obtaining sialosides. Wong et al. reported a one-pot two-enzyme system, in which sialyltransferases and CMP-NeuAc recycling enzymes were used [76,77]. The resultant sialoside was obtained in good yield. Recently, a one-pot three-enzyme system was reported by Chen et al. [78,79] (*Scheme 6*). Mannosamine was used as a starting material. This system afforded the corresponding sialosides in high yield, and could be applied to a variety of protected mannosamine derivatives.

2.2.2 Total Synthesis of DSLe^a

A total synthesis of ganglioside DSLe^a, α(2-3)/α(2-6)-disialyl Lewis A, which was isolated from human colonic adenocarcinoma [80], was recently reported by Kiso's group as illustrated in *Fig. 3* and *Scheme 7* [81,82]. DSLe^a is characterized by a sterically hindered tri-antennary structure at *O*-3, *O*-4, and *O*-6 of glucosamine residue. The crucial points of the synthesis

are regioselective α-sialylation at the 6-position, regioselective β-sialylgalactosylation at the 3-position, and α-fucosylation at the 4-position of the glucosamine moiety. According to the retrosynthetic analysis: DSLe^a is divided into the five known building blocks **16**, **17**, **18**, **19**, and **20** (*Fig. 3*). The synthetic pathway is shown in *Scheme 7*.

Trisaccharide **16** was converted to 3-*O*-*p*-methoybenzyl form **21** [83] in three steps. Sialylation of **21** with thioglycoside **18** [84] under the established conditions [61,62,63,64,85], with *N*-iodosuccinimide (NIS) and trifluoromethanesulfonic acid (TfOH) as promoters at −35 °C in acetonitrile, gave predominantly α-sialyl tetrasaccharide **22** (74%) with β-sialoside (16%). After removal of the PMB group, glycosylation of tetrasaccharide with sialylgalactosyl donor **19** [86] preferentially afforded β(1-3)-linked hexasaccharide **23** (53%) with β(1-4)-linked hexasaccharide (13%). Fucosylation of the remaining hydroxy group at the 4-position in GlcNAc was performed only when an excess amount of fucosyl donor **20** [87] (15 mol equiv.) was used, affording the desired heptasaccharide in 75% yield. Removal of the benzyl group by hydrogenolysis, followed by full acetylation of the resultant hydroxy group, furnished heptasaccharide **24**. Heptasaccharide **24** was then led to sphingoglycoside **25** via removal of the SE group, trichloro-imidation, and glycosylation with azidosphingosine **17**. Target compound DSLe^a **15** was synthesized by reduction of the azide group, *N*-acylation with octadecanoic acid, *O*-deacylation, and saponification of methyl ester.

2.3 Synthesis of Cerebrosides

Cerebroside is the generic term for monoglycosylceramides, which have been studied for over a century. Recently, there has been renewed focus on cerebrosides because of their interesting biological activities, such as immunostimulation and suppression. They are also recognized as synthetically attractive targets with regard to a wide variety of functional groups in the lipophilic part. A few cerebrosides are illustrated in *Fig. 4*. Typhoniside A is a component of traditional Chinese medicine [88]. Both OCH [89] and KRN7000 [90,91] possessing α-Gal structure exhibited immunostimulating activity. In this section, the total synthesis of plakoside A, which has a highly complex structure in the lipophilic part, is described.

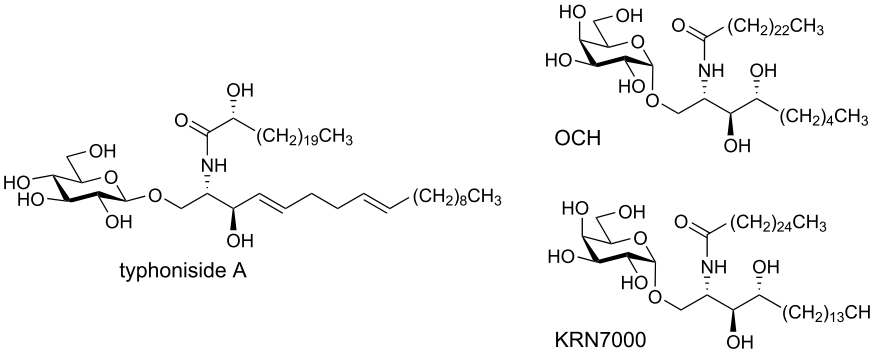

Figure 4
Chemical structures of cerebrosides

2.3.1 Total Synthesis of Plakoside A

Plakoside A and B are naturally occurring glycosphingosines, which were isolated from the marine sponge *Plakortis simplex* in 1997 by Fattorusso's group [92] (*Fig. 5*). They are composed of a prenylated D-galactose and cyclopropane-containing ceramide, and possess strong immunosuppressive activity without any cytotoxicity. Total synthesis of Plakoside A has so far been accomplished by two groups, Nicolaou's group in 2000 [93] and Mori's group in 2001 [94]. Herein, we will focus on Nicolaou's method.

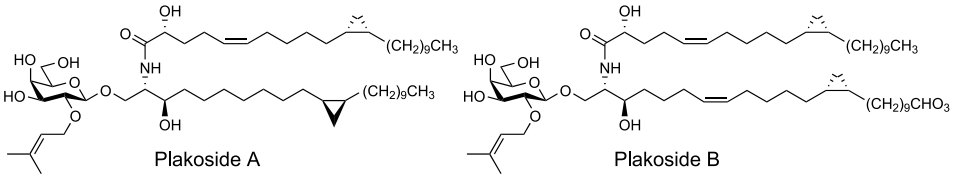

Figure 5
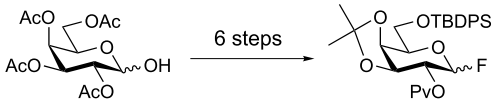
Structures of plakosides A and B

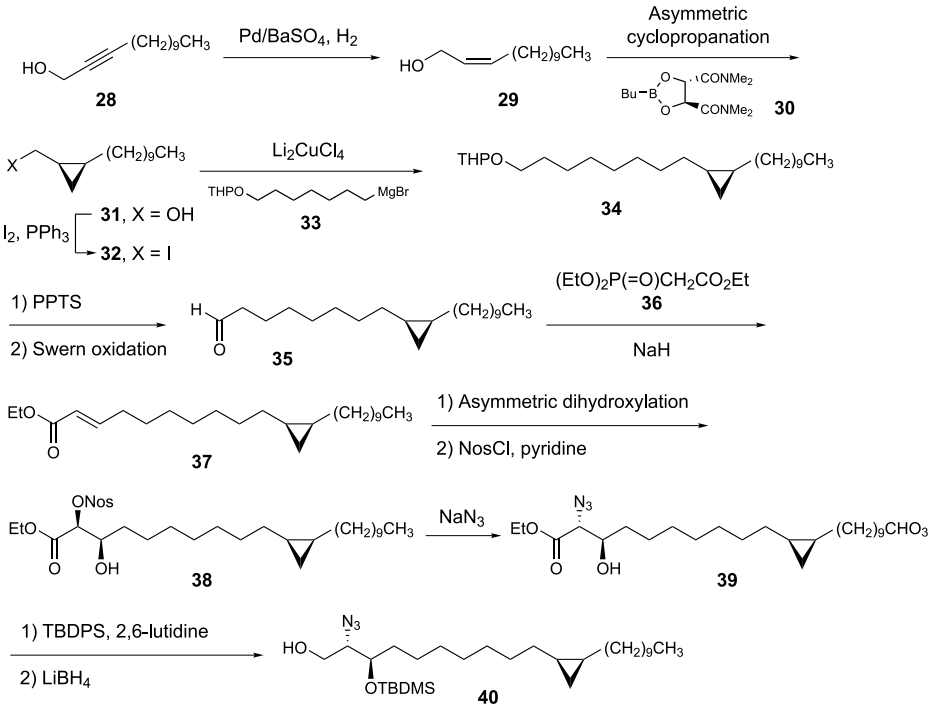
Plakoside A was synthesized by connecting three building blocks, galactose, the α-hydroxy acyl chain, and the sphingosine parts. Introduction of stereogenic centers of the cyclopropane ring and hydroxy group in the acyl side chain was carried out by Charette cyclopropanation [95,96,97,98] and Sharpless asymmetric dihydroxylation [99,100], respectively. Galactosyl fluoride **27** was synthesized from commercially available galactosyl pentaacetate **26** in six steps (*Scheme 8*).



26 **27**

Scheme 8

Azide alcohol sphingosine **40** was prepared by an asymmetric cyclopropanation and dihydroxylation as key reactions (*Scheme 9*). Commercially available tridec-2-yn-1-ol **28** was selectively hydrogenated by Pd on $BaSO_4$ under an H_2 atmosphere to give (*Z*)-alcohol **29**. Charette asymmetric cyclopropanation using bis(iodomethyl)zinc•DME complex and (*R*,*R*)-dioxaborolane **30** afforded **31** in 96% yield with 84% ee. Alcohol **31** was converted to the corresponding iodide **32** by exposure to iodine and triphenylphosphine. Elongation of the aliphatic chain was performed by the cross coupling with iodide **32** and Grignard reagent **33** in the presence of a catalytic amount of Li_2CuCl_4. Acidic cleavage of THP ether of **34**, followed by Swern oxidation of the resulting hydroxy group gave aldehyde **35** in good yields. Horner–Emmons olefination of aldehyde **35** with phosphate **36** predominantly furnished the (*E*)-α,β-unsaturated ester **37** (*E*/*Z* > 95:5). Asymmetric dihydroxylation of **38** with AD mix-β in the presence of $CH_3SO_2NH_2$ afforded the corresponding diol in 96% yield, then the resulting α-hydroxy group was selectively nosylated with nosyl chloride to give nosylate **38** in 90% yield. S_N2 reaction of **38** on the α-position with NaN_3 afforded α-azido-β-hydroxy

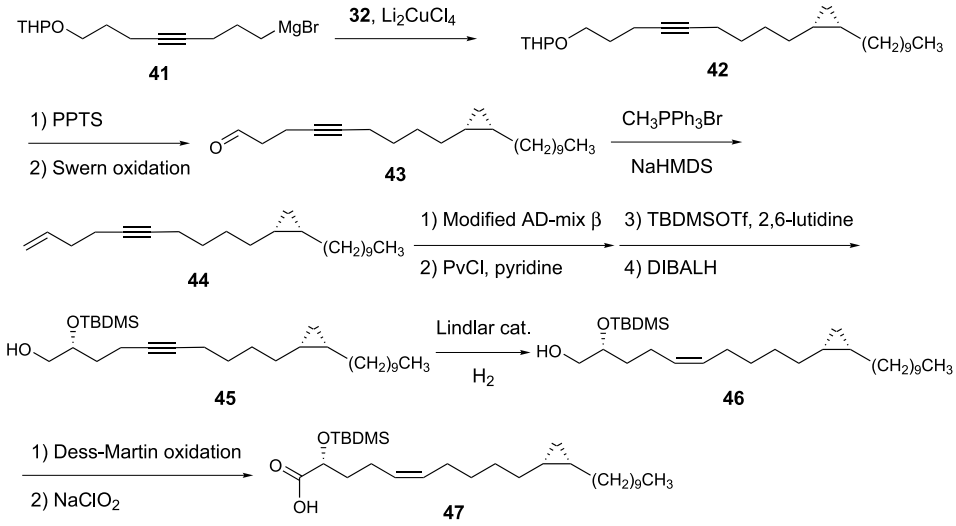


Scheme 9

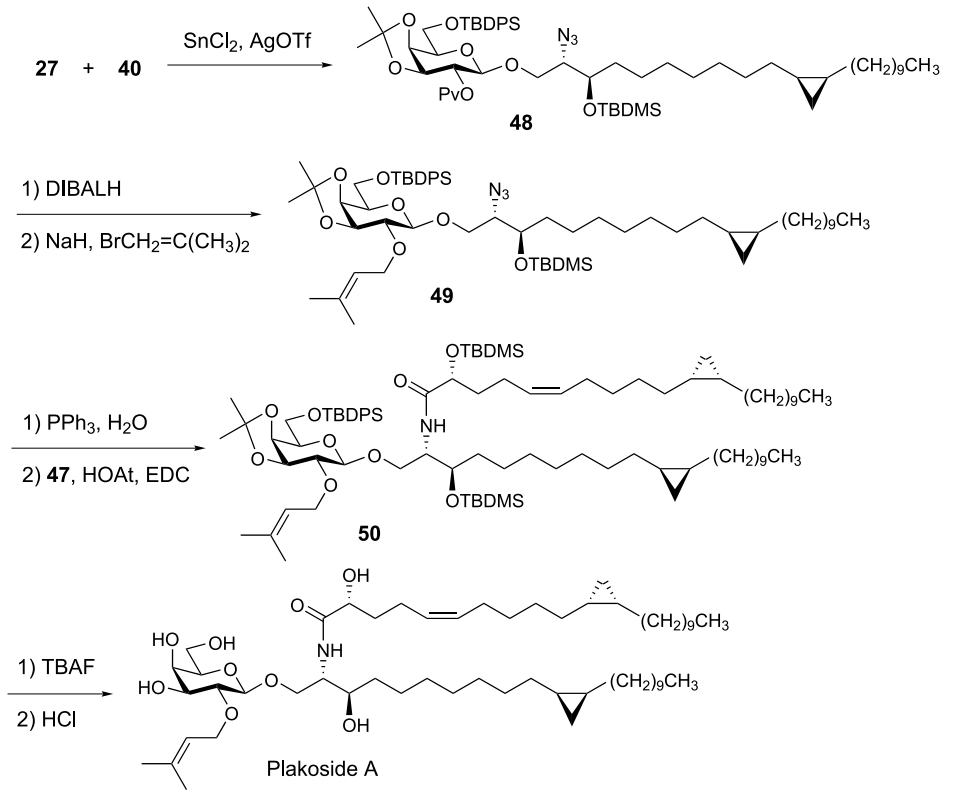
ester **39**. Silylation of **39** with *tert*-butyldimethylsilyl trifluoromethanesulfonate (TBDMSOTf) and 2,6-lutidine, and subsequent reduction of the ester moiety with lithium borohydride furnished azidosphingosine **40**.

Acyl side chain **47** was prepared as a similar strategy for the synthesis of **40** (see *Scheme 10*). Cross coupling of Grignard reagent **41** and iodide **32** in the presence of catalytic Li_2CuCl_4 gave THP ether **42** in 84% yield. THP ether of **42** was cleaved under acidic conditions, and then the resulting hydroxy group was converted to aldehyde **43** by Swern oxidation. Wittig reaction of aldehyde **43** with CH_3PPh_3Br afforded the C_1 homolog **44**. Asymmetric dihydroxylation of **44** was then performed with AD mix-β and $CH_3SO_2NH_2$ to furnish the corresponding diol, in which the primary hydroxy group was temporally protected with a pivaloyl group and the secondary one with a *tert*-butyldimethylsilyl group. After reductive cleavage of pivaloate, alkyne **45** was subjected to Lindlar hydrogenation conditions selectively and quantitatively to give (*Z*)-olefin **46**. A stepwise oxidation procedure via Dess–Martin oxidation and $NaClO_2$ oxidation afforded carboxylic acid **47**.

The three building blocks **27**, **40**, and **47** were connected as shown in *Scheme 11*. First glycosylation of azidosphingosine **40** with **27** was performed stereoselectively in the presence of $SnCl_2$ and AgOTf to give β-glycoside **48**. After removal of the pivaloyl group at the 2-position in the galactose moiety, the resulting hydroxy group was condensed with prenyl bromide in the presence of NaH to afford compound **49**. The azide group of **49** was reduced to an amino



Scheme 10



Scheme 11

group by the Staudinger reaction, which involved coupling with carboxylic acid **47** in the presence of HOAt and EDC to give compound **50**. Final deprotection was performed by sequential treatment of TBAF and aqueous HCl to afford plakoside A.

3 Synthesis of Glyceroglycolipids

Glyceroglycolipids are important constituents of cell membrane. These lipids are composed of the carbohydrate polar head group and glycerolipid [101] (*Fig. 6*). The carbohydrate moiety consists of one to eight sugar residues. Glycerolipids typically include diacylglycerol, acylalkylglycerol, or dialkylglycerol. Major structural components of cell membrane are glycosyl diacylglycerol with mono-, di-, and trisaccharides. Synthetic studies at the early stage were summarized by Gigg et al. [102].

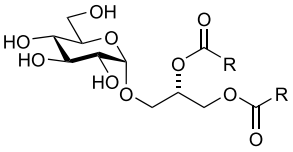


Figure 6
Chemical structure of typical glycosyl diacylglycerol

Glycerolipids from archaebacteria have very unique chemical structures. The structural feature is a tetraether-type macrocyclic component composed of two glycerols and two long saturated isoprenoid alkyl chains possessing one or two polar headgroups derived from the D-galactofuranosyl moiety and/or phosphate at the terminal ends of the lipid core [101] (*Fig. 7*). Challenges for the synthesis of macrocyclic glycolipids were (1) macrocyclic ring formation, (2) stereoselective preparation of a long isoprenoid alkyl chain, and (3) regioselective introduction of sugar and/or phosphate moieties. Macrocyclic ring formation was achieved by several groups using McMurrry [103,104,105], Glaser [106,107], or olefin metathesis [108] coupling reactions in the last decade. Elegant synthesis of the lipid moiety was achieved by Kakinuma and co-workers, in which stereoselective preparation of a long isoprenoid alkyl chain and construction of a macrocyclic framework was performed.

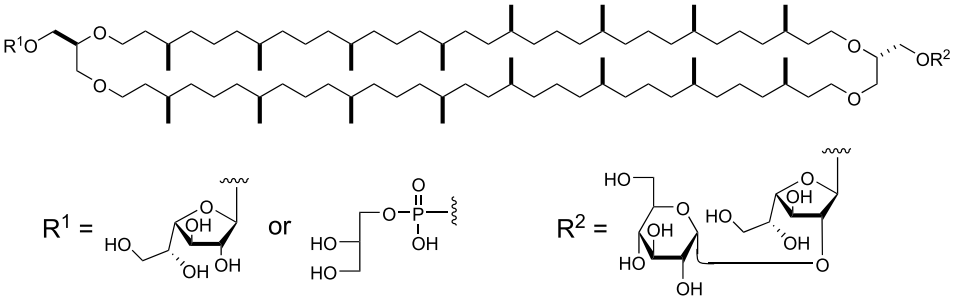

Figure 7
The chemical structure of glyceroglycolipid found in methanogenic Archaea

4 Synthesis of Lipoteichoic Acid

Lipoteichoic acid is a component of the Gram-positive bacterial cell surface. The typical chemical structure of *Staphylococcus aureus* LTA is shown in ❯ *Fig. 8* [109,110,111], which is composed of a glycolipid moiety and a hydrophilic poly(glycerol phosphate) moiety. The former moiety shows bacterial species-specific structural variation. The glycerol units in the later moiety are partially substituted with (oligo)-D-alanyl (~70%) and/or (oligo)-*N*-acetyl-α-D-glucosaminyl (~15%) residues.

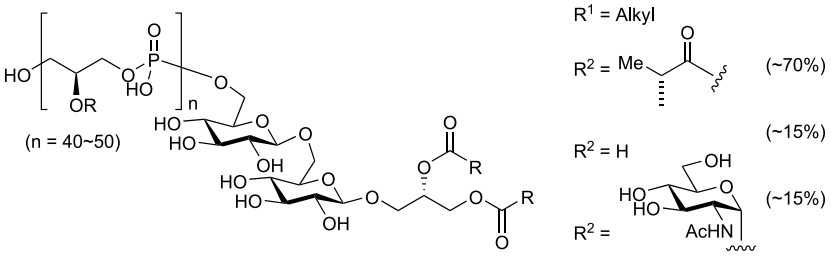

Figure 8
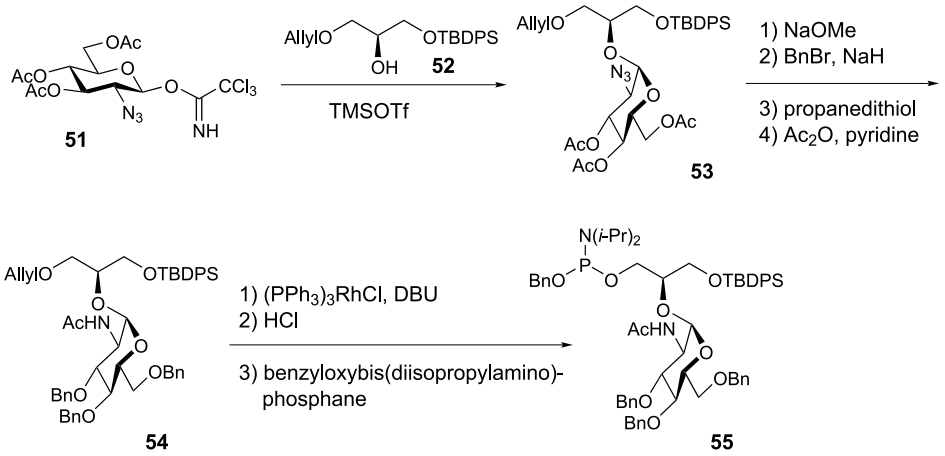
General structure of LTA from *Staphylococcus aureus*

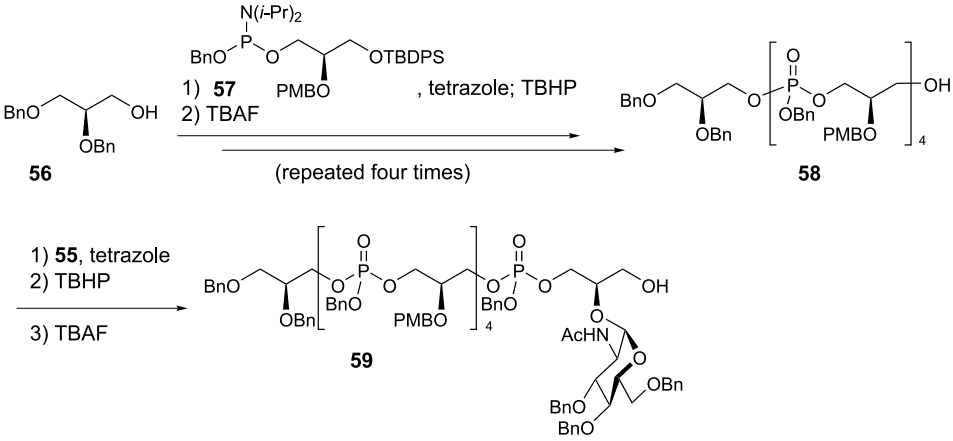
The first synthetic study regarding LTA was reported by van Boeckel's group in 1985 [112]. The syntheses of fundamental structures of *Staphylococcus pyrogenes* and *Enterococcus hirae* LTA were then reported by Kusumoto's group in 1992 [113] and 1994 [114], respectively. Recently, *Staphylococcus aureus* LTA analogue **64** was reported by Schmidt's group [115,116]. This analogue showed a similar biological activity in terms of cytokine induction from human blood leukocytes. This section deals with the synthetic work on *Staphylococcus aureus* LTA.

Target compound **64** consists of one *N*-acetyl-α-D-glucosaminyl glycerol phosphate residue, one glycerol phosphate residue, one glycolipid residue, and five D-alanyl glycerol phosphate residues in regard to the relative abundance of *N*-acetyl-α-D-glucosamine to the D-alanine residue in the natural *S. aureus* LTA. Four intermediates **55**, **56**, **57**, and **62** were prepared as key components of the *N*-acetyl-α-D-glucosaminyl glycerol phosphate, glycerol phosphate, glycolipid, and D-alanyl glycerol phosphate residues, respectively. Incorporation of alanine residues was performed at the final stage of the synthesis because of lability of alanyl ester.

N-acetyl-α-D-glucosaminyl glycerol phosphate residue **55** was prepared as shown in ❯ *Scheme 12*. Glycosylation of glycerol derivative **52** with the known azidoglycosyl donor under trimethylsilyl trifluoromethanesulfonate (TMSOTf) proceeded smoothly to give the desired α-glycoside **53** in 75% yield. After displacement of the acetyl group to the benzyl group, reduction of the azide group with propanedithiol and subsequent acetylation afforded compound **54**. The allyl group on the glycerol chain was then removed by stepwise treatment of rhodium catalyst and hydrogen chloride, and the resulting hydroxy group was phosphited to furnish phosphite **55**.



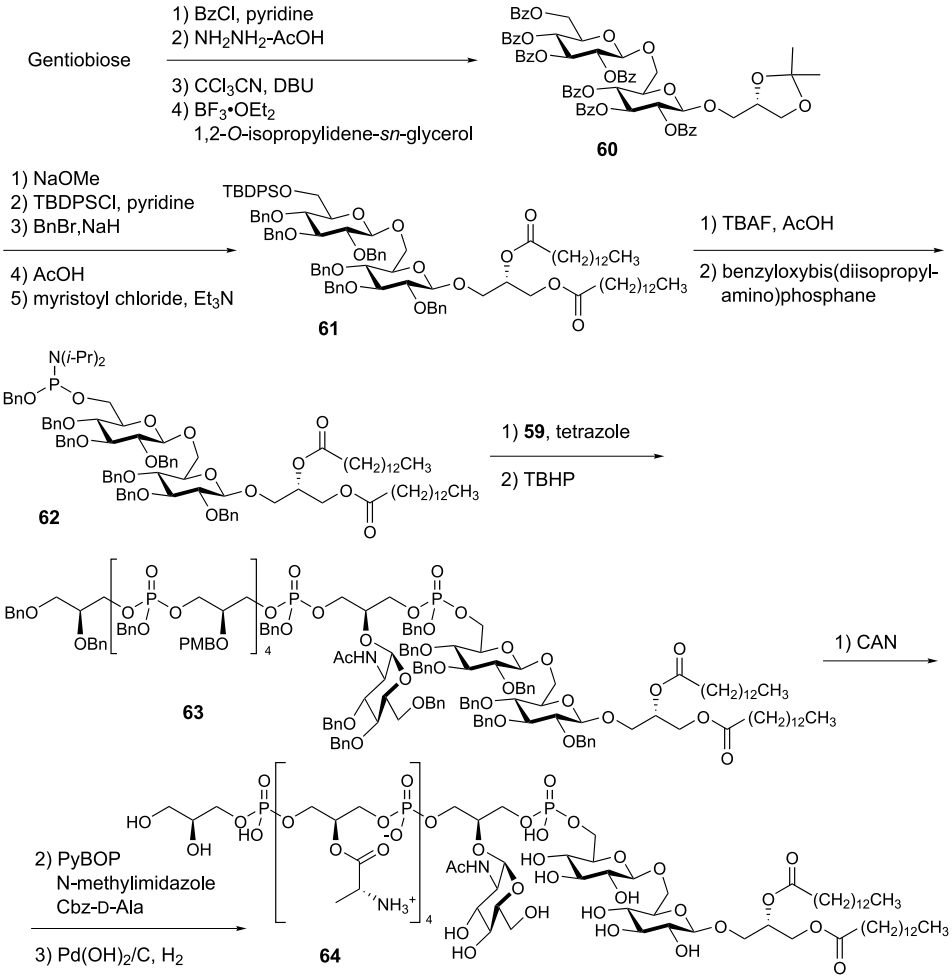
Scheme 12



Scheme 13

Hexaphosphoglycerol **59** was prepared as shown in *Scheme 13*. Condensation of **56** with **57** in the presence of tetrazole, addition of *tert*-butyl hydroperoxide, and then treatment with TBAF was performed. This reaction was repeated four times to give tri-phosphoester intermediate **58**, which was successively reacted with **55**. Oxidation and desilylation of the resultant complex furnished the desired intermediate **59**.

