Part 8
Glycoproteins

8.1 Glycoproteins: Occurrence and Significance

Valentin Wittmann
Fachbereich Chemie, Universität Konstanz, 78457 Konstanz, Germany
mail@valentin-wittmann.de

Abstract

Protein glycosylation is regarded as the most complex form of post-translational modification leading to a heterogeneous expression of glycoproteins as mixtures of glycoforms. This chapter describes the structure and occurrence of glycoproteins with respect to their glycan chains. Discussed are different carbohydrate–peptide linkages including GPI anchors, common structures of *N*- and *O*-glycans, and the structure of glycosaminoglycans contained in proteoglycans. Also covered are the bacterial cell wall polymer peptidoglycan and the glycopeptide

1 Introduction

This chapter covers natural glycoconjugates in which carbohydrates are covalently linked to amino acids which themselves are part of a peptide or protein. Three classes of biologically important compounds fulfill this criterion:

- glycoproteins including their substructures, the glycopeptides,
- the bacterial cell wall polymer peptidoglycan, and
- glycopeptide antibiotics.

Glycoproteins constitute the most diverse of these classes of glycoconjugates. Their substructures, the glycopeptides, occur as natural and artificial degradation products of glycoproteins during metabolism and structural analysis, respectively, or they are obtained synthetically in

order to probe their structure and/or function. Peptidoglycan is commonly not regarded as a glycopeptide. It forms a bag-like macromolecule (called the sacculus) wrapping bacteria and thereby contributing essentially to their mechanical stability. However, it is connected with glycopeptides not only by virtue of its composition but also because its biosynthesis is inhibited by (beside β-lactam antibiotics) glycopeptide antibiotics. The latter are secondary metabolites produced in actinomycetes and are dealt with at the end of this chapter.

2 Glycoproteins

Glycoproteins [1,2,3,4,5,6,7,8,9,10,11,12,13] consist of carbohydrate covalently linked with protein and are ubiquitous in all forms of life. Once thought to be restricted to eukaryotes, protein glycosylation is now being increasingly reported in prokaryotes [14,15,16,17]. The carbohydrate content of glycoproteins is variable from less than 1%, as in some collagens, to over 99%, as in glycogen. The carbohydrate may be in the form of a monosaccharide or disaccharide, but more frequently in the form of oligosaccharides and polysaccharides (up to hundreds of monosaccharides in size), or their derivatives (e. g. sulfo- or phospho-substituted), linear or branched, generally referred to as glycans. The number of glycans present in a glycoprotein differs greatly from a single to more than a hundred. The carbohydrate chains are attached to the polypeptide backbone by characteristic carbohydrate–peptide linkages.

Being the most complex co- and post-translational modification, glycosylation is found in most proteins including enzymes, antibodies, receptors, hormones, cytokines, and structural proteins. Glycoproteins occur inside cells, both in the cytoplasm and in subcellular organelles, in extracellular fluids as well as embedded in cell membranes. In the latter case the glycans are located extracellularly. Especially blood serum is a rich source of glycoproteins. Of the almost 100 proteins which have been identified in this fluid, almost all are glycosylated. Serum albumin is one of the rare exceptions in this respect although a genetic variant which is glycosylated has been discovered [18].

A striking feature of almost all glycoproteins is the polymorphism associated with their glycan moieties, a phenomenon known as microheterogeneity. This type of diversity derives from the fact that glycans are secondary gene products and is manifested in that individual molecules of a given glycoprotein carry different oligosaccharides at the same glycosylation site of the protein backbone. The resulting variants, referred to as glycoforms, were first observed in 1962 by Schmid et al. in α_1-acid glycoprotein from human serum by electrophoresis [19]. This glycoprotein contains five glycosylation sites modified with di-, tri-, and tetra-antennary glycans of the *N*-acetyllactosamine type [20]. In addition, the glycans can be fucosylated [21] and sialylated at different levels. Microheterogeneity is also observed in proteins with a single glycosylation site like chicken ovalbumin. Close to 20 different oligosaccharides have been identified at that site (Asn-293) [22]. One of the very rare cases in which microheterogeneity is absent is soybean agglutinin (SBA), a plant glycoprotein with a single uniform oligosaccharide per subunit, namely $Man_9(GlcNAc)_2$ [23]. This is mainly why SBA is the best source for a preparative isolation of this oligosaccharide. Up to now, many thousands of primary glycan structures have been characterized. There are several glycan databases available via the internet, for example, Glycosciences.de provided by the German Cancer Research Center (http://www.glycosciences.de) [24], KEGG Glycan, part of the Kyoto Encyclopedia of Genes and Genomes (http://www.genome.jp/kegg/glycan) [25], and the Glycan Database of the Consor-

tium for Functional Glycomics (http://www.functionalglycomics.org) [26]. These resources are increasingly linking to each other, and additional levels of integration are in development, including the EuroCarbDB initiative (http://www.eurocarbdb.org).

The observation of microheterogeneity gives rise to many interesting questions regarding the origin of this phenomenon and its biological relevance. Whereas in the early view the heterogeneity of the glycans was thought to be random and mainly a result of the lack of fidelity in their synthesis, today it appears that under constant physiological conditions the populations in a set of glycoforms are reproducible and highly regulated. Moreover, the populations change under certain conditions such as cell growth, cell differentiation, and disease, including malignant transformation, suggesting that the presence of different but defined glycoforms is indeed required for the normal functioning of an organism.

Today we know there is no single unifying function for the carbohydrates present in glycoproteins [27]. Perhaps their major function is to participate in numerous physiological and pathological molecular recognition events. In addition, they may modify the physical, chemical, and biological properties of the proteins they are attached to. It has been shown that the glycans alter charge and solubility of proteins and influence the conformation and dynamic properties of the polypeptide chain. Because of their large size, the oligosaccharides may cover functionally important areas of the proteins and thus regulate their interactions with other biomolecules or protect the protein from proteolytic degradation. Properties and functions of glycoproteins are covered in Chap. 8.2 of this book.

2.1 Monosaccharide Constituents

For a long time less than a dozen monosaccharides were considered to be the main constituents of glycoproteins. Beside these "classical" saccharides, however, refinement of the analytical methods brought up many new monosaccharides, originally considered as rare but which now appear to be more common than previously thought. *Table 1* [6,28,29,30] gives an overview of the classical and examples of rare monosaccharide constituents of glycoproteins.

2.2 Carbohydrate–Peptide Linkages

There are three major types of linkages between carbohydrates and proteins [1,2,3,4,5,6,7,8,9,30,31]:

- *N*-glycosidic, between the reducing end monosaccharide and the side chain amide group of asparagine (*N*-glycans),
- *O*-glycosidic, between the reducing end monosaccharide and the side chain hydroxy group of most commonly serine and threonine but also hydroxyproline, hydroxylysine, and tyrosine (*O*-glycans), and
- via ethanolamine phosphate, between the *C*-terminal amino acid of the protein and an oligosaccharide attached to phosphatidylinositol, generally known as the glycosyl-phosphatidylinositol (GPI) anchor.

Beside these, a number of uncommon linkages are found in nature including *C*-glycosides and carbohydrates linked via a phosphodiester bridge. The non-enzymatic condensation of

[a] Unless otherwise stated, all monosaccharides are of D-configuration and the ring form is pyranose

reducing monosaccharides, such as glucose, with the side chain amino group of lysine leads via initial Schiff bases and subsequent rearrangements to the formation of so-called advanced glycation end products (AGEs). AGEs have been implicated in alterations of proteins during aging and long-term diabetes [32,33] and are not dealt with in this chapter.

2.2.1 *N*-Glycosides

Until recently, the only type of *N*-glycosidic linkage that had been characterized in glycoproteins regardless of their origin was the *N*-acetylglucosaminyl(β1–N)asparagine bond discovered by Neuberger et al. [34] and almost simultaneously by others [35,36]. During biosynthesis, the enzyme oligosaccharyl transferase (OT) transfers a triantennary tetradecasaccharide ($Glc_3Man_9GlcNAc_2$) from dolichol pyrophosphate to the amide nitrogen of an Asn side chain in the nascent polypeptide [37]. In the subsequent trimming process this oligosaccharide is modified by action of several glycosylhydrolases and glycosyltransferases resulting in a structural diversity of glycans sharing a common core pentasaccharide (*Fig. 1*). The primary peptide sequence requirements for OT-catalyzed glycosylation include a minimum Asn-Xaa-Ser/Thr (sometimes also Cys) tripeptide recognition motif where Xaa can be any of the 20 natural amino acids except proline. However, it is found that not all such consensus tripeptides (sequons) are glycosylated. A plausible explanation arises from mechanistic studies on the OT-catalyzed glycosylation of linear and constrained model peptides [38]. It could be demonstrated that only peptides which are able to adopt an Asx-turn conformation [39] are efficient substrates of OT leading to the proposed mechanism of oligosaccharyl transfer shown in *Fig. 2a* [40,41]. In this model, the apparent failure of the glycosylation machinery most likely results from conformational influence by the neighboring polypeptide sequence that may override the potential for the tripeptide acceptor sequence to adopt an Asx-turn and therefore limit its compatibility with the OT active site. However, although necessary, formation of an Asx-turn might not be sufficient [42]. An alternate mechanistic model which can also explain both specificity and enhanced amide nitrogen nucleophilicity was proposed by Bause

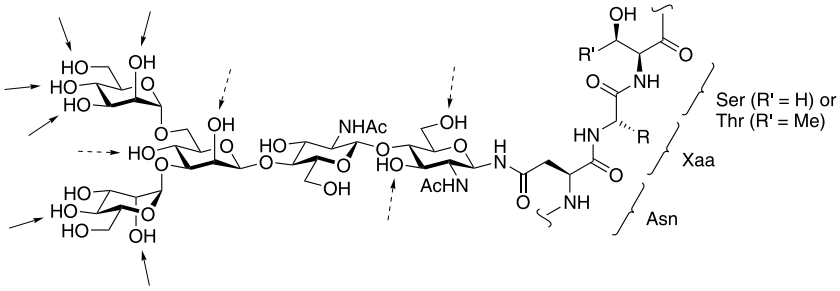

Figure 1

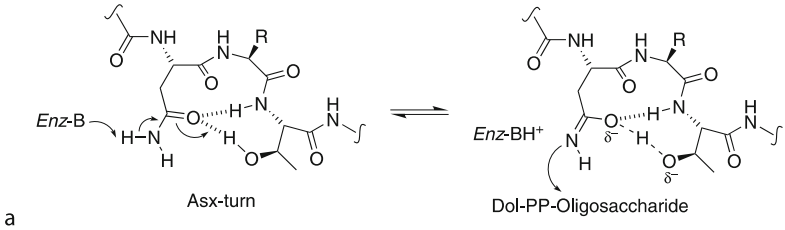
In addition, the inner-core may be substituted by several monosaccharides (*dashed arrows*)



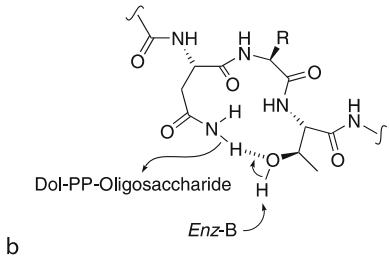


Figure 2
Proposed mechanisms of asparagine activation for oligosaccharyl transferase by (a) Imperiali et al. [40,41] and (b) Bause et al. [43,44,45]

et al. [43,44,45]. In this model the hydroxyamino acid acts as a hydrogen-bond acceptor rather than a donor (*Fig. 2b*).

During recent years, linkages between asparagine side chains and other carbohydrates such as α- [46] and β-glucose [47], β-*N*-acetylgalactosamine [48] and L-rhamnose[49] have been discovered mainly in bacterial glycoproteins [50]. However, the β-glucosyl–asparagine linkage has been found also in the mammalian protein laminin [51]. Whenever carefully studied, the saccharides are attached to the sequon Asn-Xaa-Ser/Thr except for the glycopeptide nephritogenoside in which glucose is α-linked to the amide side chain of the *N*-terminal tripeptide Asn-Pro-Leu [46]. Another example of an *N*-glycosidic bond is the linkage of β-glucose to

the guanidino group of arginine which has been reported to occur in amylogenin, a self-glucosylating protein from sweet corn [52].

2.2.2 *O*-Glycosides

In contrast to *N*-glycoproteins, biosynthesis of the glycan chains of *O*-glycoproteins is an entirely post-translational process and starts with addition of a single monosaccharide to a hydroxy amino acid of the protein backbone [53]. Therefore, a variety of carbohydrate–protein linkages are found in *O*-glycoproteins (● *Fig. 3*). The *N*-acetylgalactosaminyl (α1–O) serine/threonine linkage (also called Tn antigen) was first demonstrated in mucins and is widely distributed in nature in the so-called mucin-type glycoproteins. An increasingly important *O*-glycosidic bond is that between β-*N*-acetylglucosamine and the serine/threonine hydroxyl [54,55,56,57]. This type of attachment is present predominantly in intracellular glycoproteins (nuclear pore, chromatin proteins, transcription factors, and cytoplasmic inclusions) and indeed represents the first reported example of glycosylated proteins found outside of the secretory channels. Interestingly, no other sugars are connected to the *N*-acetylglucosamine residue. The *N*-acetylglucosaminyl (β1–O) serine/threonine modification shares many common traits with protein phosphorylation. Both are dynamic modifications processed by specific enzymes that modify serine/threonine residues and rapidly respond to extracellular stimuli.

In the epidermal growth factor (EGF) modules of several blood coagulation and fibrinolytic proteins, L-fucose was characterized to be α-linked to serine or threonine in the consensus sequence Cys-Xaa-Xaa-Gly-Gly-Ser/Thr-Cys [58]. Later on, the consensus sequence was broadened to Cys-$(Xaa)_{3-5}$-Ser/Thr-Cys to account for observations made with the proteins Notch, Serrate/Jagged, and Delta [59]. EGF modules also contain glucose β-*O*-linked to serine within the consensus sequence Cys-Xaa-Ser-Xaa-Pro-Cys, an example being the bovine blood clotting factor IX [60]. α-Galactose bound to serine is found in plant glycoproteins like extensin or potato lectin and in the glycoproteins from the cellulosome, an extracellular complex of cellulases, produced by cellulolytic bacteria [61]. When human insulin-like growth factor-I (IGF-I) was expressed in yeast, a new form of IGF-I was characterized in addition to IGF-I in which mannose α-glycosidically was linked to threonine [62]. The mannosyl Ser/Thr linkage [63] has also been reported in Ser/Thr-rich domains of the bovine peripheral nerve α-dystroglycan [64] and in rat brain proteoglycans [65,66]. Xylosyl (β1–O) serine is found in animal proteoglycans and, at present, considered to be confined to these glycoproteins. Pseudaminic acid (5,7-diacetamido-3,5,7,9-tetradeoxy-L-glycero-L-*manno*-nonulosinic acid) α-glycosidically linked to serine/threonine is an unusual bond that has been recently identified in *Campylobacter jejuni* flagellin [67,68]. It represents the first example of an acidic monosaccharide directly linked to protein. In the pili of *Neisseria meningitidis*, a 2,4-diacetamido-2,4,6-trideoxyhexose (DATDH) as part of the trisaccharide Gal(β1–4)Gal(α1–3)DATDH is linked to serine or threonine with unknown anomeric configuration [69]. In the pili of *Neisseria gonorrhoeae*, a disaccharide Gal(α1–3)DATDH has been reported to be *O*-glycosidically linked to serine [70] in contrast to an earlier publication in which Gal(α1–3)GlcNAc was assigned to be this disaccharide [71]. The *N*-acetylfucosaminyl (β1–O) serine/threonine linkage represents another recently described bacterial linkage that occurs in the pili of *Pseudomonas aeruginosa* [72].

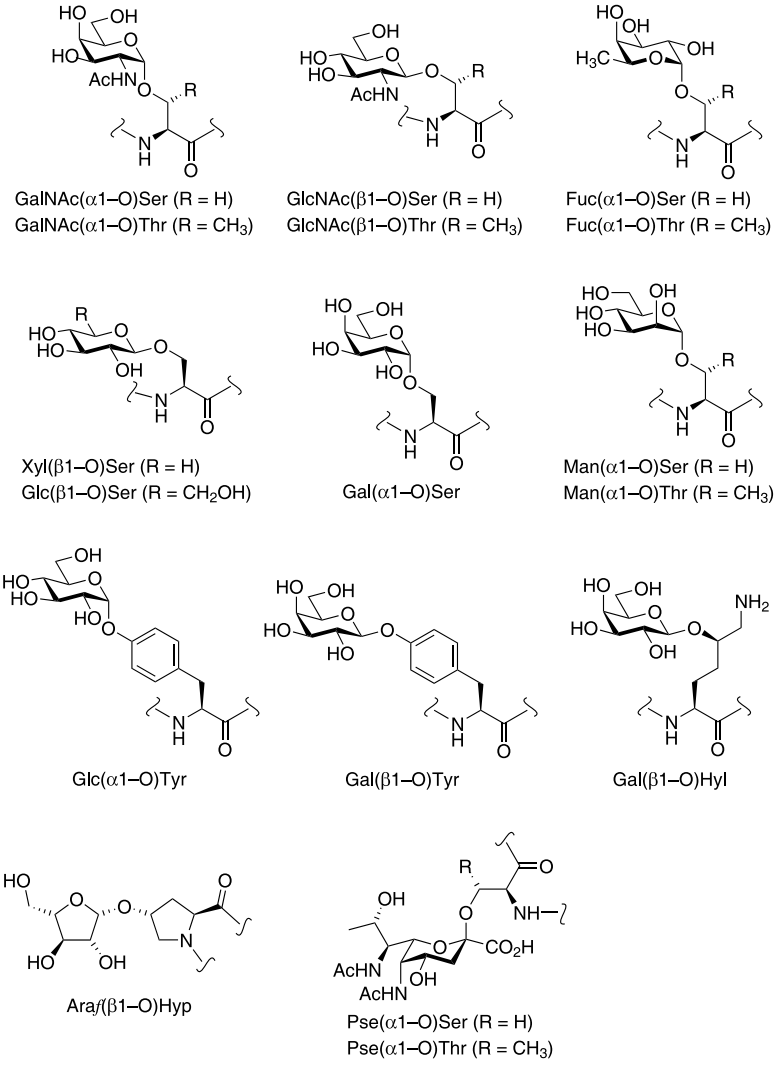

Figure 3
Carbohydrate–peptide linkages found in *O*-glycoproteins

O-Glycosylation is, however, not limited to serine and threonine. In glycogenin, the priming enzyme for glycogen synthesis, glucose is α-linked to the phenolic hydroxy group of a tyrosine residue [73,74] and galactosyl (β1–O) tyrosine has been identified in glycoproteins of the crystalline surface layers (*S*-layers) of eubacteria [75,76]. In the collagens, β-galactose is linked to hydroxylysine [77,78]. Hydroxyproline, finally, is glycosylated with α- [79] and β-L-arabinofuranose [80,81,82] in certain plant glycoproteins, with β-galactose in plants and eubacteria [83,84], and with *N*-acetylglucosamine in cytoplasmic glycoprotein of *Dictyostelium* [85].

2.2.3 GPI Anchors

Glycosyl-phosphatidylinositol anchors provide a means for anchoring proteins with a wide variety of structures and functions to the external surface of the plasma membrane of eukaryotic cells. The existence of lipid anchors for membrane proteins was initially demonstrated by the ability of phosphatidylinositol-specific phospholipase C (PI-PLC) to release alkaline phosphatase from various mammalian tissues into the medium [86,87]. Later, it was observed that fatty acids and ethanolamine were attached to the carboxy terminus of the rat Thy-1 antigen which provided direct evidence for a glycolipid anchor being covalently attached to protein [88]. In 1985 these and other results were combined to establish a common mode of membrane attachment via a GPI anchor covalently bound to the *C*-terminus through ethanolamine [89]. Today, we know well over 100 proteins which are GPI-anchored (reviewed in [90,91,92,93,94,95,96,97,98]) and the structures of several GPI anchors have been elucidated, the first being that on the *Trypanosoma brucei* variant surface glycoprotein (VSG) [99,100]. All characterized GPI anchors share a common core of ethanolamine-PO_4-6Man(α1–2)Man(α1–6)Man(α1–4)GlcN(α1–6)*myo*-Ino-1-PO_4 [99,100].

All characterized GPI anchors share a common core of ethanolamine-PO_4-6Man(α1–2)Man(α1–6)Man(α1–4)GlcN(α1–6)*myo*-Ino-1-PO_4-lipid. This may be further processed in a cell-type and protein-specific manner (*Fig. 4*). The rat brain Thy-1 anchor, for example, contains additional Man(α1–2) and GalNAc(β1–4) residues, whereas the tetrasaccharide backbone of the trypanosome VSG anchor is modified with a branched chain of α-linked galactoses. In human erythrocyte acetylcholinesterase [101] and decay accelerating factor [102] the first and second mannoses carry additional phosphoethanolamines. Attached to the phosphoinositol are lipids of varying chain length and saturation including diacylglyc-

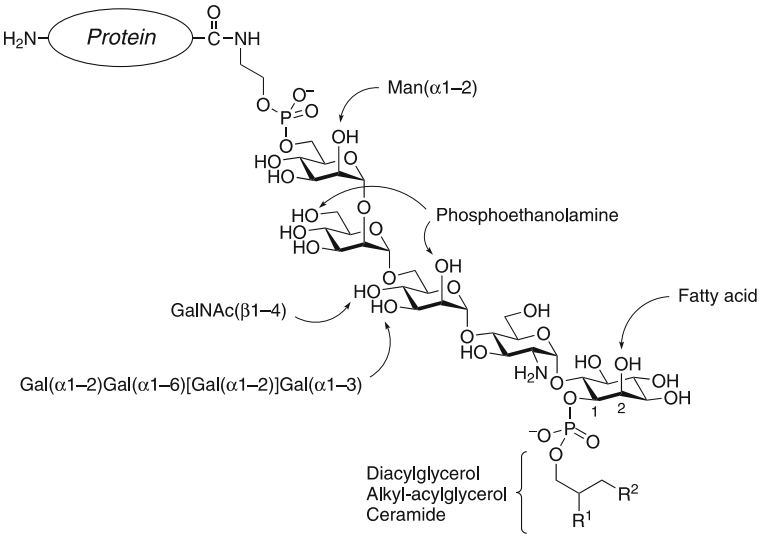

Figure 4
Minimal structure and some modifications of GPI anchors

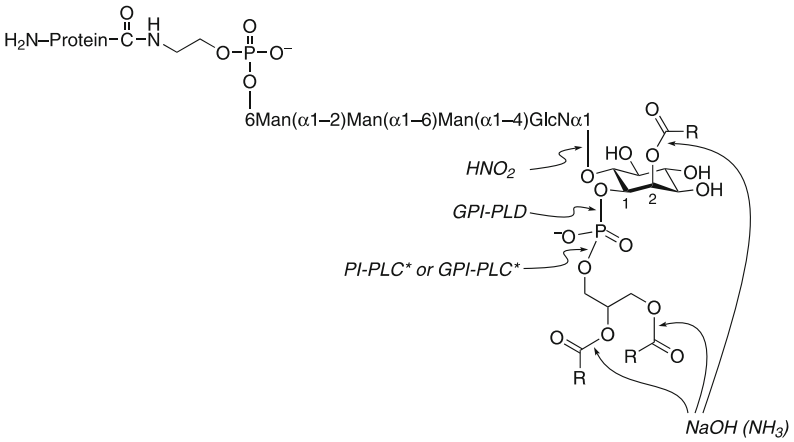

Figure 5
Enzymatic and chemical cleavage sites of GPI anchors most commonly used for the identification and structural analysis of GPI anchors. In addition, all phosphoric esters are cleavable by aqueous hydrofluoric acid. GPI-PLC*, GPI-specific phospholipase C; GPI-PLD, GPI-specific phospholipase D; PI-PLC*, phosphatidyinositol-specific phospholipase C. * Cleaves only if the inositol is unmodified

erol, alkyl-acylglycerol, stearoyl-*lyso*glycerol, or ceramide. In the VSG anchor, for example, dimyristyl glycerol has been identified. Furthermore, the inositol may be acylated with an additional fatty acid, most commonly palmitoyl, at position 2 of the inositol ring.

Biosynthesis of GPI anchors starts with the core structure assembly by sequential addition of UDP-GlcNAc (followed by *N*-deacetylation), dolichol-phosphate-mannose, and phosphoethanolamine to phosphatidylinositol and culminates in the en bloc transfer to protein shortly after the protein is synthesized. However, the biosynthetic pathways can differ strikingly between different organisms with respect to specific modifications and fatty acid remodeling occurring after completion of the core glycan. This also applies for the point when certain modifications are introduced, e. g. before or after the transfer of the GPI-moiety to the protein. GPI anchors can be cleaved at defined positions by an array of enzymatic and chemical methods, respectively (◉ *Fig. 5*). Thus, it becomes possible to identify GPI-anchored proteins and, moreover, analyze the structure and biosynthesis of GPI anchors [103].

The most obvious function of GPI anchors is to provide a stable, oriented attachment of proteins onto membranes, usually the extracellular surface of plasma membranes. However, there is much discussion over whether this highly conserved, multiple-step, complex mechanism for anchoring proteins has additional functions and it has been proposed [96,98,104,105] that GPI anchors:

- increase the lateral mobility of proteins,
- mediate the release or secretion of proteins,
- target proteins to apical surfaces,
- mediate endocytosis or protein turnover,
- play a role in protein sorting in the secretory and endocytic pathways, and
- participate in transmembrane signaling mechanisms.

In the meantime, several GPIs and GPI-anchored peptides have been synthesized as reviewed in [106].

2.2.4 Uncommon Linkages

In 1994 a previously unknown type of carbohydrate–protein linkage has been identified in human RNase 2 (identical to RNase U_s) with a mannose residue α-*C*-glycosidically attached to C2 of the indole ring of Trp-7 as a result of a post-translational modification (*Fig. 6*) [107,108,109]. In the meantime, *C*-mannosylation of tryptophan has been found in several proteins, including interleukin-12 [110] and properdin [111]. Recently, a method predicting the location of *C*-mannosylation sites in proteins was developed using a neural network approach [112]. Another uncommon linkage is the attachment of sugar to protein via a phosphodiester bridge [113] which had been first characterized in the lysosomal proteinase I of *Dictyostelium discoideum* in which α-*N*-acetylglucosamine-1-phosphate is bound to the side chain hydroxyl of serine [114,115]. Attachment of α-mannosyl phosphate to serine has been observed in several major proteins of *Leishmania* species [116].

2.3 Methods of Glycoprotein-Glycans Analysis

Structural analysis of glycans contained in glycoproteins [117,118,119,120,121,122,123,124,125] is a challenging task due to the lack of a general oligosaccharide sequencing method like those available for peptides or oligonucleotides. The situation is further complicated by the phenomenon of microheterogeneity which makes only minute amounts of homogenous material available. Fractionation of individual glycoforms of a given glycoprotein can be achieved using capillary electrophoresis but is not generally applicable because the differences in physicochemical properties between neutral glycoforms are often relatively small. Therefore, protein glycosylation analysis is usually carried out after release of the glycans either from the whole glycoprotein or from glycopeptides obtained by proteolytic digestion. A general strategy consists of four steps:

1. Release of glycans from their conjugate polypeptide.
2. Labeling of released glycans.
3. Fractionation of glycan mixtures.
4. Sequencing of individual glycans.

2.3.1 Release of Glycans from Glycoprotein

In order to release glycans from a glycoprotein a general method is required that is independent of the protein to which the saccharides are attached. In this respect, chemical release is often preferred over the use of endoglycosidases or glycoamidases. Hydrazinolysis [126] has initially been described for release of *N*-glycans producing intact glycans with a free reducing terminus (*Fig. 7*) but later on it was shown that under controlled conditions the method is also suitable for *O*-glycans [127]. In the case of *O*-glycans, however, to some extent degradation of reducing-end monosaccharides (so-called peeling) remains a problem. As long as a reducing saccharide is not required at the cleavage point, *O*-glycans can be more mildly released in the form of oligosaccharide alditols by β-elimination and subsequent reduction upon treatment with alkaline borohydride [128]. This procedure, however, prevents subsequent labeling of the glycans by reductive amination (see below). To avoid this drawback, modified β-elimination procedures that deliver glycans with intact reducing ends have been developed [129,130].

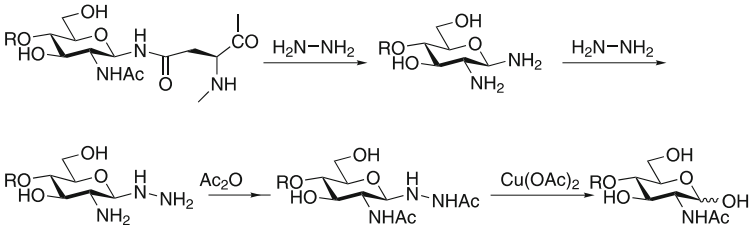

Figure 7
Hydrazinolytic release of *N*-linked glycans

Enzymatic release [131] of *N*-glycans is most frequently effected by the peptide *N*-glycanases (PNGases) F or A which, under denaturing conditions, generally cleave the Cγ–Nδ bond of glycosylated asparagines. Released are the intact *N*-linked glycans as glycosylamines, which are readily converted to regular glycans. Asparagine, in turn, is converted into aspartic acid resulting in a mass difference of 1 Dalton that may be used to assess the glycosylation site by mass spectrometry. In contrast to PNGase A, PNGase F is not able to cleave *N*-glycans containing an (α1–3)-linked fucose attached to the reducing-terminal GlcNAc residue. Alternatively, endoglycosidases can be applied which cleave between the first and second *N*-acetylglucosamine residue attached to asparagine. The various enzymes differ in their substrate specificities. Endo H, for example, cleave oligomannose-type and most hybrid-type glycans, whereas, Endo F2 and Endo F3 cleave certain complex-type chains [131]. Enzymatic release of *O*-glycans is much more difficult since most *O*-glycanases currently available are highly specific. Therefore, after PNGase treatment of *N*,*O*-glycoproteins, remaining *O*-linked glycans are often released by alkaline borohydride degradation.

2.3.2 Labeling and Fractionation of Glycans

Unless mass spectrometric analysis of the glycan pool is carried out, the released sugars need to be tagged to enable them to be detected during separation. Classically, the reducing end of the oligosaccharides had been reduced with alkaline sodium borotritide [132].

Today, radioactive labeling has been largely replaced by reductive amination with fluorescent compounds like 2-aminobenzamide [133], anthranilic acid [133], 8-aminonaphthalene-1,3,6-trisulfonic acid [134], 2-aminopyridine [135], 2-aminoacridone [136], or 1-aminopyrene-3,6,8-trisulfonate [137]. These fluorophores are compatible with a range of separation techniques including HPLC (normal phase, reversed phase, and weak anion exchange), high pH anion exchange chromatography (HPAEC), lectin-affinity chromatography, polyacrylamide gel electrophoresis (PAGE), capillary electrophoresis (CE), and gel permeation chromatography (GPC). Derivatization with ionizable functional groups has gained importance for high-resolution analysis of oligosaccharides by CE [138,139] and to enhance their otherwise low ionization efficiencies enabling sensitive detection of glycans by mass spectrometry even in the presence of peptides [140].

2.3.3 Sequencing of Glycans

For complete structural analysis of oligosaccharides, a combination of several physical, chemical, and biochemical techniques including NMR spectroscopy, mass spectrometry (MS), and chemical and enzymatic degradation is required. Mass spectrometry has developed a key technology for the analysis of glycans in glycomics [119,120,121,122,125]. The advantages of MS techniques are high sensitivity (detection limits of oligosaccharides in the low pico- to femtomolar range), high accuracy, and the possibility of being directly coupled to many separation methods. ESI-MS/MS, ESI-ion trap-MS^n, and MALDI-TOF/TOF-MS are currently the most frequently used methods. Structural information may be obtained from two types of fragmentation: cleavages of glycosidic bonds between monosaccharide units provide information on glycan sequence and branching, whereas cleavages within sugar rings (so-called cross-ring cleavages) provide extended information of branching and monosaccharide linkage positions. It is important, however, to keep in mind that mass spectrometry is not able to distinguish between different stereoisomeric sugars such as GlcNAc/GalNAc or Gal/Man/Glc all of which have the same mass. Therefore, knowledge of biosynthetic pathways of the organism which the glycans were derived from is used to reduce the number of possible glycans that are in agreement with measured data. Several algorithms for automated interpretation of MS data with integrated links to glycan databases have been developed and progress in this area has been reviewed [141].

Enzymatic analysis using highly specific exoglycosidases is a powerful means of determining the sequence of glycans especially if only very small amounts of material (picomoles or less) are available. This method is based on the determination of the susceptibility of a glycan to a series of exoglycosidases of defined specificity. In the case of the reagent array analysis method (RAAM) [142,143], the process has been automated. The glycan is divided into several aliquots and each aliquot is incubated with a defined mixture of exoglycosidases called a reagent array. Degradation occurs in each vial until a linkage is reached which is resistant to all exoglycosidases present in that mix. The remaining "stop point" fragments containing the labeled reducing end saccharides are characterized by size (GPC or MS). From these data, a computer program constructs the sequence of the glycan. Later, an improved approach was developed involving the simultaneous digestion of aliquots of a total pool of fluorescently labeled oligosaccharides with a series of multiple enzyme arrays [144]. For further details on the analysis of glycoproteins, the reader is referred to Chap. 8.5 of this book.

2.4 Structure of *N*-Glycans

Because of their biosynthesis, all *N*-glycoproteins share the common core pentasaccharide Man(α1–6)[Man(α1–3)]Man(β1–4)GlcNAc(β1–4)GlcNAc. The tremendous diversity of asparagine-linked oligosaccharides derives from attachment of several monosaccharides as well as up to five different carbohydrate chains, the so-called antennae, to the core. On the basis of the structure and the location of the glycans attached to the trimannosyl core, *N*-glycoproteins can be classified into three main groups (*Fig. 8*). These are:

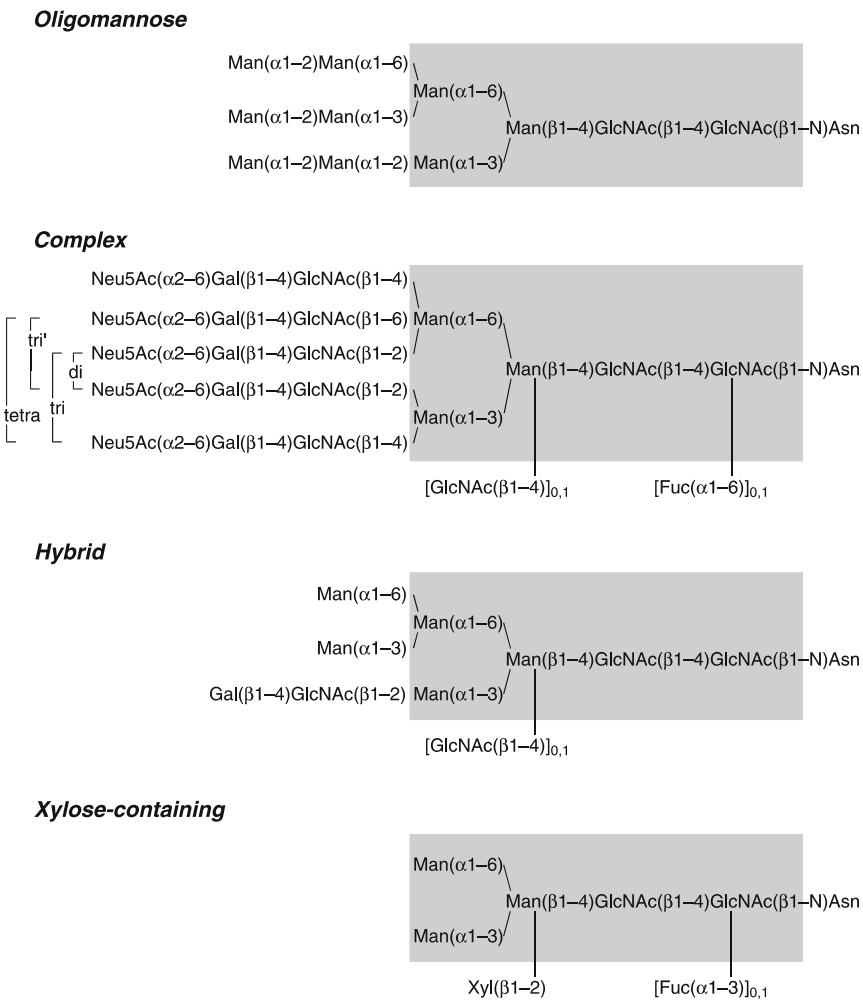

Figure 8
Examples of the main types of *N*-linked oligosaccharides of glycoproteins. The structure within the *gray box* represents the pentasaccharide core common to all *N*-glycans

- oligomannose (high mannose),
- complex, and
- hybrid type.

It has been suggested to add the xylose-containing type as a fourth group [28].
Oligomannose-type glycans usually contain two to six α-mannose residues bound to the core. The largest high mannose oligosaccharide thus contains nine mannose and two *N*-acetylglucosamine residues which were originally discovered in bovine thyroglobulin [145]. High molecular weight oligomannose chains with up to 100–200 mannose residues are, however, produced by yeasts.
Complex-type glycans contain no mannose residues other than those in the core. To the outer two α-mannose residues up to five units of the disaccharide Gal(β1–4)GlcNAc (*N*-acetyllactosamine) are β-linked. In the bi-, tri-, and tetraantennary glycans, these branches are attached to specific positions of the core as indicated in ❯ *Fig. 8*. The *N*-acetyllactosamine units are frequently substituted with sialic acid residues or additional repeats of *N*-acetyllactosamine, resulting in so-called poly-*N*-acetyllactosamines which are capped by sialic acids. Sialic acid is most commonly α-linked to the 3- or 6-position of galactose residues. Further diversification can be achieved by attachment of α1–6 linked fucose to the most inner core *N*-acetylglucosamine residue and of an *N*-acetylglucosamine residue linked β1–4 to the β-mannose of the core ("bisecting" GlcNAc). In addition, various monosaccharides can be found in the antennae.
Oligosaccharides of the hybrid typehave characteristic features of both complex-type and oligomannose-type glycans. One or two mannose residues are α-linked to the Man(α1–6) branch of the core pentasaccharide and one or two antennae like those found in complex-type oligosaccharides are β-linked to the Man(α1–3) branch of the core. This type of glycan results from partial processing of oligomannose-type glycans produced during biosynthesis and subsequent addition of sugars.
The fourth group of *N*-glycans is named xylose-containing and is characterized by a xylose residue linked β1–2 to the β-mannose of the core. Often, there is also fucose α1–3 linked to the innermost *N*-acetylglucosamine of the core.

2.4.1 Diversity of *N*-Glycans

As mentioned earlier, the structural diversity of glycans is provided by the variation of monosaccharides attached to the core, the degree of branching (antennary), and, particularly, the tremendous variation in the structure of the antennae. Some side chains commonly occurring in complex *N*-glycans are depicted in ❯ *Fig. 9*. These structures can be roughly classified into five groups. The first group is represented by *N*-acetyllactosamine which is the starting point for further modification but still being frequently found. Group two consists of side chains terminated by sialic acid, fucose, or galactose. Once these modifications have taken place, no further chain elongation is possible except for formation of polysialic acids. Following sialylation it is also still possible to transfer fucose or sialic acid to the *N*-acetylglucosamine residues, resulting in some of the structures of group three, e. g. Neu5Ac(α2–3)Gal(β1–4)[Fuc(α1–3)]GlcNAc (sialyl Lewis x), Neu5Ac(α2–3)Gal(β1–3)[Fuc(α1–4)]GlcNAc (sialyl Lewis a), or Neu5Ac(α2–3)Gal(β1–3)[Neu5Ac(α2–

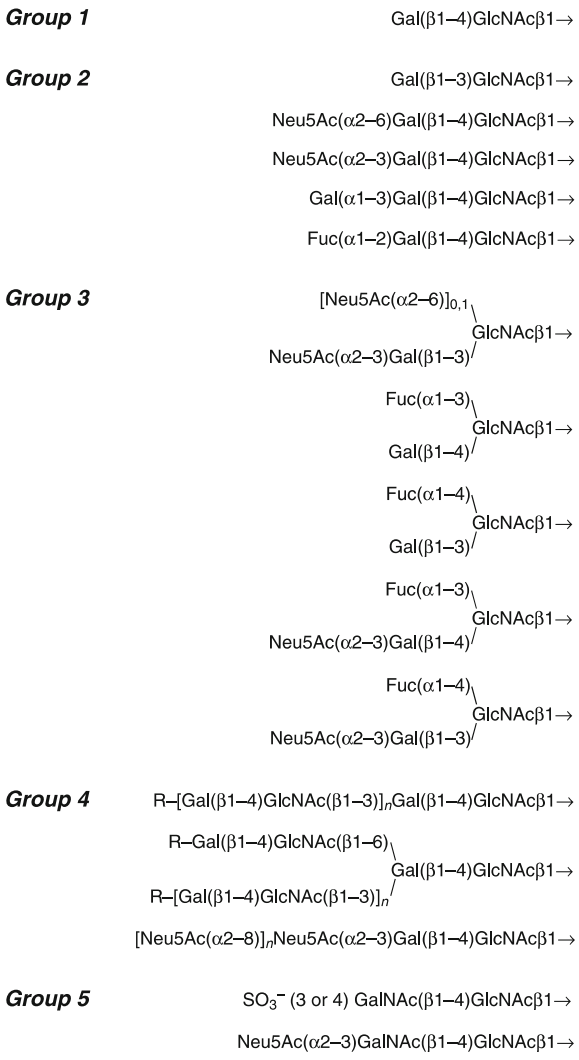

Figure 9
Commonly occurring structures of complex-type *N*-glycan side chains. The *arrows* indicate the point of attachment to the pentasaccharide core

6)]GlcNAc. On the other hand, fucosylation of a subterminal *N*-acetylglucosamine residue halts the chain elongation in nonsialylated, fucosylated form. Group four consists of long-chain structures containing either linear or branched poly-*N*-acetyllactosamine or α2–8 linked sialic acid repeatedly added to α2–3 linked sialic acid, forming polysialyl side chains. Group five side chains contain *N*-acetylgalactosamine instead of galactose. These structures may be further modified by sialylation or sulfation. There are many more variations in *N*-glycan chains identified to date and many more are expected to be found in future studies.

2.4.2 Cell-Type Specific Expression of *N*-Glycans

As described above, the enormous diversity of *N*-glycans is largely provided by variation of structures in the antennae. However, expression of specific carbohydrate epitopes, so-called antigenic determinants, is highly controlled and often cell-type specific. Critical findings revealed that poly-*N*-acetyllactosamines that are contained in many complex-type *N*-glycoproteins (but also in *O*-glycoproteins and glycolipids) provide a preferable backbone for many of the cell-type specific glycosylations, such as the ABH(O), I/i, and Lewis (Le^a, Le^x, and sialylated forms thereof) blood group and differentiation antigenic determinants [146]. Poly-*N*-acetyllactosamine repeats are not uniformly distributed among different antennae attached to the trimannosyl core. Because of the branch specificity of β1–3-*N*-acetylglucosaminyltransferase—the key enzyme for formation and elongation of poly-*N*-acetyllactosamine chains—poly-*N*-acetyllactosamine extensions are more common at the α1–6 linked mannose of the core. Tetraantennary glycans are particularly good acceptor substrates for poly-*N*-acetyllactosamine chain formation. Termination of chain elongation by sialylation leads to structures summarized in ❯ *Fig. 10*.

Glycosylation patterns of glycoproteins (and glycolipids) in human erythrocytes and granulocytes are well-established examples for cell-type specific expression of glycans. Some important carbohydrate antigenic determinants are listed in ❯ *Table 2*. Erythrocytes and granulocytes directly differentiate from the same precursor stem cells. In fetal erythrocytes, poly-*N*-acetyllactosamine is linear and expresses blood type i activity. In adult erythrocytes, poly-*N*-acetyllactosamines are branched at galactose, forming Gal(β1–4)GlcNAc(β1–3)[Gal(β1–4)GlcNAc(β1–6)]Gal(β1–4)GlcNAc, the blood group I antigen. The change from i to I specificity occurs gradually during the first year of life. Terminal galactose residues of the branched poly-*N*-acetyllactosamine chains of erythrocytes are then modified by α1–2 linked fucose, forming the H antigen. This reaction is catalyzed by an α1–2-fucosyltransferase. The H structure, Fuc(α1–2)Gal(β1–4/3)GlcNAc, is present in *O*-type blood group individuals. This structure now serves as the acceptor for α1–3-*N*-acetylgalactosaminyltransferase or α1–3-galactosyltransferase, forming A or B blood group antigens, respectively.

In granulocytes, no branching of poly-*N*-acetyllactosamines is observed. α1–3-Fucosyltransferase-catalyzed modification of the linear chains leads to the Lewis x antigen. If α2–3-sialyltransferase acts before fucosylation, sialyl Lewis x is formed. These carbohydrate structures are involved in a number of cell-cell interactions during the inflammatory response and

Representative structures of tetraantennary poly-*N*-acetyllactosamine containing *N*-glycans based on structures reported in various cells. The length of the *N*-acetyllactosamine repeats generally decreases in the order *m* > *n* > *o*. Sialic acids attached to poly-*N*-acetyllactosamine chains are usually α2–3 linked whereas α2–6 sialylation preferentially occurs at the side chain linked β1–2 to the Man(α1–3) branch of the core

Table 2
Antigenic determinants. LacNAc stands for Gal(β1–4)GlcNAc

Determinant structure	Name
Fuc(α1–2)Gal(β1–4/3)GlcNAc	Blood group H (O), type 1 or 2[a]
GalNAc(α1–3)[Fuc(α1–2)]Gal(β1–4/3)GlcNAc	Blood group A, type 1 or 2[a]
Gal(α1–3)[Fuc(α1–2)]Gal(β1–4/3)GlcNAc	Blood group B, type 1 or 2[a]
Gal(β1–3)[Fuc(α1–4)]GlcNAc	Blood group Lewis a (Le^a)
Neu5Ac(α2–3)Gal(β1–3)[Fuc(α1–4)]GlcNAc	Sialyl Lewis a (sLe^a)
Fuc(α1–2)Gal(β1–3)[Fuc(α1–4)]GlcNAc	Blood group Lewis b (Le^b)
Gal(β1–4)[Fuc(α1–3)]GlcNAc	Lewis x (Le^x)
Neu5Ac(α2–3)Gal(β1–4)[Fuc(α1–3)]GlcNAc	Sialyl Lewis x (sLe^x)
Fuc(α1–2)Gal(β1–4)[Fuc(α1–3)]GlcNAc	Lewis y (Le^y)
$[LacNAc(\beta1–3)]_n$	Blood group i
LacNAc(β1–3)[LacNAc(β1–6)]LacNAc	Blood group I

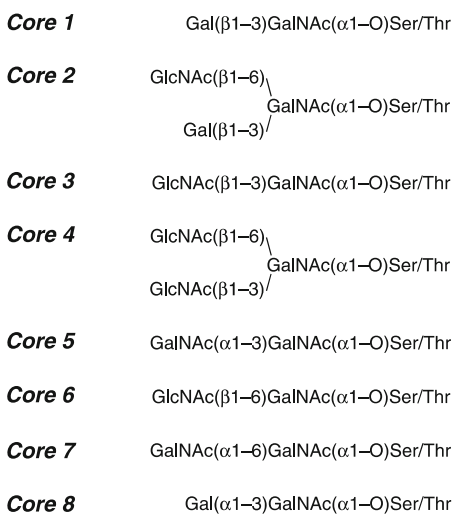
malignant transformations [147,148]. Production of Lewis x and sialyl Lewis x is restricted to myeloid cell lineage and only granulocytes and monocytes are enriched with them in blood cells. In contrast, expression of the ABH blood group antigens is restricted to erythroid cells, and no other blood cells contain ABH blood group antigens. This cell-type specific expression of glycans is caused by the presence of certain key glycosyltransferases that are essential for formation of the corresponding carbohydrate structures and of which expression is restricted to that particular cell type.

2.5 Structure of *O*-Glycans

The biosynthesis of *O*-glycans differs fundamentally from that of the *N*-glycans. *O*-Glycosylation does not begin with the transfer of an oligosaccharide from a dolichol precursor to the nascent peptide chain which is then further processed. Instead, *O*-glycosylation is mainly a post-translational and post-folding event and is initiated by glycosyltransferase-catalyzed addition of a single monosaccharide to a side chain hydroxyl of the protein. Depending on the carbohydrate–peptide linkage, various types of *O*-glycans can be distinguished. By definition, mucin-type *O*-glycoproteins are characterized by the GalNAc(α1–O)Ser/Thr bond [149,150]. This structural element, often referred to as the Tn antigen, was first identified in the mucins but is also found in other glycoproteins. Subsequent stepwise enzymatic glycosylation of the monoglycosylated polypeptide and further modification by sulfation and acetylation leads to a high degree of heterogeneity. Mucin-type *O*-glycan chains typically consist of one to 20 monosaccharide residues and they carry many of the blood group antigens and recognition signals required for intercellular and molecular interactions as well as cancer-associated and differentiation antigens.

2.5.1 Mucin-Type *O*-Glycans

Biosynthesis of mucin-type *O*-glycans starts with the transfer of *N*-acetylgalactosamine (GalNAc) from UDP-GalNAc to the side chain of serine or threonine catalyzed by an *N*-acetylgalactosaminyltransferase. More than 20 homologous *N*-acetylgalactosaminyltransferases are known to date [151]. These transferases are expressed in a tissue-specific manner and have overlapping but different substrate specificities. As a consequence, the site-specificity of mucin *O*-glycosylation is tissue specific and no simple consensus sequence can be found. However, based on statistical analysis of occupied *O*-glycosylation sites, some general rules can be deduced [9]. *O*-Glycosylation occurs preferentially at exposed regions of the protein surface like β-turns or regions with extended conformations. Such areas are usually of low hydrophobicity and, consequently, seldom contain amino acids like Trp, Leu, Ile, and Phe. Instead, Ser, Thr, and Pro are commonly found before and after occupied *O*-glycosylation sites. Also, no bulky amino acids are found near *O*-glycosylation sites, probably due to steric hindrance. However, in contrast to *N*-linked glycans which are usually well separated from each other, *O*-glycans frequently occur in clusters on short peptide sections consisting of repeating units of Ser, Thr, and Pro. It seems to be a general feature that Thr is glycosylated more efficiently than Ser. On the basis of statistical analyses, algorithms allowing the prediction of *O*-glycosylation sites have been developed [152]. The location of the subcellular compartment where *O*-glycosylation is initiated is still controversial and may depend on the type of *N*-acetylgalactosaminyltransferase. Several suggestions that have been made include subregions of the endoplasmic reticulum (ER), a proximal Golgi compartment, an intermediate ER-Golgi compartment (ERGIC), and the Golgi apparatus [153,154,155]. Subsequent stepwise enzymatic elongation of the monoglycosylated polypeptide then leads to several core structures, eight of which have been identified to date (◉ *Fig. 11*). However, under certain circumstances (e. g. in particular transformed cells), elongation does not occur and the Tn



◘ Figure 11
Core structures of *O*-glycans. Core 1 is also called T antigen

antigen is exposed which might be modified to sialyl Tn (sTn) (Neu5Ac(α2–6)GalNAc(α1–O)Ser/Thr) [156,157,158].

Depending on the cell type and its activation and differentiation status, the core structures can be further elongated or terminated by various glycosyltransferases resulting in a large number of *O*-glycans, of which some are depicted in ❯ *Fig. 12*. Many of these glycosyltransferases have been isolated and their genes have been cloned [159,160]. There are glycosyltransferases which specifically act on *O*-glycans (mainly those responsible for assembly of the core structures) and there are others with an activity restricted to *N*-glycans. However, a third group is able to assemble both *N*- and *O*-glycans. The antigenic determinants mentioned in ❯ *Sect. 2.4.2* are generated by such transferases, i. e. the structures listed in ❯ *Table 2* are found on both *N*- and *O*-glycans.

Core 1 and core 2 are the most common core structures in mucins and other secreted and cell surface glycoproteins. Core 1 (the T antigen) is usually not exposed but is monosialylated (Neu5Ac(α2–3)Gal(β1–3)GalNAc(α1–O)Ser/Thr and Neu5Ac(α2–6)[Gal(β1–3)]GalNAc(α1–O)Ser/Thr) or disialylated (Neu5Ac(α2–6)[Neu5Ac(α2–3)Gal(β1–3)]GalNAc(α1–O)Ser/Thr). Core 1 as well as other *O*-glycans is often elongated by *N*-acetyllactosamine, which is a substrate for conversion into the type 2 antigenic determinants sLe^x, Le^x, H type 2, Le^y, A type 2, and B type 2. Core 1 is, however, a poor acceptor for poly-*N*-acetyllactosamine formation. To efficiently achieve this type of extension, core 1 first has to be transformed into core 2. Then, poly-*N*-acetyllactosamine formation can take place at the new GlcNAc(β1–6) branch. Thus, the expression of core 2 *N*-acetylglucosaminyltransferase (core 2 GlcNAcT), the enzyme responsible for the conversion of core 1 into core 2, is rate limiting for the biosynthesis of poly-*N*-acetyllactosamine extensions. The fact that poly-*N*-acetyllactosamine extensions provide an excellent backbone for the expression of antigenic determinants involved in numerous recognition events highlights the biological importance of core 2 GlcNAcT.

So far, core 3 and 4 have been found only in mucins. Core 5 is contained in glycoproteins from several species and has been reported in human adenocarcinoma [161] and meconium [162,163]. It has been speculated that core 6 might be generated by a β-galactosidase-catalyzed degradation of core 2 [159]. Core 7 occurs in bovine submaxillary mucin [164]. All core structures may be unsubstituted or elongated and may carry terminal antigens. Elongation can result in type 1 chains (containing the sequence Gal(β1–3)GlcNAc) or type 2 chains (containing the sequence Gal(β1–4)GlcNAc, e. g. i antigen, poly-*N*-acetyllactosamines) and branched structures (I antigen). Neu5Ac(α2–3 and –6), Fuc(α1–2, –3, and –4), GalNAc(α1–3 and –6), GalNAc(β1–4), GlcNAc(α1–4), Gal(α1–3), and sulfated residues are typically found as terminal structures on *O*-glycans although sialic acids, sulfate, and Fuc(α1–3 or –4) may be also attached to internal carbohydrate residues. Many of the terminal structures are of the Lewis and ABH blood group system (❯ *Table 2*) and are also found on *N*-glycoproteins and glycolipids.

2.5.2 Non-Mucin *O*-Glycans

Beside the GalNAc(α1–O)Ser/Thr linkage of the mucin-type *O*-glycans a number of additional *O*-linkages have been identified. These include mainly fucose α-*O*-linked to Ser/Thr and glucose β-*O*-linked to Ser found in the epidermal growth factor domains of different proteins [58] and *N*-acetylglucosamine β-*O*-linked to Ser/Thr on cytoplasmic and nuclear proteins.

Figure 13
Some structures of non-mucin *O*-glycans (cf. text)

O-Linked fucose has been found on the EGF domains of urokinase, tissue plasminogen activator (tPA), factor VII, and factor XII, attached to the consensus sequence Cys-Xaa-Xaa-Gly-Gly-Ser/Thr-Cys. The fucosyltransferase responsible for the initiation of this type of glycosylation has been cloned [165]. On human (but not bovine) factor IX the tetrasaccharide Neu5Ac(α2–6)Gal(β1–4)GlcNAc(β1–3)Fuc(α1–O)Ser (*Fig. 13a*) was found [166,167]. In other EGF domains only Fuc(α1–O)Ser/Thr was detected.

On the same EGF modules glucose β-*O*-linked to the Ser of the conserved consensus sequence Cys-Xaa-Ser-Xaa-Pro-Cys occurs. In several proteins like the human and bovine blood clotting factors VII and IX, human and bovine protein Z, tPA, thrombospondin, and murine fetal antigen 1 (mFA1) Xyl(α1–3)Xyl(α1–3)Glc(β1–O)Ser (*Fig. 13b*) and substructures thereof (Xyl(α1–3)Glc(β1–O)Ser and Glc(β1–O)Ser) have been identified. The transferase activity responsible for addition of the second xylose has been detected [168].

The *N*-acetylglucosaminyl (β1–O) serine/threonine linkage is common on cytoplasmic and nuclear proteins [54,55,56,57]. No other sugars are connected to the GlcNAc residue. Formation of this type of modification is independent of the activity of the glycosylation machinery

in the endoplasmic reticulum and the Golgi apparatus. Addition of *O*-GlcNAc is catalyzed by a highly conserved *O*-GlcNAc transferase cloned independently by two groups [169,170]. The specificity of this enzyme resembles that of proline-directed kinases. *O*-GlcNAc is found in serine/threonine-rich sequences near Pro and Val residues. Often a negative charge is located nearby. Since the turnover of the *O*-GlcNAc glycan is faster than that of the peptide to which the sugar is attached, *O*-GlcNAc glycosylation is assumed to be reversible. Further evidence for this is the existence of a soluble *N*-acetyl-β-D-glucosaminidase [171]. It is likely that *O*-GlcNAc glycosylation plays a regulatory role that is analogous to protein phosphorylation. The mannosyl (α1–O) Ser/Thr linkage is uncommon in mammalian cells. In bovine peripheral nerve α-dystroglycan clusters of Neu5Ac(α2–3)Gal(β1–4)GlcNAc(β1–2)Man(α1–O)Ser/Thr (❯ *Fig. 13c*) have been observed in Ser/Thr-rich domains [64]. A similar glycan (Neu5Ac(α2–3)Gal(β1–4)GlcNAc(β1–3)Man(α1–O)Ser/Thr) has been found in rat brain proteoglycans [65,66].

2.6 Proteoglycans

Proteoglycans consist of glycosaminoglycan chains covalently attached to a protein backbone [172,173,174,175,176,177]. Therefore, they can be classified as glycoproteins. However, for historical reasons and because they differ substantially from other glycoproteins, they are usually treated as a separate class of compounds. Glycosaminoglycans are linear polysaccharides consisting of hexosamine residues like *N*-sulfonylglucosamine (GlcN*S*), *N*-acetylglucosamine (GlcNAc), or *N*-acetylgalactosamine (GalNAc) alternating with glucuronic acid (GlcA) or L-iduronic acid (IdoA) or galactose (Gal) residues. Different types of glycosaminoglycans are characterized by specific disaccharide repeat patterns. These oligosaccharides are substituted to varying degrees with sulfate linked to free amino and/or hydroxyl groups and range in size from ca. 15 disaccharide units to several hundred. The glycosaminoglycans contained in proteoglycans are chondroitin sulfate, dermatan sulfate, heparan sulfate, heparin, and keratan sulfate. Usually one type of glycosaminoglycan predominates but hybrid proteoglycans do exist. Another glycosaminoglycan (hyaluronan or hyaluronic acid) is not covalently attached to protein. A striking feature of all glycosaminoglycans is their negative charge caused by their sulfate and carboxyl groups which distinguishes these molecules from other glycoproteins. In addition to the glycosaminoglycan chains some proteoglycans contain *O*- and *N*-linked oligosaccharides similar or identical to those of various classes of glycoproteins. Proteoglycans are widely distributed in the animal and plant kingdom and they possess both structural and regulatory roles [177,178,179,180]. They are found in the extracellular matrix (ECM) and associated with specialized structures of the ECM like basement membranes. They also occur as part of plasma membranes where they function as receptors and co-receptors, and they are found intracellularly and intravesicularly in many hematopoietic cells. Proteoglycans have important physiological and homeostatic roles, e. g. during development, inflammation, and the immune response. Glycosaminoglycans such as heparan sulfate may encode information that is (cell) specific, spatially and temporally regulated, and instructive. Many diseases like chondrodystrophies [181], atherosclerosis [182], different types of cancer [183], or Alzheimer's disease [184] are related to abnormalities in the biosynthesis and processing of proteoglycans [172].

2.6.1 Carbohydrate–Peptide Linkage Region

Chondroitin sulfate, dermatan sulfate, heparan sulfate, and heparin are linked with their reducing end to the common core tetrasaccharide GlcA(β1–3)Gal(β1–3)Gal(β1–4)Xyl with the Xyl β-*O*-linked to a Ser residue (➤ *Fig. 14*), usually adjacent to a Gly in the protein backbone [172,173,174,177]. The GlcA residue of this tetrasaccharide is considered as part of the linkage region because the transferase involved in the addition of this residue to the Gal-Gal disaccharide is different from the enzyme that catalyzes the incorporation of GlcA into the rest of the glycosaminoglycan. The xylose may be phosphorylated and one or both galactose residues may be sulfated.

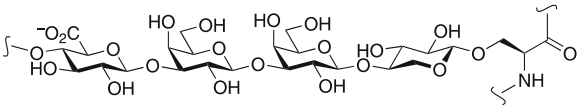

Figure 14
Structure of the linkage region GlcA(β1–3)Gal(β1–3)Gal(β1–4)Xyl(β1–O)Ser of proteoglycans

Skeletal keratan sulfate and corneal keratan sulfate are linked to core protein through *O*-linked and *N*-linked oligosaccharides, respectively, of the general types described in ➤ *Sect. 2.4* and ➤ *Sect. 2.5*.

2.6.2 Structure of Glycosaminoglycans

Hyaluronan (hyaluronic acid) is the simplest glycosaminoglycan. It consists of alternating GlcA and GlcNAc residues which are (β1–3) and (β1–4) linked, respectively (➤ *Fig. 15*) [172,173,174,177]. Hyaluronan is not sulfated and is not bound to protein, thus it is not a component of proteoglycans.

Chondroitin sulfate glycosaminoglycans are composed of the disaccharide repeat unit GlcA(β1–3)GalNAc(β1–4) with variable amounts of sulfation at the positions indicated in ➤ *Fig. 15*. Dermatan sulfate is formed from the precursor chondroitin sulfate by action of an appropriate uronosyl epimerase which converts GlcA into IdoA, giving rise to the disaccharide repeat unit IdoA(α1–3)GalNAc(β1–4) [185]. Thus, both glycosaminoglycans are found on the same protein core. However, there is still no unambiguous convention as to what the proportion of IdoA must be to name a glycosaminoglycan dermatan sulfate. Ordinarily, IdoA is only formed adjacent to 4-sulfated GalNAc and not adjacent to 6-sulfated or non-sulfated GalNAc.

Heparan sulfate glycosaminoglycans and heparin are more complex. They contain two main types of disaccharide residues, although the proportions differ greatly between heparan sulfate and heparin. Heparan sulfate consists of areas of non-sulfated GlcA(β1–4)GlcNAc(α1–4) and areas of sulfated IdoA(α1–4)GlcN*S*(α1–4) disaccharide repeat units with the latter being obtained from the former by action of modifying enzymes during biosynthesis. Heparin differs from heparan sulfate by its higher content of IdoA, *N*-sulfate, and *O*-sulfate with most of the disaccharide units containing 2-sulfated IdoA alternating with GlcN*S* which is partially 6-sulfated and occasionally 3-sulfated as well. On some heparan sulfates occasional 3-sulfation of

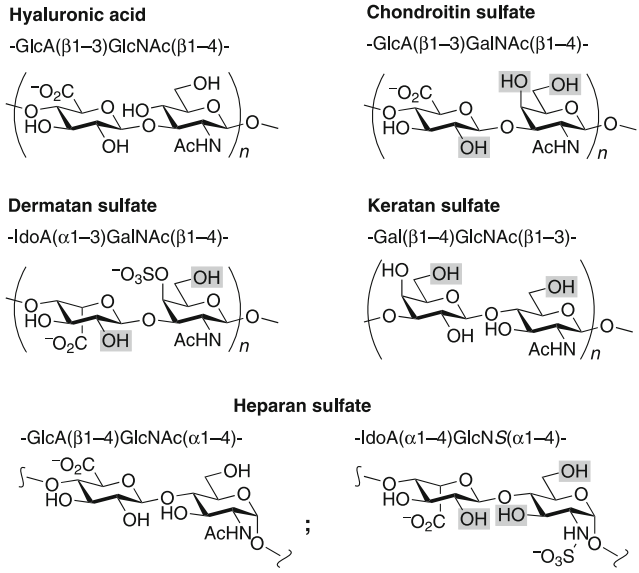

Figure 15
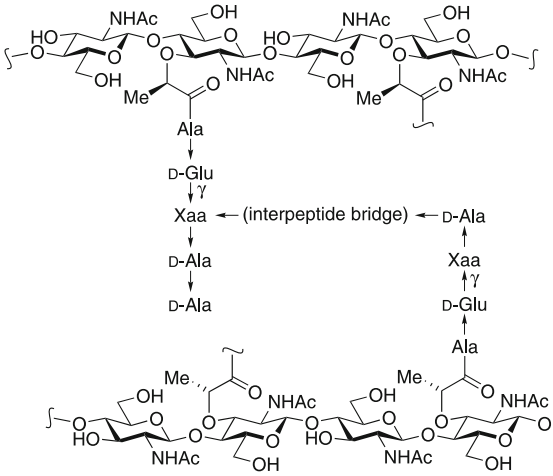
Disaccharide repeats of different glycosaminoglycans. Hydroxyl groups which may be modified by sulfation are marked gray

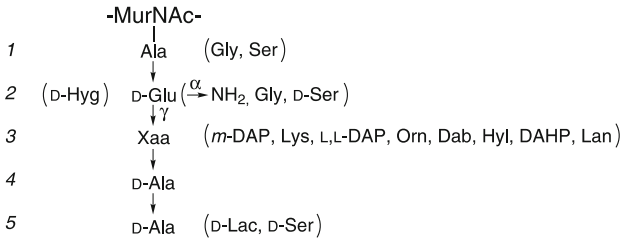
GlcN*S* is also found. Although heparan sulfate and heparin are structurally similar one should keep in mind that both are found on different core proteins.
Keratan sulfate glycosaminoglycans are sulfated poly-*N*-acetyllactosamines of the type found in *N*- and *O*-glycoproteins. The degree of sulfation which takes place at the primary hydroxyl groups is variable along the oligosaccharide chains with a higher degree at the non-reducing end.

3 Peptidoglycan

Peptidoglycan (synonym: murein) [186,187,188] is the essential cell wall polymer of most eubacteria, both Gram-positive and Gram-negative. Although it is not regarded as a glycopeptide it will be briefly treated in this chapter since it consists of carbohydrates covalently attached to peptides. Furthermore, knowledge of peptidoglycan structure is helpful for an understanding of the mode of action of the glycopeptide antibiotics of the vancomycin group. Peptidoglycan is composed of three structural features: a matrix of polysaccharide chains, the pentapeptide side chains, and the interstrand peptide cross-links, called interpeptide bridges (*Fig. 16a*). The glycan component of all peptidoglycans consists of alternating β1–4 linked GlcNAc and *N*-acetylmuramic acid (MurNAc) (a GlcNAc with a lactyl ether at O-3) residues. Average glycan-chain lengths of ca. 8 to 40 disaccharide units have been reported depending on the method used for determining them [188,189,190]. This structure is common to all bacterial peptidoglycans examined, with only minor variations. In *Staphylococcus aureus* for



a



b

Figure 16

(a) Part of the common primary structure of bacterial peptidoglycan. *Arrows* indicate the polarity of peptide chains pointing from the *N*-terminus towards the *C*-terminus. (b) Variations in the pentapeptide chain. Residues in *parentheses* may replace corresponding amino acids or, in the case of α-carboxylate modification of γ-D-Glu, may be missing. *Abbreviations*: Dab, 2,4-diaminobutyric acid; DAHP, 2,6-diamino-3-hydroxypimelic acid; DAP, diaminopimelic acid; Hyg, *threo*-3-hydroxyglutamic acid; Hyl, hydroxylysine; Lac, lactate; Lan, lanthionine

example, up to 50% of the MurNAc residues are 6-*O*-acetylated [191] and in *Micrococcus lysodeikticus*, up to 40% of the MurNAc residues are not attached to peptide chains [192].

Attached to the carboxylate of MurNAc is a pentapeptide with the common sequence Ala-γ-D-Glu-Xaa-D-Ala-D-Ala (non-specification of the amino acid configuration implies the natural L-form), where Xaa is *meso*-diaminopimelic acid (*m*-DAP) for Gram-negative bacteria and Lys for most Gram-positive bacteria, with some variations [193]. During peptidoglycan biosynthesis, the pentapeptide is cross-linked through amino acid Xaa to another peptide strand. This transpeptidation involves attack of the ε-amino group of the *m*-DAP or Lys residue (or amino terminus of the interpeptide bridge) onto the penultimate D-Ala of another chain, resulting in loss of the terminal D-Ala of the second peptide chain and peptide bond formation. As mentioned, variations in the pentapeptide side chains are possible and they are summarized in ❯ *Fig. 16b*. Variations in position 1 are rare and γ-D-Glu is found universally at position 2.

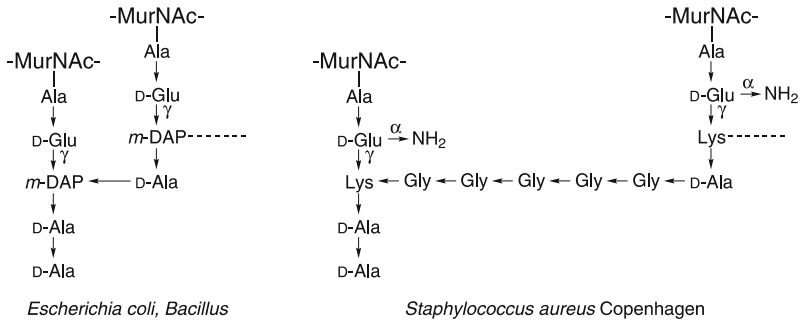


Figure 17
Peptide cross-links of *Escherichia coli*, *Bacillus*, and *Staphylococcus aureus* Copenhagen peptidoglycan

However, its α-carboxylate is often amidated or linked to an additional amino acid and in *Microbacterium lacticum* γ-D-Glu is replaced by *threo*-3-hydroxy-D-glutamic acid (3-Hyg). Most variation is found in position 3. If *m*-DAP (D,L-configuration) is incorporated, the L center is found in the pentapeptide chain and the D center in the side chain. Positions 4 and 5 (D-Ala-D-Ala) were for a long time thought to be invariant. However, the incidence of bacterial resistance to vancomycin-type glycopeptide antibiotics which recognize specifically the *N*-acyl-D-Ala-D-Ala terminus led to the discovery that these resistant strains contain altered substituents at position 5 as indicated in *Fig. 16b* [194,195,196].

Peptidoglycan strands are connected to varying degrees by a network of cross-links formed between the pentapeptide side chains. The structures of these cross-links which are quite heterogeneous have been reviewed [186,189,193] and this feature has been used for taxonomic classification of bacteria [193]. Here only two examples are presented (*Fig. 17*). In *Escherichia coli* and strains of *Bacillus* the simplest type of linkage is realized, i. e. the direct attachment of the ε-amino group of *m*-DAP to D-Ala at position 4 of the second peptide. If L-lysine is found in position 3 of the peptide chain, which is the case for most Gram-positive bacteria, usually 1–5 amino acid residues (L-configured or glycine) are incorporated between the ε-amino function of Lys and the D-Ala of the second peptide . As such, the interpeptide bridge of the well-studied *Staphylococcus aureus* Copenhagen strain consists of pentaglycine. However, other strains of *Staphylococcus* contain Ala, Ser, or Thr.

Currently, there is no generally accepted model for the three-dimensional structure of peptidoglycan. Two alternative models in which the glycan strands are arranged either parallel (classical model) or perpendicular ('scaffold' model) to the cytoplasmic membrane are discussed [188,190]. However, the models do not need to be mutually exclusive. It may also be that the cell wall exists as a mosaic of microdomains with different structures, or perhaps new cell wall is inserted in one form before being converted to another [197].

4 Glycopeptide Antibiotics

The glycopeptide antibiotics are glycosylated secondary metabolites of bacteria and fungi that are synthesized by non-ribosomal peptide synthetases. The term glycopeptide antibiot-

ic often solely refers to vancomycin and its analogues excluding other compounds, such as the bleomycins, ramoplanin, and the mannopeptimycins, that also belong to the group of glycopeptide antibiotics [198]. This section, however, will focus on the vancomycin group because it represents the biggest class of glycopeptide antibiotics.

4.1 Discovery and Medical Use

Vancomycin was discovered in the mid-1950s in a soil sample from the jungles of Borneo by coworkers of the American pharmaceutical company Eli Lilly [199]. It is produced as a secondary metabolite by the microorganism *Streptomyces orientalis* (reclassified as *Amycolatopsis orientalis*) [200] and displays antibiotic activity against the majority of Gram-positive bacteria. The discovery of vancomycin was followed a year later by the isolation of ristocetin [201]. These two antibiotics were recognized as belonging to a chemical class of antibiotics called glycopeptides [194,198,202,203,204]. Vancomycin was first used clinically in 1959. However, toxicity problems due to inadequacies during its purification precluded its widespread use in the early years and vancomycin was for the moment overshadowed by semisynthetic penicillins and later cephalosporins. However, with improved purification techniques and as the result of the emergence of multiple resistant and methicillin resistant *Staphylococcus aureus* (MRSA), vancomycin has become the drug of choice in the fight against these 'superbugs' [203]. Ristocetin appeared to be a promising antibacterial agent in the late 1950s but it was withdrawn following the death of several patients [205]. Avoparcin has shown growth-promoting activity in farm animals and has been marketed in Europe since 1976 as a feed additive. It is also used in the dairy industry for improvement of milk production of lactating dairy cows. Today two members of the group of the glycopeptide antibiotics are in clinical use—vancomycin and teicoplanin. Together with the aminoglycoside gentamycin, they are the antibiotics of last resort in our hospitals. However, in the meantime vancomycin resistant *S. aureus* strains are also being observed [206,207].

4.2 Structure and Classification

The first structural work on vancomycin were degradation studies carried out by Marshall [208] followed by extensive NMR examinations in the laboratory of Williams [209]. On the basis of these pioneering studies and on the X-ray analysis of the degradation product CDP-1 [210], Harris and Harris published the complete structure of vancomycin in 1982 [211]. The determination of the vancomycin structure then served as the basis for the structural characterization of hundreds of natural and semisynthetic glycopeptide antibiotics.

The glycopeptide antibiotics of the vancomycin group consist of a peptide backbone of 7 amino acids (see ❯ *Fig. 18* for selected examples). The side chains of amino acids 2 and 4 as well as 4 and 6 and in most cases also 5 and 7 are linked to each other, either via biaryl ether or direct biaryl bonds. The resulting structural elements give rise to the phenomenon of atropisomerism. Bound to this peptide core are 1–4 saccharides (mono- to tetrasaccharides). The vancomycin-type glycopeptide antibiotics can be subdivided in four or five groups based on chemical structure [198,204,212]. Group I, or the vancomycin type, has aliphatic amino acids at positions 1 and 3 while groups II–IV, illustrated by avoparcin, ristocetin, and

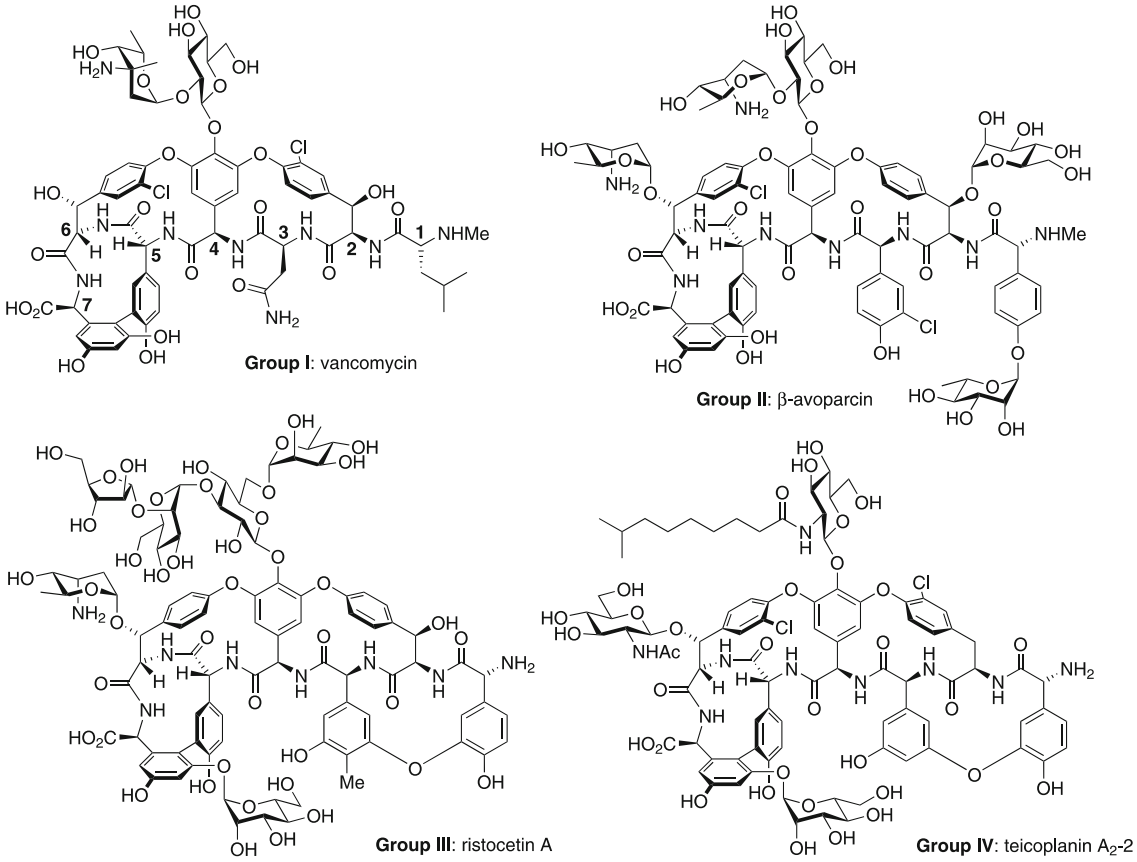

Figure 18
Selected structures of vancomycin-type glycopeptide antibiotics belonging to groups I–IV

teicoplanin, respectively, are characterized by aromatic residues at these positions. Members of group III and IV have an additional biaryl ether bridge between the side chains of amino acids 1 and 3. Type IV glycopeptide antibiotics could be considered a subgroup of III since the arrangement of the amino acids in the peptide core is the same. The antibiotics of this group have a fatty acid residue attached to an amino sugar. Finally, a fifth type of antibiotics can be defined containing a characteristic tryptophan residue at position 2. However, the members of this group identified so far (chloropeptin I, complestatin, and kistamycin A and B) are not glycosylated.

More than four centuries after its discovery and some 20 years after its structure elucidation, total syntheses of vancomycin [213,214,215,216,217] and its aglycon [218,219,220] have been accomplished by several research groups.

8.2 Glycoproteins: Properties

Valentin Wittmann
Fachbereich Chemie, Universität Konstanz, 78457 Konstanz, Germany
mail@valentin-wittmann.de

Abstract

This chapter focuses on the biological roles of the glycans contained in glycoproteins. Today we know there is no unifying function for the carbohydrates present in glycoproteins. They rather span the complete spectrum from being obviously unimportant to being crucial for the survival of an organism. In a crude scheme, their biological functions can be classified into two groups. On one hand, the carbohydrates can modify intrinsic properties of a protein by altering its size, charge, solubility, accessibility, structure, or dynamic properties. On the other hand, the glycans themselves may be specifically recognized by carbohydrate-binding proteins and thus participate in adhesion processes and signal transduction. A selection of some of these processes, that are well characterized, will be highlighted.

Keywords

Glycoproteins; Glycopeptides; Antifreeze glycoproteins; Protein stability; Protein activity; Glycopeptide conformation; Blood group antigens; Glycosyltransferases; Glycosidases; Protein folding

1 Introduction

Whereas the last chapter provided an overview of the structures of glycoproteins and glycopeptides occurring in nature, this chapter focuses on the biological roles of their carbohydrate units. However, the frequently asked question "What is the function of glycosylation?" is actually as unreasonable as would be the question "What is the function of proteins?" Today we know there is no unifying function for the carbohydrates present in glycoproteins. They rather span the complete spectrum from being relatively unimportant to being crucial for the survival of an organism. Moreover, the same glycan may have different functions at different locations on a given protein, or in different cells or developmental stages of an organism. Thus, each glycoprotein has to be studied individually in order to unravel the roles of its glycans. The aim of this chapter is to indicate some general principles of protein glycosylation.

Diverse approaches are being employed in order to uncover the roles of carbohydrates contained in glycoconjugates [1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18]. They include the localization of specific glycans using lectins or antibodies, the modification of glycans by glycosyltransferases and glycosidases, and the use of inhibitors of glycan biosynthesis or processing. Natural or synthetic ligands can be used to identify specific carbohydrate receptors. The methods of molecular biology provide a powerful tool to study glycan function. Thus, it is possible to generate cell mutants with altered glycosyltransferase expressions. Alternatively, recombinant glycoproteins can be expressed in different cells with different glycosylation properties. Chinese hamster ovary (CHO) cells, for example, are not able to generate sialic acid α2–6 linkages and galactose α1–3 linkages and bacteria like *Escherichia coli* produce completely non-glycosylated proteins. Recently, the chemical synthesis of pure glycoforms of glycoproteins or glycoprotein mimetics has become feasible providing a powerful tool for structure-activity relationship studies [19]. Metabolic engineering is another technique developed by chemists that gives access to glycoproteins containing functional groups that are selectively addressable by chemical ligation reactions [20,21]. Carbohydrate chips are used to probe carbohydrate recognition by proteins and other binding partners in a high-throughput manner [14,22,23,24,25].

In a crude scheme, the biological functions of glycans can be classified into two groups. On one hand, the carbohydrates can modify intrinsic properties of a protein by altering its size, charge, solubility, accessibility, structure, or dynamic properties. On the other hand, the glycans themselves may be specifically recognized by carbohydrate-binding proteins and thus participate in adhesion processes and signal transduction.

2 Modulatory and Structural Roles of Glycans

In the following sections some modulatory and structural roles of glycans are discussed. However, it should be kept in mind that the chosen classification of the roles of glycans is somehow arbitrary since the individual effects often cannot be separated from each other. Thus, varied stability or biological function of a protein upon glycosylation is often a result of altered structural or dynamic parameters caused by the carbohydrates.

2.1 Modulation of Physicochemical Properties

The modification of physicochemical properties of proteins by attached carbohydrates is often observed, especially in glycoproteins with high carbohydrate content [1,7,12,26]. Sialylated or sulfated glycans, e. g., change the overall charge of a protein and increase its solubility. This is important for the highly glycosylated mucins (high sialic acid content) and the highly sulfated proteoglycans. Contained in mucous secretions of most epithelial cells, they can provide a gelation function due to their ability to retain water. Thus, they function as lubricants and protection for epithelial surfaces and mediate transport. Examples include synovia, buffering excessive gastric acid, and transport of chyme. In the extracellular matrix, proteoglycans provide elasticity and tensile strength. Furthermore, both mucins [27,28] and proteoglycans [29,30,31,32,33] act as adhesion molecules in numerous cell-cell, cell-matrix, and cell-microbe recognition events.

Antifreeze glycoproteins (AFGPs) [34,35,36,37,38] circulate in the blood of Antarctic fish and enable them to avoid freezing in their perpetually icy environment where the temperature is frequently as low as −1.9 °C. These mucin-type *O*-glycoproteins are composed of repeats of the glycotripeptide unit (Ala-Ala-[Gal(β1–3)GalNAc(α1–*O*)]Thr)$_n$ (*Fig. 1*). Eight distinct fractions of these proteins have been isolated (AFGP 1–8) with the number *n* of glycotripeptide

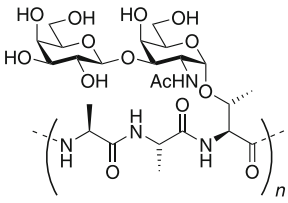

Figure 1
Structure of the glycotripeptide repeating unit (Ala-Ala-[Gal(β1–3)GalNAc(α1–O)]Thr)$_n$ contained in antifreeze glycoproteins

repeats ranging from 50 (molecular mass 33 kDa) to 4 (2.6 kDa). In smaller-sized AFGPs, proline replaces some of the alanine residues following threonine. Antifreeze glycoproteins function in a noncolligative manner by binding to and inhibiting the growth of ice crystals that enter the fish and maybe also by preventing the nucleation of ice crystals. This results in a freezing point depression without an appreciable change in the melting point. The difference between the melting and freezing temperatures is termed thermal hysteresis and is used as a measure for the magnitude of the antifreeze activity. In addition to thermal hysteresis, AFGPs effect alteration of the morphology of ice crystals into a hexagonal bipyramid. Studies revealed that chemical modification (acetylation, priodate oxidation, and complexation with borate but not oxidation of the two primary hydroxyls with galactose oxidase to give the bisaldehyde) or removal of the sugar residues results in a complete loss of antifreeze activity [35,38].
Recently, Nishimura et al. presented a detailed study on synthetic AFGPs composed of one to seven glycosylated Ala-Thr-Ala repeating units [39]. It was shown that a minimum of two

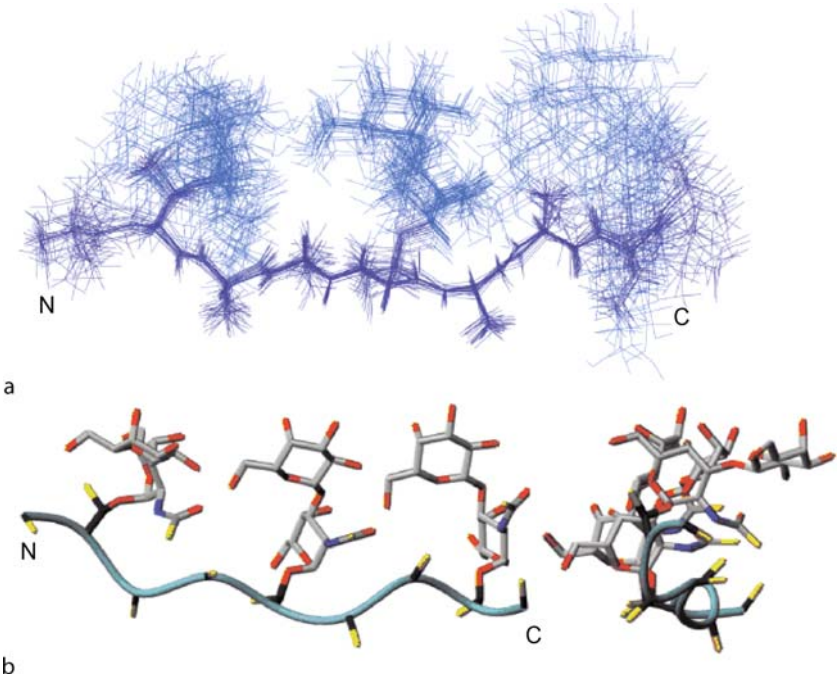

Figure 2
a Superposition of the 25 lowest energy structures of (Ala-[Gal(β1–3)GalNAc(α1–O)]Thr-Ala)$_3$ calculated from NMR-based constraints. The peptide backbone is navy, and the carbohydrate moieties are royal blue. b Structure closest to the average of the 25 best calculated models: yellow, methyl carbon; white, carbon in carbohydrate; gray, carbon in peptide side chains except for methyl carbon; blue, nitrogen; red, oxygen; the *N*- and *C*-terminal ends are identified. The peptide backbone folds into a left-handed helix similar to the polyproline type II helix. The disaccharides point to one side of the amphiphatic helix, thus constructing a hydrophilic face, while the Ala-CH_3 groups and acetyl methyl groups in the GalNAc residues are clustered into the hydrophobic face of the molecule. (Reprinted from [39] with permission from Willey-VCH)

repeating glycopeptide units is necessary to obtain compounds that give rise to thermal hysteresis. All compounds including the monomeric glycotripeptide, however, were capable to alter the morphology of ice crystals into hexagonal bipyramids. Varying the disaccharide part of oligomeric AFGP revealed three key motifs required for antifreeze activity, namely the *N*-acetyl group at the C-2 position of the reducing hexosamine, α-configuration of the *O*-glycosidic linkage between sugars and peptide chain, and the γ-methyl group of the threonyl residue. Strong evidence indicated that the peptide backbone conformation plays a critical role for antifreeze activity. Compounds lacking the mentioned key motifs either lost secondary structure or changed from a polyproline type II helix in the active compounds to a largely α-helical structure in the case of the glycosylated Ala-Ser-Ala repeating unit as determined by CD spectroscopy. Despite the absence of long- and medium-range NOE contacts, a surprisingly well-defined NMR-based structure could be calculated for the three repeating units containing glycopeptide (Ala-Ala-[Gal(β1–3)GalNAc(α1–O)]Thr)$_3$ (*Fig. 2*). The authors propose that the amphiphatic nature of the observed left-handed helix is crucial for antifreeze activity. However, even though the study by Nishimura et al. presents a consistent picture, the situation for naturally occurring AFGPs seems to be more complicated and structural studies on these molecules have a long history of controversial interpretations [38].

Genetic studies have shown that the AFGPs present in the two geographically and phylogenetically distinct Antarctic notothenioids and Arctic cod have evolved independently, in a rare example of convergent molecular evolution [38]. Recently, a novel antifreeze glycoprotein has been isolated from *Pleuragramma antarcticum* which was shown to be a proteoglycan [35]. Beside these antifreeze glycoproteins, several non-glycosylated antifreeze proteins are known [34,35,36,37,38].

2.2 Protective and Stabilizing Functions

There is little doubt that the "coating" of oligosaccharides on many glycoproteins can protect the peptide backbone from recognition by proteases and antibodies [1,7,12,26]. An example is the decay accelerating factor (DAF, CD55) which is proteolyzed upon removal of its *O*-linked sugars [40]. Decoration of the surfaces of most types of cells with different kinds of glycoconjugates gives rise to the so-called glycocalyx which can present a substantial physical barrier. Glycosylation can also alter the heat stability of proteins which has been shown for two different β1–3/4 glucanases from *Bacillus* species. Expression in *Saccharomyces cerevisiae* resulted in heavily glycosylated enzymes (carbohydrate content of about 45%) which were significantly more heat stable than their non-glycosylated counterparts expressed in *Escherichia coli* [41]. Such findings are of special interest for the industrial use of proteins. Other examples of the stabilizing function of carbohydrates [42,43,44] are ovine submaxillary mucin [45], an isolated tailpiece from human serum immunoglobulin M [46], RNase B [47,48,49], human CD2 [50], and the protease inhibitor PMP-C [51]. In these cases, the glycans had little overall effect on the conformation of the proteins but rather globally decreased the dynamic fluctuations of the glycoproteins, as revealed by NMR spectroscopy. The stabilizing function can be achieved even by a single carbohydrate unit [50,51].

2.3 Modulation of Biological Activity

There are many examples for the ability of carbohydrates to modulate the biological activity of functional proteins [1,7,12]. Bovine pancreas ribonuclease (RNase) for example occurs in unglycosylated (RNase A) and glycosylated (RNase B) forms, the latter being a set of nine different glycoforms of the high mannose type ($Man_{5-9}[GlcNAc]_2$) with respect to the only *N*-glycosylation site (Asn-34) of the protein [7]. Using double stranded RNA as substrate, it was shown that RNase A is more than three times as active as RNase B [49]. Furthermore, enzyme activities of several glycoforms of RNase, prepared by exomannosidase treatment of naturally occurring RNase B, have been determined and may be ranked in terms of decreasing activity as: RNase A > RNase ($Man_0[GlcNAc]_2$) > RNase ($Man_1[GlcNAc]_2$) > RNase ($Man_5[GlcNAc]_2$) > RNase B. These differences in activities were attributed to an overall increase in dynamic stability of the protein upon glycosylation and to steric hindrance between the oligosaccharides and the RNA substrate which is also supported by molecular modeling [47,48,49,52]. The dynamic properties of the protein were studied by NMR spectroscopic determination of proton/deuterium exchange rates of the various glycoforms. The presence of the glycan reduces solvent access to many regions of the peptide backbone both close to and remote from the glycosylation site as much as 30 Å away (*Fig. 3*), suggesting

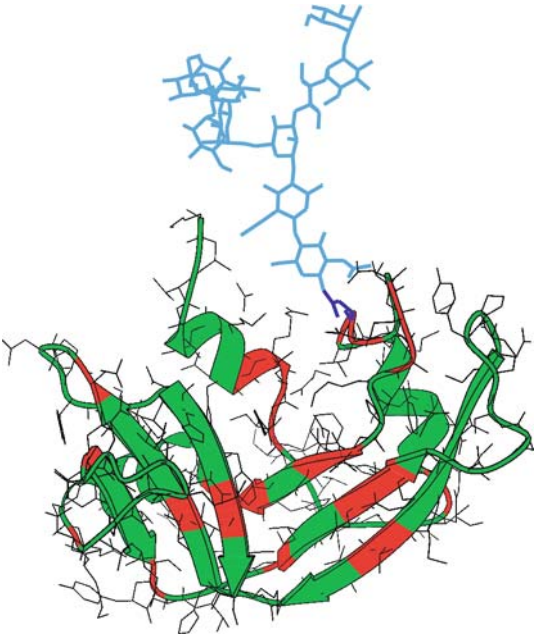

Figure 3
The presence of the glycan (light blue) on ribonuclease B reduces the amide proton/deuterium exchange rates compared with ribonuclease A for extensive regions of the peptide backbone (shown in red) both local to and remote from the glycosylation site [47]. The glycoprotein structure is based on the crystal structure of ribonuclease B [53] and one of the structures of $Man_9GlcNAc_2$ determined by NMR and molecular dynamics. (Reprinted from [44] with permission from Elsevier), [54]

that it reduces fluctuations of the backbone. This was confirmed by circular dichroism (CD) studies that indicated that the glycan has a small stabilizing effect on the peptide fold.

Tissue plasminogen activator (tPA) is another enzyme whose activity is affected by glycosylation [7]. tPA is a serine protease which converts plasminogen into plasmin which itself is a serine protease with fibrinolytic activity. There are two major classes of glycoforms of naturally occurring tPA. Type I contains three *N*-linked glycans at Asn-117, Asn-184, and Asn-448, whereas type II has only two, at Asn-117 and Asn-448. Variable occupancy of Asn-184 affects the population of glycoforms at Asn-448. Plasminogen is also a mixture of two major glycoforms containing one *O*-glycan and one *N*-glycan (type 1) or one *O*-glycan (type 2). For an efficient proteolytic activity of tPA, formation of a ternary complex with plasminogen and fibrin is required. Rate of formation and turnover of the complex is dependent on the glycosylation site occupancy of both tPA and plasminogen [55]. Thus, clot lysis occurs 2–3 times faster with type II tPA in combination with type 2 plasminogen versus participation of type I tPA and type 1 plasminogen. Both the *N*-glycan linked to Asn-184 in type I tPA and the *N*-glycan contained in type 1 plasminogen reduce the enzymatic activity of the serine proteases. In contrast to this tuning function of the *N*-glycans, it has been shown that the *O*-glycan contained in plasminogen is crucial for its proteolytic activity.

Glycosylation of a ligand can also mediate such an on-off or switching effect. Deglycosylation of the hormone human β chorionic gonadotropin (β-HCG) for example leads to a species which is still able to bind to its receptor with similar affinity but fails to stimulate adenylate cyclase [1]. In most cases, however, such effects of glycosylation are incomplete, i. e., the carbohydrates provide a means of tuning the primary function of the proteins. From numerous examples studied, it was concluded that the relatively large *N*-linked glycans generally downmodulate the activities of enzymes and signal molecules whereas *O*-glycosylation can result in both a downregulation and an upregulation [10,56,57].

2.4 Influence on Peptide Secondary Structure

Glycosylation can affect protein structure in several capacities [7,9,10,42,43,44,58,59]. Structural roles of glycans associated with protein stability and the regulation of protein function have already been mentioned in the preceding sections. Oligosaccharides attached to matrix molecules like collagens and proteoglycans are important in the physical maintenance of tissue structure, porosity, and integrity. *N*-Glycosylation is a co-translational process that is believed to play a major role in the initiation of correct folding of the nascent polypeptide chain in the rough endoplasmic reticulum [9,43,58,60,61]. Indeed, numerous examples exist in which removal of certain *N*-glycosylation sites by site-directed mutagenesis results in improper folding of glycoproteins [9,58,62,63,64,65,66]. The impact of *N*-glycosylation on the conformation of model peptides was nicely demonstrated by Imperiali et al. in a series of publications using time-resolved fluorescence resonance energy transfer (FRET) [67] and NMR techniques [68,69]. The examined peptides were derived from the A282-A288 sequence (Ile-Thr-Pro-Asn-Gly-Ser-Ile) of the hemagglutinin glycoprotein from influenza virus containing the critical Asn-A285 glycosylation site. This sequence represents a β-turn surface loop in the native protein which is of considerable interest as this motif is a common feature among the *final* structures of glycosylation sites in many glycoproteins.

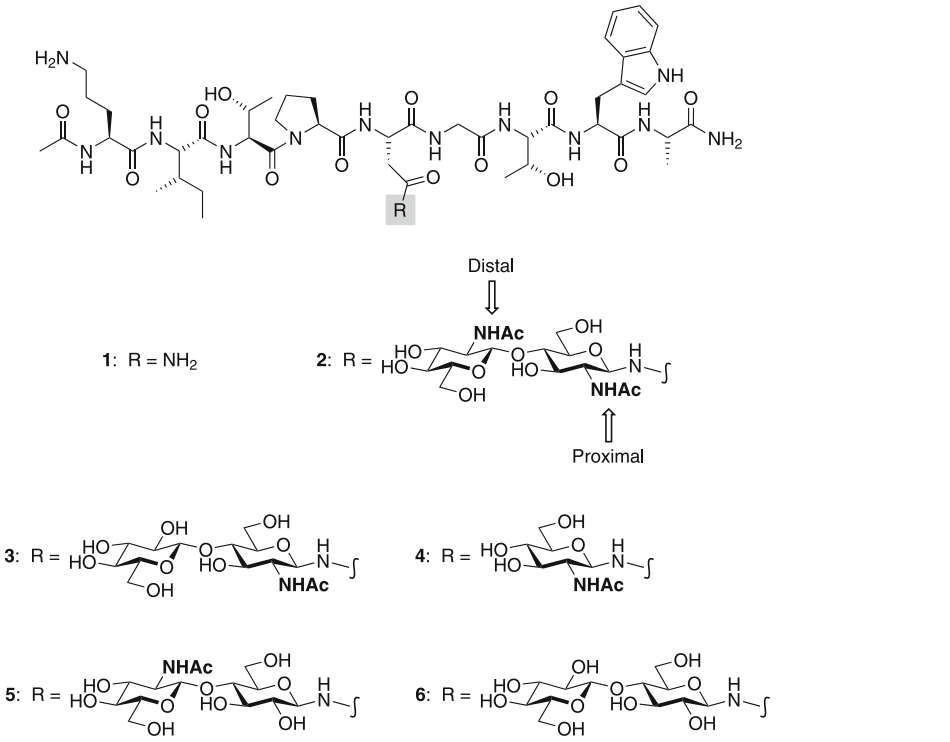

Figure 4
Peptide 1 and glycopeptides 2–6 synthesized in order to probe the influence of asparagine-linked glycosylation on peptide secondary structure [67,68,69]

In the FRET study [67], fluorescently labeled analogues of peptide **1** and glycopeptide **2** (*Fig. 4*) with a dansyl group at N_δ of Orn were examined. The study revealed that glycosylation of **1** with a chitobiosyl moiety (→ **2**) promoted the adoption of a more compact peptide secondary structure. Subsequent 2D ^{1}H NMR investigations in aqueous solution [68] supported this analysis and indicated that peptide **1** adopts an open and extended Asx-turn conformation prior to glycosylation whereas glycopeptide **2** exhibits a compact type I β-turn conformation (*Fig. 5*), quite similar to that observed in the final native protein structure. Both the FRET and NMR studies provide direct evidence that glycosylation of peptide **1** with chitobiose, a disaccharide representing the first two *N*-acetylglucosamine residues of the native tetradecasaccharide (cf. Chap. 8.1), induces a conformational switch in the peptide backbone. This observation is important with respect to the role glycosylation plays in the correct folding of glycoproteins. It was suggested that *N*-linked glycosylation may serve as a critical trigger to help the polypeptide chain to adopt a conformation that is populated in the native folded protein, but not in the nascent unmodified sequence.

Despite the strong influence of glycosylation on peptide conformation, no specific interactions between the chitobiose moiety and the peptide backbone were detected in the NMR analysis in aqueous solution. Therefore, it was proposed that the conformational change observed upon

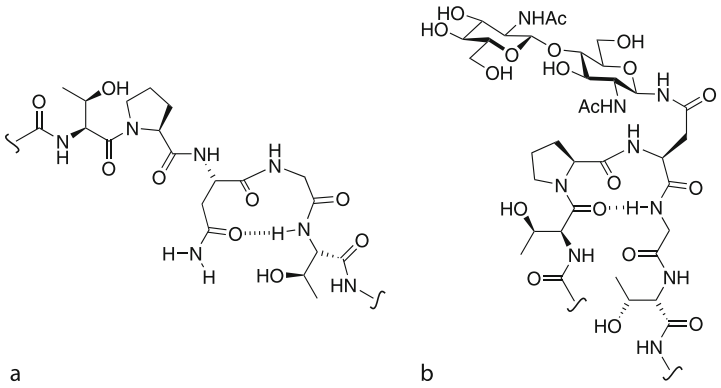

Figure 5
Glycosylation-induced conformational switching from an (a) Asx-turn to a (b) type I β-turn [68]

glycosylation results from either a steric effect in which the disaccharide alters the conformational space available to the peptide or from a modulation of the local water structure that influences the environment that the peptide experiences [68]. To address the important question if chitobiose may be replaced with other disaccharides, glycopeptides **3**–**6**, containing the saccharides Glc(β1–4)GlcNAc, GlcNAc, GlcNAc(β1–4)Glc, and Glc(β1–4)Glc, respectively, were examined (*Fig. 4*) [69]. In all cases, less well-ordered peptide conformations as compared to **2** were determined by NMR analysis. The study revealed that the *N*-acetyl group of the proximal sugar is critical for maintaining a β-turn conformation. Surprisingly, the *N*-acetyl group of the distal sugar also plays an important role in rigidifying both the saccharide and the peptide.

Recently, Imperiali et al. reported a synergistic experimental and computational study of a glycopeptide analogous to glycopeptide **2** but with the chitobiose moiety α-*N*-glycosidically linked to asparagine [70]. Thereby, the effect of the stereochemistry of the carbohydrate-peptide linkage on glycopeptide structure could be evaluated. It was shown that only the β-linked glycopeptide **2** adopted a type I β-turn whereas the α-anomer adopted an Asx-turn-like conformation comparable to that of the unmodified peptide **1**. In this regard, it is worth mentioning that statistical analyses of the conformation of *N*-glycosylation sites revealed that only about a quarter of glycosylated asparagines are located at a β-turn [71,72,73]. This could mean that the induction of a β-turn structure by *N*-glycosylation is of transient character and of major importance only during the early stages of the folding process [59]. A lectin-mediated mechanism by which *N*-glycans participate in quality control of protein folding will be discussed in *Sect. 3.3.2*.

An influence of *N*-glycosylation on peptide conformation has also been observed by Danishefsky et al. upon attachment of the non-natural trisaccharide Gal(β1–6)Gal(β1–6)GlcNAc β-*N*-glycosidically to the Asn side chain of the model peptide H-Ala-Leu-Asn-Leu-Thr-OH [74]. Whereas the unglycosylated peptide failed to manifest any appreciable secondary structure, the glycopeptide was assumed to exist in an equilibrium between an ordered and a random state. When carried out at –12 °C using a 90:10 mixture of H_2O/acetone-d_6, NMR analysis

revealed nuclear Overhauser enhancement (NOE) effect crosspeaks between the methyl of the sugar *N*-acetyl group and backbone amide protons.

In contrast to *N*-glycosylation, *O*-linked glycosylation is an entirely post-translational and post-folding event in mammalian cells. Nevertheless, *O*-Glycans may have major impact on the secondary, tertiary, and quaternary structure of fully folded proteins [10]. Otvos et al. showed that glycosylation distorts the α-helicity of an epitope on the rabies virus glycoprotein, and that *O*-glycosylation of threonine is more effective in perturbing the secondary structure of the peptide than *N*-glycosylation of asparagine [75]. In several NMR studies it has been shown that the peptide backbone of model peptides responds to *O*-glycosylation as evidenced by changes in sequential amide-amide NOE interactions [76,77,78,79,80]. The examples include the mucin-type GalNAc(α1–O)Thr [76,77,78] as well as the GlcNAc(β1–O)Thr linkages [79,80]. In all cases, the NMR data, which were supplemented in part by CD and fluorescence measurements [78,79], molecular modeling calculations [78,79,80], and chemical evidence [80], were indicative for a glycosylation-induced conformational change from a random structure to a turn-like structure. The conformational response is further modulated by whether the sugar component is a mono-, di-, or oligosaccharide [77,80].

In recent times, more detailed conformational analyses of *O*-glycopeptides have been published by several groups [81,82,83,84,85,86,87,88]. Very recently, Griesinger and Kunz and coworkers reported the effect of *O*-glycosylation with the α(2,6)-sialyl-T antigen on the conformational propensities of a 20-residue peptide representing the full length tandem repeat sequence of the human mucin MUC1 [89]. The peptide contained both the GVTSAP sequence, which is an effective substrate for GalNAc transferases, and the PDTRP fragment, a known epitope recognized by several anti-MUC1 monoclonal antibodies. NMR experiments were carried out in a H_2O/D_2O mixture (9 : 1) close to physiological conditions (25 °C, pH 6.5). Cluster analysis of the conformational ensemble yielded a rod-like structure with the GalNAc methyl group oriented towards the *C*-terminus, similar to results obtained by Danishefsky et al. [81].

3 Involvement of Glycans in Recognition Events

Oligosaccharides have an enormous information-storing potential, being substantially higher than that of oligopeptides and oligonucleotides [90]. Thus, it is not surprising that the carbohydrates contained in glycoconjugates, beside their role in modulating intrinsic properties of glycoproteins, can act as recognition markers in numerous physiological and pathological processes [1,7,12,15,91,92,93,94,95,96,97,98,99,100]. Responsible for deciphering the encoded information are carbohydrate-binding proteins. They can be subdivided into antibodies, enzymes involved in sugar utilization and glycoconjugate turnover, and carbohydrate-binding proteins which are neither immunoglobulins nor enzymes. The latter have been referred to as lectins [101,102,103,104,105,106,107]. Carbohydrate-lectin interactions play a crucial role in many cellular recognition processes including clearance of glycoproteins from the circulatory system, control of intracellular traffic of glycoproteins, bacterial and viral adhesion to host cells, recruitment of leukocytes to inflammatory sites, cell interactions in the immune system, and tumor metastasis just to name a few. In the following sections some of these processes will be highlighted.

3.1 Carbohydrate Recognition by Blood Group Antibodies

The discovery of the ABO blood group system 100 years ago by Landsteiner et al. [108] was based on the observation that humans could be divided into different groups according to the presence or absence of serum constituents that would agglutinate red cells isolated from other humans. Although they were not aware of the underlying glycan basis, the work of Landsteiner and colleagues laid the basis for the safe transfusion of blood from one individual to another [109]. Today we know that the agglutinating serum constituents are antibodies and that their cognate antigens are oligosaccharides whose structures are genetically polymorphic [12,110,111,112,113]. The first discovery of these antigens on the surface of human erythrocytes led them to be classified as "blood-group antigens". However, they are also found in human secretions and mucosal tissues and it was suggested that they are more accurately defined as "histo-blood group antigens" [114].

The A, B, and H antigens (the latter being the one expressed by blood group O individuals) are formed by sequential action of distinct glycosyltransferases on different precursor saccharides, most often terminal residues of glycolipids and proteins. According to the nature of these peripheral disaccharide core structures on which the blood group antigens are synthesized, different types are distinguished. In type-1 structures, the antigen synthesis starts from Gal(β1–3)GlcNAc(β). Similarly, modification of Gal(β1–4)GlcNAc(β), Gal(β1–3)GalNAc(α), and Gal(β1–3)GalNAc(β) leads to type-2, type-3, and type-4 antigens, respectively. Fucosylation of these precursors by an α1–2 fucosyltransferase encoded by the *H* or the *Secretor* locus produces the blood group H determinant represented by the disaccharide Fuc(α1–2)Gal(β) (*Scheme 1*). Further glycosylation by an α1–3 *N*-acetylgalactosaminyltransferase (α1,3-GalNAcT) (corresponding to the *A* allele of the *ABO* locus) or an α1–3 galactosyltransferase (α1,3-GalT) (corresponding to the *B* allele of the *ABO* locus) then leads to GalNAc(α1–3)[Fuc(α1–2)]Gal(β) (blood group A determinant) and Gal(α1–3)[Fuc(α1–2)]Gal(β) (blood

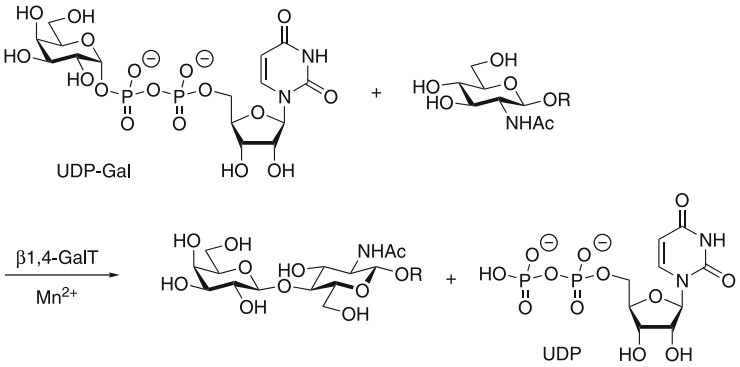
Selected antigenic determinants (LacNAc = Gal(β1–4)GlcNAc)

Determinant structure	Name
Gal(β1–3)[Fuc(α1–4)]GlcNAc	Blood group Lewis a (Le^a)
Neu5Ac(α2–3)Gal(β1–3)[Fuc(α1–4)]GlcNAc	Sialyl Lewis a (sLe^a)
Fuc(α1–2)Gal(β1–3)[Fuc(α1–4)]GlcNAc	Blood group Lewis b (Le^b)
Gal(β1–4)[Fuc(α1–3)]GlcNAc	Lewis x (Le^x)
Neu5Ac(α2–3)Gal(β1–4)[Fuc(α1–3)]GlcNAc	Sialyl Lewis x (sLe^x)
Fuc(α1–2)Gal(β1–4)[Fuc(α1–3)]GlcNAc	Lewis y (Le^y)
[LacNAc(β1–3)]$_n$	Blood group i
LacNAc(β1–3)[LacNAc(β1–6)]LacNAc	Blood group I
GalNAc(α1–O)Ser/Thr	Tn
Gal(β1–3)GalNAc(α1–O)Ser/Thr	T
Fuc(α1–2)Gal(β1–3)GalNAc(β1–3)Gal(α1–4)Gal(β1–4)Glc	Globo H

group B determinant), respectively. The ABO classification is based on the presence or absence of the A and B antigens and the two antibodies anti-A and anti-B which always occur in the plasma when the corresponding antigen is missing (*Table 1*). With rare exceptions the H antigen is expressed on the cells of all blood group O individuals, but in persons belonging to phenotypes A, B, and AB there is complete or partial masking of H activity. Despite the vast accumulated knowledge of serology, chemistry, and genetics of the blood group structures, it is still not possible to assign a clearly defined physiological function to the *ABO* locus.
Beside the ABO blood group system a number of additional carbohydrate-based antigenic determinants are known (*Table 2*), which are, however, not only recognized by antibodies. Some of them are more highly expressed on tumor cells and therefore can be described as tumor-associated antigens [115]. Synthetic tumor-associated antigens such as Lewis y or Globo H have been used in the development of antitumor vaccines [116,117].

3.2 Carbohydrate-Modifying Enzymes

Of the many enzymes involved in carbohydrate metabolism, glycosyl transferases and glycosidases are of special interest for the biosynthesis and processing of glycoconjugates. The

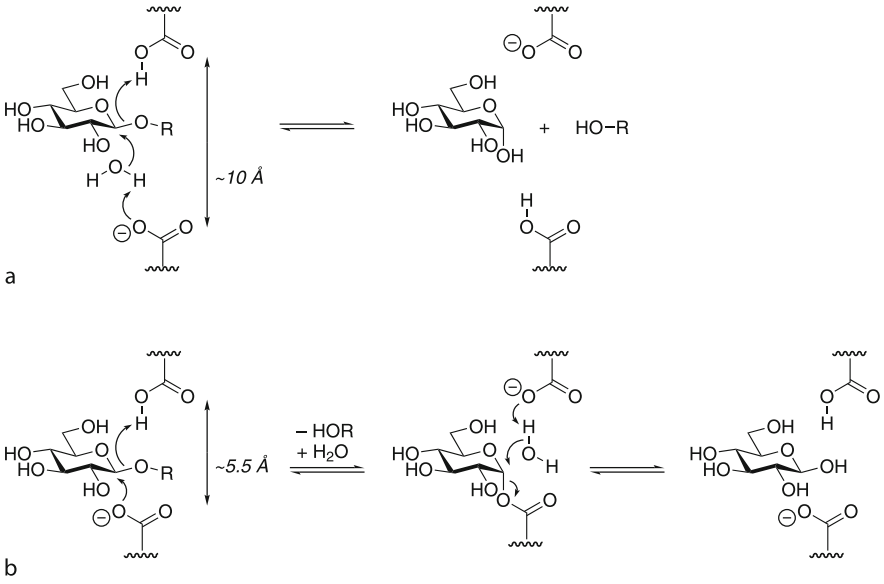


Scheme 2
Enzymatic galactosyl transfer from UDP-Gal to the 4-position of GlcNAc catalyzed by β1–4 galactosyltransferase (β1,4-GalT)

glycosyl transferases of the Leloir pathway [118] which are responsible for the synthesis of most glycoproteins and glycolipids in mammalian systems [119] are membrane-bound or membrane-associated enzymes. They utilize as glycosyl donors monosaccharides which are activated as glycosyl esters of nucleoside mono- and diphosphates (so-called sugar nucleotides) to transfer a glycosyl moiety to an acceptor [120,121,122]. The eight sugar nucleotides applied for the synthesis of most oligosaccharides are uridine 5′-diphosphoglucose (UDP-Glc), UDP-*N*-acetylglucosamine (UDP-GlcNAc), UDP-galactose (UDP-Gal), UDP-*N*-acetyl-galactosamine (UDP-GalNAc), UDP-glucuronic acid (UDP-GlcA), guanosine 5′-diphosphomannose (GDP-Man), GDP-fucose (GDP-Fuc), and cytidine 5′-monophospho *N*-acetylneuraminic acid (CMP-Neu5Ac). Non-Leloir transferases typically utilize glycosyl phosphates as donors. For each sugar nucleotide glycosyl donor, several Leloir transferases exist each of which acts on a different acceptor in a regio- and stereospecific manner. The transferases are generally considered to be specific for a given glycoside bond, however, some deviations from this picture of absolute specificity have been observed, both in the glycosyl donors and acceptors. β1–4 Galactosyltransferase for example catalyzes the transfer of galactose from UDP-Gal to the 4-position of β-linked GlcNAc residues to produce the Gal(β1–4)GlcNAc substructure (◉ *Scheme 2*). In the presence of lactalbumin, glucose is the preferred acceptor, resulting in the formation of lactose, Gal(β1–4)Glc [123].

Many glycosyltransferases have been employed in the in vitro synthesis of oligosaccharides [124,125]. Since the nucleoside mono- or diphosphates released during the reaction, e. g. UDP, usually cause product inhibition, in situ regeneration cycles have been developed in which they are transformed back to the sugar nucleotides [126]. Alternatively, the nucleoside mono- or diphosphates may be degraded by use of alkaline phosphatase [127].

Glycosidases (glycosyl hydrolases, EC 3.2.1) [128] catalyze the hydrolysis of glycosidic bonds. For the naturally occurring polysaccharides cellulose and starch typical rate constants up to 1000 s^{-1} are observed. Taking the half-lives for spontaneous hydrolysis of these materials (about 5 million years [129]) into account, these enzymes achieve rate enhancements of up to 10^{17}-fold, placing them amongst the most proficient of enzymes. In nature, glycosidases play important roles ranging from the degradation of polysaccharides as food sources



Scheme 3
Mechanisms of (a) inverting and (b) retaining glycosidases. Both mechanisms involve transition states with substantial oxocarbenium character present at the anomeric center

through to the trimming process of glycoproteins. The hydrolysis reaction can occur with either inversion or retention of anomeric configuration. Depending on the stereochemical outcome, two different mechanisms have been suggested 1953 by Koshland [130] and later on refined [131,132,133,134]. Both mechanisms involve a pair of carboxylic acids at the active site (*Scheme 3*). In inverting glycosidases, these residues are approximately 10 Å apart from each other on average. Reaction occurs by a single-displacement mechanism with one carboxylic acid acting as a general base activating a water molecule and the other as a general acid (*Scheme 3a*). In retaining enzymes, the carboxyl groups are only approximately 5.5 Å apart and the hydrolysis proceeds by a double-displacement mechanism involving a covalent glycosyl-enzyme intermediate (*Scheme 3b*). In both mechanisms, substantial oxocarbenium character has been shown to be present at the anomeric center in each transition state. The design of transition-state analogs mimicking the shape and charge of the oxocarbenium species has been extensively used to arrive at glycosidase inhibitors [135]. An example of a designed inhibitor which was approved by the Food and Drug Administration (FDA) in 2000 for the treatment of influenza virus A and B infections is the sialidase inhibitor zanamivir (Relenza^{TM}) [136]. The search for a drug with improved pharmacokinetic properties led to the zanamivir mimic oseltamivir that came on the market in 2000 under the name of Tamiflu^{TM} which is the phosphate salt of an ethyl ester prodrug [137].

In contrast to glycosyltransferases, glycosidases show broader, sometimes overlapping substrate specificities, especially with respect to the aglycon. Endoglucanases, for example, whilst typically considered to be cellulases, are also active to various degrees on xylan, xyloglucan, β-glucan, and various artificial substrates. Retaining glycosidases, run in the transglycosyla-

tion mode, have also been used for the construction of glycosidic bonds, albeit in moderate yields, the major problem being the thermodynamically favored hydrolysis of the reaction product [125,138]. Withers et al. could overcome this problem with a mutated β-glucosidase, wherein the nucleophilic carboxyl had been substituted with alanine [139]. The mutated glycosidase (a so-called glycosynthase [140,141,142]) folds correctly but lacks hydrolase activity since it cannot form the requisite α-glycosyl-enzyme intermediate. It possesses, however, high transglycosylation activity. Employing an activated α-glycosyl fluoride having the opposite anomeric configuration to that of the normal substrate, the ligation to a suitable acceptor sugar bound in the aglycon pocket is catalyzed. Once the oligosaccharide is formed, it cannot be hydrolyzed by the enzyme, thus allowing yields of over 90% to be achieved.

3.3 Carbohydrate-Lectin Interactions

3.3.1 Classification of Lectins

Lectins [102,103,104,105,143,144,145,146] are carbohydrate-binding proteins other than immunoglobulins without enzymatic activity towards the recognized sugars [101]. They are present throughout nature including the animal kingdom and the microbial world. Originally, they were classified according to their monosaccharide binding specificity. However, with the advent of molecular cloning a more consistent classification based on amino acid sequence homology and evolutionary relatedness emerged [147]. Whereas the biological function of plant lectins is still unclear, their use as biochemical tools has made an enormous contribution to the understanding of the structures and functions of carbohydrate structures in animal cells. Today, we have a much more detailed picture of the function of animal lectins than of plant lectins. ❯ *Table 3* shows selected examples of the 13 currently known families of animal lectins [12,102,105].

C-Type lectins were named after their requirement of calcium ions for recognition. They are all characterized by an extracellular carbohydrate recognition domain (CRD) and bind a diver-

Table 3
Selected families of animal lectins classified according to known sequence homologies[a] [12,102,105]

Lectin family	Defining structural motif	Carbohydrate ligand	Calcium dependence
C-type (includes selectins, collectins, endocytic lectins)	Conserved CRD	Variable	Yes (most)
Galectins (formerly *S*-type)	Conserved CRD	β-galactosides	No
P-type	Unique repeating motif	Mannose-6-phosphate on high-mannose-type *N*-glycans	Variable
I-type (includes Siglec family)	Immunoglobulin-like CRD	Variable (Siglecs: sialic acids)	No
Calnexin, calreticulin, calmegin	Homology with each other	Glucosylated high-mannose-type *N*-glycans in the ER	Yes
Hyaluronan-binding proteins	Homologue CRD	Hyaluronan chains	No

[a] Abbreviations: CRD, carbohydrate recognition domain; ER, endoplasmic reticulum

sity of sugars. However, not all calcium-requiring lectins are *C*-type lectins, as exemplified by calnexin and calcireticulin which recognize glucose residues on newly synthesized *N*-glycoproteins. Galectins, formerly named *S*-type lectins due to their dependency on free thiols for full activity, are soluble β-galactoside-specific lectins that combine preferentially with lactose and *N*-acetyllactosamine. P-Type lectins bind mannose-6-phosphate as their ligand and I-type lectins share a common immunoglobulin-like CRD. Another class of evolutionarily very ancient circulating soluble lectins are the pentraxins. They are characterized not so much by primary sequence homologies, but by a pentameric arrangement of their subunits and a probable role in the primary host immune response.

Multivalency appears to play an important role in lectin-mediated interactions [106,148,149,150,151], and many lectins are found to recognize individual carbohydrate epitopes only with low affinity. Indeed, most lectins are either intrinsically multivalent because of their defined multisubunit structure or by virtue of having multiple CRDs within a single polypeptide or they can become functionally multimeric by noncovalent association or by clustering on cell surfaces. High-avidity binding can result from multiple interactions of adequately presented low-affinity single sites, and this appears to be a common mechanism of modulating lectin function in vivo [144,152,153,154].

The following sections will focus on selected, well-characterized carbohydrate-lectin recognition processes.

3.3.2 Lectin Control of Protein Folding

N-Linked glycan moieties of glycoproteins which are incorporated co-translationally in the endoplasmic reticulum (ER) during biosynthesis are in many cases essential for proper folding of the protein. Their conformational influence on nascent or newly synthesized glycoproteins may be either direct by inducing local structure elements, such as β-turns, (cf. ❯ *Sect. 2.4*) or indirect by interaction with calnexin or calreticulin within the so-called calnexin-calreticulin-cycle (❯ *Fig. 6*) [92,96,155,156]. Membrane-bound calnexin (CNX) and soluble calreticulin (CRT) are homologous lectins found in the ER of nearly all eukaryotes. They bind to a monoglucosylated form of *N*-glycoproteins after two of the glucoses have been trimmed away by glucosidases I and II. Binding by calnexin or calreticulin retains the unfolded glycoprotein in the ER, permitting foldases to help folding into the correct 3D arrangement. Folding factor ERp57 is a thiol oxidoreductase homologue of protein disulfide isomerase that also binds to both calnexin and calreticulin and thereby is exposed to the substrate glycoprotein. If the glycoprotein contains cysteines, the formation of proper disulfide bonds is catalyzed through the formation of transient mixed disulfides with ERp57. Association of the glycoprotein with calnexin and calreticulin is dynamic and exposes the single terminal glucose residue to hydrolysis by glucosidase II. If the deglucosylated glycoprotein is incorrectly or incompletely folded, it is either reglucosylated by UDP-glucose glycoprotein glucosyltransferase, which has the remarkable function of a folding sensor, or degraded. Reglucosylation allows another cycle of binding by calnexin or calreticulin and interaction with ERp57. Once correctly folded, the protein is no longer recognized by the glucosyltransferase and, therefore, does not bind back any more to calnexin and/or calreticulin but can leave the ER. Exit of certain glycoproteins from the ER to the Golgi complex is assisted by another membrane-bound lectin, ERGIC-53, which binds to mannose residues.

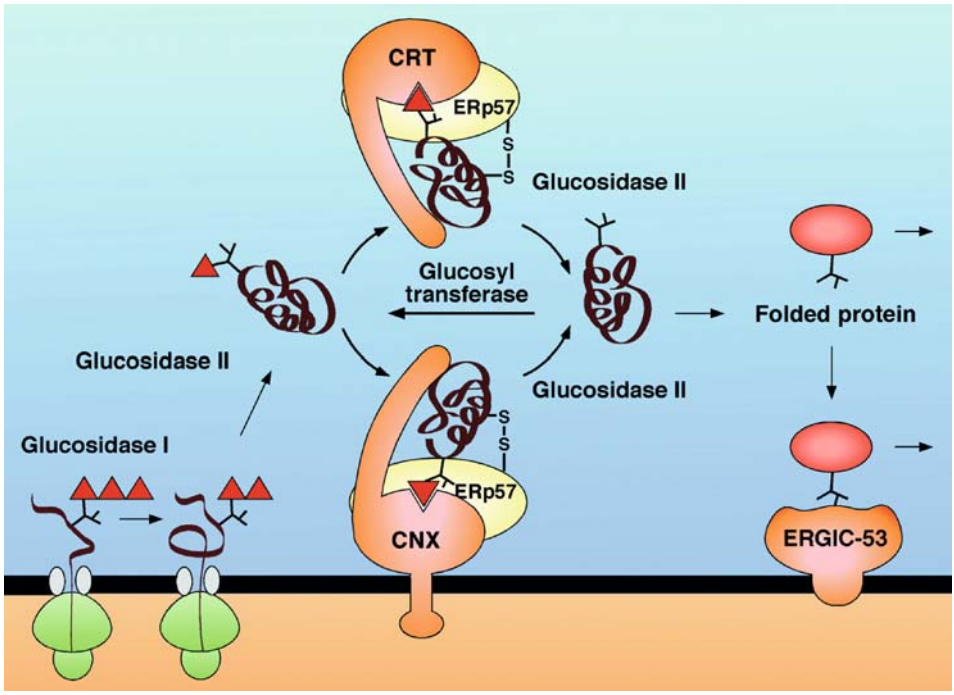


Figure 6
The calnexin-calreticulin-cycle (cf. text). Triangles represent glucose residues (Reprinted from [92] with permission from AAAS)

The calnexin-calreticulin-cycle promotes correct folding, inhibits aggregation of folding intermediates, and provides quality control by preventing incompletely folded glycoproteins from exiting to the Golgi complex. It seems to be essential in vivo. Transgenic mice devoid of calreticulin die on embryonic day 18 [157].

3.3.3 Clearance and Targeting of Glycoproteins

Some effects of glycosylation on the stability of proteins have already been mentioned in *Sect. 2.2* and they can presumably affect their half-life in single cells. In the intact organism, recognition of glycan structures by certain receptors can result in removal of the glycoconjugate or even a whole cell from the circulation. This has first been observed in the late 1960s by Ashwell and coworkers who serendipitously found that desialylation of glycoproteins resulted in significantly shorter serum half-lives [158,159]. This led to the characterization of the asialoglycoprotein receptor [160] (a hepatic lectin of the *C*-type) which has recently been crystallized [161] and not only recognizes desialylated, i. e. galactose terminated, *N*-linked oligosaccharides but also GalNAc structures as they occur on some *O*-linked glycans. These findings were traditionally interpreted as representing a physiological clearing mechanism for glycoproteins [160] which has, however, not yet proven beyond doubt [162]. Another exam-

ple of a receptor responsible for glycoprotein clearing is the GalNAc-4-sulfate receptor. Rapid removal of luteinizing hormone, for example, which contains this (*N*-linked) sugar is important to generate a circadian rhythm [163].

The mannose 6-phosphate (Man6*P*) receptors are the best understood examples of receptors responsible for intracellular trafficking of glycoproteins [164,165,166]. These P-type lectins mediate the routing of lysosomal hydrolases from the trans-Golgi network to their final destination in the lysosomes. Two such receptors are known, one cation-dependent and of low molecular weight (ca. 45 kDa) which has been crystallized [165], the other cation-independent and of high molecular weight (ca. 275 kDa). The targeting is mediated by recognition of Man6*P* residues on oligomannose-type *N*-glycans of lysosomal enzymes by the Man6*P* receptors. A defect in the synthesis of the Man6*P* markers, caused by a deficiency of GlcNAc-phosphotransferase (the first enzyme in the mannose phosphorylation pathway), results in I-cell disease (also called mucolipidosis II or MLII), an inherited lysosomal storage disease.

3.3.4 Leukocyte Trafficking

The leukocyte trafficking to inflammatory sites is a highly regulated multistep process, referred to as the inflammatory cascade [167]. The initial events, the tethering and rolling of leukocytes along the vascular endothelium, are mediated by the interaction of a family of adhesion molecules, termed selectins, and their carbohydrate containing ligands [168,169,170]. The cascade begins with the release of cytokines and other signaling molecules at the site of injury that stimulate the transient expression of E- and P-selectin on the endothelium surface. These *C*-type lectins bind to their ligands displayed on the circulating leukocytes and promote leukocyte adhesion to the stimulated endothelial cells. L-Selectin is constitutively expressed on leukocytes, and it recognizes its ligands on endothelial cells. The rolling leads to activation of integrins on the leukocytes that interact with their counter-receptors on endothelial cells (e. g. intercellular adhesion molecule-1, ICAM-1) and promote firm adhesion. This stronger interaction then allows emigration or extravasation of the leukocytes into the underlying damaged tissue. However, if too many leukocytes are recruited to the site of injury, normal cells can also be destroyed. This occurs in the condition known as septic shock, in chronic inflammatory diseases such as psoriasis and rheumatoid arthritis, and in the reperfusion tissue injury that occurs following a heart attack, stroke or organ transplant.

The selectins are membrane-bound proteins comprising five domains: a cytosolic tail that may play a role in signal transduction, a transmembrane domain, several complement regulatory domain repeats, an epidermal growth factor (EGF) domain, and an *N*-terminal, calcium-dependent *C*-type carbohydrate recognition domain (CRD). Both the EGF domain and the CRD are required for ligand binding, although the site of binding has been localized to the CRD. The tetrasaccharide sialyl Lewis x (sLe^x) Neu5Ac(α2–3)Gal(β1–4)[Fuc(α1–3)]GlcNAc (*Fig. 7*) is the minimum structure recognized by all three selectins. It is bound, however, only weakly with K_D values of 0.7, 3.9, and 7.8 mM for binding to E-, L-, and P-selectin, respectively [171]. Since the interaction of the selectins with their natural glycoprotein ligands which contain sLe^x and modifications thereof as terminating structures is much stronger, additional receptor-ligand contacts seem to be important for high-affinity binding. The natural ligand for L-selectin (GlyCAM-1) for example contains sLe^x sulfated at Gal-6, GlcNAc-6, or both positions and in the natural ligand for P-selectin, PSGL-1, the 19 amino acid *N*-terminus of the

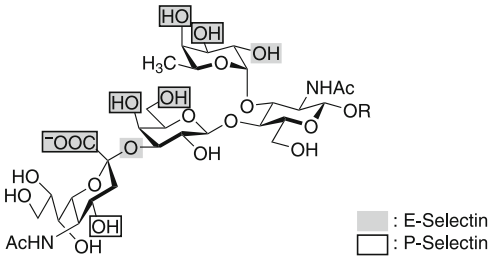

Figure 7
The tetrasaccharide Neu5Ac(α2–3)Gal(β1–4)[Fuc(α1–3)]GlcNAc (sialyl Lewis x), the minimum structure recognized the selectins. Indicated are functional groups involved in specific contacts to E-selectin (*gray boxes*) and P-selectin (*light boxes*) according to crystal structures [172]

protein which contains several sulfated tyrosine residues beside the *O*-linked, sLe^x-bearing glycan was found to be critical for binding. Recently, the crystal structures of human E- and P-selectin constructs containing the lectin and EGF (LE) domains co-complexed with sLe^x as well as the crystal structure of P-selectin LE in complex with the *N*-terminal domain of human PSGL-1 modified by both tyrosine sulfation and sLe^x have been reported [172]. This study offers a structural basis for affinity differences between sLe^x and E- and P-selectin, respectively and the high-affinity interaction between P-selectin and PSGL-1. In addition, it may well be that multivalent interactions between the selectins clustered on cell surfaces with multiple sLe^x residues presented on the highly glycosylated mucin-type counter-receptors contribute to high-affinity binding in vivo.

Inhibition of the selectin-ligand interactions is an attractive strategy for treating inflammation-related diseases [173,174,175]. As such, sLe^x has been intensively used as lead structure for development of anti-inflammatory drugs both in industry and academia [176,177,178].

Abstract

Over the past two decades interest in glycopeptides and glycoproteins has intensified, due in part to the development of new and efficient methods for the synthesis of these compounds. This includes a number of chemical and enzymatic techniques for incorporating glycosylation onto the peptide backbone as well as the introduction of powerful peptide ligation methods for the construction of glycoproteins. This review discusses these methods with a special emphasis on biologically relevant glycopeptides and glycoproteins. This includes the development of a number of antigens which hold promise as potential vaccines for HIV, cancer, or a host of other clinically important diseases. In addition the development of new antibiotics aimed at overcoming the problem of resistance will be discussed. Finally, chemical and enzymatic methods for the construction of glycopeptide mimetics will be described.

Solid-phase; Ligation; Chemoenzymatic; Vaccine; Antigen; Conjugation; Antibiotic; Immune response; Inflammatory response; Conformation; Mimetic

1 Introduction

Glycosylation is a post- or co-translational modification of proteins that has extensive biological significance [1,2,3]. In general, protein function is influenced by the covalent attachment of an oligosaccharide to its surface. Altered protein glycosylation patterns often modify intercellular recognition processes, through modulation of protein–protein or protein–carbohydrate interactions [4]. Moreover, glycosylation increases peptide hydrophilicity, resulting in increased aqueous solubility and altered clearance properties compared with the naked peptide [5]. Glycosylation may also play a role in protein folding, as well as functioning as an inducer of protein secondary structure [6]. As such, the fields of glycobiology and carbohydrate chemistry offer a myriad of research opportunities in the biological arena.

At the structure-function level, however, the study of glycoproteins has been hampered by glycoprotein microheterogeneity [7]. Glycoproteins with identical peptide backbones intrinsically exist in numerous isoforms as a result of the attachment of diverse arrays of heterogeneous oligosaccharide chains. A single glycoprotein may present several different glycans, thereby making assessment of the contribution of a single glycoform to bioactivity difficult. To avoid this problem, many studies have taken an "all-or-none" approach, comparing function between glycosylated and fully de-glycosylated proteins [8,9]. Although research of this nature has provided valuable information, it does not allow exploration of the intricacies of specific glycan function.

Methods for the preparation of complex homogeneous glycopeptides have recently been developed [10,11,12,13,14]. Although research in this area is being actively pursued, it remains a relatively new field with a practical total synthesis of a natural homogeneous glycoprotein still to be achieved. The most comprehensive studies of specific glycoprotein function to date have been derived through the characterization of glycopeptide activity. Partial structures of relevant glycoproteins can usually be prepared synthetically in homogenous form, and in adequate quantity for biological research. Nevertheless, it is unclear whether structure-function relationships derived from synthetic glycopeptides are relevant to those of native glycoproteins. Recent efforts have therefore been largely directed toward the development of efficient methods for the preparation of homogeneous glycoproteins with well-defined carbohydrate structure. The development of new reliable chemical and enzymatic methods for glycopeptide synthesis has been instrumental in this field.

1.1 Naturally Occurring Glycopeptide Structure

The majority of all naturally occurring glycosidic linkages can be categorized into two groups. The first are the *N*-linked glycosides that are attached to the side chain amide of asparagine residues. The other, more diverse structures are *O*-linked glycosides, which are linked to the side chain hydroxyl groups of serine, threonine, or tyrosine. Less common linkages, which include *O*-glycosidic linkages to hydroxylysine or hydroxyproline, and *C*-glycosidic linkages to tyrosine, will not be discussed in the context of this chapter. A more detailed discussion of all known glycosyl-peptide linkages can be found in a number of detailed reviews [15,16,17].

1.1.1 *N*-Linked Glycans

Glycosylation through the side-chain amide of asparagine is referred to as *N*-linked glycosylation. This biosynthetic modification of proteins occurs co-translationally in the endoplasmic reticulum through the action of oligosaccharyltransferase (OT) [18]. The characteristic *N*-linked glycan contains a reducing terminal *N*-acetylglucosamine (GlcNAc) β-linked to asparagine (Fig. 1). In nature, this terminal GlcNAc is linked to an extensive network of other carbohydrates of the high mannose, hybrid, or complex type. OT is responsible for glycosylation of the peptide chain at the sequence Asn-X-Ser/Thr, referred to as the "Asx-turn motif" [19].

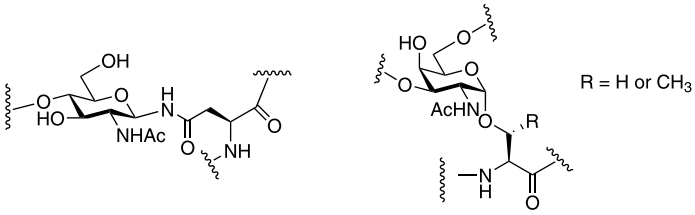

Figure 1
***N*-linked and *O*-linked glycosylation of peptides**

1.1.2 *O*-Linked Glycans

Glycosylation through the side chain hydroxyl of serine, threonine, or tyrosine is referred to as *O*-linked glycosylation. This glycosidic linkage is formed by transfer of the carbohydrate from a nucleotide sugar to the peptide chain, a reaction catalyzed by one of several glycosyltransferases [20]. The most commonly displayed *O*-linked glycan consists of a reducing terminal *N*-acetylgalactosamine (GalNAc) α-linked to serine or threonine (Fig. 1). Addition of subsequent carbohydrates to the GalNAc bridgehead is catalyzed by a number of tissue specific glycosyltransferases, hundreds of which have been characterized to date [3,21]. There are many other *O*-linked glycans observed in nature, examples include GlcNAc, fucose (Fuc), xylose (Xyl), mannose (Man), and glucose (Glc). In general no specific consensus sequence for *O*-glycosylation can be identified, however an important exception is the ser/thr/pro rich regions in the so called mucin domains. Mucins are expressed on the surface of a variety of epithelial cell types and contain numerous *O*-glycosylation sites [22]. These proteins represent an important class of tumor-associated antigens and, as such, are potential targets for tumor therapy.

1.2 Biologically Relevant Glycopeptide Target Structures

Synthetic glycopeptide target structures of interest are largely those associated with disease processes. For example, certain glycopeptide structures found on malignant cells, the so called tumor-associated glycopeptide antigens, have potential as vaccines for certain cancers [23,24]. In addition, the study of glycopeptide antigens mimicking glycoproteins on HIV has been

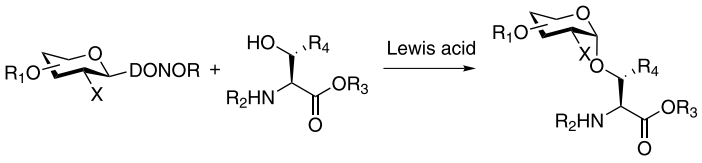
the subject of extensive efforts directed towards the development of HIV vaccines [25,26]. Furthermore, glycopeptides associated with intercellular adhesion events may be suitable for interference of the inflammatory pathway in reperfusion injury and asthma [27]. Certain glycopeptides are also potent antibacterial and antimicrobial agents [28]. Glycoprotein therapeutics have also found wide applicability for the effective treatment of anemia [29]. This chapter provides an overview of synthetic glycopeptide target structures of biological relevance along with synthetic and chemoenzymatic approaches aimed toward the synthesis of such targets. When available, results of biological studies are also included.

2 Synthetic Strategies

Synthetic approaches toward glycopeptide targets is a rapidly maturing field, and methodology has advanced to the point where most desired glycosylated amino acids are now routinely accessible, or even commercially available. Synthetic strategies for the construction of these amino acids have been reviewed in great detail previously and will not be discussed in detail here [15,16,30,31]. This section will highlight general synthetic and chemoenzymatic methods for the synthesis of glycopeptides available to the glycoscientist, including a discussion of methods for ligating glycopeptides to form more complex glycopeptide and glycoprotein structures.

2.1 Sequential Coupling of Glycosyl Amino Acids

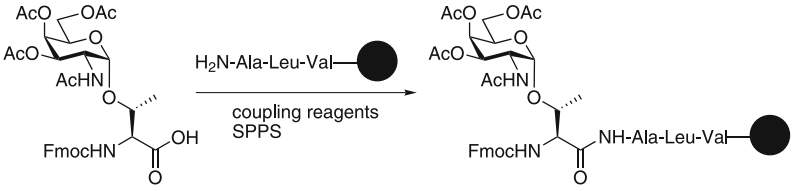
Numerous methods are available for the glycosylation of amino acids [32]. In the synthesis of *O*-linked constructs, the reaction of a suitable glycosyl donor with serine or threonine as the glycosyl acceptor is performed under conditions of Lewis acid catalysis (*Scheme 1*).



Scheme 1

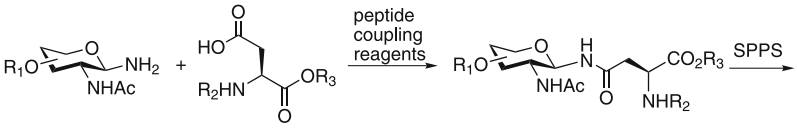
Depending on the carbohydrate protecting group pattern, α or β linkages can be formed specifically. Glycosyl donors employed can be any appropriate donor generally used for the synthesis of oligosaccharides. Suitably protected glycosyl amino acids can then be directly incorporated into solution-phase or solid-phase peptide synthesis (SPPS) [33] (*Scheme 2*). In one notable example, the Bock group has developed an efficient multiple column solid-phase synthetic method that allows facile construction of glycopeptide libraries. This procedure utilizes glycosyl amino acids activated as pentafluorophenyl esters [34]. More recently, Nishimura and coworkers demonstrated that microwave irradiation can facilitate coupling of hindered glycosyl amino acids [35].

In the synthesis of *N*-linked glycosyl amino acids, the coupling strategy is usually not a glycosylation at all, but merely amide bond formation [36]. In most common practice, glycosyl



Scheme 2

amines are synthesized and then attached to a protected aspartic acid through standard amide coupling strategies (*Scheme 3*). This type of *N*-linked building block can also be directly incorporated into SPPS to afford glycopeptides.

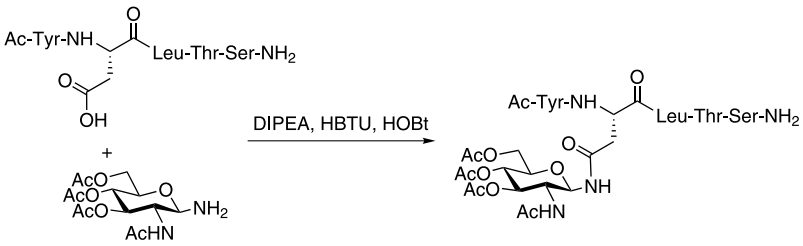


Scheme 3

2.2 Convergent Coupling of Glycans to Peptide Sequences

A convergent approach to glycopeptide synthesis was pioneered by Lansbury and coworkers [37,38]. This method allows the creation of *N*-linked glycopeptides by coupling of a glycosyl amine directly to a polypeptide chain containing an aspartic acid residue. The reaction conditions were optimized to minimize aspartamide side product formation (*Scheme 4*). Due to the nature of the coupling conditions, extensive protection of the peptide backbone and oligosaccharide are not necessary with this methodology. Danishefsky and co-workers have demonstrated the utility of this method through the synthesis of several glycopeptides [39].

Examples of convergent strategies for the synthesis of *O*-Glycopeptides have been reported, where the serine or threonine hydroxyl is used as a glycosyl acceptor [40]. These methods require extensive protection of the peptide and carbohydrate. Other pitfalls in this strategy



Scheme 4

include poor solubility of the peptide in organic solvents required for the glycosylation reaction, and lack of stereocontrol, thus leading to anomeric mixtures of the final product.

2.3 Chemical Glycopeptide Ligation Strategies

The methods described above permit facile access to structurally diverse, but relatively short glycopeptide structures (consisting of 10–50 amino acid residues). Above this limit, the linear nature of SPPS results in low yields of the target glycopeptides. For example, SPPS of a 50 amino acid peptide, averaging 95% yield per coupling step, would produce the desired oligomer in an overall yield of 7.7%. In addition, the accumulation of uncoupled sequences, side products and epimerization greatly increases the difficulty of purification of the final product. To overcome these limitations, the convergent ligation of fully unprotected glycopeptides has emerged as a viable strategy for the total synthesis of glycoproteins. Over the past decade many efficient chemoselective ligation methods have been developed, a summary of these is covered in the sections that follow. For a more detailed account of these methods, and their applications in the synthesis of glycopeptides and glycoproteins, the reader is referred to several recently published review articles [10,14,41,42].