Synthesis of glycolipid **62** was initiated from commercially available gentiobiose (*Scheme 14*). Gentiobiose was fully benzoylated under standard conditions and treated with hydradine-acetic acid. The resulting 1-hydroxy group was reacted with trichloroacetonitrile under DBU, which was then condensed with 1,2-*O*-isopropylidene-*sn*-glycerol in the presence of a catalytic amount of boron trifluoride ether complex to give glycoside **61**. After removal of the benzoyl group, the primary hydroxy group was selectively reacted with TBDP-



Scheme 14

SCl and the remaining hydroxyl group was benzylated. Acidic cleavage of the isopropylidene group and then condensation of the resulting hydroxy group with myristoryl chloride furnished compound **61**. Desilylation of **61** with TBAF followed by the same phosphitylation gave the desired glycolipid **62**. Reaction of **62** with **59** in the presence of tetrazole and then addition of *tert*-butyl hydroperoxide (TBHP) afforded compound **63** in 75% yield. Treatment of **63** with ceric(IV) ammonium nitrate (CAN) resulted in four glycerol hydroxy groups, which were then coupled with benzyloxycarbonyl (Cbz) protected D-alanine residue in the presence of benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP) to afford the fully protected LTA analogue. Target molecule **64** was generated by hydrogenolysis of the resultant complex with Pearlman's catalyst.

5 Synthesis of Mycoloyl Arabinan

Mycobacterium bovis Bacillus Calmette–Guérin (BCG) was established for the vaccine against tuberculosis. The BCG cell wall skeleton (BCG-CWS) contains a very complex and polymeric glycoconjugate, composed of mycolated arabinogalactan linked to peptidoglycan (PG) through linker disaccharide (β-Rhap-(1-3)-α-GlcNAc) (*Fig. 9*) [117]. BCG-CWS is related to the innate immunity [118,119]. It was suggested that it activates macrophages via Toll-like receptors [120,121,122]. However, it is not obvious which structures are responsible to the activation due to the inherent complexity of BCG-CWS. Recently, synthesis of a non-reducing terminal structure of BCG-CWS consisting of pentaarabinofuranose and mycolate was achieved by Ito's group [123], and the activity was evaluated extensively. This section deals with their work.

The non-reducing terminal structure of BCG-CWS contains both α- and β-arabinofuranoses. To construct the structure [124,125,126,127,128], the methodology for both α- and β-con-

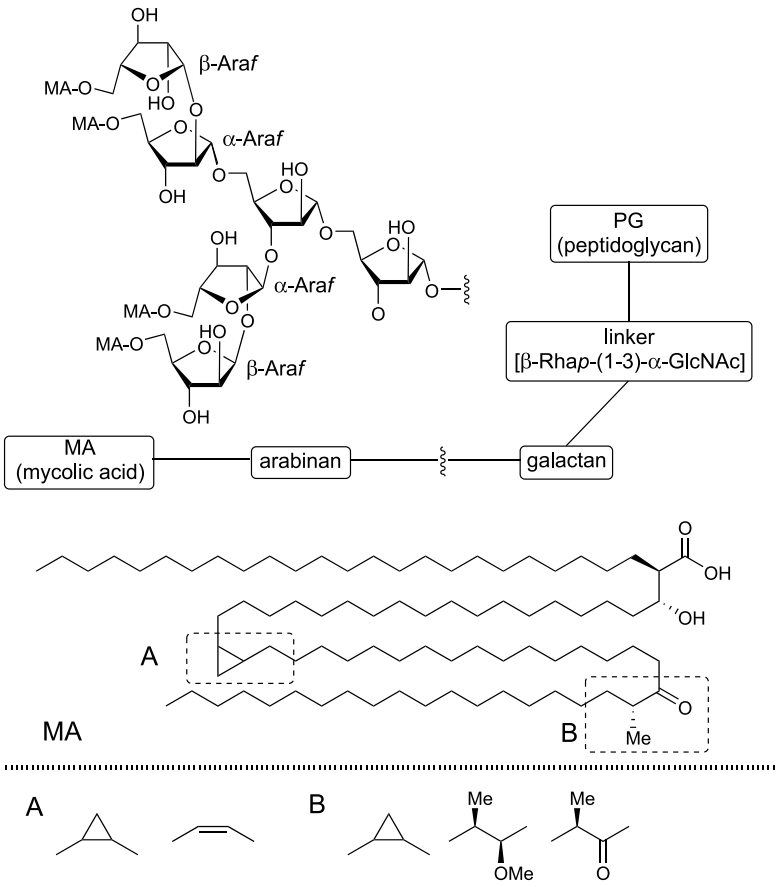


Figure 9
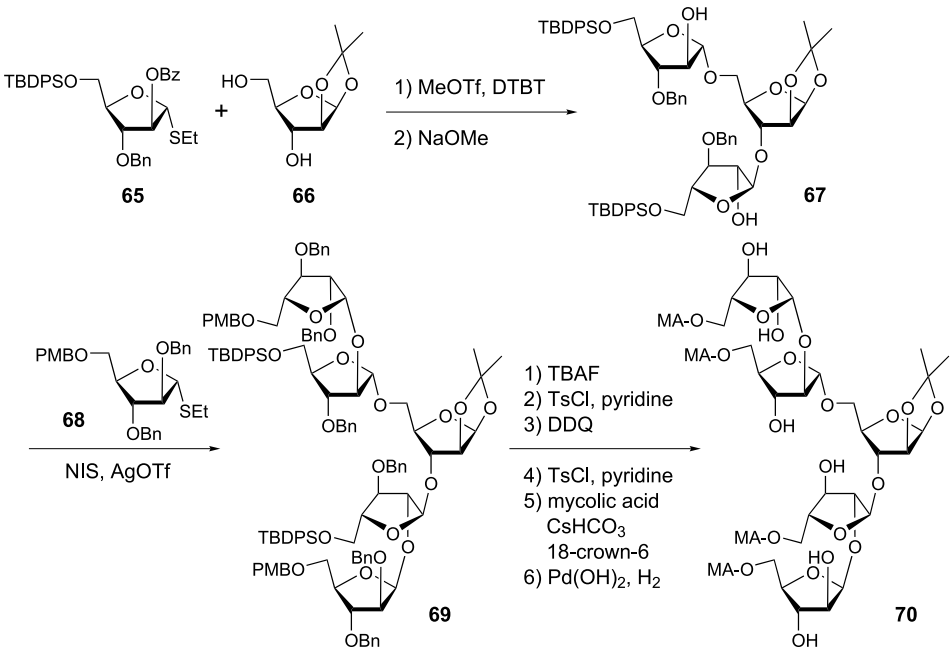
BCG-CWS structure and synthetic target, terminal pentaarabino mycolate



Scheme 15

figurated arabinofuranoside was required. However, the basic method for the stereoselective synthesis of the furanosidic linkage had not matured, compared with that of the pyranosidic linkage. In addition, the construction of β-configurated arabinofuranoside was a challenging issue because of the 1,2-*cis* orientation [129].

Synthesis of mycolated pentafuranoside **70** was performed as shown in *Scheme 15*. Glycosylation of **66** [130] with thioglycoside **65** [131] under conditions using methyl trifluoromethanesulfonate and 2,6-di-*tert*-butyl-4-methylpyridine (DTBMP) and subsequent deacetylation gave trisaccharide **67**. The resulting hydroxy groups in **67** were then glycosylated with thioglycoside **68**, which was the optimized substrate for α-linked glycoside, to give the desired pentaarabinoside **69** in 57% isolated yield, together with 35% yield of a stereoisomeric mixture. The mycolate moieties were efficiently introduced via S_N2-type alkylative esterification with tosylate as the eliminating group. After deprotection of TBDPS and PMB groups and subsequent tosylation, the resulting tosylated pentaarabinoside was treated with mycolic acid (MA) in the presence of cesium hydrogencarbonate and 18-crown-6 ether. Finally, the mycolated pentaarabinoside **70** was prepared by removing the benzyl protecting groups with $Pd(OH)_2$ and H_2.

6 Synthesis of Re-Type Lipopolysaccharide (Re-LPS)

LPS is located in the outer membrane of Gram-negative bacteria and composed of *O*-antigen polysaccharide, core polysaccharide, and lipid A. It was found that lipid A is the key compo-

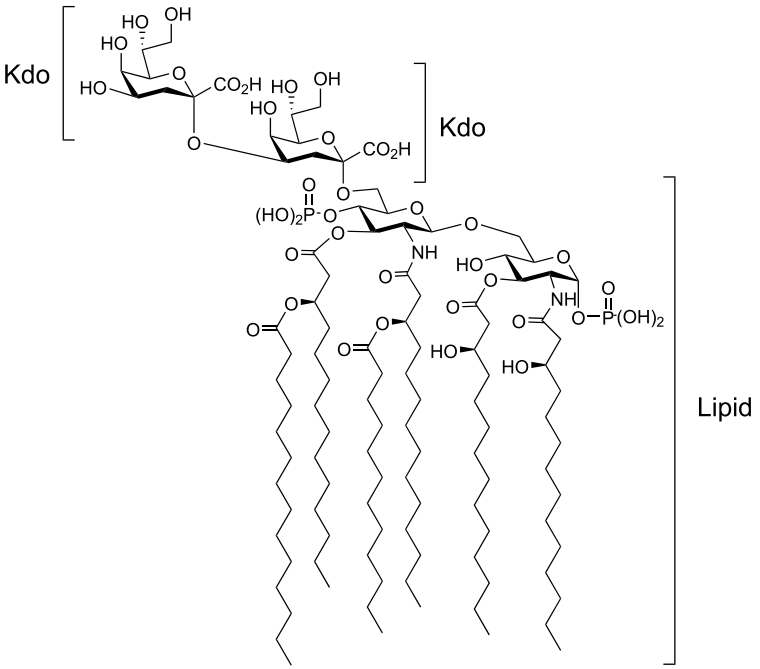


Figure 10
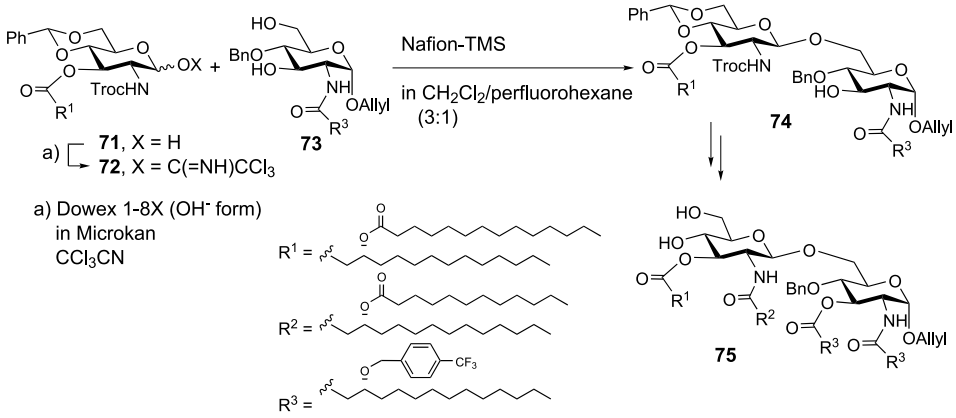
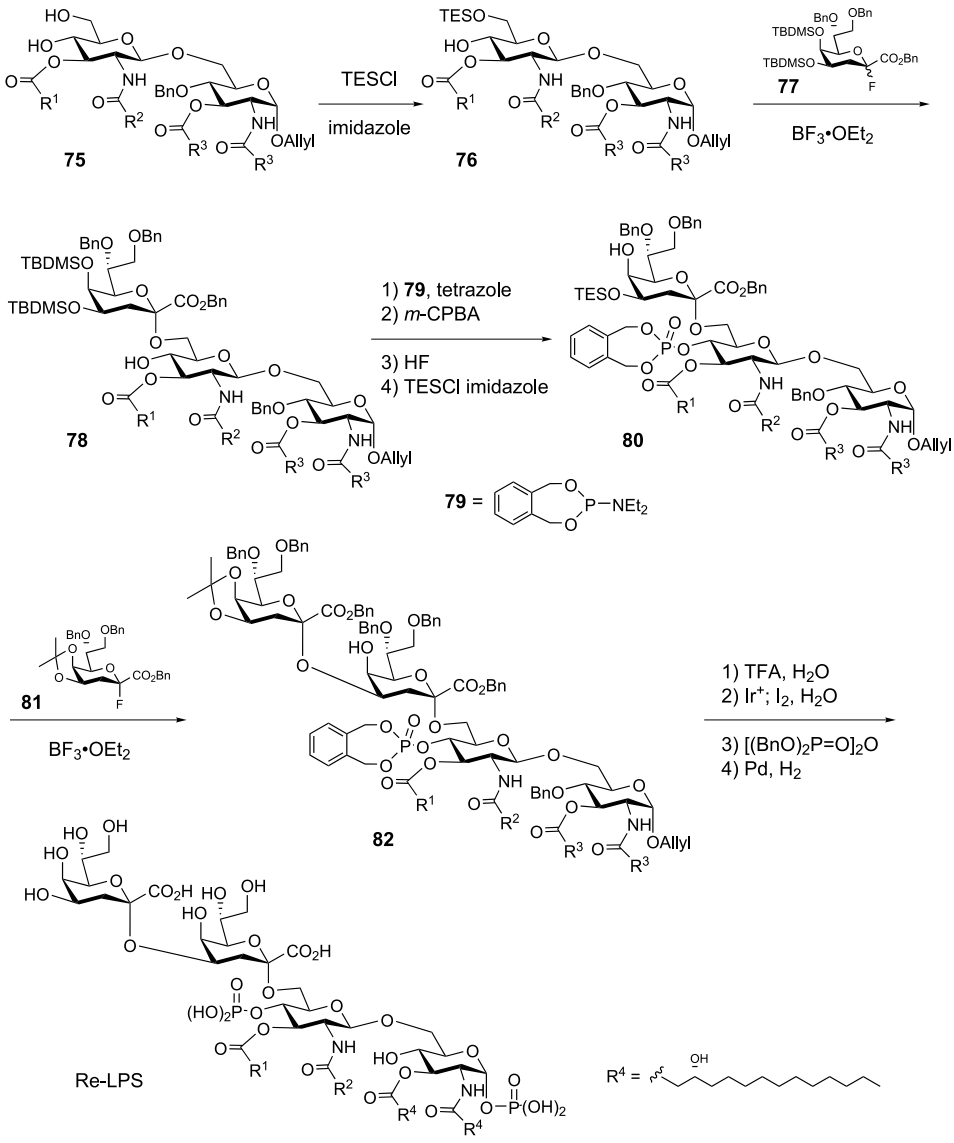
Structure of Re-type LPS

nent for the endotoxic activity of LPS [132]. Among LPS, Re-type LPS from the *Escherichia coli* Re mutant strain is known as the smallest LPS. The structure of Re-LPS is composed of lipid A and two units of 3-deoxy-D-*manno*-2-octuronic acid (Kdo) (*Fig. 10*) [133]. The structure contains highly acid-labile glycosyl phosphate and base-labile ester functional



Scheme 16

groups. For these reasons, although partial syntheses of Re-LPS had been reported [134,135, 136], the first total synthesis of Re-LPS was achieved by Kusumoto et al. in 2001 [137]. An acylated disaccharide **75** was efficiently prepared using polymer-supported reagents. Formation of glycosyl imidate **72** was carried out with Dowex 1-8X (OH^- form) as a polymer-supported base, and glycosylation of acceptor **73** with the imidate **72** was carried out using



Scheme 17

Nafion-TMS as a Lewis acid [138,139,140]. The work-up in both reactions was very easy compared with conventional methods using inorganic or organic bases because of the removal of resin from the reaction mixture (*Scheme 16*). The desired β(1-6)-glycoside **74** was thus prepared in 73% yield. Disaccharide **75** was then synthesized via 3-*O*-acylation, removal of the Troc group, *N*-acylation, and debenzylidenation.

Synthesis of Re-type LPS was then started with disaccharide **75** (*Scheme 17*). The key step in the synthesis was an efficient and stereoselective glycosylation with Kdo residue. The glycosylation was accomplished using TBDMS-protected fluoride **77** as a donor and TES ether **76** as an acceptor in the presence of BF_3Et_2O [141], affording the desired α(2-6)-glycoside in 89% yield with complete regio- and stereoselectivity. The remaining hydroxy group was phosphorylated, and subjected to desilylation of TBDMS and subsequent selective silylation to afford TES trisaccharide **80**. A second glycosylation proceeded successfully with isopropylidene-protected fluoride **81** to furnish the desired α(2-4)-glycoside **82** in 75% yield with complete regio- and stereoselectivity. In contrast, using TBDMS-protected fluoride **77** gave a low yield of **82** (26%), probably due to the steric repulsion between both substrates. After deprotection of isopropylidene and allyl groups, the anomeric hydroxy group was selectively phosphorylated. Finally, the protected precursor **82** was then subjected to hydrogenation with Pd black to afford Re-LPS. Pure Re-LPS was obtained by liquid-liquid partition column chromatography using a two-layered solvent system (*n*-BuOH/THF/H_2O/MeOH = 16/7/1/20) on Sephadex LH-20 gel.

7 Synthesis of Glycosylphosphatidylinositol (GPI)

Glycosylphosphatidylinositols are naturally occurring glycophospholipids on a cell surface. Full structural assignment was reported by Ferguson et al. in 1988 [142,143]. The core structure was composed of a carbohydrate residue with an ethanolamine side chain, inositol residue, and a phosphoglycerolipid residue (*Fig. 11*). The carbohydrate residue, ethanolamine side chain or lipid moiety is species specific [144,145,146,147,148], and depends on species and

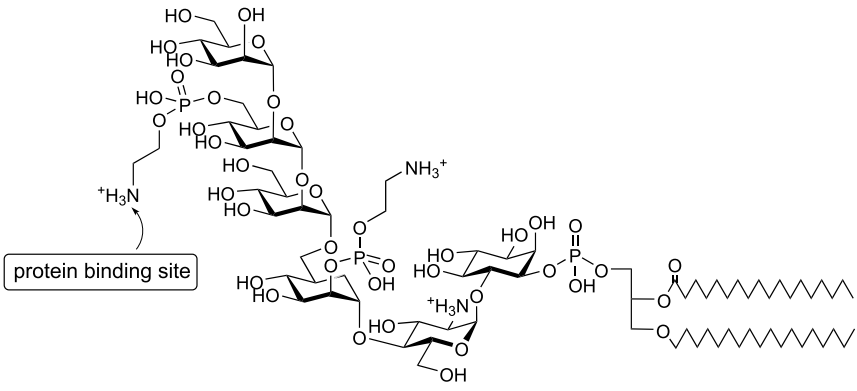


Figure 11
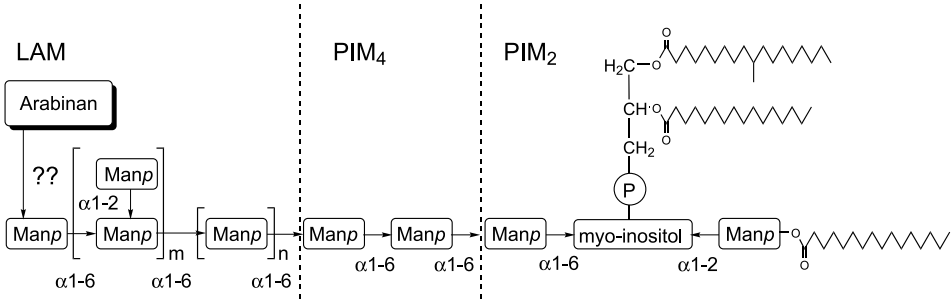
Typical structure of GPI anchor of rat brain Thy-1

on cell-type. Total synthesis of GPI anchors was started in the early 1990s and successfully carried out for a ceramide containing GPI anchors of yeast [149,150] and for acylglycerol containing GPI anchors of *Trypanosoma brucei* [151,152], of rat brain Thy-1 [153,154], of *Plasmodium falciparum* [155], and of *Mycobacterium tuberculosis* [156,157,158,159,160,161,162,163,164]. This section deals with recent work by Seeberger et al. on the total synthesis of phosphatidylinositol mannoside (PIM).

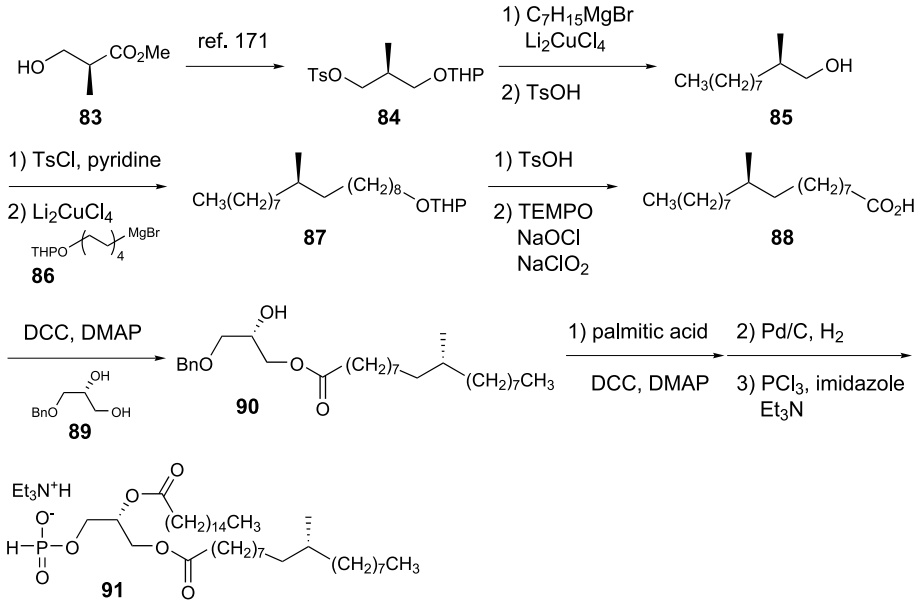
PIM is included in the fraction of lipoarabinomannan (LAM), which is the major component of the mycobacterial envelope accompanied with mycoloyl arabinogalactan-peptidoglycan complex. The structures of PIMs and LAMs are shown in ❯ *Fig. 12* [165,166]. PIMs are terminal components of LAMs, which consist of diacylglycerphosphorylinositol residue, acyl mannosyl residue, and oligomannoside residue. The diacylglycerol moiety contains the carboxylic acid named tuberculostearic acid (TBSA) [167,168]. Although LAMs have been shown to exert profound physiological effects and emerge to modulate the host immune response [169,170], PIMs, particularly PIM_2 and PIM_6, that are predominantly found in the cell wall, show an immune response and act as agonists of Toll-like receptor 2 (TLR2) [165,166].



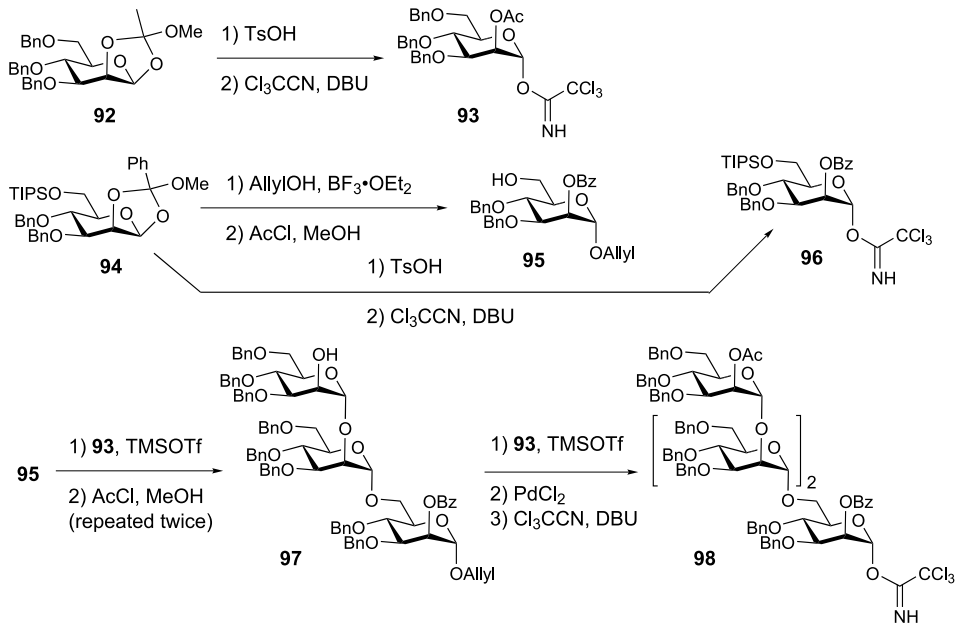
❯ Figure 12
Structure of LAM (typical lipid composition shown)

The glycerophospholipid moiety was prepared as shown in ❯ *Scheme 18*. The synthesis was started with (*S*)-3-hydroxy-2-methylpropionate **83**, a commercially available chiral building block, which was converted to tosylate **84** according to the literature [171]. Cross-coupling of tosylate **84** and heptylmagnesium bromide in the presence of a catalytic amount of Li_2CuCl_4 followed by treatment with toluenesulfonic acid gave alcohol **85**. Alcohol **85** was then tosylated and was subjected to the second Cu-catalyzed alkylation. After removal of the THP group in **87**, the resultant complex was converted to the desired tuberculostearic acid **88** by TEMPO-catalyzed oxidation. Regioselective acylation of glycerol **89** with acid **88** using DCC and DMAP gave the monoacylated compound **90** in 75% yield. The remaining hydroxy group was acylated with palmitic acid using DCC, and the benzyl protecting group was removed by hydrogenolysis. H-Phosphonate **91** was obtained by the treatment with phosphoryl trichloride and imidazole.

Syntheses of mannosyl and oligomannosyl moieties are shown in ❯ *Scheme 19*. Mannosyl imidates **93** and **96** were prepared from the appropriate orthoester **92** and **94** via hydrolysis with TsOH and then treatment with CCl_3CN and DBU, respectively. Allyl mannoside **95** was also prepared from orthoester **94** via glycosylation with allyl alcohol and then desilylation of



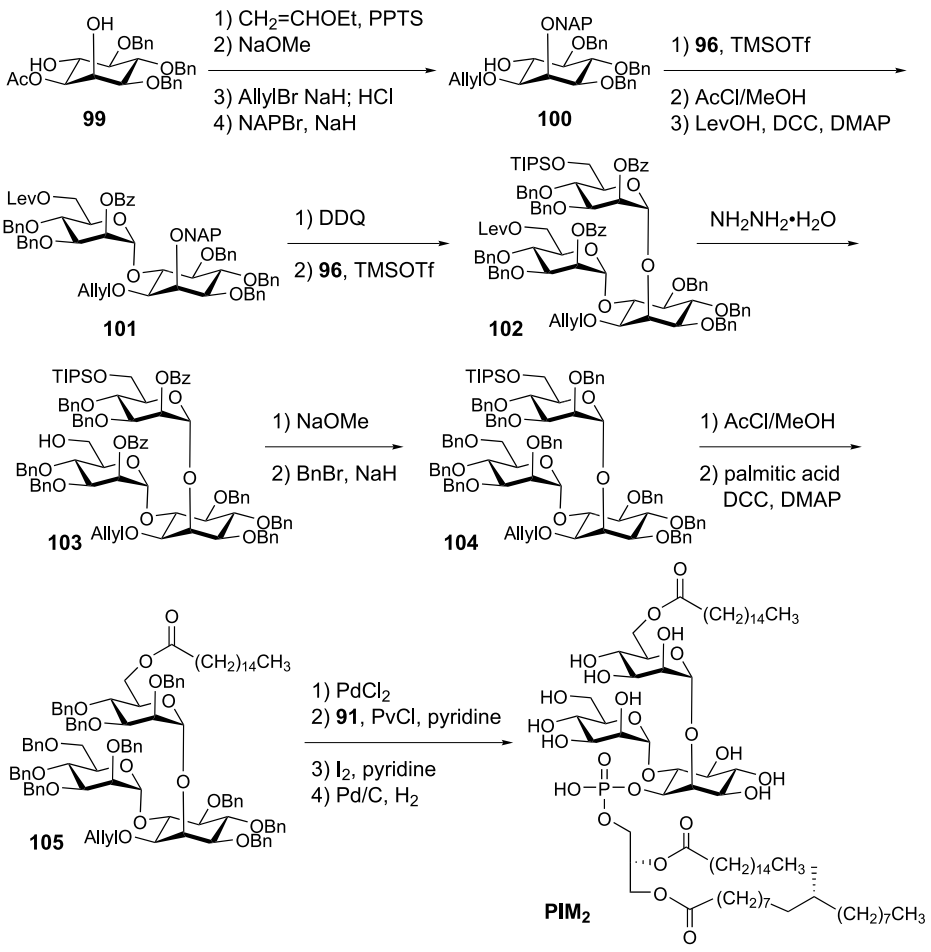
Scheme 18



Scheme 19

the TIPS group. Trimannoside **97** was derived from imidate **93** and allyl mannoside **95** via sequential glycosylation and deprotection of the acetyl group. Tetramannosyl imidate **98** was prepared from **97** by the further glycosylation with imidate **93**, removal of the anomeric allyl group, and treatment with CCl_3CN and DBU.