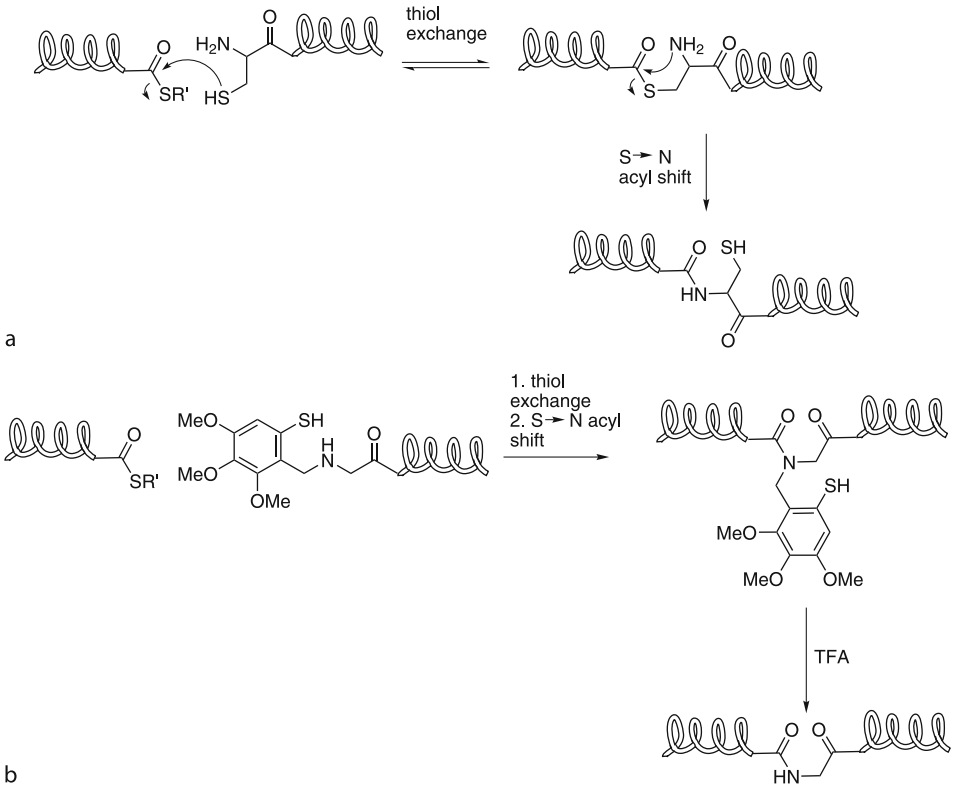
2.3.1 Native Chemical Ligation (NCL)

Native chemical ligation (NCL) is a chemoselective condensation reaction between a peptide thioester and a peptide bearing an *N*-terminal cysteine residue (❯ *Scheme 5a*). The first step of the ligation involves a rapid, reversible transthioesterification step. The resulting thioester intermediate then undergoes a spontaneous and irreversible S→N acyl transfer resulting in the formation of a new amide bond. The concept of NCL dates back to the 1950's with the pioneering work of Wieland et al. [43], however it was not until the 1990's that this method gained widespread attention as an efficient method for the ligation of peptides [44]. The scope of NCL has been extensively examined, and most amino acids undergo facile ligations, with the exception of those containing sterically encumbered side chains (Leu, Thr, Val, Ile, and Pro) [45]. The effectiveness of this technique is evident by its application in the synthesis of hundreds of different proteins [46]. The success of this method for the synthesis of peptides and proteins has inspired many laboratories to employ this technology for the synthesis of glycopeptides and glycoproteins. One key application of NCL was in a study towards the total synthesis of the glycopeptide antibiotic diptericin, which will be discussed in more detail in ❯ *Sect. 4.2* [47].

The obvious limitation of NCL is the requirement for a cysteine residue at the ligation junction. Cysteine has a relatively low abundance in proteins (ca. 1.7%) therefore there is a high probability that the target protein does not have cysteine at a synthetically useful position. This led to the development of a number of "cysteine-free ligation" strategies, namely auxiliary-assisted NCL, sugar-assisted ligation (SAL) and the traceless Staudinger ligation.

2.3.2 Cysteine-Free NCL

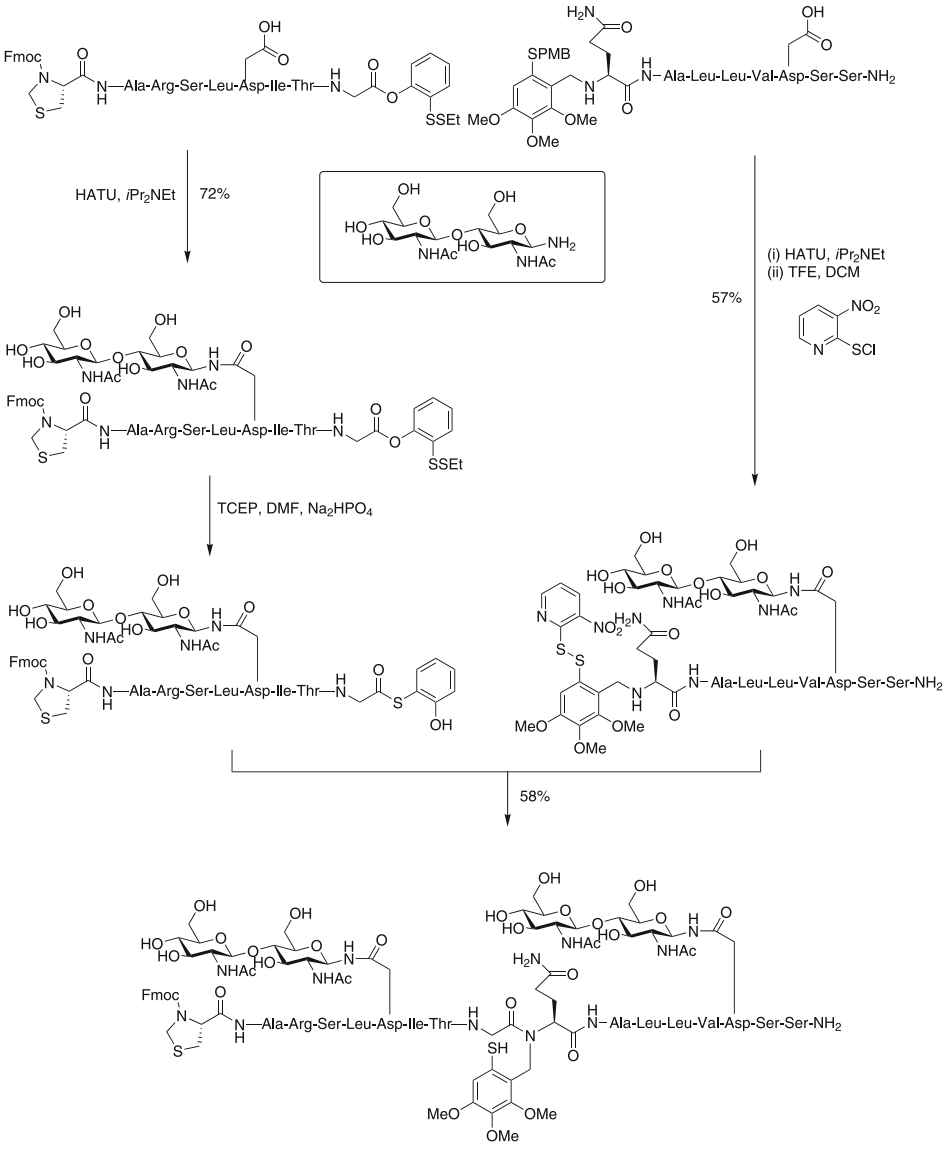
Initial studies directed at overcoming the requirement of an *N*-terminal cysteine in NCL led to the development of two thiol auxiliaries, 1-aryl-2-mercaptoethyl and 4,5,6-trimethoxy-2-mer-



Scheme 5

captobenzyl (Tmb) (*Scheme 5b*) [48,49]. These moieties are attached to the *N*-terminus of a synthetic peptide and can be readily removed following ligation by treatment with trifluoroacetic acid (TFA). The thiol of the auxiliary partakes in the chemical ligation in an identical fashion to the side chain of a cysteine residue. The application of this method to glycopeptide synthesis was first demonstrated by Macmillan and co-workers who used both auxiliaries to synthesize fragments of the *O*-linked glycoprotein GlyCAM-1 [50].

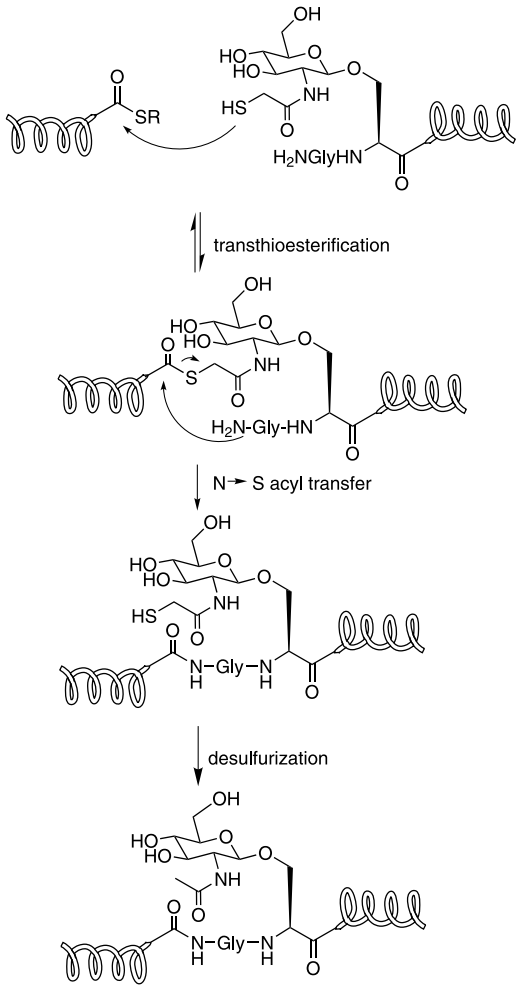
More recently, several elaborate examples of cysteine-free NCL were reported by Danishefsky and co-workers [51]. One example of this study is outlined in *Scheme 6*. The first step involved the synthesis of a masked glycopeptide thioester and a Tmb containing glycopeptide, using SPPS and the convergent Lansburn aspartylation for the introduction of glycans. The masked thioester was equipped with a *C*-terminal phenolic ester, which is converted to the desired thioester via an O→S acyl migration under the ligation conditions. The resulting thioester undergoes ligation with the Tmb containing glycopeptide (following in situ reduction of the disulfide bond) to afford a new peptide containing two glycosylation sites. This example is notable considering the established difficulty of ligations at a Gly-Gln junction. Following the ligation and removal of the auxiliary, the *N*-terminal cysteine can be unmasked to afford a handle for further ligations.



Scheme 6

2.3.3 Sugar Assisted Ligation (SAL)

Recently, another cysteine-free ligation strategy has been reported for the synthesis of glycopeptides. The method, dubbed sugar assisted ligation (SAL), utilizes a peptide thioester and a glycopeptide in which the carbohydrate is derivatized with a thiol auxiliary at the C-2 acetamide [52,53]. The proposed mechanism of this ligation, depicted in *Scheme 7*, involves

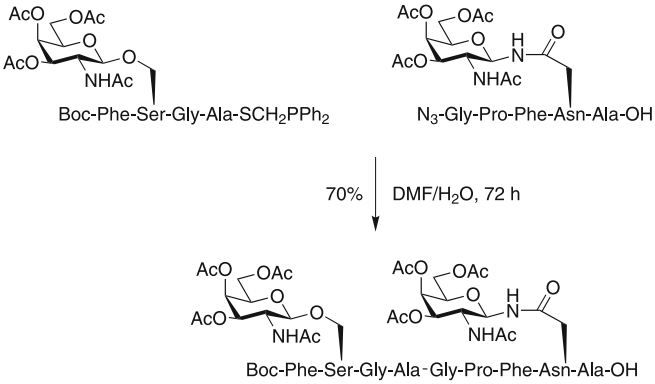


Scheme 7

an initial transthioesterification step, followed by an S→N acyl shift to afford the native peptide bond. The method has shown applicability to both *O*- and *N*-linked glycopeptides and tolerates a number of different amino acids at the ligation junction. Upon completion of the ligation, the thiol auxiliary can be efficiently cleaved under reducing conditions (H_2/Pd) to yield the native acetamide functionality at C-2.

2.3.4 Traceless Staudinger Ligation

A conceptually different ligation strategy that is currently being pursued in the synthesis of glycoproteins and glycopeptides is the "traceless Staudinger ligation." In this method an azide reacts with a phosphinothioester to form an iminophosphorane, which undergoes



Scheme 8

an intramolecular S→N acyl transfer to generate an amidophosphonium salt intermediate (*Scheme 8*). Subsequent hydrolysis of the amidophosphonium salt yields the desired amide product [54]. Raines and coworkers recently reported that the 'traceless Staudinger ligation' proceeds in high yields (80–99% for dipeptide model systems) and is compatible with unprotected peptides [55,56]. More recently, this method has been extended to the synthesis of glycopeptides [57]. While the reaction requires sterically unencumbered amino acids at the ligation junction, both coupling partners were shown to tolerate glycosylation. The authors have also demonstrated that the *N*-terminal azide can be enzymatically coupled to a peptide using the engineered protease subtilisin BPN, opening up the possibility of extending this method to expressed protein ligation (EPL).

2.3.5 Expressed Protein Ligation (EPL)

The peptide ligation methods described above are powerful tools for the construction of complex glycopeptides, however for larger targets it often desirable to produce one of the two coupling partners recombinantly, a process known as expressed protein ligation (EPL). Methods have been developed for recombinant production of both *C*-terminal and *N*-terminal coupling partners. Production of the *C*-terminal coupling partner involves introduction of an *N*-terminal affinity tag followed by a protease recognition sequence and a cysteine residue. After the protein is isolated by affinity chromatography, it can be treated with an appropriate protease to afford a protein containing an *N*-terminal cysteine which can undergo NCL. Sequences which are susceptible to cleavage by both Factor Xa and tobacco etch virus protease (TEV protease) have been used in this process (*Scheme 9a*) [58,59].

Production of an *N*-terminal coupling partner requires that the protein be expressed as a thioester. This can be achieved by taking advantage of naturally occurring self-splicing elements called inteins (*Scheme 9b*) [60,61]. Inteins catalyze their excision from a protein through a series of acyl-transfer reactions in which a cysteine thioester is a key intermediate. This intermediate can be isolated, and upon exposure to an appropriate ligation partner will undergo NCL to afford a new protein. It is important to note that the two approaches to EPL are orthogonal, a property which Macmillan and Bertozzi took advantage of in a recent synthesis of the glycoprotein GlyCAM-1 [62].

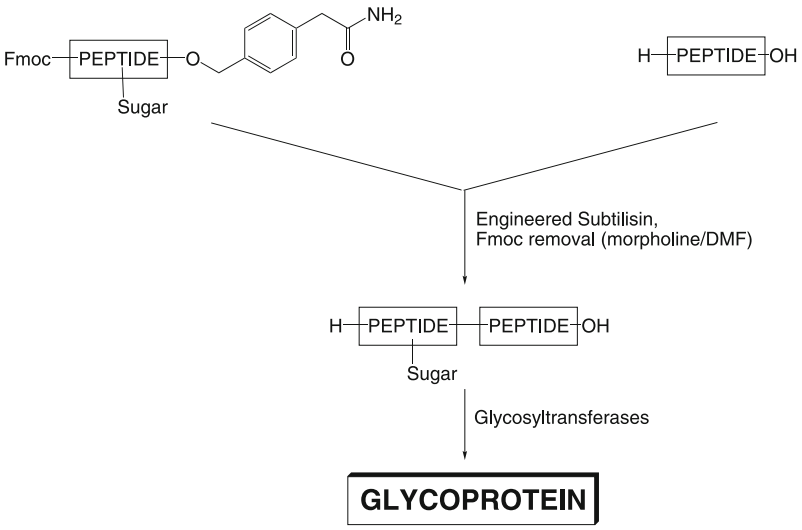
2.4 Enzymatic Ligation and Glycosyltransferase Reactions

Enzymatic synthesis has become an invaluable tool in the assembly of glycopeptides. Proteases such as subtilisin can be utilized as catalysts for *O*-linked glycopeptide couplings (*Scheme 10*) [63]. Similarly, thiosubtilisin [64] has been utilized as a catalyst in the synthesis of both *O*-linked and *N*-linked glycopeptides. Protease-catalyzed peptide bond formation has the advantage of proceeding at neutral conditions that are compatible with acid- and base-labile glycosidic linkages.



Scheme 10

Glycosyltransferases are also essential tools for glycopeptide synthesis [65,66]. Their use allows formation of specific linkages in a carbohydrate chain, and the enzymes often tolerate an array of functionality at the carbohydrate reducing terminus. Glycosyltransferase activity derived from whole cells has also been utilized in glycopeptide synthesis [67].

Glycosylhydrolases have also found utility in oligosaccharide synthesis. While these enzymes have the advantage of being less expensive and easier to handle than glycosyltransferases, they suffer from the drawbacks of poor regioselectivities and competitive hydrolysis of the desired product. Recently, Withers and coworkers reported a solution to this problem through the use of mutant glycosylhydrolases termed glycosynthases, which use glycosyl fluorides as donors [68]. To date, numerous glycosynthases have been created for a wide variety of sugars [69]. In addition to peptide and sugar synthesis, enzymes are also useful reagents for the removal of protecting groups [70,71] or cleavage of glycopeptides from solid supports under neutral conditions [72].

2.4.1 Endo-Glycosidase Activity in Synthesis

A special class of glycosylhydrolases, the endo-β-*N*-acetylglucosaminidases (Endo), have been utilized for the synthesis of homogeneous glycopeptides and glycoproteins. These

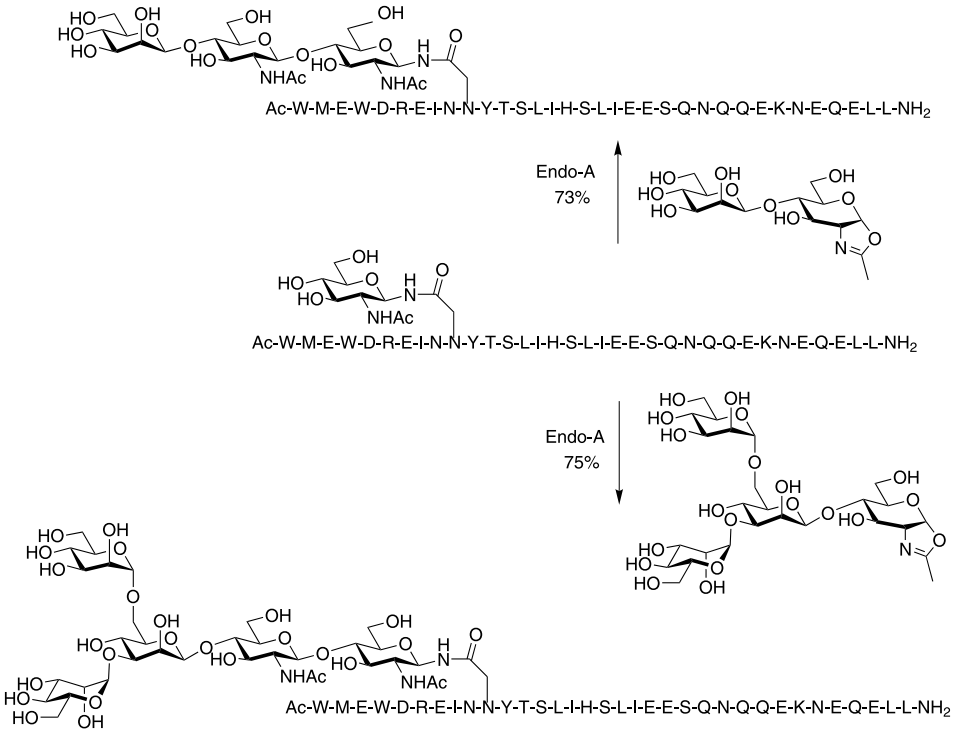
enzymes function by hydrolyzing the chitobiose core of *N*-linked glycans. The resulting product is a protein where each *N*-linked glycosylation site bears a single GlcNAc residue which can be used as a handle for enzymatic elaboration (Scheme 11) [12].
In addition, two of these enzymes, Endo A and Endo M, have been shown to catalyze the transfer of complex sugars to GlcNAc residues on glycopeptides and glycoproteins via transglycosylation [11,13]. While the yield of the reaction is low, it has been found that it can be increased through the addition of organic solvents to the reaction media [73]. More recently, Wang and coworkers have demonstrated that the enzymes catalyze the transfer of oligosaccharide oxazolines, putative transition-state mimetics for hydrolysis, in high yield in aqueous media (Scheme 12) [74]. Using this technology they have been able to synthesize numerous potential glycopeptide-based HIV vaccines (see Sect. 3.2).



Scheme 12

The above methods for glycopeptide synthesis have started to gain tremendous attention for applications in the preparation of various biologically relevant glycopeptides and glycoproteins. The role of these techniques in the areas of vaccine development, antibiotics, and novel therapeutics is discussed in the sections that follow.

3 Glycopeptide-Based Vaccines

Vaccination is the procedure whereby the immune system is induced to create antibodies against a foreign molecule involved in a specific disease process or viral infection. The strategy relies on the fact that if the body is "challenged" with the molecule again at a later date, the immune response to eradicate it will be enhanced and rapid. In effect, a vaccine educates the immune system to foreign entities that may be harmful to the body. In many disease states, the oligosaccharide chains presented on cell surface glycoproteins are altered [75], and therefore represent targets for therapeutic intervention. Since glycoproteins play major roles in cell-cell recognition, it can be expected that any alteration in carbohydrate structure will interfere with communication between cells [76]. This is thought to be the underlying cause of tumor cell metastasis and invasiveness into surrounding tissues. In addition, many pathogens have been shown to possess unique glycosylation patterns on their surface. The development of vaccines for certain cancers, HIV and other pathogens using glycopeptide antigens has been the subject of extensive research over the past decade.

3.1 Synthesis of Glycopeptide Cancer Antigens

Traditional cancer therapies based on surgery, irradiation and chemotherapy are accompanied by significant side effects. The first of these involves invasive removal of the tumor, while the latter two destroy diseased cells by capitalizing on differences between cancerous and healthy cells. It has been recognized for decades, that a phenotype of malignant cells is characterized by aberrantly glycosylated proteins [77,78], often arising from down regulation of certain cell-bound glycosyltransferases that normally function to elongate the saccharide chains. In the case of T_N and T antigens [79], the polysaccharide chains have been abbreviated to mono- and disaccharide structures, respectively. These truncated glycans are often observed on mucin-type proteins, thus affecting the conformation of the protein and allowing the tandem repeat region to become accessible to the immune system.

In addition to simplified glycan core structures, alterations in terminal glycan structures are also associated with malignancy. Certain glycosyltransferases, for example fucosyltransferases and sialyltransferases, tend to be over-expressed in tumor tissue, leading to the over-production of these terminal glycans. Examples of these glycan epitopes, commonly found on certain cancerous cells, include sialyl Lewis x (sLe^x), sialyl Tn (sTn), Globo H, Lewis y (Le^y) and polysialic acid (PSA) (*Fig. 2*) [80,81,82].

3.1.1 Carbohydrate-Based Vaccines

As the structures of cancer cell glycans differ from those that appear on their healthy counterparts, many research groups have focused on recruiting the immune system to target cancer cells on the basis of these altered glycosylation patterns. To date the synthesis of many tumor-associated glycans have been accomplished. Potential anti-cancer vaccines are then created by linking multiple copies of the glycan to immunogenic carrier proteins such as bovine serum albumin (BSA) and keyhole limpet haemocyanin (KLH) [83].

Several carbohydrate-based vaccines are currently undergoing clinical evaluation [83,84], however, vaccines based on immunization with oligosaccharides alone have been met with

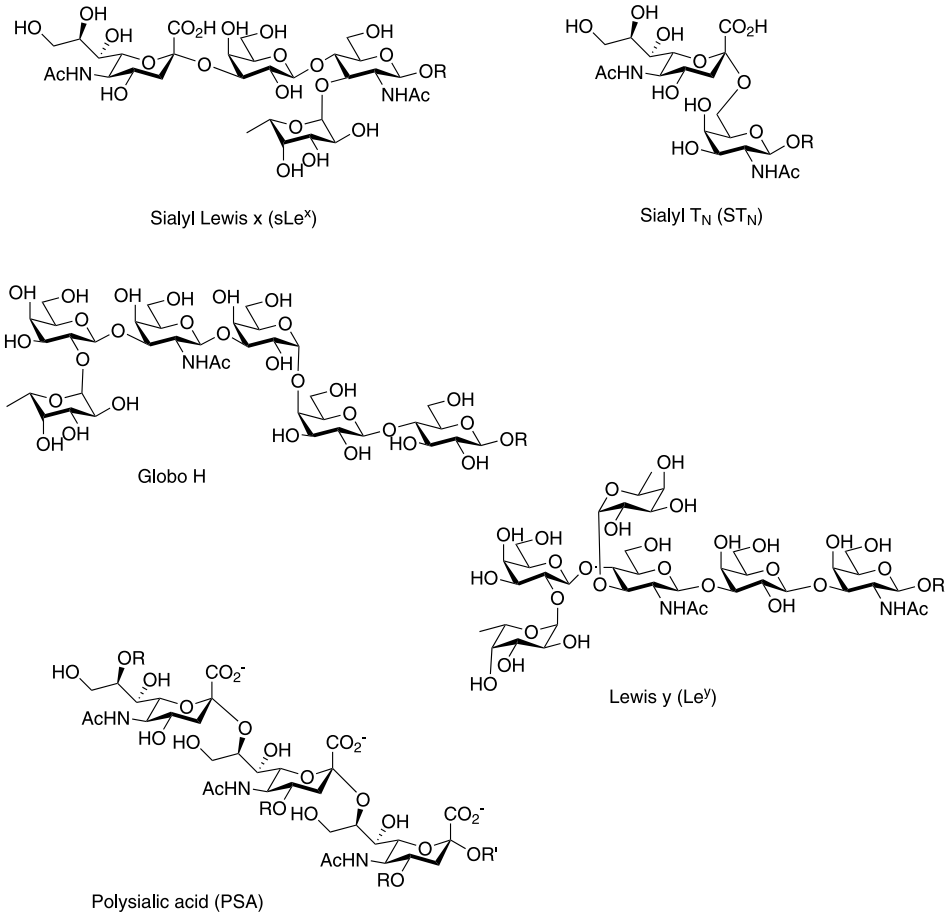


Figure 2
Glycans associated with cancer

limited success in most cases. Exceptions to this are the sialyl-T_N vaccine [85,86] developed by Biomira and the globo H vaccine developed by Danishefsky and coworkers, both of which are currently in clinical trials [87]. Experimental results suggest that the peptide chain may be as important as the carbohydrate portion of the antigen in terms of antibody recognition. The peptide may provide a scaffold for correct spatial orientation of the carbohydrate, perhaps by constraining it in a clustered array. Alternatively, the peptide may provide additional contacts for binding with the antibody.

3.1.2 Glycopeptide-Based Vaccines

Another common feature of tumors is the over-production of certain glycoproteins and glycolipids. In particular, epithelial tumors often overproduce mucin glycoproteins, which are

characterized by dense clustering of *O*-linked glycans on the protein surface. Mucins represent important diagnostic markers for cancer, and function as scaffolds for most of the cancer-associated glycan epitopes listed previously [88,89].

3.1.3 The T_N Antigen

The T_N antigen is a GalNAc α-linkage to serine or threonine on a mucin-like core peptide and is known to accumulate on the surface of tumor cells as a result of incomplete glycan synthesis (*Fig. 3*) [90]. Therefore, several groups have focused on, and reported syntheses of glycopeptides incorporating the T_N antigen. Most of these syntheses target multivalent α-T_N presentation, in order to mimic the proposed clustered array of sugars in the serine/threonine rich mucin domain.

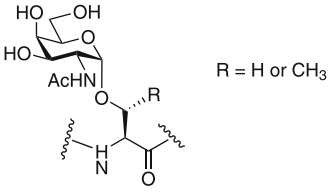

Figure 3
The T_N antigen

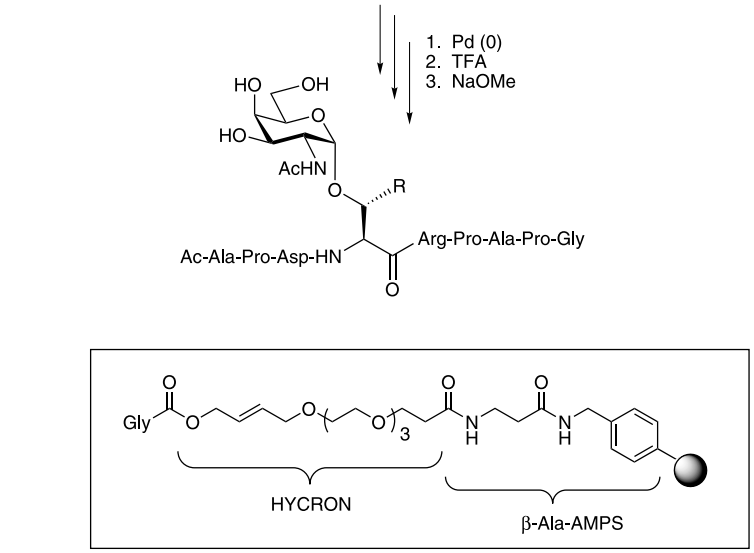
The Kunz laboratory has reported several formulations of the T_N antigen. In one study, tripeptides containing two sites of α-*O*-GalNAc glycosylation were synthesized by chemical methods, then conjugated to BSA for generation of antibodies [91]. In later work on the same system, lipase M was utilized for deprotection of the glycopeptide *C*-terminal carboxylate under neutral conditions [70]. Other instrumental work by this group has focused on the generation of novel solid support linkers, such as HYCRON. With this resin, cleavage of the glycopeptide from the solid-phase occurs under conditions that are not destructive to sensitive glycopeptide functionalities. Employing this methodology, several mucin glycopeptides have been synthesized. *Scheme 13* depicts a reported synthetic sequence of the MUC1 mucin displaying the T_N antigen [92]. Other glycopeptide sequences synthesized by HYCRON methodology include the homophilic recognition domain of Epithelial Cadherin-1 [93] and a partial sequence of MAdCAM-1 [94].

Solid-phase synthesis of another highly T_N glycosylated sequence of MUC1 was reported by Dupradeau et al. [95]. After conjugation to KLH, reactivities of the glycopeptide and unglycosylated control peptide against specific antibodies were assessed. In this case, the authors did not observe a difference between the reactivity of the glycosylated versus the unglycosylated peptides.

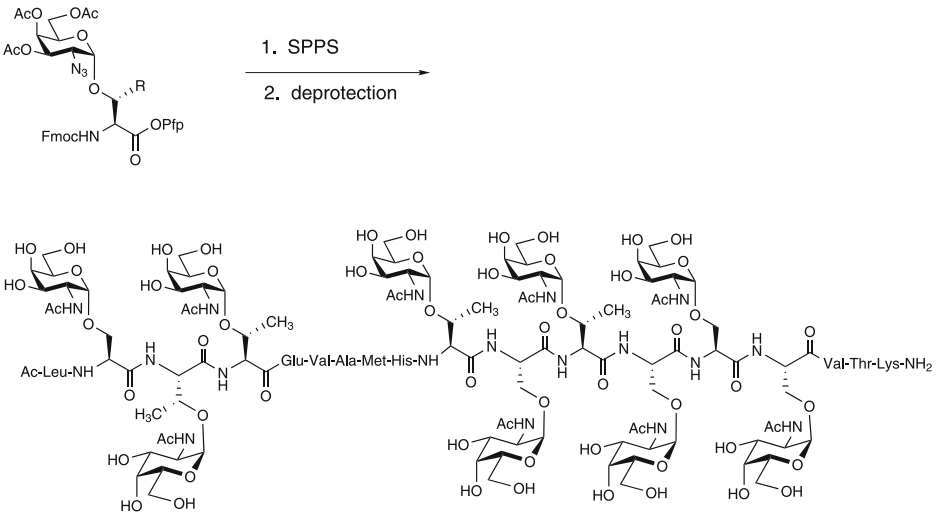
Klich et al. have also accomplished the synthesis of extensively glycosylated sequences of glycophorin A containing the T_N antigen [96] (*Scheme 14*).

Danishefsky and coworkers have prepared tripeptide T_N structures which incorporate handles for conjugation to immunogenic carriers [97] such as KLH, BSA or the lipopeptide Pam_3Cys, which was included as an immunostimulatory feature known to activate B cells and macrophages (*Scheme 15*) [98]. The synthetic strategy centered around the coupling of glycosyl amino acid building blocks in a sequential fashion.

Ac-Ala-Pro-Asp(OBu^t)-Thr(αAc$_3$GalNAc)-Arg(Mtr)-Pro-Ala-Pro-Gly-HYCRON-βAla-AMPS



Scheme 13



Scheme 14

In this case, all conjugates were subject to immunological studies in mice. The KLH conjugate induced high antibody titers, while the lipopeptide conjugate failed to show a strong reaction [83]. This result emphasizes that more than one factor needs to be considered when attempting to generate an immune response. Furthermore, the method of hapten conjugation may be as important as the antigenic structure itself. Interestingly, the antibody response

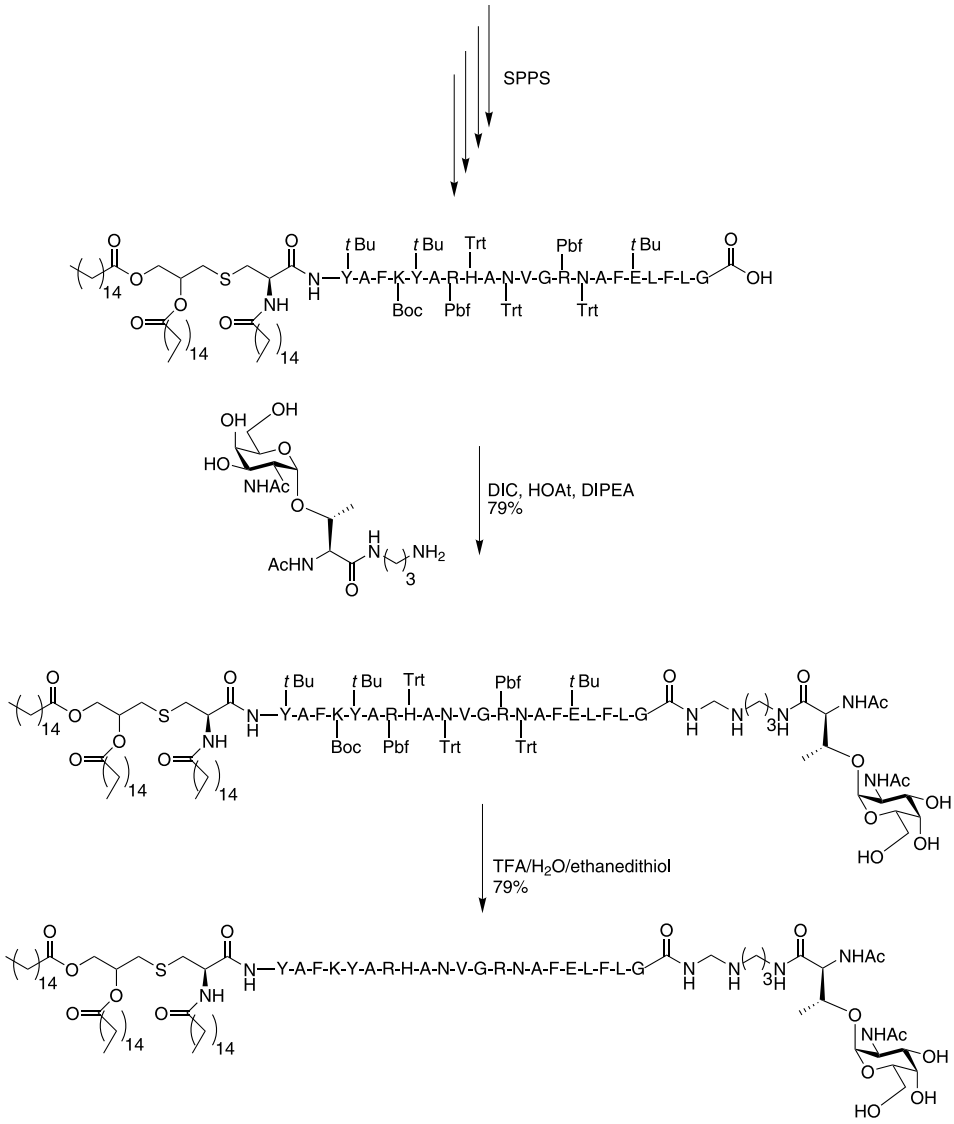
observed was polyclonal, whereby the antibodies generated recognized several different clustered antigen presentations.

Boons and coworkers have also reported the synthesis of a lipated T_N containing glycopeptide as a potential cancer antigen [99]. In this study the T_N antigen was linked to the 20-amino acid peptide YAF, a MHC class II restricted site for human T cells. It was envisioned that the YAF epitope would induce a T cell dependant immune response leading to the production of IgG antibodies [100]. The target was constructed by coupling the T_N antigen to the



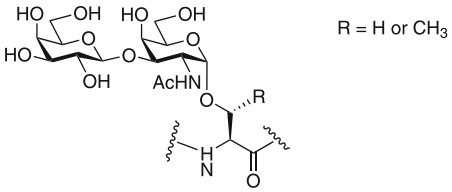
Scheme 16

lipopeptide (obtained through SPPS) through a polyamine linker (◉ *Scheme 16*). Following incorporation into liposomes, the antigen was able to successfully elicit IgM and IgG responses in mice.

To date, the T_N antigen has been studied to a greater level as a vaccine than the other antigenic glycopeptide cancer epitopes. The reason for this can be attributed to its simplicity and ease of synthesis. Recently, more complex antigens have been synthesized, using the approaches established on the T_N core structure as a foundation for which to build upon.

3.1.4 The T Antigen

The T antigenic structure (the "Thomsen-Friedenreich" or "TF" antigen) is derived from the precursor T_N antigen [90]. The disaccharide is also α-*O*-linked to serine or threonine in the peptide backbone (◉ *Fig. 4*).



◘ Figure 4
The T antigen

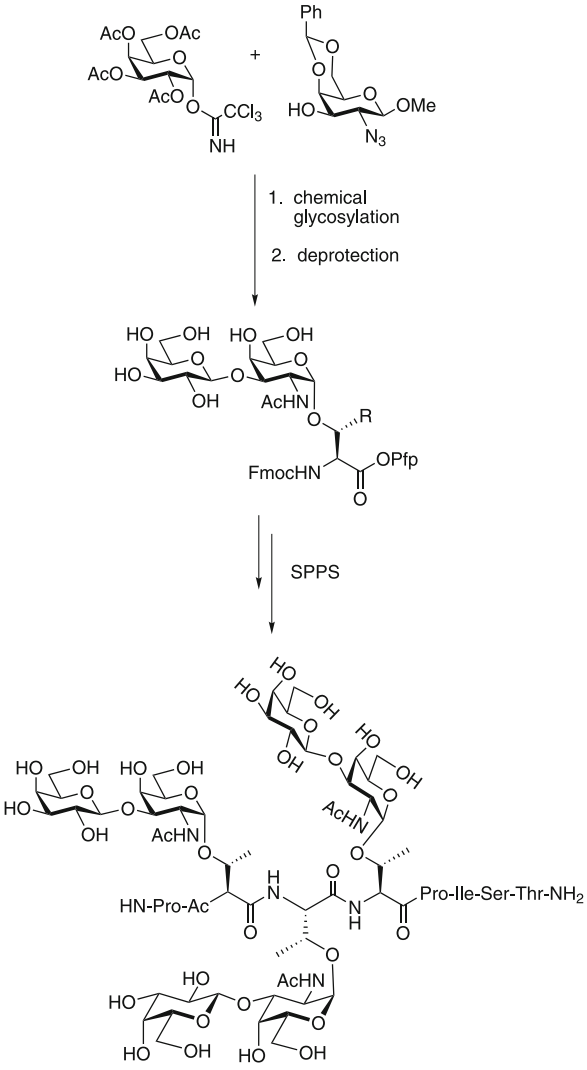
Syntheses of these structures have often been reported in conjunction with that of the T_N antigen [91,97,101]. Again, the clustered glycopeptide motif is often the form of interest. Notably, Paulsen et al. accomplished the construction of eight triply glycosylated mucin sequences, as well as the corresponding mono-glycosylated sequences in a single study [102] (◉ *Scheme 17*).

Kuduk et al. have also prepared clustered T antigens through glycal methodology that are appropriate for conjugation [97] (◉ *Scheme 18*). The approach centered on the synthesis of the Gal-β-1,3-GalNAc-α-Thr building block, which was subsequently coupled to a protected diamine handle for conjugation studies to appropriate carrier proteins (BSA or KLH). This cassette was then sequentially incorporated into a tripeptide T cluster. Immunological evaluation of these constructs is currently under investigation [83].

3.1.5 Sialyl-T_N and Sialyl-T Antigens

The next level of complexity, in the case of synthetic methods, is construction of the sialylated antigenic structures. The sialylated antigens contain sialic acid in either an α2-6 linkage to the GalNAc residue of the T_N or T antigens or in an α2-3 linkage to the terminal galactose of the T antigen [90] (◉ *Fig. 5*).

Nakahara et al. accomplished an early synthesis of a trimeric α2-6 sialyl-T_N glycopeptide. The resultant glycopeptide corresponds to a partial structure of glycophorin A [103] (◉ *Scheme 19*).

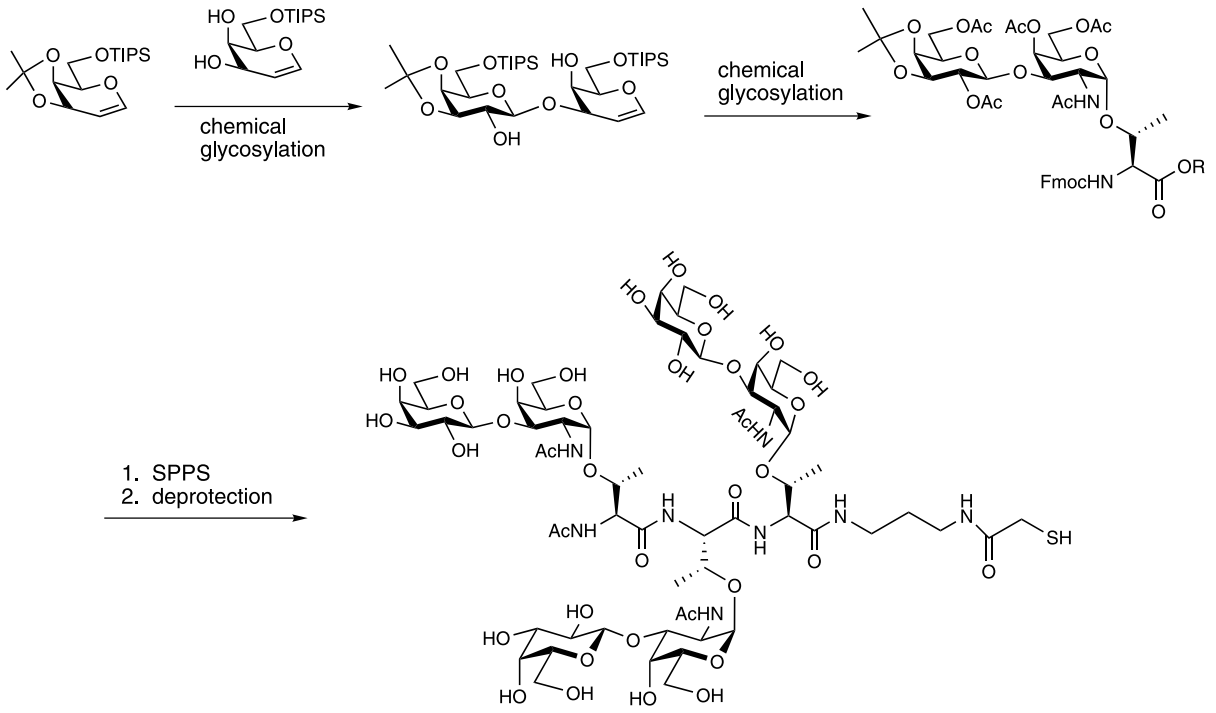


Scheme 17

Liebe and Kunz made further use of the HYCRON linker methodology in the construction of the α2-6 sialyl-T_N antigen attached to a portion of the mucin MUC1 repeat peptide [104] (*Scheme 20*).

Danishefsky's laboratory has recently reported syntheses of the clustered motif of both the α2-6-sialyl-T_N and α2-6 sialyl-T antigens (*Fig. 6*) using a similar procedure to that described for the clustered T antigen described above [105,106]. Conjugation and immunological evaluation of these constructs is currently in progress.

Only one of the aforementioned glycopeptide vaccine candidates has exhibited a proliferating effect on the peripheral blood lymphocytes, an essential property for a vaccine. This led to



chemical glycosylation
chemical glycosylation
1. SPPS
2. deprotection

Scheme 18

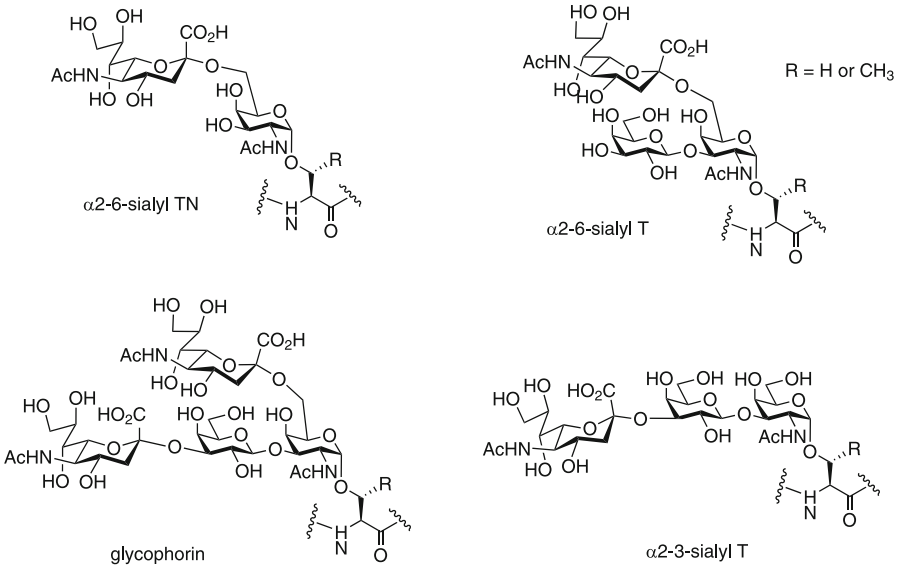


Figure 5
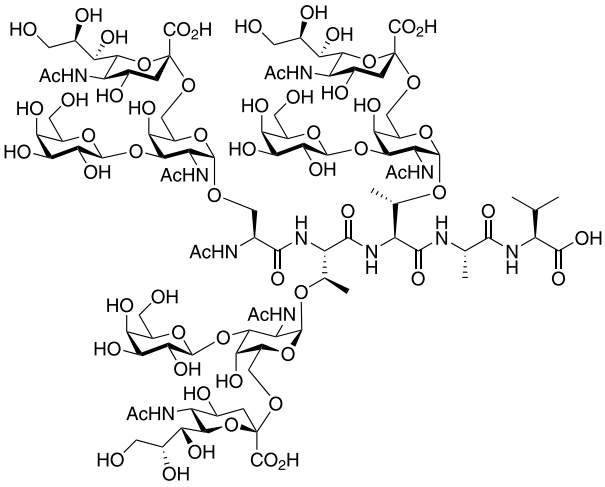
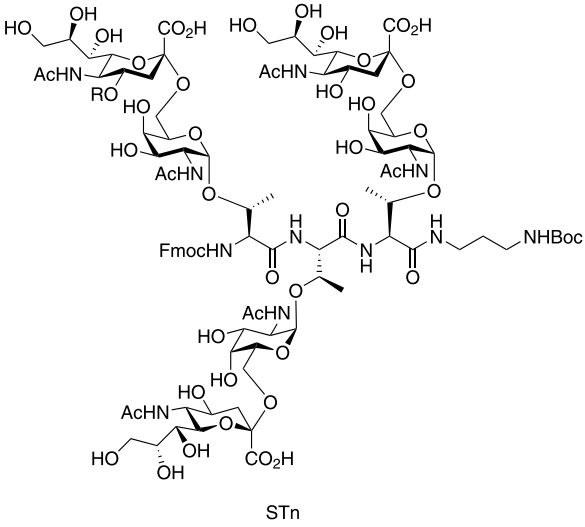
Sialic acid-containing cancer-associated antigens

the development of a novel concept for the incorporation of glycopeptides into antitumor vaccines, whereby the tumor associated MUC1 glycopeptide antigen was combined with a T-cell epitope of tetanus toxin as an immunostimulant [107]. Following the synthesis of the desired glycopeptide, using HYCRON linker strategy SPPS [92], the resin bound glycododecapeptide was coupled to the tetanus toxin peptide prior to cleavage from the resin (*Scheme 21*). The synthetic vaccine was able to induce proliferation of human blood lymphocytes after three stimulations with the conjugate. Importantly, proliferation was observed only in the presence of antigen presenting cells, indicating an antigen specific response. This conjugate was found to induce the proliferation of $CD3^+$ cells, including cytotoxic $CD8^+$ cells. It is important to note that it was necessary to incorporate all of the elements on the construct into the antigen to proliferate $CD8^+$ cells.

In addition to the production of $CD8^+$ cells, a sialyl-T_N containing glycopeptide has been used to elicit a T-helper cell mediated immune response. This approach involved coupling the sialyl-T_N glycododecapeptide to a T_H cell peptide epitope (*Scheme 22*) [108]. The concept was to utilize the T_H cell peptide epitope, residues 323–339 from ovalbumin (OVA), to initiate strong production of antibodies specific for the MUC1 epitope also present in the vaccine. It was envisaged that binding of the MUC1 epitope to surface Ig receptors of a B lymphocyte would result in endocytosis of the entire construct. In this approach the glycopeptide antigen was synthesized by SPPS using a 2-phenyl-2-trimethylsilyl-ethyl ester (PTMSEL) linker, which allows facile cleavage of the peptide from the resin under mild conditions [109]. The glycopeptide was then conjugated to the OVA sequence through a triethylene glycol linker. This conjugate was found to elicit an immune response in transgenic mice whose T cells expressed a receptor for the ovalbumin T cell epitope presented by MHC(III) molecules.



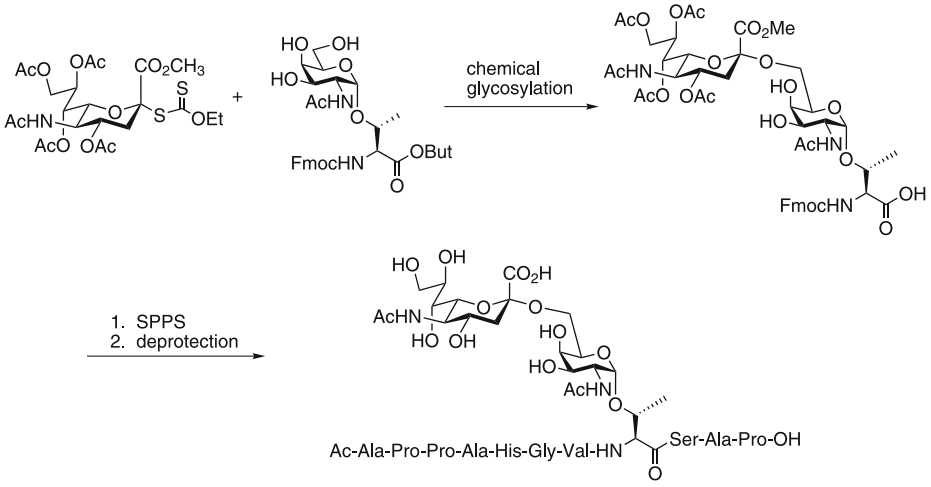
2,6-ST



STn

Scheme 19

Following three rounds of immunization one of the mice was found to exhibit significantly increased levels of anti-T_N antibodies. Importantly, significant increases in antibody concentration were observed between the first and second rounds of immunization, implying the establishment of an immunological memory (specific IgG response).



Scheme 20

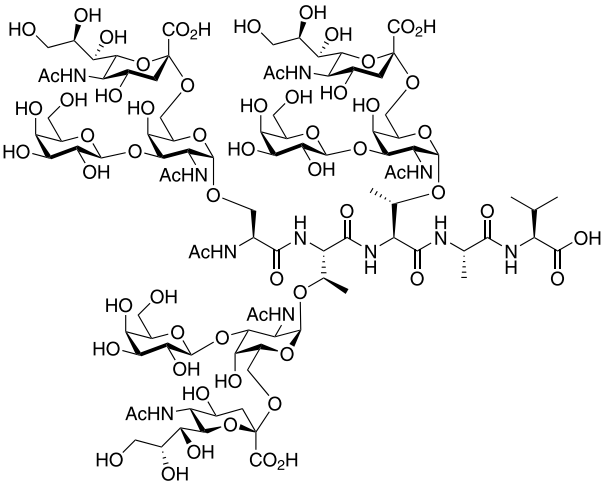
3.1.6 Lewis^y-Glycopeptides

With the successful synthetic studies on clustered T_N, T, sialyl-T_N and sialyl-T motifs in hand, Danishefsky and coworkers embarked on the synthesis of clustered glycopeptides containing the more complex Lewis^y (Le^y) determinant (*Scheme 23*) [110]. The synthesis was achieved using the cassette strategy in which a complex glycan donor was coupled to α-GalNAc-Ser to afford the protected Le^y hexasaccharide derivative. The glycosyl amino acid was subsequently submitted to iterative solution phase peptide couplings as executed in previous cluster syntheses to provide the trimeric Le^y cluster. Global deprotection, followed by coupling of the immunostimulatory Pam_3Cys moiety to the *C*-terminus of the peptide gave the desired antigenic cluster. The reactivities of the Pam_3Cys glycopeptide along with a Le^y-ceramide control compound against the anti-Le^y antibody 3S193 (elicited against tumor cells displaying the cell surface mucin motif) were determined using an ELISA assay. The compound displayed comparable reactivity to the control suggesting that the hexasaccharide was a reliable mimic of the tumor-associated Le^y mucin. Vaccinations of mice with the antigen resulted in a powerful IgM immune response, producing antibodies that bound strongly to the natural Le^y-mucin moiety.

3.1.7 Other Glycopeptide Cancer Antigens

Von dem Bruch and Kunz have prepared *N*-linked divalent Lewis x glycopeptides as potential tumor antigens (*Scheme 24*). Following chemical block synthesis, the glycohexapeptides were conjugated to BSA or KLH for immunological study [111].

Chen et al. have also reported the synthesis of a related cancer antigen, the F1α antigen [112]. Although the core peptidic-glycan linkage remains conserved, the pendant sugar is lactosamine, rather than sialic acid (*Fig. 7*).



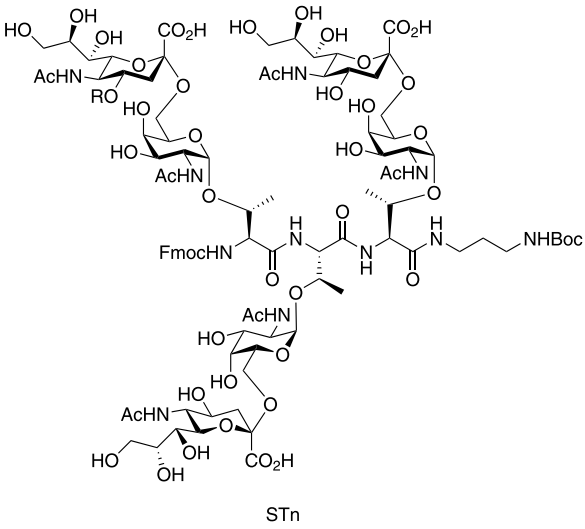


Figure 6
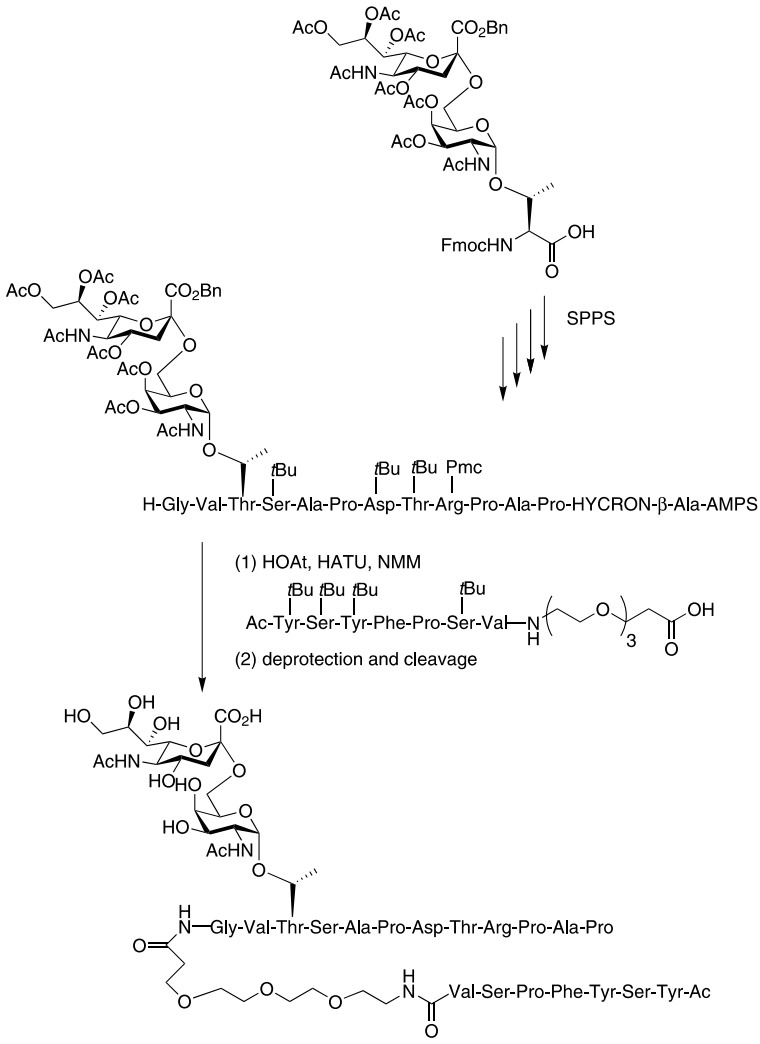
Clustered glycopeptide antigens as cancer vaccine candidates.

More recently Danishefsky and coworkers have evaluated multiantigenic glycopeptides as cancer vaccine candidates [84]. It was reasoned that vaccination strategies utilizing a range of tumor-associated antigens attached to one mucin-type peptide may trigger a more diverse immune response than those presenting only one antigenic glycan. An example of such a mucin-based construct displays T, Le^y, and Tn antigens (*Fig. 8*). Immunogenicity of the multivalent species (conjugated to KLH) was investigated and was shown to induce IgM



Scheme 21

and IgG antibodies when injected into mice. Interestingly, the glycopeptide containing the T antigen displayed significantly less antigenic behavior than the trishomoserine construct containing the Globo-H epitope.

3.2 Synthesis of Glycopeptide HIV Antigens

Acquired immune deficiency syndrome (AIDS) is caused by infection with the human immunodeficiency virus (HIV) [113]. At present 40 million people are infected with the virus worldwide, with an estimated five million new infections in 2004 alone [114]. A vaccine that limits HIV-associated disease states or prevents HIV infection would be a valuable tool for stemming

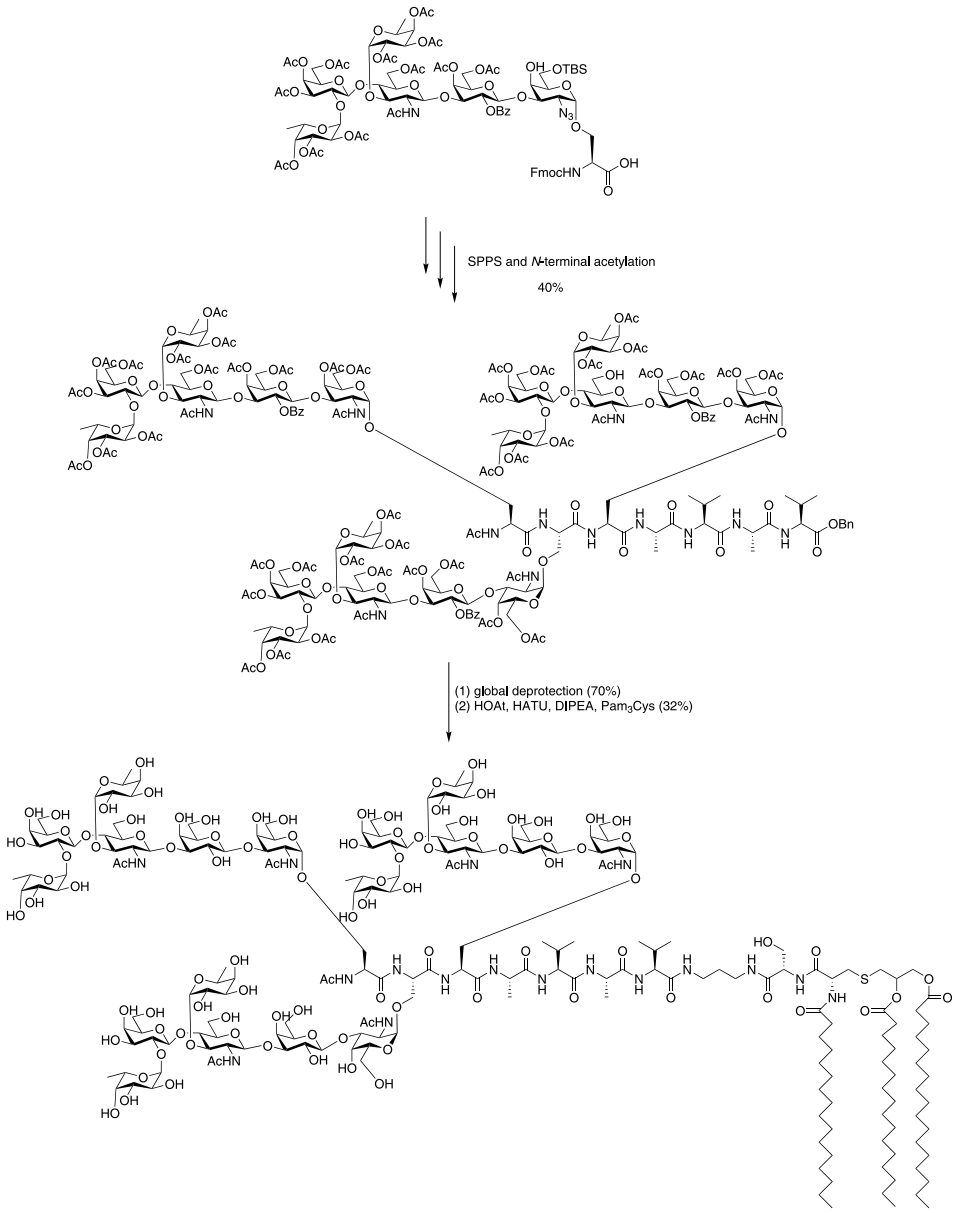
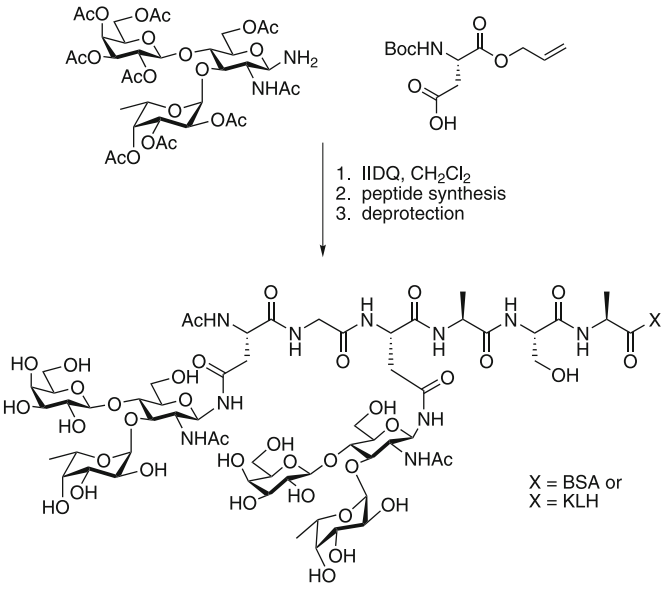


Scheme 23

the HIV epidemic [25]. Currently, more than 30 HIV vaccine candidates are in various stages of clinical trials through-out the world, however, the problem is extremely complex and most have been met with limited success to date [115,116].

One of the major impediments of vaccine development is the extensive glycosylation of HIV envelope proteins, which shields them from antibody recognition. HIV-1 contains two enve-



Scheme 24

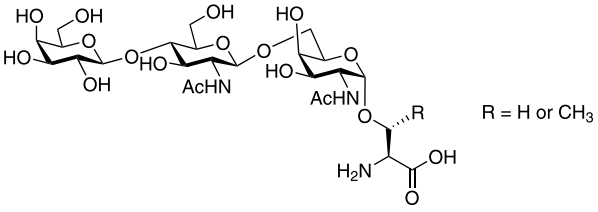


Figure 7
Synthetic F1α antigen

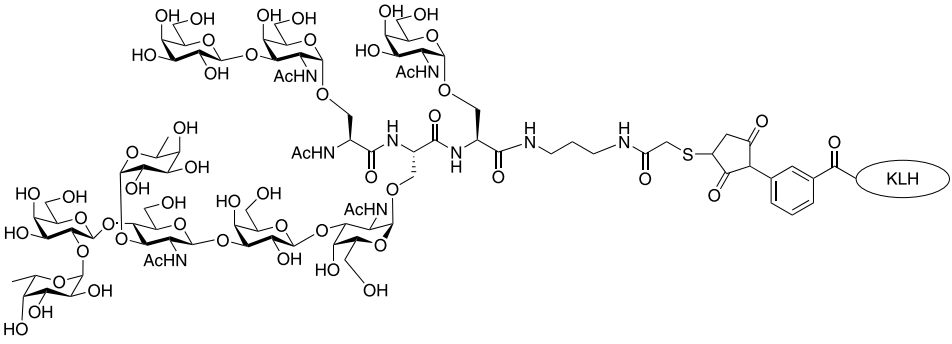

Figure 8
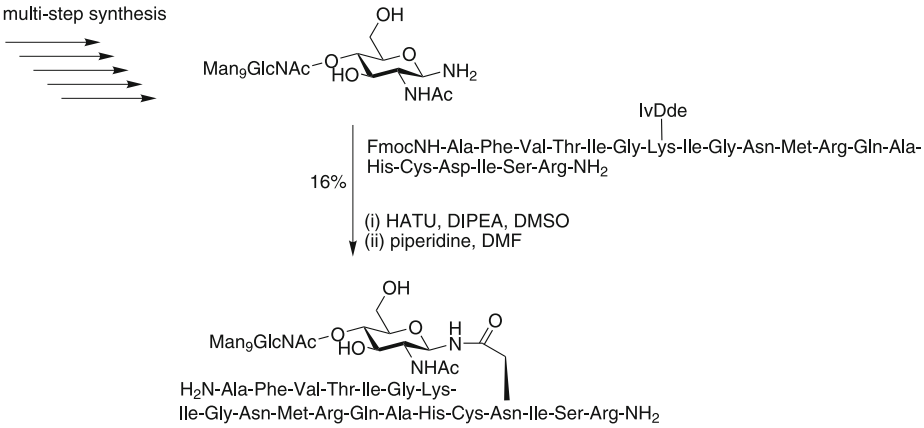
Glycopeptide conjugate displaying multiple carbohydrate antigens

lope glycoproteins, gp120 and gp41 that form trimeric complexes on the viral surface. The outer envelope glycoprotein gp120 typically contains 24 *N*-linked glycans [117,118,119], while the inner envelope glycoprotein gp41 contains four conserved *N*-glycans [120,121]. Two distinct oligosaccharide cluster domains are observed on the surface of gp120. One consists of high mannose-type *N*-linked glycans, while the other consists of complex type *N*-linked glycans [119]. Recently, the concept of using gp120 carbohydrates as antigens for eliciting broadly neutralizing immune responses gained recognition when the structure of the HIV neutralizing antibody 2G12 was solved [122]. A number of detailed studies by several research groups have shown that the antibody recognizes key features in the oligomannose epitope, in particular the mannose-α1,2-mannose sugar residues [122,123]. Importantly, studies with synthetic oligosaccharides showed that Man_9 glycans were necessary for optimal binding [124,125,126]. Recent X-ray crystal studies with these synthetic oligomannoses verified that the mannose-α1,2-mannose subunit is critical for recognition along with a sufficient oligomannose arm [127].

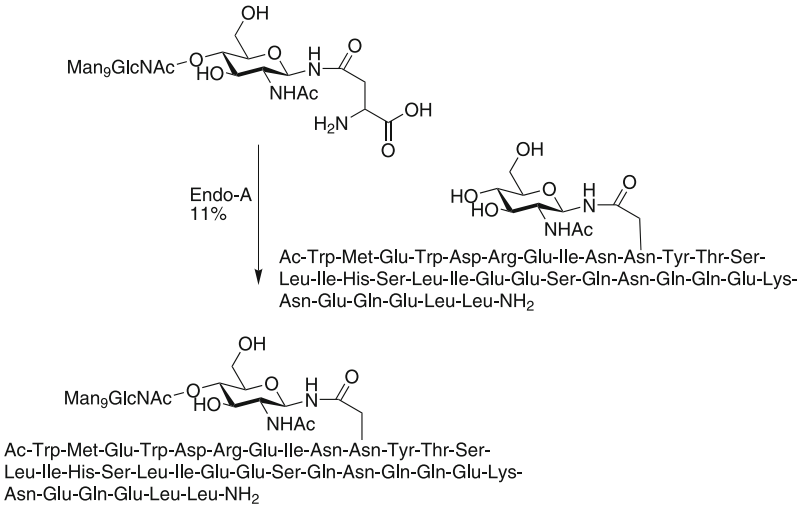
The wealth of information gained from the 2G12 binding studies has been applied to the development of novel synthetic glycopeptide vaccine candidates. Danishefsky and coworkers reported the chemical synthesis of HIV-1 gp120 glycopeptide fragments (amino acid residues 316–335), displaying either a hybrid-type or a high mannose-type *N*-linked glycans [128,129]. The preparation of the glycopeptides involved a multi-step synthesis of the fully elaborated 1-amino-oligosaccharides [130], followed by ligation to a selectively protected peptide displaying a free aspartic acid (corresponding to Asn-332 in the natural sequence). This was achieved using the block condensation approach described in ❯ *Sect. 2.2* (❯ *Scheme 25*).

Wang and co-workers have adopted a chemoenzymatic approach, using Endo A, to construct potentially immunogenic HIV-1 glycopeptides. This strategy involves enzymatic transglycosylation of a complex *N*-linked glycan to synthetic glycopeptides containing a single GlcNAc moiety to yield the desired glycopeptide. Several glycoheptapeptides (corresponding to amino acids 336 to 342) of HIV-1 gp120 possessing Man_9, Man_6 and Man_5 glycans were synthesized using this methodology [131].



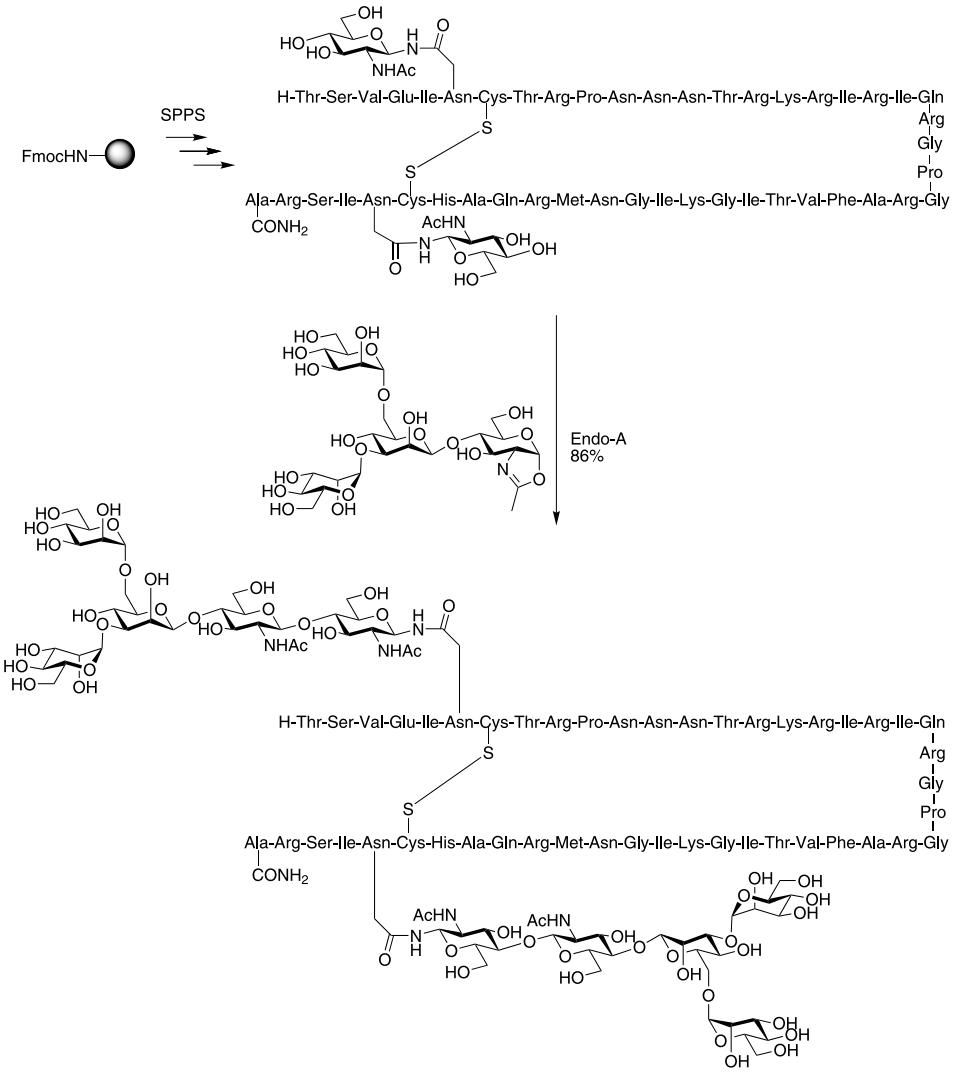
Scheme 25

This group also utilized endoglycosidases to synthesize homogeneous glycoforms of the peptide C34, derived from the *C*-terminal ectodomain of HIV-1 gp41 [132]. This sequence contains a conserved *N*-linked glycan at Asn-637 in the native gp41, and is responsible for the formation of α-helical bundles with the gp41 fragment N36, providing the driving force for the fusion of virus-host membranes [133]. Endo A was used to transfer $Man_9GlcNAc$ to a synthetic C34 peptide possessing a GlcNAc residue at Asn-637, providing the desired conjugate in 11% yield (▶ *Scheme 26*). The resulting $Man_9GlcNAc_2$-C34 conjugate was assessed for its inhibitory activities against HIV-1 using a cell-fusion assay. The glycopeptide exhibited an IC_{50} of 7.7 nM, less potent than the unglycosylated C34 peptide ($IC_{50} = 1.1$ nM). However, with respect to the development of an anti-HIV therapeutic, $Man_9GlcNAc_2$-C34 glycopeptide may be superior to C34 due to its increased solubility and resistance to proteolytic degradation. Conformational studies of the glycosylated C34 using circular dichroism (CD) analysis showed the C34 glycoprotein to have a similar solution conformation to the unglycosylated peptide. Glycosylation did, however, disrupt the ability of C34 to form six-helix bundles with the peptide N36. This led to the proposal that the less-compact six α-helix bundle may mimic some transition-state character of gp41 exposed during membrane fusion, providing novel conformational epitopes for the development of HIV vaccines.



Scheme 26

More recently, Wang and coworkers have exploited sugar oxazolines in the pursuit of HIV active glycopeptides [74]. Two C34 fragments containing core tri- and pentasaccharides were synthesized using sugar oxazoline donors in the Endo A catalyzed reactions. The new methodology significantly improved the yield of the target protein (73–75%). This method has also been applied a to 47-mer cyclic glycopeptide corresponding to the third variable (V3) domain of gp120 [134]. The V3 domain represents an important target for the development of HIV-1 vaccines and as such was once named "the principal neutralization determinant" [135]. This region of the native V3 domain contains two high-mannose type *N*-linked glycans at two con-



Scheme 27

served Asn residues (Asn-295 and Asn-332) which are recognized by the antibody 2G12 [123]. The synthesis of the V3 domain involved SPPS of the cyclic 47-mer V3 domain peptide containing two GlcNAc-Asn residues. Endo A was used to transfer disaccharide and tetrasaccharide oxazoline substrates to the GlcNAc residues to afford products containing tri- and pentasaccharide glycans respectively (*Scheme 27*). The effect of glycosylation on the conformations of the V3 domain was investigated by CD spectroscopy and attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR). These studies again suggested that glycosylation could be exploited as a tool to induce favorable epitopes for an effective gly-

copeptide-based HIV vaccine. In addition, the glycopeptides were significantly more stable to protease digestion when compared to unglycosylated V3 peptide, suggesting increased in vivo lifetimes.

3.3 Other Glycopeptide-Based Vaccines

Reichel et al. have reported the construction of a lipoglycopeptide that may serve as a vaccine against bacterial meningitis [136]. This novel conjugate comprises several different recognition motifs. The carbohydrate portion mimics the inner core of meningococcal lipopolysaccharides (LPS, the "B-epitope"). The peptide chain serves as a T-epitope for immunological memory. Finally, the lipid portion functions in the activation of B-cells, as well as membrane anchoring (*Fig. 9*).

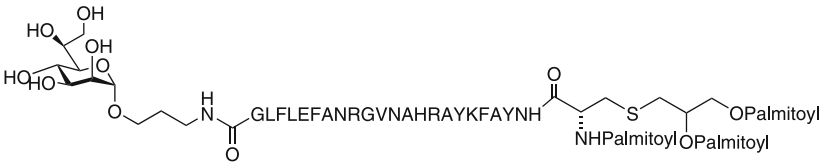


Figure 9
Lipoglycopeptide vaccine of bacterial meningitis

Antigenic haptens to *Shigella*, a genus of bacteria which causes dysentery in humans, have also been reported [137]. Glycoconjugates of this nature may function as a vaccine against dysentery. Numerous synthetic carbohydrates based on the repeating *O*-linked saccharides found in *Shigella* were conjugated to human serum albumin (HSA) carrier protein through a spacer arm for immunization purposes. These glycoconjugates were found to induce immune responses in mice [138]. More recently, potential *Shigella* vaccines were synthesized by attachment of oligosaccharide antigens to the non-natural T-helper peptide human leukocyte antigen (HLA) DR-binding epitope [139,140].

Helicobacter pylori which binds to blood group determinants on the gastric epithelium is responsible for stomach ulcers and gastro adenocarcinoma along with a host of other ailments [141,142]. The specific carbohydrate structures to which the bacterium adheres have been elucidated recently [143]. These antigens are also prime targets for the creation of a vaccine. Capsular polysaccharide conjugates serve as additional vaccine target structures [144]. This type of vaccine may aid in the eradication of pathogenic bacteria from the body through targeting of the carbohydrate coat presented on the bacterial cell surface.

Plasmodium falciparum is a single celled parasite, infections of which are responsible for malaria. The mortality and morbidity associated with this disease are largely the result of inflammatory cascades triggered by the glycosylphosphatidylinositol (GPI) expressed in large quantities on the pathogen's surface [145]. Recently, Seeberger and coworkers developed malarial vaccine candidates by conjugating multiple copies of synthetic GPI to BSA (*Fig. 10*) [146]. Preclinical evaluation of this synthetic vaccine was extremely promising, with vaccinated mice exhibiting a 60–75% survival rate when exposed to the parasite, as opposed to a 0–9% survival rate in untreated mice.

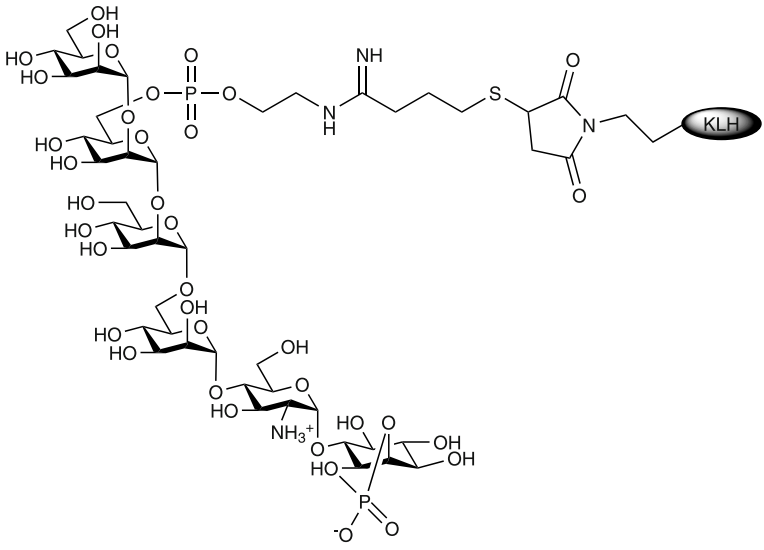

Figure 10
Synthetic GPI-KLH conjugate as a potential malarial vaccine

The unusual lipophosphoglycan (LPG) found on protozoa of the genus *Leishmania* is a promising target for the development of vaccines against these parasites. Recently, Hewitt, Seeberger and coworkers have described the synthesis of two potential Leishmaniasis vaccines based on conjugating the cap tetrasaccharide of the LPG to either KLH or Pam_3Cys [147]. More recently, this group has developed antigens formed by conjugating the cap tetrasaccharide to immunostimulating reconstituted influenza virosomes (IRIVs) through phospholipids or hemagglutinin [148]. Both of these later constructs were shown to induce production of IgG which recognize *Leishmania donovani*.

4 Glycopeptides as Antibiotics and Other Drug Targets

Glycopeptides have the potential to function as bactericidal agents, and as such, are currently used clinically in the treatment of microbial infections. Bacteria have the capability to evolve resistance to antibiotics [149], and as such, constant research into the development of new antibacterial agents is necessary.

Vancomycin is most often the antibiotic of last resort for the treatment of resistant bacterial strains, however, bacterial strains resistant to vancomycin are now emerging [19]. The health threat posed by these strains has led to intense research into both the mechanism by which resistance develops and the development of pharmaceutical antibacterial agents with novel modes of action.

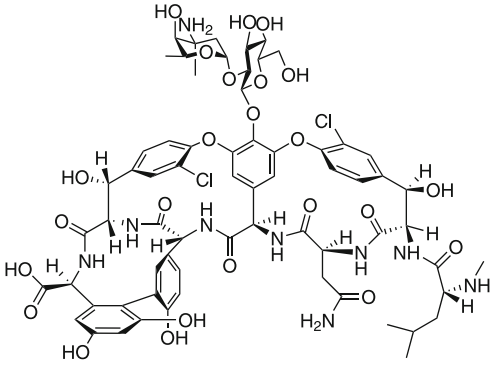
Glycopeptides are also being explored as drug candidates for other means. Addition of a carbohydrate to a peptide backbone often decreases proteolytic degradation and increases oral availability of peptide-based drugs. These are favorable qualities of pharmaceuticals that need to be optimized for agents to reach clinical trials.

4.1 Cyclic Glycopeptide Antibiotics

4.1.1 Vancomycin and Teicoplanin

Vancomycin and teicoplanin are complex cyclic glycopeptide antibiotics (*Fig. 11*). Although the structures of these compounds were elucidated decades ago, total syntheses of vancomycin aglycone [150,151,152,153,154,155], fully glycosylated vancomycin [156], and teicoplanin [157,158] have only recently been reported.

With the emergence of bacterial strains that are resistant to these glycopeptides, the first line of defense is often to synthetically modify the natural antibiotic. In the case of these glycopeptides, synthetic alteration of the aglycone structure is not practical, due to their complexity. However, the carbohydrate portion of the molecule [vancosamine(α1-2)glucose in the case of vancomycin] is readily accessible to modification. This strategy has led to new antibiotics that have potential for treatment of vancomycin-resistant strains.



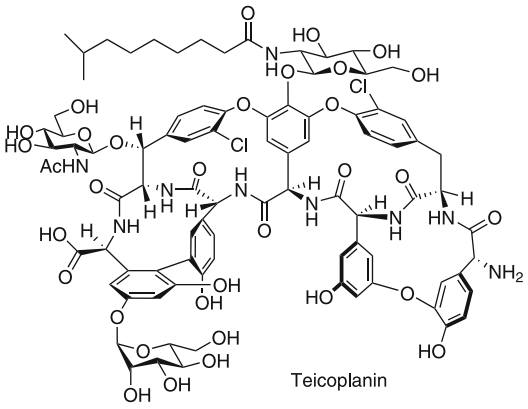


Figure 11
Structures of vancomycin and teicoplanin

It has been observed that the incorporation of lipophilic chains into vancomycin can increase the potency of the drug [159,160,161,162]. This is best exemplified by the observation that teicoplanin retains activity against some vancomycin-resistant bacterial strains. In one early study directed at improving the efficacy of these antibiotics, Ge et al. investigated the mechanism of action of a chloro-biphenyl derivative of vancomycin that showed activity against resistant bacteria [163]. The sulfoxide method of glycosylation was utilized to achieve the desired modification of the gluco-vancomycin precursor (*Scheme 28*).

The analog containing the biaryl moiety was found to act by a different mechanism than vancomycin itself. While vancomycin inhibits transpeptidase activity, the modified structure is thought to inhibit transglycosylase activity (*Scheme 29*). This finding reveals an alternative target for the development of antimicrobial agents. The glycosylation strategy described above provides facile access to numerous novel glycopeptide antibiotics based on the vancomycin core.

While chemical methods provide a powerful tool for the construction of vancomycin derivatives, they suffer from the need for extensive protection/deprotection chemistry. Over the past several years a significant amount of work has been devoted to identifying the glycosyltransferases (Gtfs) responsible for the synthesis of the vancomycin and teicoplanin glycosides [161]. The substrate specificities of these enzymes has been extensively studied and it was found that certain Gtfs were highly promiscuous, i. e. able to transfer a variety of non-natural UDP and TDP sugars to the glycopeptide aglycone [164,165,166]. Importantly, it has been shown that one of these enzymes (GtfE) is tolerant of azido modification of the glucose sugar, opening up the possibility for selective chemical modification of vancomycin derivatives via Huisgen 1,3-dipolar cycloaddition (*Scheme 30*) [167].

In addition to the glycosyltransferase enzymes, the substrate specificity of the teicoplanin acyltransferase (Atf), responsible for the installation of the fatty acid amide in teicoplanin, has been examined [168]. This enzyme appears to be tolerant to modifications in the amide chain length, carbohydrate structure and nature of the aglycone. This finding is of particular interest as it has been shown that installation of the lipid containing monosaccharide from teicoplanin onto vancomycin can restore antibiotic activity against several resistant strains [159].

Besides modification of the glycan, other strategies to overcome vancomycin resistance have been undertaken. Dimeric and trimeric vancomycin constructs bind the D-Ala-D-Ala peptide more tightly than vancomycin itself and have shown antibacterial activity against vancomycin resistant strains [169,170,171]. A potential inhibition pathway that acts through dimerization and membrane-anchoring is also being actively pursued [172,173].

In addition to vancomycin and teicoplanin, several other fused cyclic glycopeptide derivatives have been studied [161,174,175]. In all cases examined, the glycan portion of the molecule is necessary for optimal activity.

4.1.2 Mannopeptimycins

The mannopeptimycins are cyclic (*DL*)-glycohexapeptides which display potent antibacterial activity against gram positive bacteria including methicillin and vancomycin resistant enterococci (*Fig. 12*) [176]. This class of glycopeptides are thought to interfere with bacterial cell wall synthesis by binding to lipid II, although the exact mechanism of action remains unknown [177]. While there is limited SAR data on these molecules, it has been demonstrated

1. chemical glycosylation

that the presence of an isovaleryl ester on the terminal mannose group is essential for retaining activity.

4.1.3 Ramoplanin

Ramoplanin is a lipoglycodepsipeptide isolated from a fermentation broth of Actinoplanes which showed potent antibiotic activity against a number of vancomycin resistant bacterial strains [178]. This compound is currently undergoing phase III clinical trials. While the mechanism of action of ramoplanin remains to be elucidated, it appears that the glycans are not necessary for biological activity and their function remains to be established.

4.2 Linear Glycopeptide Antibiotics

4.2.1 Drosocin

Several linear glycopeptides also show promise as antibacterial agents. Drosocin is a 19 amino acid peptide glycosylated with the disaccharide Gal(β1-3)GalNAc(α1-*O*)Thr (the T antigen) at position 11 (*Fig. 13*). The attached sugars are necessary for optimal biological activity. A recent study by Bulet et al. examined native drosocin, two truncated forms, and the

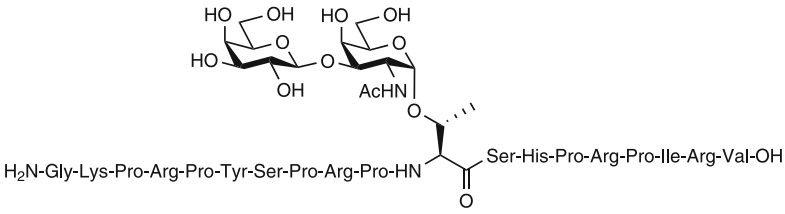

Figure 13
Structure of drosocin

unglycosylated peptide (synthesized by SPPS) in antibacterial assays against several bacterial strains [179]. The requirement of the sugar portion of the glycopeptide for full activity was confirmed by these studies.

4.2.2 Diptericin

The antimicrobial diptericin is an 82-amino acid glycopeptide containing two glycosylation sites. In nature the peptide exists as a mixture of glycoforms, the simplest of which possesses only two *O*-linked GalNAc residues [180]. In addition to two syntheses of this compound by SPPS [181,182], Bertozzi and coworkers have synthesized an analogue of the simplest glycoform using NCL (*Scheme 31*) [47]. As the peptide is devoid of cysteines it was necessary to introduce a Gly25-Cys mutation to facilitate NCL, as well as Asp29-Glu and Asp45-Glu mutations to facilitate the synthesis. The synthesis was initiated by SPPS of a 24-residue *N*-terminal thioester and a 58-residue *C*-terminal fragment containing an *N*-terminal cysteine. In order to circumvent problems associated with thioester hydrolysis, the authors used Ellman's "safety-catch" linker in the synthesis of the *N*-terminal fragment [183]. These fragments underwent smooth NCL to afford, after deprotection, synthetic diptericin which retained antimicrobial activity despite the amino acid substitutions. This report is of note as it was the first complex glycopeptide to be synthesized using NCL.

4.2.3 β-KDO

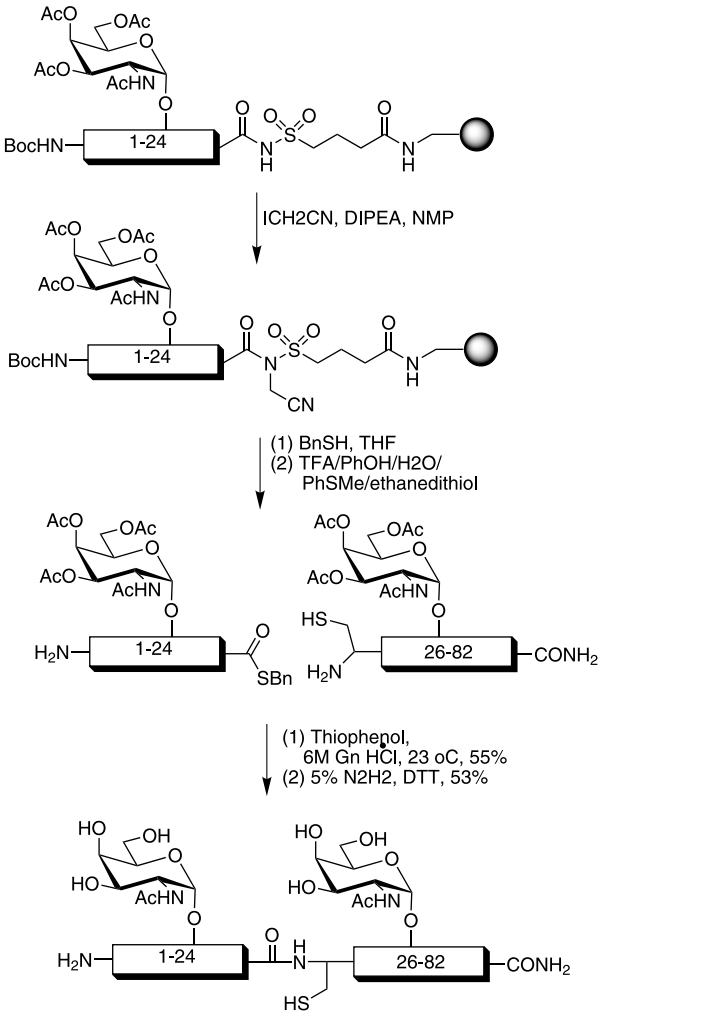
Another interesting antibiotic construct is a peptide-conjugated form of β-KDO. β-KDO is an inhibitor of the CMP-KDO synthetase that is involved in lipopolysaccharide (LPS) synthesis, a major constituent of the bacterial cell wall. Antibacterial activity is thus accomplished by interference with cell wall construction. β-KDO is incapable of membrane permeation, and therefore is not useful as an antibiotic in its native form. Hammond et al. have shown that conjugation of a β-KDO analog to certain dipeptides resolves this problem [184] (*Fig. 14*). Attachment of the β-KDO analog to a dipeptide allows the glycopeptide construct to permeate the bacterial membrane. Inside the cell, proteases hydrolyze the peptide and release the inhibitor, resulting ultimately in bacterial cell death.

4.3 Other Drug Targets

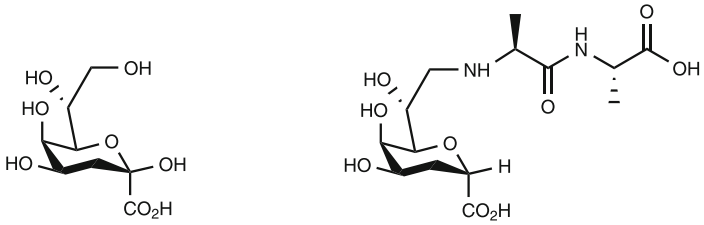
4.3.1 Erythropoietin (epo)

Erythropoietin is a 166 amino acid glycoprotein used to treat anemia arising from a wide range of clinical conditions. The glycoprotein exists as a complex mixture of glycoforms possessing three *N*-linked glycosylation sites and one *O*-linked site. It has been demonstrated that optimal in vivo activity is observed when the *N*-linked glycosylation sites possess tetrasialylated tetra-antennary glycans [29]. Recently, Danishefsky and coworkers have initiated a program directed at synthesizing a homogeneous glycoform of epo in order to gain better insight into the role of the carbohydrate moieties on biological activity. To date this group has synthesized two fragments, the 23–37 glycopeptide domain, and the 114–166 domain.

The synthesis of the 23–37 domain entailed coupling of a complex biantennary glycan to a masked peptide thioester, corresponding to residues 22–28 of epo, under conditions

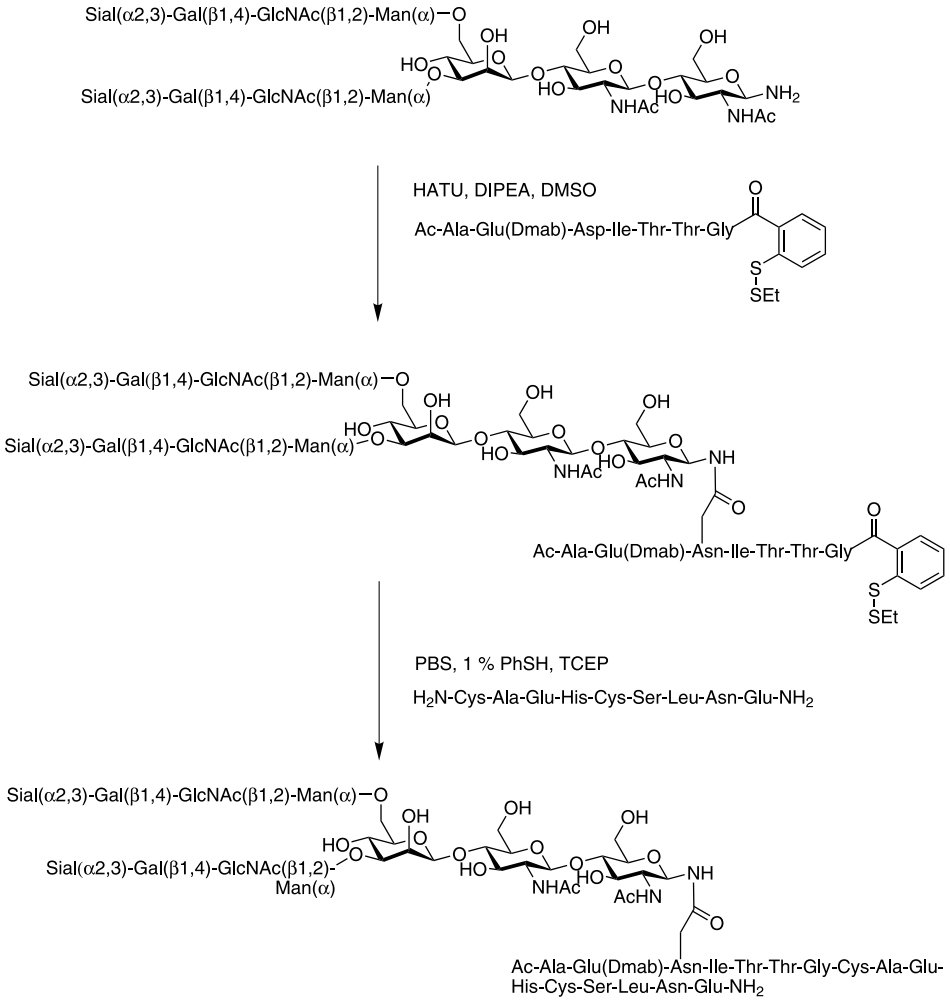


Scheme 31



β-KDO β-KDO di-Alanine analog

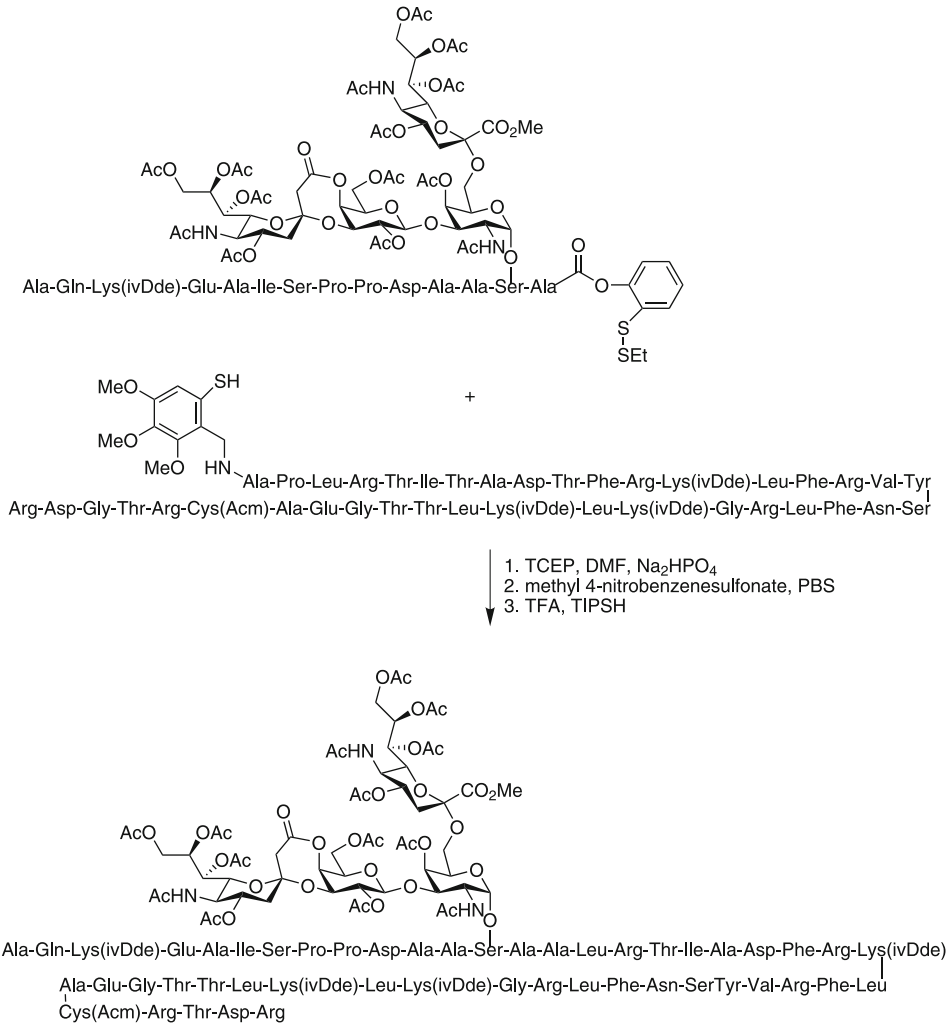
Figure 14
Structure of β-KDO and a glycopeptide variant



Scheme 32

described by Lansbury and coworkers (*Scheme 32*) [38,185]. The resulting glycopeptide was then exposed to reducing conditions where it underwent a reversible O→S acyl transfer to afford the corresponding thioester. This thioester then underwent in situ NCL with a peptide corresponding to residues 29–37 of epo to afford the desired product.

Synthesis of the 114–166 glycopeptide domain proved to be more challenging due to the presence of the glycophorin tetrasaccharide and the need to protect a number of cysteines in the molecule in order to carry out an auxiliary assisted cysteine-free NCL (*Scheme 33*) [186]. To this end, the glycophorin glycopeptide fragment (residues 114–127) was synthesized using the cassette approach and SPPS to afford a protected thioester. This fragment underwent smooth ligation with a Tmb containing acceptor corresponding to epo residues 128–166. Following



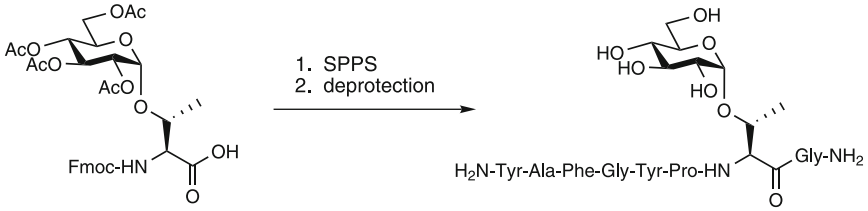
Scheme 33

ligation removal of the Tmb moiety proved to be problematic due to acid induced N→S acyl transfer reactions. It was therefore necessary to mask the aromatic thiol prior to auxiliary removal. It is of note that the sialic acid residue in the glycophorin was not affected by the acidic conditions used for auxiliary removal.

4.3.2 Opioid Receptor Agonists

Glycopeptide derivatives of the μ-and δ-opioid receptor agonists deltorphin and dermorphin have been examined for in vivo activity [187,188]. Peptide agonists themselves generally only reach the central nervous system in low quantities, mainly due to their inability to cross the

blood brain barrier. However, it was hypothesized that conjugation of known peptide agonists to glucose might facilitate uptake through the endothelial barrier by the glucose transporter GLUT-1 (◉ *Scheme 34*).



dermorphin glycosylated analogs

Scheme 34

In keeping with theory, it was found that the deltorphin and dermorphin analogs had excellent oral availability profiles, while still retaining selectivity for the appropriate opioid receptor. Polt and colleagues have examined the effect of glycosylation on enkephalin-based opioid peptides by synthesizing glycopeptides containing monosacccharides, disaccharides or trisaccharides [189]. In this study it was found that the glycopeptides presenting a disaccharide were the most active compounds, with antinociceptive potencies 100–200 times that of morphine. Cyclic glycopeptide enkephalin analogs have also been prepared by Polt et al. [190]. The constructs were prepared by solid-phase methods, and found to be active against the μ- and δ-opioid receptors.

4.3.3 Renin Inhibitors

Glycoconjugate inhibitors of the renin aspartyl protease have also been formulated for increased solubility and altered clearance. Known peptide inhibitors were conjugated to either GlcNAc or mannose, and then evaluated for renin inhibition [191] (◉ *Fig. 15*).

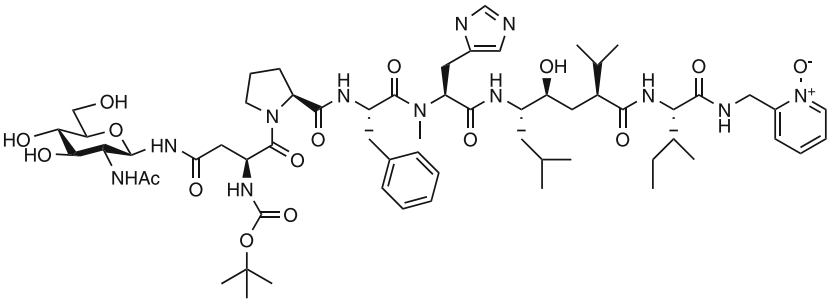


Figure 15
Glycopeptide-based renin inhibitor

The resulting compounds were found to have excellent oral activity as well as elevated serum concentrations due to slower clearance. Other studies of a similar nature have also been reported [192].

5 Other Biologically Relevant Glycopeptide Targets

Glycopeptides serve as target structures in the investigation of a variety of other biological events. For example, peptides presenting sialyl Lewis x (sLe^x) may act as inhibitors of excessive leukocyte extravasation in the inflammatory response [193].
Glycopeptide constructs may also interfere with protein-protein interactions that lead to platelet aggregation and transcriptional regulation. Moreover, studies to determine glycosyltransferase specificity in mucin biosynthesis have also been undertaken. Certain target structures can also be used to detect antibody responses in diseases such as multiple sclerosis. Overall, the specific biological roles of glycopeptides are continually pursued as novel glycoprotein functions are identified.

5.1 Anti-Inflammatory Agents

The inflammatory response is initiated by stimuli released from sites of tissue injury that results in the expression of selectins on the endothelial layer. These selectins (E(endothelial)-selectin and P(platelet)-selectin) function through recognition of oligosaccharides on the opposing leukocyte cell surface [194]. This interaction eventually weakly tethers the leukocyte to the endothelial layer, at which point integrin binding events lead to firm adhesion and extravasation of the leukocyte into the tissue. In certain disease processes, excessive leukocyte infiltration becomes deleterious to the body, and inhibitors of this process are desirable. Rheumatoid arthritis, asthma, organ transplant rejection, and reperfusion injury are just a few of the cases in which these events occur [27].

5.1.1 Polyvalent Selectin Ligands

Several groups have prepared glycopeptide constructs as inhibitors of specific selectins. Sprengard et al. have synthesized *N*-linked trivalent sialyl $Lewis^x$ (sLe^x) cyclic glycopeptides as inhibitors of E-selectin (*Fig. 16*) [195]. Cyclic heptapeptides were prepared, followed by peptide coupling to sLe^x formulated as the glycosyl amine. The trivalent constructs were found to be two to three times as effective as monovalent sLe^x in the inhibition of HL-60 cells binding to immobilized E-selectin.
Baisch and Ohrlein have synthesized unnatural sLe^x containing glycopeptides by chemoenzymatic methods [196]. Asparagine-linked GlcNAc was incorporated into a peptide chain, followed by glycosyltransferase mediated addition of galactose, sialic acid, and fucose. These enzymatic coupling reactions afforded divalent and trivalent sLe^x target structures as E-selectin ligands.
Bruning and Kiessling have prepared divalent glycopeptides bearing 3-sulfo-lactose as inhibitors of L(leukocyte)-selectin [197]. The aim of this study was to investigate the distance-dependence of carbohydrate attachment for optimal selectin inhibition.

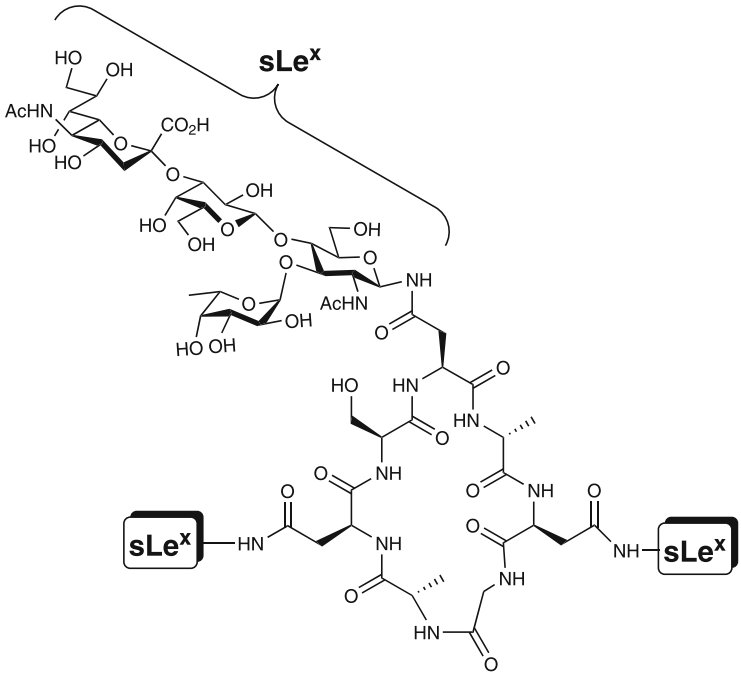

Figure 16
Cyclic trivalent sialyl Lewis X glycopeptide

5.1.2 Dual Function Ligands

Dual function inhibitors of the inflammatory response are also of interest. Sprengard et al. have synthesized an Arg-Gly-Asp-sialyl Lewis^x (RGD-sLe^x) glycopeptide as an "adhesion hybrid" (*Fig. 17*) [198]. The sLe^x portion of the molecule provides a selectin ligand, while the RGD portion targets recognition through an integrin binding motif. The *N*-linked glycopeptide construct was found to bind with higher affinity than most carbohydrate-based selectin ligands to immobilized P-selectin as an inhibitor of leukocyte adhesion.

Matsuda et al. have also reported the synthesis of a Sialyl Lewis^x-RGD conjugate [199]. In this example the authors placed a flexible linker between the two binding epitopes and examined their ability to bind to both integrin and P-selectin. Not only did this conjugate bind tightly to the selectin and integrin molecules, it was found to form stable crosslinks between the two molecules.

Another selectin target ligand whose carbohydrate structure has recently been characterized is P-Selectin Glycoprotein Ligand-1 (PSGL-1) (*Fig. 18*) [200].

The *N*-terminal portion of the dimeric protein contains both a sLe^x glycan and a tyrosine sulfate residue (*Fig. 19*). Both the sulfate and the glycan are required for recognition by P-selectin and L-selectin, whereas E-selectin only requires the presence of the glycan [201]. More detailed studies using a small library of PSGL-1 fragments showed that optimal binding to P-selectin required not only sialyl Lewis^x present on a core 2 mucin structure, but also the presence of three sulfated tyrosine residues [202].

5.1.3 Inhibitors of Mannose-6-Phosphate Receptors (MPRs)

An alternative pathway for inhibition of the inflammatory response targets the mannose-6-phosphate receptors (MPRs). Mannose-6-phosphate inhibits the inflammatory process through binding an MPR, possibly interfering with the transport of lysosomal enzymes. Franzyk et al. have prepared divalent linear and constrained glycopeptides bearing phosphorylated dimannosyl residues (*Scheme 35*) [203]. The resulting compounds were assayed for inhibition of MPR binding to an immobilized phosphomannan core.
Optimal positioning of the glycosidic linkage between the mannose residues was assessed, as well as peptide spacer length between the glycosyl amino acids. In this case, the linear constructs showed more potent inhibition than the constrained cyclic analogs.

5.2 Other Glycopeptide-Based Inhibitors

RGD-containing glycopeptides have also been prepared as inhibitors of platelet aggregation. Vegad et al. have synthesized *O*-linked rhamnose, mannose, or glucose-containing linear and cyclic glycopeptides by solid-phase methodology [204]. In this case, addition of the sugar to the peptide resulted in compounds of equal or lesser potency in platelet aggregation assays.
An *N*-linked glycopeptide from vitamin K-dependent protein S was prepared by Holm et al. [205]. The chitobiose containing polypeptide corresponding to amino acid sequence 447–461 of protein S was synthesized by solid-phase protocols, utilizing the glycosyl amino acid. It was observed that the glycopeptide was a more efficient inhibitor of complex formation between compliment associated proteins C4BP and protein S than the unglycosylated peptide. These results suggest that the peptide sequence containing the potential *N*-glycosylation site (Asx-turn motif) may naturally present an *N*-glycan.

5.3 Studies of Glycosyltransferase Specificity

Glycopeptides corresponding to the core one through core seven structures present in mucin glycoproteins have been prepared. The aim of these studies was to synthesize various glycopeptides for the analysis of glycosyltransferase specificity in mucin biosynthesis. The Bock group has simultaneously prepared a library of glycopeptides by utilizing multiple column SPPS methodology [206,207]. Instrumental to the synthetic strategy was the use of glycosyl amino acids activated by pentafluorophenyl esters. The resulting library can be employed to screen specificity of core one through seven glycosyltransferases, as well as sialyltransferases and sulfotransferases.
Polypeptide *N*-α-acetylgalactosaminyltransferases (ppGalNAcTs) are responsible for transferring GalNAc to Ser/Thr on the backbone of mucin type proteins [22]. In order to probe the substrate preferences of this family of enzymes, a library of mucin type glycopeptides containing a variety of glycan clustering motifs was prepared [208]. This study demonstrated that different ppGalNAcTs preferred different densities of glycosylation along the peptide backbone for catalytic activity.

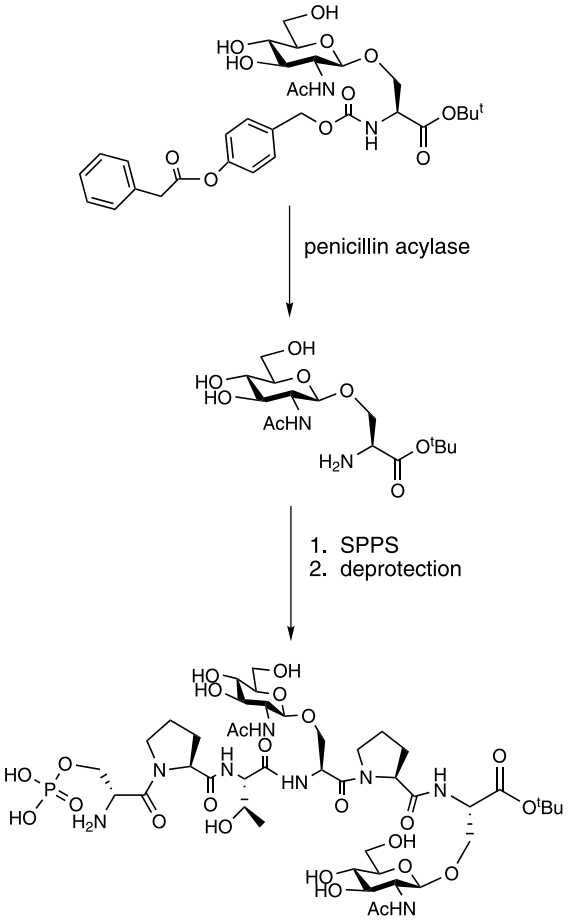
5.4 Studies of Transcriptional Regulation

RNA Polymerase II (RNA Pol II) contains a recently identified mono-GlcNAc modification attached to the polypeptide chain [209]. This β-*O*-GlcNAc residue is thought to act in a regulatory fashion, potentially in a reciprocal role with phosphorylation [210]. In the cell, glycosylated RNA Pol II is transported from the cytosol into the cell nucleus. In the nucleus, the glycosides are cleaved and RNA Pol II is heavily phosphorylated. Only after this transformation occurs can the enzyme function in its transcriptional role. Pohl and Waldmann have synthesized a glycophosphopeptide that is a postulated intermediate in this regulatory process (*Scheme 36*) [211]. The glycophosphopeptide was synthesized utilizing enzymatic protecting group cleavage and block chemical synthesis.



Scheme 36

5.5 Detection of Antibody Response

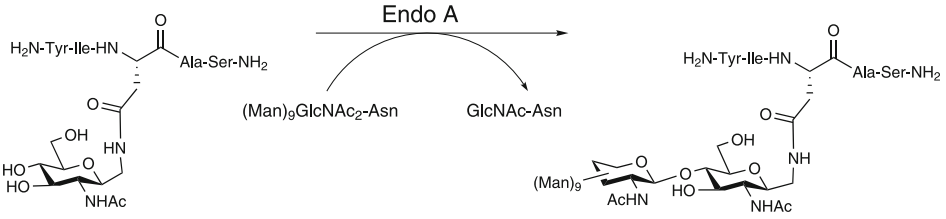
Mazzucco et al. have prepared glycopeptides of human myelin oligodendrocyte glycoprotein (hMOG) to detect antibody responses in multiple sclerosis (MS) [212]. SPPS afforded three glycopeptide constructs with varying glycosylation patterns. Antibody reactivity to the *N*-linked glycopeptide was found in the serum of patients affected by MS, but not in that of normal donors. Neither the unglycosylated peptide nor *O*-linked glycopeptides produced antibody responses in the serum of patients affected by MS. These results suggest that a specific glycopeptide epitope is required for detection of MS antibodies generated in affected patients.

6 Glycopeptide Mimetics

Mimetics of naturally occurring structures often find use as pharmaceuticals. In other cases, they may help clarify issues of biological relevance that are not accessible using natural products. Often times, designed mimetic structures are isosteric with the structure they are designed to resemble, but contain a non-hydrolyzable linkage.

6.1 *C*-Linked Glycopeptide Glycoamidase Inhibitor

Wang et al. have reported the synthesis of a *C*-linked high mannose containing glycopeptide that acts as a broad-spectrum inhibitor of glycoamidases [213]. The *C*-linked glycosylated asparagine residue was synthesized from the corresponding anomeric cyanide, and was subsequently incorporated into the peptide chain using standard peptide coupling methods. Endo A was then utilized to transfer $Man_9GlcNAc$ from $Man_9GlcNAc_2$-Asn to the synthetic peptide to give the target *C*-glycopeptide (*Scheme 37*). The natural *N*-linked glycopeptide was synthesized in an identical fashion, starting with the glycosyl amine.



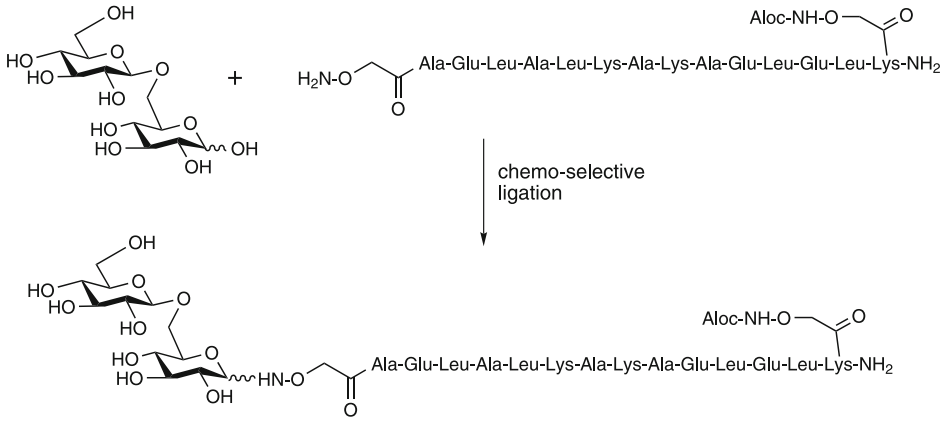
Scheme 37

The *C*-glycopeptide was assayed for inhibition against several glycoamidases of bacterial, plant, and animal origin. The assay results indicated that the *C*-glycopeptide was capable of inhibiting the entire range of enzymes tested. As such, mechanistic studies of further enzymatic activity are possible with constructs of a similar nature.

6.2 Chemoselective Ligation

Another potential avenue to the construction of glycopeptide mimetics is through "chemoselective" ligation of functional groups with matched reactivities. Cervigni et al. have report-

ed the ligation of carbohydrates to a peptide scaffold through the formation of an oxime bond [214]. The ingenuity of this strategy lies in the fact that both the carbohydrate and peptide can be ligated in largely unprotected forms. The ligation was found to be selective, independent of the peptide sequence (*Scheme 38*).



Scheme 38

A second approach relies on the traceless Staudinger ligation between an appropriately functionalized phosphine and an azide to produce a new amide bond [54]. This method has found extensive utility in the labeling of peptides and proteins [215]. Importantly, this method has also been used for the construction of native *N*-linked glycans through the reaction between a glycosyl azide and a phosphine containing amino acid [216,217].

The Huisgen [3+2] cycloaddition between azides and alkynes is another bioorthognal ligation reaction for incorporation of probes into protein and peptide scaffolds. Two variants of this reaction have been developed using either copper(I) [218] or strained cyclooctyne molecules [219] to promote the reaction. As with the Staudinger ligation this method has found extensive use in protein and peptide labeling studies.

In addition to using bioorthogonal reactions, several investigators have synthesized neoglycoproteins by harnessing the reactivity of naturally occurring cysteine residues [220]. In one recent example, it was shown that PhSeBr could promote the reaction between a 1-thiosugar and a cysteine containing protein to form a neoglycoconjugate [221]. It was found that regardless of which reaction partner was activated with PhSeBr, the reaction proceeds through a (phenylselenyl)sulfide containing protein.

6.3 Chemoselective Ligation and Enzymatic Methods

As an extension of this method, Rodriguez et al. combined SPPS, enzymatic functional group conversion, and chemoselective ligation to construct a mimetic of the glycopeptide antibiotic drosocin [222]. Initially, GalNAc was incorporated into the peptide sequence in a standard α-*O*-linkage to threonine. The primary 6-hydroxyl was then oxidized to the aldehyde utilizing galactose oxidase. Chemoselective ligation of the aldehyde with the β-glycosyl amine of

Scheme 39

GalNAc then provided the desired oxime linkage (*Scheme 39*).

The glycopeptide mimetic structure was found to have antibacterial activity that exceeded that of the unglycosylated drosocin construct. As such, the authors concluded that altered carbohydrate structure outside of the conserved glycosyl-peptide bond was a tolerated modification in the biological system.

These authors have described other functionality that can be utilized for chemoselective ligation to form glycopeptide mimetics. Glycopeptides with an inserted ketone functionality were conjugated to carbohydrates formulated as anomeric thiosemicarbazides or aminooxy groups [223]. The resulting "neoglycopeptides" were mimetics of selectin ligands or the *N*-linked glycoprotein motif.

More recently, using suppressor tRNA technology the Schultz and Wong labs were able to incorporate a ketone moiety into expressed proteins [224]. Using an orthogonal tRNA/tRNA synthetase pair from *Methanococcus jannaschii*, which was evolved to charge amber suppressing tRNA, the investigators were able to incorporate *p*-acetyl-L-phenylalanine site specifically into proteins in response to a stop codon (TAG). Using this methodology, a mutant of the Z domain of staphylococcal protein A containing an unnatural ketone moiety was expressed in *E. coli*. Following derivatization with 1-aminoxy-GlcNAc the authors were able to incorporate galactose and sialic acid into the protein backbone using glycosyltransferases. Alternatively,

it was demonstrated that the aminooxy trisaccharide could be assembled prior to conjugation to the protein without loss in efficiency. Subsequent work in this area has allowed the direct introduction of GlcNAc-β-serine [225] and GlcNAc-α-threonine [226] into proteins expressed in *E. coli.*

An even broader extension of this methodology has been applied to expression of chemoselective ligation sites on the cell surface. By exploiting the biosynthetic pathway that produces cell surface sialic acid, Mahal et al. were able to produce an unnaturally occurring ketone functionality on Jurkat cells [227]. Through the use of ligation procedures successfully demonstrated on isolated glycopeptides, the authors have an accessible route to "molecular landscaping" on the cell surface. This work has recently been extended to include the incorporation of azido moieties (for Staudinger ligations [228] and "click chemistry" [229,230]) and alkynes (for "click chemistry" [230]) into whole cell expression systems.

7 Concluding Remarks

Glycopeptide synthesis represents an essential tool for the study of the structure and function of glycoproteins. Despite enormous progress, a superior route for the preparation of adequate amounts of material for biological study remains elusive. The area of glycoprotein and glycopeptide research will continue to supply valuable information about biological systems and is expected to intensify in the future.

Abstract

Naturally occurring glycosylation of glycoproteins varies in glycosylation site and in the number and structure of glycans. The engineering of well-defined glycoproteins is an important technology for the preparation of pharmaceutically relevant glycoproteins and in the study of the relationship between glycans and proteins on a structure-function level. In pharmaceutical applications of glycoproteins, the presence of terminal sialic acids on glycans is particularly important for the in vivo circulatory half life, since sialic acid-terminated glycans are not recognized by asialoglycoprotein receptors. Therefore, there have been a number of attempts to control or modify cellular metabolism toward the expression of glycoproteins with glycosylation profiles similar to that of human glycoproteins. In this chapter, recent methods for glycoprotein engineering in various cell culture systems (mammalian cells, plant, yeast, and *E. coli*) and advances in the chemical approach to glycoprotein formation are described.

1 Introduction

Naturally occurring glycoproteins vary in glycosylation site as well as in the number and structure of glycans within the molecule, and typical glycan structures often vary from species to species and even between cell types within the same species. However, though glycosylation is essential for stability and activity of many proteins, the precise role of this process has not yet been fully clarified. Nevertheless, the engineering of well-defined glycoproteins is an important technology with two main objectives; the preparation of pharmaceutically relevant glycoproteins and the study of the relationship between glycans and proteins on a structure-function level. There have been a multitude of studies focusing on protein glycosylation; however, in this chapter, we focus on recent advances in the methodology of glycoprotein engineering. Details of pharmaceutical applications and synthesis of biologically relevant glycoproteins can be found in other chapters.

2 Protein Expression in Cells

2.1 Mammalian Cells

The most commonly used method for formation of glycoproteins is through their expression as recombinant proteins in mammalian cell cultures [1]. However, the glycosylation process is affected by many factors, particularly the enzyme repertoire of the host cell and the availability of intracellular sugar-nucleotide donors. Therefore, one of the goals of recombinant glycoprotein formation is to achieve maximum and consistent sialylation of these recombinant glycoproteins. The presence of terminal sialic acids on the glycans is particularly important to the in vivo circulatory half life of glycoproteins, since sialic acid-terminated glycans are not recognized by asialoglycoprotein receptors. Toward this end, there have been a number of attempts to control or modify cellular metabolism to allow the expression of human glycosylation profiles in producer cell lines such as genetically engineered Chinese hamster ovary (CHO) cells.

2.1.1 Using Metabolic Control in Mammalian Cells

With the exception of sialic acid, which is activated as CMP-sialic acid in the nucleus, most nucleotide sugars are synthesized in the cytosol and are unable to penetrate the microsomal

membranes. Thus, nucleotide sugar transporter proteins are essential to the translocation of the nucleotide sugars from the cytosol into the Golgi lumen in which glycosylation proceeds as a series of enzyme-catalyzed reactions.

A major focus in studies on improving glycosylation efficiency is the manipulation of intracellular sugar pools through the addition of nucleotide sugar precursors. *N*-acetyl mannosamine (ManNAc), in particular, has been used to increase intracellular sialic acid pools, resulting in a significant increase in the sialylation of recombinant human interferon-gamma (IFN-γ) produced by CHO cells [2].

However, the augmentation of intracellular sialic acid pools by the introduction of ManNAc was found to be ineffective in increasing the overall level of sialylation of human tissue inhibitor of metalloproteinases 1 (TIMP-1) produced by CHO cells and mouse NS0 cells [3]. Therefore, the overexpression of nucleotide sugar transporters, particularly the CMP-sialic acid transporter (CMP-SAT), was investigated as a means of improving the sialylation process in CHO cells. Increasing cellular CMP-SAT levels by recombinant means results in increased transport of CMP-sialic acid into the Golgi, and subsequent increase in the CMP-sialic acid intra-lumenal pool affords increased sialylation of the proteins expressed [4].

2.1.2 Glycosyl Modification Combined with Metabolic Control by Unnatural Sugars

A metabolic oligosaccharide engineering technique that exploits the tolerance of unnatural substrates by carbohydrate biosynthetic pathways has opened new avenues to the chemical modification of glycoproteins. The introduction of unnatural substrates is limited by the range of substrates that an enzyme will accept. One solution to overcome this limitation is the use of simple enzyme-recognizable sugars possessing functional groups for participation in subsequent chemical reactions. The technique makes use of ketone-containing C2-carbon isosteres of the 2-*N*-acetamidosugars, *N*-acetylglucosamine (GlcNAc) and *N*-acetylgalactosamine (GalNAc) [5,6]. The 2-keto isostere of GalNAc could be incorporated into secreted glycoproteins as well as cell surface molecules allowing the ketone group to react selectively with aminooxy or hydrazide reagents. This technique enables the introduction of reactive groups for the further modification of secreted glycoproteins produced in large-scale recombinant expression systems.

Saxon et al. reported the use of mannosamine and glucosamine derivatives containing azide groups for conversion to cell-surface sialosides [7]. Here, Staudinger ligation [8] is used to label glycoconjugate-bound azidosugars. Cell-surface Staudinger ligation can also be utilized for the formation of hydrazones from metabolically introduced ketones. Both strategies afford an avenue to the selective modification of cell-surface glycans via the use of unnatural sugars [7,9].

2.1.3 Antisense Strategies

Antisense gene transfer technology has been used to limit enzymatic activity in the oligosaccharide biosynthesis pathway, allowing modification of glycans on glycoproteins [10]. Prati et al. use antisense technology to target the fucosyltransferase VI (FucT-VI) enzyme, which is essential to Sialyl Lewis X (sLex) synthesis, and thereby reduce the expression of sLex on the

cell surface [11]. The positive results from this method suggest that the targeting of glycosyltransferase by antisense technology can be applied to the production of novel glycoproteins in CHO cells.

2.2 Baculovirus-Insect Cell Expression Systems

Baculovirus-insect cell expression systems have been used to form glycosylated recombinant glycoproteins [12,13], though this system is incompatible with the formation of terminally sialylated *N*-glycans. The development of transgenic insect cell lines expressing mammalian genes has allowed the expression of "mammalianized" recombinant glycoproteins, since these cell lines are able to salvage sialic acids from extracellular sources, such as proteins found in fetal bovine serum, for glycoprotein sialylation. Transformation of SfSWT-1 cells with two additional mammalian genes encoding sialic acid synthase and CMP-sialic acid synthetase, led to a new insect cell line (SfSWT-3) that was capable of synthesizing its own sialic acid and CMP-sialic acid, and could sialylate recombinant glycoproteins when cultured in a serum-free growth medium supplemented with ManNAc [14]. This new cell line thus offers an improvement on conventional baculovirus-mediated recombinant glycoprotein production systems.

2.3 Yeast Expression Systems

A yeast expression system by itself cannot offer human type glycosylation. However, considering the advantages associated with the use of yeast expression systems, such as chemically defined culture media and shorter expression time, protein expression using yeast systems are expected to be applied to the production of therapeutic glycoproteins. The engineering of an artificial glycosylation pathway has allowed the replication of human *N*-glycosylation in yeast [15,17]. As a recent example for engineering of glycosylation in yeast, Bobrowicz et al. reported that the blocking of core oligosaccharide assembly succeeded in formation of humanized glycoproteins with terminal galactose moieties. This method allowed the synthesis of GlcNAc2Man3GlcNac2 *N*-glycans in yeast strain *Pichia pastoris* in high yield and with high homogeneity [18].

2.4 Plant Expression Systems

As well as insect cell lines, transgenic plant cell lines have also been produced to allow the *N*-glycosylation of therapeutic glycoproteins. The use of transgenic plants offer a number of advantages in the production of therapeutic glycoproteins in that they significantly reduce the potential for contamination with human pathogens, allow for easier genetic manipulation and lower production costs [19].

In order to compensate for the lack of β1,4-galactosylated and sialylated glycans, which play important roles in biological functions in animal cells, Palacpac et al. used mammalian glycosyltransferase to alter the glycosylation pathway of plant cells. The transformed cells containing the full-length human galactosyltransferase gene can be used to produce glycoproteins free from the immunogenic glycans common in plant cells. Using this approach, *N*-linked glycans with modified and defined sugar chain structures approximating those in mammalian

glycoproteins can be synthesized in plants [20]. Further to this approach, the introduction into tobacco suspension-cultured cells of genes encoding human CMP-*N*-acetylneuraminic acid synthetase and CMP-sialic acid transporter opened an avenue to a novel sialic biosynthetic pathway. Recombinant human proteins expressed in this plant cell line system maintain their biological activities, demonstrating that plant cells can be effectively utilized for the production of human glycoproteins [21].

3 Enzymatic Introduction of Glycans onto (Mutated) Proteins Expressed in *E. coli*

Unlike the abovementioned systems, systems based on *E. coli* do not permit the expression of glycoproteins without enzymatic modification. Instead, enzymatic approaches are employed to attach the targeted glycan to the proteins expressed in the cells. The great benefits of this enzymatic approach are (i) that proteins can be readily produced in *E. coli* on a far larger scale than in systems based on mammalian, insect, plant or yeast cells and (ii) easy application of enzymatic reactions in vitro.

Initially, the site-specific modification of chimeric proteins was performed using a guinea pig liver transglutaminase (G-TGase)-mediated procedure. However, more recently, various groups have exploited an alternative approach that utilizes microbial transglutaminase (M-TGase) as the catalyst [22]. An example of this methodology uses microbial transglutaminase (TGase) for the enzymatic preparation of *N*-linked neoglycopeptides from suitably modified oligosaccharides. *N*-allyl glycosidic derivatives are coupled with cysteamine to yield amino-terminated thioether spacers. Transglutaminase then accepts these spacers for the transamidation of the side-chain carboxamide group in the dipeptide Z-Gln-Gly [22].

Sato et al. [23] expanded the applicability of the TGase-mediated preparation of clinical protein conjugates by use of recombinant human interleukin 2 (rhIL-2) as a target protein and two synthetic alkylamine derivatives of poly(ethyleneglycol) (PEG12; MW 12 kDa) and galactose-terminated triantennary glycosides ((Gal)3) as modifiers.

The enzymatic approach using TGase also enabled the site-specific introduction of sialic acid-terminated glycans into proteins. To achieve this, a lactose derivative is introduced by TGase and then sialic acid is transferred to the lactose moiety using 2,6-sialyltransferase (α2,6-SiaT). Using this approach we reported the synthesis of cyclic glycopeptides, toward a tailored blocker of influenza virus hemagglutinin [24] A cyclic peptide, cyclo(Ser-Gly-Gly-Gln-Ser-His-Asp)3, provides an excellent scaffold for the synthesis of a cyclic glycopeptide carrying GM3 oligosaccharides with a potent inhibitory effect on the hemagglutination induced by the influenza virus.

In another example, a glycosylation site was first introduced into insulin by point mutation without loss of biological activity. Next, a lactose derivative was attached to the mutated site by TGase and, finally, sialic acid was transferred to the lactose moiety using 2,6-sialtransferase (α2,6-SiaT) [25] (*Fig. 1*). The results with mice clearly show that the introduction of a sialic acid residue is crucial in prolonging glucose-lowering activity in the blood. Using a similar approach, divalent- and trivalent-sialyloligosaccharide-displaying insulins were also created, with the trivalent sugar-displaying insulin showing further prolongation of the glucose-lowering activity [26].

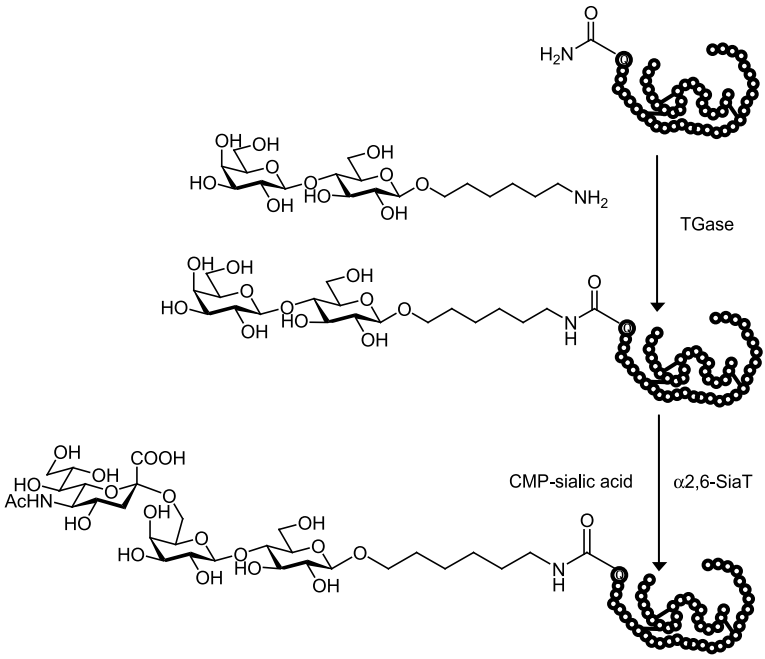

Figure 1
Introduction of sialyllactose into insulin using transglutaminase and sialyltransferase

4 Unnatural Amino Acid Incorporation into Proteins

The presence of a number of enzyme-recognizable amino acid residues, such as glutamine residues in the case of TGase, restricts the site-specific introduction of glycans. When the target protein has many glutamine residues, site specific modification can not be performed artificially. The introduction of an unnatural amino acid, however, allows the exact glycosylation site to be determined.

For the introduction of unnatural amino acids, several unnatural codons are used; for example, the stop (amber) codon and 4-base (or 5-base) codon [27,29]. An example of site-specific incorporation of an unnatural amino acid containing a keto group into a protein using the amber nonsense codon was reported by Liu et al. [30]. The introduced keto group can react specifically with an aminooxy saccharide derivative to give homogeneous glycoprotein mimetics.

We also demonstrated the direct and chemoselective coupling between unmodified simple sugars and *N*-methylaminooxy group displayed on the engineered streptavidin using the 4-base codon, which allowed for the combinatorial synthesis of novel glycoprotein mimetics (*Fig. 2*) [31].

In another study, proteins containing both mono- and diglycosylated amino acids, including glycosylated serine and tyrosine moieties, have been obtained by the suppression of nonsense codons in a cell-free expression system through the application of misacylated suppressor tRNAs activated with glycosylated serine and tyrosine derivatives (*Fig. 3*) [32].

Cell-free expression of protein containing a glycosylated amino acid

5 Chemical Ligations and Synthesis

Whereas relatively short peptides can be readily obtained by solid-phase peptide synthesis (SPPS), native chemical ligation (NCL) [33] has now enabled the total chemical synthesis of proteins with molecular weights far in excess of those achievable by conventional stepwise SPPS. This method proceeds through the ligation of a C-terminal thioester and an *N*-terminal cysteine residue, respectively, by two unprotected peptides to give a protein with a native amide linkage at the ligation site. However, glycopeptides synthesis using NCL is problematic since the reaction conditions used in tert-butoxycarbonyl(Boc)-based SPPS is known to damage glycosidic linkages and those used in 9-fluorenylmethoxycarbonyl (Fmoc)-based SPPS to cleave the thioesters of *O*-linked glycans.

To overcome the problems associated with these reaction conditions, Backes et al. developed an alkanesulfonamide "safety-catch" linker for solid-phase synthesis [34]. In this method, acylation of a sulfonamide support affords a support-bound *N*-acylsulfonamide that is able to withstand the basic and strongly nucleophilic reaction conditions required for Fmoc-based SPPS. On completion of the solid-phase synthesis sequence, iodoacetonitrile treatment yields *N*-cyanomethyl derivatives that can be cleaved under mild nucleophilic reaction conditions to afford the target compounds. Coupling conditions of alkanesulfonamide resin with Boc- and Fmoc-amino acids were developed to minimize the racemization. Using this method, a short synthesis sequence, followed by iodoacetonitrile activation and nucleophilic displacement is able to form dipeptide products from a number of support-bound amino acids incorporating diverse side-chain functionalities.

Based on this method, Shin et al. reported the total synthesis of an 82-residue glycoprotein with two glycosylation sites through the ligation of a 24-residue glycopeptide-thioester, prepared using standard Fmoc chemistry protocols, with a 58-residue glycopeptide bearing an *N*-terminal cysteine residue (*Fig. 4*) [35].

The expressed chemical ligation method was developed for the total synthesis or recombinant formation of proteins displaying natural or unnatural post-translational modifications. This method is based on the construction of semi-synthetic glycoproteins, in which recombinantly derived peptide α-thioesters are covalently joined by NCL with synthetic glycopeptides. Macmillan et al. applied an extension of this technique to the construction of glycoproteins bearing mucin-like domains [36]. Macmillan et al. also reported a cysteine-free NCL method. The use of mild conditions for cleavage reaction and rapid synthesis in this method is useful especially for the preparation of glycoproteins [37].

Chemical synthesis of glycopeptides and glycoproteins based on NCL also allows the synthesis of glycopeptides from cysteine-free peptides. This method utilizes a peptide thioester and a glycopeptide in which a thiol handle is engineered into the sugar moiety at the C-2 position. Once the ligation reaction is complete, reduction of the thiol handle with H_2/metal to the acetamide moiety affords unmodified glycopeptides [38].

Dudkin et al. describe the synthesis of globally deprotected multi-branched glycans and these glycans are aminated prior to aspartylation with a hexapeptide, which is then extended using NCL to afford *N*-linked glycopeptides for use as possible antigens against prostate cancer (*Fig. 5*) [39].

Aziridine-incorporated peptides, capable of site- and stereoselective modification, have been formed using FmocAzyOH in Fmoc solid-phase peptide synthesis. This nonproteinogenic

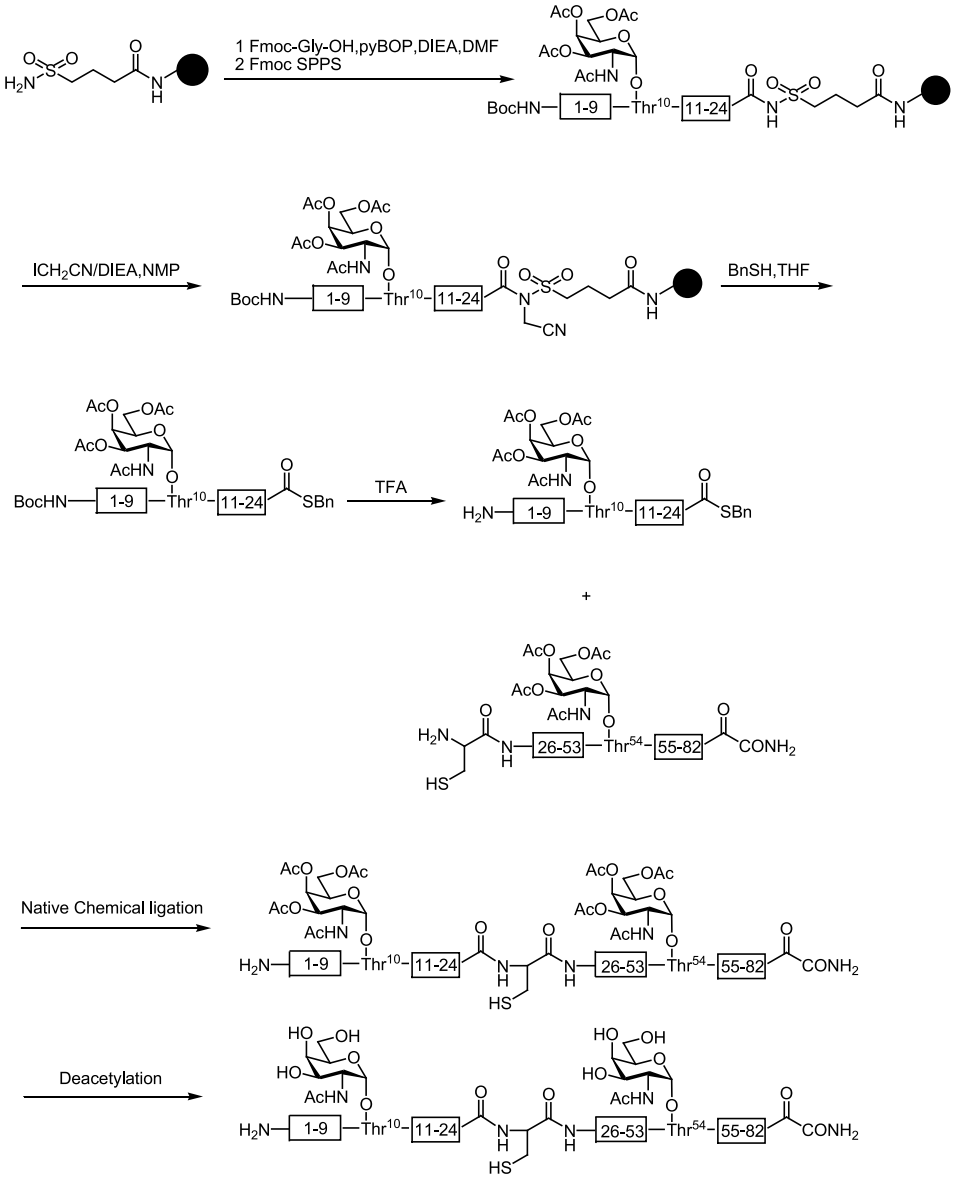

Figure 4
Chemical synthesis of a glycoprotein via native chemical ligation

amino acid possesses a unique electrophilic nature that enables site-selective conjugation with a variety of thiol nucleophiles, such as anomeric carbohydrate thiols, farnesyl thiol, as well as biochemical tags. The combination of this strategy with NCL offers a convergent and rapid avenue to the generation of complex thioglycoconjugates (*Fig. 6*) [40,41].