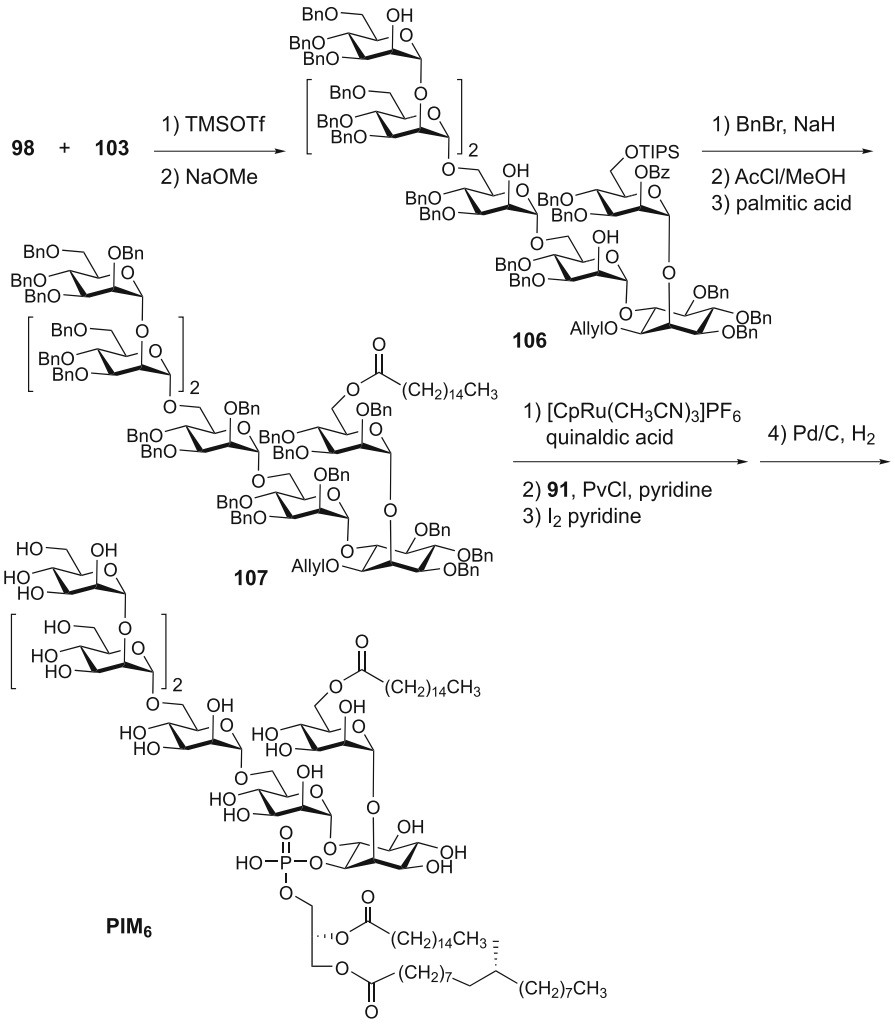
Synthesis of PIM_2 is illustrated in *Scheme 20*. The enantio pure inositol derivative **99** prepared from methyl α-D-glucoside [172] was led to the compound **100** via temporal masking with an ethoxyethyl group at the 2- and 6-positions, deacetylation and subsequent allylation at the 1-position, and introduction of a naphthyl (NAP) group at the 2-position. After glycosylation of **100** with imidate **96**, the triisopropylsilyl (TIPS) group was converted to the levulinoyl (Lev) group. The NAP group of mannosyl inositol **101** was removed by treatment with DDQ, and the resulting hydroxy group was glycosylated with imidate **96** again. Removal of the Lev group gave a common intermediate **103** for the syntheses of PIM_2 and PIM_6. After removal of



Scheme 20

benzoyl groups, the resulting hydroxy groups were benzylated. Desilylation and subsequent acylation with palmitic acid afforded palmitate **105**. The desired PIM_2 was obtained via deallylation, condensation with H-phosphonate **91**, oxidation of phosphonate to phosphate, and hydrogenolysis. At this stage, removal of the allyl group in inositol was found to be a problematic reaction because of a simultaneously occurring Wacker-type oxidation. In addition, an iridium complex was also ineffective in this reaction. This problem was solved using a cationic Ru^{II} complex [173] as described in the synthesis of PIM_6.

PIM_6 was synthesized as shown in ❯ *Scheme 21*. Glycosylation of dimannosyl inositol **103** with tetramannosyl imidate **98** was performed using TMSOTf, followed by deacetylation to



Scheme 21

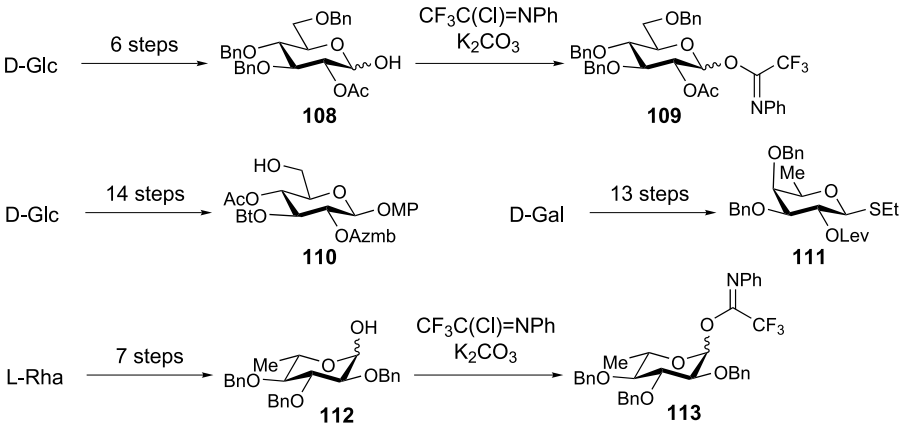
give hexamannosyl inositol **106**. After benzylation of hydroxy groups, the TIPS group was removed. The resulting hydroxy group was acylated using palmitic acid and DCC. Removal of the allyl group in compound **107** was then evaluated. Among many explorations, it was found that a stoichiometric cationic $CpRu^{II}$ was effective for the deallylation, while the use of cationic Pd^{II} or Ir^{I} was ineffective. After removal of the allyl group, the resulting hydroxy was phosphorylated with H-phosphonate **91**. Finally, PIM_6 was accomplished by hydrogenolysis of the obtained phosphate.

8 Synthesis of Other Glycolipids

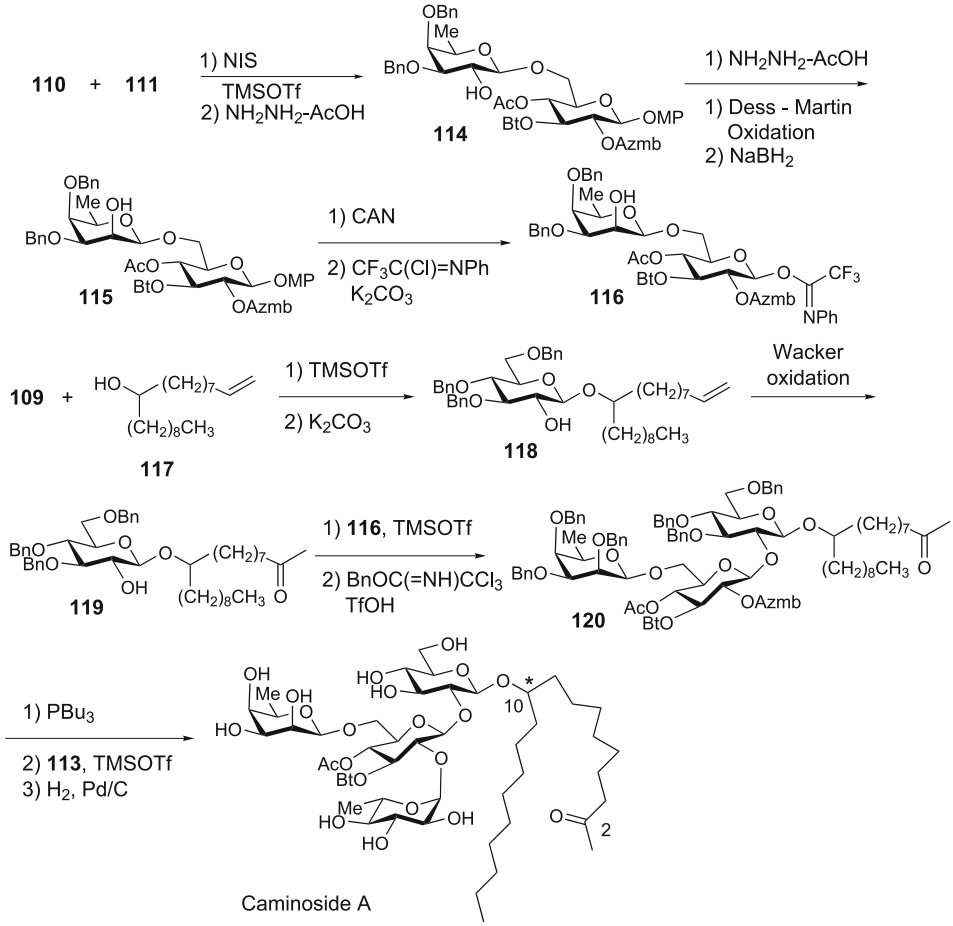
8.1 Total Synthesis of Caminoside A

Caminoside A is a novel antimicrobial glycolipid containing a tetrasaccharide part, which was isolated from marine sponge *Caminus sphaeroconia*, and was reported to have an inhibitory activity against a bacterial type III secretory system [174]. The tetrasaccharide part is composed of two D-glucose, 6-deoxy-D-talose, and L-quinovose with a 1,2-*cis*-β-mannopyranose-type linkage of 6-deoxy-D-talose. That may be the most difficult linkage to construct stereoselectively. Other structural features are (i) the center glucose residue is fully substituted, (ii) 6-deoxy-D-talose and L-quinovose are rare in nature, and (iii) methyl ketone lipid aglycon, in which the stereochemistry at the 10-position was recently determined [175], is unprecedented in marine sponge metabolites.

The first total synthesis of Caminoside A was recently achieved by Yu's group [176]. In their synthetic strategy, an indirect approach for the construction of the 1,2-*cis*-β-mannopyranose-type linkage of 6-deoxy-D-talose was performed: β-selective glycosylation with 1-thiofucopyranoside **111** introduced 2-*O*-Lev as a directing group followed by an inversion of the 2-OH configuration affords the desired 6-deoxy-1,2-*cis*-β-talopyranosidic linkage. Monosaccharide building blocks **109**, **110**, **111**, and **113** were prepared (*Scheme 22*).



Scheme 22



Scheme 23

As shown in *Scheme 23*, glycosylation of **110** with **111** using NIS/TMSOTf [177,178] afforded the β-disaccharide **114** in 76% yield. After selective removal of the 2-*O*-Lev group in the presence of Ac, Bt, and Azmb, the resulting equatorial 2-OH group was converted to the axial one via oxidation, followed by selective reduction. No equatorial isomer was obtained in the reduction step. The oxidative cleavage of the anomeric MP group followed by the treatment with trifluoroacetimidoyl chloride gave the disaccharide trifluoroimidate **116**. The axial 2-OH group was not reacted due to the steric hindrance. Glycosylation of 1-nonadecen-10-ol (**117**) with 2-*O*-Ac glucosyl donor **109** was carried out using TMSOTf [179] and subsequent removal of the 2-*O*-Ac group provided the desired glycoside **118**. A terminal C=C double bond in the lipid moiety was converted into a methyl ketone functional group by Wacker oxidation [180,181] at this stage. Glycosylation of **119** with the disaccharide trifluoroacetimide **116** was performed under conditions similar to those for **118**. The remaining free axial

2-OH group of the talose moiety was then protected with a benzyl group by the reaction with benzyl trichloroimidate in the presence of a catalytic amount of TfOH, to prevent an unexpected glycosylation at the next step. After selective removal of the 2-*O*-Azmb group of **120** with tributylphosphine, the resulting 2-OH group was glycosylated with trifluoroimidate **113** under conditions similar to those for **118** and **120**. The obtained fully protected caminoside A derivative was then deprotected by hydrogenolysis in the presence of Pd/C to accomplish the synthesis of caminoside A.

8.2 Total Synthesis of Woodrosin I

Resin glycosides obtained from plants belonging to the morning glory family (*Convolvulaceae*) are composed of complex oligosaccharides and (11*S*)-hydroxyhexadecanoic acid (jalapinolic acid) as a common aglycon in this series. This aglycon lipid moiety frequently forms a macrolactone ring spanning two or more sugar units of the backbone [182,183,184,185,186,187,188,189,190,191,192]. This intricate structure stimulated the interest of synthetic chemists, and many works have been devoted to it [193,194,195,196,197,198,199,200,201]. Among them, three independent approaches for tricolorin A [196,197,198,199,200,201] and for the congener tricolorin G [200,201] are focused on here. Their structures are illustrated in ❯ *Fig. 13*. The first synthetic study of tricolorin A was reported by Heathcock'group in 1997 [196,197], where Yonemitsu protocol lactonization was utilized as a key macrocyclization.

Fürstner's group reported syntheses of tricolorin A and G [200,201] based on macrocyclization by ring-closing metathesis (RCM), affording macrocycles in high yields. In this section, total synthesis of woodrosin I [202], which may possess the most intricate structure in this series, reported by Fürstner's group is described [203,204,205].

Woodrosin I is composed of four glucose, one rhamnose, and lipid moieties. The lipid consists of a 27-membered macrolide ring spanning four glucose units. The convergent synthesis of woodrosin I was performed via intermediates **134** and **135**, and the macrocyclization was achieved by RCM using Grubbs carbene ruthenium complex or phenylindenylidene ruthe-

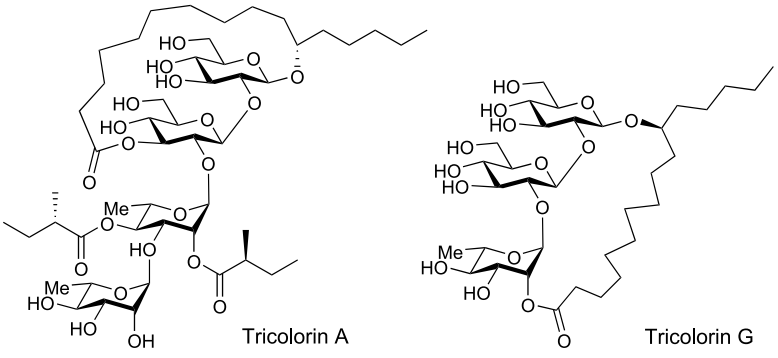


Figure 13
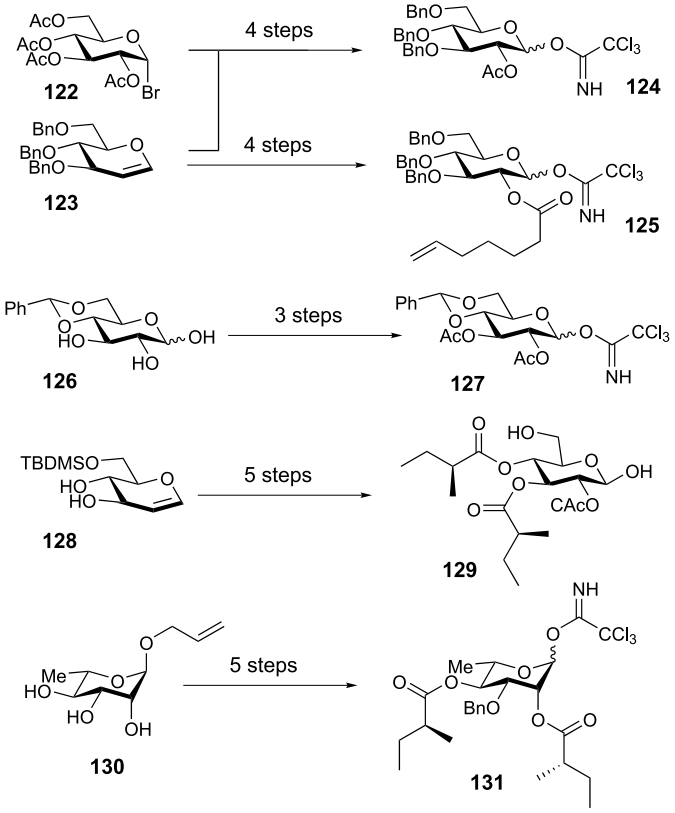
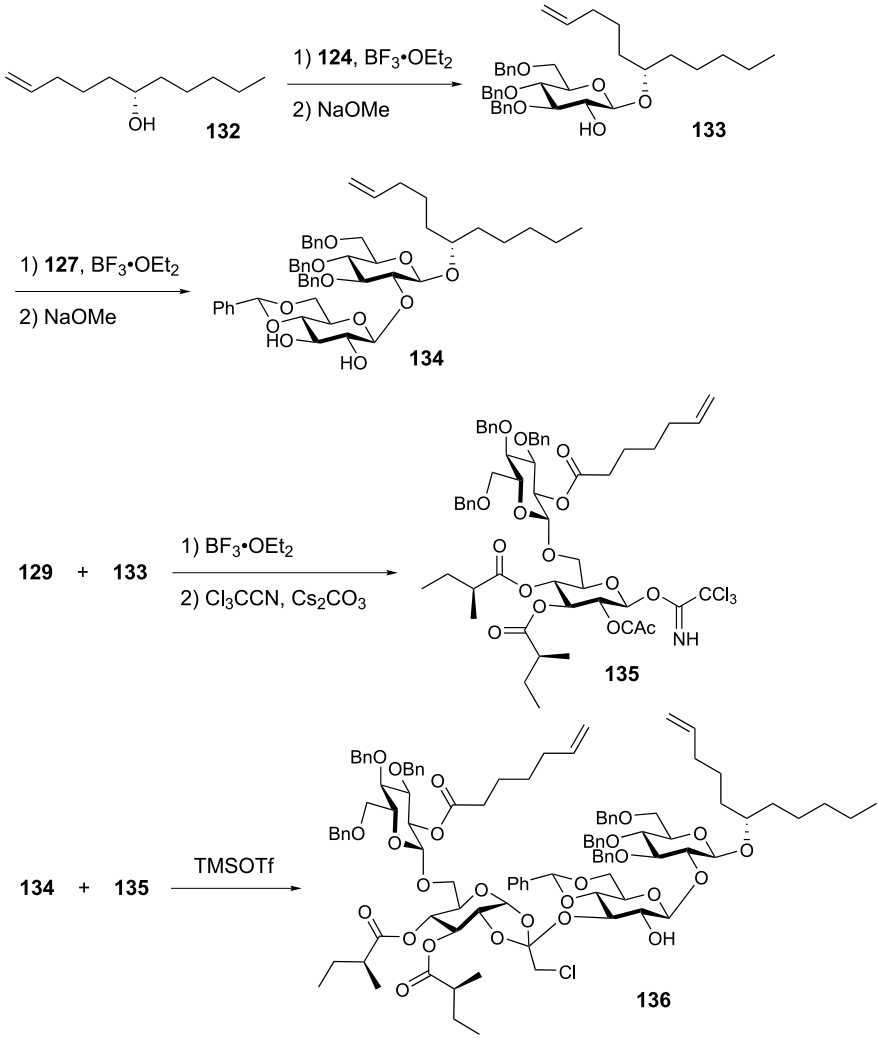
Chemical structures of tricolorin A and G



Scheme 24

nium complex. Glucose and rhamnose building blocks **124**, **125**, **127**, **129**, and **131** were derived from appropriate monosaccharide components as shown in *Scheme 24*. The reducing terminal glucosyl donor **124** was prepared from glycosyl bromide **122** or commercially available benzyl glucal **123** in four steps. Non-reducing terminal glucosyl donor **125** was also prepared from benzyl glucal **123**. A second glucosyl donor **127** was derived from 4,6-benzylidene acetal **126** [206] in three steps. A third glucose moiety **129** was prepared from TBDMS-protected glucal **128** [207] in five steps. Rhamnosyl donor **131** was derived from allyl L-rhamnoside **130** [208].

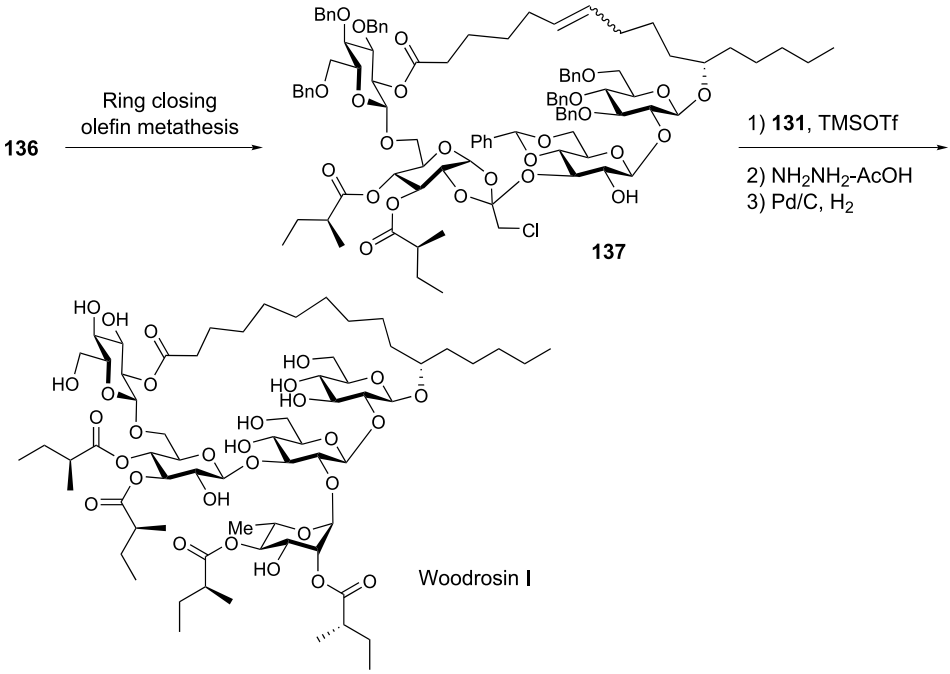
As shown in *Scheme 25*, the glycosylation of alcohol **132**, which was prepared by an enantioselective condensation of 5-hexanal and dipentylzinc in the presence of $Ti[O(i\text{-}Pr)]_4$ and chiral bis-trifluoromethanesulfonamide [209], with glucosyl donor **124** followed by treatment of NaOMe gave glycoside **133**. The resultant 2-OH group was then glycosylated with 4,6-benzylidene donor **127** under similar conditions to those described above. Removal of the acetyl group at the 2′- and 3′-positions was then carried out to afford right-hand building block **134**. Glycosylation of acceptor **133** with donor **129** proceeded regioselectively at the 6-position of the acceptor to form the corresponding glycoside, which was then treated with trichloroace-



Scheme 25

tonitrile and cesium carbonate to furnish left-hand building block **135**. Then, the glycosylation of diol **134** with **135** in the presence of TMSOTf was performed, where the coupling reaction proceeded regioselectively at the more reactive 3′-position without unexpected formation of orthoester **136**, although the neighboring effect of the chloroacetyl group may engage β-glycoside in the presence of a strong Lewis acid catalyst. In addition, rhamnosylation to the 2′-position of orthoester **131** did not occur because of steric hindrance exerted by the orthoester moiety.

The formation of the macrocycle (*Scheme 26*), which had been a serious problem, was achieved by ring-closing olefin metathesis (RCM). RCM of orthoester **136** was performed



Scheme 26

with Grubbs carbene ruthenium complex [210,211] or phenylindenylidene ruthenium complex [212] as a catalyst to afford the corresponding macrocycle **137** in high yield with an *E*:*Z* mixture (*E*:*Z* = 9:1). The rearrangement to β-glycoside and the introduction of the rhamnose moiety to the 2′-position of **137** were effectively accomplished by an "inverse glycosylation procedure" developed by Schmidt [213], where glycosyl donor **131** was added slowly in a premixed solution of acceptor **137** and TMSOTf. Final deprotection was performed by treatment with hydrazinium acetate and subsequent hydrogenolysis with Pd/C to furnish the desired woodrosin I.

8.3 Total Synthesis of Cycloviracin B_1

Cycloviracin B_1 (see *Fig. 14*) [214,215], isolated from the soil microorganisms *Kibdelosporangium albatum* (R761-7) [216], is a macrocyclic glycolipid showing antiviral activity [214,215]. This compound is composed of five glucose and two acyl units with different acyl chain lengths. Two of the glucose units form the macrocyclic dilactone (macrodiolide). The constitution of the cycloviracin was elucidated by an extensive NMR study. However, several structural details, such as the absolute stereochemistry of the six chiral centers on the acyl units, were solved by the total synthesis of Fürstner's group [217,218].