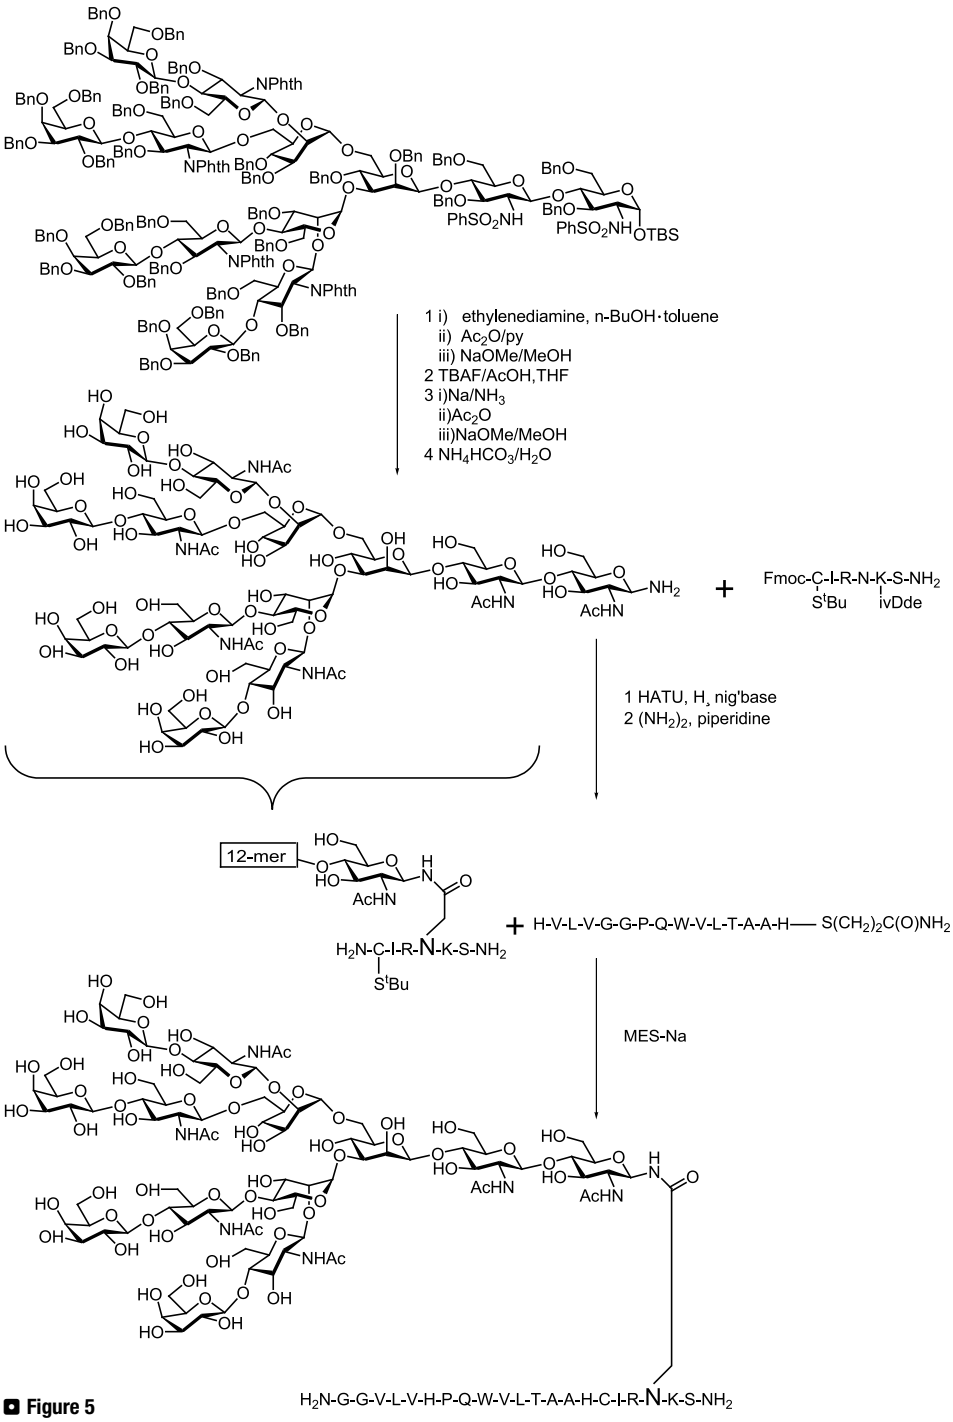

Figure 5
Synthesis of multi-carbohydrate-branched glycopeptides

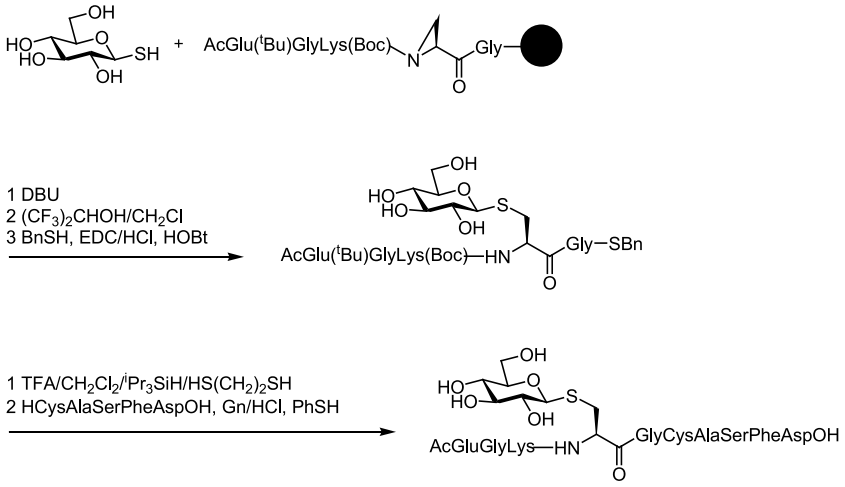

Figure 6
Synthesis of a thioglycoconjugate using aziridine-incorporated peptide

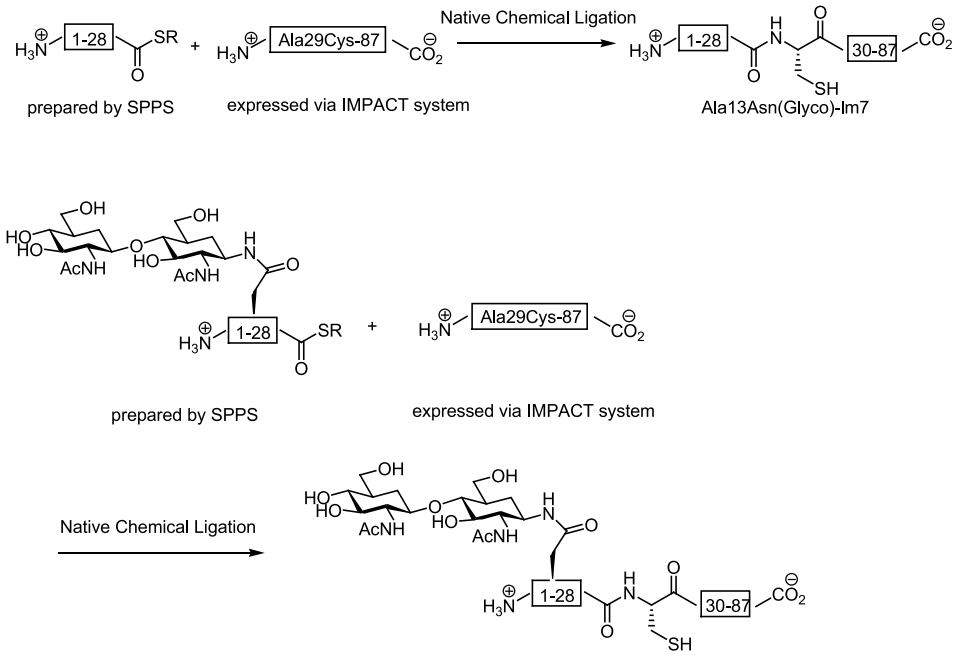

Figure 7
Glycosylated and unglycosylated analogs of Im7 prepared by native chemical ligation

Chemical synthesis allows the preparation of proteins with different glycosylation patterns aiding the study of the effects of glycosylation on protein folding. To examine the influence of glycosylation on protein folding pathways, Hackenberger et al. utilized NCL in the preparation of *N*-linked chitobiose glycoprotein analogues of the immunity protein Im7. The NCL method afforded both glycosylated and unglycosylated analogs, enabling further study of the influence of glycosylation on peptide structure (◉ *Fig. 7*) [42].

6 Summary

The use of glycosylation engineering in various expression systems has aided the move toward "human-type" glycosylation and efficient sialylation. The incorporation of unnatural amino acids into the protein back bone with site specificity has also enabled the precise control of glycosylation sites. Further, chemical modification of expressed proteins or peptides and/or enzymatic glycan elongation has been used to solve problems of length- and quantity limitation in the expression of glycoproteins.

Abstract

This chapter provides an overview of practical methods for glycosylation analysis of glycoprotein therapeutics. The topics include glycoprofiling methods for glycoforms, monosaccharides (neutral and *N*-acetylated species as well as sialic acids), oligosaccharides (chemical and enzymatic methods for glycan release, post-release purification, labeling and derivatization, different types of glycan HPLC and MS), and glycosylation site profiling.

Keywords

Glycoprofiling; Biopharmaceutical glycosylation

1 Introduction

This chapter focuses on procedures for glycosylation analysis of recombinant therapeutic glycoproteins such as monoclonal antibodies (mAbs) and erythropoietin (EPO). For these and many other biopharmaceuticals, glycosylation can profoundly influence drug safety and efficacy and so must be measured and tightly controlled during biomanufacturing. However, measurement is not always straightforward since current approved glycoprotein therapeutics are invariably highly heterogeneous populations of glycoforms, often bearing complex glycosylation and with multiple glycosylation sites. Most of these drugs have *N*-linked oligosaccharides and some have both *N*- and *O*-linked glycans. The regulations governing biopharmaceutical characterization are strict and glycoprofiling of therapeutics must be performed using well-characterized analytical procedures and be demonstrated to be accurate and reproducible both over time and between different laboratories. Accuracy in relative quantitation of the many glycan species found in each drug batch is particularly important so that biomanufacturers can reliably demonstrate comparability with reference batches. The procedures used for glycan characterization of biopharmaceuticals can be extended to analysis of other glycoproteins.

2 Glycoprofiling Scheme

Figure 1 shows a typical biopharmaceutical glycoprofiling scheme consisting of a number of analysis modules each of which measures a different glycosylation parameter of the glycoprotein drug sample. The data from these modules are used to build a forensic profile of the glycosylation [1].

With current technology, there is no single universal glycoanalysis technique–the complexity of biopharmaceutical glycosylation makes it imperative to use several orthogonal analysis methods.

The choice of analysis modules employed in a glycoprofiling scheme and the procedures used in each module is influenced by many factors including what types of glycans are possible in

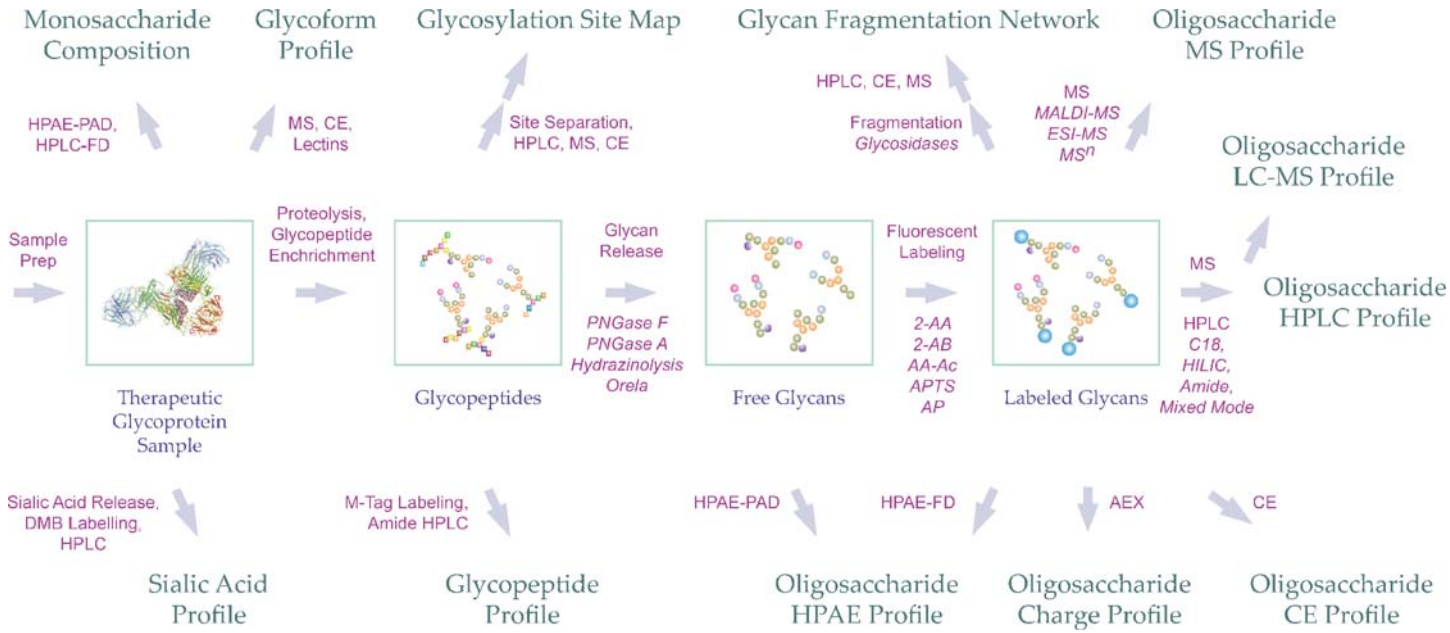

Figure 1
A typical biopharmaceutical glycoprofiling scheme

the glycoprotein expression system, the desired glycosylation pattern, aberrant glycosylation that could compromise drug safety or efficacy and the analytical instrumentation available.

3 Glycoform Profile

The glycoform profile is a map of the glycoprotein sub-populations that share the same peptide backbone but are decorated with different glycan structures. Detailed glycoform profiling remains a challenge but valuable low-resolution maps can be obtained by using a variety of methods. For some glycoproteins, capillary electrophoresis (CE) can give useful separation of the glycoforms [2] while Rosenfeld et al. [3] have employed lectin and antibody arrays to detect changes in glycoform distributions during biopharmaceutical production.
Both MALDI-MS and ESI-MS can be used to obtain mass distribution profiles of intact glycoproteins. The main experimental challenges here are (a) to get uniform and linear responses in MS by every glycoform and (b) to achieve sufficient accuracy and resolution of complex mixtures of such large molecules. The problem of overlapping of isobaric glycoforms is reduced by combining MS of intact glycoproteins with analysis of the glycopeptides or oligosaccharides. Glycoform profiling by MS is now routinely used by some biomanufacturers as part of a process analytical technology (PAT) system to monitor the quality of glycoprotein therapeutics during production.

4 Monosaccharide Profile

For biopharmaceuticals, quantitative monosaccharide profiling allows detection of residues indicative of undesired glycosylation (e. g. NeuGc) or the classes of glycans (for example, the presence of GalNAc indicates *O*-glycosylation). For technical reasons, neutral and *N*-acetylated residues are generally profiled separately from sialic acids.

4.1 Neutral and *N*-Acetylated Monosaccharides

The general form for neutral and *N*-acetylated monosaccharide profiling is: release of the monomer residues by acid hydrolysis, derivatization then analysis by HPLC, CE, or GC. In practice, reliable monosaccharide quantitation is an issue. In a study comparing monosaccharide profiles of glycoprotein standards from several laboratories, Townsend et al. [4] found that values of neutral and amino sugars determined using HPAE-PAD analyses varied by up to 50% between different labs. In our experience, the keys to obtaining accurate, reproducible profiles are (a) ensuring clean, stoichiometric release and derivatization, (b) using relevant, well-characterized quantitative internal and external standards and (c) choosing an analysis system that gives good resolution of all the monosaccharide species found in the analyte. The following method has proven to be suitable for use with most biopharmaceuticals:

1. Addition of 3-*O*-methyl-glucose as a quantitative internal standard.
2. Use of quantitative external standards matched to the analytes–e. g. fetuin or antibody for glycoprotein analyses and the equivalent glycan libraries for oligosaccharide analyses.

3. Release of monosaccharide residues by acid hydrolysis (typically using 4 mol dm^{-3} trifluoroacetic acid, 100 °C, 4 h). This will liberate hexoses and de-acetylated hexosamines.
4. Re-*N*-acetylation of the amino sugars using acetic anhydride in aqueous sodium bicarbonate buffer.
5. De-salting on a cation exchange resin (e. g. AG50WX12 H^+ form).
6. Derivatization by reductive amination with a small hydrophilic fluorophore or chromophore such as 2-AA (see below).
7. HPLC with fluorescence or UV detection either on a C18 column using a gradient of acetonitrile / sodium acetate (aq) or on HPAE-FD.

This method is not suitable for profiling of sialic acids, which are destroyed by the harsh acid hydrolysis and cannot be labeled by reductive amination, but does give reliable data for neutral monosaccharides.

4.2 Sialic Acids

The two main types of sialyl residues found in recombinant biopharmaceuticals are NeuAc and NeuGc. These usually occur as terminal structures attached to galactose residues at the non-reducing termini of both *N*- and *O*-linked glycans. Controlling the ratio of NeuAc to NeuGc is critical for biomanufacturers–NeuAc is the desired, normal human-type sialylation while NeuGc is found in non-human glycoproteins and is considered an undesired form of sialylation for injected therapeutics [5].

Our preferred method of sialic acid profiling is to use the DMB / HPLC system. The first step is release of the sialic acids from the glycoprotein by mild acid hydrolysis (typical conditions are incubation with 2 mol dm^{-3} acetic acid for 2 h at 80 °C) followed by fluorescent labeling using DMB and stabilization of the tagged conjugates by reduction with sodium dithionite. Analysis of the DMB labeled sialic acids is done by HPLC with a C18 column and fluorescence detection (λ_{ex} = 295 nm, λ_{em} = 352 nm).

With DMB analysis (as with all glycoprofiling) good calibration is essential for accurate, reliable results. For NeuAc:NeuGc determinations we recommend calibration using three standards:

a. A sialic acid reference panel containing a mixture of sialic acids found in human and animal tissue.
b. A quantitative NeuAc standard. Serial dilutions of this are used to obtain samples for a standard concentration- fluorescence response curve on the HPLC.
c. A qualitative NeuGc standard. This can either be used alone or can be added to aliquots of the NeuAc standard for calibration of retention on HPLC.

Alternatives to DMB analysis include HPLC of OPD (o-phenylenediamine) labeled sialic acids [6] as well as HPAE-PAD and hybrid variants of these procedures.

5 Oligosaccharide Profile

The general form for oligosaccharide profiling is: release of the glycans, derivatization (e. g. fluorescent labeling), then analysis by HPLC, CE, or MS.

5.1 Glycan Release

Glycan release can be achieved either enzymatically with endoglycosidases (e. g. PNGase F or PNGase A) or chemically. **PNGase F** is widely used for enzymatic release of *N*-glycans from therapeutic glycoproteins [7]. Sample preparation prior to PNGase F treatment typically involves disruption of the protein backbone with a chaotropic agent then reduction and alkylation to open disulfide bridges. The aim of this is to make the oligosaccharide-protein linkages more accessible to the enzyme. However, in some cases (e. g. with certain mAbs), better release kinetics and stoichiometry are obtained with the intact glycoprotein. One possible reason for this is steric hindrance of the glycan attachment sites after disruption of the protein. Various preparations of both natural and recombinant forms of PNGase F are available but commercial preparations do vary significantly in quality (particularly in their stability and levels of contamination). In our experience, the natural enzyme is generally more stable and works better in simple, clean formulations than the recombinant form. This may be related to alterations to the natural protein structure required for expression and isolation of the recombinant enzyme.
PNGase A is used for release of *N*-glycans from glycopeptides. It has a broader oligosaccharide substrate specificity than PNGase F and is more suitable for analysis of glycopeptides from plant and insect expression systems. PNGase A is particularly useful for analysis of tryptic digests of glycoproteins from proteomics gels [8].
Currently, there are no broad-specificity endoglycosidases for *O*-linked glycans. To liberate these one must turn to chemical release methods which include hydrazinolysis and beta-elimination.
Beta elimination is a well-established and widely used method for releasing *O*-glycans from glycoproteins. The process gives high yields, however, the glycans are reduced to alditols. These cannot be labeled by reductive amination and so are usually analyzed by techniques such as HPAE-PAD or MS which can give good structural information but generally give less reliable quantitation data than fluorescent HPLC [9].
Hydrazinolysis involves use of anhydrous hydrazine to break the sugar-peptide links and release free glycans in the reducing form. These are suitable for fluorescent labeling by reductive amination which makes hydrazinolysis the method of choice for a number of glycoprofiling laboratories. A typical protocol is incubation of the dried, salt-free glycoprotein with anhydrous hydrazine (85–100 °C, 6–16 h) under an inert, dry atmosphere, removal of excess hydrazine by evaporation, *N*-acetylation with acetic anhydride in sodium bicarbonate buffer, de-salting on a cation exchange resin in H^+ form then purification of the released oligosaccharides. Optimization of the temperature-time profile of the hydrazine incubation step allows tuning to release either *O*-glycans (under mild conditions), *N*-glycans (harsher conditions) or a mixture of both. Successful hydrazinolysis requires use of very pure hydrazine with low water content (<0.1%) to minimize 'peeling' side reactions (i. e. progressive removal of reducing terminus residues). However, when performed with good quality reagents, hydrazinolysis is capable of giving very reproducible glycan release with high yield and good stoichiometry [10].

5.2 Post-Release Purification

Whichever method is used for glycan detachment, the released oligosaccharides should be purified to remove non-carbohydrate material that could interfere with subsequent derivatization and analysis. Post-release methods described in the literature include precipitation of peptide material in cold ethanol, retention of peptides on hydrophobic resins or precipitation of the oligosaccharides on HILIC resins. The most effective post-release purification that we have seen for biopharmaceutical oligosaccharides has been use of SPE cartridges containing electron interaction resin (EIR). EIR is a versatile matrix that binds a wide range of biopharmaceutical glycans with high efficiency, allowing effective removal of contaminating salts, detergents, and protein. The washing regime for EIR cartridges are similar to those for C18 SPE purification of hydrophobic analytes with glycans being eluted in a mixture of volatile components. The benefits of glycan purification using EIR include higher efficiencies and better stoichiometry for fluorescent labeling and cleaner profiles and better signal to noise on HPLC and MS. Furthermore, microplate SPE versions of EIR are currently being developed for high-throughput analyses.

5.3 Labeling and Derivatization

Fluorophore or chromophore labeling of the purified oligosaccharides allows quantitative detection on HPLC and CE and can improve analysis of certain glycan species on MS. The most common labels are aromatic amines which are attached to the reducing termini by reductive amination. These include 2-AA and 2-AB which are small and hydrophilic, conjugate to the glycan efficiently and have good spectral properties. Furthermore, they have minimal effect on the specificities of glycosidases used in enzymatic glycan sequencing. A typical one-pot labeling reaction involves dissolution of purified, dried glycans with free reducing termini in a solution of 1 mol dm^{-3} of fluorescent label and 1 mol dm^{-3} sodium cyanoborohydride in 30% acetic acid and 70% dimethyl sulfoxide (v/v) followed by incubation at 65 °C for 3 h [11]. Post-reaction purification of the labeled glycans can be achieved using *S*-cartridges which contain a hydrophilic glycan binding membrane. The labeling mixture is applied to the membrane then air-dried. Excess label is removed by washing with 96% acetonitrile (aq) then the bound glycans are eluted with water. *S*-cartridges give very reproducible post-labeling cleanup but can be slow. However, faster SPE alternatives including those in microplate format for high throughput work are becoming available.

2-AA and 2-AB are routinely used for characterization of biopharmaceutical glycosylation at all stages of the drug development cycle, including glycoprofiling during production and final lot release tests for approved drugs. For most applications the two labels can be used interchangeably, giving similar profiles and reliable performance on amide HPLC (see below). The main differences are seen in anion exchange HPLC where 2-AA labeled glycans are retained longer than those tagged with 2-AB (2-AA bears a negative charge while 2-AB has no charge) and performance in mass spectrometry.

2-AP is another common glycan label and is especially popular with academic research groups in Japan. Takahashi and colleagues have developed a sophisticated system for multi-dimensional mapping of 2-AP labeled oligosaccharides on orthogonal chromatography phases (including amide, C18 and anion exchange HPLC) [12].

APTS is a label used for glycoprofiling by CE. The molecule bears three strong anionic groups which allows fast transit through the CE column towards the cathode [13].
AA-Ac is a versatile label which is gaining popularity for high throughput glycoprofiling and glycoproteomics. The molecule has an acridine ring structure that improves HPLC on hydrophobic phases, enhances analysis by MALDI–MS and electrospray MS and allows good separation on CE. Furthermore, the labeling reaction is faster than other labels (typically 1 h), post-labeling purification is fast and efficient and stoichiometry and efficiency seem excellent [14].

5.4 HPLC

HPLC is a key glycoprofiling tool that allows partial identification of species by their retention time, quantitation from peak areas, and separation of complex glycan mixtures into different fractions that can be taken for further analysis. Typically, a range of different HPLC columns with a variety of separation mechanisms is used to slice up the glycan population according to different physical properties such as molecule size and charge. The following describes the main HPLC profiles currently used for biopharmaceutical glycoprofiling.
High performance anion exchange (**HPAE**) chromatography relies on deprotonation of the sugar hydroxyl groups in a high pH buffer to yield anion species. These can then be separated on a high pH stable, anion exchange column. A typical washing regime is equilibration of the column in 150 mmol dm^{-3} sodium hydroxide and elution of glycans of increasingly high charge to mass ratio with a gradient of 0–250 mmol dm^{-3} sodium acetate (aq). Eluted glycans can be followed using pulsed amperometric detection (PAD) which is a specialized electrochemical detector. The system is capable of excellent resolution of glycan species, does not require derivatization of the sugars, and can be used for profiling both monosaccharides and large, highly charged oligosaccharides. In the past, for many labs, these factors have made **HPAE-PAD** the method of choice for biopharmaceutical glycoprofiling. However, reproducibility of quantitation is a concern–different PAD cells give different relative responses to standard sugars so HPAE-PAD profiles from different instruments are not always comparable. Fortunately, this problem can be overcome by labeling the glycans with a small, noncharged hydrophilic fluorophore such as 2-AB and switching to **HPAE-FD**. This combines the superb resolving power of HPAE chromatography with the reliability of 2-AB fluorescence quantitation [15]. HPAE-FD is now routinely used by some biomanufacturers for in-process checking and final lot release QC of biopharmaceutical glycosylation.
Glycan charge profiles can be determined by weak or strong anion exchange chromatography (**WAX** or **SAX**). At neutral pH, fluorophore labeled glycans, typically 2-AB label, will separate on a strong anion exchange column according to their charge state. Uncharged glycans will pass straight through the column while glycans bearing an anionic charge (e. g. sialylation or phosphorylation) will be retained and can be eluted with a salt gradient (typically 0–500 mmol dm^{-3} ammonium acetate, pH 4.5). This technique allows determination of the relative ratios of charged glycans in any given sample, but generally gives little information on the detailed structure of the glycans.
EIR HPLC allows reproducible separation of fluorophore labeled glycans with high resolution. The solvents and gradient regime are similar to those used for analysis of hydrophobic

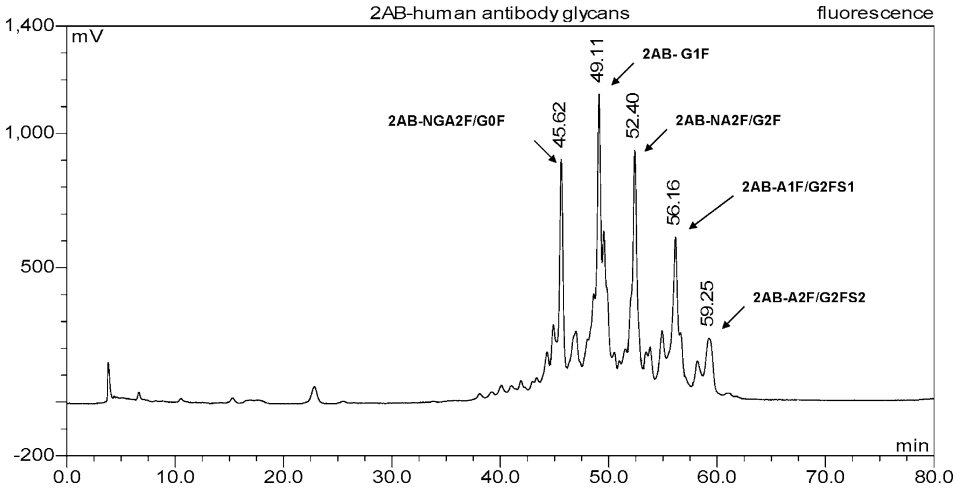

Figure 2
LudgerSepN1-amide HPLC of 2AB labeled human antibody glycans

analytes on C18 HPLC except that, generally, higher concentrations of the organic solvent–typically up to 60% (v/v) acetonitrile in 0.1% trifluoroacetic acid (aq)–are used to elute the glycans. EIR columns have excellent retention of a broad range of glycans and glycan derivatives including hydrophilic species that are not retained by C18 resins.

Hydrophilic interaction chromatography (**HILIC**) on **amide** columns (sometimes called 'normal phase' HPLC) is now widely used for detailed oligosaccharide profiling of biopharmaceuticals. The technique relies on interactions of the glycan hydroxyls with amide groups on the chromatography resin in a gradient of decreasing organic solvent. The separation roughly follows the size of the glycan, larger glycans having a greater number of hydroxyl groups. A typical elution regime is a gradient from 65–35% (v/v) acetonitrile in 250 mM ammonium formate, pH 4.4 (aq) over 75 minutes. *Figure 2* shows a typical amide HPLC profile of glycans from human serum antibody. To allow comparison of profiles between different HPLC runs, the retention times of glycans can expressed in terms of glucose units (GU) by comparison with an external standard of 2-AB labeled glucose homopolymer (GHP) ladder which contains chains from 1 to 23 glucose residues. Tables of glycan GU values are available for oligosaccharides found on monoclonal antibodies and other biopharmaceuticals [16]. Glycan amide HPLC is capable of giving excellent resolution and reproducibility and can be performed on oligosaccharides tagged with many types of fluorophore label including AA-Ac, 2-AB, 2-AA and 2-AP. Furthermore, the separation is sensitive to small changes in glycan structure allowing resolution of closely related and isobaric oligosaccharides and the solvents are volatile making it an excellent partner to detailed structural analysis by mass spectrometry.

5.5 MS

The details of glycan analysis by mass spectrometry are presented elsewhere in this book. Here, we concentrate on the compatibility of glycan fluorophore labeling and HPLC with MS.

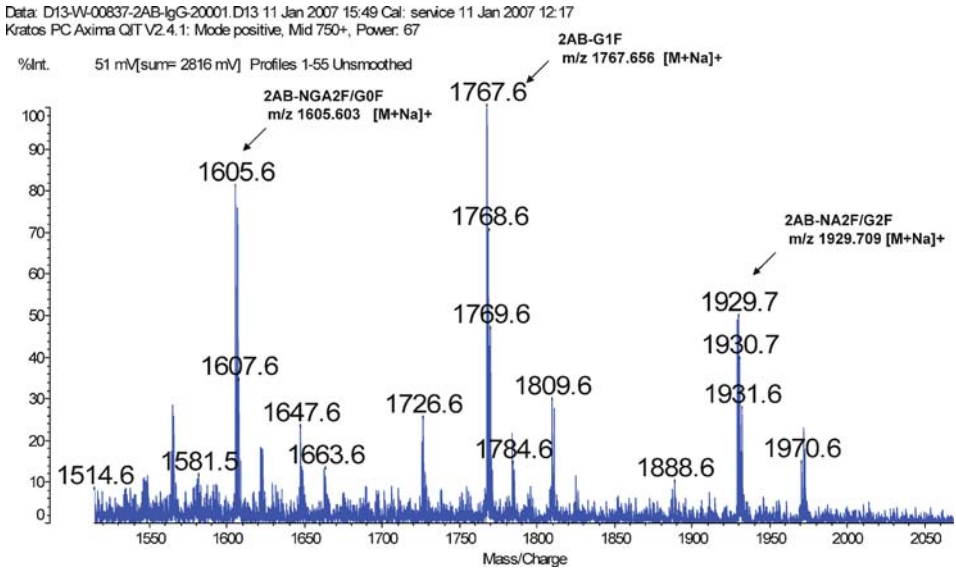

Figure 3
MS mass spectrum of 2AB labeled human antibody glycans. Axima-QIT, positive ion mode, DHB matrix

As well as aiding glycan detection, labeling with fluorophores such as 2-AB can significantly enhance ionization in a mass spectrometer. This is particularly useful when dealing with anionic oligosaccharides which can be particularly difficult to analyze by MS, suffering from severe signal attenuation by non-glycan contaminants such as salts and peptides. *Figure 3* shows a typical MS profile of 2-AB labeled glycans from human serum antibody.

Of the glycan fluorophores available, one of the most useful for HPLC and MS is AA-Ac. The structure of this label allows very efficient ionization of a broad range of glycans including highly sialylated species which often give poor signals on MS. This increases sensitivity and will typically allow femtomol amounts of glycan to be readily detected. LC/MS can be performed with AA-Ac labeled glycans run on either amide or EIR based chromatography before the electrospray mass spectrometer. Advantages of LC/MS over straight MS include the purification of glycans away from contaminants (e. g. salts and peptides) that interfere with ionization in the MS and separation of isobaric species that would overlap in the mass spectrum. Furthermore, the extra information given by the retention on HPLC can reduce the need for MS fragmentation, simplifying the analysis of routine samples.

AA-Ac labeled glycans also give excellent results in MALDI-MS and on current ion-trap instruments detailed MS^n studies can be performed with sub-picomole samples. The combination of this analysis with fractionation of complex samples on EIR or amide HPLC is particularly useful allowing reliable quantitation of the AA-Ac tagged glycans by HPLC and detailed structural characterization by MS^n fragmentation.

One of the biggest challenges in biopharmaceutical glycoprofiling is analysis of the negatively charged sialylated oligosaccharides. The main problems are non-ionization of the anionic glycans–especially in the presence of salts and peptides–and the lability of the sialyl residues

which can fall off as a result of in-source decay. These can be reduced by derivatization of the sialyl residues by methyl esterification or permethylation of the hydroxyls. The derivatized glycans will have altered characteristics on HPLC–which can be used to advantage–and the sialyl residues will be stabilized.

Successful glycoprofiling by MS requires optimization of MS conditions and calibration of the mass spectrometer. These must be done with well-characterized analytical standards. In the past these have been difficult to obtain but the range and availability of commercially available standards are improving. It is important to match the standards to the analytes–particularly in relation to the size of the glycans, degree of branching, degree of sialylation and other anionic groups, derivatization (particularly fluorophores or modifications to sialyl residues and hydroxyl groups). If possible, use pre-derivatized standards as well as glycans that you have derivatized in parallel to your own samples. Careful use of standards and instrument calibration will help you to get develop a well-characterized, robust mass spectrometry system for glycoprofiling.

In summary, the combination of HPLC and mass spectrometry is a very powerful technique, allowing detailed characterization of complex glycosylation with good relative quantitation.

6 Glycosylation Site Profile

With current technology detailed glycosylation site profiling is a lengthy process and not widely performed. However, it can yield valuable information, particularly during glycoprotein drug development and glycan characterization to support regulatory submissions or intellectual property rights. The general scheme is to isolate individual glycosylation sites as glycopeptides then perform a detailed glycan profile of each site. The challenges are to isolate pure sites, without contamination or selective loss of glycopeptide species, and to retain relative quantitation information between sites.

The simplest method for site isolation is to perform an exhaustive proteolytic digestion of the glycoprotein. Typically this is done using a very high-grade modified trypsin after reduction and alkylation. The sample should be monitored for completeness of digestion and aberrant digestion by contaminating proteases. If digestion yields glycopeptides with multiple glycosylation sites then one should use another complementary protease to affect cleavage between the connected sites. It is important to use proteases that give glycopeptides with sufficient size of peptides to allow good separation on the stage which is hydrophobic interaction chromatography (typically C18 or C8 HPLC with a wide pore resin using elution by aqueous acetonitrile with trifluoroacetic acid as an ion pair reagent). With care, this should give a peptide map with separation of glycosylation sites and co-elution of differently glycosylated variants of each site. Identification of glycosylation sites can be done by LC/MS using precursor ion scanning for masses indicative of glycosylation or collection of HPLC fractions then MS of each fraction. After this, each glycosylation site can be subjected to the full range of glycoprofiling analyses described above.

7 Summary

With current technology, quantitative glycosylation analysis of therapeutic glycoproteins can be very challenging. The glycosylation patterns can be extremely complex with species that

can be difficult to separate and refractory to simple analysis on mass spectrometry. However, with care, one can build a scheme for reliable quantitative glycoprofiling using a combination of glycoprofiling modules composed of selected sample preparation and derivation methods, HPLC and mass spectrometry. This chapter has overviewed some of the most useful glycoprofiling modules and how these tools can be integrated into a robust, flexible glycoprofiling system.

Abstract

A large number of alkaloids mimicking the structures of monosaccharides or oligosaccharides have been isolated from plants and microorganisms. The sugar mimicking alkaloids with a nitrogen in the ring are called azasugars or iminosugars. Naturally occurring azasugars are classified into five structural classes: polyhydroxylated piperidines, pyrrolidines, indolizidines, pyrrolizidines, and nortropanes. They are easily soluble in water because of their polyhydroxylated structures and inhibit glycosidases because of a structural resemblance to the sugar moiety of the natural substrate. Glycosidases are involved in a wide range of anabolic and catabolic processes, such as digestion, lysosomal catabolism of glycoconjugates, biosynthesis of glycoproteins, and the endoplasmic reticulum (ER) quality control and ER-associated degradation of glycoproteins. Hence, modifying or blocking these processes in vivo by inhibitors is of great interest from a therapeutic point of view. Azasugars are an important class of glycosi-

dase inhibitors and are arousing great interest for instance as antidiabetics, antiobesity drugs, antivirals, and therapeutic agents for some genetic disorders. This review describes the recent studies on isolation, characterization, glycosidase inhibitory activity, and therapeutic application of azaglycomimetics.

1 Introduction

Alkaloids mimicking the structures of monosaccharides are now believed to be widespread in plants and microorganisms [1,2]. Azasugars (or iminosugars) in which the ring oxygen has been replaced by nitrogen must be one of the most interesting discoveries in the field of natural products of recent years. Naturally occurring azasugars are classified into five structural classes: polyhydroxylated piperidines, pyrrolidines, indolizidines, pyrrolizidines, and nortropanes. They bind specifically to the active sites of glycosidases by mimicking the corresponding natural substrates. Glycosidases are involved in a wide range of important biological processes, such as intestinal digestion, post-translational processing of glycoproteins, quality control systems in the endoplasmic reticulum (ER) and ER-associated degradation (ERAD) mechanism, and the lysosomal catabolism of glycoconjugates. Inhibition of these glycosidases can have profound effects on carbohydrate catabolism in the intestines, and maturation, transport, and secretion of glycoproteins. The realization that glycosidase inhibitors have enormous therapeutic potential in many diseases such as diabetes, viral infection, and lysosomal storage disorders has led to increasing interest and demand for them [3,4]. This review describes the recent studies on isolation, characterization, glycosidase inhibitory activity, and therapeutic application of azaglycomimetics.

2 Natural Occurrences

2.1 Piperidines (Azapyranose)

In 1966, NJ (nojirimycin) (**1**) was discovered as the first natural glucose mimic, with a nitrogen atom in place of the ring oxygen [5]. NJ was originally described as an antibiotic produced by *Streptomyces roseochromogenes* R-468 and *S. lavendulae* SF-425 [5,6], and was shown to be a potent inhibitor of α- and β-glucosidases from various sources. Thereafter, *manno*-NJ (nojirimycin B) (**2**) [7] and *galacto*-NJ (galactostatin) (**3**) [8] as azasugars with the hydroxyl group at C-1 were also isolated from the fermentation broths of species of *Streptomyces*. *Manno*-NJ was co-produced with NJ by *S. lavendulae* SF-425, while *galacto*-NJ was isolated as a potent β-galactosidase inhibitor produced by *S. lydicus* PA-5726. However, because these iminosugars with the hydroxyl group at C-1 are fairly unstable, they are usually stored as bisulfite adducts; they may be reduced by catalytic hydrogenation with the platinum catalyst or by $NaBH_4$ to the stable 1-deoxy derivatives (see ❯ *Fig. 1* for structures of **1**–**24**).

DNJ (1-deoxynojirimycin) (**4**) was first prepared by the reduction of nojirimycin as described above [5] and chemically synthesized from L-sorbofuranose [9] but later isolated from the roots of mulberry trees and called moranoline [10]. DNJ is also produced by many strains of the genera *Bacillus* [11] and *Streptomyces* [12,13]. The first naturally occurring *N*-methyl derivative of DNJ was isolated from the leaves and roots of *Morus* spp. (mulberry trees) and, furthermore, the genus *Morus* has been shown to co-produce many kinds of glycosides of DNJ such as 2-*O*-, 3-*O*-, 4-*O*-α-D-glucosides, 2-*O*-, 3-*O*-, 4-*O*-, 6-*O*-β-D-glucosides, and 2-*O*-, 6-*O*-α-D-galactosides [14,15]. *Manno*-DNJ (1-deoxymannojirimycin) (**5**) was first isolated from the seeds of the legume *Lonchocarpus sericeus*, a native of the West Indies and tropical America [16] and later isolated from the neotropical liana, *Omphalea diandra* (Euphorbiaceae) [17], and the legume *Angylocalyx pynaertii* [18] growing in tropical African forests. *Manno*-DNJ was also isolated from the culture broth of *Streptomyces lavendulae* GC-148 [19], which had already been reported as a high-yielding strain of DNJ [13]. Very recently, our group has isolated *manno*-DNJ in high yields of 0.083% and 0.17% w/w from Thai medicinal plants "Thopthaep" and "Cha em thai" [20]. The biological origin of "Thopthaep" and "Cha em thai" were identified as *Connarus ferrugineus* (Connaraceae) and *Albizia myriophylla* Benth (Leguminosae), respectively. *C. ferrugineus* is used traditionally to treat scabies, as an ointment, and to treat stomach ache and constipation as an oral drug, while the roots and wood of *A. myriophylla* are used traditionally to relieve thirst and sore throats and to substitute for licorice owing to a sweet taste. Furthermore, 2-*O*-α-D-galactopyranosyl-*manno*-DNJ and 3-*O*-β-D-glucopyranosyl-*manno*-DNJ from *C. ferrugineus* and 2-*O*-β-D-glucopyranosyl-*manno*-DNJ and 4-*O*-β-D-glucopyranosyl-*manno*-DNJ from *A. myriophylla* have also been isolated [20].

Streptomyces subrutilus ATCC 27467 produces both DNJ and *manno*-DNJ in its culture broth, and *manno*-NJ has been suggested as an intermediate in the biosynthesis of *manno*-DNJ [21]. In this organism, it has also been suggested that epimerization of mannojirimycin can occur at C-2 to give NJ which is then dehydrated and reduced to DNJ. *Agrobacterium* spp. strain 19-1 has been shown to be able to epimerize DNJ to *manno*-DNJ [22]. Although the natural occurrence of *galacto*-DNJ (1-deoxygalactonojirimycin) (**6**) has not been reported to date,

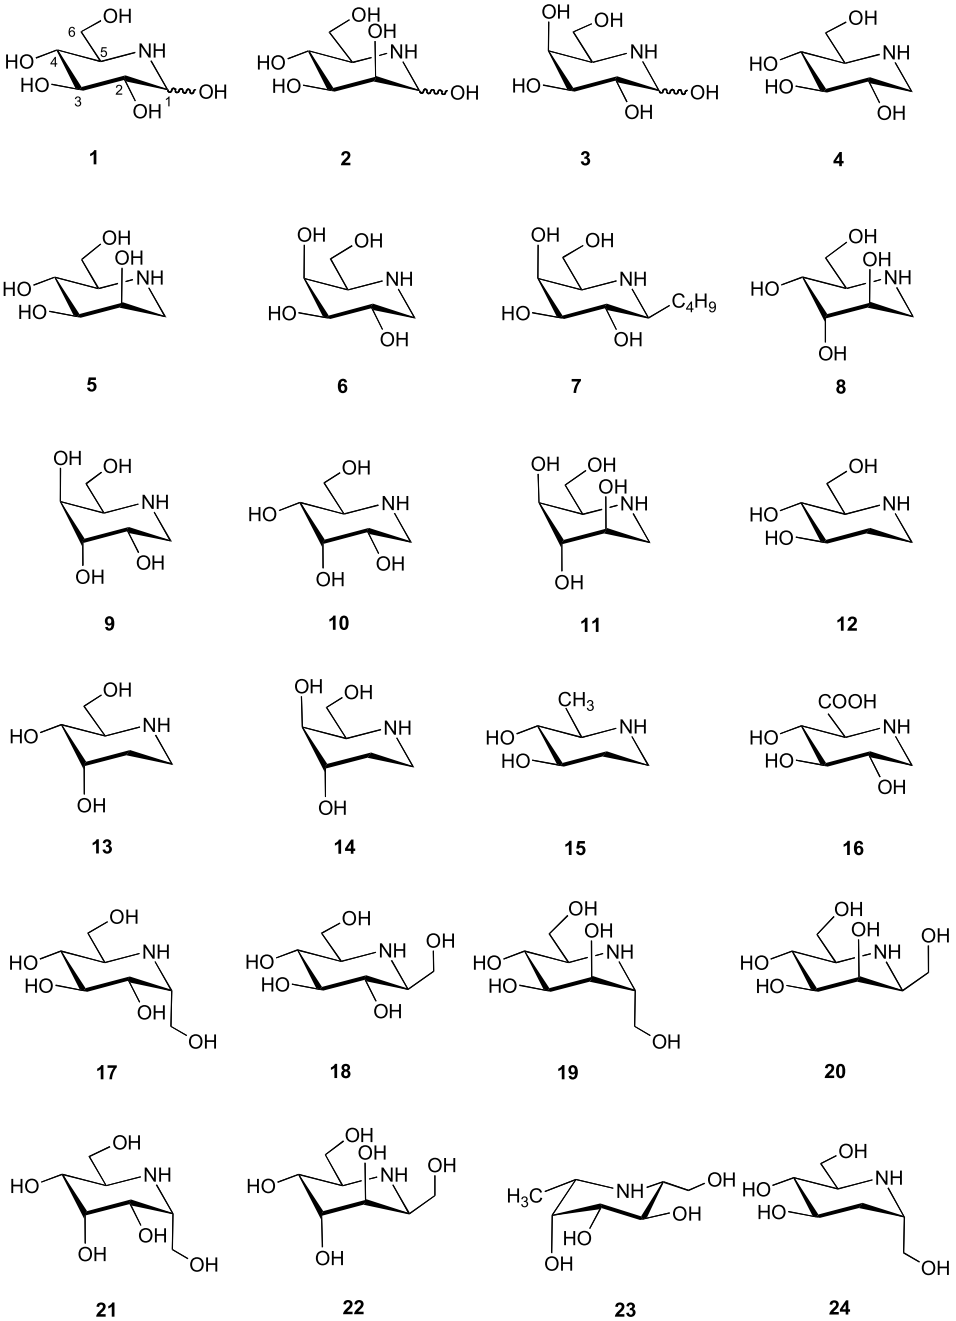

Figure 1
Structures of 1–24

β-1-*C*-butyl-*galacto*-DNJ (**7**) has been isolated from a commercially available Chinese crude drug "Sha-sheng," which is the roots of *Adenophora* spp. (Campanulaceae) [23].

Five naturally occurring 1-deoxyazasugars have been isolated to date. DNJ and *manno*-DNJ have been isolated from many plants and microorganisms as described above. *Altro*-DNJ (1-deoxyaltronojirimycin) (**8**) and *gulo*-DNJ (1-deoxygulonojirimycin) (**9**) have been discovered from *Scilla sibirica* (Hyacinthaceae) [24] and *Angylocalyx pynaetii* (Legminosae) [25]. The ^{1}H and ^{13}C NMR spectroscopic data of *allo*-DNJ (1-deoxyallonojirimycin) (**10**) isolated from "Thopthaep" [20] were in accord with those of synthetic *allo*-DNJ [26]. Recently, the L-enantiomers of DNJ, *manno*-DNJ, *allo*-DNJ, *altro*-DNJ, *galacto*-DNJ, *gulo*-DNJ, and *ido*-DNJ (**11**) were enantiospecifically synthesized [27]. The absolute configurations of natural DNJ, *manno*-DNJ, *allo*-DNJ, *altro*-DNJ, and *gulo*-DNJ were determined to be D-, D-, D-, D-, and L-enantiomers, respectively, from the value and sign of the optical rotation.

1,2-Dideoxynojirimycin, fagomine (**12**), was isolated from the seeds of Japanese Buckwheat (*Fagopyrum esculentum*) [28] and the Moreton Bay chestnut (black bean), *Castanospermum australe* (Leguminosae) [29], and it also occurs as the 4-*O*-β-D-glucoside in the seeds of the legume *Xanthocercis zambesiaca* [30]. The search for azasugars in the leaves and roots of *X. zambesiaca* led to the isolation of fagomine, 3-*epi*-fagomine (**13**), 3,4-di-*epi*-fagomine (**14**), and 3-*O*-β-D-glucopyranosylfagomine in addition to the 4-*O*-β-D-glucoside [31]. From the Chinese crude drug "Ti-koppi," the roots of *Lycium chinense* (Solanaceae), fagomine and 6-deoxyfagomine (**15**) have been isolated, together with many kinds of polyhydroxylated nortropane and tropane alkaloids [32]. 2*S*-Carboxy-3*R*,4*R*,5*S*-trihydroxypiperidine (**16**), which is a mimic of glucuronic acid, was discovered from the seeds of the legume *Baphia racemosa* as a novel specific inhibitor of human liver β-D-glucuronidase and α-L-iduronidase [33].

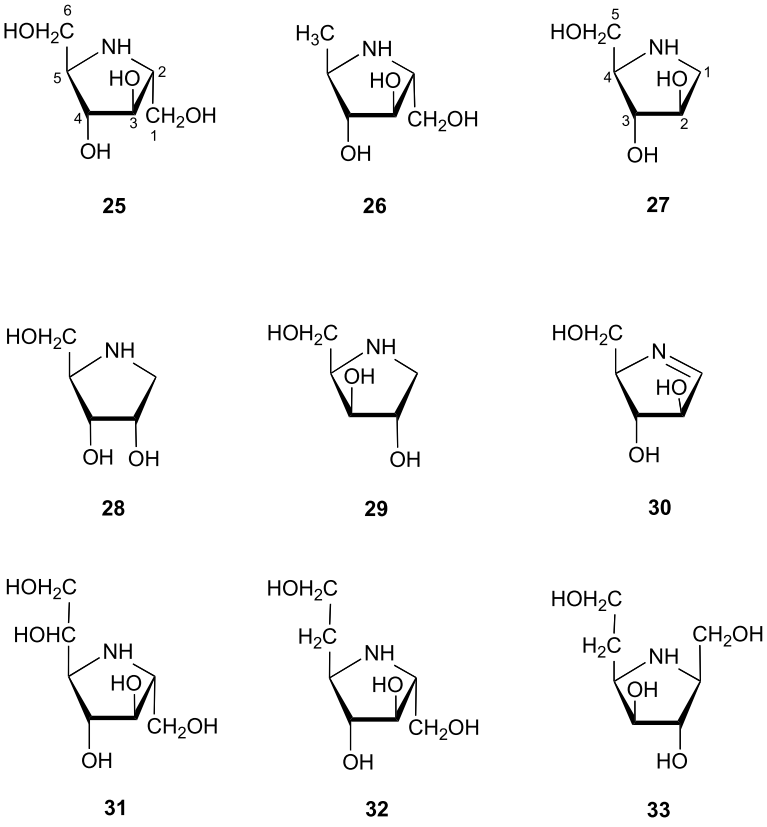
In 1988, α-HNJ (α-homonojirimycin) (**17**) was isolated from *O. diandra*, together with *manno*-DNJ [17], as the first report of a naturally occurring DNJ derivative with a carbon substituent at C-1. However, before the isolation of the natural product, its 7-*O*-β-D-glucoside (MDL 25637) had been designed as a potential drug for the treatment of diabetes mellitus [34,35]. α-HNJ has been detected in adults, pupae, and eggs of the neotropical moth, *Urania fulgens*, whose larvae feed on *O. diandra* [36]. α-HNJ has also been isolated from whole plants of *Aglaonema treubii* (Araceae) [37,38] and the bulbs of *Hyacinthus orientalis* (Hyacinthaceae) [39]. These plants also co-produce the isomers and glycosides of α-HNJ such as β-HNJ (β-homonojirimycin) (**18**), α-*manno*-HNJ (α-homomannojirimycin) (**19**), β-*manno*-HNJ (β-homomannojirimycin) (**20**), α-*allo*-HNJ (α-homoallonojirimycin) (**21**) [40], β-*altro*-HNJ (β-homoaltronojirimycin) (**22**) [38], and the 5-*O*-α-D-galactoside and 7-*O*-β-D-glucoside of α-HNJ. The isomers **21** and **22** and the 5-*O*-α-D-galactoside are new natural products, while the isomers **18**, **19**, and **20** have been chemically synthesized previously [41,42,43]. Amazingly, the 7-*O*-β-D-glucoside of α-HNJ (MDL 25637), which had been developed as an antidiabetic agent, was also isolated from these plants. The 7-deoxy derivative of β-*manno*-HNJ was isolated from the pods of *A. pynaetii* (Legminosae) [25] and the bulbs of *Scilla sibirica* (Hyacinthaceae) [24]. This compound was identical with β-L-fuco-HNJ (**23**) which had been chemically synthesized as a powerful inhibitor of α-L-fucosidase [44].

In the course of a search for α-glucosidase inhibitors, Kitaoka et al. found that such inhibitors are present in some Thai traditional crude drugs [45]. For example, α-HNJ occurs in "Non tai yak" at a level of 0.1% (dry weight). The "Non tai yak" sample is known to be *Stemona tuberosa* (Stemonaceae), which has been used in China and Japan for various medicinal pur-

poses. In particular, an extract from the freshly tuberous roots of *S. tuberosa* is used to treat respiratory disorders, including pulmonary tuberculosis and bronchitis, and also recommended as an insecticide [46,47,48]. In 2005, the re-examination of polyhydroxylated alkaloids in *S. tuberosa* led to the isolation of 13 alkaloids containing **4**, **5**, **17** (0.1% of dry weight), **18**, **19**, **20**, **21**, **22**, and α-5-deoxy-HNJ (**24**) as piperidine alkaloids [20].

2.2 Pyrrolidines (Azafuranose)

In 1976, DMDP (2*R*,5*R*-bis(dihydroxymethyl)-3*R*,4*R*-dihydroxypyrrolidine, 2,5-dideoxy-2,5-imino-D-mannitol) (**25**; see ● *Fig. 2* for structures of **25**–**33**), mimicking β-D-fructofuranose, was found in leaves of the legume *Derris elliptica* [49] and later shown to be present in many disparate species of plants and microorganisms [2], which would indicate that this is a common metabolite. The 6-deoxy derivative of DMDP (6-deoxy-DMDP, 2,5-imino-1,2,5-trideoxy-D-mannitol) (**26**) was isolated from the seeds of *Angylocalyx pynaertii* as



● **Figure 2**
Structures of 25–33

a weak β-mannosidase inhibitor [18]. Removal of one hydroxymethyl group from DMDP leads to DAB (1,4-dideoxy-1,4-imino-D-arabinitol) (**27**), which was first found in the fruits of *Angylocalyx boutiqueanus* [50] and subsequently in many disparate species of plants as well as DMDP [2]. DAB also occurred as the 2-*O*-β-D-glucoside in the leaves and roots of *Morus* spp. [14,15]. The 2-epimer of DAB, 1,4-dideoxy-1,4-imino-D-ribitol (**28**), has also been isolated from *Morus* spp. [15] and 1,4-dideoxy-1,4-imino-D-xylitol (**29**) from *A. pynaertii* [25]. The polyhydroxypyrroline nectrisine (FR-900483) (**30**) was isolated as an immunomodulator from the culture broth of the fungus *Nectria ludica* [51] and further shown to be a powerful inhibitor of yeast α-glucosidase [52]. 2,5-Dideoxy-2,5-imino-D-*glycero*-D-taloheptitol has been chemically synthesized as an iminofuranose [53]. In 1997, the first naturally occurring 2,5-dideoxy-2,5-iminoheptitol, homoDMDP (2,5-dideoxy-2,5-imino-DL-*glycero*-D-*manno*-heptitol) (**31**), was found in the leaves of bluebell (*Hyacinthoides non-scripta*) [54]. This compound was isolated later from the bulbs of Hyacinths (*Hyacinthus orientalis*) [39] and *Scilla campanulata* (Hyacinthaceae) [55] and also isolated as the 7-*O*-apioside and 7-*O*-β-D-xyloside in *H. non-scripta* and *S. campanulata* [54,55]. Hyacinths further co-produced 6-deoxy-homoDMDP (2,5-imino-2,5,6-trideoxy-D-*manno*-heptitol) (**32**) and 2,5-imino-2,5,6-trideoxy-D-*gulo*-heptitol (**33**) [39].

The structure of homoDMDP has been given as 2,5-dideoxy-2,5-imino-DL-*glycero*-D-*manno*-heptitol or its enantiomer from its NMR spectroscopic data [54]. However, the relative configuration at C-6 has not yet been determined since it cannot be determined from the NMR data. In 1999, in the course of the synthesis of a series of five-membered iminosugars, Takebayashi et al. reported the enantiospecific synthesis of (1′*S*,2*R*,3*R*,4*R*,5*R*)-3,4-dihydroxy-2-(1,2-hydroxyethyl)-5-hydroxymethyl)pyrrolidine [56]. The ^{1}H NMR and ^{13}C NMR spectroscopic data of homoDMDP reported in ref. 54 and 55 were superimposable with those of the synthetic compound in ref. 56, and the optical rotation {$[\alpha]_D$ +28.8° (c 3.75, H_2O)} of homoDMDP was also similar to that {$[\alpha]_D$ +25.6° (c 0.3, H_2O)} of the synthetic compound. Hence, we determined that both compounds are identical and the structure of homoDMDP is 2,5-dideoxy-2,5-imino-D-*glycero*-D-*manno*-heptitol. The structure of 6-deoxy-homoDMDP isolated from *H. orientalis* has been determined to be 2,5-dideoxy-2,5-imino-D-*manno*-heptitol or its enantiomer [39]. Fleet et al. have synthesized both enantiomers of 6-deoxy-homoDMDP (the detailed synthesis and their biological activities will be reported elsewhere). From comparison of the optical rotation values {natural product, $[\alpha]_D$ +59.2° (c 1.77, H_2O); D-enantiomer, $[\alpha]_D$ +62.2° (c 0.19, H_2O); L-enantiomer, $[\alpha]_D$ −89.1° (c 0.55, H_2O)}, the natural product was determined to be D-enantiomer.

2.3 Indolizidines

There are three groups of bicyclic polyhydroxyheterocycles, with two five-membered rings (pyrrolizidines) or one five-membered ring and one six-membered ring (indolizidines and nortropanes) fused together. These bicyclic alkaloids have a less obvious structural relationship to monosaccharides but in each case the configuration of hydroxyl substituents on the ring can be compared to those of sugars.

Certain poisonous plants often cause serious livestock losses. The Australian legumes, *Swainsona*, are known as “poison peas,” and sheep eating them develop a syndrome called “pea

struck" [57,58]. There is also the livestock poisoning by the closely related *Astragalus* and *Oxytropis* species, which are found throughout most of the world, and intoxication of livestock by certain of those species known as locoweeds in the western United States is called "locoism" [58,59]. The poisoning is characterized by cytoplasmic vacuolation of neuronal cells due to accumulation of mannose-rich oligosaccharides in lysosomes [60]. The trihydroxyindolizidine alkaloid swainsonine (**34**) occurs in these legumes and has been identified as a causative agent in locoism [59,61]. The toxicity of the other legume *Castanospermum australe* for livestock led to the isolation of the toxic principle castanospermine (**35**) [62] and these two alkaloids gave rise to a great impetus in research on *N*-containing sugars and their application (see ❯ *Fig. 3* for structures of **34**–**41**).

In 1981, castanospermine was first isolated from the immature seeds, with a yield of 0.057% [62]. X-ray crystallography showed that the stereogenic centers of the six-membered ring of castanospermine correspond to the *gluco* configuration [62], while 6-*epi*-castanospermine (**36**) isolated later from the seeds has the D-*manno* configuration in the piperidine ring [63]. *C. australe* co-produces 7-deoxy-6-*epi*-castanospermine (**37**) [64] and 6,7-di*epi*-castanospermine (**38**) [65]. Very recently, we have isolated a new castanospermine isomer 6,8-di*epi*-castanospermine (**39**) from the leaves and twigs, which contain castanospermine at the high level of 1% (unpublished data). In 2003, the first naturally occurring glycoside of **35**, castanospermine-8-*O*-β-D-glucoside, was isolated from the seeds [66]. Lentiginosine (**40**) and 2-*epi*-lentiginosine (**41**) have been isolated from the leaves of *Astragalus lentiginosus* and these two dihydroxyindolizidines are probably biosynthesized from 1-hydroxyindolizidine by hydroxylation at C-2 [67].

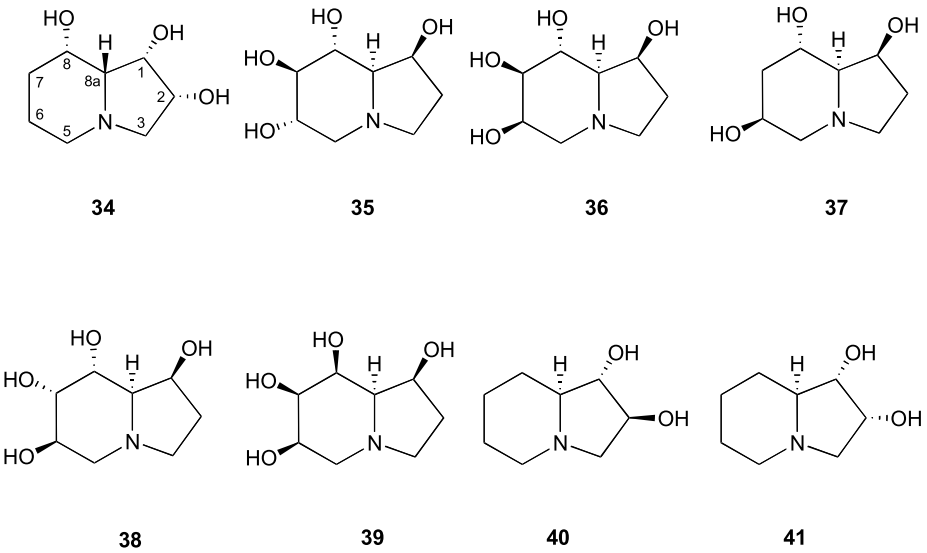


Figure 3
Structures of 34–41

2.4 Pyrrolizidines

In 1988, alexine (**42**), a polyhydroxylated pyrrolizidine alkaloid, was isolated from the pods of legume *Alexa leiopetala* [68] (see ❯ *Fig. 4* for structures of **42–48**). Although the broad class of pyrrolizidine alkaloids bear a carbon substituent at C-1 [69,70], alexine is the first example of a pyrrolizidine alkaloid with a carbon substituent at C-3. At about the same time, australine (**43**) was isolated from the seeds of *C. australe* and found to be 7a-*epi*-alexine from X-ray crystallographic analysis [71]. The isolation of 1-*epi*-australine (**44**), 3-*epi*-australine (**45**), and 7-*epi*-australine (**46**) from the same plant was later reported [72,73,74]. The structure of 1-*epi*-australine was firmly established by X-ray crystallographic analysis of the corresponding 1,7-isopropylidene derivative [73], and the absolute configurations of 3-*epi*-australine were also identified by X-ray crystal structure analysis [73]. Alkaloid **46** was tentatively assigned as 7-*epi*-australine based on the difference between its NMR parameters and those reported for australine [74]. The unambiguous synthesis of australine [75] and 7-*epi*-australine [76,77] and extensive NMR studies on the natural and synthetic isomers of australine [77] by Denmark et al. elucidated that the natural product reported as 7-*epi*-australine is really australine. This means that 7-*epi*-austaline has not yet been found as a natural product. Reinvestigation of the natural occurrence of 7-*epi*-australine in *C. australe* led to the isolation of new alkaloids, 2,3-di*epi*-australine (**47**), 2,3,7-tri*epi*-australine (**48**), and 2-*O*-β-D-glucopyranosyl-1-*epi*-australine [66].

Polyhydroxylated pyrrolizidine alkaloids with a hydroxymethyl substituent at C-3 have been thought to be of very restricted natural occurrence. The alexines and australines have been reported in only two small genera of the Leguminosae (*Castanospermum* and *Alexa*). However, a number of such pyrrolizidine alkaloids were found from a quite different family, Hyacinthaceae. In 1999, new polyhydroxylated pyrrolizidines different from

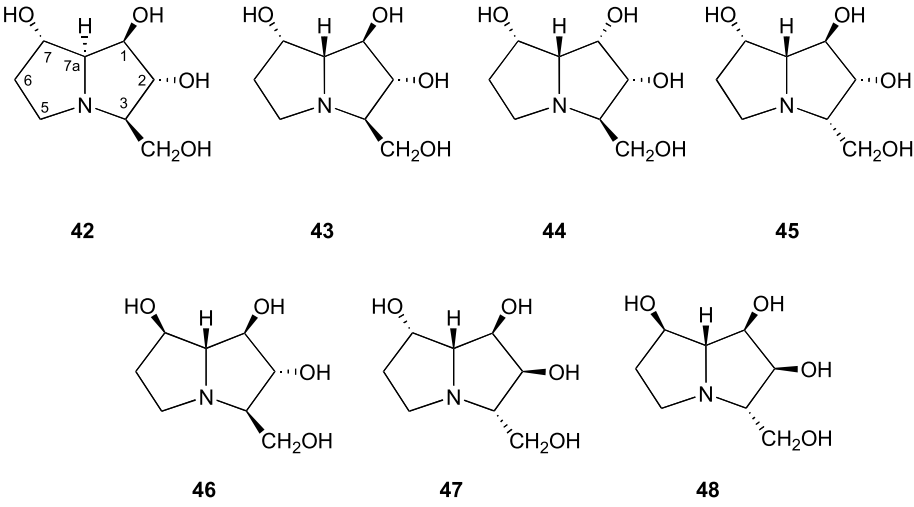

Figure 4
Structures of 42–48

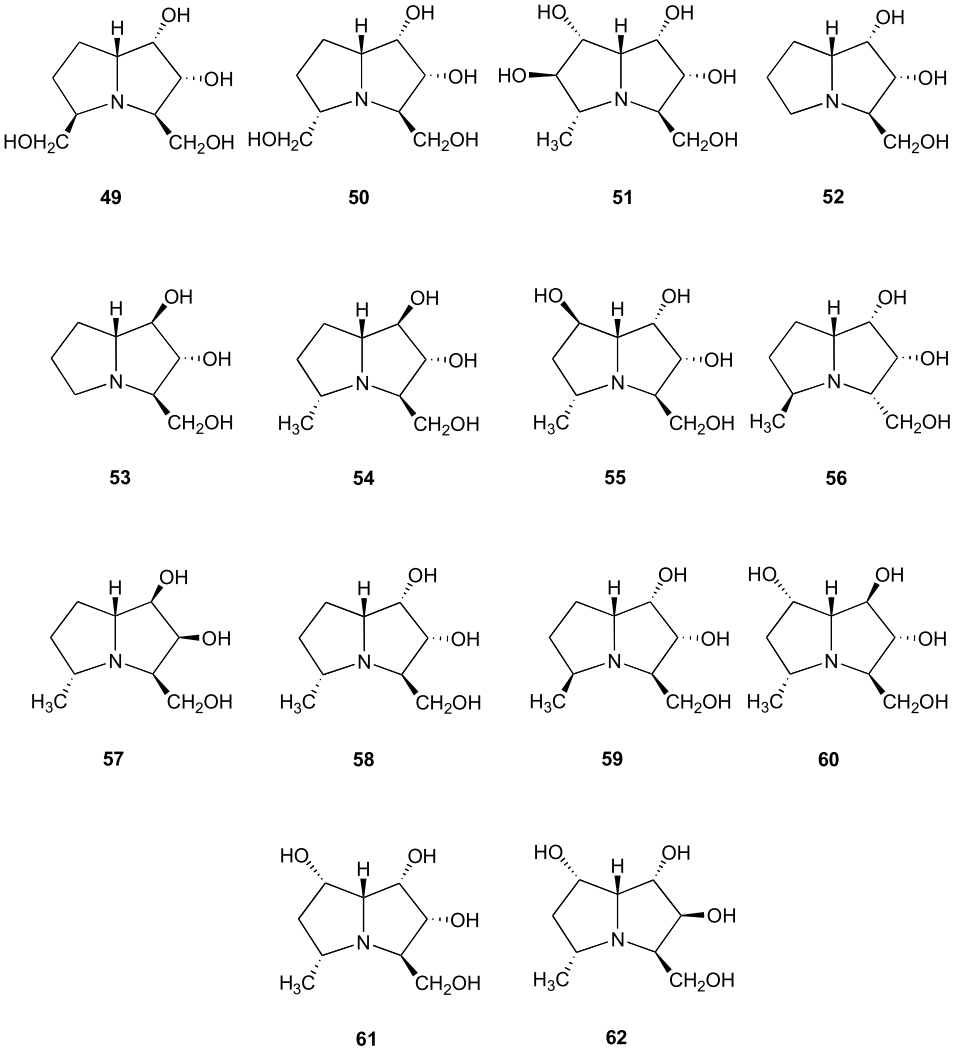

Figure 5
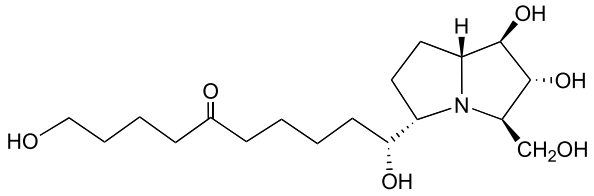
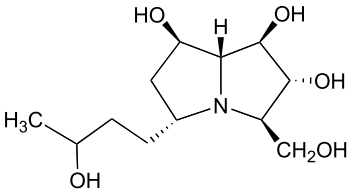
Structures of 49–62

alexines and australines were isolated from the Hyacinthaceae family plants, designated as hyacinthacines: hyacinthacines B_1 (**49**) and B_2 (**50**) from the immature fruits and stalks of *Hyacinthoides non-scripta* and hyacinthacine C_1 (**51**) from the bulbs of *Scilla campanulata* [55] (see *Fig. 5* for structures of **49–62**). Shortly after their isolation, four new hyacinthacines A_1 (**52**), A_2 (**53**), A_3 (**54**), and B_3 (**55**) were isolated from the bulbs of *Muscari armeniacum* in addition to **50** [78]. In 2001, Martin and co-workers reported the first synthesis of (+)-hyacinthacine A_2 from commercially available 2,3,5-tri-*O*-benzyl-D-arabinofuranose, and confirmed the absolute configuration of the natural (+)-hyacinthacine

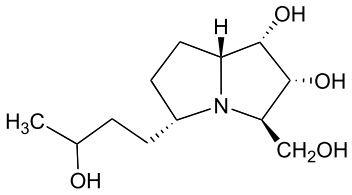
A_2 as (1*R*,2*R*,3*R*,7a*R*)-1,2-dihydroxy-3-hydroxymethylpyrrolizidine [79]. Subsequently, the natural (+)-hyacinthacine A_3 was enantiospecifically synthesized from an adequately protected DMDP and its absolute configuration was determined to be (1*R*,2*R*,3*R*,5*R*,7a*R*)-1,2-dihydroxy-3-hydroxymethyl-5-methylpyrrolizidine [80]. More recently, the absolute configuration of the natural (+)-hyacinthacine A_1 has been determined to be (1*S*,2*R*,3*R*,7a*R*)-1,2-dihydroxy-3-hydroxymethylpyrrolizidine from its total synthesis [81]. Many species of the genera *Muscari*and *Scilla*are very common as garden plants. The GC-MS analysis of the extract of commercially available bulbs of *S. sibirica* elucidated the existence of many kinds of polyhydroxylated alkaloids, five pyrrolidines and two pyrrolidine glycosides, six piperidines and one piperidine glycoside, and eight pyrrolizidines [82]. Surprisingly, seven pyrrolizidines other than the known alkaloid **55** were new hyacinthacines. They are hyacinthacines A_4 (**56**), A_5 (**57**), A_6 (**58**), A_7 (**59**), B_4 (**60**), B_5 (**61**), and B_6 (**62**).



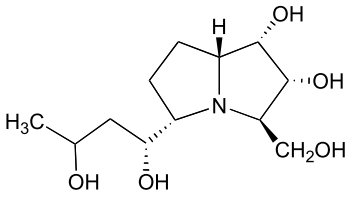
63



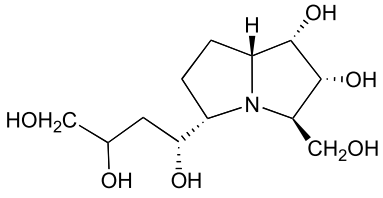
64



65



66



67

Figure 6
Structures of 63–67

In 1999, it was reported that *Broussonetia kajinoki* (Moraceae) produces a pyrrolizidine alkaloid with the C_{10} side chain at the C-5α position, which was designated as broussonetine N (**63**; see *Fig. 6* for structures of **63**–**67**), together with pyrrolidine alkaloids with a long (C_{13}) side chain [83]. Broussonetine N can be regarded as the α-5-*C*-(1,19-dihydroxy-6-oxodecyl)-hyacinthacine A_2. In 2004, four new hyacinthacine A_1 and 7-*epi*-australine derivatives with the hydroxybutyl side chain at the C-5α position were produced from the bulbs of *S. peruviana*, which also co-produces pyrrolidine alkaloids with a highly hydroxylated long side chain [84]. These four pyrrolizidine alkaloids were determined to be α-5-*C*-(3-hydroxybutyl)-7-*epi*-australine (**64**), α-5-*C*-(3-hydroxybutyl)hyacinthacine A_1 (**65**), α-5-*C*-(1,3-dihydroxybutyl)hyacinthacine A_1 (**66**), and α-5-*C*-(1,3,4-trihydroxybutyl)-hyacinthacine A_1 (**67**). The NOE experiments of pyrrolizidines **66** and **67** suggested that the absolute configurations of C-1′ are *R*.

2.5 Nortropanes

Until recently, four structural classes were encompassed as naturally occurring azasugar mimetics: polyhydroxylated piperidines, pyrrolidines, indolizidines, and pyrrolizidines. An entirely new class has now been added to this group with the discovery of the calystegines. Calystegines possess three structural features in common: a nortropane ring system; two to four hydroxyl groups varying in position and stereochemistry; and a novel aminoketal functionality, which generates a tertiary hydroxyl group at the bicyclic ring bridgehead. Calystegines were first discovered as secondary metabolites of plants and were implicated in the establishment and maintenance of specific plant-bacterium relationships [85]. Calystegines are abundant in the underground organs and root exudates of *Calystegia sepium*, *Convolvulus arvensis* (both Convolvulaceae), and *Atropa belladonna* (Solanaceae). The calystegines were subsequently extracted from root cultures of *C. sepium* transformed from *Agrobacterium rhizogenes*, grown in vitro and classified into two groups, calystegines A and B, on the basis of their relative mobility on paper electrophoresis [85]. The calystegine A group was separated by HPLC into four components (A_1, A_2, A_3, and A_4), of which the structure of the major component, calystegine A_3 (**68**; see *Fig. 7* for structures of **68**–**87**), was identified as 1α,2β,3α-trihydroxynortropane by a combination of high-resolution mass spectrometry and ^{1}H and ^{13}C NMR spectroscopy [86]. The calystegine B group was separated into two constituents, B_1 and B_2, and the structures of B_1 (**69**) and B_2 (**70**) were determined to be 1α,2β,3α,6α-tetrahydroxynortropane and 1α,2β,3α,4β-tetrahydroxynortropane, respectively, in a similar manner. A recent thorough examination of *M. bombycis* and *M. alba* (both of the Moraceae) resulted in the discovery of calystegines B_1, B_2, and C_1 (**71**) [14,15,87]. Calystegine C_1 was determined to be 1α,2β,3α,4β,6α-pentahydroxynortropane by a thorough NMR study. Since tropane alkaloids had not hitherto been isolated from the Moraceae, their occurrence therein is unique at the present time. A recent survey for the occurrence of calystegines in plants of Solanaceae and Convolvulaceae discovered that they are widely distributed in these families [1,2,88,89,90].

The occurrence in Solanaceae is documented for 12 genera, *Atropa*, *Brunfelsia*, *Datura*, *Duboisia*, *Hyoscyamus*, *Lycium*, *Mandragora*, *Nicandra*, *Physalis*, *Scopolia*, *Solanum*, and *Withania* [2,89]. Our group isolated and characterized calystegines A_3, A_5 (**72**), B_1, B_2, and

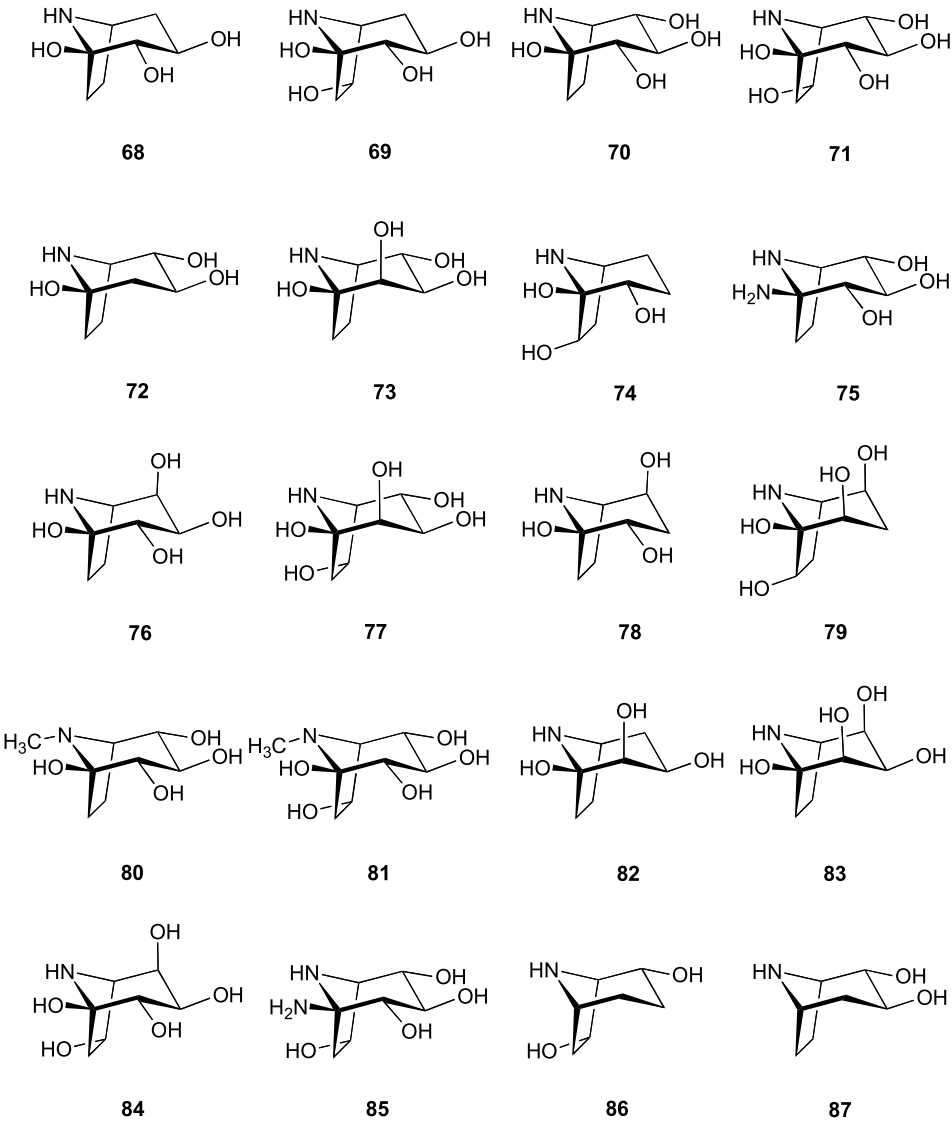


Figure 7
Structures of 68–87

B_3 (**73**) from the roots of *Physalis alkekengi* var. *francheti* [91], calystegines A_5, A_6 (**74**), B_1, B_2, B_3, and N_1(**75**) from the whole plant of *Hyoscyamus niger* [92], calystegines A_3, A_5, B_1, B_2, B_3, B_4 (**76**), and C_1 from the roots of *Scopolia japonica* [93], and calystegines B_1, B_2, B_4, C_1, and C_2 (**77**) from the leaves and twigs of *Duboisia leichhardtii* [94]. An examination of the roots of *Lycium chinense* led to the discovery of two new calystegines A_7 (**78**) and

B_5 (**79**), and two novel tropane alkaloids *N*-methylcalystegines B_2 (**80**) and C_1 (**81**), unlike the previously reported nortropane alkaloids [95]. Our recent works elucidated the presence of calystegine A_8 (**82**) in *H. niger*, and calystegine B_6 (**83**) in *S. japonica*, and calystegines C_3 (**84**) and N_2 (**85**) in *D. leichhardtii* (unpublished data). Calystegines N_1 and N_2 are assigned to an entirely new group of calystegines (the N series). The FABMS analysis of calystegines N_1 and N_2 gives odd-numbered $[M+H]^+$ ions of *m*/*z* 175 and 191 due to the replacement of an OH group by a NH_2 group relative to calystegines B_2 and C_1, respectively. The additional amino groups are located on C-1 in the parent alkaloids with the chemical shifts of the sole quaternary carbon at δ 78.3 (N_1) or 79.2 (N_2) in the ^{13}C NMR, in contrast to all other calystegines in which the hydroxyl-substituted quaternary carbon resonance occurs at an essentially invariant value of δ 93–94 ppm.

Besides free calystegines, calystegine B_1 occurs as the 3-*O*-β-D-glucoside in *Nicandra physalodes* fruits [96], and *Atropa belladonna* contains several glycosides including 3-*O*-β-D-glucopyranosylcalystegine B_1 and 4-*O*-α-D-galactopyranosylcalystegine B_2 [97]. The latter galactoside is also found in the mulberry fruits, as previously described [87]. Microbial β-transglucosylation of calystegine B_1 or B_2 using the whole cells of the yeast *Rhodotorula lactosa* gives 3-*O*-β-D-glucopyranosylcalystegine B_1or 4-*O*-β-D-glucopyranosylcalystegine B_2, respectively [98]. The glucose transfer to calystegine B_1 by commercially available rice α-glucosidase provides 3-*O*-α-D-glucopyranosylcalystegine B_1, but this enzyme does not transfer D-glucose to calystegine B_2 [98]. The lack of α-glucosyl transfer to calystegine B_2 could be due to the inhibition of rice α-glucosidase by calystegine B_2.

The enantioselective syntheses of (+)- and (−)-calystegines B_2 have determined that (+)-calystegine, (1*R*,2*S*,3*R*,4*S*,5*R*)-1,2,3,4-tetrahydroxynortropane, is the natural molecule [99,100], while the absolute configuration of the natural (−)-calystegine A_3 has been established as (1*R*,2*S*,3*R*,5*R*)-1,2,3-trihydroxynortropane by the syntheses of both enantiomers [101]. Later, natural (+)-calystegine B_3 and (−)-calystegine B_4 were prepared from D-galactose and D-mannose, respectively, for the first time and their absolute configuration confirmed [102,103].

Calystegines appear to be further widely distributed in the Convolvulaceae [88,90]. Eich and co-workers focused on the occurrence of seven calystegines (A_3, A_5, B_1, B_2, B_3, B_4, and C_1) identified by GC-MS analysis with authentic samples as references and analyzed the extracts of 65 Convolvulaceous species from predominantly tropical provenances belonging to all continents except Australia [88]. Consequently, they revealed their occurrence in 30 species belonging to 15 genera in this family. The qualitatively dominant alkaloid of the A series is calystegine A_3, detected in 43% of the 30 positive species followed by A_5 (20%). In the B series, calystegine B_2 exhibits the highest occurrence (86%) followed by B_1 (70%), B_3 (20%), and B_4 (13%). Calystegine C_1 is found in less than 1% of the species.

Convolvulaceous species produce polyhydroxylated alkaloids other than calystegines, as seen in ❯ *Table 1*. 2α,7β-Dihydroxynortropane (**86**) was isolated from seven species in Convolvulaceae, while only *Calystegia soldanella* contained both 2α,7β-dihydroxynortropane and 2α,3β-dihydroxynortropane (**87**) [90]. More interestingly, *Ipomoea carnea*produces the indolizidine alkaloids swainsonine (**34**) and 2-*epi*-lentiginosine (**41**) in addition to calystegines B_1, B_2, B_3, and C_1 [104]. *I. carnea* is a plant of tropical American origin but is now widely distributed in the tropical regions of the world. Chronic ingestion of *I. carnea* sometimes causes outbreak of natural poisoning in livestock. Swainsonine is also found in other species of the Convolvulaceae family. *Ipomoea* sp. Q6 aff. *calobra* (Weir Vine) grows in a small

area of southern Queensland in Australia and is reported to produce neurological disorders in livestock. The clinical symptoms are similar to those caused by swainsonine-containing legumes. Molyneux et al. detected swainsonine in the seeds and estimated the level as 0.058% by GC-MS and furthermore, the existence of swainsonine and calystegine B_2 in the seeds of *I. polpha* collected in the Northern Territory [105].

3 Chemical Biology/Biomedicine

Glycosidase inhibitors are currently of great interest as potential therapeutic agents because modifying or blocking biological processes using glycosidase inhibitors can significantly affect carbohydrate anabolism and catabolism. It has been increasingly realized that glycosidase inhibitors have enormous potentials in many diseases such as diabetes, viral infection, and lysosomal storage disorders [1,2,3,4].

3.1 Glycosidase Inhibition

3.1.1 α-Glucosidase Inhibitors

The intestinal oligo- and disaccharidases are fixed components of the cell membrane of the brush border region of the wall of the small intestine. These enzymes digest dietary carbohydrate to monosaccharides which are absorbed through the intestinal wall. They include sucrase, maltase, isomaltase, lactase, trehalase, and hetero-β-glucosidase. In the late 1970s, it was realized that inhibition of all or some of these activities by inhibitors could regulate the absorption of carbohydrate and these inhibitors could be used therapeutically in the oral treatment of the non-insulin-dependent diabetes mellitus (NIDDM or type 2 diabetes) [11]. Acarbose (**88**; see *Fig. 8* for structures of **88**–**92**) is a potent inhibitor of pig intestinal sucrase with an IC_{50} value of 0.5 µM and this was also effective in carbohydrate loading tests in rats and healthy volunteers, reducing postprandial blood glucose and increasing insulin secretion [106]. After intensive clinical development, acarbose (Glucobay) was first launched in Germany in 1990 and has since then been successfully marketed in Europe and Latin America. In 1996, it was introduced onto the market in the United States under the brand name Precose.

Valiolamine (**89**), an aminocyclitol produced by *Streptomyces hygroscopicus* var. *limoneus*, is a potent inhibitor of pig intestinal maltase and sucrase, with IC_{50} values of 2.2 and 0.049 µM, respectively [107]. Numerous *N*-substituted valiolamine derivatives were synthesized to enhance its α-glucosidase inhibitory activity in vitro and the very simple derivative voglibose (**90**), which is obtained by reductive amination of valiolamine with dihydroxyacetone, was selected as the potential oral antidiabetic agent [108]. Its IC_{50} values toward maltase and sucrase were 0.015 and 0.0046 µM, respectively. Voglibose (the brand name Basen) has been commercially available for the treatment of type 2 diabetes in Japan since 1994.

Mulberry leaves have traditionally been used to cure "Xiao-ke" (diabetes) in Chinese medicine. The strong inhibition of digestive α-glucosidases by DNJ attracted the interest of various research groups and a large number of *N*-substituted DNJ derivatives were prepared in the hope of increasing the in vivo activity. Miglitol (**91**) was identified as one of the most favorable candidates showing a desired glucosidase inhibitory profile [109]. Miglitol differs from acarbose in that it is almost completely absorbed from the intestinal tract, and may possess systemic effects in addition to the effects in the intestinal border [110,111]. In 1996, Glyset (miglitol) tablets were granted market clearance by the US Food and Drug Administration (FDA) and introduced onto the market in 1999 as a more effective second-generation α-glucosidase inhibitor with fewer gastrointestinal side effects. In 2006, it was introduced onto the market in Japan under the brand name Seibule.

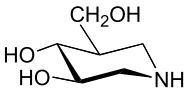
91



92

Figure 8
Structures of 88–92

α-Glucosidase inhibitors are especially suited for patients whose blood glucose levels are slightly above normal and can also benefit those who have high blood glucose right after they eat, a condition known as postprandial hyperglycemia. These drugs slow the rate at which carbohydrates are broken down into monosaccharides in the digestive tract and therefore lengthen the digestive process. Other antidiabetic agents such as sulfonylureas and biguanides sometimes are prescribed in combination with α-glucosidase inhibitors to help increase the effectiveness of this therapy. Protective effects of the α-glucosidase inhibitors have been reported for various diabetic complications. Interestingly, α-glucosidase inhibitors are also being studied as a possible treatment for heart disease, a common complication in diabetic patients. Although repetitive postprandial hyperglycemia increases ischemia/reperfusion injury, this effect can be prevented by treatment with α-glucosidase inhibitors [112].

3.1.2 Glycogen Phosphorylase Inhibitors

In type 2 diabetes, hepatic glucose production is increased [113]. A possible way to suppress hepatic glucose production and lower blood glucose in type 2 diabetes patients may be through inhibition of hepatic glycogen phosphorylase [114]. In enzyme assay, Fosgerau et al. reported

that DAB (**27**) is a potent inhibitor of hepatic glycogen phosphorylase [115]. Furthermore, in primary rat hepatocytes, DAB was shown to be the most potent inhibitor (IC_{50} 1 μM) of basal and glucagon-stimulated glycogenolysis ever reported [116]. Recently, Jakobsen et al. have reported that (3*R*,4*R*,5*R*)-5-hydroxymethylpiperidine-3,4-diol (isofagomine) (**92**) synthesized chemically is a potent inhibitor of hepatic glycogen phosphorylase, with an IC_{50} value of 0.7 μM, and furthermore, is able to prevent basal and glucagon-stimulated glycogen degradation in cultured hepatocytes with IC_{50} values of 2–3 μM [117]. However, its *N*-substitution always resulted in a loss of activity compared to the parent compound, and fagomine ((2*R*,3*R*,4*R*)-5-hydroxymethylpiperidine-3,4-diol) (**12**) was a weak inhibitor of this enzyme, with an IC_{50} value of 200 μM [117]. Glycogen phosphorylase inhibitors would be a beneficial target to attack in the development of new antihyperglycemic agents.

3.1.3 Herbal Medicines

Current scientific evidence demonstrates that morbidity and mortality of diabetes can be eliminated by aggressive treatment with diet, exercise, and new pharmacological approaches to achieve better control of blood glucose levels. In recent years, the possibility of preventing the onset of diabetes using dietary supplements and/or herbal medicines has attracted increasing attention. Mulberry leaves have been shown to have some antidiabetic properties. It was found that the mulberry leaf extract administered in a single dose of 200 mg/kg led to significant improvements in blood glucose levels in streptozotocin (STZ)-induced diabetic mice [118]. A study of 24 humans with type 2 diabetes found that patients treated with the mulberry agent had significant improvement in blood glucose control compared to a group treated with glibenclamide [119]. It is known that DNJ, fagomine, and DAB are contained in the mulberry leaves [14]. The evaluation for antihyperglycemic effects in STZ-induced diabetic mice has been carried out with fagomine [120]. Fagomine significantly reduced the blood glucose level 2 hours after intraperitoneal administration and its effect was sustained over 2 to 6 hours after administration. The effect of fagomine on immunoreactive insulin (IRI) release was investigated with the perfused pancreas of normal rats. The 8.3 mM glucose-induced IRI release was increased in the presence of fagomine in a concentration-dependent manner. The antihyperglycemic effects of the mulberry leaf extract would be a combination of α-glucosidase inhibition by DNJ and related compounds, the insulin releasing effect by fagomine, and glycogen phosphorylase inhibition by DAB.

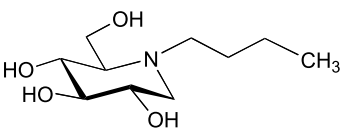
Thus, although traditional herbal medicines which have been used for a long time are candidates for diabetes prevention, it is very important to give scientific evidence for their antidiabetic effects. *Commelina communis*(Commelinaceae) has been used in traditional Chinese medicine as an antipyretic for noninfectious fever and to treat ascites, edema, and hordeolum [121], and is now very popular in Korea for the treatment of diabetes [122]. The MeOH extract of this plant shows a strong inhibitory activity against porcine intestinal α-glucosidases and contains DNJ (**4**), *manno*-DNJ (**5**), α-HNJ (**17**), 7-*O*-β-D-glucopyranosyl-α-HNJ, and DMDP (**25**) [123]. Alkaloids **4**, **17**, and 7-*O*-β-D-glucopyranosyl-α-HNJ are very potent inhibitors of digestive α-glucosidases, and DMDP as well as fagomine shows antihyperglycemic effects in STZ-induced diabetic mice [120]. These results support the pharmacological basis of this herb which has been used as a folklore medicine for the treatment of diabetes.

3.2 Molecular Therapy for Lysosomal Storage Disorders

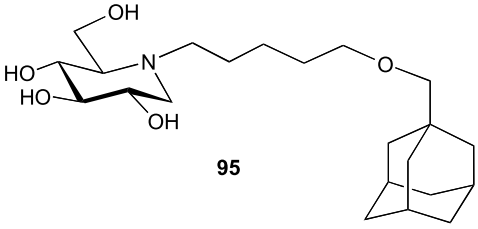
Recent experimental data show that some human genetic diseases are due to mutations in proteins that influence their folding and lead to retaining of mutant proteins in the ER and successive degradation [124,125]. Lysosomes are membrane-bound cytoplasmic organelles that serve as a major degradative compartment in eukaryotic cells. The degradative function of lysosomes is carried out by more than 50 acid-dependent hydrolases contained within the lumen [126]. The glycosphingolipid (GSL) storage diseases are genetic disorders in which a mutation of one of the GSL glycohydrolases blocks GSL degradation, leading to lysosomal accumulation of undegraded GSL [127]. Possible strategies for the treatment of these lysosomal storage diseases include enzyme replacement therapy, gene therapy, substrate deprivation, and bone marrow transplantation. The successful treatment for such diseases to date is the enzyme replacement therapy for patients with type 1 Gaucher disease and Fabry disease. However, this enzyme replacement therapy is useful only in the absence of neuropathology since enzymes do not cross the blood–brain barrier, and another problem with this therapy is the cost, which prevents many patients from obtaining this treatment. In recent years, remarkable progress has been made in developing a molecular therapy for the GSL storage disorders [3,4,128,129]. There are two novel approaches in this field. One is substrate reduction therapy and another is pharmacological (or chemical) chaperone therapy.

3.2.1 Substrate Reduction Therapy

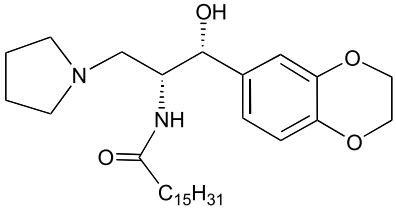
As long as the biosynthesis of substrate continues under the decrease of corresponding enzyme activity, the pathological accumulation of undegraded substrate in the lysosomes proceeds.



93



95



94

Figure 9
Structures of 93–95

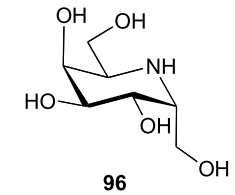
The aim of substrate reduction therapy is to reduce GSL substrate influx into the lysosomes by inhibitors of GSL synthesis. *N*-Butyl-DNJ (miglustat, Zavesca) (**93**; see *Fig. 9* for the structures of **93**–**95**) is an inhibitor of ceramide-specific glucosyltransferase [130]. Miglustat is the first orally active agent in the treatment of type 1 Gaucher disease. Gaucher disease is the most common lysosomal storage disorder caused by a deficiency of lysosomal β-glucosidase (known as β-glucocerebrosidase), resulting in the progressive accumulation of glucosylceramide. Type 1 Gaucher disease is non-neuronopathic and sometimes called the "adult" form. Ceredase in 1991 and its recombinant successor Cerezyme in 1994 were introduced as the enzyme replacement therapy of this type.

In 2001, Genzyme released preclinical data supporting Genz-78132 (the 3′ of D-threo-1-phenyl-2-palmitoilamino-3-pyrrolidino-1-propanol) (**94**) as the second-generation substrate reduction agent. The company has reported that Genz-78132 is 100–5000 times more potent in vitro for inhibition of cell surface ganglioside GM1, an indicator of glycosphingolipid synthesis, than the first-generation miglustat and *N*-(5-adamantane-1-yl-methoxypentyl)-DNJ (**95**). Furthermore, Genz-78132 is at least 20 times more potent in vivo than **95**, the most potent DNJ derivative [131]. Although there is no supporting clinical data, in preclinical studies Genz-78132 has a substantially greater therapeutic index than the first-generation inhibitors, which have shown limited efficacy and significant toxicity.

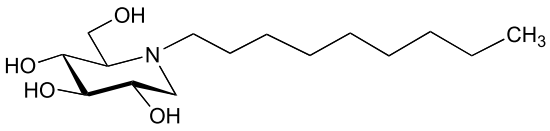
3.2.2 Pharmacological Chaperone Therapy

The concept of pharmacological chaperone therapy is that intracellular activities of misfolded mutant enzymes can be restored by administering competitive inhibitors that serve as pharmacological chaperones. These inhibitors appear to act as a template that stabilizes the native folding state in the ER by occupying the active site of the mutant enzyme, thus allowing its maturation and trafficking to the lysosome [128]. This concept was first introduced with Fabry disease [132]. Residual α-galactosidase A (α-Gal A) activity in lymphoblasts derived from Fabry patients and in tissues of R301Q α-Gal A transgenic mice was enhanced by treatment with *galacto*-DNJ (**6**), a competitive inhibitor of α-Gal A with a K_i value of 40 nM. Very recently, Yam et al. showed that *galacto*-DNJ induces trafficking of ER-retained R301Q α-Gal A to lysosomes of transgenic mouse fibroblasts and *galacto*-DNJ treatment results in efficient clearance of the substrate, globotriaosylceramide (Gb3) [133]. By testing a series of α-Gal A inhibitors for both in vitro inhibitory and chaperoning activities in lymphoblasts from Fabry patients, it was demonstrated that a potent inhibitor shows an effective chaperoning activity, whereas less potent inhibitors require higher concentrations to achieve the same effect [134]. *Galacto*-DNJ, α-*galacto*-HNJ (α-homogalactonojirimycin) (**96**; see *Fig. 10* for structures of **96**–**100**), **7**, and **21** are inhibitors of α-Gal A with IC_{50} values of 0.04, 0.21, 4.3, and 16 µM, respectively, and the respective addition at 100 µM to culture medium of Fabry lymphoblasts increases the intracellular α-Gal A activity by 14-, 5.2-, 2.4-, and 2.3-fold. Thus, potent and specific inhibitors of lysosomal glycosidases are expected to have therapeutic effects at lower concentrations.

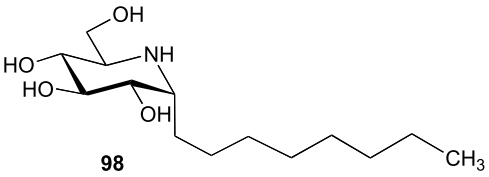
Sawker et al. reported that *N*-nonyl-DNJ (**97**) is a potent inhibitor of lysosomal β-glucosidase, with an IC_{50} value of 1 µM, and the addition of subinhibitory concentration (10 µM) of this compound to a fibroblast culture medium leads to a 2-fold increase in the mutant (N370S) enzyme activity [135]. Very recently, examination of a series of DNJ analogues on the resid-



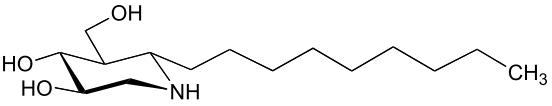
96



97



98



99

Figure 10
Structures of 96–100

ual activities of various lysosomal β-glucosidase variants has revealed that the nature of the alkyl moiety greatly influences their chaperoning activity: *N*-butyl-DNJ is inactive, the DNJ derivatives with *N*-nony and *N*-decyl chains are active, and *N*-dodecyl-DNJ is predominantly inhibitory [136]. However, it is also known that *N*-nonyl-DNJ is a potent inhibitor of ER

processing α-glucosidases like *N*-butyl-DNJ and hence has potential as anti-viral agents to inhibit folding and trafficking of viral envelope glycoproteins [137,138]. Inhibitors targeting a host function such as ER processing α-glucosidases must be carefully considered in terms of side-effects since they may inhibit folding, secretion, and trafficking of other glycoproteins in patient's cells or may inhibit directly lysosomal α-glucosidase after being taken up into cells. In fact, addition of *N*-nonyl-DNJ at 10 μM lowered the cellular lysosomal α-glucosidase activity by 50% throughout the assay period (10 days) in spite of the excellent chaperoning activity for the mutant β-glucosidase. The inhibition of lysosomal α-glucosidase as the side effect may induce storage of glycogen in the lysosomes, as observed in Pompe disease. On the other hand, α-1-*C*-octyl-DNJ (**98**), with a K_i value of 0.28 μM, showed a novel chaperoning activity for N370S Gaucher variants, minimizing the potential for undesirable side effects such as lysosomal α-glucosidase inhibition [139]. In addition, isofagomine [140], α-6-*C*-nonylisofagomine (**99**) [141], and α-1-*C*-nonyl-1,5-dideoxy-1,5-imino-D-xylitol (**100**) [142] are very potent inhibitors of lysosomal β-glucosidase and candidates as pharmacological chaperones for Gaucher disease.

A number of different pharmacological chaperones that correct folding states of mutant proteins and enable their trafficking to the proper locale would be excellent candidates for a new molecular therapy of human genetic disorders. It can be expected that orally administered pharmacological chaperones will become the standard treatment for broad genetic disorders with protein misfolding.

Abstract

It is well recognized that glycosidase inhibitors are not only tools to elucidate the mechanism of a living system manipulated by glycoconjugates but also potential clinical drugs and insecticides by inducing the failure of glycoconjugates to perform their function. In this chapter, the syntheses and functions of natural glycosidase inhibitors (cyclophelitol, allosamidine, and trehazoilin), which possess highly oxygenated and functionalized cyclohexanes or cyclopentanes in their structures and are defined as carbasugars, and the structure and activity relationships (SAR) of their derivatives are described. Also, recently much attention has been focused on

neuraminidase inhibitors as anti-influenza drugs since relenza, which was derived from sialic acid, and also, tamiflu, which is the artificial carbasugar designed as a transition state analogue in the hydrolysis pathway of substrates by neuraminidase, were launched in the market. Herein, the medicinal chemistry efforts to discover tamiflu and some efficient syntheses applicable to process chemistry are described. Finally, useful synthetic methodologies for carbasugar formation from sugars are also introduced in this chapter.

1 Introduction

Recently, a great deal of attention has been focused on the glycosidase inhibitors under the premise that glycoconjugates such as oligosaccharides, glycolipids, and glycoproteins play pivotal roles in living systems, and recently a scientific field called "glycogenomics" has been developed as a part of genomics science. Glycosidase inhibitors possess interesting enzyme-specific inhibitory activities, therefore, they are expected not only to be tools to elucidate the mechanisms of a living system manipulated by the glycoconjugates but also to be potential clinical drugs and insecticides by inducing the failure of glycoconjugates to perform their function: anti-obesity drugs, anti-diabetics, anti-fungal, and anti-viral including substances active towards the human immunodeficiency virus (HIV) [1,2,3,4,5,6,7].

Most of the glycosidase inhibitors are isolated from natural sources, and they possess interesting structures in their molecules. Some of them possess the highly functionalized and oxygenated cyclohexane or cyclopentane moieties. In general, these moieties are called cyclitols, and also in this chapter, glycosidase inhibitors possessing cyclitols in their molecular structures are defined as carbasugars. Biochemically, carbasugars and cylitols themselves are recognized as the pseudo-sugars in a living system, and they show interesting biological activities based on the structure similarity to sugars. In the meantime, chemically, such highly functionalized molecules are quite challenging targets for synthetic studies. The most interesting and significant points for the synthesis of glycosidase inhibitors possessing cyclitols are how we can form the frameworks of the cyclitols and how we can introduce the functional groups essential to generate their specific and interesting biological activities.

In the last few decades new generations of glycosidase inhibitors, e. g., cyclophelitol, allosamidin, mannnostatin, and trehazolin, have been isolated from natural sources, and the appearance of these natural products has contributed to the development of the new methodologies needed to perform the aforementioned synthetic tasks. Also, due to technical developments in the field of structure biology, the interaction between enzymes and inhibitors can now be visualized. This is helpful in the design of new scaffolds and elucidation of the detailed mechanisms of action involved. The creation of tamiflu, which is an artificially designed carbasugar showing neuraminidase (NA) inhibitory activity, is a good example favored by structure biology, and it has already been approved by US Food and Drug Administration (FDA) as an orally available anti-influenza drug.

Herein, I will describe a variety of synthetic strategies directed to total syntheses and chemical modifications of these glycosidase inhibitors and the structure and activity relationships of their derivatives. Also, the methodologies of carbasugar formation from sugars will be described.

2 Overview

One of the key points in the synthesis of carbasugars is the formation of the scaffolds of the cyclitol moieties, and three types of synthetic strategy can be considered:

(a) Transformation of sugars to cyclitols;
(b) Synthesis from nonsugar substrates by using asymmetric synthetic methodologies;
(c) Utility of the framework of intact cyclitols.

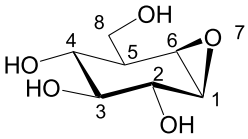
Also, in addition, much attention should be focused on the structure-activity relationships (SAR) on enzyme inhibitory activities influenced by their stereochemistry and their functional groups. Therefore, the synthetic strategies should be applicable to the synthesis of their stereoisomers and congeners, and, in practice, some of the synthetic strategies have also been designed in consideration of this point. In this chapter, case studies on total synthesis of cyclophelitol, tamiflu, allosamidin, and trehazolin, including the synthesis of their stereoisomers and congeners, will be described, and SAR of these compounds will be discussed. Finally, $SnCl_4$-promoted cyclitol formation and SmI_2-mediated cyclitol formation will be described as useful methodologies for the conversion of sugars to cyclitols as well as SmI_2-mediated carbasugar formation.

3 Synthesis of Carbasugars: New Generations of Glycosidase Inhibitors

3.1 New Generations of Glycosidase Inhibitors Bearing 6-Membered Cyclitol

3.1.1 Cyclophelitol: A β-Glucosidase Inhibitor

Cyclophelitol (**1**) is a β-glucosidase inhibitor isolated from a culture filtrate of the mushroom strain, *Phellinus* sp., and shows inhibitory activity towards almond β-glucosidase. In general, a series of β-glucosidase inhibitors such as castanospermine and 1-deoxynojirimycin have been reported to inhibit syncytium formation and infection with human immunodeficiency virus (HIV), possibly by perturbing the gp 120-linked glycan structure [8]. The structural feature of cyclophelitol is the fully oxygenated cyclohexane, which possesses the stereochemistry of the hydroxyl groups corresponding to that of D-glucose and the β-epoxy group at the C1, C6 positions. This β-epoxy group is recognized to be the equivalent of a β-glycoside moiety by enzyme, and it is considered that this is possibly the reason for the inhibitory activities exhibited towards β-glucosidases [9,10].

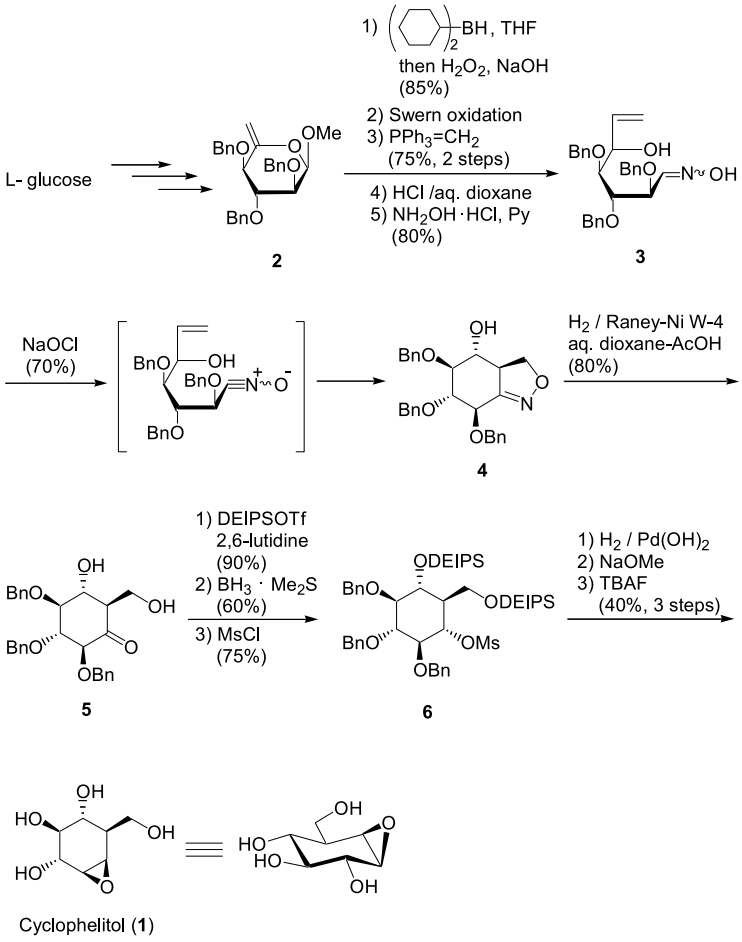


Cyclophelitol (**1**)

This interesting structure encouraged many organic chemists to undertake synthetic projects to develop appropriate synthetic methodologies, and several elegant syntheses of this compound have been reported.

The first total synthesis of cyclophelitol was achieved by Tatsuta's group in 1990 [11]. The key point of their synthetic strategy is the construction of this highly oxygenated cyclohexane via intramolecular [3+2] cycloaddition of a nitrile oxide to an alkene.

Oxime **3**, which was derived from L-glucose via stereoselective hydroboration of the *exo*-olefin of L-*xylo*-hex-5-enopyranoside **2** [12] with dicyclohexyl borane, Swern oxidation of the

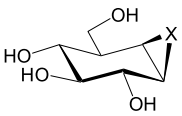


Scheme 1

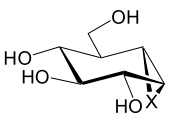
corresponding alcohol, subsequent Wittig alkenylation of the resulting unstable aldehyde with $Ph_3P{=}CH_2$, and acid hydrolysis, was treated with NaOCl to obtain isoxazoline **4** as a single product via the corresponding nitrile oxide [13,14]. The ring opening of isoxazoline **4** was achieved with H_2 and Raney nickel W-4 in aqueous dioxane in the presence of AcOH to afford the corresponding keto-diol **5**.

After diethylisopropylsilylation [15], which can be easily removed under hydrogenolysis conditions using $Pd(OH)_2$ on carbon, the resulting ketone was reduced with $BH_3{\cdot}SMe_2$ stereoselectively, to furnish the desired α-alcohol. Mesylation of this α-alcohol provided the labile mesylate **6**, which was subjected to hydrogenolysis with $Pd(OH)_2$ on carbon to give the de-*O*-benzylated compound. Epoxidation of this debenzylated compound with NaOMe and subsequent removal of the silyl groups of the corresponding epoxide with TBAF afforded cyclophelitol (**1**) (*Scheme 1*).

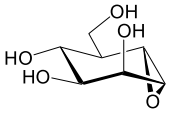
For further studies regarding structure-activity relationships on the enzyme inhibitory activities influenced by the stereochemistry of cyclophelitols, Tatsuta's group also synthesized a series of cyclophelitol-related compounds.



1:X=O (Cyclophelitol)
9:X=NH
11: X=S

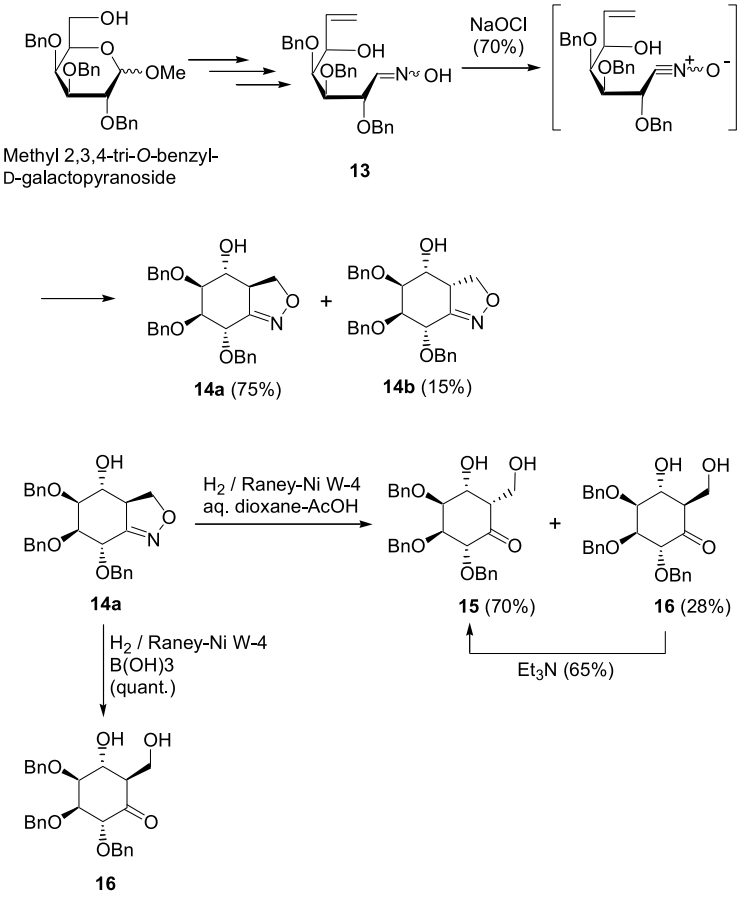


7: X=O (1,6-*epi*-Cyclophelitol)
10: X=NH
12: X=S

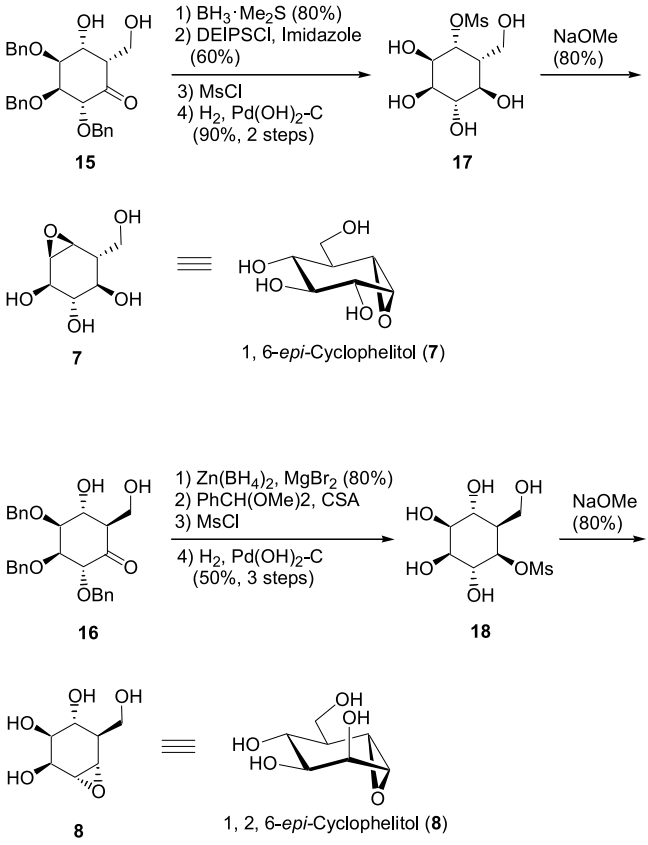


8: 1,2, 6-*epi*-Cyclophelitol
α-mannno-type analogue

The syntheses of 1,6-epi-cyclophelitol (**7**) and the 1,2,6--cyclophelitol *α-manno*-type analogue (**8**) are outlined in ❯ *Scheme 2* and ❯ *Scheme 3* [16]. These compounds were synthesized from



Scheme 2



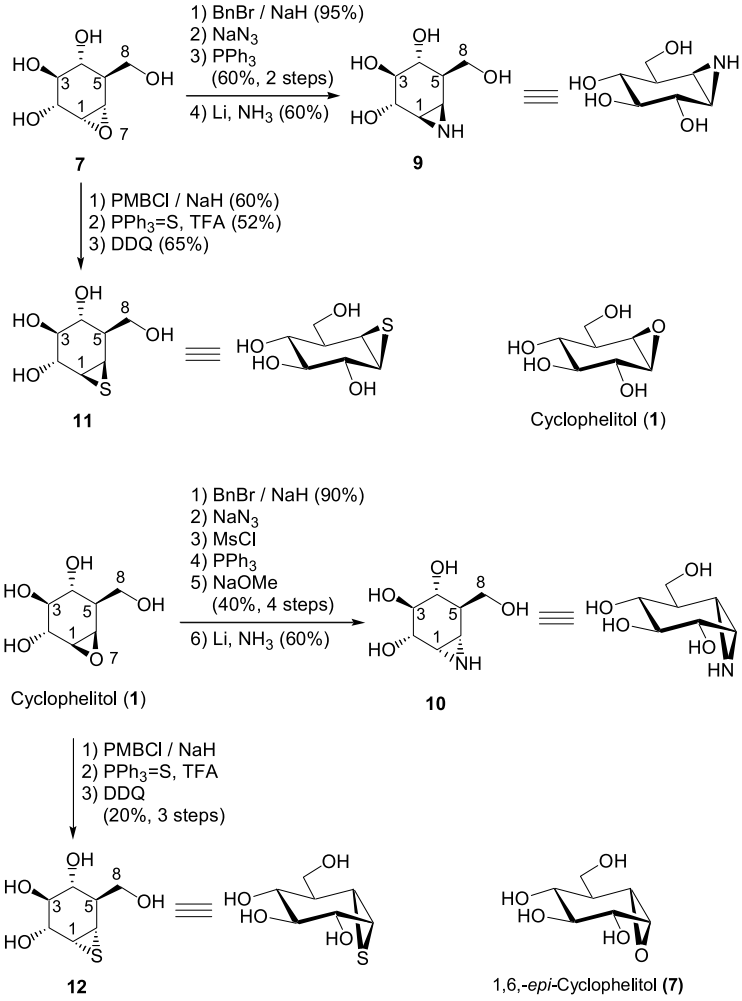
Scheme 3

a common intermediate, isoxazoline **14a**, which was derived from methyl 2,3,4-tri-*O*-benzyl-α-D-galactopyranoside via the above-mentioned intramolecular [3+2] cycloaddition. Interestingly, in the case of the synthesis of 1,6-*epi*-cyclophelitol (**7**), isoxazoline **14a** although substantially undesired to produce compound **7**, which is derived from oxime **13**, was subjected to acidic hydrogenolysis with Raney nickel W-4 to afford the desired keto-alcohol **15** with epimerization at the C1 position.

In contrast, in the case of the synthesis of the α-*manno*-type analogue, hydrogenolysis of isoxazoline **14a** which is desired to obtain compound **8** was conducted using Raney nickel and $B(OH)_3$ to furnish the desired keto-alcohol **16** in a quantitative yield (*Scheme 2*).

These keto-alcohols **15** and **16** were converted into 1,6-*epi*-cyclophelitol (**7**) and the 1,2,6-*epi*-cyclophelitol α-*manno*-type analogue (**8**), respectively, according to the synthetic route shown in *Scheme 3*.

Furthermore, on the basis of these syntheses, this group also synthesized the β-azirizine analogue (**9**) from 1,6-*epi*-cyclophelitol (**7**) and the α-azirizine analogue (**10**) from cyclophelitol (**1**), respectively [17,18]. In addition, the thiirane analogues (**11**) and (**12**) were also synthe-



Scheme 4

sized from 1,6-*epi*-cyclophelitol (**7**) and cyclophelitol (**1**), respectively, by treatment of their *O*-PMB derivatives with $Ph_3P{=}S$ and trifluoroacetic acid, followed by de-*O*-*p*-methoxybenzylation with DDQ (*Scheme 4*) [18].

As shown in *Table 1*, glycosidase inhibitory activities of these cyclophelitol-related compounds were evaluated [19].

In contrast to cyclophelitol (**1**) with inhibitory activity toward only β-D-glucosidase at an IC_{50} of 0.8 µg/ml, 1,6-*epi*-cyclophelitol (**7**) exhibited inhibitory activity toward only α-D-glucosidase at an IC_{50} of 10 µg/ml and α-*manno*-type analogue (**8**) showed inhibitory activity toward α-mannosidase at an IC_{50} of 19 µg/ml. Also, the β-azirizine analogue (**9**) exhibited high inhibitory activity toward β-glucosidase at an IC_{50} of 0.22 µg/ml, while the α-azirizine analogue (**10**) showed little α-glucosidase inhibitory activity. Interestingly, both thiirane ana-

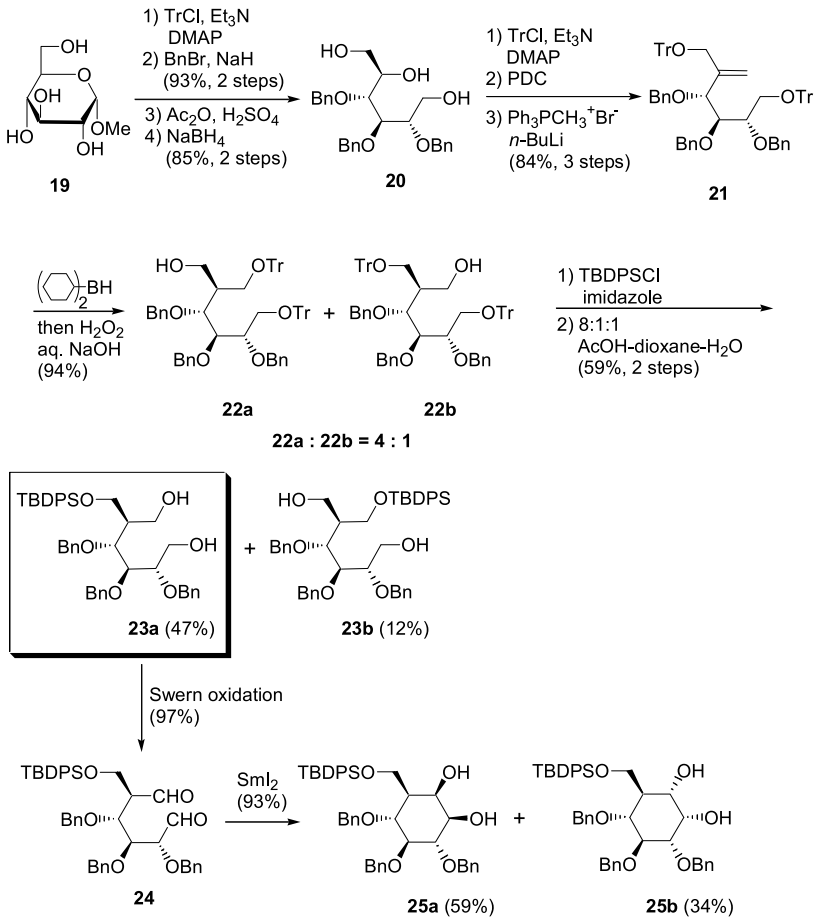
Table 1
Inhibitory activity of cyclophelitol (1) and its related compounds 7–9 towards glycosidases

Inhibitory activity of cycliphelitol (**1**) and its related compounds **7- 9** towards glycosidases

Glycosidase	Inhibitors (IC_{50} : μg/ml)		
α-D-glucosidase[a]		 **7** (10)	
β-D-glucosidase[b]		 **1** (0.8)	 **9** (0.22)
α-D-mannosidase[c]		 **8** (19)	

[a]Baker's yeast α-D-glucosidase; [b]Almond β-D-glucosidase;
[c]Snail β-D-mannosidase

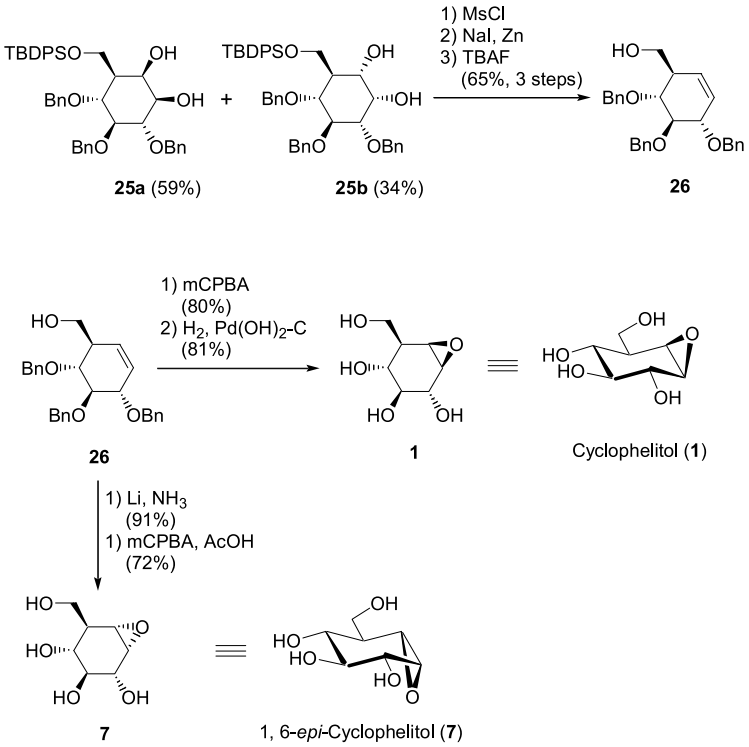
logues (**11**) and (**12**) showed no significant activities. With respect to this SAR on glycosidase inhibitory activities of these compounds, Tatsuta's group concluded the following;
Structurally, cyclophelitol (**1**) and its *β*-azirizine analogue (**9**) have *quasi*-equatorially oriented C1–O and C1–N bonds, which correspond to the equatorial C1–O bond *β*-glucopyranosides, whereas 1,6-*epi*-cyclophelitol (**7**) and *α*-*manno*-type analogue (**8**) have *quasi*-axial C1–O bonds corresponding to the axial C1–O bond of *α*-D-glycopyranosides. Their glycosidase inhibitory activities emphasized that the *α*- and *β*-glycosidase recognized especially the C-1 positions and the residual portions as corresponding to those of *α*- and *β*-glycopyranosides. Consequently, these glycosidase inhibitors (**1**), (**7**), (**8**), and (**9**) serve as antagonists of the corresponding *α*- and *β*-D-glycopyranosides.
Nakata et al. reported the straightforward and practical synthesis of cyclophelitol (**1**) and 1,6-*epi*-cyclophelitol (**7**) from D-glucose via SmI_2-mediated reductive coupling [20]. Hydroboration of olefin **21**, which was derived from methyl *α*-D-glucopyranoside (**19**) in seven steps, with dicyclohexylborane afforded the mixture of alcohols **22** (**22a**:**22b** = 4:1). After silylation with TBDPSCl, followed by selective acid hydrolysis of the Tr group, which furnished both the desired diol **23a** and the undesired one **23b** in 47 and 12% yield, respectively, subsequent Swern oxidation of the desired alcohol **23a** afforded dialdehyde **24**. This dialdehyde **24** was treated with SmI_2 [21,22,23,24,25], to give separable *cis*-diols **25a** and **25b** (*Scheme 5*).
Each diol was converted to the same olefin **26** by mesylation, reduction, and subsequent desilylation. Compound **26** was transformed to cyclophelitol (**1**) via stereoselective epoxidation, and on the other hand, debenzylation of **26** followed by epoxidation provided 1,6-*epi*-cyclophelitol (**7**) (*Scheme 6*).



Scheme 5

Fraser-Reid's group reported the synthesis of Tatsuta's penultimate intermediate, the mesylates for cyclophelitol (**1**) and 1,6-*epi*-cyclophelitol (**7**) via a 6-*exo-dig* radical cyclization of 2-deoxy-2-iodo-6-alkenyl glycoside and completed the formal total synthesis of cyclophelitol (**1**) and 1,6-*epi*-cyclophelitol (**7**) [26]. Swern oxidation of glucal **27**, alkynylation of the corresponding aldehyde and subsequent acetylation of the resulting alcohols afforded an epimeric mixture **28**. Thiem's iodoalkylation of **28** [27,28] provided the 2-deoxy-2-iodo-6-alkynyl glycoside **29**, and the radical cyclization of **29** with Bu_3SnH and AIBN [29,30,31,32] gave a quantitative yield of material which, after deacetylation, could be fractionated into two sets of isomers comprised of diastereomeric [2.2.2]oxabicycloglycoside **30** and 2-deoxy epimer **31**. Finally, compound **30** was converted into mono alcohol **35** in four steps (*Scheme 7*).

On the basis of the configuration at C1 (cyclophelitol numbering), the components of this diastereomeric mixture were divided into **35a** and **35b**, which were correlated to Tatsuta's intermediates. Compound **35a** was transformed to Tatsuta's mesylate **39** for 1,6-*epi*-

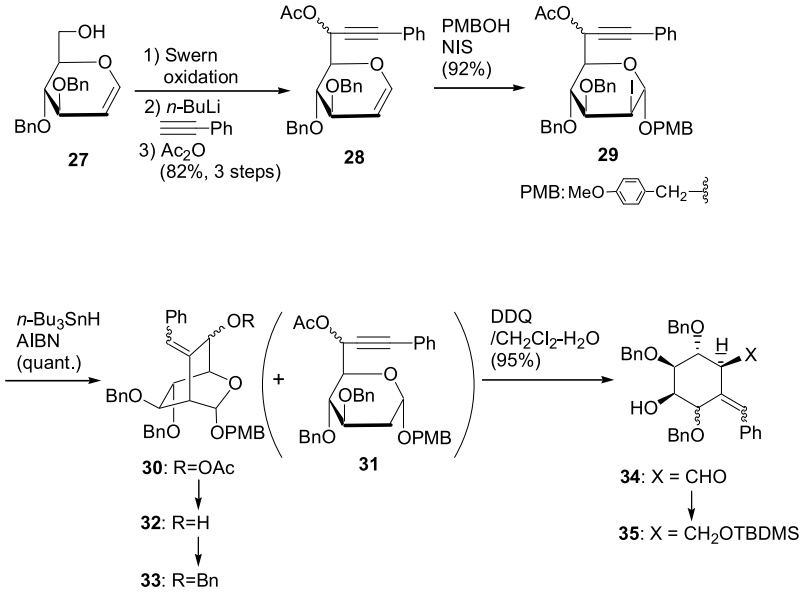


Scheme 6

cyclophelitol (**7**) in seven steps including C2–OH inversion via oxidation/reduction with the Dess–Martin reagent [33]/$NaBH_4$, ozonolysis followed by $BH_3{\cdot}SMe_2$ reduction, and mesylation of the corresponding alcohol. On the other hand, **35b** was also converted into Tatsuta's mesylate **47** for cyclophelitol (**1**) in ten steps involving ozonolysis followed by stereocontrolled reduction with $NaBH(OAc)_3$ [34,35] via complex **40** and C2–OH inversion via oxidation/reduction with the Dess–Martin reagent/$BH_3{\cdot}SMe_2$ (*Scheme 8*).

Ferrier reaction [36,37] is well-known as a representative of the synthetic methodologies for the conversion of intact sugars into cyclitols. It is not exceptional that Ferrier reaction was also used for total synthesis of cyclophelitol as a key step for cyclitol formation.

The synthesis reported by Sato et al. [38] is shown in *Scheme 9*. The features of this synthesis are the stereoselective introduction of a dichloromethyl function to C2-ketone **48** [39], which was derived from D-glucose, and the conversion of **49** with $NaBH_4$ in DMSO into the 2-deoxy-2-*C*-hydroxymethyl α-D-glucopyranoside derivative **50**, and furthermore, Ferrier reaction of *exo*-olefin **51**, which was derived from **50** in two steps, with $HgCl_2$ in acetone/H_2O, and subsequent treatment of the product with MsCl and Et_3N provided the desired α,β-unsaturated ketone **52**. Stereoselective 1,2-reduction of **52** with $NaBH_4$ and $CeCl_3{\cdot}7H_2O$, protection of the corresponding alcohol with a TBDMS group, and subsequent cleavage of acyl groups under the basic conditions afforded triol **53**. The epoxidation to the olefin part of triol **53** was proceeded stereoselectively favored by the bulky TBDMS group, to afford epoxide **54** which

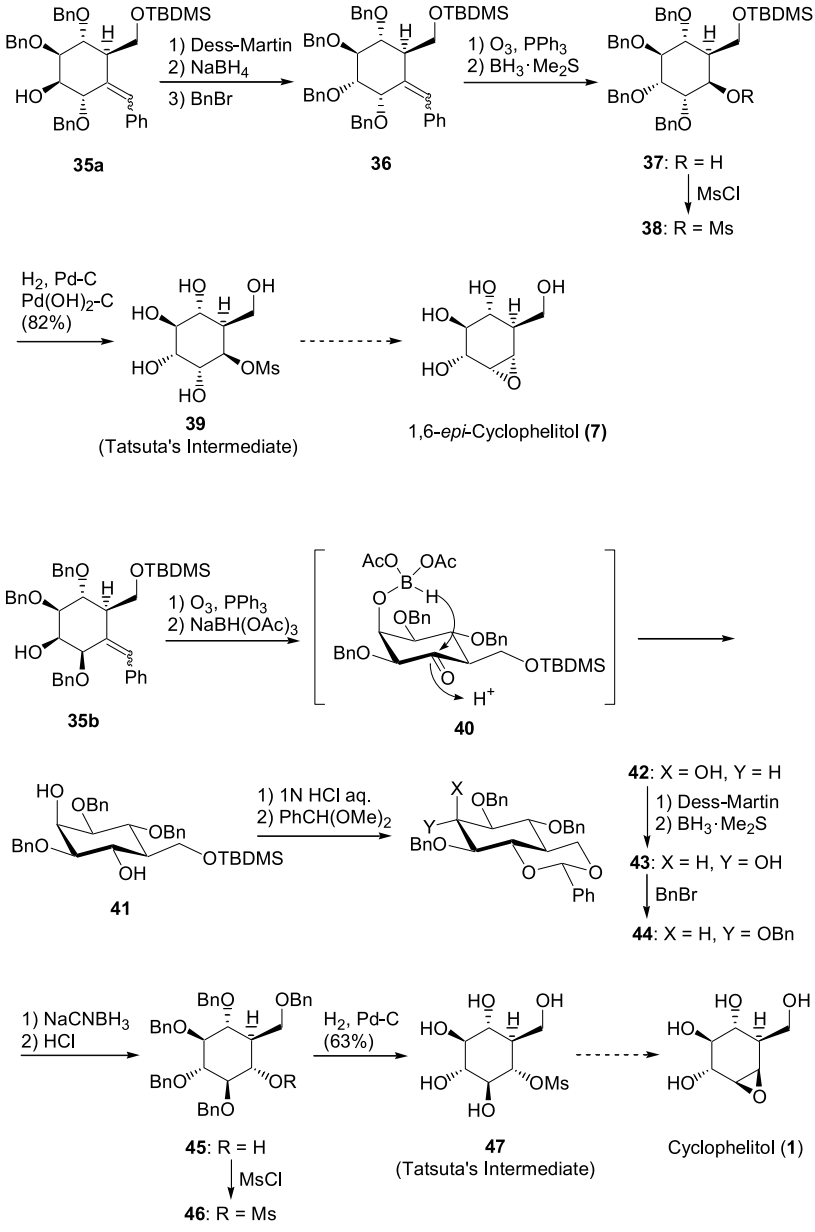


Scheme 7

possesses the desired stereochemistry, and subsequent acid desilylation furnished cyclophelitol (**1**) (*Scheme 9*).

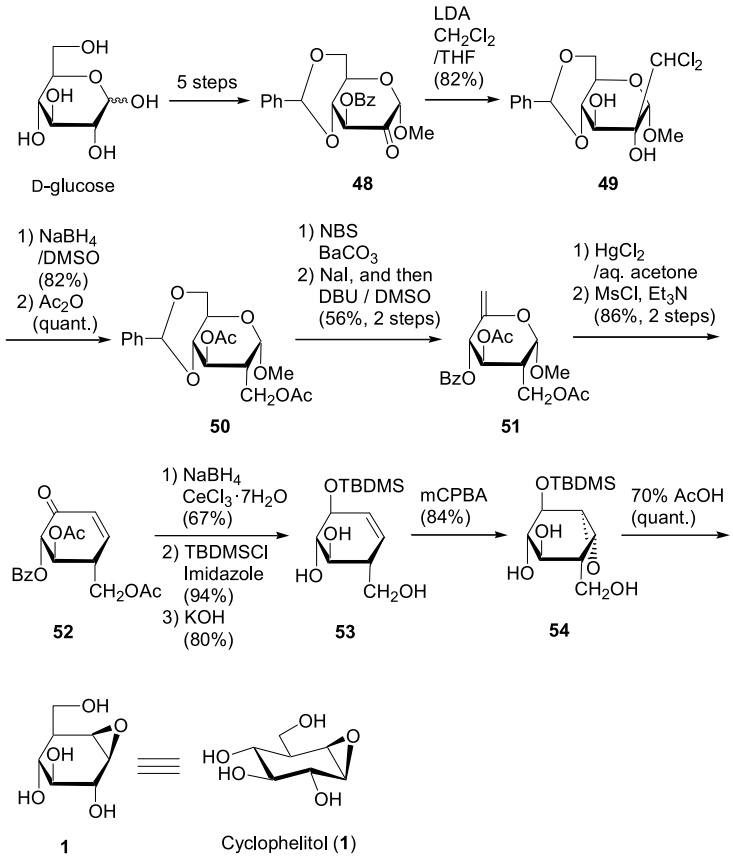
Also, Jung et al. reported the total synthesis of cyclophelitol (**1**) and 1,6-*epi*-cyclophelitol (**7**) using Ferrier reaction as its key steps for cyclitol formation [40]. The known methyl benzylidenemannoside **55** [41], which was derived from D-mannose in two steps, was converted into alkene **56** via regioselective benzylation of the equatorial hydroxyl group of **55** [42,43], Swern oxidation of the remaining hydroxyl group, and subsequent Wittig reaction. Hydroboration of **56** was expected to occur preferentially from the axial direction, *anti* to the sterically hindering axial methoxy group. However, unexpectedly, the reaction furnished a 1:1 mixture of two isomeric hydroxymethyl compounds **57a** and **57b**. Even with a sterically bulky borane such as 9-BBN the reaction afforded a 1:2 mixture in favor of **57b**. The problem of the production of exclusively the equatorial isomer was solved by Swern oxidation of the mixture, subsequent quantitative equilibration to the β-aldehyde in a mild base, and reduction of the corresponding α-aldehyde to give only the desired equatorial hydroxymethyl compound **57a**. Benzylation, reductive opening of the benzylidene acetal, iodination, and elimination furnished *exo*-olefin **58**. Ferrier reaction of **58** and subsequent elimination gave the desired enone **59**. 1,2-reduction of **59** to the corresponding allylic alcohol and subsequent benzoylation gave compound **60**, and epoxidation of **60** with mCPBA provided a mixture of the epoxides. Cleavage of all protective groups produced cyclophelitol (**1**) and 1,6-*epi*-cyclophelitol (**7**) (*Scheme 10*).