The synthesis was performed according to a two-directional synthesis strategy [219] since the macrodiolide core part in the target compound has C_2-symmetry. The synthetic pathway is

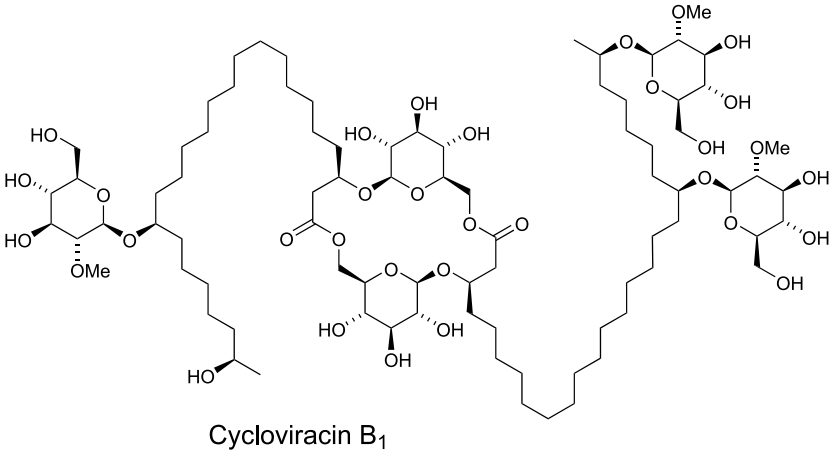


Figure 14
Structure of cycloviracin B_1

shown in *Scheme 27*, *Scheme 28* and *Scheme 29*. α-Methylation of cycloheptanone **138** and subsequent Baeyer–Villiger oxidation gave the desired lactone **139**, which was then subjected to enzymatic hydrolysis using an esterase from porcine liver, resulting in carboxylic acid **140** in a high enantiopurity (95% ee). Compound **140** was activated with carbonyl diimidazole and reacted with magnesium carboxylate **141** [220,221] to afford β-keto ester **142**. Stereoselective hydrogenation of the ketone at the β-position of **142** was carried out in the presence of catalytic [(*R*)-BINAPRuCl$_2$]$_2$•Et$_3$N [222,223] to afford diol **143** in quantitative yield with a high diastereoselectivity (de = 99%). Glycosylation of diol **143** with glycosyl imidate donor **144** [224] in the presence of TMSOTf gave glycoside **145** with a complete β-selectivity. Subsequent reduction of ester groups in **145** with $LiAlH_4$ gave the corresponding triol, whose primary alcohol then reacted with *o*-nitrophenylselenocyanate in the presence of Bu_3P. The resulting selenide was oxidized with aqueous H_2O_2, and was converted to the corresponding alkene **146** with spontaneous elimination of selenide [225,226]. Methylation of the remaining secondary hydroxy groups followed by ozonolysis of the alkene moiety in **146** furnished aldehyde **147**, which represents a fully functional right-side component.

Macrodiolide core **156** was synthesized as shown in *Scheme 28*. Commercially available 1,6-anhydoglucose **148** was benzylated, and then subjected to acetolysis with Ac_2O and H_2SO_4. Selective deacetylation with hydrazine acetate gave acetal **149**. Glycosyl donor **150** was prepared by the treatment with trichloroacetonitrile and a catalytic amount of NaH. Claisen condensation of pentadecanolide **151** with lithio *tert*-butyl acetate gave the corresponding β-keto ester, which was subsequently hydrogenated with [(*R*)-BINAPRuCl$_2$]$_2$•Et$_3$N as described above. Silylation of the resultant primary hydroxy group with TBDPSCl afforded β-hydroxy ester **152**. Glycosylation of **152** with glycosyl imidate **150** was performed in the presence of BF_3•OEt using the β-directing effect of acetonitrile to furnish the corresponding glycoside **153** (68%, α:β = 1:5). Subsequent treatment of **153** with TFA gave carboxylic acid **154**. Macrodiolide core **156** was constructed by a template-directed cyclodimerization. Namely, cyclization precursor **154** was reacted with 2-chloro-1,3-dimethylimidazolium chlo-

ride as a dehydrating agent in the presence of a K^+ cation to furnish macrodiolide **156** in 71% isolated yield. In this reaction, it was suggested that the K^+ cation worked as a promotor for preorganization of the cyclization precursor **154** and resulted in chelate intermediate **155**. Desymmetrization of terminal functional groups on lateral chains was accomplished by desilylation and monosilylation of hydroxy groups. Mitsunobu reaction of the remaining terminal hydroxy group and subsequent oxidation gave sulfone compound **157**.

Introduction of the right segment **147** into **157** was performed by Julia–Kocienski olefination [227], and the resultant alkene was hydrogenated. After removal of the TBDPS group, the resulting hydroxy group was oxidized by pyridinium chlorochromate (PCC) to afford aldehyde **158**. Left lateral chains of cycloviracin was constructed by condensation of organozinc in the presence of Ti[O(*i*-Pr)]$_4$ and (*S*,*S*)-ditriflate. Compound **159** was then glycosylated with **160**, which was subjected to final deprotection by hydrogenolysis, affording the desired cycloviracin B_1.

Abstract

Gangliosides, abundant in the nervous system, are known to play crucial modulatory roles in cellular recognition, interaction, adhesion, and signal transduction, particularly during early developmental stages. The expression of gangliosides in the nervous system is developmentally regulated and is closely related to the differentiation state of the cell. Ganglioside biosynthesis occurs in intracellular organelles, from which gangliosides are transported to the plasma membrane. During brain development, the ganglioside composition of the nervous system undergoes remarkable changes and is strictly regulated by the activities of glycosyltransferases, which can occur at different levels of control, including glycosyltransferase gene transcription and posttranslational modification. Genes for glycosyltransferase involved in ganglioside biosynthesis have been cloned and classified into families of glycosyltransferases based on their amino acid sequence similarities. The donor and acceptor substrate specificities are determined by enzymatic analysis of the glycosyltransferase gene products. Cell-type specific regulation of these genes has also been studied. Gangliosides are degraded by lysosomal exoglycosidases. The action of these enzymes occurs frequently in cooperation with activator proteins. Several human diseases are caused by defects of degradative enzymes, resulting in massive accumulation of certain glycolipids, including gangliosides in the lysosomal compartment and other organelles in the brain and visceral organs. Some of the rep-

resentative lysosomal storage diseases (LSDs) caused by the accumulation of lipids in late endosomes and lysosomes will be discussed.

Keywords

Glycosphingolipid; Ganglioside; Biosynthesis; Catabolism; Nervous system; Endoplasmic reticulum; Golgi; Glycosyltransferase; Glycosidase; Lipid-storage disorder

Abbreviations

GSL	glycosphingolipid
GEM	GSL-enriched microdomain
ER	endoplasmic reticulum
S1P	sphingosine-1-phosphate
GT	glycosyltransferase
ST	sialyltransferase
Gal-T	galactosyltransferase
GalNAc-T	*N*-acetylgalactosaminyltransferase
UDP-	uridine-diphospho-
SAP	sphingolipid activator protein
Hex	hexosaminidase
LSD	lysosomal storage disease
CNS	central peripheral nervous system
PNS	peripheral nervous system

Nomenclature for gangliosides and related glycosphingolipids based on that of Svennerholm [1] in accordance with the IUPAC recommendations [2].

1 Introduction

Gangliosides, sialic acid-containing glycosphingolipids (GSLs), are diverse and highly complex molecules located primarily on plasma membranes and are particularly abundant in the central and peripheral nervous systems (CNS and PNS). Structural diversity of gangliosides is a hallmark of these molecules. About 200 gangliosides differing in carbohydrate components are known today [3,4]. The number of ganglioside molecular species increases manyfold if heterogeneity of the lipophilic components is considered. Gangliosides are known to have various biological functions depending on their ceramide and carbohydrate structures. Many studies have indicated that they play a variety of functions in cellular growth and differentiation, modulation of signal transduction, and immune reactions, as well as in several aspects of cancer metastasis and malignant transformation [5,6,7]. Gangliosides are also involved in the pathogenesis of certain immune-mediated neurological diseases because of their highly antigenic carbohydrate moieties that facilitate the production of antibodies that react with individual GSLs [3,8,9,10,11].

In the plasma membrane, GSLs are believed to segregate into microdomains that are also enriched in glycosylphosphatidylinositol-anchored proteins, sphingomyelin, and cholesterol [12]. Because of their specific localization on the plasma membrane, especially in

specialized microdomains or lipid raft structures, they are also involved in intercellular signaling [13,14,15,16,17] and in trafficking and/or sorting [18,19]. Certain biological functions of GSLs are better understood based on clustered units of GSLs, termed lipid rafts or GSL-enriched microdomains (GEMs) [17]. Although the exact functions of these clusters have not yet been fully elucidated, some of the functional roles of GSLs will be discussed based on this concept.

Ganglioside biosynthesis is catalyzed by specific glycosyltransferases (GTs) that transfer specific sugar residues from activated donor substrates, usually a sugar nucleotide, to a proper lipid or an oligosaccharide receptor. GTs are typically grouped into different families based on the type of sugar they transfer (e. g., galactosyltransferases, sialyltransferases, and so on). Over the past decade, many GT genes, including those involved in the ganglioside biosynthetic pathway (❯ *Fig. 1* and ❯ *Fig. 2*), have been cloned and classified into GT families by amino-acid-sequence similarities [20,21,22] (available at http://cazy.org/fam/acc_GT.html and http://glycob.oupjournals.org). These GTs differ in their donor- and acceptor-substrate specificities and other parameters, such as their microenvironment, local pH, and subcellular local-

ization [7,20,22,23]. This sequence-based classification is assumed to integrate both structural and mechanistic features within each family [20,21,22]. In vitro enzymatic analysis, however, indicates that multiple GTs can synthesize occasionally one linkage, and that one GT may be responsible for synthesis of multiple products [23]. Tissue-specific expression of these genes has been demonstrated by hybridization using cDNA fragments. Following cloning of the ganglioside synthase genes, the promoters of the key GT genes in the ganglioside biosynthetic pathway have been analyzed [7,23]. All promoters of these GT genes are TATA-less and do not possess any known core promoter element, and little is known about how genes that lack any of the conventional core promoter elements are regulated. Although these genes are characterized as housekeeping genes, recent studies on the promoters of these GT genes indicate that their expression is subject to complex developmental and cell type-specific regulation.
Here, we will focus on the current topics of biosynthesis of GSLs, including gangliosides in the ER and Golgi apparatus. We will review the cloned GT genes involved in ganglioside biosynthesis and their transcriptional regulation. We will also describe degradation or catabolism of gangliosides and, in particular, aspects of ganglioside metabolism in lipid-storage diseases that may be involved in GSL-trafficking via detergent insoluble GEMs, lipid rafts, or caveolae.

2 Biosynthesis of Glycosphingolipids

Glycosphingolipids (GSLs) are primarily synthesized in the endoplasmic reticulum (ER) and Golgi apparatus [24,25,26] and are internalized by endocytosis [27]. The known biosynthetic pathways of GSLs and gangliosides are depicted in *Fig. 1* and *Fig. 2*, respectively.
The synthesis of GSLs commences with the synthesis of ceramides in ER membranes. At least three enzymatic reactions are known to take place in this compartment: serine palmitoyltransferase, which catalyzes the condensation of palmitoyl coenzyme A and serine for the formation of 3-ketosphinganine; (dihydro)ceramide synthase, which converts sphingoid bases as well as fatty acid coenzyme A to produce dihydroceramide; and dihydroceramide desaturase, which coverts dihydroceramides to ceramides [24,25,28]. Ceramide is the common precursor of all GSLs and sphingomyelin. Ceramide, sphingosine, and a metabolite of sphingosine, sphingosine-1-phosphate (S1P), not only serve as important building blocks of complex sphingolipids but also have emerged as a new class of lipid biomodulators of various cellular functions. These metabolites are known to function as intracellular second messengers and as ligands in extracellular space. S1P especially has numerous functions as an important extracellular mediator that binds to cell-surface S1P receptors. Recent studies have also shown that sphingolipid-metabolizing enzymes function in intracellular organelles and in extracellular space, including the outer leaflet of the plasma membrane [29].

To continue the biosynthesis of complex sphingolipids, ceramide is transferred to the Golgi apparatus with the aid of a transfer protein, CERT [30]. The transferred ceramide is converted to glucosylceramide (GlcCer), which is catalyzed by GlcCer synthase, which transfers a glucose residue from uridine-diphospho (UDP)-glucose to the 1-position of ceramide. The reaction occurs at the cytosolic leaflet of the Golgi apparatus [31]. GlcCer is then translocated to the luminal face of the Golgi membranes, presumably by multidrug transporters [32,33]. Ceramide can also be galactosylated by the action of ceramide galactosyltransferase to form galactosylceramide (GalCer), which also serves as the precursor of sulfatides and GM4 ganglioside [34]. GalCer, sulfatides, and GM4, once formed, are then transferred to the luminal Golgi [27]. Lactosylceramide (LacCer), the common precursor for many GSLs, such as lacto(neo)-series, globo-series (see *Fig. 1*), and ganglio-series GSLs, is formed by the addition of a galactose moiety from UDP-galactose to GlcCer. The reaction is catalyzed by galactosyltransferase-I that has been purified and cloned from rat brain [28,35].

From LacCer, two main families of complex GSLs are derived: the neutral and acidic GSLs, including gangliosides (*Fig. 2*). These GSLs are synthesized by stepwise addition of monosaccharide residues onto LacCer. Subsequent glycosylation reactions are catalyzed by glycosyltransferases in the Golgi apparatus [7,36]. In the case of gangliosides, the limited specificity of some of the transferases [7,37] gives rise to complex GSL patterns on the cell surface within a combinatorial biosynthetic pathway [24]. The biosynthesis of these GSLs is strictly regulated by the activities of glycosyltransferases [7].

With the exception of GM4, a major ganglioside of the myelin membrane [38], gangliosides are all derived from LacCer. The addition of the first sialic acid residue converts LacCer to GM3, the precursor of most complex brain gangliosides. The reaction is catalyzed by either sialyltransferase I (ST-I) or GM3-synthase. Further addition of sialic acid residues generates GD3 (catalyzed by ST-II or GD3-synthase) and GT3 (catalyzed by ST-III or GT3-synthase). ST-I, ST-II, and ST-III are all distinct enzyme entities arising from different genes. GM3, GD3, and GT3 represent the entry substrates for biosynthesis of complex-type gangliosides in the a-, b-, and c-series pathways, respectively (*Fig. 2*). These enzymes include *N*-acetylgalactosaminyltransferase I (GalNAcT-I) or GM2/GD2-synthase, galactosyltransferase II (GalT-II) or GM1/GD1b-synthase, ST-IV or GD1a/GT1b-synthase, and ST-V or GT1a/GQ1b-synthase. The development of a parallel c-pathway was achieved by Yu and Ando [39] and Ando and Yu [40] after structural characterization of the c-series gangliosides, including GT3, GT2, GT1c, and GQ1c.

In order to produce asialo-series gangliosides, LacCer is converted to GA1 by two enzymatic reactions catalyzed by GalNAcT-I and GalT-II. ST-IV and ST-V are responsible for sialylation to GM1b from GA1 and to GD1c from GM1b, respectively. The complex gangliosides with sialic acid moieties α2,6-glycosidically linked to *N*-acetylgalactosamine residues, such as GD1α, GT1α, GQ1bα, and GP1cα, have been added later to the biosynthetic scheme [28,41,42,43]. In adult human tissues, gangliosides from the asialo- and c-series are found only in trace amounts [28] (*Fig. 2*). So far, it should be noted that (a) ST-I, ST-IV, and ST-V catalyze the formation of α2,3 sialyl linkage to galactose; (b) ST-II and ST-III are involved in the formation of α2,8 sialyl linkage to sialic acid; and (c) sialyl-transferase (ST-X, possibly ST-V) involving the formation of α2,6 sialyl linkage to *N*-acetylgalactosamine has not been characterized [27] although Irie et al. [44], using a rat liver Golgi preparation, reported GT1aα and GQ1bα are synthesized from GD1a and GD1b, respectively. Further synthesis

of the complex hexosamine-containing gangliosides is unique in that several identical GTs may participate in catalyzing the addition of various sugar residues to different ganglioside acceptor substrates [7].

Unlike lysosomal lipid-storage diseases (see below), very few metabolic diseases are known to be related to mutations of glycosyltransferases in ganglioside synthesis. The one new finding has been from that of Simpson et al. [45], who showed that a nonsense mutation of ST-I (GM3-synthase) is the cause of human autosomal recessive infantile-onset symptomatic epilepsy syndrome. Because ST-I is a key enzyme in the synthesis of all complex gangliosides, this report clearly indicates that the precise expression of complex gangliosides has critical biological functions in human nervous system development.

At this time, the precise intracellular localization of the enzymes that catalyze biosynthesis of gangliosides has not yet been achieved. It is assumed that the sequence of events in GSL biosynthesis resembles that of glycoprotein biosynthesis, i. e., early reactions occur in early subcellular organelles (endoplasmic reticulum and *cis*/medial Golgi) of the pathway, and late reactions occur in late stations (trans Golgi/trans Golgi network) [46]. GSLs are also known to recycle via the Golgi apparatus, especially in endosomes [47,48].

3 Glycosyltransferase Genes Involved in Ganglioside Biosynthesis and their Transcriptional Regulation

Glycosyltransferases (GTs; EC 2.4.x.y) constitute a large family of enzymes, which have been classified into families by amino acid sequence similarities [21]. By the end of 2006, the database at http://cazy.org/fam/acc_GT.html comprises more than 12,000 known and putative GT sequences that have been divided into 87 families. Here, we review the cloned GTs that are involved in the ganglioside biosynthetic pathway (*Fig. 2*), with respect to their classification, donor, and acceptor substrate specificities, as well as the linkages these enzymes catalyze. We also discuss the regulatory mechanisms of these genes, emphasizing their cell type-specific regulation.

3.1 Genes of GTs for Ganglioside Synthesis

GTs involved in ganglioside biosynthetic pathways (*Fig. 2*) include at least six sialyltransferases (STs, EC 2.4.99.y), three galactosyltransferases (GalT, EC 2.4.1.x), one galactosaminyltransferase (GalNAcT, EC 2.4.1.92), and one glucosyltransferase (GlcT, EC 2.4.1.80). All these GTs have been cloned except STIII, which remains unknown (see below). All cloned STs share four peptide-conserved motifs: L (large), S (small) [49,50], motif III [51], and VS (very small) [52,53] and are classified into three ST families (ST3Gal, ST8Sia, and ST6GalNAc) based on the linkage in which the sialic acid is transferred and the acceptor saccharide-specificity. The ST3Gal family consists of ST3Gal I, II, III, IV, V, and VI, which fall into two main branches (subfamilies) by phylogenetic analysis: ST3Gal I/II and ST3Gal III/IV/V/VI [54]. The enzymes in the ST3Gal family transfer Neu5Ac residues in the α2,3-linkage to terminal galactose residues found in glycoproteins and GSLs, but only ST3Gal I and V can use a GSL as an acceptor substrate, and thus are defined as ganglioside synthases. The cDNA for ST3Gal I (EC 2.4.99.4) was cloned from mouse [55] and

human [56]. The transiently expressed product of the ST3Gal I cDNA in host cells catalyzes the formation of GM1b, GD1a, and GT1b [55], indicating that this enzyme is an STIV (GM1b/GD1a/GT1b-synthase). The cDNA for human, mouse, and rat ST3Gal V (EC 2.4.99.9) has been cloned [53,57,58]. Assays for the expressed enzyme activity showed that ST3Gal V exclusively uses lactosylceramide (Galβ1-4Glcβ1-Cer) as an acceptor substrate to catalyze the synthesis of the ganglioside GM3, and thus is an STI (GM3-synthase) [57,58]. It should be noted that ST3Gal V (GM3-synthase) is the only ganglioside synthase to use Galβ1-4Glcβ1-1′Cer (LacCer) to synthesize GM3.

Two other ganglioside synthases, STII and STV, are classified into the ST8Sia I and III of the ST8ia family. This family consists of six members (ST8Sia I, II, III, IV, V and VI) in two main branches in the phylogenetic tree (ST8Sia I/V/VI and ST8Sia II/III/IV) [54]. The ST8Sia I gene has been cloned from human [59,60,61], mouse [62], and rat [63] and show high sequence similarity among the species. Analysis of these cDNA products showed that the cloned ST8Sia I catalyzes the formation of GD3 and thus is an STII (GD3 synthase). However, it was reported that this enzyme could utilize gangliosides GM1b, GD1a, and GT1b as exogenous substrates, in addition to GM3, indicating that this enzyme catalyzes the formation not only of GD3 but also of GD1c, GT1a, and GQ1b in vitro [64]. In addition, a cloned human ST8Sia I can also efficiently synthesize GT3 in vitro using GD3 as an acceptor [65]. The latter results are likely due to an artifact as our study showed that over-expression of exogenous GD3-synthase cDNA in cells resulted in both GD3 and GT3 [66] and that many cell lines expressing high levels of GD3 do not necessarily synthesize GT3. ST8Sia V of this family also catalyzes the synthesis of several gangliosides. The cDNAs for mouse [67] and human [68] ST8Sia V have been cloned. Enzymatic assays show ST8Sia V to be involved in the synthesis of gangliosides GD1c, GT1a, GQ1b [69] and that ST8SiaV is considered an STV. However, the ST8Sia I (GD3-synthase) may also synthesize GD1c, GT1a, and GQ1b [67]. Therefore, which (or both) of the ST8Sia I and V enzymes is responsible for the synthesis of GD1c/GT1a/GQ1b remains unclear. In vitro assays also indicate that GT3 is an additional product of ST8Sia V [67] but this result also may be an in vitro artifact as discussed in the case of ST8Sia I. Besides, the cDNA for mouse [69], rat [70], and human [71]. ST8Sia III has been cloned, and the common product was initially suggested to be GT3. However, further analysis of the expressed products of the ST8Sia III cDNA showed extremely high catalytic activity in transferring sialic acid residue through an α2,8-linkage to glycoproteins, and this enzyme is much more specific to *N*-linked oligosaccharides of glycoproteins than of GSLs. Therefore, whether a unique cDNA coding only for STIII (GT3-synthase) exists is still an open question.

ST6GalNAc catalyzes the transfer of Neu5Ac residues in an α2,6 linkage to GalNAc residues found in *O*-glycosylproteins or GSLs. A number of the ST6GalNAc genes have been cloned [72,73,74,75,76,77,78] and classified into ST6GalNAc I, II, III, IV, V, and VI. These six members fall by phylogenetic analysis into two main subfamilies, ST6GalNAc I/II and ST6GalNAc III/IV/V/VI [54]. Interestingly, these two subfamilies are in agreement with their substrate specificities: ST6GalNAc I and II of the first subfamily exhibit broad substrate specificity and catalyze the transfer of Neu5Ac onto Galβ1-3GalNAc peptides [75,76,77], whereas ST6GalNAc III/IV/V/VI of the second subfamily exhibits more restricted substrate specificity, only utilizing sialylated acceptor substrates (Neu5Acα2-3Galβ1–3GalNAc-R) found either in glycoproteins or GSLs [72,73,74,78]. As far as can be determined by in vitro assays of the expressed recombinant ST6GalNAc, only two members of the second

subfamily, ST6GalNAc III [72,73] and V [74], can act on the synthesis of GSLs GM1b and GD1α. Therefore, at least four expressed recombinant sialyltransferases, ST8Sia V, ST3Gal I, ST6GalNAc III, and ST6GalNAc V, catalyze the formation of GM1b in vitro. It is unclear, however, whether GM1b is actually synthesized from GlcCer by the four GTs (aside-series; ❯ *Fig. 2*) under physiological conditions.

Three galactosyltransferases (GalTI, II, and III) in the ganglioside biosynthetic pathways (❯ *Fig. 2*) have been cloned, and all exhibit a conserved putative *N*-linked glycosylation site. GalTI (UDP-galactose:glucosylceramide β1,4-galactosyltransferase) catalyzes the synthesis of LacCer by transferring galactose from UDP-Gal to GlcCer, generating a β1,4-glycosidic linkage. The cDNA for the enzyme catalyzing this reaction has been cloned from rat [79] and human [80]. The deduced amino-acid sequence of the rat GalTI shows 39% homology with mouse β1,4-galactosyltransferase (EC 2.4.1.38), which catalyzes the transfer of Gal to β1,4-GlcNAc in glycoproteins. The GalTI prefers GlcCer as a substrate for GSL synthesis, however, indicating that this cloned GalTI is different from the glycopeptide β1,4-Gal T (EC 2.4.1.38) [79]. GalTII (UDP-galactose: GD2 β1,3-galactosyltransferase) catalyzes the synthesis of GD1b, GM1, or GA1 by transferring a galactose moiety from UDP-Gal to β-GalNAc in the receptor substrates, generating a β1,3-glycosidic linkage. The cDNA for GalTII has been cloned from rat [81], human [82], and mouse brains [83]. The GalTII gene has no significant homology with other galactosyltransferase genes and consists of a single exon, which is different from other GT genes. In addition, GalTII, as well as GalTIII, contains a very hydrophobic putative stem region differing significantly from other animal GTs [82]. GalTIII (ceramide UDP-galactosyltransferase, EC 2.4.1.45) catalyzes the synthesis of GalCer, the precursor of ganglioside GM4, in embryonic chicken brain and in mouse brain. The GalTIII cDNA was first cloned from rat [84], and then from mouse [85,86] and then from human [87,88]. Analysis of the deduced amino-acid sequences showed common structural features of GalTIII in three species, such as the putative *N*-glycosylation sites, the *C*-terminal hydrophobic part of the protein, the terminal signal peptide, and the KKVK endoplasmic reticulum retention signal [85].

GalNAcT (β1,4 *N*-acetylgalactosaminyltransferase) catalyzes the transfer of *N*-acetylgalactosamine onto the receptor substrates to form a β1,4 linkage. The cDNA for GalNAcT has been cloned from human [89], rat [90], and mouse [91,92]. The deduced amino-acid sequences of the cDNA indicate that GalNAcT is a typical type II membrane protein, similar to other GTs, and consists of a short *N*-terminal residue, a transmembrane region, and a long *C*-terminal residue, including the catalytic domain. GalNAcT shows no significant homology with other GalNAc transferases but shows 39% identity of the amino-acid sequence with another β1,4-*N*-acetylgalactosaminyltransferase, which is responsible for biosynthesis of the blood group Sda/Cad antigen [93,94]. In vitro assays of the expressed recombinant GalNAcT showed that it catalyzes the formation not only of GM2 and GD2 from GM3 and GD3, respectively, but also of GA2 from LacCer, and thus GalNAcT is designated as a GA2/GM2/GD2/GT2-synthase. This enzyme lacks activity to transfer GalNAc to glycoproteins; another purified GalNAcT, however, can transfer GalNAc to both GSL and oligosaccharides [95]. It is unclear whether these two GalNAcTs are the same or different enzyme entities.

GlcT (UDP-glucose:*N*-acylsphingosine D-glucosyltransferase) transfers glucose from UDP-Glc to ceramide in brain tissues, which is the first step in biosynthesis of the major gangliosides except GM4 (❯ *Fig. 1*). The cDNA of GlcT has been cloned from human [96], mouse [97], and

rat [98]. The amino-acid sequence shows that GlcT has a type III structure: a short *N*-terminal segment to the exoplasmic side, a single transmembrane segment, and a long cytosolic tail [99]. Moreover, the catalytic domain of GlcT is in the cytosolic face of the Golgi membrane [96,99]. These two features of GlcT are different from most of the features of the cloned GTs. This enzyme is involved only in GSL synthesis, as suggested by the fact that no β-glucosyl residues have been found in either glycoproteins or the lipid precursors.

In summary, STI and GlcT are highly specific in both donor and receptor substrates, which exclusively catalyze the reactions for synthesis of the gangliosides GM3 and GlcCer, respectively. The other GTs discussed above show broad substrate specificities and are responsible for the synthesis of more than one ganglioside or even both GSLs and glycoproteins. This sequence-based classification is assumed to integrate both structural and mechanistic features within each family [21]. However, prediction of the donor and acceptor specificity of a GT based on sequence homology can be problematic because there are many examples of closely related sequences, such as the sequences of blood group A and B transferases with only four different amino acids [100], having different catalytic activity. Determination of the X-ray crystal structures of these transferases will provide a structural basis accounting for the specificities as well as for the catalytic reactions. More than 100 crystal structures have been described for proteins corresponding to 23 different GTs from prokaryotes and eukaryotes [101]. The 3-dimensional GT database, containing structural information for 17 distinct GT families, is available at http://www.cermav.cnrs.fr/glyco3d. Unfortunately, due to difficulties with expression level, purification, and crystallization, no crystalline structure for ganglioside synthases have so far been determined.

3.2 Transcriptional Regulation of the Genes of GTs for Ganglioside Synthesis

Cells can switch between expressing simple and complex gangliosides or among different series of gangliosides during brain development and cell differentiation, indicating that expression of the GTs for ganglioside synthesis is under strict regulation. Interestingly, all of the promoters of ganglioside synthase genes analyzed so far are TATA-less, lacking a CCAAT box but containing G*C*-rich boxes, characteristic of the housekeeping genes [7]. The term "housekeeping" means that there is little or no strict regulation. This lack of regulation may no longer be considered accurate because prevalence of the TATA box has in the past been overestimated in the eukaryotic genome; the majority ($\sim$76%) of eukaryotic genes, in fact, are TATA-less [102]. Very little is known about TATA-less promoter activation. The GT genes for ganglioside synthases are TATA-less genes under strict regulation in a cell type-specific manner.

The promoter of ST8Sia I (GD3-synthase, STII), which has attracted much more attention than have other promoters of the ganglioside synthase genes, has been cloned from rat [103], mouse [104] and human [105]. The promoter of all three species is TATA-less and does not possess known core- promoter elements, including the initiator (INR), the downstream promoter (DPE), the TFIIB recognition elements (BRE), and the "motif ten element" (MTE). Similar to other TATA-less promoters, it has a high GC content and is enriched in Sp1-binding sites. The proximal promoter region is defined within 500 or 700 bp upstream of the ATG

codon in rat and mouse promoters or human promoter, respectively [103,104,105]. The rat and mouse promoters have a single transcription start site [103,104], and the human promoter possesses multiple initiation sites [105]. Although there are no common binding sequences among the species, all the promoters have several Sp1-binding sites in the proximal promoter region, and deletion of the Sp1 sites results in a dramatic loss of the proximal promoter activities of the mouse [104] and rat gene (Zeng and Yu, unpublished data), suggesting that Sp1 plays a significant role in the transcriptional regulation of the gene. Our recent data from the DNA pull-down experiments show that at least seven transcription factors, Sp1, AP1, AP2, GATA, Ets-1, NFκB, and MRE, bound to their consensus sites on the proximal promoter fragment of the rat ST8Sia I gene (Zeng and Yu, unpublished data). In vivo binding of these factors to the promoter is cell-type specific as determined by ChIP assays in the rat F-11 that express a high level of ST8Sia I and in the rat PC12 cells that express little ST8Sia I (Zeng and Yu, unpublished data). The results show that Sp1 and NFκB bind to the promoter in both cells, while AP2 or Ets-1 binds to the promoter only in F-11 or PC12 cells, respectively. No binding of AP1 and GATA has been found in vivo in either of the cells. Results from deletion of the corresponding binding sites have confirmed the involvement of these transcription factors in regulation of the proximal ST8Sia I promoter in a cell-type specific manner (Zeng and Yu, unpublished data). We have also identified an unknown mutation close to the 3′-end of the rat promoter that decreases proximal promoter activity in F-11 cells and increases it in PC12 cells (Zeng and Yu, unpublished data). ST8Sia I is highly expressed in melanoma and in many types of brain tumors, although ST8Sia I is almost undetectable in melanocytes and adult brain; thus it is clinically significant to understand the mechanism regulating ST8Sia I gene expression in a cell-type-specific manner. Other features of this promoter include a negative control region and a GT/CG repeat sequence in the distal regulatory region [103,104,105]. These unique GT/CG repeats present a structure of Z-DNA and are located in the negative control regions. Whether the GT/CG repeat sequence contributes to the suppressive activity in the transcriptional regulation of the ST8Sia I gene remains to be elucidated.

ST3Gal V (GM3-synthase, STI) catalyzes the synthesis of GM3, a substrate for synthesis of all gangliosides and possibly also of GM4 (❯ *Fig. 2*). Regulation of ST3Gal V expression is critical for initiation of ganglioside synthesis. There are four isoforms of ST3Gal V mRNA in human fetal brain, differing in the 5′-untranslated region, but only one of these isoforms can be detected in adult brain [106], suggesting that expression of the ST3Gal V gene is developmentally regulated, and that alterative splicing or transcriptional initiation of the ST3Gal V RNA occurs in a tissue-specific manner [58,107]. Analysis of the promoters of the human [108,109] and mouse [110] ST3Gal V genes found that the mouse ST3Gal V gene uses multiple transcriptional initiation sites, including several downstream sites [110], and the human ST3Gal V gene uses at least two initiation sites [111], consistent with the fact that there are multiple isoforms of transcripts from the ST3Gal V genes [106]. Minimum promoter regions of 177 bp and 254 bp lie upstream of the initiation site of the human and mouse promoters, respectively, and display the highest level of promoter activity [108,109,110], although longer promoter fragments from the proximal regions to 1,600 bp do not significantly contribute to transcriptional activity [108,109,110]. The proximal region contains no TATA or CCAAT boxes but has multiple Sp1 and AP2 sites. It has recently been reported that a juxtaposed Sp1/AP2-binding site and one of the six AP2-binding sites in the proximal region are essential in maintaining a high lev-

el of promoter activity [110]. Chromatin immunoprecipitation confirmed binding of the transcription factors Sp1 and AP2 to the two sites inside cells [110]. DNA pull-down experiments revealed that 7 factors (CREB, PPAR, Pax-5, Smad3/4, Stat6, MEF-1, and MEF-2) bound to both human and mouse promoter fragments [109,110]. Among them, the CREB-binding site has been further demonstrated to be critical in transcription of the human ST3Gal V gene in HL-60 cells when activated by PMA (phorbol 12-myristate 13-acetate) [111]. These results indicate that multiple factors, including Sp1, AP2, and CREB, contribute to activation of ST3Gal V gene transcription and that expression of human and mouse ST3Gal V genes may be under a similar regulatory mechanism. Future studies may focus on how these factors and regulatory elements function coordinately in vivo in development-dependent or cell-type specific expression of the gene.

GalNAcT is a key enzyme controlling the expression of more complex gangliosides (*Fig. 2*), and the GalNAcT gene is highly expressed in tumor cell lines such as in neuroblastoma and melanoma [112,113], and also in mouse brain at the late stage of development [62,90]. Studies on the promoter and genomic organization of the human GalNAcT gene show that it has three transcription start sites and three alternative exons (exon 1a, exon 1b, and exon 1c). Three promoter regions (P1, P2, and P3) in GalNAcT have been defined for individual transcription start sites, respectively and one of them is located in the first intron [114]. There are consensus binding sites for transcription factors EGR-1, HNF-5, Sp1, and PEA3 in the 5′-flanking region of exon 1a, three binding sites for Sp1 and one for AP2 and PEA3 in the 5′-flanking region of exon 1b, and one site for AP2 and E2F and S1 HS sites in the 5′-flanking region of exon 1c. The activities of promoters P1 and P2 are strongly enhanced by a sequence (enhancer) located in exon 1. Furukawa et al. [114] also proposed a suppressive sequence (silencer) of 42 bp located upstream of exon 1c, which suppressed the transcriptional activity of the P3 promoter in a melanoma cell line in which no promoter activity had been detected. These results indicate that alternative promoter regions or the enhancer/silencer may regulate cell type-specific expression of the GalNAcT gene.

The three GTs above are the key enzymes that regulate synthesis of the more complex gangliosides: “a”, “b”, and “c” series. The transcriptional regulation of these GT genes is itself complex and tissue-/cell-specific. Other promoters for ganglioside synthase genes, including promoters of the GlcT, GalTII, and GalTIII genes, have also been cloned and analyzed [7]. They are all TATA-less and contain no CCAAT box, but they do have G*C*-rich boxes. The proximal promoter (578 bp) of the mouse GlcT gene contains four Sp1-binding sites located between −558 and −439 bp upstream of the ATG codon [115]. Deletion of a 41-bp fragment (from −538 to −578) dramatically decreases the activity of the proximal promoter. This 41-bp fragment contains one Sp1-binding site, indicating an essential role of this site in maintaining a high level of proximal promoter activity [115]. Since GlcT catalyzes the formation of glucosylceramide, which serves as a core structure for more than 300 species of GSLs, it is unclear whether regulation of the GlcT gene pertains to ganglioside biosynthesis.

Analysis of the promoter of the mouse GalTII gene reveals several features different from other ganglioside synthase promoters [116]. The proximal 550-bp fragment that shows the highest level of promoter activity contains no Sp1-binding site, but does show a number of other consensus sequences. The GalTII gene has a single exon and a single transcription start site. A 350-bp fragment beyond the proximal region strongly suppresses promoter activity. As many as 27 transcription factors have been characterized as binding to their consensus

sites in the promoter region in vitro [116]. Those data characterizing the transcription factors may indicate a quite different mechanism for regulation of GalTII gene expression. GalTII is responsible for synthesis of GA1, GM1, GD1b, and GT1c. GM1 is known to play important roles in the development and functions of the neural system [117]. How GalTII gene expression is regulated, particularly during neuronal differentiation, remains to be elucidated.

The promoter of the human GalTIII gene has been cloned and analyzed [118,119]. The gene is transcribed from a single initiation site 322 bp upstream of the ATG codon. The *cis*-acting regulatory elements were found in two small regions at −292/−256 and −747/−688. The region at −292/−256 contains putative binding sites for transcription factors Ets and Sp1, and the region at −747/−688 exhibits binding sites for ERE, NF-1, TGGCA-BP, and CRE [118]. A third *cis*-acting region, distally located at −1325/−1083, consists of multiple binding sites for TCF-1, TGGCA-BP, NF-IL6, CF1, bHLH, NF-1, GATA, and Q-IRE. A negative regulatory domain localized in a far region at −1594/−1326 was also identified [118]. Further analysis of the two small regulatory regions demonstrated that the functional elements are a Sp1-binding site at −292/−256 and a CRE-binding site at −747/−688 [119]. The cell type-specific activities of those promoters have been observed between the human oligodendroglioma (HOG) and human neuroblastoma (LAN-5) cell lines, and the factor CREB may account for the different levels of GalTIII promoter activity in those lines [119]. GalTIII is a key enzyme in the biosynthesis of Galcer, the most abundant GSL in the myelin sheath. Galcer serves as the precursor for the biosynthesis of GM4, the simplest ganglioside present in the myelin of the central nervous system [120]. Whether cell-type specific regulation of the GalTIII gene controls GM4 synthesis in cells is a subject for further investigation.

4 Ganglioside Catabolism and Gangliosidoses

4.1 Ganglioside Degradative Pathways

The constitutive degradation of GSLs occurs primarily in the acidic compartments, the endosomes and the lysosomes [121]. Here, water-soluble glycosidases sequentially cleave off the terminal carbohydrate residues from GSLs (*Fig. 3*). Ganglioside catabolism consists of the sequential removal of individual sugar residues, starting from the non-reducing terminal unit by (exo)glycohydrolases, which are soluble enzymes [27]. The catabolism of gangliosides requires the so-called sphingolipid activator proteins (SAPs) [122] or saposins [123], which are derived from a protein, SAP-precursor or prosaposin, by proteolytic processing in the ER [124,125].

Lysosomal sialidase is required for the degradation of complex gangliosides for the formation of GM1 ganglioside [126]. GM1 is degraded to GM2 by the action of a β-galactosidase in the presence of either the GM2-activator protein (AP) or SAP-B [127]. GM2 is degraded to GM3 by hexosaminidase (HEX) A. Hydrolysis of GM2 requires a normal GM2 ganglioside-GM2 activator-Hex A complex. Hex A consists of a dimer and has the structure α-β. The α subunit is encoded by the *HEXA* gene at band 15q23-q24 [122]. GM3 is degraded to LacCer and sialic acid by SAP-B [126]. The galactose residue in the GSLs is removed by either galactosylceramide-β-galactosidase or GM1-β-galatosidase to form glucosylceramide in the presence of either SAP-B or -C [28,128]. The membrane-bound lysosomal hydrolase, glu-

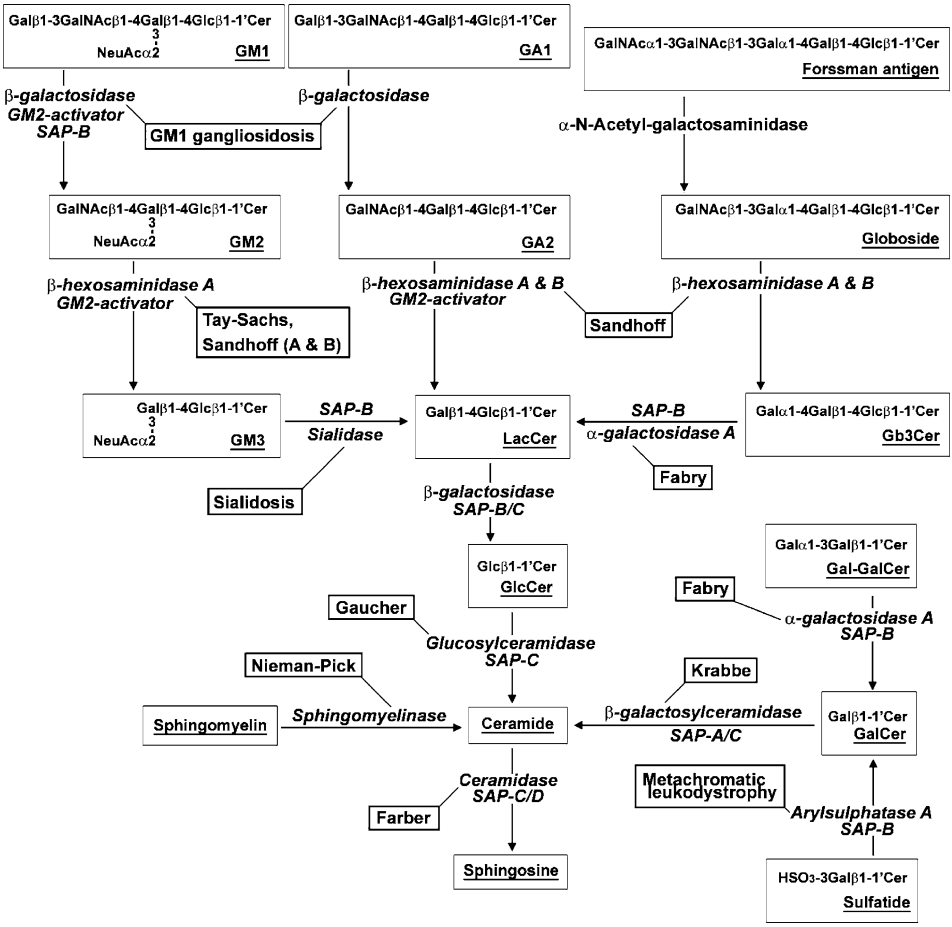

Figure 3

Degradation of GSLs in the lysosomes. Figure includes enzymes of individual lysosomal storage diseases (LSDs). Sphingolipid activator proteins (SAPs) are required in this process

cocerebrosidase (glucosylceramide-β-glucosidase), participates in the degradation of glucosylceramide to yield glucose and ceramide [129]. The end product, ceramide, is eventually degraded into a long-chain base residue and a fatty acid moiety by ceramidase [130]. The lysosomal hydrolysis of ceramide is catalyzed by acid ceramidase and requires sphingolipid activator proteins (SAP-D) as a co-factor in vivo [131].

4.2 Glycosphingolipid Lysosomal Storage Diseases

The importance of gangliosides in human health is evident in neurodegenerative diseases associated with defects in the degradation of gangliosides. It is well known that serious neurological deficits develop in humans with aberrant GSLs or ganglioside metabolism. Most

Table 1
Shingolipisosis

Disease	Defected enzyme	Accumulated substance
GM1 gangliosidosis	β-galactosidase	GM1, oligosaccharides & glycoproteins having terminal β-galactose
GM2 gangliosidosis		
B variant (Tay–Sachs disease)	β-hexosaminidase A	GM2
O variant (Sandhoff disease)	β-hexosaminidase A & B	GM2, GA2, oligosaccharides & glycoproteins having terminal β-*N*-acetylglucosamine
Fabry disease	α-galactosidase	Globotriaosylceramide
Metachromatic leukodystrophy	Arylsulfatase A	Sulfatide
Krabbe disease (Globoid-cell leukodystrophy)	Galactosylceramidase	Galactosylceramide & psycosine
Gaucher disease	Glucosylceramidase	Glucosylceramide
Nieman–Pick disease (types A & B)	Sphingomyelinase	Sphingomyelin
Farber disease	Ceramidase	Ceramide

of the human lysosomal-storage diseases are associated with GSL catabolism, the so-called degradation disorders or lipid-storage disorders (LSDs or lipidoses) [33]. LSDs are caused by deficiencies in lysosomal enzymes and abnormalities in lysosomal functions within the lysosomes [132]. LSDs are generally classified by accumulated substrates, which include sphingolipidoses, glycoproteinoses, mucolipidoses, mucopolysaccharidoses, and others. Glycosphingolipidoses are a group of inherited metabolic disorders in which harmful amounts of GSLs accumulate, resulting in an increase in the size and number of lysosomes and endosomes. This excessive storage of GSLs can cause permanent cellular and tissue damage, particularly in the brain, peripheral nervous system, liver, spleen and bone marrow (*Fig. 3* and *Table 1*). In addition, defects in co-factors, such as SAPs, that are involved not only in the lysosomal degradation of GSLs, but also in targeting of the transport systems in the degradation process can also lead to LSDs [33,121]. LSDs are clinically heterogeneous with respect to the age of onset, progression of symptoms, and the particular organs involved. Varying levels of residual enzyme activity, associated with different defective alleles that cause the respective diseases, are responsible in part for this clinical heterogeneity [133]. These events can possibly occur with the accumulation of lipids in lipid rafts in late endosomes/lysosomes [134,135]. In this section, we will focus on gangliosidoses that are caused by inherited defects within the ganglioside degradative pathway.

GM1 gangliosidosis is an autosomal recessive disorder caused by a deficiency of lysosomal β-galactosidase, resulting in accumulation of GM1 in the brain and keratosulfate-like mucopolysaccharide in the visceral organs. GM1 gangliosidosis is a progressive neurological disease with three clinical subtypes, infantile (type 1)-, juvenile (type 2)- and adult-onset variant (type 3) [136,137,138]. In type 1, motor and mental retardation are most rapidly progressive, which resembles features of some neurolipidosis (i. e., neurodegeneration, progressive organomegaly, dysostosis multiplex, facial coarsening, macular cherry-red spots) Patients with type 1 gangliosidosis are usually associated with mucopolysaccharidosis-like dysmorphic

features (e. g., visceromegaly, dysostosis multiplex, and coarsened facial features) that typically develop between birth and 6 months. Death usually occurs during the second year of life due to infection (usually pneumonia, resulting from recurrent aspiration) and cardiopulmonary failure [139]. Type 2 disease develops later (age 1–2) with onset of progressive psychomotor retardation. Some visceromegaly and milder skeletal disease develop compared to the infantile form. Death usually occurs before the second decade of life. Type 3 disease shows a late onset (in the teens) and typically presents during childhood or adolescence as a slowly progressive dementia with Parkinsonian features and extrapyramidal disease, particularly dystonia. Chronic forms of type 3 disease are variable and reported in fewer cases [140] than the other two types. Age at death may vary greatly, from 20 to 50. Several β-galactosidase-deficient animal models have been reported, i. e., in mice [141,142,143], cat [144,145], sheep [146], and dog [141,148,149]. These animal models appear to mimic closely the pathological, biochemical, and clinical abnormalities of human disease [141].

In type 1 disease, the deposition of GM1 in tissues is significantly increased, with less deposition in type 2. In type 3, GM1 deposits appear primarily in the basal ganglia. In some cases, no increase of GM1 is found in plasma or in cerebrospinal fluid; the metabolism of GM1 in the cultured skin fibroblasts of individuals with type 3 is almost normal although the residual activity of GM1 β-galactosidase activity is only 10% of normal [138]. The storage of substances in the peripheral tissues decreases from type 1 to type 3. Kobayashi et al. [150] have demonstrated the accumulation of lyso-GM1 in late-infantile type and adult type GM1 gangliosidosis. Lyso-asialo-GM1 is also expressed in late-infantile type, but not in adult type.

GM2-gangliosidosis is a family of three autosomal recessive, lysosomal storage disorders, characterized by the intralysosomal accumulation of GM2 ganglioside and related GSLs, primarily in the central and peripheral neural tissues [33,151,152]. GM2 gangliosidosis is caused by mutations in at least 1 of 3 recessive genes: *HEXA, HEXB*, and *GM2A* [153]. Recently, Lemieux et al. [153] have reported that the crystal structure of Hex A reveals an α-β heterodimer, with each subunit having a functionally active site. Only the α-subunit active site can hydrolyze GM2 gangliosides because of its flexible loop structure, removed post-translationally from β, and the presence of αAsn423 and αArg424. The loop structure is involved in binding the GM2 activator protein, while αArg424 is critical for binding the carboxylate group of the *N*-acetylneuraminic acid (NeuAc) residue of GM2. The β-subunit lacks these key residues and has βAsp452 and βLeu453 in its place; the β-subunit therefore cleaves efficiently only neutral substrates. Deficiencies of either the α- or the β-subunit of the heterodimeric β-hexosaminidase A (Hex A) protein or of the small monomeric GM2 activator protein (a substrate-specific co-factor for Hex A) lead to the three devastating phenotypic neurodegeneration-associated disorders: Tay–Sachs disease, Sandhoff disease, and the AB variant form [153].

Tay–Sachs disease is the B-variant of GM2 gangliosidosis due to α-chain deficiency and to the subsequent deficiency of hexosaminidases A and S, but with normal hexosaminidase B. Depending on the residual enzyme activity of β-hexosaminidase, the onset of symptoms may occur anywhere from late infancy to adulthood and are usually subclassified into infantile (type 1)-, juvenile (type 2)-, chronic-, and adult-onset forms [33]. In type 1, the most common disease with a carrier frequency of 1 in 27 among Ashkenazi Jews [154], patients are normal at birth but then show symptoms, such as mild motor weakness, between 3 and 6 months, resulting in hypotonia, poor head control, decreasing attentiveness, and visual symptoms (cherry red

spot). About 10 months later, infants with type 1 Tay–Sachs have severe motor, mental, and visual disabilities, usually leading to death between age 2 and 4. In type 2, the first onset of motor symptoms occurs between 2 and 6 years. Juveniles exhibit abnormalities such as loss of speech and vision, increasing spasticity, seizures. and progressive dementia. Death often occurs due to infections. In the chronic form of Tay–Sachs disease, onset occurs between 2 and 5 years, and patients can live to about age 40. In the adult form, the symptoms are heterogeneous. Individuals show neurological disorders, such as spinal muscular atrophy and psychoses, but their intelligence and visual functions are not affected.

Sandhoff disease is the 0-variant of GM2 gangliosidosis due to a β-chain deficiency, resulting in deficient activity of β-hexosaminidases A and B but with normal β-hexosaminidase S, which causes accumulation of GM2 and asialo-GM2 in the brain and globoside in the visceral organs [33]. Sandhoff disease is classified into three types: infantile (type 1)-, juvenile (type 2)-, and adult (type 3)-forms [33]. In type 1, organomegaly and slight bone deformations may occur in addition to the clinical and pathological manifestations of classical Tay–Sachs disease. In the type 2, symptoms such as slurred speech, cerebellar ataxia, and psychomotor retardation appear at age 3 to 10. In addition, juveniles with type 2 have increasing spasticity and gradual deterioration of mental function although visual function is normal. In type 3, the onset of symptoms is delayed to later in adult life. The clinical manifestations in this chronic variant are similar to those of Tay–Sachs disease variants of corresponding ages. The AB-variant of GM2-gangliosidosis is caused by deficiency of the GM2 activator protein, but β-hexosaminidase A, B, and S activities are normal, resulting in the accumulation of GSLs, e. g., GM2 and asialo-GM2 (GA2) [33]. In this AB variant, the clinical picture resembles that of classical Tay–Sachs disease with a delayed appearance of symptoms. In its histopathological aspects, Sandoff disease in these patients is characterized by swollen neurons with massive accumulations of stored lipids in membranous cytoplasmic bodies (MCBs) throughout the central and peripheral nervous systems. Signs and symptoms begin in infancy. Infants appear normal until age 3 to 6 months. Children with the AB variant can live only into early childhood. Several β-hexosaminidase-deficient animal models have been reported, i. e., mice [155,156,157,158], cat [159,160], sheep [159], and dog [159,161,162]. Lyso-GM2 was expressed in the brain of Tay–Sachs patients [163]. Kobayashi et al. [150] have also demonstrated the accumulation of lyso-GM2 and lyso-GA2 in the brain of individuals with Sandhoff disease and lyso-GM2 in the brain of those with Tay–Sachs disease. Li et al. [164] reported the presence of an unusual ganglioside, taurine-conjugated GM2, as minor components in the brain of individuals with Tay–Sachs disease. Itoh et al. [165] reported the accumulation of GalNAc-GM1b in the brain of those with Tay–Sachs disease. Further study revealed that GalNAc-GD1a was expressed in the brain of individuals with the same disease [166].

With respect to gangliosidoses, a unique form of gangliosidosis in emu (*Dromaius novaehollandiae*) has been reported [167,168]. Ultrastructural examination of the affected neurons reveals numerous MCBs similar in appearance to those seen in mammalian gangliosidoses. Neurological examination reveals hypermetric gait, persistent head tremor, and mild ataxia. Histopathologic and electron microscopic abnormalities are found, which include swollen, pale neurons were present in the cerebrum, pons, medulla, cerebellum, spinal cord, spinal ganglia, autonomic ganglia, myenteric plexus, and the ganglion cell layer of the retina. Analysis of brain gangliosides of the affected 7-month-old emu revealed 14- and 25-fold increases of GM1 and GM3 gangliosides, respectively, compared with control emus.

5 Concluding Remarks

Early research on gangliosides focused on understanding the genetic basis of ganglioside storage diseases, which led to major advances in the analysis of ganglioside structure, tissue and cellular/subcellular distributions. In the 1960s, extensive research was extended to the metabolism of these GSLs, which formed the basis of developing the various biosynthetic and catabolic pathways that have now become known. With the advent of contemporary molecular and cellular biology, remarkable success has been made in understanding the genetic and regulatory mechanisms of ganglioside metabolism during development. Current efforts have focused on the functional roles of gangliosides during development, and the concept of lipid rafts, where many of the membrane signaling events involving gangliosides are launched, has revolutionized our studies on their biological functions. Understanding the genetic basis of the various ganglioside storage disorders has also provided rational strategies for their diagnosis and treatment with enzyme replacement or gene therapy. Future studies will most likely continue to focus on areas related to their biological functions, both in normal development and in disease.

Abstract

Glycosylphosphatidylinositols (GPIs) are a class of natural glycolipids that are ubiquitously expressed by eukaryotic cells. One of the fundamental functions of GPIs is to anchor proteins, glycoproteins, and other molecules onto cell surfaces. The structures of GPIs are diverse and heterogeneous. To obtain homogeneous and well-defined GPIs for various studies, the chemical synthesis of GPIs has become a hot topic. This chapter summarizes the recent progress in the chemical synthesis of GPIs as well as related structures, such as the GPI-linked peptides and glycopeptides.

TIPS	triisopropylsilyl
TPAP	tetrapropylammonium perruthenate
Trt	trityl (triphenylmethyl)
VSG	variant surface glycoprotein

1 Introduction

Glycosylphosphatidylinositol (GPI) anchors are a class of natural glycolipids which share a common core structure: Manα(1→4)GlcNH$_2\alpha$(1→6)-*myo*-Inositol-1-PO$_4$-lipid (**1**, ❯ *Fig. 1*). Presently, there are two types of GPIs identified. One type of GPIs, such as free glycoinositol phospholipids (GIPL) and the GPIs of lipophosphoglycans (LPGs) [1,2], anchor non-protein extracellular glycoconjugates onto cell surfaces. These GPIs are observed in protozoal parasites, and the common structure that they share is the basic GPI core mentioned above. Another type of GPIs are membrane protein and glycoprotein anchors ubiquitously expressed by mammals and by lower eukaryotes as well [3]. All GPI anchors of the second type have the conserved structure Manα(1→2)Manα(1→6)Manα(1→4)GlcNH$_2\alpha$(1→6)-*myo*-Inositol-1-PO$_4$-lipid (**2**, ❯ *Fig. 1*). The *C*-termini of GPI-anchored proteins and glycoproteins are coupled to the 6-*O*-position of the non-reducing end mannose of GPIs through a phosphoethanolamine group (P-OEtNH$_2$).