Recently, ring-closing metathesis (RCM) using Grubbs catalyst [44] became popular in the field of the synthesis of natural products. This methodology was also used in the synthesis of cyclophelitols. The synthesis using RCM was reported by Ziegler et al. and started from D-xylose as shown in *Scheme 11* [45]. Didithioacetal **61**, which was derived from D-xylose,



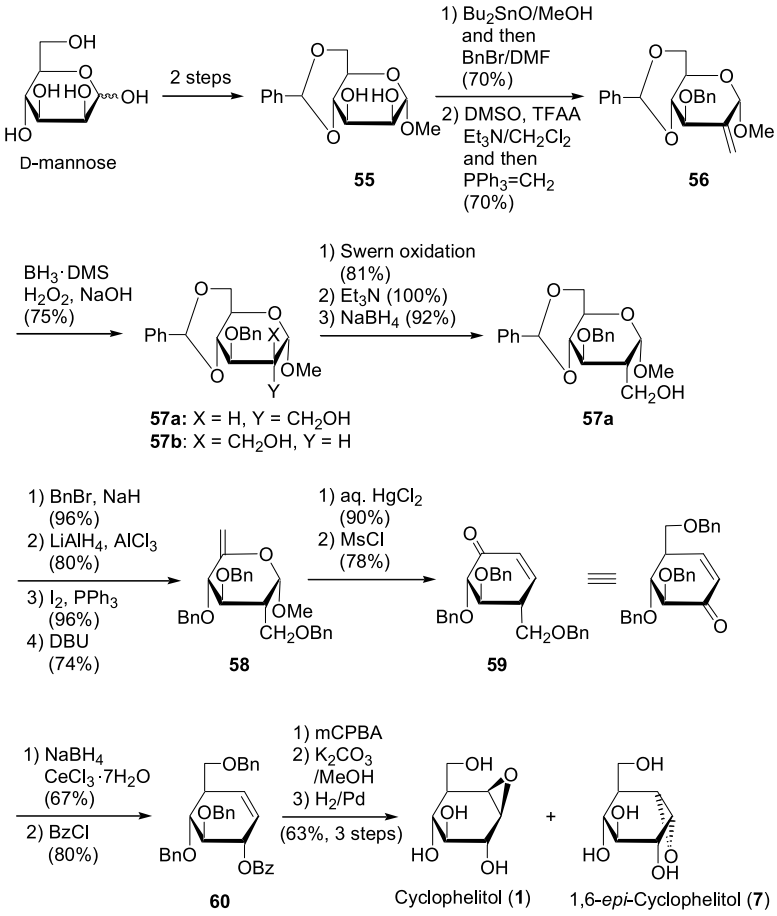
Scheme 8

was converted into aldehyde **63** in three steps that were silylation of the primary alcohol, benzylation of all the remaining secondary hydroxyl groups, and subsequent removal of dithioacetal with HgO and $HgCl_2$. Methylenation to aldehyde **63** was performed with Tebbe's reagent in place of the Wittig reaction because the basic methylenation with Wittig reaction gave sev-



Scheme 9

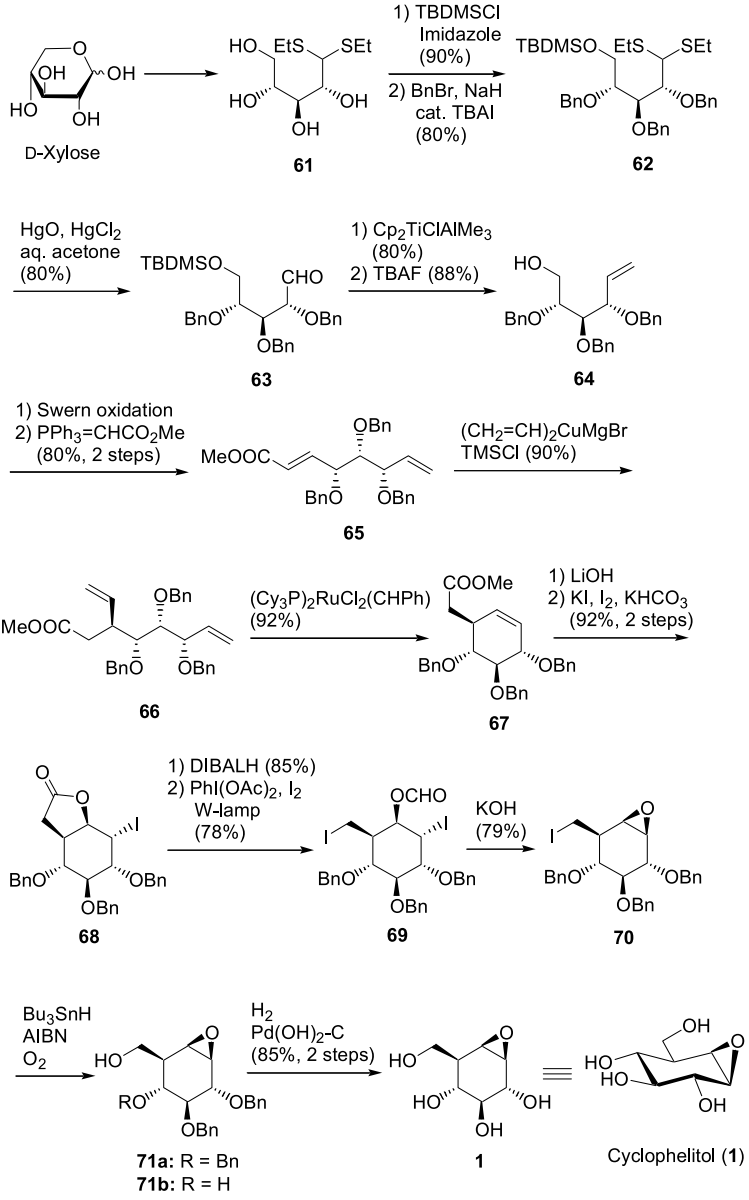
eral by-products such as the unsaturated aldehyde and its diene derived from β-elimination of benzyl alcohol from aldehyde **63** as well as the desired olefin **64**. After Swern oxidation of the remaining primary hydroxyl group, Wittig reaction of the corresponding aldehyde with PPh_3=$CHCO_2Me$ afforded α, β-unsaturated ester **65**. One of the problems to be solved here was the stereoselective 1,4-addition to α, β-unsaturated ester **65**. In this case, the best method for this objective is the magnesium-based vinyl cuprate, which was employed under the protocol reported by Hanessian [46] to give **66** with both high yield and high stereoselectivity. Afterwards, RCM to **66** using Grubbs catalyst provided cyclohexene **67** efficiently, and subsequent iodolactonization to **67** afforded iodide **68**. Iodide **68** was converted into the β-epoxide **70** according to the Saurez procedure [47,48]. After reduction of **68** with DIBALH, the resulting lactol efficiently afforded diiodideformate **69** upon irradiation in the presence of $PhI(OAc)_2/I_2$ [49]. Subsequently, base treatment of **69** gave iodoepoxide **70**. The transformation of iodine to a hydroxyl group was accomplished by radical oxygenation to afford a mixture of epoxyalcohol **71a** and epoxydiol **71b**. Finally, hydrogenolysis of a mixture of the epoxides **71a** and **71b** removed the benzyl groups to afford cyclophelitol (**1**) (*Scheme 11*).



Scheme 10

Kornienko's group reported the formal synthesis of cyclophelitol (**1**) via RCM to the diene derived from D-xylose [50]. Their synthetic strategy was interestingly focused on the latent plane of chirality present in D-xylose as shown in *Fig. 1*, and the enantiodivergent synthesis of (+)- and (–)-cyclophelitol from D-xylose was achieved (*Fig. 1*).

Their enantiodivergent strategy relies on the synthesis of both enantiomeric forms of Ziegler's enoate **72 (=65)**. They have reported a straightforward preparation of enoate **72** from 2,3,4-tri-*O*-benzyl-D-xylopyranose by way of Wittig methylenation, Swern oxidation, and reaction of the resulting aldehyde with $PPh_3{=}CHCO_2Me$ [51]. On the other hand, the synthesis of *ent*-**72** by directly reversing the order of the two olefination steps was not always successful because of an enoate reactivity problem. To circumvent this problem, the anomeric position of 2,3,4-tri-*O*-benzyl-D-xylopyranose was protected to form ethyl thioacetal, and subsequent Swern oxidation of the remaining primary hydroxyl group, followed by the intermediate treatment of the corresponding aldehyde with $PPh_3{=}CH_2$, deprotection of ethyl thioacetal, and olefination of the corresponding aldehyde with $PPh_3{=}CHCO_2Me$ cleanly provided the desired



Scheme 11

enantiomeric enoate *ent*-**72** in excellent yield. With the synthetic route to **1** and *ent*-**1** available, the feasibility of accessing each cyclophelitol enantiomer was demonstrated by completing the synthesis of the (+)-antipode. Addition of a vinylcopper reagent to enoate **72** provided ester **73** in excellent yield and exclusive *anti* selectivity. Treatment of potassium enolate of ester

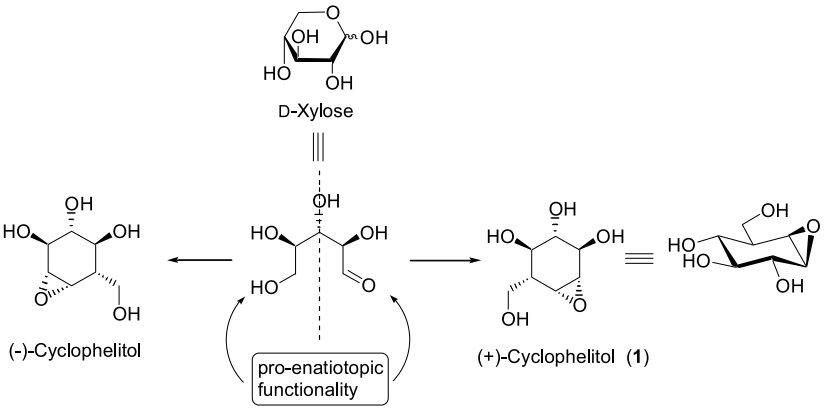


Figure 1
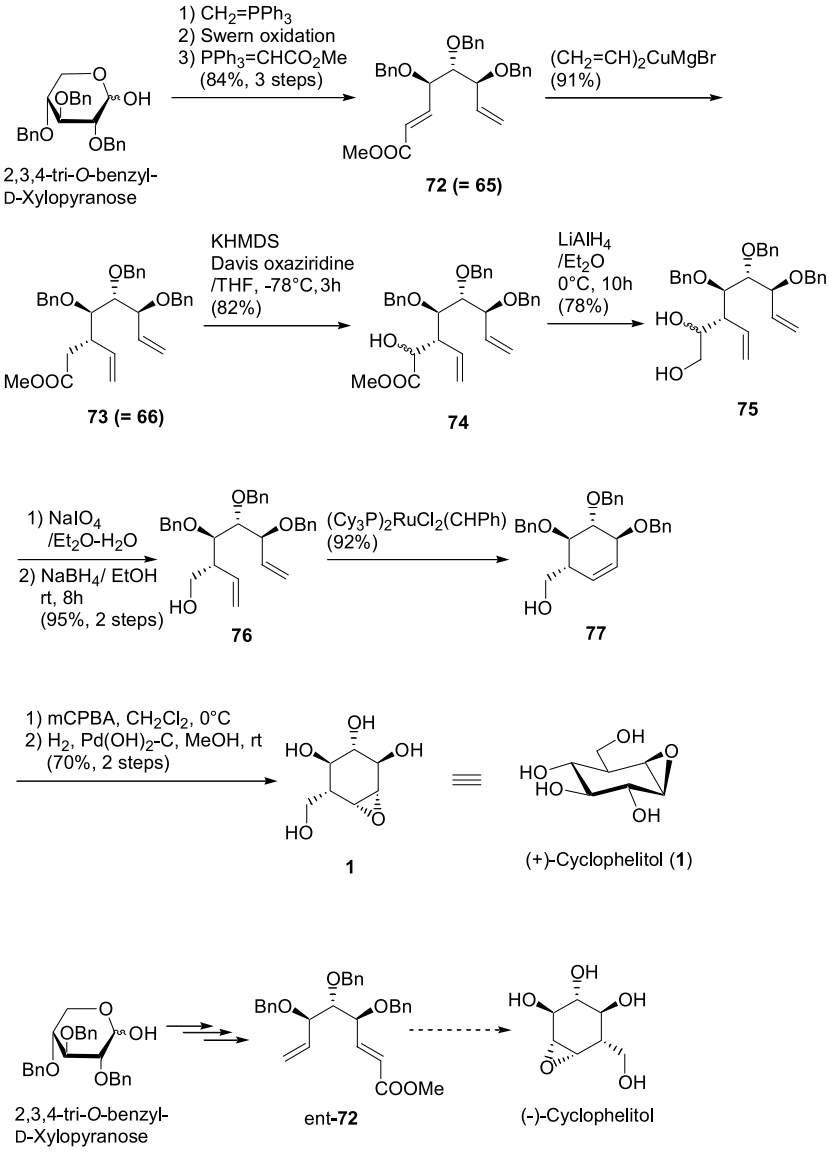
"Latent symmetry" approach for the synthesis of cyclitol enantiomers

73 with Davis oxaziridine gave a 1:1 mixture of α-hydroxylated derivatives **74**, which was reduced to diols **75**. Cleavage of the vicinal diol functionality with $NaIO_4$ followed by treatment of the corresponding aldehyde with $NaBH_4$ gave alcohol **76**. Finally, RCM of alcohol **76** with the first generation Grubbs' ruthenium catalyst resulted in conduritol analogue **77**. Since the transformation of **77** to (+)-cyclophelitol (**1**) by way of directed epoxidation and hydrogenolytic deprotection was reported by Trost's group [52,53], this pathway constituted a formal synthesis of the natural product (*Scheme 12*).

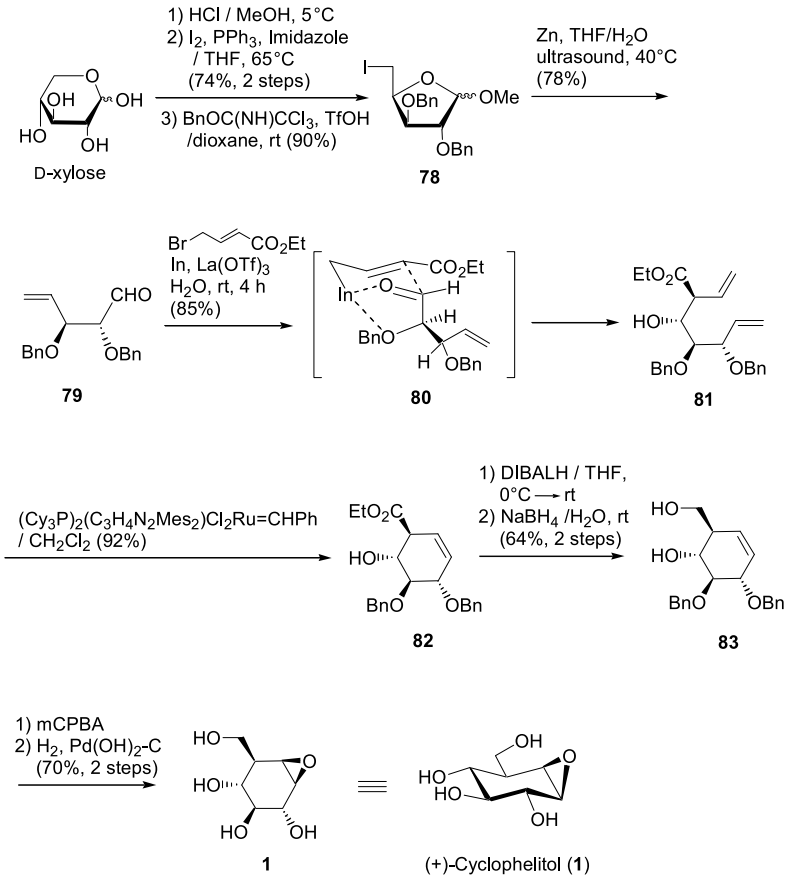
Madsen et al. also reported the synthesis of cyclophelitol (**1**) from D-xylose via RCM [54]. The key transformations involve a zinc-mediated fragmentation of benzyl protected methyl 5-deoxy-5-iodo-xylofuranoside (**78**) followed by a highly diastereoselective indium-mediated coupling with ethyl 4-bromocrotonate as shown in *Scheme 13*. Compound **78**, which was derived from D-xylose in three steps including acidic methyl glycosylation, iodination to primary alcohol, and subsequent benzylation to the remaining hydroxyl groups with benzyl trichloroacetimidate under acidic conditions, was sonicated with zinc to afford unsaturated aldehyde **79**. The indium-mediated addition reaction to **79** with ethyl 4-bromocrotonate and 60 mesh indium powder (99.999% pure) in the presence of $La(OTf)_3$ [55,56,57] provided the desired product **81** as only one diastereomer. The generation of the only desired diastereomer **81** can be explained by invoking a chelated intermediate such as **80**. Diene **81** was converted into the corresponding cyclohexene **82** by RCM with Grubbs' second generation catalyst [58]. The ester functionality was reduced with DIBALH to afford diol **83**. This reduction was quite sluggish and afforded minor amounts of the intermediate aldehyde as a byproduct. Using a larger excess of DIBALH or a higher temperature did not solve the problem. It is interesting that water and $NaBH_4$ instead were added in the workup to drive the reaction to completion. Epoxidation of **83** with mCPBA was completely stereoselective to afford the desired epoxide without another isomer, and finally the corresponding epoxide was deprotected by hydrogenolysis to furnish cyclophelitol (**1**) (*Scheme 13*).

An interesting approach to cyclophelitol (**1**) is its synthesis via the nonracemic Diels–Alder reaction to form the scaffold of cyclophelitol as performed by Schlessinger's group, shown



Scheme 12

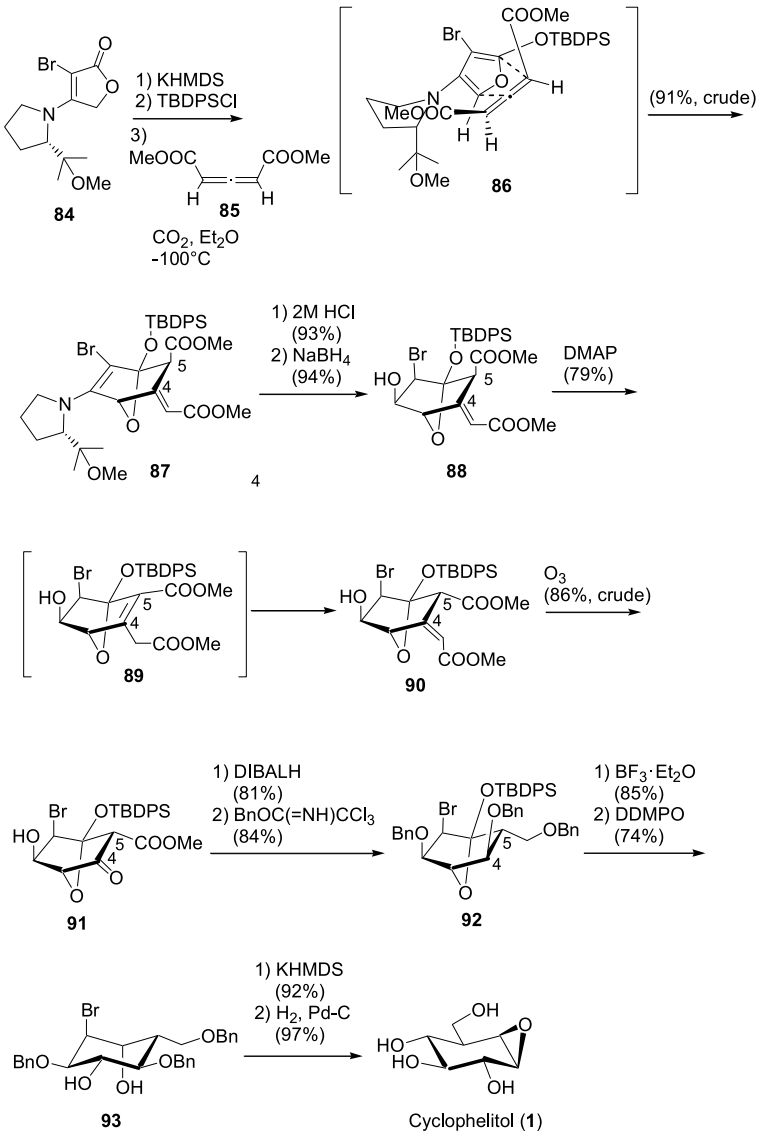
in *Scheme 14* [59]. To the nonracemic furan which was prepared by deprotonation of the vinylogous lactone **84**, followed by treatment of the resulting potassium enolate with TBDPSCl, dimethyl 2,3-pentadienedioate **85** was added [60], and the resulting compound **87**, which contained the requisite elements of structure and functionality for conversion to cyclophelitol (**1**), was obtained as a crude product via the proposed transition state **86**. Acid hydrolysis of **87**, and subsequent reduction of the corresponding bromoketone with $NaBH_4$ gave the *syn*-



Scheme 13

bromohydrin **88**, which possesses the correct functionality and stereochemistry at C1 and C2, respectively, as required by the structure (**1**). To reform C4 and C5 of **88** for the structure (**1**), firstly the stereochemistry of the axial ester at C5 was adjusted by treatment with DMAP via intermediate **89**, to afford the epimerized C5 equatorial ester **90**. Ozonolysis of **90**, reduction of the resulting ketone of **91** with DIBALH, and subsequent benzylation of the corresponding alcohol under acidic conditions afforded compound **92** possessing the correct stereochemistry at C4 for cyclophelitol synthesis. The oxabicycloketal moiety of tribenzyl ether **92** was cleaved smoothly with $BF_3{\cdot}Et_2O$ to afford the tractable cyclohexanone. Diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide (DDMPO) [61,62] treatment of this cyclohexanone gave **93** stereoselectively. After the transformation of bromohydrin **93** to the epoxide with KHMDS, hydrogenolysis of the corresponding, fully protected epoxide furnished cyclophelitol (**1**) (*Scheme 14*).

Finally for this section, as another asymmetric synthesis of cyclophelitol (**1**), the synthetic effort of Trost's group will be introduced [52]. Their synthesis was conducted based on the palladium-catalyzed kinetic resolution of racemic conduritol B tetraacetate (±)-**94**. Since racemic



Scheme 14

conduritol B is easily accessed from benzoquinone, two issues needed to be addressed: (1) how could racemic conduritol B easily be resolved and (2) how could the hydroxyl groups be readily differentiated. Trost's group considered that asymmetric palladium catalysts offer a simple solution to both of these issues. On the basis of their preliminary study on a palladium-catalyzed kinetic resolution of the racemic C_2-symmetric tetraacetate (±)-**94**, they expected that it should be possible using the chiral ligand (*R*, *R*)-**95**, since, with respect to the ligand, one enantiomer of (±)-**94** would provide a "matched" substrate for ionization while the oth-

er would be "mismatched" [63]. In the meantime, a pivalate was chosen as the carboxylate nucleophile for the resolution because the resultant allyl pivalate was anticipated to ionize much more slowly than the starting material and the pivalate should provide a means for easy differentiation of the alcohol protecting groups later on. The kinetic resolution of (±)-**94**, which was synthesized from in three steps from benzoquinone, was carried out using 0.65 equiv. of sodium pivalate (formed in situ from 0.80 equiv. of PvOH and 0.65 equiv. of NaOH) with 1 mol% of **96** and 3 mol% of **95** at 0.5 M in a two-phase methylene chloride/water system with tetrahexylammonium bromide (THAB) as a phase transfer catalyst. The reaction stopped cleanly at 50% conversion providing a quantitative yield (based on 50% theoretical yield) of recovered tetraacetate (+)-**94** and an 88% yield (based upon a 50% theoretical yield) of monopivalate (–)-**97** with only 1% of dipivalate isolated. Chiral HPLC analysis of (–)-**97** showed it to have 97% ee. Cleavage of Ac groups of (–)-**97** in the presence of the Pv group was straightforward with NH_4OH in MeOH to provide triol **98**. With access to enantiomerically pure triol **98**, the conversion of **98** into cyclophelitol (**1**) was carried out as summarized in ❯ *Scheme 15*. They made the synthetic strategy using 2,3-sigmatropic rearrangement of an alkoxymethyl anion [64] as the key step, and use of this rearrangement required protection of the free hydroxyl groups as the benzyl ethers. After pivalate cleavage of the corresponding benzyl ethers, the tin derivative **99** was readily formed. Tin-lithium exchange promoted the 2,3-sigmatropic rearrangement to put the hydroxymethyl group in place with correct regio- and diastereochemistry with production of **101 (=77)** via transition state **100**. Epoxidation with mCPBA, directed by the homoallylic alcohol, gave a 78% yield of the desired epoxide, with a 7% yield of the diastereomeric epoxide. Completion of the synthesis by the hydrogenation procedure published by Ziegler et al., gave (+)-cyclophelitol (**1**) (❯ *Scheme 15*).

In this section, a variety of the synthetic efforts on cycliphelitol (**1**) were introduced. From these efforts, useful synthetic methodologies to synthesize highly functionalized cyclitols were developed, and, in practice, they favored SAR analysis on glycosidase inhibitory activities of cyclophelitol (**1**) and its stereoisomers. This means that the appearance of cyclophelitol (**1**) paved the way for a new wave of drug discovery based on the science of glycosidase inhibitors and this will contribute to the further development of glycoscience and the development of new synthetic methodologies for total synthesis.

3.1.2 Tamiflu: A Neuraminidase Inhibitor

Despite considerable progress in elucidating the molecular mechanism and cellular biology of influenza virus, influenza infection continues to be the most serious respiratory disease both in terms of morbidity and mortality [65]. Amantidine and its analogue rimantidine represent the compounds licensed for the treatment and prophylaxis of influenza A infection. However, these compounds are not effective against influenza B viruses, and their clinical use has been limited by side effects and the rapid emergence of resistant viral strains [66]. On the other hand, vaccine development has been partially successful in the control of influenza epidemics due to the highly variable mutation of the influenza virus [67,68]. This means that promising anti-influenza drugs don't always exist in medical practice. Recently, a great deal of attention in this field has been focused on the unique replication mechanism of the influenza virus, and this has allowed the relevant scientists to identify a number of potential molecular targets for drug design. Those targets include hemagglutinin (HA) [69,70], neuraminidase [71,72], M2

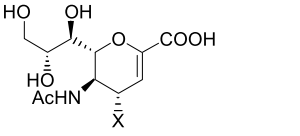
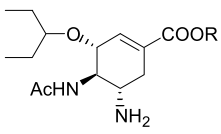
protein [73], and endonuclease [74]. Hemagglutinin and neuraminidase are two major surface glycoproteins expressed by both influenza A and B viruses. HA is known to mediate binding of viruses to target cells via terminal sialic acid residue in glycoconjugates. This binding is the first step of viral infection. In contrast to HA activity, NA catalyzes removal of terminal sialic acids linked to glycoproteins and glycolipids. Although the biological consequences of this activity are not completely understood, it has been postulated that NA activity is necessary in the elution of newly formed viruses from infected cells by digesting sialic acid in the HA receptor [75,76]. NA may also promote viral movement through respiratory tract mucus, thus enhancing viral infectivity [74. 75]. Therefore, NA has been considered to be a suitable target for designing new types of anti-influenza drugs.

In earlier studies, 2,3-didehydro-2-deoxy-*N*-acetylmeuraminic acid (Neu5Ac2en, **102**) was found to be an influenza NA inhibitor with a *Ki* of 4 μM [78,79]. Biochemical studies [80] indicate **102** is considered a transition state-like analogue binding to the active site of NA [81,82]. Afterward, on the basis of structural information generated from X-ray crystallographic study of **102** complexed with NA, the following rationally designed NA inhibitors were prepared: 2,3-didehydro-2, 4-dideoxy-4-amino-*N*-acetylneuraminic acid (4-amino-Neu5Ac2en, **103**) and its guanidine analogue (4-guanidino-Neu5Ac2en, **104**) [81,83,84]. In comparison to **102**, both **103** and **104** are more potent NA inhibitors with *Ki* values of 10^{-8} M and 10^{-10} M, respectively. Both the amino group in **103** and the guanidino group in **104** are suggested to form salt bridges with Glu119 in the NA active site, while the latter adds a strong charge-charge interaction with Glu227 [84]. In addition, **104** also exhibited potent antiviral activity against a variety of influenza A and B strains in the cell culture assay [85]. Eventually, **104** was approved by the FDA, and it has been launched as an anti-influenza drug called relenza [86,87,88,89]. However, poor oral bioavailability and rapid excretion precluded **104** as a potential oral agent against influenza infection and **104** has to be administered by either intranasal or inhaled routes. In the case of an influenza epidemic, oral administration may be a more convenient and economical method for treatment and prophylaxis. Therefore, it would be desirable to have a new class of orally active NA inhibitors as potential agents against influenza infection. The research group of Gilead Science tried to discover a new class of compounds by using a carbocyclic template in place of the dihydropyran ring of the Neu5Ac2en system, and it was expected that the carbocyclic ring would be chemically more stable than the dihydropyran ring and easier to modify for optimization of antiviral and pharmacological properties. Consequently, they succeeded in identifying GS-4071 (**105**) and its prodrug GS-4104 (**106**), which is called tamiflu and has been launched as an orally available neuraminidase inhibitor for the treatment of influenza [90]. In this section, I will describe the story of the discovery of tamiflu. This represents a success story of an artificial carbasugar launched as an actual drug.



102: X = OH
103: X = NH_2
104: X = –HN–C(=NH)–NH_2 (Relenza)



105: R = H (GS-4071)
106: R = Et (GS-4104, Tamiful)

Design NA has been classified into nine subtypes for type A influenza virus strains according to their serological properties. However, there are no subtypes in the B-type virus. Although amino acid sequence homology among NA from both type A and type B virus strains has been found to be only 30% [91,92], the enzyme activity of NA among the different strains is the same, indicating the highly conserved nature of the active site of the enzyme [93]. The X-ray crystallographic structures of NA have been determined from three influenza subtypes: A/Tokyo [94], A/Tern [95], and B/Beijing [96]. The structures displayed a symmetrical folding pattern of six four-stranded antiparallel β-sheets arranged like blades of a propeller. NA exists as a mushroom-shaped spike with a boxlike head on top of a long stalk containing a hydrophobic region by which it is embedded in the viral membrane. Crystallographic studies of NA reveal that, in the active site, the amino acids which line and surround the walls of the binding pocket are highly conserved among all influenza strains examined so far. The high-resolution crystallographic structure of sialic acid (**107a**) complexed with NA revealed that sialic acid binds the enzyme in a considerably deformed conformation due to the strong ionic interactions between the carboxylate of the substrate and Arg118, -292, and -371 in the active site of the enzyme [97]. In solution the carboxylate of sialic acid is axial, but the deformation of the ring on binding places the carboxylate into a pseudoequatorial position. This binding mode is similar to that found in the X-ray crystal structure of Neu5Ac2en (**102**) complexed with NA [95]. In this case, the double bond of Neu5Ac2en constrains the pyranose ring of the sugar into a planar structure around the ring oxygen. On the basis of this structural information, it has been proposed that the catalytic mechanism for the cleavage of sialic acid from glycoconjugates (**107b**) implicates the formation of the C_2 carbonium cation (**108**) which is stabilized by the neighboring oxygen atom as shown in ❯ *Fig. 2* [81,82]. Furthermore, kinetic isotope studies have provided convincing evidence for the C_2 carbonium cation formation as an intermediate structurally similar to the transition state in the sialic acid cleavage by NA [80]. In general, transition-state mimics frequently are potent inhibitors for the catalyzing enzyme. The concept of structural similarity to the transition state has found wide application in drug design over the years. The multitude of enzyme-inhibitor interactions are governed by steric as well as electronic factors. In theory, compounds that closely resemble the transition-state structure should give high binding affinity toward the target enzyme [98,99], and the cases of neuraminidase inhibitors are not exceptional. Using intermediate **108** as a key transition-state mimic is a reasonable approximation in view of the X-ray crystallographic studies described above. Their earlier attempts to mimic the intermediate **108** with a completely flat benzene ring did not lead to potent NA inhibitors [100,101], suggesting the importance of the stereochemistry of substituents around the ring in the design of inhibitors with high affinity for NA. Therefore, considering the flat oxonium cation in **108** as an isoster of the double bond and the fact that the carbocyclic system would be expected to be chemically versatile for the manipulation of side chains attached to the ring, Gilead's group selected the cyclohexene scaffold as a replacement for the oxonium ring of **108** which would keep the conformational changes to a minimum (❯ *Fig. 2*).

Syntheses of the Prototypes In their initial stage of designing carbocyclic NA inhibitors, the olefinic isomers that are shown in structures **109** (Type [**I**]) and **110** (Type [**II**]) were considered as two possible prototypes of transition-state analogues. The isomer **109** is structurally closer to transition-state **108** than isomer **110**. However, Gilead's group expected that it would be

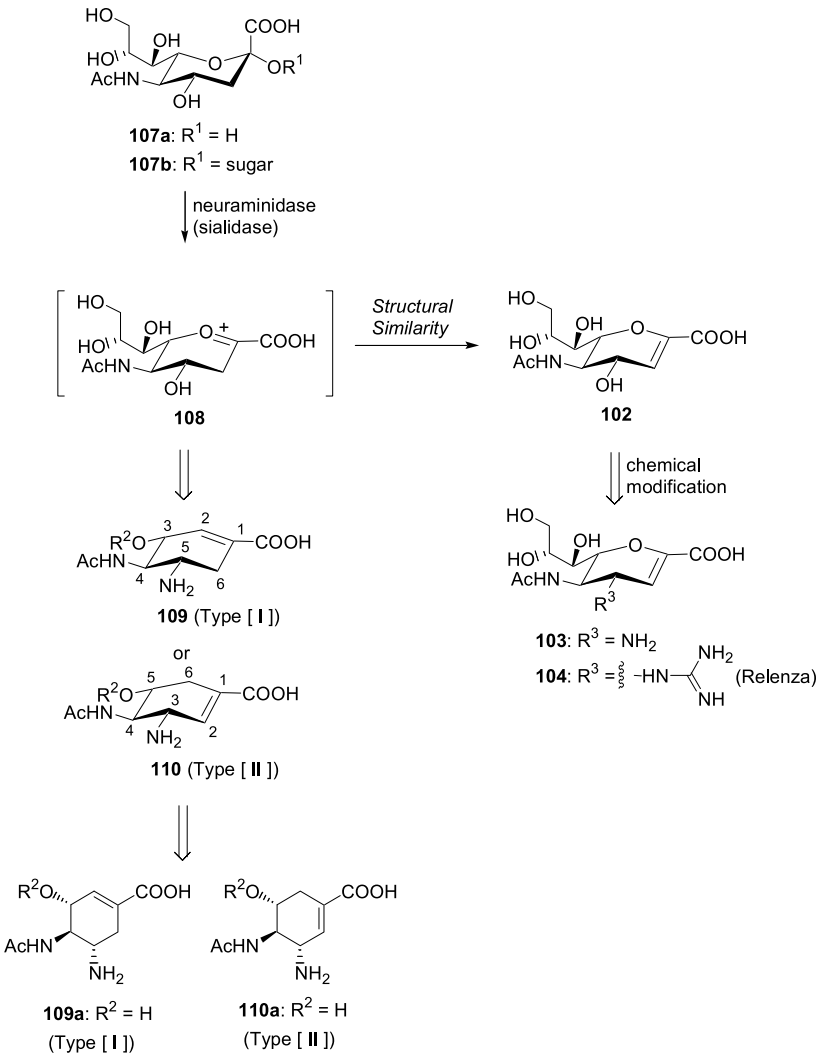


Figure 2
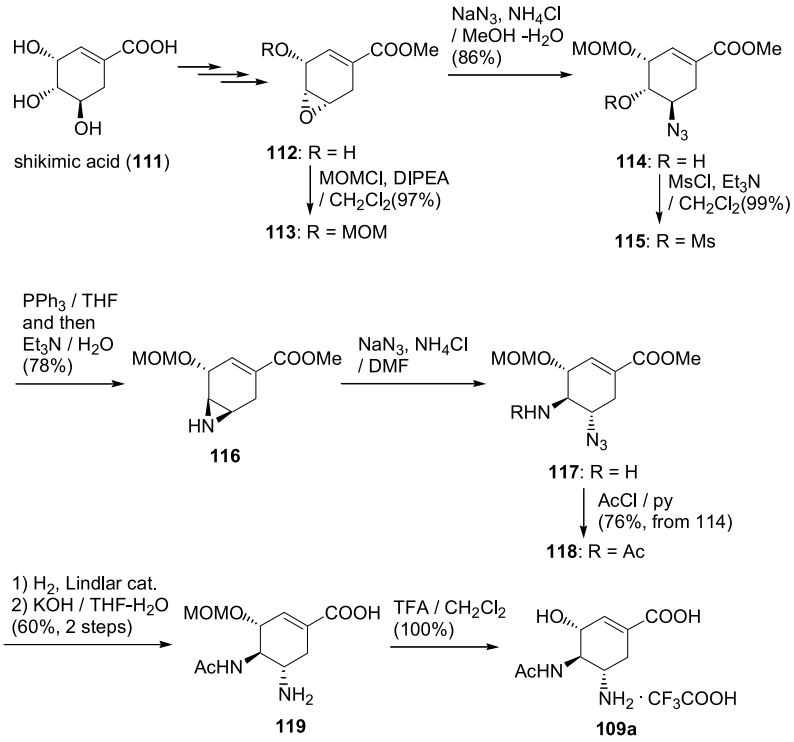
Rational design of carbocyclic transition-state analogues

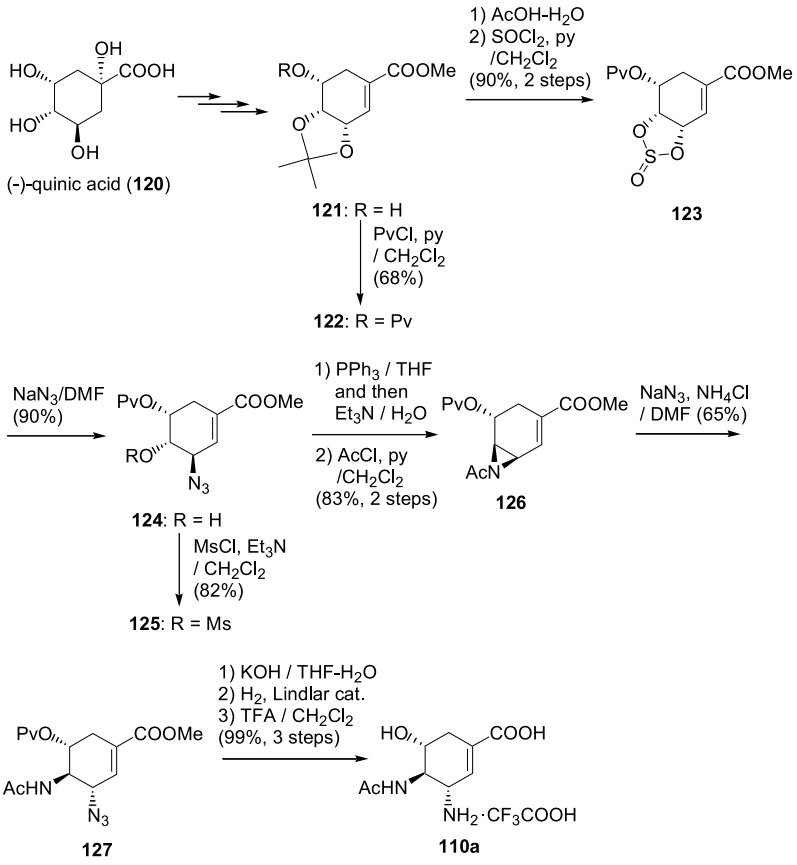
difficult to assess a priori which isomer would be a preferred NA inhibitor, especially, in light of the potent NA inhibitory activity displayed by Neu5Ac2en (**102**) and its analogues **103** and **104**, in which the double bond was located in the position corresponding to isomer **110** and the fact that Chandler et al. reported carbocyclic analogues have some interesting NA inhibitory activity [102]. In the meantime, the molecular modeling of isomers **109** and **110** indicated that these two molecules overlay well. Therefore, Gilead's group synthesized the simple compounds **109a** and **110a**, and evaluated which would be a more appropriate prototype for further extensive structure-activity relationships studies (*Fig. 2*).



Scheme 16

A comparison of structural similarities revealed that (–)-shikimic acid (**111**) and **109a** share common structural features. However, the conversion of **111** to **109a** requires the effective stereochemical control for transforming the trans C_4 and C_5 hydroxyls of **111** to the trans C_4 and C_5 amino groups of **109a**. The approach selected for this transformation, as outlined in *Scheme 16*, relied on the conversion of **111** to aziridine **116** followed by azide ion attack in a regio- and stereospecific manner as a key reaction.

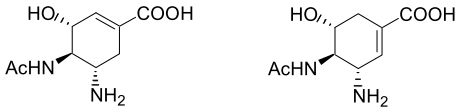
The synthesis began with the preparation of epoxide **112** from **111** as described in the literature [103]. Nucleophilic ring opening of MOM-protected epoxide **113** with NaN_3 in the presence of NH_4Cl generated azido alcohol **114**. The ring-opening of the epoxide was both region- and stereospecific as depicted in **114**, and this could be attributed to the steric and electronegative inductive influence of the MOM group in **113**. Conversion of azide **114** to aziridine **116** was efficiently accomplished via a two-step sequence: (1) mesylation of the hydroxyl group in **114** and (2) reduction of the azide functionality in **115** with PPh_3 in the presence of Et_3N and H_2O. The aziridine ring opening of **116** with NaN_3 gave **117** exclusively. This selective ring opening was again a consequence of the favored azide ion attack at the C_5 position due to the steric and electronegative inductive effects of the MOM group. Finally, acetylation of **117** followed by reduction of the azide group in **118** and saponification of the methyl ester and deprotection of the MOM group in **119** with TFA provided **109a** (*Scheme 16*).



Scheme 17

On the other hand, **110a** was synthesized from (–)-quinic acid (**120**). The cyclohexene intermediate **122**, readily available from **121** by literature methods [104], possesses considerable structural similarity to **110a**. The C_5 hydroxyl of **121** was protected as a pivaloyl ester, and mild acid hydrolysis of **122** furnished the corresponding diol. Exposure of the diol to $SOCl_2$ in the presence of Et_3N generated cyclic sulfite **123**. The sulfite ring opening of **123** with NaN_3 gave azide **124** as a single product. This complete regiospecific ring opening is a consequence of the favored azide ion attack at allylic C_3 position of **123**. The β-hydroxy azide moiety in **124** was then converted in a three-step sequence to aziridine **126**, analogous to the conversion of **114** to **116**. Ring opening of acetylated aziridine **126** with NaN_3 was completely regiospecific, giving azide **127** followed by reduction of azide functionality which provided **110a** (*Scheme 17*).

109a and **110a** showed interesting inhibitory activities in a NA enzymatic assay (*Fig. 3*). While **109a** proved to be a potent NA inhibitor with an IC_{50} of 6.3 μM, **110b** did not exhibit inhibitory activity at concentrations up to 200 μM.



109a **110a**

Influenza Neuraminidase Inhibition (IC_{50}, μM)	6.3	> 200

Figure 3
Influenza neuraminidase inhibition by prototypes 109a and 110a

It was concluded that this result demonstrated that the double bond position in the design of carbocyclic NA inhibitors plays an important role in NA activity; however, further structural investigation is required to illustrate the binding differences of **109a** and **110a** in the NA active site. Eventually, based on this result, the structure of **109** was selected as the prototype for further drug discovery attempts.

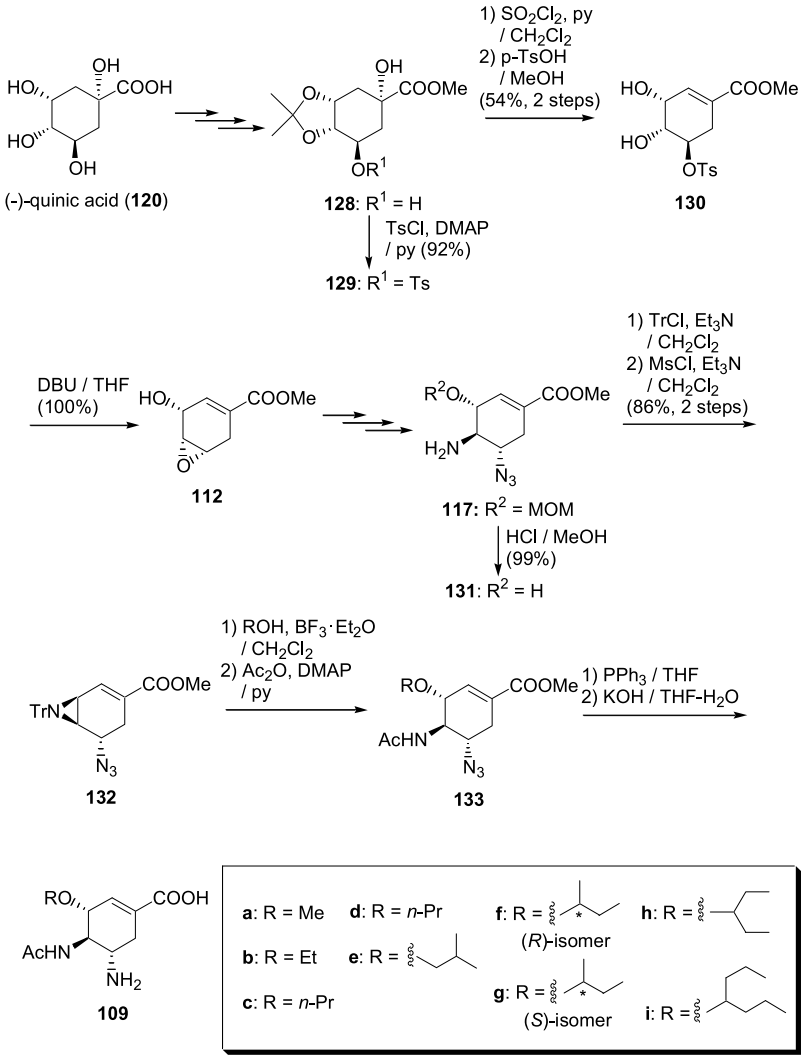
SAR Analysis Crystallography studies of Neu5Ac and its analogues bound to NA appear to indicate that the C_7 hydroxyl of the glycerol side chain does not interact with any amino acids of the NA active site [72]. This suggested that the C_7 hydroxyl could be eliminated from the carbocyclic analogues without losing binding affinity to NA. Furthermore, it was also realized that, in the transition-state intermediate **108**, the oxonium double bond is highly polarized and electron deficient. Considering these features, in the carbocyclic structure, the CHOH group at the C_7 position of the glycerol side chain in the Neu5Ac system was replaced with an oxygen atom as shown in structure **109**. This C_3 oxygen atom would reduce the electron density of the double bond via the σ bond electronegative inductive effect. In addition to these rationales, Gilead's decision to have the C_3 oxygen atom was based on the synthetic practicality of modifying R^2 groups to optimize NA inhibitory activity and pharmacological properties (*Fig. 2*).

X-ray crystallographic structures of Neu5Ac and its analogues complexed with NA show that two terminal hydroxyls of the glycerol side chain form a bidentate interaction with Glu276 [94,96]. However, it is also noted that C_8 of the glycerol chain makes hydrophobic contacts with the hydrocarbon chain of Arg224 [72]. Therefore, it was expected that the optimization of this hydrophobic interaction would lead to new NA inhibitors with increased lipophilicity while maintaining potent NA inhibitory activity. This consideration was especially important for designing orally bioavailable drugs since balancing lipophilicity and water solubility could be as critical as the size of the molecule for its absorption from the intestinal tract. For optimization of hydrophobic interactions, the dimensions of the spacer would be expected to play an important role in binding affinity to the enzyme, as factors such as length, geometry, and conformational mobility. On the basis of this premise, a systematic modification of the R^2 portion in **109** with various aliphatic side chains was conducted. Previous studies [72] suggested that the carboxylate of Neu5Ac2en (**102**) and its analogues form strong ionic interactions with three guanidino groups of Arg118, -292, and -371. The acetamido

moiety at C_5 of Neu5Ac2en and its analogues interacts with Arg152 and Glu227, and the methyl group fits nicely into a hydrophobic pocket formed by Trp180, Ile224, and Arg226. The acetamido group was also demonstrated to be optimal for antiviral activity [105]. The amino and guanidino groups at the C4 position of the Neu5Ac2en system were optimal for NA activity as described above [79,84]. Therefore, in the carbocyclic structure **109**, the C_1 carboxylate, C_4 acetamido, and C_5 amino groups were kept constant, while the C_3 aliphatic group was optimized for antiviral activity.

For structure-activity relationship studies of carbocyclic analogues **109**, a general and efficient route to introduce various alkyl ethers at the C_3 position was required. Also, although shikimic acid as a chiral starting material is convenient because of easy conversion to the key epoxy intermediate **112**, its high cost and low availability in large quantities made it impractical for scale-up of **112**. This meant that this would become a formidable challenge when multi-kilograms of material were needed for evaluation of clinical candidates for further drug development as well as frequent consumption of common synthetic intermediate **112** for SAR studies. In this stage, the development of the synthetic route, including the solutions of these issues, was achieved. With respect to the improvement of the synthetic route of **112**, (–)-quinic acid (**120**), which was used as a starting material for the synthesis of **110a** as shown in ❯ *Scheme 17*, appeared to be an ideal starting material because of its low cost and commercial availability. The focus on the synthesis is the selective dehydration of the C_2 hydroxyl in **129**. Tosylate **129** was reacted with sulfuryl chloride in pyridine, followed by acetonide cleavage in refluxing methanol in the presence of *p*-TsOH. Interestingly, the desired diol **130** was directly crystallized out of the reaction mixture in 54% overall yield, and in the dehydration and acetonide removal sequence for the conversion of **129** to **130**, the other olefinic regioisomer of **130** was aromatized under the reaction condition and easily separated by crystallization. Gilead's group reported that this procedure would be amenable to a several hundred gram scale. Finally, epoxide **112** was produced in quantitative yield by treatment of **130** with DBU in THF, and the synthesis of epoxide **112** from quinic acid has been achieved in good overall yield without column chromatography. Also, regarding a general and efficient route to introduce various alkyl ethers at the C_3 position, the approach, as outlined in ❯ *Scheme 18*, relied on the aziridine opening of **132** with alcohols, which should in principle be highly regioselective due to the preferred nucleophilic attack at the C_3 allylic position. The requisite aziridine **132** was derived from the *trans* amino alcohol **131** by the two-step, one-pot process: (1) selective protection of the amino functionality with TrCl and (2) mesylation of the hydroxyl in the presence of Et_3N. Under these conditions, the mesylate intermediate was converted into aziridine **132**. Treatment of **132** with various alcohols in the presence of $BF{\cdot}Et_2O$ followed by acetylation of the crude product provided the ether **133** in 55–88% yield. This aziridine ring opening proceeded regio- and stereospecifically, and no other regio- and stereoisomer were observed. Finally, reduction of the azide functionality and saponification of the ester group in **133** gave **109**. Thus, the convergent and efficient synthesis of various ether analogues of **109** has been achieved from intermediate **112** which is readily available from quinic acid as well as shikimic acid (❯ *Scheme 18*).

The NA inhibitory activities of the carbocyclic analogues were evaluated in two assay systems (❯ *Table 2*). The intrinsic activity of each compound was assessed by measuring the inhibition of enzymatic activity, and compounds that exhibited potent NA inhibitory activity were further evaluated in cell culture by a plaque reduction assay using an influenza A (H1N1) strain.



Scheme 18

As shown in *Table 2*, the length, size of branching, and geometry of the alkyl groups in **109** profoundly influence the NA inhibitory activity. In a series of linear alkyl analogues (**109b–e**), steady increases in the enzyme inhibitory activity were observed up to the *n*-propyl analogue **109d**. The over 20-fold increase in the NA inhibitory activity for **109d** compared to the methyl counterpart **109b** implicated a significant hydrophobic interaction of the *n*-propyl group with amino acids in the active site. Branching at the β-carbon of the *n*-propyl group (compound **109f**) resulted in no enhancement of NA inhibitory activity compared to that of **109d**. In contrast, branching at the α-carbon of the *n*-propyl group resulted in almost 20-fold enhance-

ment of NA inhibitory activity. This improved potency undoubtedly arose from additional hydrophobic interactions in the NA active site generated by the α-methyl group. Remarkably, the absolute stereochemistry of the α-methyl group (**109g** and **109h**) did not influence the NA inhibitory activity as they exhibited almost equal potency. Gilead's group concluded that this result means it can be speculated that the methyl and ethyl groups in the *sec*-butyl analogues **109g** and **109h** contribute almost the same binding energy by an equal degree of interaction with amino acids in the active site. This hypothesis was further supported by NA activity of 3-pentyl analogue **109i (=105)**, which possesses two identical branched ethyl groups and shows the NA inhibitory activity increase of almost 10-fold that of either isomers **109g** and **109h**. Further extension of the two ethyl groups to the 4-heptyl analogue **109j** resulted in a decrease of NA inhibitory activity, suggesting that the 3-pentyl group in **109i (=105)** might provide the optimum hydrophobic contact with the NA active site. Interestingly, the enzymatic and plaque reduction activities of **109i (=105)** were comparable to those of **104**, which exhibited over 100-fold increase in activity compared to that of amino analogue **103**. Replace-

ment of the amino group in **109i (=105)** with the guanidino moiety resulted in a significant increase in its enzymatic and cell culture activity compared to **109i (=105)**. Thus, carbocyclic NA inhibitors represented by **109i (=105)** and its guanidino analogue are more potent NA inhibitors than any inhibitors including compounds **103** and **104**. Finally, ethyl ester of **109i (=105)** (designated as GS-4104, **106**) exhibited good oral bioavailability in several animals (mice, rats, and dogs) and demonstrated oral efficacy in the mouse and ferret influenza model. On the basis of potent in vitro/in vivo activity and favorable pharmacological properties, GS-4104 (**106**) has been selected as a clinical candidate for the oral treatment and prophylaxis of influenza infection.

Synthetic Method for Process Chemistry After GS-4104 (**106**) was identified as a clinical candidate, a practical kilogram-scale preparation of **106** was necessary to supply an accelerated program of clinical and toxicological studies. The key structural feature in **106**, in terms of both pharmacological activity and synthetic challenge, was the 3-pentyl ether group. The aforementioned discovery synthesis of **106** constructed this 3-pentyl ether by acid-catalyzed opening of the tritylaziridine **132** with 3-pentanol (Route [A], ❯ *Fig. 4*). The tritylaziridine **132** was prepared stereospecifically from either (–)-quinic acid (**120**) or (–)-shikimic acid (**111**), but both sequences required double inversion and repeated protection/deprotection of the (*R*)-3-hydroxyl group. The generality of the tritylaziridine opening for a wide variety of alcohols and other nucleophiles facilitated the rapid creation of structural diversity in the discovery program. However, identification of the lead compound **106** allowed for the design of a more efficient approach. Rohloff et al. developed a new 12-step synthesis of **105** utilizing a novel and efficient reductive ketal opening of **134** to construct the 3-pentyl ether (Route [B], ❯ *Fig. 4*) [106]. This new process is highly applicable to kilogram-scale synthesis in that it fea-

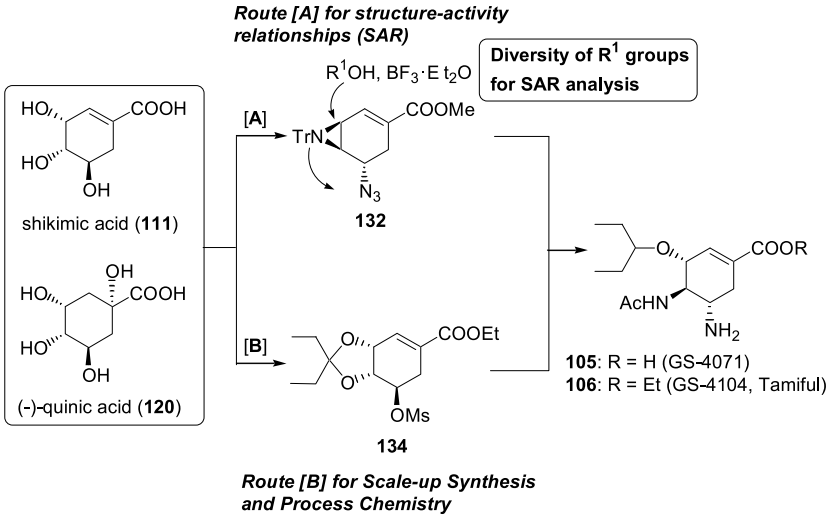

Figure 4
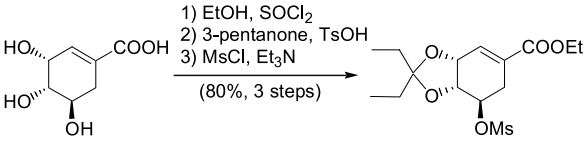
Synthetic strategies of 105 and 106

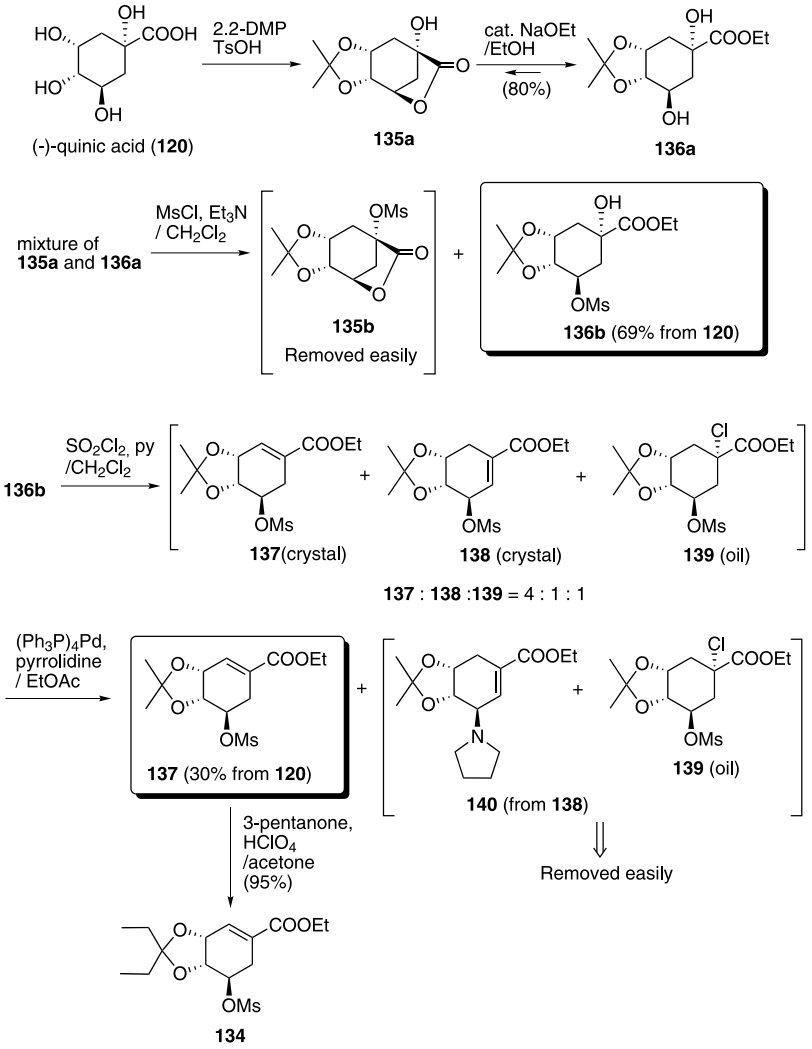


(-)-shikimic acid (**111**) **134**

Scheme 19

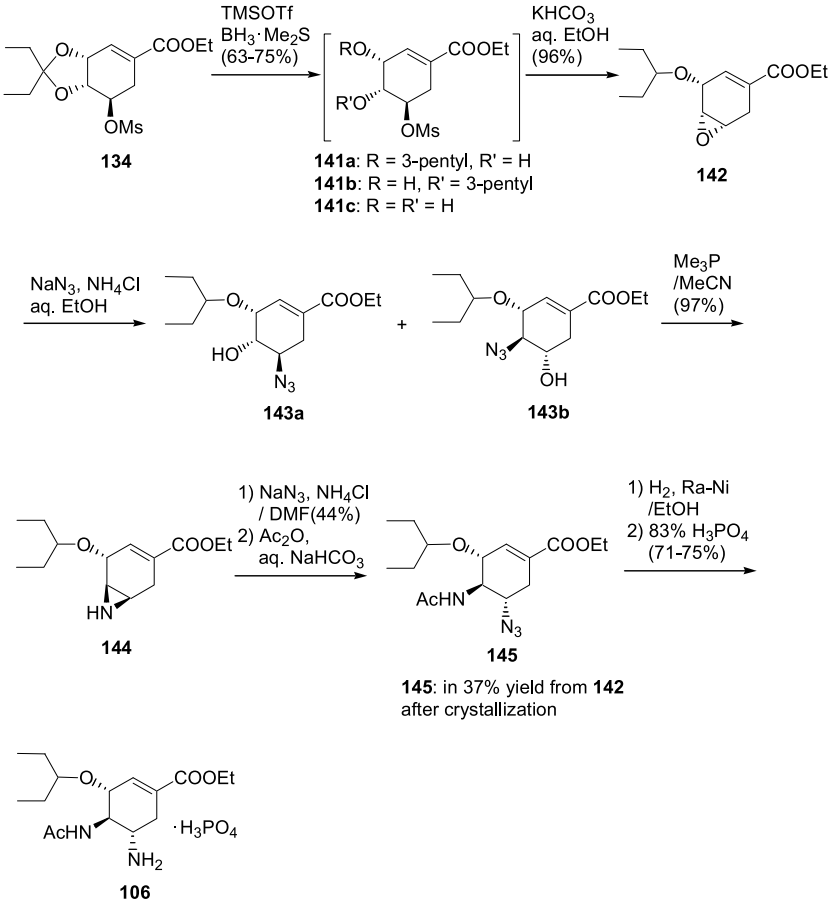
tures only three isolated crystalline intermediates and requires no chromatography (*Fig. 4*). Compound **134** was synthesized in 80% yield from natural shikimic acid (**111**) (*Scheme 19*). However, due to the limited commercial availability of (–)-shikimic acid (111), an efficient preparation of ketal 134 from (–)-quinic acid (120) was developed as shown in *Scheme 20*. The quinic lactone acetonide **135a** was prepared in 90% yield from **120** by modification of the method of Shing [107], and this was converted to a 1:5 equilibrium mixture of lactones : hydroxyl ester **135a**:**136a** in anhydrous EtOH (1 M) containing catalytic NaOEt. Separation of the **135a**:**136a** mixture by fractional crystallization was found to be inefficient on the kilogram scale, and instead, the crude **135a**:**136a** mixture was treated with MsCl (1.1 equivalents) in CH_2Cl_2 in the presence of Et_3N to chemoselectively afford the monomesylates **135b**:**136b** in an unchanged ratio of 1:5. Undesired, but highly crystalline, lactone mesylate **135b** was readily removed by filtration of an EtOAc slurry of the **135b**:**136b** mixture. Upon evaporation of the filtrate, crude oily **136b** was isolated in 69% overall yield from (–)-quinic acid (120). Dehydration of **136b** to form the unsaturated "shikimic" ring system was accomplished with SO_2Cl_2 and pyridine in CH_2Cl_2 at –20°. A mixture of 1,2- and 1,6-olefin regioisomers **137**:**138** (ratio 4:1) was obtained in 60% yield along with 10–15% of oily α-chloro compound **139**. Because of the high crystallinity of both olefin isomers, a high-throughput fractional crystallization could not be accomplished. Instead, it was found that treatment of the crude **137**:**138**:**139** mixtures with pyrrolidine and catalytic $(Ph_3P)_4Pd$ in EtOAc led to selective conversion of the undesired 1,6-olefin (*allylic* mesylate) **138** into pyrrolidine substitution product **140** [108,109]. This 1,6-olefin adduct was readily removed by aqueous H_2SO_4 extraction. The pure 1,2-olefin isomer **137** was then isolable by crystallization from EtOAc/hexane in 30% overall yield from **120**. In order to complete the link to the (–)-shikimic acid route, the quinic acid-derived acetonide **137** was transketalized using catalytic perchloric acid in 3-pentanone at ambient temperature with continuous vacuum distillation of acetone. The 3,4-pentyliden ketal **134** was isolated in nearly quantitative yield and was identical in all respects to the ketal **134** prepared from (–)-shikimic acid (**111**). A more concise route based on initial formation of the 3,4-pentylidene ketal analogues of **135a**, **136a**, and **136b** from (–)-quinic acid (**120**) was found to be impractical for scale-up due to the lack of crystallinity in the 3,4-pentylidene series (*Scheme 20*).

Treatment of **134** with TMSOTf and $BH_3{\cdot}Me_2S$ in CH_2Cl_2 under modified Hunter conditions [110], gratifyingly afforded a 10:1:1 mixture of isomeric pentyl ethers **141a**:**141b** and diol **141c** in 75% yield. Separation of the **141a**:**141b**:**141c** mixture was not possible through fractional crystallization or chromatography, but heating the crude mixture in aqueous EtOH in the presence of $KHCO_3$ selectively converted **141a** into the alkane-soluble epoxide **142**. Heptane extraction gave crystalline epoxide **142** in 60% overall yield from ketal **134**. Epoxide



Scheme 20

142 was heated at 70°C with NaN_3 and NH_4Cl in aqueous EtOH to afford an oily 10:1 mixture of isomeric azido alcohols **143a**:**143b**. Intramolecular reductive cyclization of the crude **143a**, **b** mixture with Me_3P in anhydrous MeCN at 35°C cleanly afforded a single aziridine **144** of ca. 70% purity. Aziridine opening proceeded smoothly at 80°C with NaN_3 and NH_4Cl in DMF affording the corresponding azidoamine, which was directly acylated with Ac_2O. The resulting azidoacetamide **145** (m.p 137–8°C) was isolated, after recrystallization in 37% overall yield from epoxide **142**. Because of its stability and high crystallinity, azidoacetamide **145** has proven to be an excellent final intermediate for drug substance synthesis. To complete

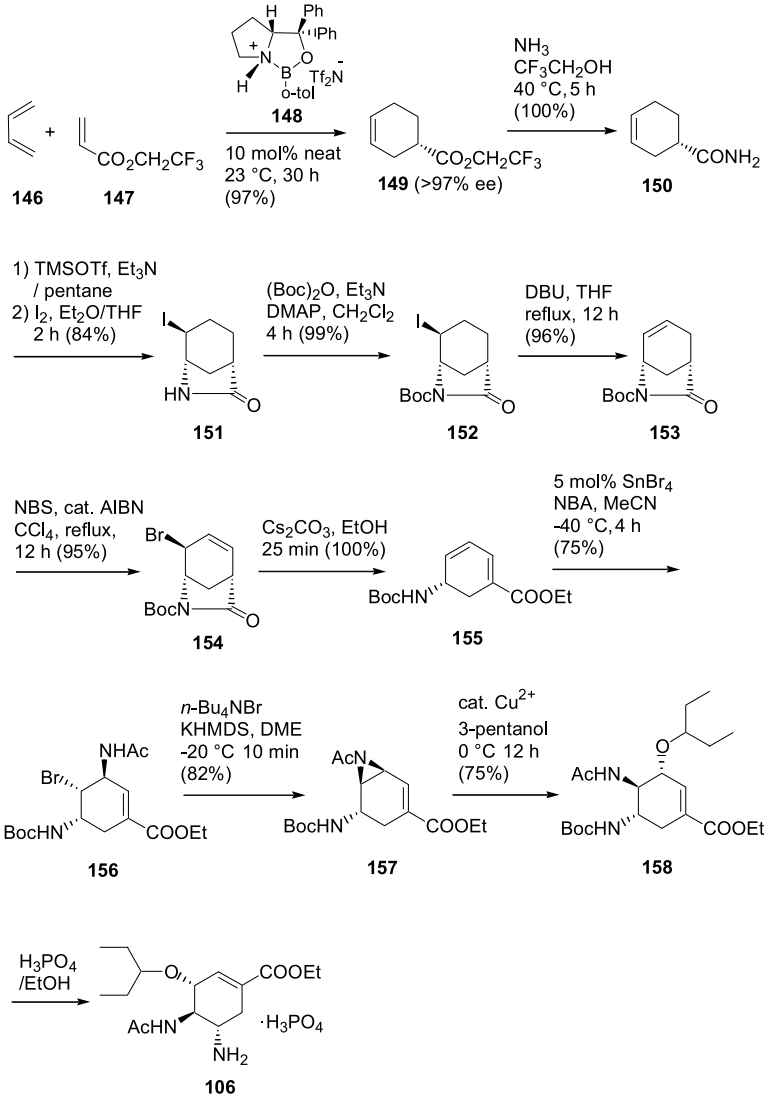


Scheme 21

the synthesis, azide reduction of substrate **145** was accomplished using catalytic hydrogenation with Raney Ni in EtOH (1 atm H_2) at 35°C. After removal of catalyst by filtration, 85% phosphoric acid was added. The salt **106**·H_3PO_4 crystallized as feathery needles, and it was isolated in 71% yield from **145**. Consequently, overall, **106** was prepared in 12 steps and 4.4% yield from (–)-quinic acid (**120**) (Average 77.2% yield/step), and (formally) in ten steps and 21% yield from (–)-shikimic acid (**111**), and kilogram quantities of drug substance for clinical and toxicological studies have been prepared by this route (*Scheme 21*).

Novel Synthetic Routes The recent emergence of the avian virus H5N1 raises the possibility of a pandemic wave of life-threatening influenza that requires prompt action. Currently, a four-pronged effort to avert widespread disease is now underway, and the effort consists of the following components: (1) worldwide surveillance of both wild and domesticated birds with quick culling of the latter, (2) development of recombinant vaccines against the H5N1

virus and its mutated forms whose production can be scaled up rapidly, (3) procedure for quarantine, and (4) ramped up production of the orally effective, synthetic neuraminidase inhibitor tamiflu (**106**). Especially, the stock of tamiflu (**106**) is becoming a serious social problem, and it is true that many nations have planned to stock a significant amount of **106** to protect against a possible influenza outbreak. The current commercial synthetic route of **106** uses naturally occurring (–)-shikimic acid (**111**) or quinic acid (**120**) as a starting material. However, as mentioned in previous sessions, these starting materials are complex, relatively expensive, and of



Scheme 22

limited availability, therefore, a more reliable source is desired for constant and large-scale supply of **106**.

In 2006, two groups independently reported the novel asymmetric synthesis of tamiflu (**106**). Corey et al. reported a short enantioselective pathway for the synthesis of **106** from 1,3-butadiene and acrylic acid shown in ❯ *Scheme 22* [111]. The key steps of the synthesis are (1) Diels–Alder reaction of 1,3-butadiene (**146**) and trifluoroethyl acrylate (**147**) in the presence of chiral ligand **148** developed in the laboratory [112], (2) the introduction of two amino groups in tamiflu (**106**) without using potentially hazardous and explosive azide reagents, and (3) a novel $SnBr_4$-catalyzed bromoacetamidation.

The initial Diels–Alder step easily provided adduct **149** at room temperature on multigram scale in 97% yield and with >97% ee; recovery of the chiral ligand corresponding to **148** is simple and efficient. Ammonolysis of **149** produced amide **150** quantitatively, and subsequent iodolactamization of **150** using the Knapp protocol [113,114] generated lactam **151**, which was transformed by *N*-acylation with $(Boc)_2O$ into Boc derivative **152** in very high yield. Dehydroiodination of **152** occurred cleanly with DBU to give **153**, which was allylically brominated using NBS to generate **154** very efficiently. Treatment of **154** with $CsCO_3$ in EtOH afforded the diene ethyl ester **155** quantitatively. The next step in the synthetic sequence was a novel $SnBr_4$-catalyzed bromoacetamidation reaction which was completely region- and stereoselective using *N*-bromoacetamide (NBA) in MeCN at −40°C that converted the diene **155** to the bromodiamide **156**. It is surmised that this bromoacetamidation process involves the transfer of Br^+ from a $SnBr_4$-NBA complexed to the γ, δ-bond of the diene ester **155** followed by nucleophilic attack on the intermediate bromonium ion. Cyclization of **156** to the *N*-acetylaziridine was rapid and efficient using in situ generated tetra-*n*-butylammonium hexamethyldisilazane and provided the bicyclic product **157**. Reaction of **157** in 3-pentanol solution containing a catalytic amount of cupric triflate at 0°C occurred regioselectively to generate the ether **158**. Finally, removal of the Boc group and salt formation with H_3PO_4 in EtOH afforded **106**·H_3PO_4 (tamiflu) (❯ *Scheme 22*).

On the other hand, Shibasaki et al. reported the synthesis of **106** utilizing a general catalytic enantioselective ring-opening of *meso*-aziridines with $TMSN_3$ (❯ *Fig. 5*, ❯ *Scheme 23*) [115].

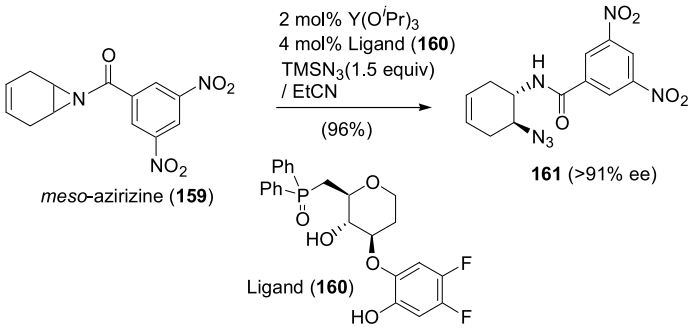


Figure 5
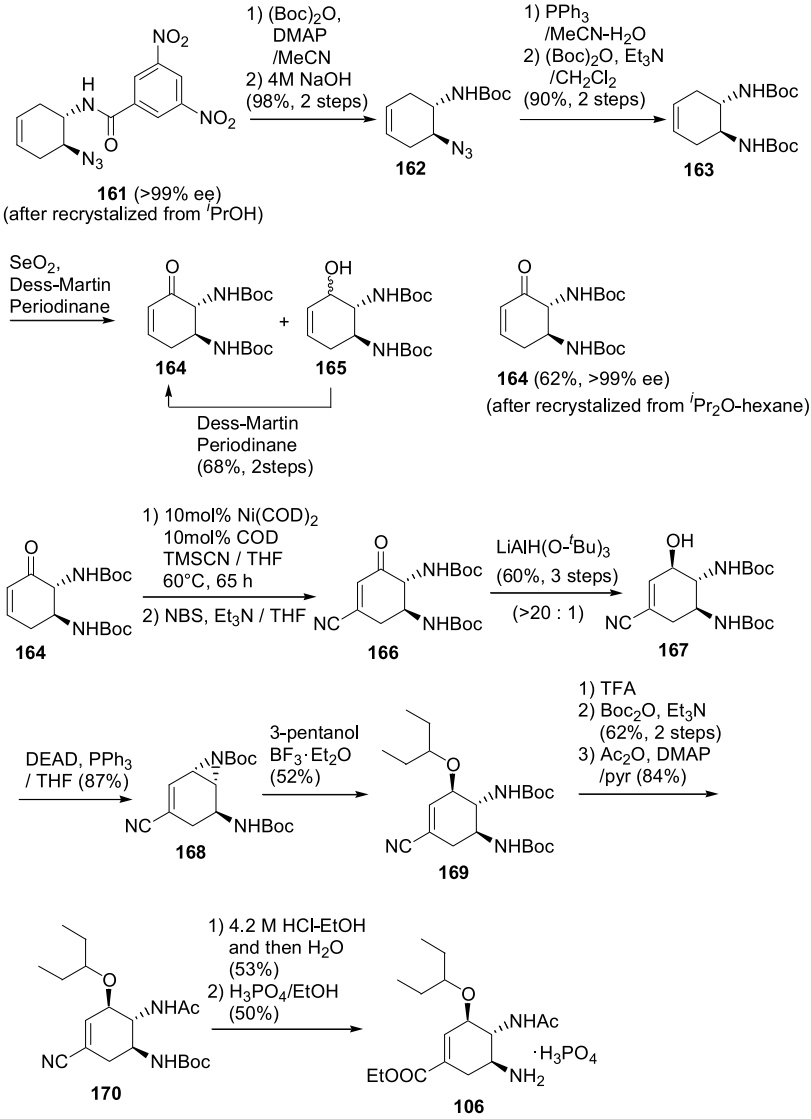
Key step of asymmetric synthesis of tamiflu (106) utilizing a general catalytic enantioselective ring-opening of *meso*-aziridines with $TMSN_3$



Scheme 23

The basic concept of this synthesis is on the extension of catalytic desymmetrization of *meso*-azridines (CDMA) with TMSCN using a poly Gd complex derived from ligand **160** [116], and this synthesis also includes the investigation of the possibility of extending this catalysis to using $TMSN_3$ as the nucleophile. As the results of optimization of the reaction conditions, *N*-3, 5-dinitrobenzoyl aziridines were selected as the substrates and the screening of rare earth alkoxides as the catalyst metal source indicated that $Y(O^iPr)_3$ was optimum. On the basis of these results, *meso*-azirizine **159** was treated with 2 mol% of $Y(O^iPr)_3$, 4 mol% of ligand **160**,

and 1.5 equivalents of $TMSN_3$ in EtCN to afford the product **161** in 96% yield with > 91% ee (*Fig. 5*). It can be predicted that the reaction should proceed through a mechanism similar to the CDMA with TMSCN [116]: generation of a reactive yttrium azide from $TMSN_3$ through transmetalation [117] and intramolecular transfer of the azide to an activated acylaziridine by a Lewis acidic yttrium in the same poly Y catalyst [118]. Finally, products were converted to optically active C_2 symmetric 1,2-diamines in excellent yield.