As depicted in ❯ *Fig. 1*, the lipid chains of GPIs can insert into cell membranes, enabling the anchoring of proteins and glycoproteins onto cell surfaces. Consequently, GPIs, as well as GPI-anchored proteins and glycoproteins, play an important role in a broad range of biological and pathological processes, from cell recognition, binding, and signal transduction to extracellular enzymatic reactions and microorganism invasion [3,4,5,6,7,8].

The first complete structural characterization of a GPI, achieved by Ferguson and coworkers in 1988, was of the *T. brucei* variant surface glycoprotein (VSG) anchor [9]. This study was assisted by the fact that the African trypanosome system exhibits abundant VSG (ca. 10^7 copies per cell) [10], which also facilitated the development of the first cell-free

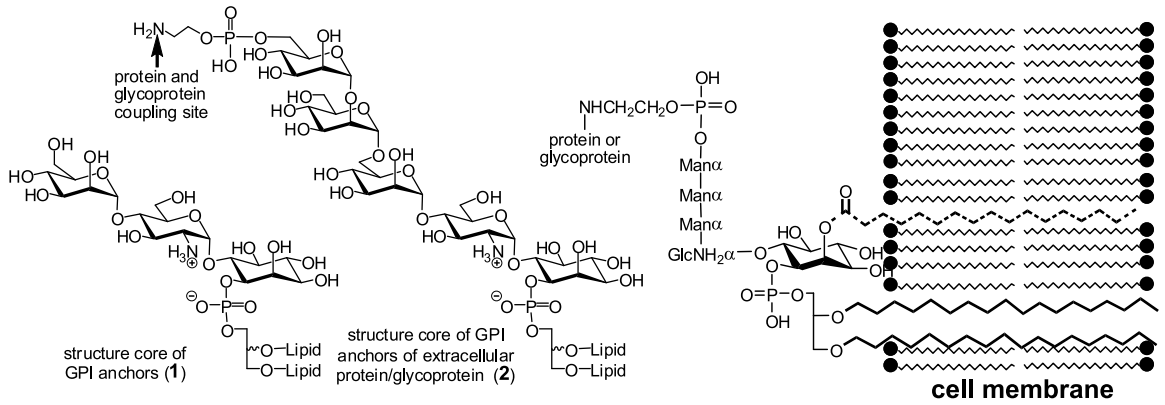

Figure 1
The core structures of glycosylphosphatidylinositol (GPI) anchors and the GPI anchoring of proteins and glycoproteins onto cell surfaces

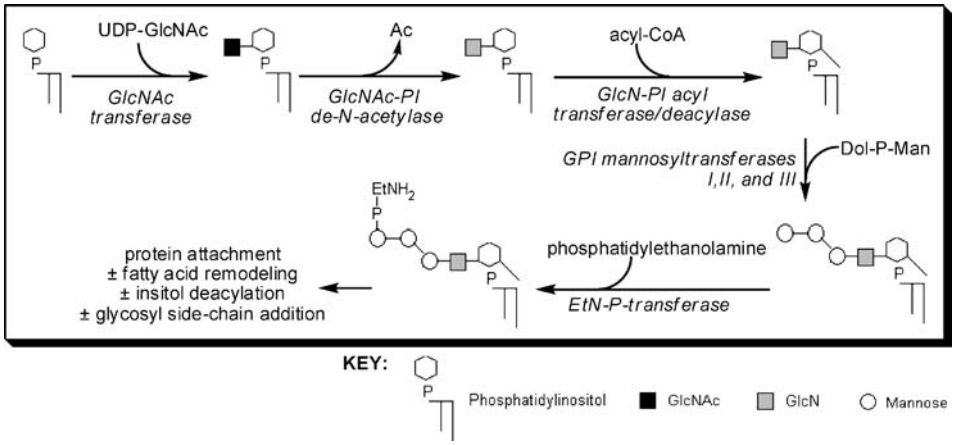

Figure 2

Biosynthesis of GPIs in mammalian cells. After a GlcNAc residue is added to PI followed by deacetylation, an acyl group is added to the inositol 2-*O*-position. Then, three mannose residues are added sequentially to form the GPI glycan core. The final step of GPI biosynthesis is the addition of a P-OEtNH_2 function to the 6-*O*-position of Man III. The GPI is added to proteins or glycoproteins before further modifications. Some mammalian biosynthetic intermediates are found to contain other phosphoethanolamine residues linked to either mannose I or III

system by Masterson and coworkers [11] that was employed to examine the biosynthesis of GPIs and GPI-linked proteins/glycoproteins. The conserved glycan core of GPI anchors suggests a generally conserved biosynthetic pathway among different species, which has been depicted in *Fig. 2*.

The biosynthesis of GPI anchors begins with the transfer of GlcNAc to phosphatidylinositol (PI) from UDP-GlcNAc to form GlcNAc-PI, which is followed by de-*N*-acetylation to form GlcNH_2-PI. The third step in the biosynthetic pathway is the reversible acylation of the 2-*O*-position of the inositol ring. This acylation is dependent on the presence of acyl coenzyme A (acyl-CoA), and has been shown to be stimulated in cell-free systems by its mere presence [12]. Inositol acylation confers resistance of the final GPI anchor product to cleavage catalyzed by PI-specific phospholipase C (PI-PLC) [13,14]. Most GPI anchors undergo cleavage of this acyl group prior to the addition to protein; however, some GPI anchors, such as the procyclic acidic repetitive protein (PARP) of procyclic *T. brucei*, the human CD52 antigen, and the human acetylcholinesterase (AChE), retain the inositol acyl group [13,15,16,17,18,19,20,21,22,23]. Thereafter, the biosynthetic pathway is continued by sequential addition of three mannose residues from the donor dolicholphosphomannose (Dol-P-Man) catalyzed by GPI mannosyltransferases I, II, and III, respectively. The final biosynthetic step completing the GPI anchor core is addition of P-OEtNH_2 to the 6-*O*-position of the terminal mannose from donor phosphatidylethanolamine. Following this step, the original lipid anchors are replaced in a process called fatty acid remodeling [24,25]. The completed GPI core is then added to proteins/glycoproteins through what is thought to be a transamidation reaction. The addition of glycosyl side chains and other functional groups to the GPI anchor core occurs after the completed anchor core is added to proteins/glycoproteins.

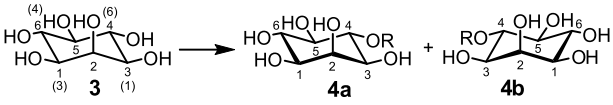
Notes: All membrane protein/glyocprotein GPI anchors contain the conserved structure shown above with various substituents (R^1-R^6) and lipids as noted. Brackets denote residues for which it has not been determined to which sugar the residue is linked. Question marks denote residues for which the position and orientation (α/β) of the linkage to the specified sugar have not been determined. A ± symbol was used where the associated residue is found only on a proportion of the structures. Other abbreviations include: n. d., complete structure not determined at a specified position; AG, acyl glycerol; alk-AG, alkyl acyl glycerol; NeuNAc, *N*-acetyl neuraminic acid (sialic acid); VSG, variant surface glycoprotein; PARP, procyclic acidic repetitive protein; PSP, promastigote surface protease; PsA, prespore-specific antigen; AChE, acetylcholinesterase; Prp, prion protein; FBP, folate binding protein

To date, more than 20 GPI anchors of extracellular proteins and glycoproteins have been characterized, all of which retain the general core structure described above. Some of these GPI anchors are depicted in *Table 1*. As shown, the structures of GPI anchors are highly diversified, and their structural diversity arises mainly from the variation in the side chains and other functional groups attached to the glycan core of GPIs, as well as the long lipid chains attached to the inositol residue. As a result, it is very difficult to obtain homogeneous GPI anchors and GPI-linked proteins and glycoproteins from nature, while the demand for these molecules from various studies has been ever growing. Consequently, the chemical synthesis of homogeneous and well-defined GPIs and related structures has become a very hot topic in carbohydrate research.

Thus far, a number of GPI anchors have been chemically synthesized [26,27], and there are many more reports about the chemical synthesis of related structures such as various inositol derivatives [28] and GPI fragments. For a short review like this, it is impossible to cover the literature completely. Therefore, this chapter will briefly summarize the recent developments in this field by especially focusing on the synthetic studies of intact GPI anchors, in their natural and unnatural forms, and GPI-linked glycoconjugates, as well as a few representative syntheses of some complex GPI core glycans by unique strategies such as solid-phase synthesis.

2 General Issues in GPI Synthesis

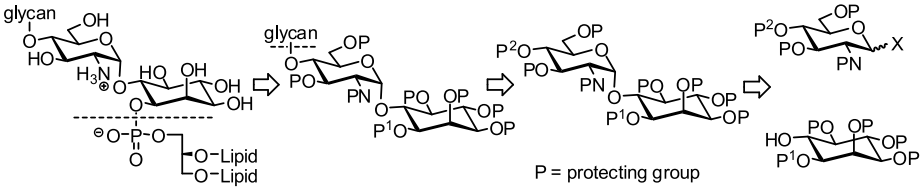
Consisting of carbohydrates, lipids, inositol, and often several phosphate moieties, the structure of GPI anchors is complex. Therefore, the chemical synthesis of GPIs denotes a significant challenge [27]. GPI anchors share some common structural features that deserve special consideration. First, all GPIs contain a *myo*-inositol residue **3** (*Scheme 1*) which, when free, is symmetric; thus, its positions 1 and 4 are chemically identical to positions 3 and 6, respectively. However, substitution at any of these sites will produce a racemic mixture, and commonly, *myo*-inositol in natural products, such as GPIs, are optically active. Consequently, the chemical synthesis of GPIs usually starts with the preparation of enantiomerically pure and 1,6-*O*- or 1,2,6-*O*-differentially protected *myo*-inositol derivatives, which itself poses an interesting problem in GPI synthesis [28]. Numerous strategies based on resolution of racemic mixtures or based on de novo synthesis [27,28] have been developed to deal with this problem, and some of these strategies will be discussed in the presentation of specific GPI anchor syntheses.



Scheme 1
The structure of *myo*-inositol and its optically active derivatives

Second, the glucosamine residue in the GPI core is linked to the inositol residue through an α-glycosidic linkage which is relatively difficult to achieve chemically. To facilitate the desired α-glycosylation during the coupling reaction between glucosamine and inositol, the amino group of a glucosaminosyl donor must be masked by a non-participating protecting group. For this purpose, most GPI syntheses employ derivatives of 2-azido-2-deoxy-D-glucose as donors,

because an azido group, which can be readily converted to a free amino group later on, may serve dually as a "latent amino group" and as a non-participating protecting group. Other non-participating protecting groups have also been used as well. Still, this glycosylation reaction often gives relatively low stereoselectivity or poor yield; therefore, it is usually realized at the initial stage of GPI synthesis (◉ *Scheme 2*).



◘ Scheme 2
Generally adopted retrosynthetic scheme for GPI syntheses

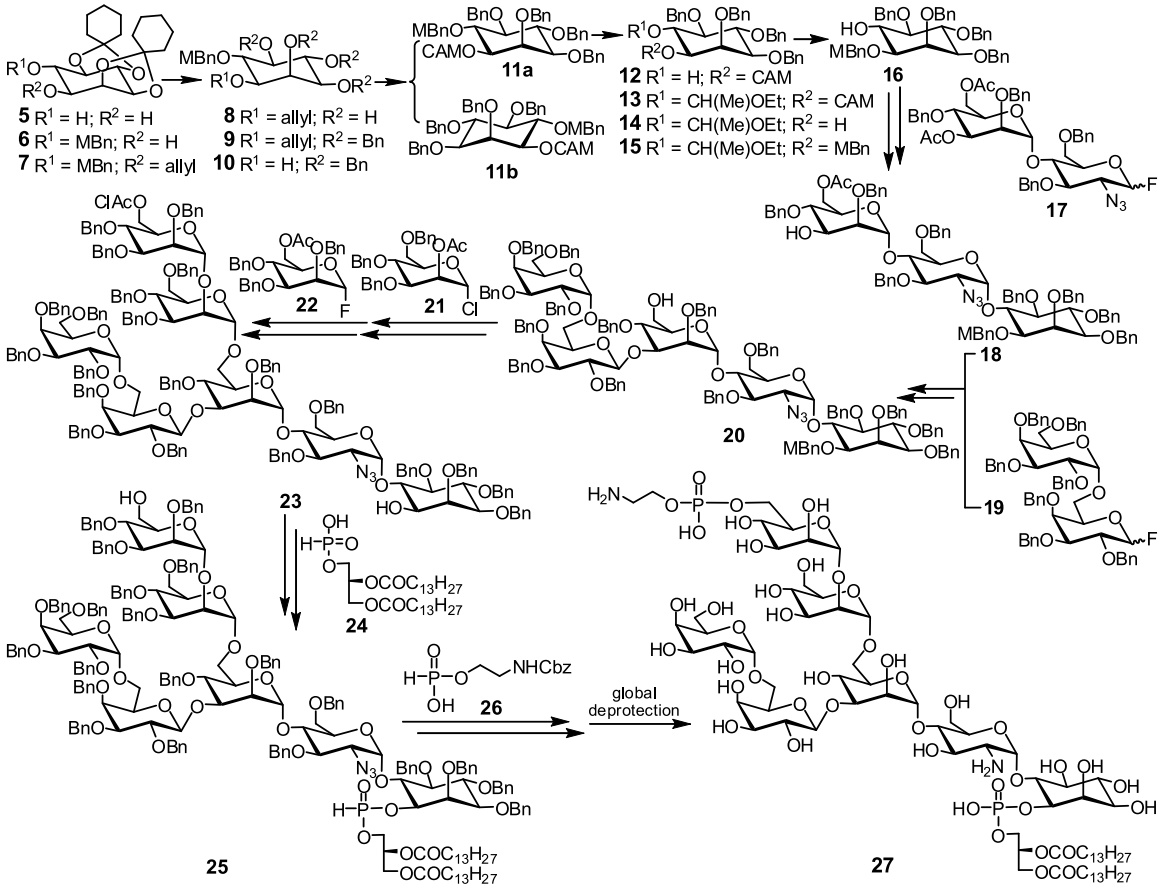
Third, including the phospholipid, all GPI anchors contain two or more phosphate moieties. Because of the concern of potential chemical incompatibility, the vast majority of reported GPI syntheses have adopted a strategy in which the phosphate functionalities are introduced at the final stage of the synthesis (◉ *Scheme 2*).

3 Chemical Synthesis of GPIs

3.1 Synthesis of the *T. brucei* GPI Anchor by Ogawa and Coworkers

Ogawa and coworkers [57,58,59,60,61] achieved the first total synthesis of a natural GPI anchor, i. e., the *T. brucei* GPI anchor, in 1991. They began their synthesis with the preparation of an optically active inositol derivative starting from the racemic diol **5** [62], as shown in ◉ *Scheme 3*. Diol **5** was treated first with dibutyltin oxide and then with 4-methoxybenzyl (MBn) chloride to give **6** (60%) which was readily converted to a tetraol **8** upon allylation and hydrolysis. After benzylation of the resulting tetraol, the allyl group was selectively removed to afford racemic **10**. To resolve the two enantiomers of **10**, it was transformed into diastereomeric (−)-ω-camphanates **11a** and **11b**, which were separable by column chromatography. After a series of manipulations of the protecting groups in **11a**, the desired alcohol **16** was obtained. In **16**, the 6-*O*-position was free and the 1-*O*-position was protected by an MBn group to differentiate them from other positions of inositol.

What was unique concerning this synthesis was that a disaccharide **17**, instead of a glucosamine derivative, was employed as a donor for the glycosylation of **16**. The reaction of glycosyl fluoride **17** and inositol derivative **16** was carried out in the presence of zirconocene dichloride and silver perchlorate in dry ether [63] to give the α- to β-pseudotrisaccharide with a 3.7 : 1 ratio. This was followed by deacetylation and regioselective acylation to give **18**. Subsequently, a galactobiose was introduced to **18** by the same glycosylation method to give the desired pentasaccharide (68%) along with 8% of its β anomer, which was followed by deacetylation. Further elongation of the resulting glycosyl acceptor **20** was realized by linear assembly of monosaccharides **21** and **22**. These glycosylation reactions were promoted by mercury(II)



Scheme 3
Ogawa's synthesis of the *T. brucei* GPI anchor

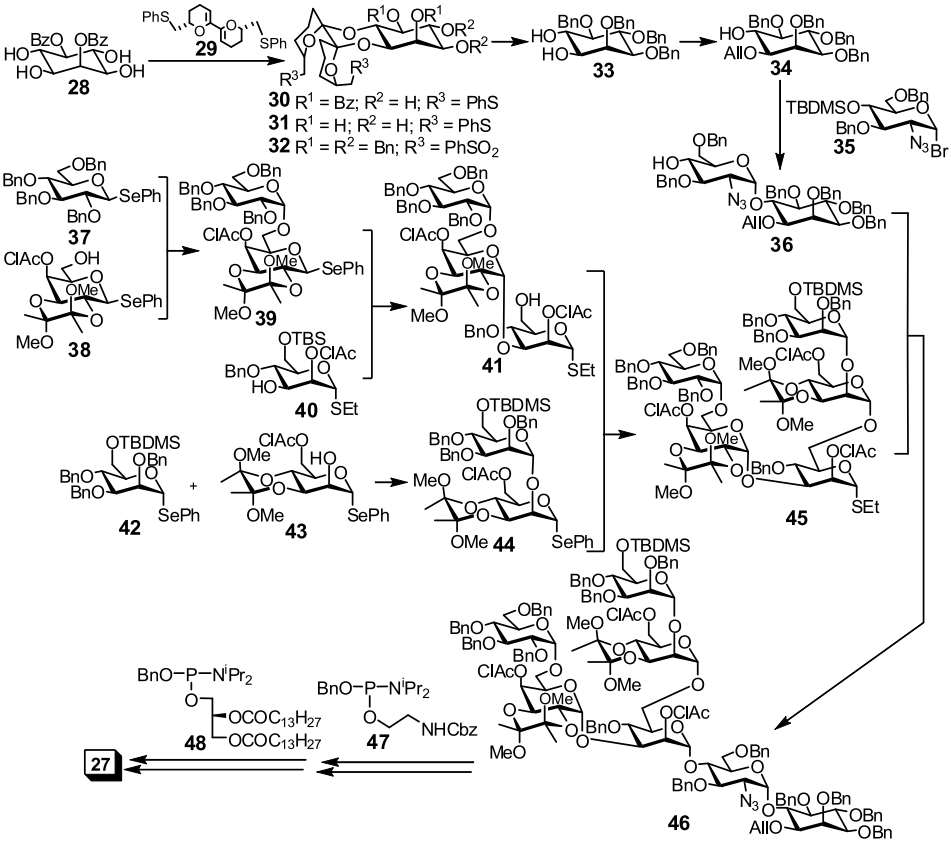
bromide/mercury(II) cyanide and zirconocene dichloride/silver perchlorate, respectively. Protecting group manipulation of the product eventually afforded **23** which was ready for introduction of the phosphate groups.

First, the phospholipid moiety was introduced to the 1-*O*-position of inositol by the phosphonate approach developed by Lindh and coworkers [64]. The reaction between **23** and **24** in the presence of pivaloyl chloride in pyridine gave the phosphitylation product in 64% yield. Next, the 2-chloroacetyl group (ClAc) on the non-reducing end mannose unit was selectively removed, and again the phosphonate approach was employed to attach a phosphityl group to the 6-*O*-position, which gave 40% yield of the desired product as a mixture of four diastereomers due to the presence of two chiral phosphorus atoms. It is worthy pointing out that the attempt to introduce a phosphodiester functionality to the non-reducing end mannose by the phosphorimidite method was unsuccessful. However, it was observed that, before phospholipidation of the inositol residue, phosphitylation of the non-reducing end mannose via the phosphorimidite methodology was successful, but removal of the MBn protection of the inositol group was a problem. Obviously, the functional groups on inositol could affect the reactivity of the non-reducing end mannose, and vice versa, even though these two residues seem well separated from each other. Finally, oxidation of the phosphitylation products with iodine (68%) followed by global deprotection by hydrogenolysis afforded the desired *T. brucei* GPI anchor **27**.

3.2 Synthesis of the *T. brucei* GPI Anchor by Ley and Coworkers

In their total synthesis of the *T. brucei* GPI anchor (◉ *Scheme 4*) [65,66], Ley and coworkers used a tetraol **28** [67] to prepare the asymmetric inositol derivatives. Its desymmetrization was realized by reacting with chiral bis(dihydropyran) **29** to offer a single diastereomer **30** (71%). Debenzoylation of **30** followed by benzylation and oxidation produced the sulfone **32**, of which the dispiroketal moiety was removed using lithium hexamethyldisilazide (LHMDS). Selective allylation of **33** by means of tin complex eventually gave the desired inositol derivative **34** (65%). Thereafter, **34** was glycosylated by bromide donor **35** using Lemieux's glycosylation protocol [68] to give the α-linked pseudodisaccharide with excellent selectivity, which was finally desilylated to yield the pseudodisaccharide acceptor **36**.

Further elongation of the carbohydrate chain of **36** was achieved in a highly convergent fashion (◉ *Scheme 4*). Therefore, after the properly protected monosaccharide units were obtained, they were assembled to form short oligosaccharide blocks, including a trisaccharide **41** and a disaccharide **44**. Then, **41** and **44** were coupled to afford a pentasaccharide **45**, which was finally linked to **36** to give the GPI backbone **46**. This convergent assembly was made possible largely owing to the successful use of selective glycosylation strategies based on "armed-disarmed" and semiorthogonal glycosyl donors. For example, the presence of a rigid cyclic 1,2-diketal group in **38** and **43** creates significant torsional strains in these structures, making them "disarmed" (less reactive); as a result, the armed glycosyl donors **37** and **42** could be selectively activated in the presence of **38** and **43**, even though all these substrates had the same phenylseleno group at their anomeric centers. On the other hand, because selenoglycosides are more reactive than thioglycosides, it was also possible to activate glycosyl donors **39** and **44** in the presence of **40** and **41**, respectively, to achieve their selective glycosylations. Meanwhile,

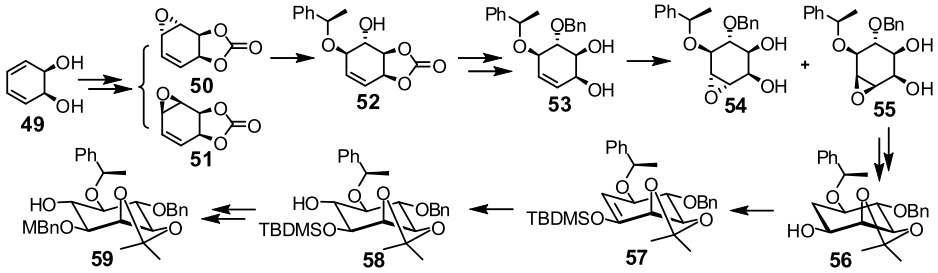


Scheme 4
Ley's synthesis of the *T. brucei* GPI anchor

thioglycoside **45** was activated by a stronger promoter to be directly used as a donor for glycosylation of the pseudodisaccharide **36**. By using selective activation for glycan assembly, transformations required to manipulate the anomeric centers in the traditional glycosylation methods were eliminated. Consequently, this synthesis could effectively save a few potentially necessary synthetic steps.

For installing the phosphate functionalities, the phosphorimidite method was employed. First, the *t*-butyldimethylsilyl (TBDMS) group on the non-reducing end mannose unit was selectively removed for the successful attachment of a P-OEtNH$_2$ group following tetrazole-promoted phosphitylation by phosphorimidite **47** and oxidation by *m*-chloroperbenzoic acid (*m*-CPBA). The phospholipid moiety was introduced to the inositol 1-*O*-postion by the same method using **48**. Finally, global deprotection was achieved in three steps to afford the *T. brucei* GPI anchor **27**.

Ley and coworkers [69,70,71] have also developed a de novo synthesis of optically pure derivatives of inositol starting from benzene (*Scheme 5*). Conversion of benzene to an optically

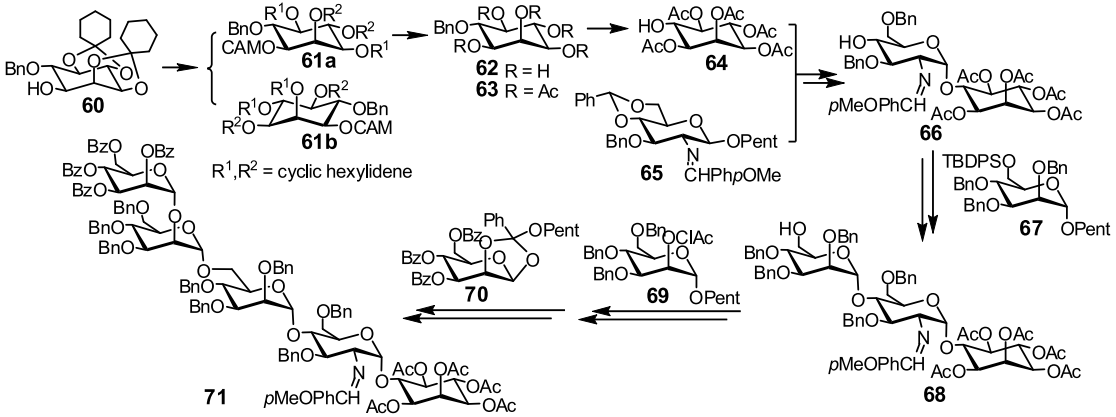


Scheme 5
Ley's alternative synthesis of the optically pure inositol derivative

active diol **49** by microbial oxidation was achieved with *P. putida*, and subsequent acylation gave a cyclic carbonate which was stereoselectively epoxidized by *m*-CPBA to form the α- and β-epoxides **50** and **51** in a 4.6 : 1 ratio. Epoxide ring opening of **50** by 1-phenyl ethanol with camphorsulfonic acid as catalyst proved to be regioselective, which was followed by benzylation and deacylation to produce **53**. Epoxidation of **53** using *m*-CPBA afforded **54** and **55** in a 1 : 9 ratio. Separation of the epoxides was more easily achievable after their conversion to acetonides, and then, the desired product was subjected to regioselective ring opening by lithium aluminum hydride to yield **56** (81%). Further oxidization with tetrapropylammonium perruthenate (TPAP) and subsequent treatment with TBDMS chloride gave a silyl enol ether **57**. Hydroboration of **57** turned out to be regio- and stereoselective to afford the differentially protected *myo*-inositol derivative **58**. An interesting feature of this reaction was the silyl migration from C1 to C6, occurring prior to *p*-methoxybenzylation of C-1. Further manipulation of protecting groups gave **60** that was used to construct a partial structure of the *T. brucei* GPI anchor, following a strategy similar to that discussed above.

3.3 Synthesis of the GPI Anchors of Rat Brain Thy-1 and *P. falciparum* by Fraser-Reid and Coworkers

In their synthesis of the glycan core of GPIs, Fraser-Reid and coworkers [72] developed a strategy to synthesize optically pure inositol derivatives (*Scheme 6*), which was similar to that of Ogawa and coworkers [57,58,59,60,61] in that both started from **2** and both used camphanic acid to resolve the enantiomers. However, after regioselective benzylation via phase transfer catalysis to get racemic **60**, Fraser-Reid and coworkers [73] immediately resolved it into **61a** and **61b** [74]. Following further manipulation of the protecting groups, an optically pure inositol derivative **64** was obtained, which only had the 6-*O*-position differentiated. Evidently, **64** was only suitable to synthesize the GPI glycan core but not the whole GPI, since regioselective 1-*O*-phospholipidation of the inositol residue was impossible. Compound **64** was subsequently glycosylated by **65**, and the product was subjected to reductive ring opening by sodium cyanoborohydride to produce pseudodisaccharide **66** in a good overall yield. In **65**, the glucosamine amino group was protected with the non-participating *p*-methoxybenzaldehyde to promote α-glycosylation. The carbohydrate chain was further elongated by sequential assem-



Scheme 6
Fraser-Reid's synthesis of the core glycan of GPI anchors

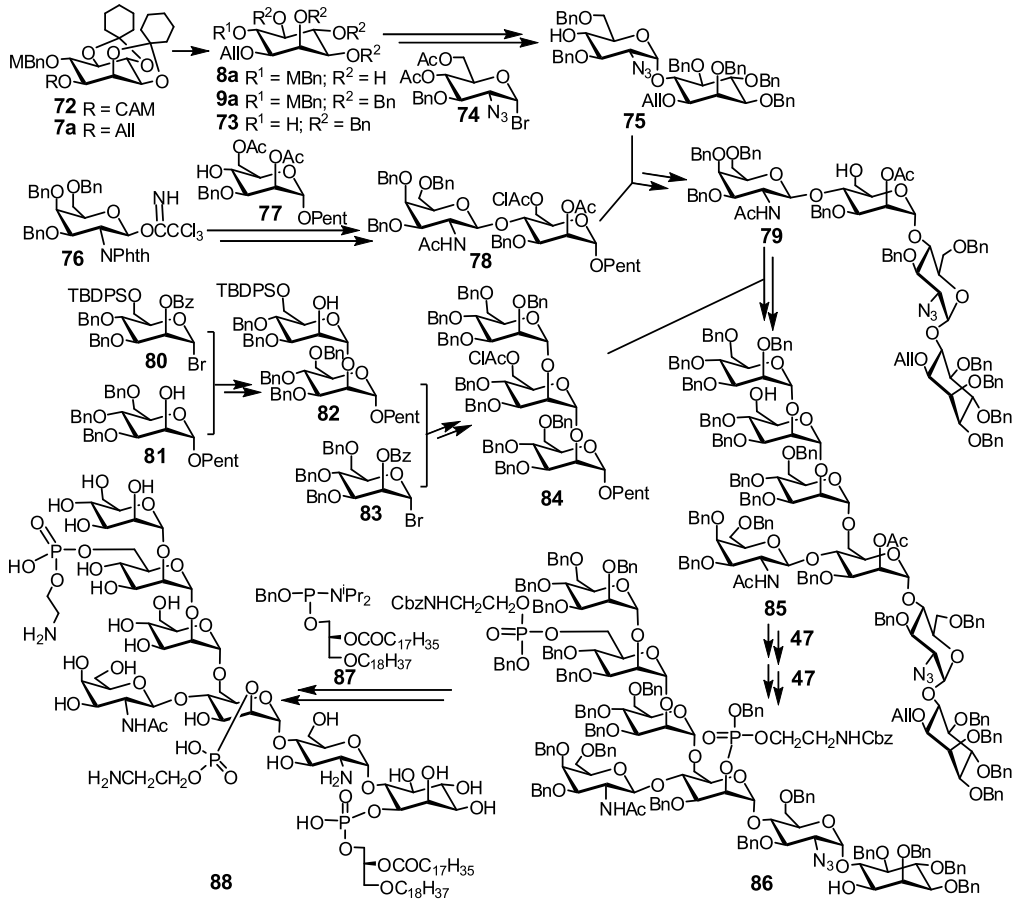
bly of monosaccharides **67**, **69**, and **70** to yield the GPI core glycan. In this synthesis, all glycosidic linkages were constructed by their own glycosylation method using *n*-pentenyl glycosides or *n*-pentenyl orthoesters as donors. It is interesting to point out that an attempt to prepare the same structure by direct coupling of a disaccharide unit to **68** was unsuccessful.

In their total synthesis of a fully phosphorylated GPI anchor of rat brain Thy-1, Fraser-Reid and coworkers [75,76,77,78] developed a process to prepare optically pure inositol derivatives with 1-*O*- and 6-*O*-positions differently protected (*Scheme 7*). Therefore, after **2** was *p*-methoxybenzylated to get **6** along with its regioisomer, the two enantiomers of **6** were resolved as camphanates to obtain the desired diastereomer **72**. Then, the camphanoic group in **72** was replaced with an allyl group, and the optically pure product **7a** was treated with acid to remove the ketals, followed by benzylation. The regioisomer of **6** was also treated by a similar procedure and converted to **9a**. Thereafter, MBn was removed under acidic conditions, and the resultant **73** was coupled to the azido sugar **74** using silver perchlorate as a promoter [79] to afford the α-product in a 63% yield along with 22% of the β-anomer. Further manipulation of the protecting groups eventually afforded the pseudodisaccharide **75** as a glycosyl acceptor.

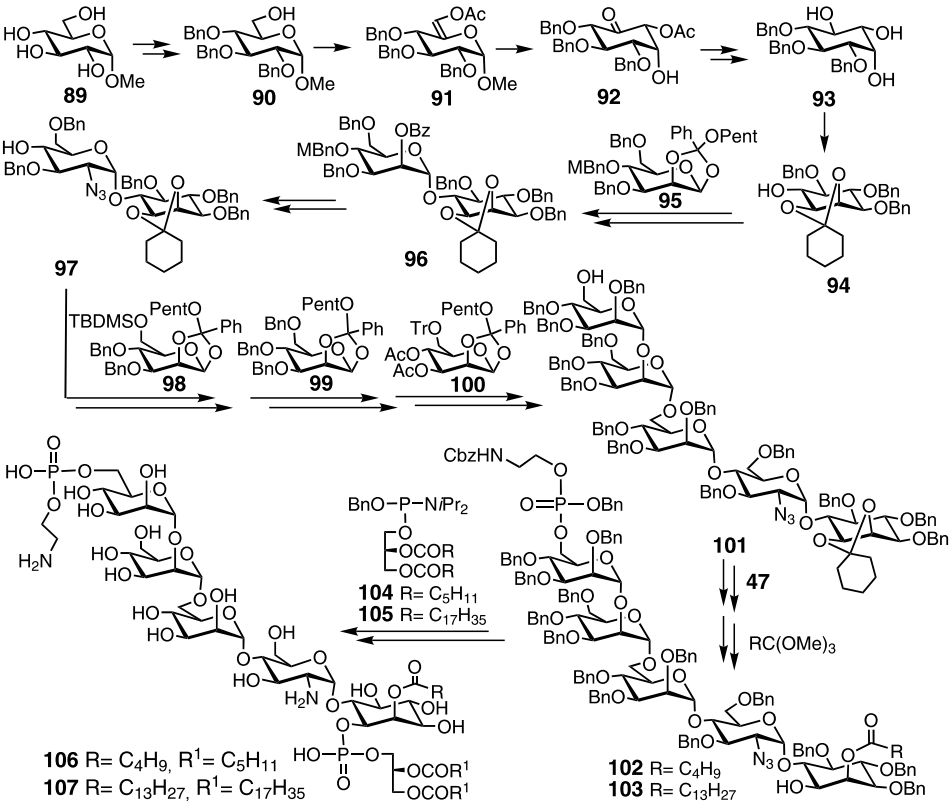
A highly convergent strategy was employed to assemble the desired GPI (*Scheme 7*). After **75** was available, a disaccharide **78** and a trisaccharide **84** were prepared from properly protected and activated monosaccharides via semiorthogonal glycosylations. Then, **78** was coupled to **75** first with *N*-iodosuccinimide (NIS) as a promoter, which was followed by coupling of the resultant tetrasaccharide **79** to **84** to yield the GPI glycan **85**. The dechloroacetylation steps were achieved with thiourea. Next, two phosphoethanolamine functionalities were separately introduced to Man-I and Man-III by the phosphorimidite method described above. The phospholipid moiety was introduced to **86** also by the phosphorimidite method to finally afford a mixture of all eight stereoisomers of the fully protected GPI. Global deprotection was performed by hydrogenolysis over palladium hydroxide to give the GPI anchor **88** of rat brain Thy-1.

Fraser-Reid and coworkers [80] also developed another method to prepare optically pure inositol derivatives using methyl α-D-glucopyranoside **89** as the starting material (*Scheme 8*). After **90** was obtained from **89** via several steps of protecting group manipulation, it was converted to an enol acetate **91**. Next, stereoselective Ferrier reaction of **91** afforded the cyclic hexanone derivative **92** (63%). Eventually, the inositol derivative **93** was obtained after chelation-mediated reduction and subsequent methanolysis to remove the acetyl group. Regioselective 1,2-*O*-protection of the triol **93** by a cyclohexylidene group was possible to afford the glycosyl acceptor **94** which was used to synthesize the *P. falciparum* GPI anchor [81].

In their synthesis of *P. falciparum* GPI anchor, Fraser-Reid and coworkers [81,82] utilized a unique strategy to achieve the pseudodisaccharide. As shown in *Scheme 8*, a mannose donor **95**, instead of a glucosamine derivative, was employed to glycosidate **94** to give a benzoylated pseudodisaccharide **96** in an excellent yield (99%). After the benzoyl group was replaced with a triflic group, Deshong's azide displacement method [83] was used to transform the mannose unit into an azido sugar, which served as a latent glucosamine unit, and give pseudodisaccharide **97**. Further elongation of the GPI glycan was realized by linear assembly of monosaccharides **98**, **99**, and **100**. After the GPI glycan was constructed, the trityl group on the nonreducing end mannose residue was removed to give **101**, to which a phosphoethanolamine group was introduced by the phosphorimidite method. This was followed by acidic removal of the cyclohexylidene group of the inositol moiety and regioselective 2-*O*-acylation of the



Scheme 7
Fraser-Reid's synthesis of the rat brain Thy-1 GPI anchor

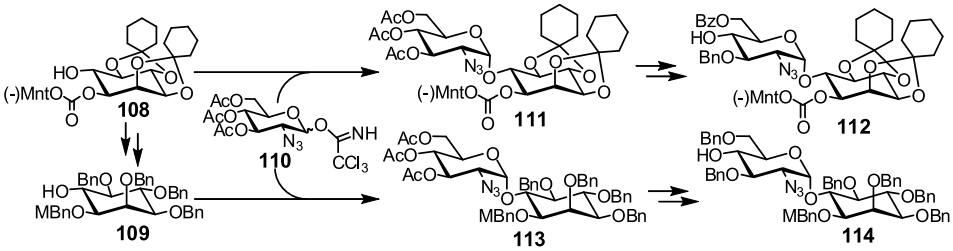


Scheme 8
Fraser-Reid's synthesis of the *P. falciparum* GPI anchor

resultant diol based on stereoelectronic ring opening of a cyclic orthoester developed by King and Allbutt [84]. Accordingly, treatment of the diol with trimethyl orthoesters produced the corresponding cyclic orthoesters that were treated with ytterbium(III) triflate to afford **102** and **103** as major products. Phospholipidation of the free inositol hydroxyl group was achieved through reaction with **104** or **105** followed by one pot oxidation using *m*-CPBA. Hydrogenolysis over Pearlman's catalyst finally gave the fully deprotected *P. falciparum* GPI anchors **106** and **107**. An important conclusion about 2-*O*-acylated derivatives of GPIs was that no sign of acyl migration was observed over a period of several months based on ^{1}H NMR studies.

3.4 Synthesis of the GPI Anchors of Rat Brain Thy-1, *T. gondii*, and *S. cerevisiae* by Schmidt and Coworkers

As shown in *Scheme 9*, two types of inositol derivatives were prepared and used by Schmidt and coworkers [85,86,87,88,89] in their synthesis of several GPI anchors. The synthesis of *S. cerevisiae* GPI started with optically pure **108** [86,90], while the syntheses of Thy-1 [87,88]

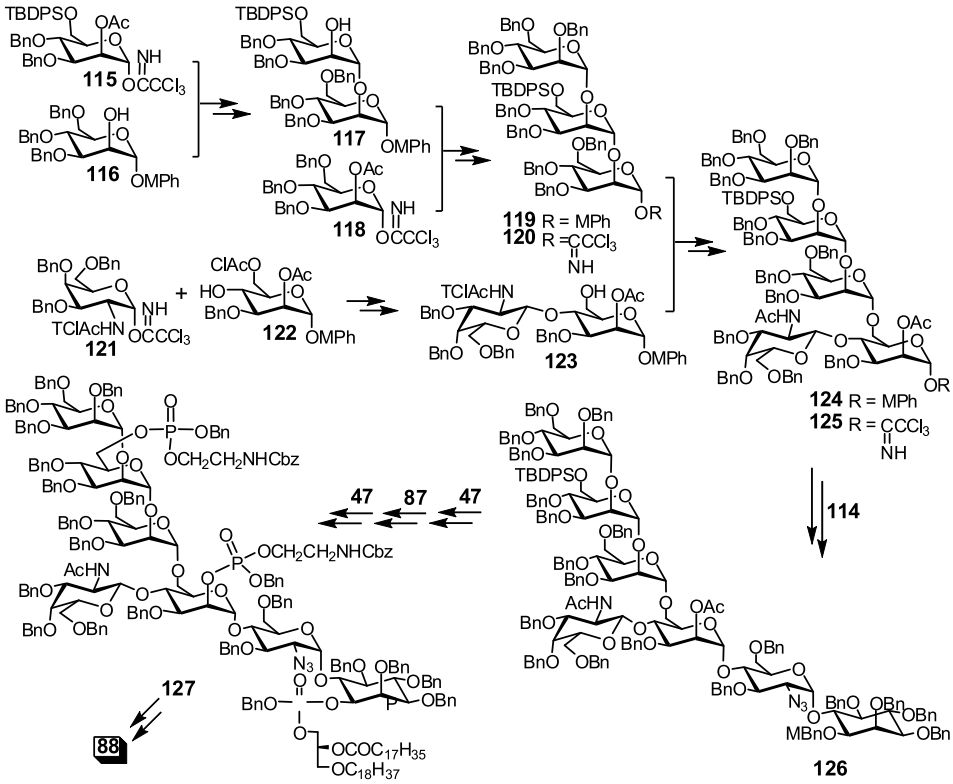


Scheme 9
Schmidt's synthesis of the pseudodisaccharides as glycosyl acceptors

and *T. gondii* [89] GPIs started with **109**. Treating **2** [62] with bis(tributyltin)oxide followed by (−)-menthyl chloroformate led to **108** and its diastereomer that were easily separable by crystallization in petroleum ether [91]. Compound **108** was then converted to **109** following a series of transformations including replacement of the menthyloxycarbonyl group with an MBn group, acid-catalyzed hydrolysis of the cyclohexylidene groups, benzylation of the exposed hydroxyl groups, and finally, selective 6-de-*O*-allylation. The trichloroimidate glycosylation method using **110** as a glycosyl donor was used to introduce the α-linked glucosamine unit to **108** and **109**. The reaction of **108** and **110** afforded **111** exclusively, which, after protecting group manipulation, was converted to **112** that was used to synthesize *S. cerevisiae* GPI [85,86]. On the other hand, the reaction of **109** and **110** gave **113** exclusively, which was converted to **114** following deacetylation, 4,6-*O*-benzylidenation, 3-*O*-benzylation, and then regioselective opening of the benzylidene ring. Pseudodisaccharide **114** was used to synthesize rat brain Thy-1 [87,88] and *T. gondii* [89] GPI anchors.

The heptaosyl core of rat brain Thy-1 GPI was constructed by a highly convergent approach (*Scheme 10*) [87], beginning with the preparation of the trimannose **120** and disaccharide **123** blocks. So, after monosaccharides **115**, **116** and **118** were obtained, they were assembled to form **119** by the trichloroimidate glycosylation method. Then, the reducing end of **119** was selectively deprotected by oxidative removal of the *p*-methoxyphenyl group followed by reaction with trichloroacetonitrile to form trichloroacetimidate **120** that was used as a glycosyl donor. Meanwhile, glycosylation of **121** by **122** and then selective removal of ClAc group by thiourea afforded the glycosyl acceptor **123**. Next, **120** and **123** were coupled to give α- and β-linked pentasaccharides in a 94% yield and 9 : 4 ratio. The *N*-trichloroacetyl group (TClAc) in the desired α-pentasaccharide was then changed to the acetyl group by treatment with tributyltin hydride and azoisobutyronitrile (AIBN) [92] to give **124** that was converted to trichloroacetimidate **125** as described above. The pentasaccharide was coupled to pseudodisaccharide **114** to give the glycan core **126**. Thereafter, the 2-*O*-, 1-*O*-, and 6-*O*-positions of Man-I, inositol, and Man-III were sequentially deprotected and phosphorylated using **47**, **87**, and **47**, respectively, to give the fully protected GPI anchor **134**. Finally, **134** was deprotected to yield the free GPI anchor **88** of rat brain Thy-1.

In another synthesis of the rat brain Thy-1 GPI anchor, Schmidt and coworkers [88] have adopted the linear strategy to construct the pentasaccharide building block. As shown in *Scheme 11*, after all monosaccharide units were obtained, they were assembled sequentially by the trichloroimidate glycosylation method to form pentasaccharide **130**. It was manipulated

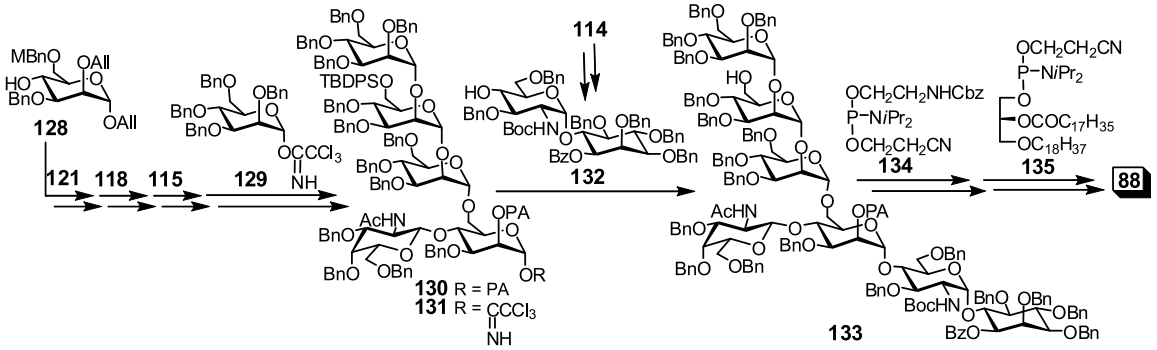


Scheme 10
Schmidt's synthesis of the rat brain Thy-1 GPI anchor

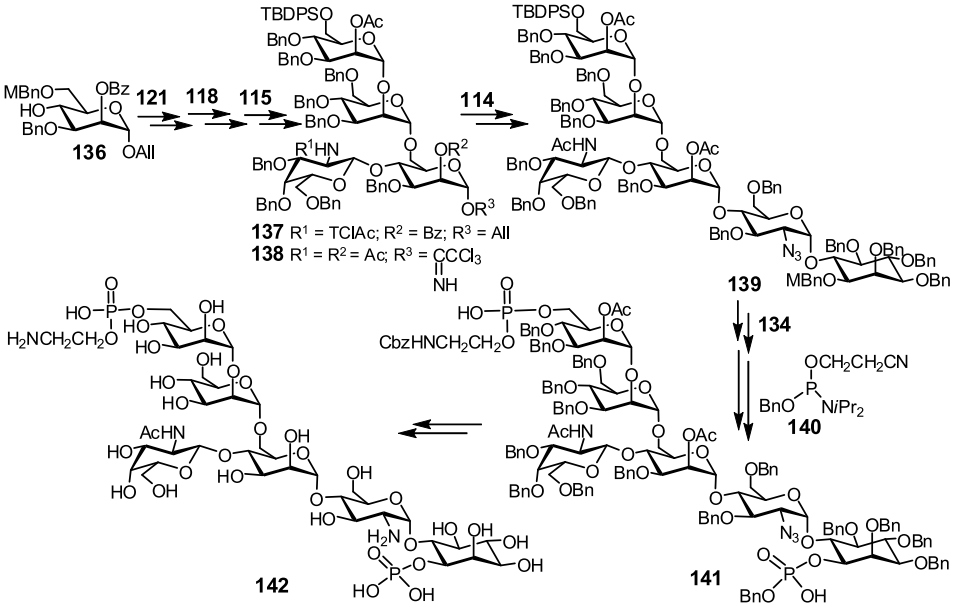
by the same procedure described above to give trichloroimidate donor **131** and then coupled to **132** that was derived from **114** to subsequently afford the core heptasaccharide **133**. The phosphate moieties were installed by the phosphorimidite method using **134** and **135** as substrates. In this synthesis, the cyanoethyl group was employed as a protecting group of phosphorimidites and phosphates. The cyanoethyl group could be removed concomitantly during the deprotection of the phenoxyacetyl and benzoyl groups. Global deprotection of the protected GPI anchor in two steps eventually produced the free GPI anchor **88** of rat brain Thy-1.

By similar strategies, Schmidt and coworkers have also prepared a partial structure of the GPI anchor of *T. gondii* (*Scheme 12*) [89]. First, the trichloroacetimidate **138** of a tetrasaccharide as the glycosyl donor was prepared and utilized to glycosidate pseudodisaccharide **114**. The resultant hexasaccharide **139** was then selectively deprotected and phosphorylated at Man III and inositol respectively to yield **141**. Quantitative deacylation followed by debenzylation over Pearlman's catalyst gave the deprotected GPI anchor **142** in a 92% yield.

Furthermore, Schmidt and coworkers [86,90] also achieved the *S. cerevisiae* GPI anchor (*Scheme 13*). After a tetramannose block **144** was assembled from monosaccharides **143**,



Scheme 11
Schmidt's alternative synthesis of the rat brain Thy-1 GPI anchor

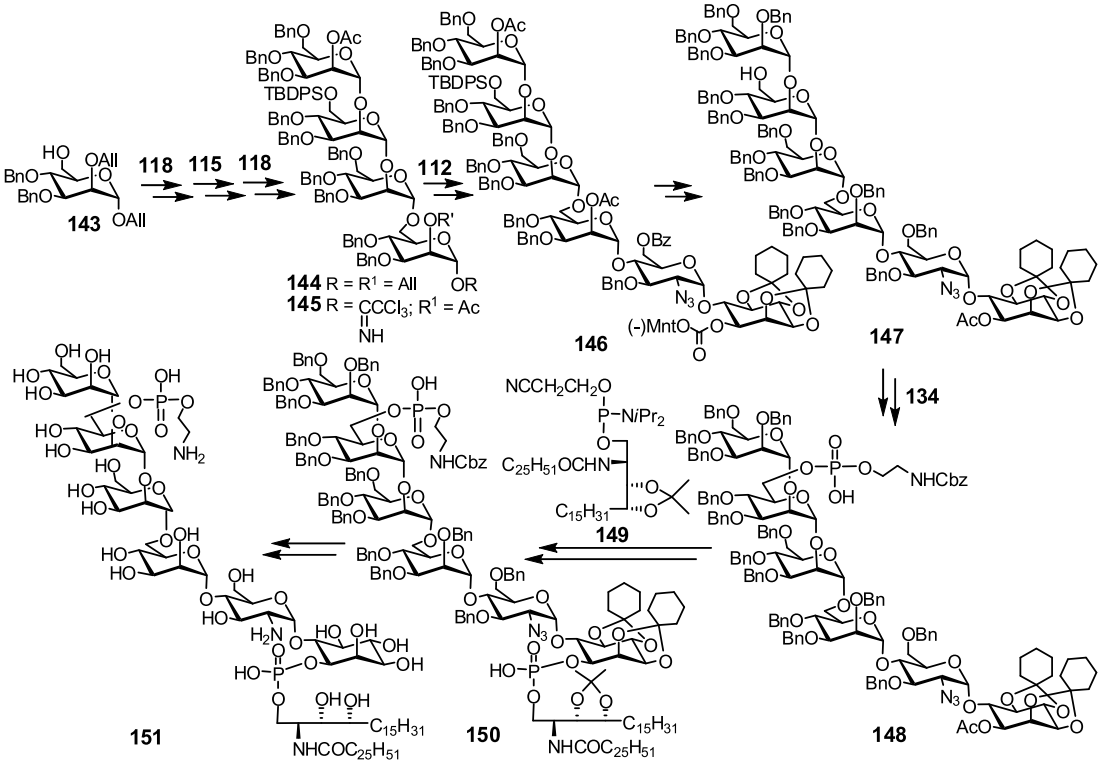


Scheme 12
Schmidt's synthesis of the *T. gondii* GPI anchor

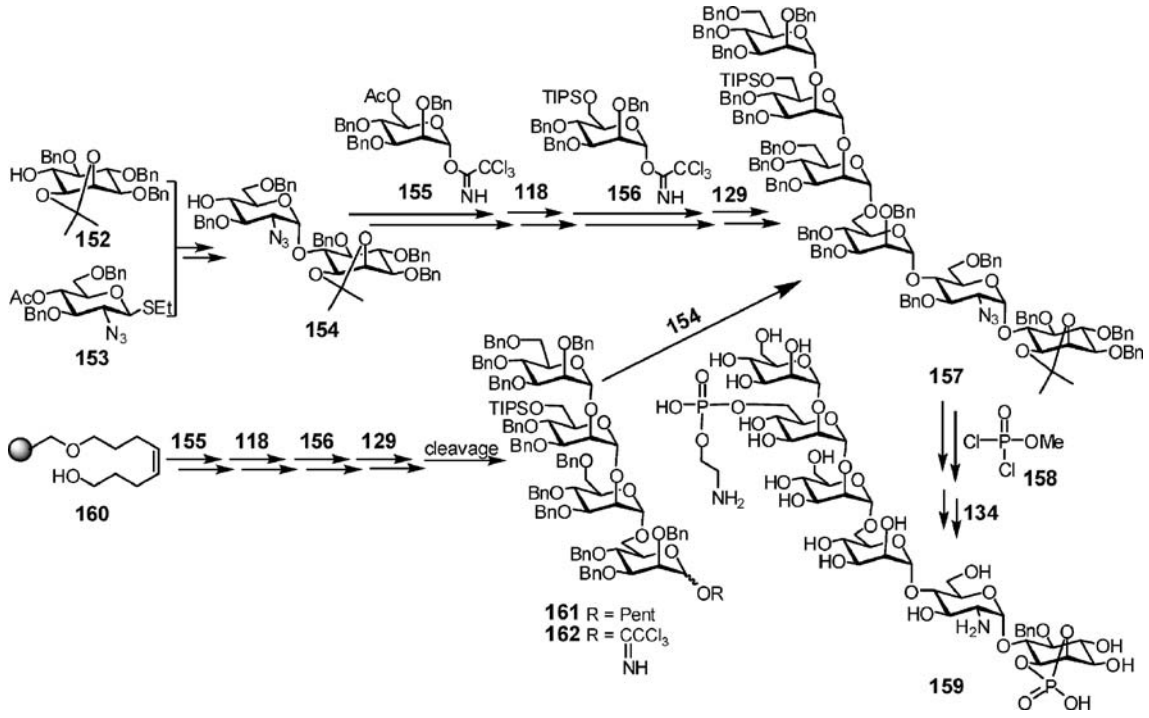
115, and **118** in a linear fashion, it was converted to the glycosyl donor **145** following a series of protecting group manipulation and trichloroacetimidation. Then, **145** was coupled to the pseudodisaccharide **112** to yield the hexasaccharide core **146** of *S. cerevisiae* GPI anchor. Further modification of protecting groups afforded **147** which was ready for installing the phosphate moieties. The phosphate attached to 6-*O*-position of Man III was introduced first using **134**, which was followed by phospholipidation using **149** to give the fully protected GPI anchor **150**. Finally, all protecting groups were removed to produce the free GPI anchor **151** of *S. cerevisiae*.

3.5 Synthesis of the GPI Anchor of *P. falciparum* by Seeberger and Coworkers

Seeberger and coworkers have achieved the non-lipidated GPI anchor of *P. falciparum* by both solution phase [93] and solid phase [94] synthesis (*Scheme 14*). Their syntheses started from the optically pure inositol derivative **152** which was prepared according to a method reported by Fraser-Reid and coworkers [80,81]. After **152** was coupled to an azido sugar by the thioglycoside glycosylation method to get pseudodisaccharide **154**, further elongation of its carbohydrate chain was realized by either linear assembly or coupling of a tetrasaccharide block prepared by solid-phase synthesis. In the first case, monosaccharide units were installed through a series of glycosylation reactions performed in solution to the give fully protected pseudohexasaccharide **157**. In the later case, a tetrasaccharide was first assembled on the Mer-



Scheme 13
Schmidt's synthesis of the *S. cerevisiae* GPI anchor

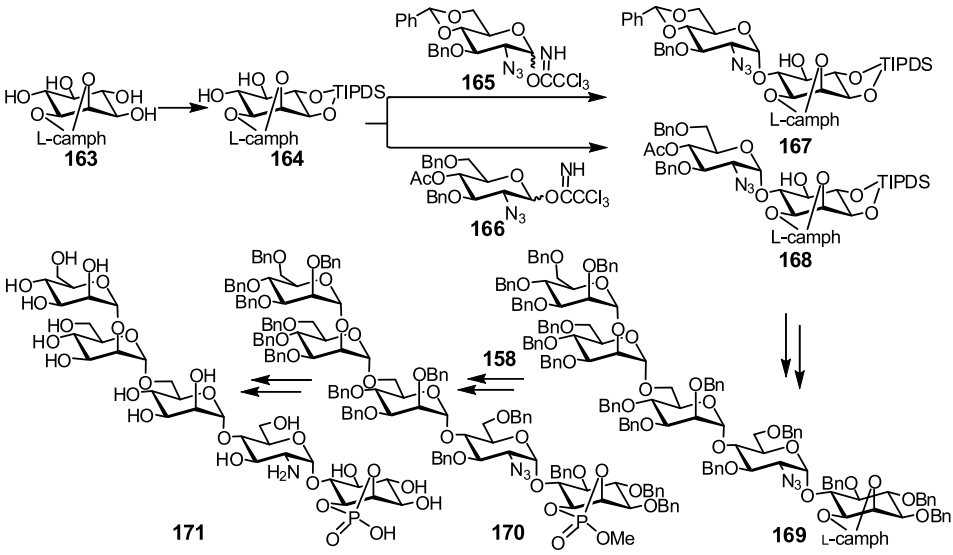


Scheme 14
Seeberger's synthesis of the *P. falciparum* GPI anchor

rifield resin with octenediol as a linker [95]. After the resin was treated with Grubb's catalyst in an ethylene atmosphere, the *n*-pentenyl glycoside **161** was obtained. The attempt to directly couple **161** to **154** failed; therefore, **161** was converted to trichloroacetimidate **162**. Glycosylation of **154** with **162** as a donor produced the desired GPI glycan core **157** in a 32% yield. Thereafter, the isopropylidene group on the inositol residue was removed, and to the exposed hydroxyl groups was introduced a cyclic phosphate using **158**. A phosphoethanolamine group was finally attached to the nonreducing end mannose, which was followed by global deprotection to afford the non-lipidated GPI anchor **159** of *P. falciparum*. The product was linked to a carrier protein to form a promising glycoconjugate vaccine [93].

3.6 Synthesis of the Core Glycan of GPI Anchors by Martin-Lomas and Coworkers

Martin-Lomas and coworkers [96] desymmetrized *myo*-inositol according to a procedure originally reported by Bruzik and Tsai [97]. Reaction of *myo*-inositol with L-camphor dimethyl ketal followed by resolution of the diastereomeric products gave optically pure ketal **163** in a 39% yield. Treatment of **163** with 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane ($TIPDSCl_2$) gave the diol **164** (93%), the 6-*O*-position of which could be regioselectively glycosylated to afford desired pseudodisaccharides (*Scheme 15*) [98]. Glycosylation of **164** with **165** as a donor offered good stereoselectivity (α/β 5.5 : 1) but poor regioselectivity, as 16% of the 5-*O*-glycosylation product was formed. The glycosylation of **164** with **166** as a donor gave the pseudodisaccharides in a 75% yield as a 3 : 2 mixture of α- and β-anomers. The latter synthetic route was more practical due to its higher yield and easy separation of the anomers. After iso-



Scheme 15
Martin-Lomas's solution-phase synthesis of the glycan core of GPI anchors

lation and then deacetylation of the desired product **168**, its carbohydrate chain was elongated to get **169**. Thereafter, the L-camphor ketal was selectively removed, which was followed by phosphorylation to form a cyclic phosphate. Global deprotection with concomitant reduction of the azido group eventually afforded the monophosphorylated GPI glycan **171**.

Martin-Lomas and coworkers [99] have also studied solid-phase synthesis of the glycan core of GPI anchors (*Scheme 16*). However, the pseudodisaccharide was prepared first in solution and then attached to the resin. This can avoid solid-phase formation of the problematic glycosidic linkage, so as to increase the efficiency of solid-phase synthesis and the product purification. The carbohydrate chain was elongated through sequential introduction of monosaccharide units **173**, **174** and **175** by the trichloroimidate glycosylation method. The 9-fluorenylmethoxycarbonyl (Fmoc) group which can be easily removed under moderate basic conditions was utilized as the temporary protection of the involved hydroxyl groups. The resultant glycan core **176** was finally released from the resin and isolated in a 20% overall yield.

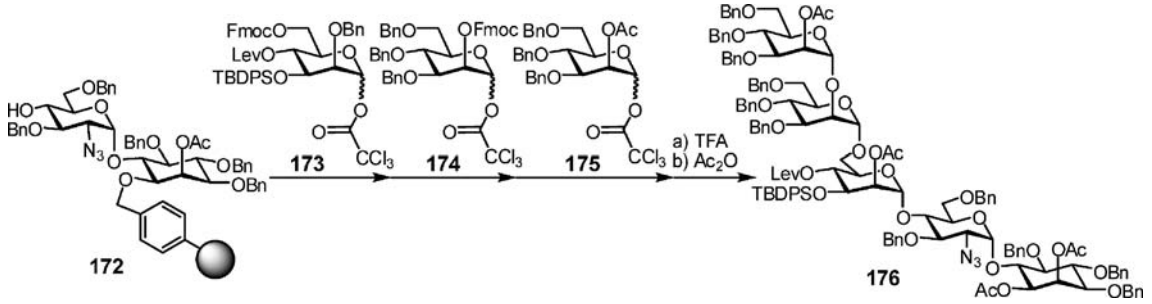
3.7 Synthesis of the *T. cruzi* GPI Anchor by Vishwakarma and Coworkers

An important feature of the synthesis of *T. cruzi* GPI reported by Vishwakarma and coworkers (*Scheme 17*) [100] was that the racemic mixture of an inositol derivative **177** was employed to prepare the desired pseudodisaccharide. After glycosylation with **110** as a glycosyl donor, a mixture of diastereomeric pseudodisaccharides **178** (1 : 1) was obtained. These diastereomers were modified and then separated by silica gel column chromatography to produce the desired isomer **114**. In this way, the process of resolving a racemic mixture was avoided. The carbohydrate chain elongation of **114** was achieved in a highly convergent fashion. Therefore, two disaccharides **181** and **183** were prepared first and then coupled to form the tetramannose segment **184**. Next, **184** was coupled to pseudodisaccharide **114** to yield the GPI glycan core **185** of *T. cruzi* GPI anchor. Thereafter, the 6-*O*-position of Man III was deprotected and phosphorylated, which was followed by deprotection of inositol 1-*O*-position and phospholipidation. Global deprotection and concomitant reduction of the azido group was realized by hydrogenation to eventually afford the *T. cruzi* GPI anchor containing saturated lipid chains.

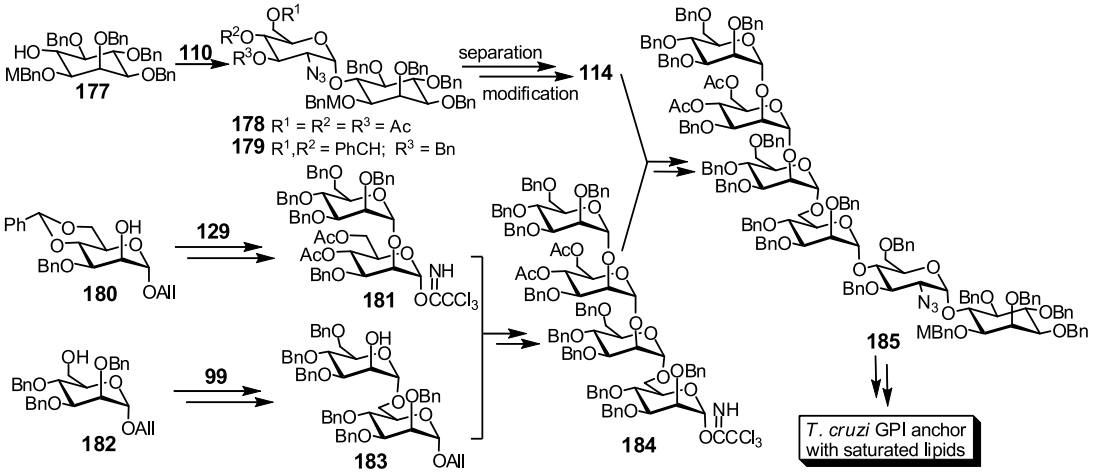
3.8 Synthesis of the *T. cruzi* GPI Anchor by Nikolaev and Coworkers

One of the most outstanding features of the GPI synthesis reported by Nikolaev and coworkers (*Scheme 18*) [101] was that the benzoyl group (Bz), instead of the benzyl group (Bn), was utilized as the permanent protecting group. Since Bz can be selectively removed under basic conditions at the final stage, this allowed the presence of unsaturated lipid chains in the synthetic GPI anchor, which was not easily achievable when Bn was employed as the permanent protecting group in most other syntheses.

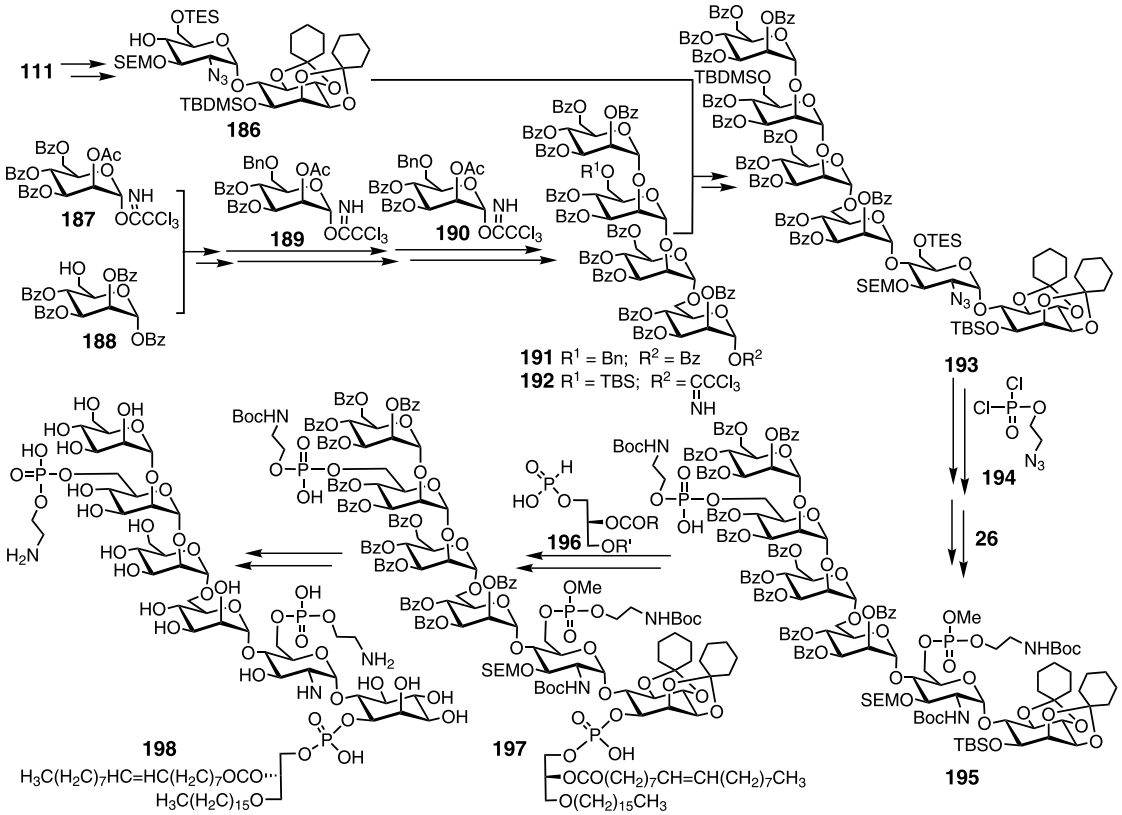
For pseudodisaccharide synthesis, Nikolaev and coworkers [101] adopted a strategy similar to that of Schmidt and coworkers [86,90], using the diastereomeric (−)-menthyl carbonates of inositol as the starting materials. However, instead of separating the diastereomeric mixture at the initial stage and using optically pure inositol derivative for glycosylation, both **108** and its diastereomer were glycosylated by **110**, and the diastereomeric pseudodisaccharides



Scheme 16
Martin-Lomas's solid-phase synthesis of the glycan core of GPI anchors



Scheme 17
Vishwakarma's synthesis of the *T. cruzi* GPI anchor



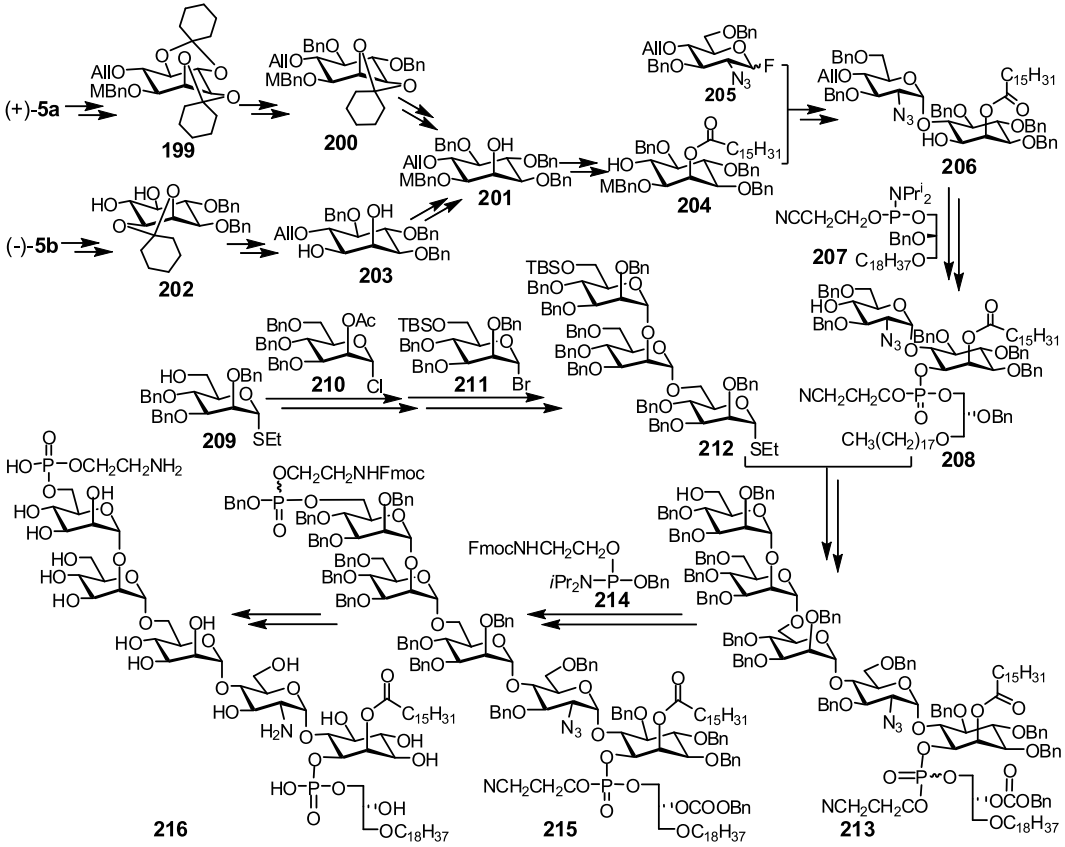
Scheme 18
Nikolaev's synthesis of the *T. cruzi* GPI anchor

were then separated to obtain the desired isomer **111**. After manipulation of the protecting groups, the product **186** was applied to carbohydrate chain elongation, which was achieved in a convergent fashion. Thus, a tetramannose segment **191** was first constructed through sequential assembly of monosaccharide units **187–190** and protecting group manipulation. Then, the tetrasaccharide was coupled to **186** to obtain the GPI glycan core **193** of *T. cruzi*, which was followed by sequential deprotection and phosphorylation of the glucosamine 6-*O*-position and Man III 6-*O*-position, respectively. Finally, the inositol 1-*O*-position was selectively deprotected and phospholipidated to produce the protected GPI anchor **197**. Global deprotection of **197** was achieved in 3 separate steps, namely, removal of the methyl phosphate by thiophenol, de-*O*-benzoylation using 0.05 M sodium methoxide in methanol, and then removal of the *t*-butyloxycarbonyl (Boc) groups by 10% trifluoroacetic acid (TFA) in water, to afford the free GPI anchor **198** of *T. cruzi* that contained an unsaturated lipid chain.

3.9 Synthesis of the Human Sperm CD52 GPI Anchor by Guo and Coworkers

As mentioned above, the GPI anchor of CD52 antigen retains the inositol 2-*O*-acyl group, which will increase the synthetic challenge, including the preparation of necessary inositol derivatives and the assembly of the target structure. Guo and coworkers [102,103] started their synthesis with the preparation and resolution of enantiomers **5a** and **5b** according to the reported chemoenzymatic procedure [104]. Both optically pure enantiomers **5a** and **5b** were used to synthesize the same inositol derivative **201**, in which the 1-*O*-, 2-*O*-, 6-*O*-positions were differentiated from each other and from other inositol positions as well (➤ *Scheme 19*). These syntheses were highlighted by several steps of regioselective deprotection reactions and tin-complex directed regioselective alkylation reactions. After **201** was obtained, a palmitoyl group was introduced to its 2-*O*-position, which was followed by deallylation to give **204** that was ready for installation of the carbohydrate chain. The glucosamine unit was introduced first with glycosyl fluoride **151** as a donor, affording a mixture that contained both α- and β-pseudodisaccharides, slightly in favor of the former (4 : 3). These isomers were easily separated after removal of the MBn group to obtain the desired pseudodisaccharide product **206**.

Before further elongation of the carbohydrate chain, Guo and coworkers [102,103] first installed the phospholipid moiety to the inositol 1-*O*-position, because they found that final stage installation of the phospholipid moiety, as reported for all other GPIs without the inositol 2-*O*-acyl group, caused problems. After the phospholipidated pseudodisaccharide **208** was obtained by reacting **206** with **207** followed by oxidation using *t*-butyl peroxide, the carbohydrate chain of **208** was elongated in a convergent fashion. Thus, monosaccharides **209**, **210**, and **211** were used to construct a trimannose **212**, which was directly coupled to **208** to yield the pseudopentasaccharide core **213**. Thereafter, a phosphoethanolamine moiety was introduced to the 6-*O*-posiiton of Man III to give the protected GPI anchor **215**. Global deprotection of **215** was accomplished in two steps, including base treatment to remove Fmoc and cyanoethyl groups and hydrogenolysis to remove Bn groups, to finally afford the GPI anchor **216** of CD52 antigen.



Scheme 19
Guo's synthesis of the CD52 GPI anchor

4 Chemical Synthesis of GPI-Linked Peptides/Proteins and Glycopeptides

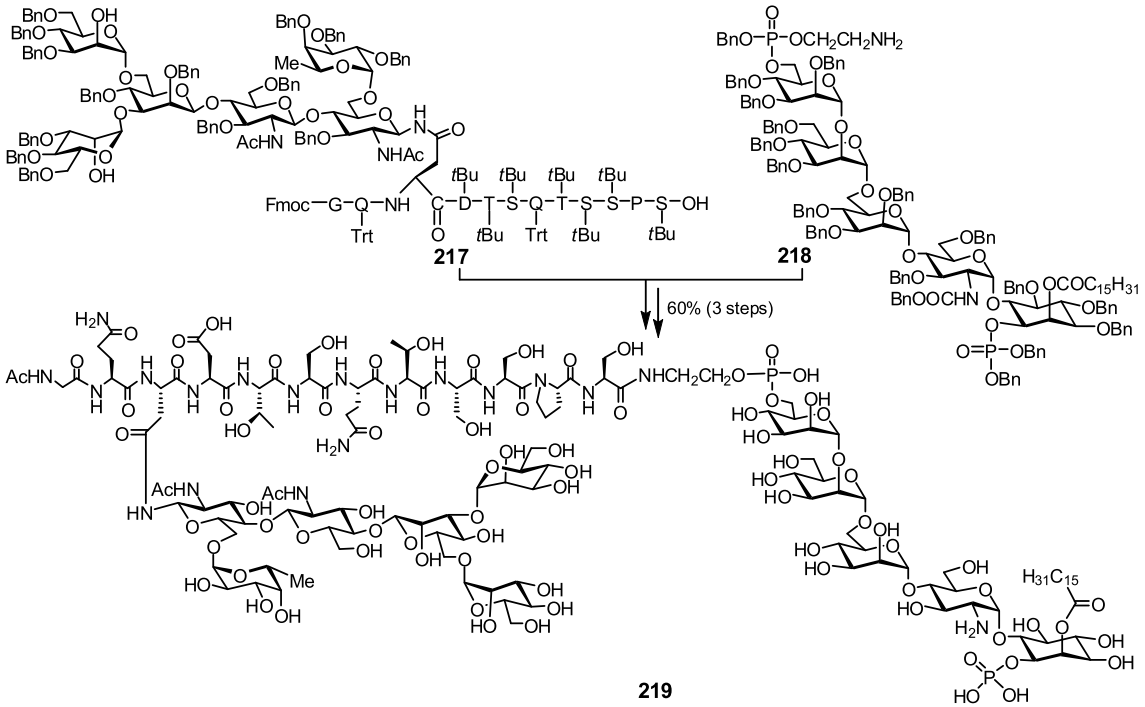
In the literature, there are very few reports concerning the chemical synthesis of GPI-linked structures. In the study of GPI-based malaria vaccines, Seeberger and coworkers [93] coupled their synthetic GPI **159** to a carrier protein to form an immunogenic glycoconjugate. For this purpose, the GPI was treated with 2-iminothiolane to introduce a thio group at the ethanolamine moiety and then conjugated to maleimide-activated ovalbumin or to keyhole limpet haemocyanin (KLH). This material was used to immunize mice for induction of protective immune responses against malaria. Evidently, the linkage between the GPI and the carrier protein was artificial.

Nakahara and coworkers [105] have recently studied the coupling between amino acids or peptides and GPIs through the native amide linkage using an unprotected dimannose containing a P-OEtNH_2 group as the GPI model. Both thioesters and pentafluorophenyl esters of amino acids were explored for this coupling reaction. The pentafluorophenyl esters gave complex results, as amino acids were attached to the free hydroxyl groups of the sugar units as well. The thioesters using silver nitrate as the promoter turned out to give a clean reaction with the desired product formed in a good yield (76%). However, this coupling method was significantly less effective for free peptides. Then, they proved that the native ligation method could couple free peptides to the GPI model in a good yield (78%). These results indicate that direct coupling of free peptides or proteins to free GPIs may not be easy, but the native ligation method is potentially useful for this problem.

Guo and coworkers have recently achieved the first chemical synthesis of a GPI-peptide [103] and a GPI-glycopeptide **219** [106] that contained the native amide linkage between the GPI and the peptide backbone. In these syntheses, they employed protected GPIs and peptides or glycopeptides for the coupling reaction with *N*-hydroxybenzotriazole (HOBt) and *N*,*N*′-dicyclohexylcarbodiimide (DCC) or 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC) as the condensation reagents. For example, the coupling reaction between **217** and **218** in the presence of EDC/HOBt (*Scheme 20*) was conducted in a homogeneous solution in dichloromethane and *N*-methylpyrrolidinone (2 : 1) to give an excellent yield (70%) of the desired conjugation product that was easily purified by column chromatography. Two-step global deprotection of this product, including catalytic hydrogenolysis to remove the benzyl groups and further treatment with 15% TFA in dichloromethane to remove the peptide side chain protections, eventually afforded the backbone structure of CD52 antigen **129**. The final product was then purified by reversed-phase HPLC.

5 Summary

Since the first total synthesis of a GPI anchor by Ogawa and coworkers in 1991 [59], several GPIs have been synthesized chemically. In this process, many generally useful strategies have been established for the synthesis of GPIs and related structures. However, these synthetic strategies are not always applicable to all GPIs. In fact, any additional functional group or even the change of the linking position of a functional group may necessitate completely different protection and/or synthetic strategies, so each GPI synthesis needs to be taken



Scheme 20
Guo's synthesis of a principal structure of CD52 antigen

as a unique challenge that requires specific attention. For example, most of the reported GPI syntheses were based on benzyl group-protected sugars, which are not compatible with GPIs that contain unsaturated lipid chains. Only lately have Nikolaev and coworkers [101] achieved some progress with regard to this issue by using benzoyl group, instead of benzyl group, as the universal and permanent protection of hydroxyl functionalities. Currently, an unsolved and important problem is the synthesis of natively-linked GPI-protein and glycoprotein conjugates. Although glycoconjugates with short peptides or glycopeptides attached to GPIs have been achieved by Guo and coworkers [103,106] through coupling protected peptides or glycopeptides to protected GPIs, the reactions between large proteins or glycoproteins and GPIs are much more complex. A hopeful solution to this problem may be the native ligation between proteins and GPIs, as suggested by Nakahara's work [105]. Nevertheless, because one of the most important functions of GPIs is to anchor proteins and glycoproteins onto cell surfaces and almost all GPIs in nature are coupled with proteins, glycoproteins, or other molecules, it is highly desirable to have a practical method to synthesize GPI-protein/glycoprotein conjugates. In conclusion, during the past two decades, the chemical synthesis of GPI anchors has gained significant progress, as proved by the number of GPIs prepared chemically. With these synthetic, homogeneous, and well-defined GPIs and GPI conjugates available, other related studies of GPIs will witness rapid growth. These studies will eventually help our understanding of the structures and activities of GPIs and GPI-anchored molecules, while presently the mechanism concerning how GPIs function is still largely unclear. Consequently, the synthetic studies of GPIs and GPI-linked glycoconjugates will have a major impact on many other areas of GPI research.