The main tasks required for the synthesis of **106** from **161** were the introduction of an oxygen functionality at the allylic position and an ethoxycarbonyl group at the olefin. After obtaining enantiomerically enriched **161** by recrystallization, C_2 symmetric diamide **163** was synthesized in four steps. Allylic oxidation of **163** with SeO_2 in the presence of Dess–Martin periodinane produced a mixture of enone **164** and allylic alcohol **165** (ca. 2:3), which was treated without purification by Dess–Martin periodinane, giving **164** in 68% yield. Enantiomerically pure (> 99% ee) **164** was obtained at this stage by recrystallization. A 1,4-addition of TMSCN in the presence of 10 mol% of $Ni(COD)_2$ followed by treatment with NBS and Et_3N produced γ-keto nitrile **166**, which was selectively reduced with bulky aluminum reagent, $LiAlH(O\text{-}^tBu)_3$ to give alcohol **167**. Aziridine formation of **167** under Mitsunobu conditions furnished **168** and, subsequently, $BF_3{\cdot}Et_2O$-mediated aziridine opening of **168** with 3-pentanol afforded **169**. Treatment of **169** with TFA, followed by protection of the sterically less hindered amine with a Boc group and acetylation afforded **170**, and conversion of nitrile **170** to ethoxycarbonyl in acidic EtOH concomitant with removal of the Boc group, and H_3PO_4 salt formation afforded tamiflu (**106**) (*Scheme 23*).

Recent advances in structural biology have led to new drug discovery processes with the neuraminidase inhibitors such as tamiflu (**106**) and relenza (**104**) being notable achievements from this scientific area. It should be emphasized that tamiflu (**106**) does not originate from a natural substrate but is an artificially designed glycosidase inhibitor based on structural biological data, which has already been prescribed for influenza patients in practice. A variety of drugs designed using structural biology, in addition to tamiflu, will appear in the clinical market in the near future.

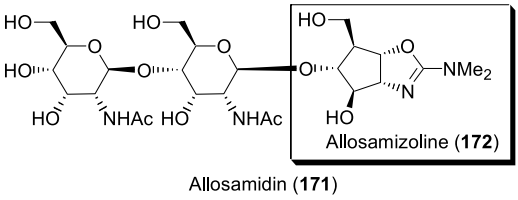
3.2 New Generations of Glycosidase Inhibitors Bearing 5-Membered Cyclitols

Among the glycosidase inhibitors, there is a type containing 5-membered cyclitol, which also exhibits interesting enzyme-specific inhibitory activities. Interestingly, most of the 5-membered cyclitols are aminocyclitols. For instance, mannostatine, which is a 5-membered aminocyclitol derivative, shows β-mannosidase-specific inhibitory activity, and allosamidin possessingthe [3.3.0] bicyclic aglycone called allosamizoline, which consists of a 5-membered aminocyclitol, exhibits inhibition towards chitinase specifically. Furthermore, trehazolin possessing the [3.3.0] bicyclic aglycone called trehalamine, which also consists of a 5-membered aminocyclitol, shows the trehalase-specific inhibitory activity. One of the scientific focuses on the researches of allosamidin and trehazolin is the elucidation of structure and activity relationships on the stereochemistry of their aglycons and their enzyme-specific inhibitory activities. . Therefore, while a variety of synthetic methodologies to form their scaffolds and to introduce the functional groups focused on total synthesis of the aforementioned glycosidase

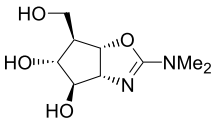
inhibitors, have been developed, the general application of the methodologies for the synthesis of their related compounds to investigate the SAR have also been reported. Herein, the new generations of glycosidase inhibitors, allosamidin and trehazolin, which possess the 5-membered aminocyclitol unit and exhibit interesting tri- or disaccharide hydrase-specific inhibitory activities, will be introduced and a variety of syntheses of the aglycones of allosamidin, allosamizoline, and trehazolins will be described.

3.2.1 Allosamizoline: The Aglycone of the Chitinase-Specific Glycosidase Inhibitor, Allosamidin

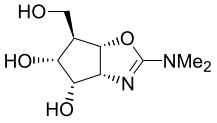
The importance of chitin as one of the main structural components of insect cuticles [119,120] and fungal cell walls [121,122] generates interest in discovering agents that may interact with its biosynthesis. With this in mind, allosamidin was discovered as expected. Allosamidin (**171**) is a novel pseudotrisaccharide as shown in Structure 4; it was isolated from the mycelial extract of *Streptomyces* sp. no. 1713, and shows the chitinase-specific inhibitory activity [123]. Its structure was deduced from hydrolysis experiments which produce 2 equivalents of D-allosamine and 1 equivalent of the aglycone moiety, allosamizoline (**172**). In particular, its aglycone moiety, allosamizoline has an interesting structure; it is a [3.3.0] bicyclic compound possessing aminocyclitol and dimethyl aminooxazoline parts. At first, the structure of allosamizoline was suggested to be the *cis*-diol (*allo*-isomer) **173** [124] and later revised to the *trans*-diol **172** [123. 124]. In the course of its correct structural assignment, the necessity for the synthesis of a series of allosamizolines (**172**–**175**) appeared and many chemists directed their efforts to the construction of these fascinating structures.



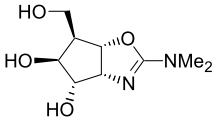
Allosamidin (**171**)



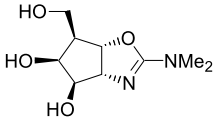
Allosamizoline (**172**)



Allo-isomer (**173**)



Gulo-isomer (**174**)



Galacto-isomer (**175**)

Trost's group and Danishefsky's group reported the total syntheses of allosamizoline independently and almost simultaneously. Both groups chose the racemic cyclopetenediol deriva-

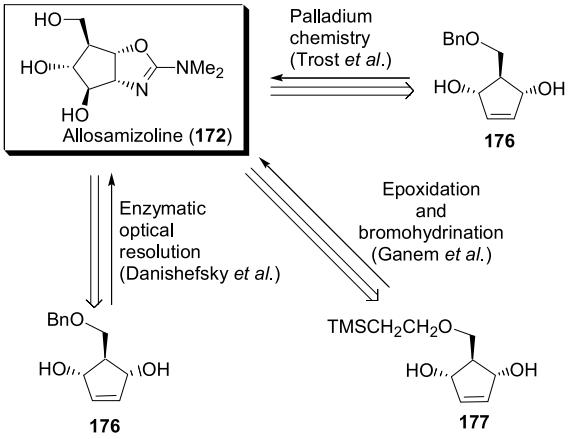


Figure 6
Diversity of the syntheses of allosamizoline (172) from cyclopentendiols 176 and 177

tive **176**, which was derived from cyclopentadienylthallium [127], as the starting material, and also Ganem's group also reported the synthesis of allosamizoline from the relevant cyclopentenediol derivative **177** later (*Fig. 6*).

First, Trost's allosamizoline synthesis will be discussed [128,129]. The basic concept of their synthesis is shown in Fig. *Fig. 7*. They have studied the use of Pd(0)-catalyzed reactions to provide the aminocyclitols with varying regio- and stereoselectivity. Also, they envisioned that the *cis*-vicinal aminocyclitols might be derived either from epoxides in a single step as in *Fig. 7* (Eq. (1), path a) [130,131] or from their synthetic equivalents such as 2-alkene-1,4-diols as illustrated in the one-pot sequence of *Fig. 7* (Eq. (1), path b) [132,133,134], with the bisurethane being generated in situ, and, in both cases, the regio- and diastereoselectivity might be assured by covalent tethering of the nitrogen nucleophile to the substrate. Moreover, they have found that significant levels of enantioselectivity may be achieved in the ionization process of the Pd(0)-catalyzed alkylation illustrated in *Fig. 7* (Eq. (2)) and have developed a class of easily prepared chiral phosphine ligands which allow the prediction of the absolute stereochemistry of the oxazolidinone product based on the stereochemistry of the ligand precursors [133,134,135,136,137,138,139,140,141].

On the basis of their preliminary synthetic concept, the allosamizolines **172–175** were synthesized as shown in *Scheme 24*, 25, and 26. The first synthesized allosamizolines were racemates and were separated as optically pure components after glycosidation with a sugar moiety, to give di-D-allosamine derivatives. Furthermore, they are continuing development of the asymmetric version by using chiral phosphine ligands. The cyclopentenediol **176**, which was derived from cyclopentadienylthallium, was treated with TsNCO and a Pd(0) catalyst to afford the oxazolidinone **178**. In a further study of this step, the use of 3 mol% of $(dba)_3Pd_2CHCl_3$ and 6 mol% of (–)-BINAPO at ambient temperature gave a 91% yield of oxazolidinone **178** with 59–65% ee [134]. After reductive de-*N*-tosylation of **178**, subsequent *O*-methylation of oxazolidinone **179** with MeOTf and exposure of the resultant imino ether to dimethylamine furnished the aminooxazoline **180**. Treatment of aminooxazoline **180** with

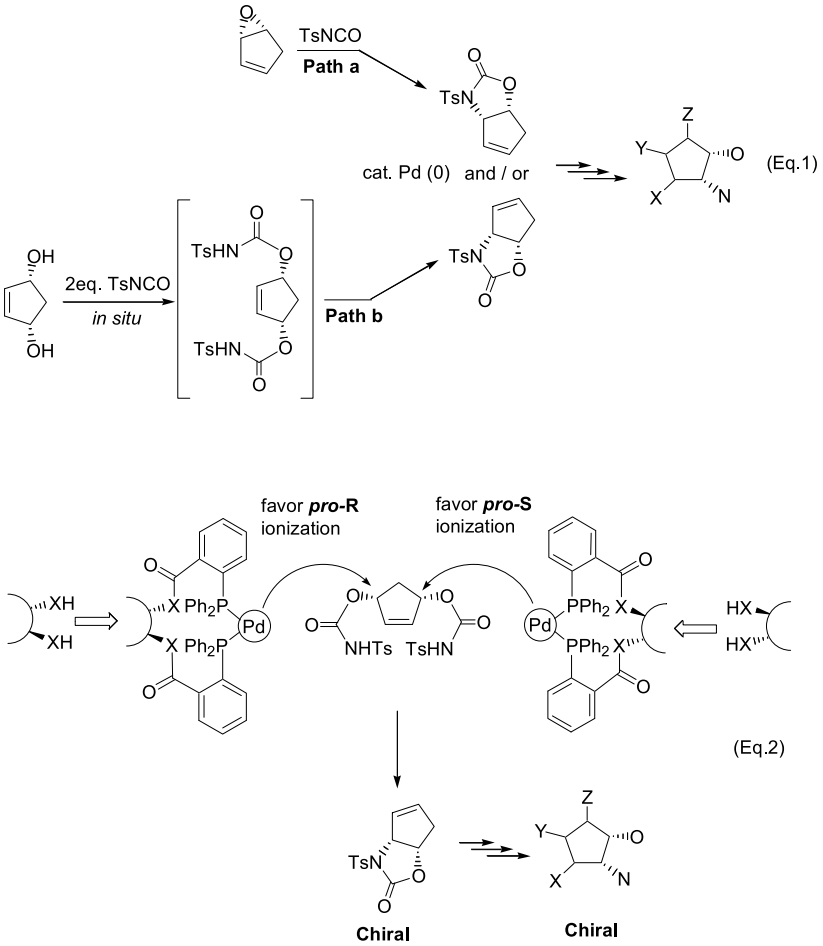

Figure 7
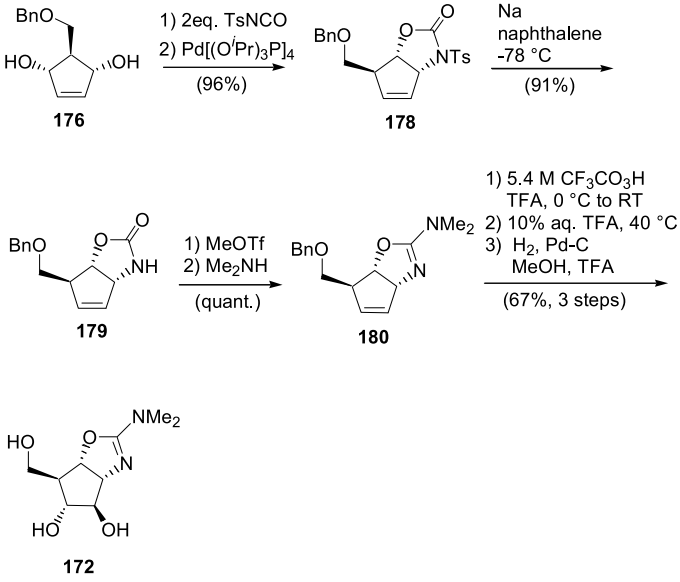
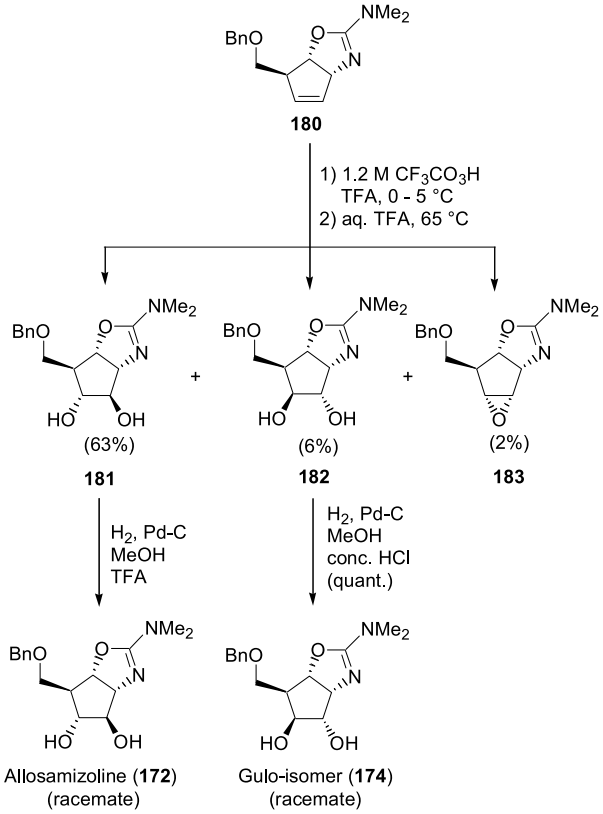
Basic concept of Pd(0)-mediated optical resolution for the synthesis of allosamizoline (172) reported by Trost's group

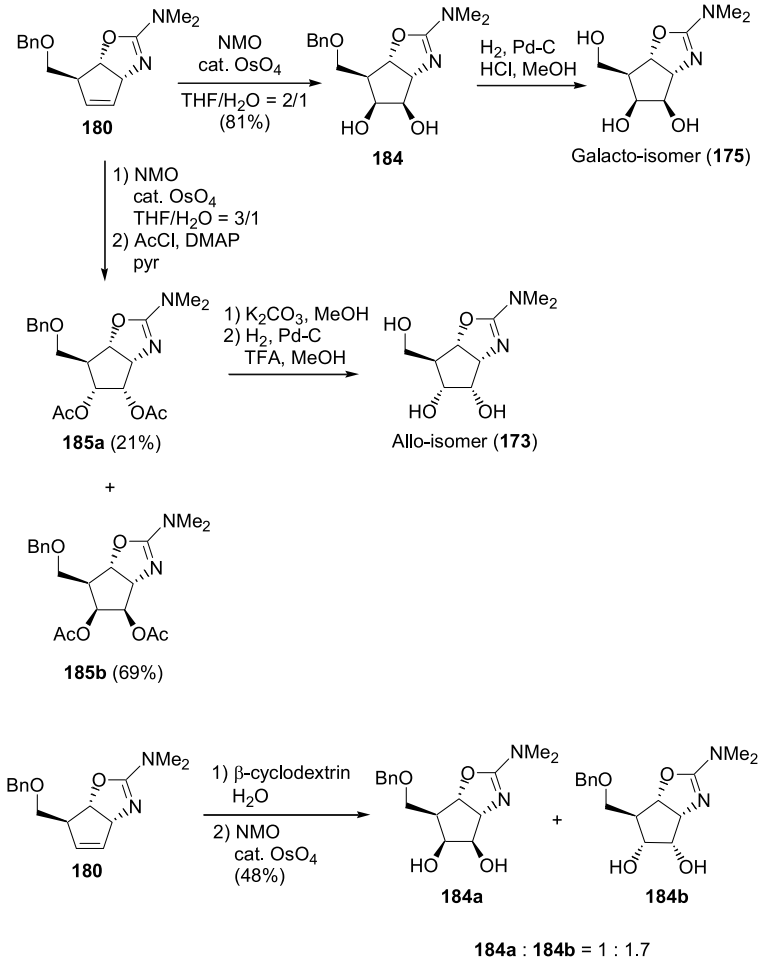
5.4 M CF_3CO_3H, exposure of the corresponding epoxide to 10% aqueous TFA at 40°C, and subsequent hydrogenolysis afforded allosamizoline **172** (*Scheme 24*).
In the meantime, the *gulo*-isomer **174** was also derived from the intermediate **180**, via minor product **182** after the treatment with 1.2 M CF_3CO_3H and subsequent exposure of the corresponding epoxide to 10% aqueous TFA at 65°C (*Scheme 25*).
On the other hand, the initially proposed structure, the *cis*-diol (*allo*-isomer) **173** and its *galacto*-type isomer **175** were synthesized from the same aminooxazoline **180** via dihydroxylation with OsO_4 as shown in *Scheme 26*.
Also, the concept and outcomes for this synthetic study were applied to the syntheses of mannostatine A [129] and valienamine [142].



Scheme 24



Scheme 25



Scheme 26

Next, Danishefsky's allosamizoline synthesis will be described [143,144]. The key point of their synthetic strategy is the utilization of enzymatic optical resolution to the racemic substrate. As illustrated in *Fig. 8*, there are two approaches for the enzymatic optical resolution. One is the enzymatic hydrolysis of a diester [145,146,147], and the other is the enzymatic transacylation of the *meso*-diol [148,149,150] (*Fig. 8*). In Danishefsky's group, the former route was chosen as the key step. Treatment of diacetate **186** with electric eel acetylcholinesterase provided the monoacetate **187**, which was reported by Deardorrf et al. [147]. This work was also applied to the synthesis of PG F_{2a} in Danishefsky's laboratory [151]. On the basis of the success of their synthesis of PG F_{2a}, diacetate **188**, which was derived from the 2-alkene-1,4-diol derivative **176**, was treated with electric eel acetylcholinesterase as well. Interestingly, this treatment provided the unexpected monoacetate **189** in 95% yield, > 95% ee (*Fig. 8*).

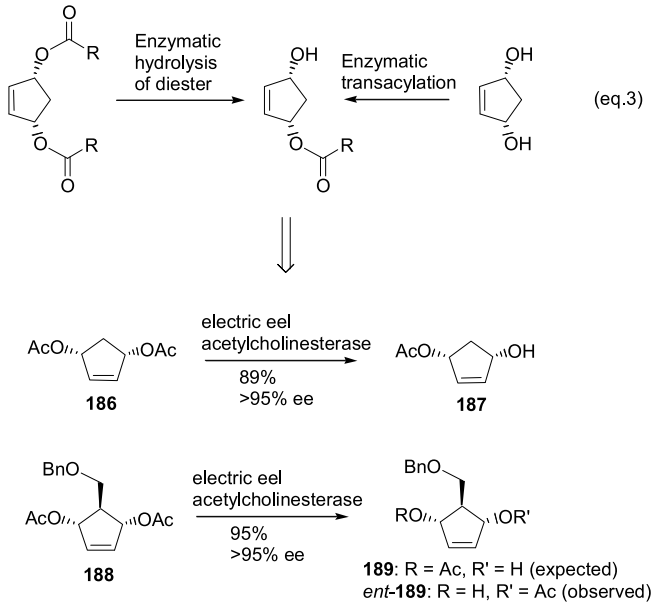


Figure 8
Basic concept of enzymatic optical resolution for the synthesis of allosamizoline (172) reported by Danishefsky's group

This result initially discouraged Danishefky's group to complete the synthesis of the intact allosamizoline **172**. However, eventually, Danishefsky et al. succeeded in the conversion of this undesired monoacetate *ent*-**189** to the intact allosamizoline (**172**) shown in *Scheme 27*. After silylation of the corresponding hydroxyl group of *ent*-**189**, the remaining Ac group was removed with NH_3 in MeOH to give the alcohol **190**. After introduction of a carbamate group by reaction with $ClCO_2Ph$ and NH_3, the TBDMS group was cleaved to provide the alcohol **191**. Treatment of **191** with TFAA and Et_3N furnished the optically active oxazolidinone **179**, which was the intermediate in Trost's synthesis. *O*-Methylation of the optical active oxazolidinone **179** with MeOTf and exposure of the resultant imino ether to dimethylamine furnished the corresponding optical active aminooxazoline. This aminooxazoline was treated with CF_3CO_3H and the corresponding epoxide was exposed to 10% aqueous TFA; subsequent hydrogenolysis under acidic conditions afforded the optical active allosamizoline (**172**). In the meantime, the resulting dibenzyl ether **192**, which was regioselectively benzylated after treatment of **181** with Bu_2SnO, was converted into allosamidine (**171**) via the KHMDS-promoted coupling with bromosulfonamide-disaccharide, which is by way of the interesting glycosidation developed by this group (*Scheme 27*).

As mentioned above, Ganem's group also synthesized allosamizoline (**172**) from the 2-alkene-1,4-diol derivative **177** [152]. They derived the 2-alkene-1,4-diol derivative **177** from cyclopentadienylthallium [127] via alkylation with SEMCl, cycloaddition of the corresponding cyclopentadiene **193** with singlet oxygen, and subsequent reduction in situ of the transient endoperoxide. This 2-alkene-1,4-diol derivative **177** was treated with NBS in DMSO to afford

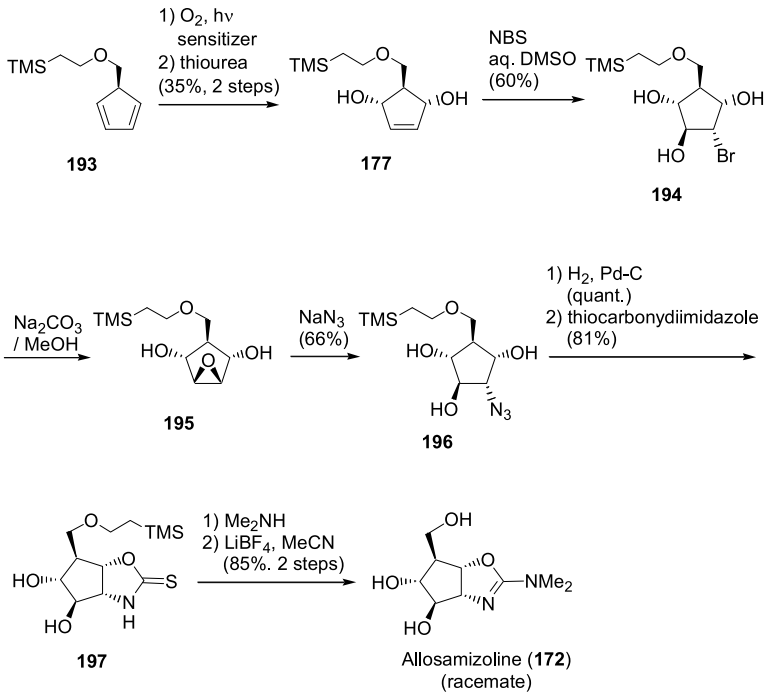
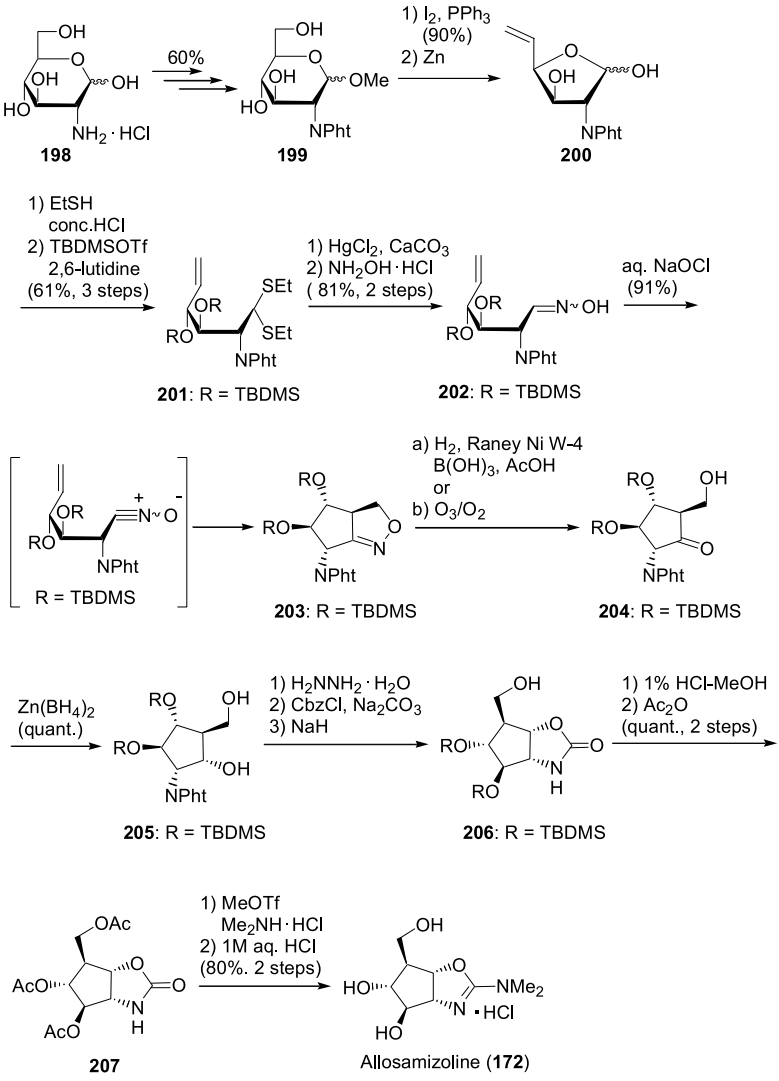


Scheme 28

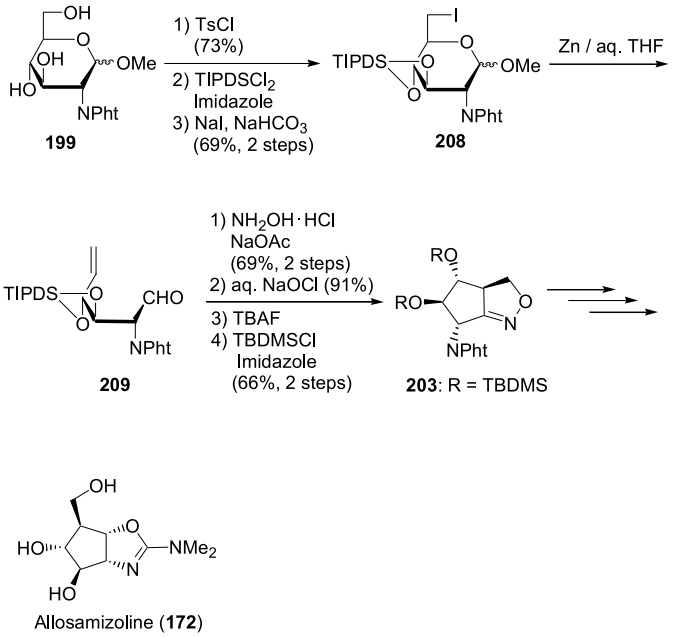
a single bromohydrin **194**. The structure was confirmed by cyclization with Na_2CO_3-MeOH to furnish exclusively the epoxide **195** possessing the desired stereochemistry. Ring-opening with NaN_3 furnished the racemic azidotriol **196**, and subsequently compound **196** was reduced to corresponding aminotriol. Cyclization with thiocarbonyldiimidazole produced the thiooxazolidinone **107**. After a one-step construction of the dimethylaminooxazoline ring had been achieved by heating with Me_2NH-MeOH, deprotection of the silyl group gave the racemic allosamizoline (**172**) (*Scheme 28*).

Allosamizoline (**172**) was also synthesized from natural sugar. Tatsuta et al. reported the synthesis of allosamizoline (**172**) from D-glucosamine using an intramolecular [3+2] cycloaddition as a key step [153]. On the other hand, Kitahara's group also independently achieved the synthesis of allosamizoline using the same key step [154]. First, Tatsuta's allosamizoline synthesis will be described. Iodination of methyl 2-deoxy-2-phthalimide-D-glucopyranoside **199**, which was readily derived from D-glucosamine **198**, and subsequent reductive β-elimination of the corresponding iodide gave the 5-enofuranose **200** concomitant with the reductively dehalogenated C6 product. Treatment of this mixture with EtSH and concentrated HCl, and subsequent silylation, furnished dithioacetal **201**. Dedithioacetalization of **201** with $HgCl_2$ and $CaCO_3$ provided the corresponding aldehyde, and, subsequently, the aldehyde was treated with $NH_2OH{\cdot}HCl$ to afford oxime **202**. Intramolecular [3+2] cycloaddition of oxime **202** with aqueous NaOCl furnished the isoxazoline **203** via nitrile oxide [13,14]. Isoxazoline opening



Scheme 29

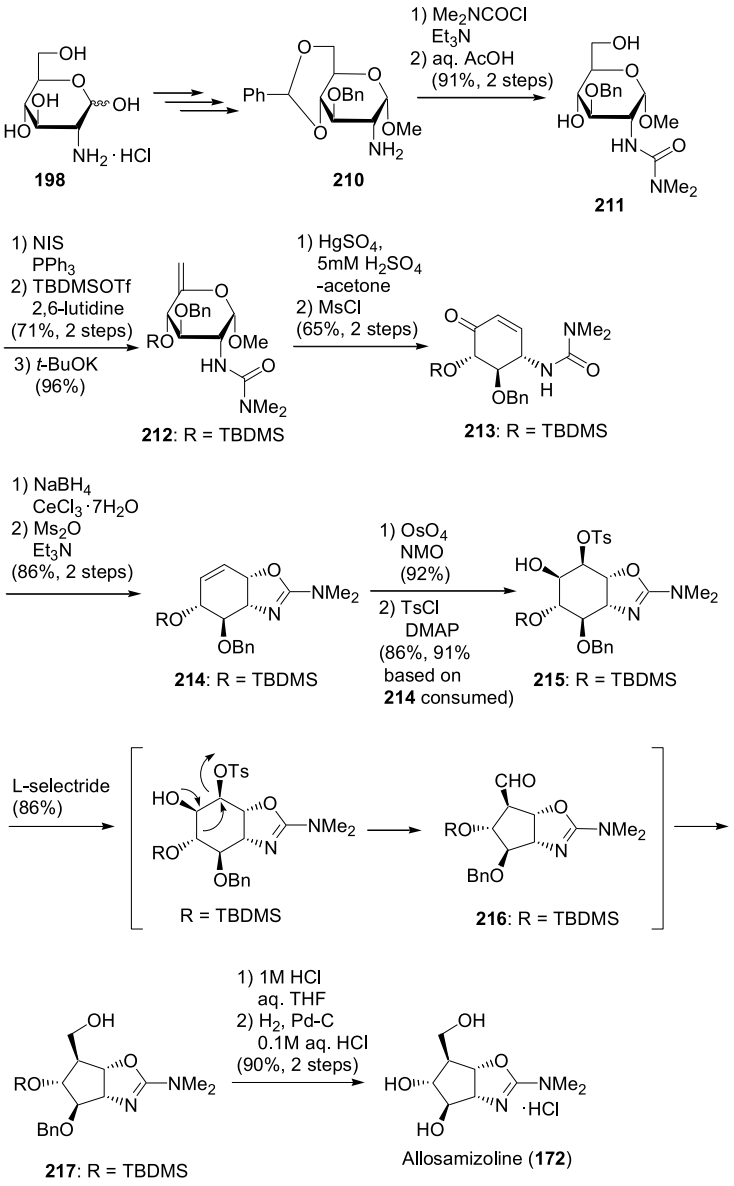
of **203** was a troublesome step, however, and as a result of screening the reaction conditions, it was completed by hydrogenolysis with Raney-Ni W4 in the presence of $B(OH)_3$ and AcOH or ozonolysis [155] to give the β-hydroxy ketone **204**. The reduction of **204** with $Zn(BH_4)_2$ proceeded stereoselectively and afforded a single diol **205**. After de-*N*-phthaloylation of **205**, benzyloxycarbonylation followed by base treatment gave the oxazolidinone **206**. Acid desilylation and subsequent acetylation afforded the triacetate **207**. Then *O*-methylation of **207** with MeOTf, followed by the treatment with $Me_2NH \cdot HCl$ and Et_3N, as well as further acidic deacetylation furnished allosamizoline (**172**) (*Scheme 29*).



Scheme 30

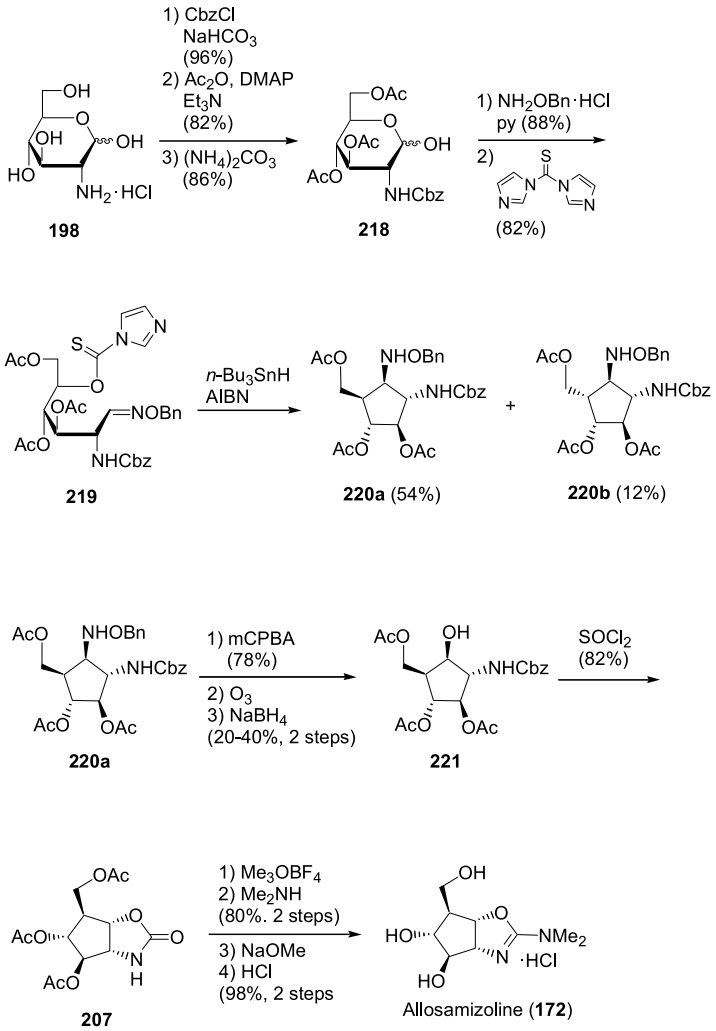
As shown in *Scheme 30*, Kitahara et al. also derived allosamizoline (**172**) from D-glucosamine **198** via Tatsuta's intermediate, isoxazoline **203**, as well [154].

As described in the session on cyclophelitol, the Ferrier reaction is a very useful method to transform sugars into carbasugars, and Kuzuhara's group used this reaction in the synthesis of allosamizoline (**172**) shown in *Scheme 31* [156]. A further interesting point in their synthesis is the transformation of the [4.3.0] bicyclic structure, which was derived from D-glucosamine **198** via the Ferrier reaction, to the [3.3.0] bicyclic scaffold of allosamizoline (**172**). It was performed by reductive ring contraction to the α-hydroxy tosylate under the action of L-selectride. Selective iodination of the *N*, *N*-dimethylurea-diol derivative **211** with NIS and PPh_3 [157], whereby **211** was derived from D-glucosamine **198** via the 4, 6-*O*-benzylidene compound **210**, silylation of the secondary hydroxyl group, and subsequent dehydroiodination of the corresponding iodide with *t*-BuOK gave the enol ether **212**. For conversion of the ring system from pyranose to cyclohexane, the modified Ferrier reaction with $HgSO_4$ [158] was employed and, furthermore, β-elimination of the resulting ketol with MsCl-pyridine provided the enone **213**. 1,2-Reduction of this enone **213** with $NaBH_4$ and $CeCl_3{\cdot}7\ H_2O$ proceeded stereoselectively and subsequent treatment of the corresponding allyl alcohol with Ms_2O and Et_3N furnished the dimethylaminooxazoline ring **214** simultaneously [159]. Dihydroxylation of **214** with OsO_4 proceeded exclusively from the convex face and, fortunately, the subsequent sluggish monotosylation gave the desired monotosylate **215**. Ring contraction of **215** in basic media was regarded as the key step in this synthesis. As the expected rearrangement product **216** bearing an aldehyde group was assumed to lack stability in basic media,



Scheme 31

an appropriate basic reducing agent [160] was screened for the ring contraction followed by immediate reduction of aldehyde. As the result, L-selectride was selected to give the desired cyclopentanemethanol **217**. Finally, compound **217** was converted into allosamizoline (**172**) by deprotection of the TBDMS and Bn groups (*Scheme 31*).



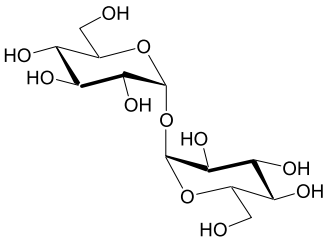
Scheme 32

Another synthesis of allosamizoline (**172**) from sugar was reported by Simpkins' group, and the key step of their synthesis is a radical cyclization to construct the 5-membered aminocyclitol [161,162]. So far, radical cyclization for the conversion of carbohydrates to carbasugars has been problematic because of the suitability of carbon-centered radicals for the preparation of the highly functionalized 5-membered ring [163]. However, significant contributions in this field, most notably by Rajanbabu [164], the possibility of using an aldehyde as the radical acceptor in the key cyclization reported by Fraser-Reid [165,166], and the cyclizations of radicals onto oxime ether reported by Bartlett [167] have paved the way to the formation of the highly functionalized 5-membered rings. Finally, Simpkins et al., focusing their attention

on a report by Bartlett [167], accomplished the synthesis of allosamizoline (**172**). In a way, Simpkins' group has verified the usefulness of the concept of radical cyclization for the formation of the highly functionalized cyclitols through the synthesis of allosamizoline (**172**) shown in *Scheme 32*. Treatment of the *N*-Cbz-tri-*O*-acetyl sugar **218**, which was derived from D-glucosamine **198** in three steps, with the *O*-benzyl ether of hydroxylamine, followed by derivatization of the secondary alcohol with thiocarbonylimdazole gave the compound **219**. This oxime derivative was treated with Bu_3SnH and AIBN according to Bartlett's protocol, to afford a mixture of diastereomeric products **220**. Judging from the configuration of the major product **220a**, obtained as a mixture of C1 epimers, it was expected to be convertible into allosamizoline (**172**). Oxidation of the mixture of benzyloxyamines with mCPBA afforded the corresponding oxime [168], and ozonolysis of the resulting oxime, followed by direct reductive work up gave the alcohol **221**. Treatment of **221** with $SOCl_2$ provided the oxazolidinone **207**, and the reaction proceeded with inversion at C1. *O*-Methylation of **207**, followed by the exposure to Me_2NH, and deacetylation gave allosamizoline (**172**) (*Scheme 32*).
Interestingly, in each case of the synthesis of allosamizoline (**172**) from sugar, D-glucosamine **198** was chosen as the starting material, and, in fact, there is the notion that D-glucosamine **198** is considered to be a biosynthetic precursor of allosamizoline (**172**). In a way, these syntheses from D-glucosamine might pave the way to elucidate the biosynthetic route of allosamizoline (**172**).

3.2.2 Trehazolin, Trehalamine and Its Aminocyclitol Moiety, Trehazolamine: A Trehalase-Specific Glycosidase Inhibitor

Trehalose (**222**) is a structurally interesting disaccharide in which two D-glucoses are linked by an $\alpha(1\text{–}1)\alpha$ glycosyl bond.



Trehalose (**222**)

Biologically, it is considered that D-glucose degraded from trehalose (**222**) with trehalase, which is a kind of glycosidase and is possibly used as an energy source by insects, and a series of glycosidase inhibitors exhibiting inhibitory activity towards this enzyme, would be expected to be a new type of potential insecticide. In 1991, Ando et al. reported the isolation of trehazolin (**223**) from the culture broth of *Micromonospora* sp. strain SANK 62390 [169,170]. This compound is a unique natural pseudodisaccharide showing a strong trehalase-specific inhibitory activity. Nearly concomitantly, the isolation of a compound named trehalostatin (**224**) from the culture broth of *Amicoratopsis trehalostatica* was also reported [171].

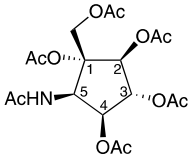
D-Glucose

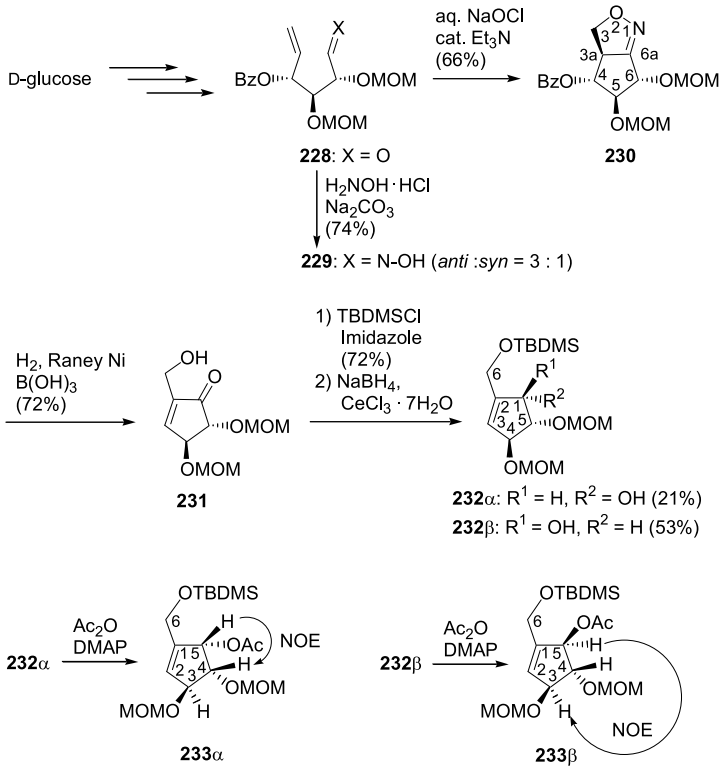


Aminocyclitol moiety
(Trehazolamine)
hexaacetate (**227**)

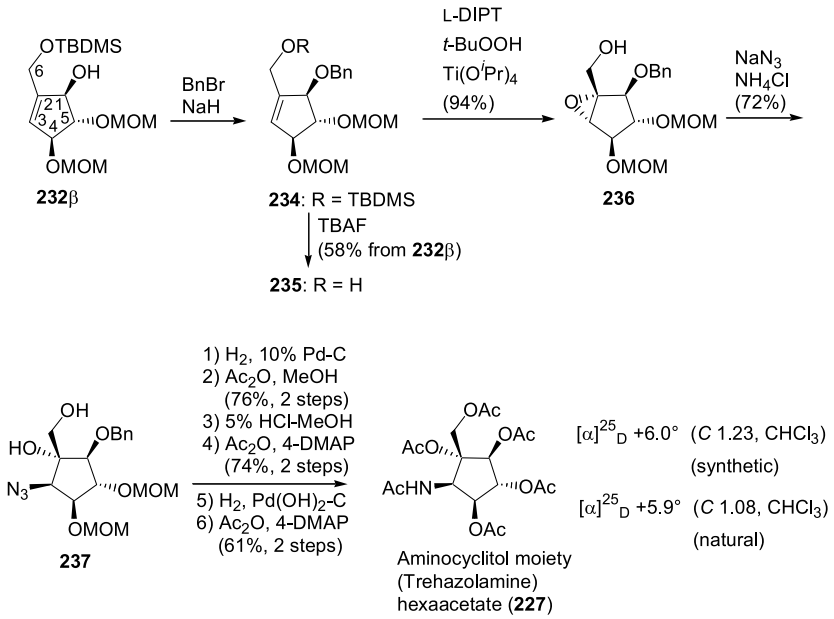
Trehalostatin (**224**) was reported to be the C5 epimer of the aglycone of trehazolin (**223**). According to the reported physical and biological data, trehalostatin (**224**) seems to be identical to trehazolin (**223**). Because both compounds are noncrystalline, X-ray crystallography could not be used to determine the correct stereochemistry; hence, the stereochemistry at the C5 position of the aglycones remains unknown. Therefore, a series of degradation studies of trehazolin (**223**) was attempted to try to obtain degradation products from which the correct stereochemistry could be deduced. Hydrochloric acid degradation provided degradation products: the aglycone moiety trehalamine (**225**), D-glucose, and the aminocyclitol moiety (**226**), from which we next obtained the acetylated product **227**. However, all products were also noncrystalline. Consequently, they could not be used to determine the correct stereochemistry. In the meantime, further NMR analysis of trehazolin (**223**) and a series of biochemical studies to elucidate its trehalase-specific inhibitory activity were undertaken, and on the basis of

these studies, it was surmised that the actual structural resemblance between trehazolin (**223**) and trehalose (**222**) may bear on the generation of trehazolin's activity towards various trehalases, and the absolute configuration of its aminocyclitol moiety (**226**) was hypothesized as [1*R*-(1α, 2β, 3α, 4β, 5β)]. Then, in order to verify the proposed correct structure of trehazolin (**223**), a series of synthetic studies were performed. The first enantioselective synthesis of trehazolin (**223**) and its components was accomplished by Kobayashi and Shiozaki et al. [172,173,174]. It was performed from D-glucose, and intramolecular [3 + 2] cycloaddition was used as the key step to form the 5-membered scaffold of the aminocyclitol moiety. As the first stage of the synthesis, the hexaacetate of the aminocyclitol moiety was synthesized to determine the absolute configuration of the aminocyclitol unit shown in *Scheme 33* and *Scheme 34* [173,174].

Intramolecular [3+2] cycloaddition of the oxime **229**, derived from D-glucose according to the method developed by Bernet and Vasella [175], furnished the corresponding isoxazoline **230**. In general, hydrogenolysis of isoxazolines **230** with Raney Ni in the presence of boric acid [176] results in conversion to a hydroxymethyl ketone. However, in this case, by virtue of the electron-withdrawing effect of the benzoyl group, β-elimination of the benzoyloxy group by the generated ketone was induced and the corresponding hydroxymethyl



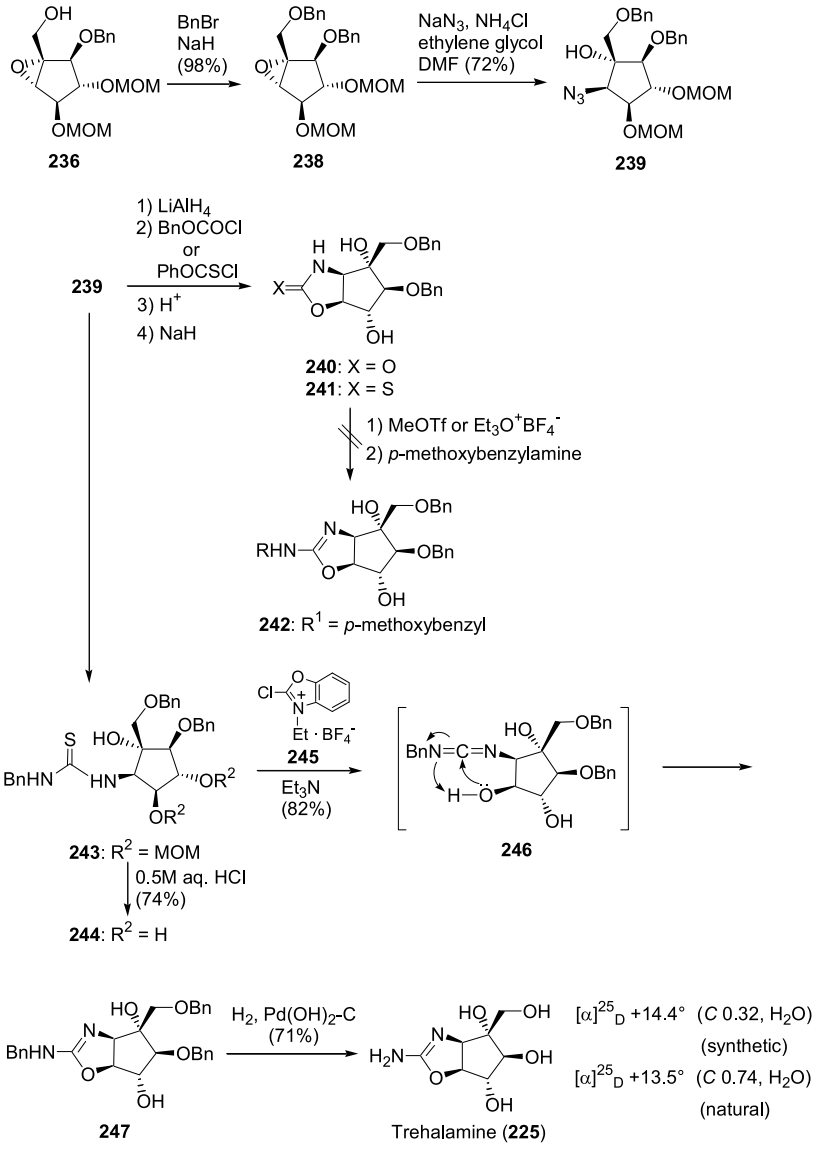
Scheme 33



Scheme 34

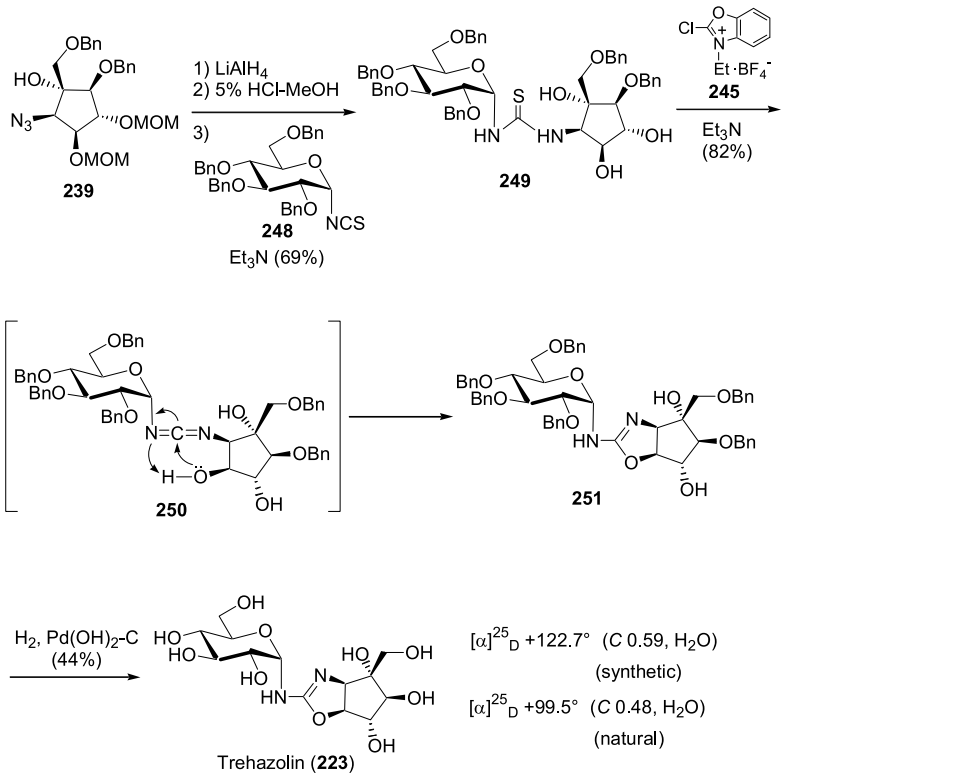
enone **231** was obtained. Silylation of the enone **231** and subsequent 1,2-reduction of the corresponding ketone afforded a separable 1:2.5 mixture of alcohols **232**. The configurations at the C1 positions of these alcohols **232** were determined by analysis of the ^{1}H-NMR data of the acetates **233**; that is, NOEs were observed between C5-H and C4-H of compound **233***α* and between C5-H and C3-H of compound **233***β* (*Scheme 33*).

Benzylation of the alcohol **232*β***, possessing the desired configuration, and subsequent removal of the TBDMS group of compound **234** afforded the corresponding allyl alcohol **235**. Several types of epoxidation towards the allyl alcohol **235** were attempted; Sharpless' epoxidation using diisopropyl L-tartrate [177] furnished the desired epoxide **236** as a single isomer. Finally, the synthesis of hexaacetate of the aminocyclitol moiety (**227**) was accomplished by regiospecific azide opening towards the chiral epoxide **236**, deprotection, and subsequent complete acetylation. This synthetic aminocyclitol hexaacetate was identical in all respects to the aminocyclitol hexaacetate obtained from the degradation product of natural trehazolin, and the absolute configuration was found to be [1*R*-(1*α*, 2*β*, 3*α*, 4*β*, 5*β*)] as expected (*Scheme 34*). Next, the synthesis of trehazolin aglycone, trehalamine (**225**) was conducted as shown in *Scheme 35*. The key point of this synthesis was the method by which the aminooxazoline ring was formed. Initially, the aminooxazoline formation, which was used for allosamizoline synthesis [128,129,143,144,153,161,162], was attempted via *O*-methylation of **240** or **241** derived from epoxide **236**. The *O*-alkylated compounds derived from **240** and **241** were exposed to benzylamine derivatives, but this method did not yield the desired product **242**. Finally, the cyclization of thiourea alcohol via the carbodiimide alcohol was attempted. The aminooxazoline ring can be considered as an equivalent of the *cis*-carbodiimide alcohol,



Scheme 35

and a number of methods to generate carbodiimides were investigated with the method of Mukaiyama [178,179] being selected. This synthetic method to derive carbodiimides from thiourea alcohol uses 2-chloro-3-ethylbenzoxazolium tetrafluoroborate **245** and related reagents, and was also applied to the synthesis of indolemycine [180]. The thiourea alcohol **244** derived from the azide alcohol **239** was treated with 2-chloro-3-ethylbenzoxazolium tetrafluoroborate **245**, furnishing the aminooxazoline derivative **247** via transformation of



Scheme 36

the *cis*-thiourea alcohol **244** to the corresponding carbodiimide alcohol **246** and subsequent cyclization of **246**. Finally, the aminooxazoline **247** was hydrogenolyzed to cleave three benzyl groups and to give trehalamine (**225**). This synthetic trehalamine was identical in all respects to natural trehalamine (*Scheme 35*).

On the basis of the synthesis of trehalamine (**225**), the synthesis of trehazolin (**223**) was undertaken. Coupling between the amino alcohol derived from the azide compound **239**, and the α-D-glucopyranosyl isothiocyanate derivative **248**, as synthesized by Camarasa [181], afforded the α-D-glucopyranosylthiourea derivative **249**. Treatment of this thiourea **249** with 2-chloro-3-ethylbenzoxazolium tetrafluoroborate **245** furnished the aminooxazoline derivative **251** via carbodiimide alcohol **250** as the intermediate. Finally, this aminooxazoline **251** was hydrogenolyzed to cleave the benzyl groups and to generate trehazolin (**223**). This synthetic trehazolin was identical to the natural trehazolin in all respects, including biological activities (*Scheme 36*).

Also, Ogawa's group reported the synthesis of racemic trehazolin aminocyclitol derivatives, as well as trehazolin and its diastereoisomers from *myo*-inositol, and thus contributed independently to the determination of the correct stereochemistry of trehazolin [182,183,184,185,186]. The successful total synthesis of trehazolin (**223**) encouraged Kobayashi and Shiozaki et al. to investigate structure-activity relationships regarding the inhibitory activities towards vari-

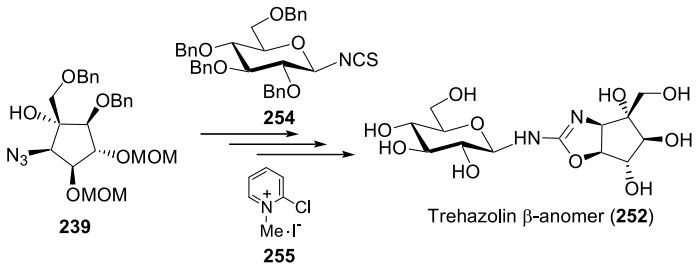


Figure 9
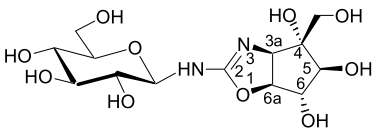
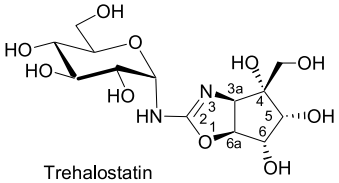
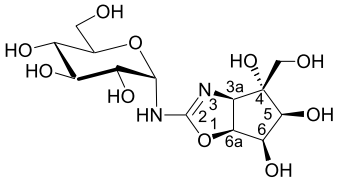
Synthesis of the trehazolin β-anomer

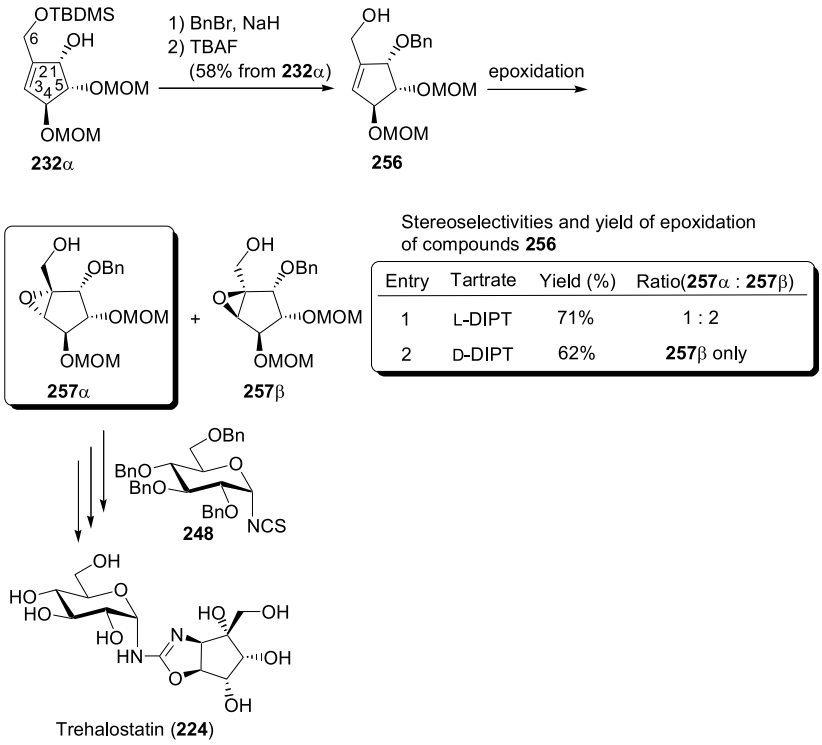
ous α-glucosidases resulting from the stereochemistry of trehazolin. They then designed the trehazolin stereoisomers.







To investigate the influence of the stereochemistry of the anomeric position on the inhibitory activities, the β-anomer of trehazolin (**252**) was synthesized from the azide **239** and the β-D-glucopyranosyl isothiocyanate derivative **254** [187]. To avoid anomerization and contamination of the α-anomer, 2-chloro-1-methylpyridinium iodide **255** was used in place of 2-chloro-3-ethylbenzoxazolium tetrafluoroborate **245** for the ring formation (*Fig. 9*).
At the step of the 1,2-reduction of the hydroxymethylenone **231**, the allyl alcohol **232**α was also obtained. Trehalostatin (the C5-epimer of trehazolin) (**224**) was then synthesized from this allyl alcohol **232**α according to the synthetic route to trehazolin (**223**) [188]. The physical data, including the ^{1}H-NMR spectrum, of trehalostatin (**224**), were quite close to those of trehazolin (**223**) itself, but the inhibitory activities of this compound towards trehalases were much weaker than those of trehazolin (**223**). As a result, the argued stereochemistries of the aminocyclitol moiety of trehazolin (**223**) and trehalostatin (**224**) were determined to be [1*R*-(1α, 2β, 3α, 4β, 5β)] and [1*R*-(1α, 2α, 3α, 4β, 5β)] by these synthetic studies, respectively (*Scheme 37*).



Scheme 37

Next, in order to investigate further the structure-activity relationships regarding the inhibitory activities towards various α-glucosidases resulting from the stereochemistry of the aminocyclitol moiety, the C-6 epimer of trehazolin (**253**) was synthesized [189,190]. In this synthesis, the challenging tandem aldol-Wittig type reaction was performed to construct the enone **[II]**. As shown in *Fig. 10*, it was expected that treatment of the silylenol lactone **[III]**, which was derived from D-ribonolactone, with the α-lithiated phosphorane [191] would give the enone **[II]** via the aldol reaction and subsequent intramolecular Wittig reaction in one pot (*Fig. 10*). *Scheme 38* shows the practical synthesis of the C-6 epimer of trehazolin (**253**). Treatment of the silylenol lactone **259**, which was derived from D-ribonolactone **258** in three steps, with the lithiated phosphorane furnished the cyclopentenone **260** in moderate yield. This reaction should thus have synthetic utility for the one-step synthesis of cyclic α, β-unsaturated ketones from cyclic enol ester-type derivatives. Afterwards, the synthesis proceeded basically according to the trehazolin synthesis, including 1,2-reduction of the enone **260**, stereoselective epoxidation, regiospecific azide-opening of the epoxide **262**, coupling between the amine derived from compound **263** and the isothiocyanate **248**, and cyclization to form the aminooxazoline ring **265**. Finally, compound **265** was hydrogenolyzed to cleave the benzyl groups and to furnish trehazolin C-6 epimer (**253**) (*Scheme 38*).

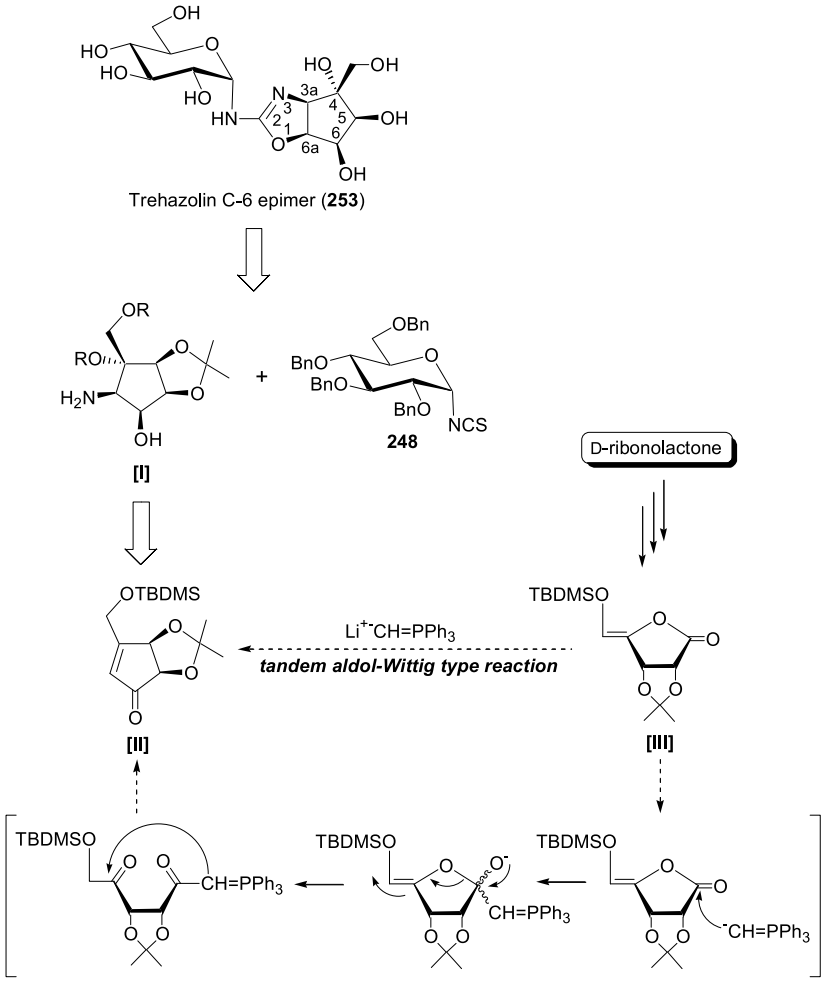


Figure 10
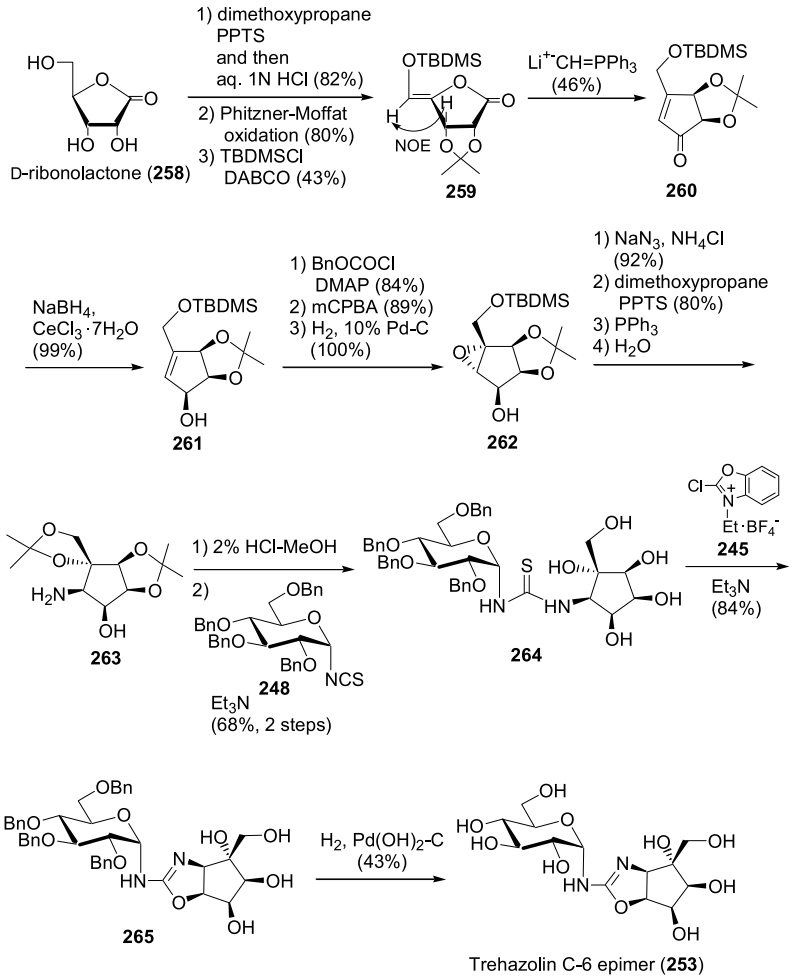
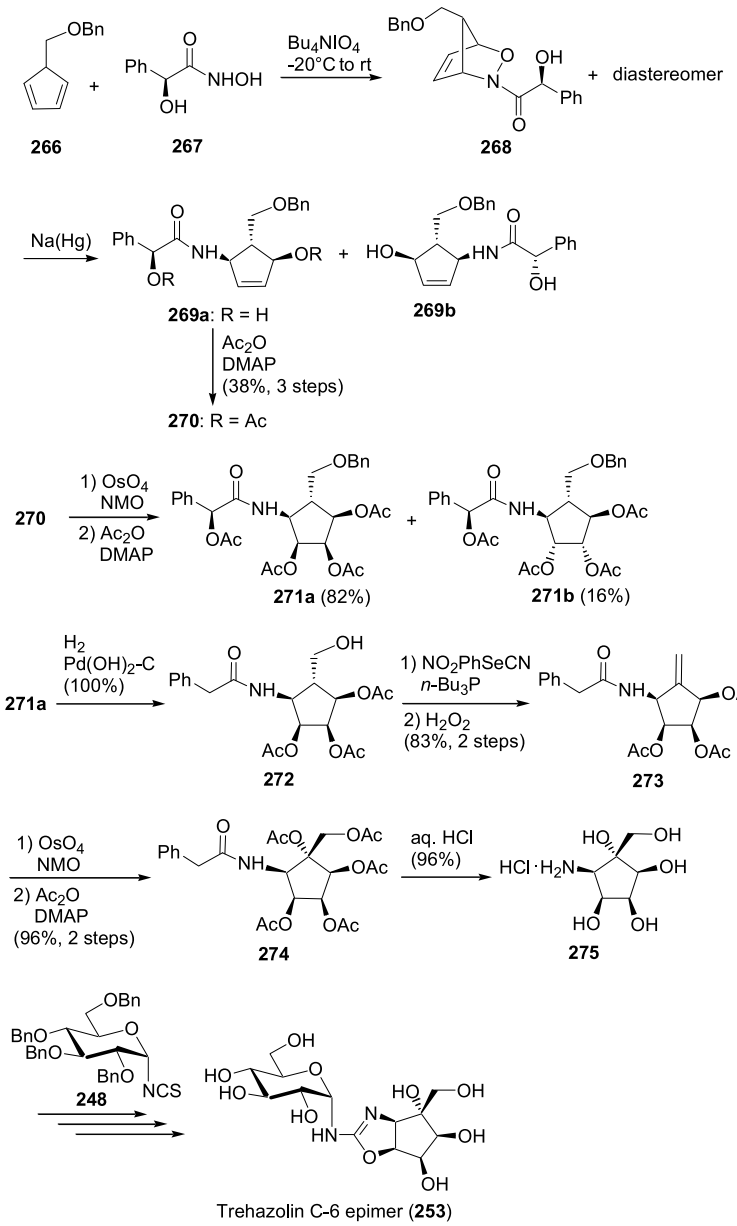
Synthetic strategy of trehazolin C-6 epimer (253) via tandem aldol-Wittig reaction

Ganem et al. also reported the synthesis of the trehazolin C-6 epimer (**253**) and the formal total synthesis of trehazolin (**223**) [192,193]. The synthetic strategy used was related to the synthesis of allosamizoline, and involved the cyclopentadiene derivative **266**, which was also used for the synthesis of allosamizoline, as the starting material. Treatment of the cyclopentadiene **266** [194] with (*S*)-mandelohydroxamic acid **267** in the presence of Bu_4NIO_4 led to a mixture of the desired cycloadduct **268** and its diastereomers. The inseparable mixture was reduced using Na(Hg) for separation to afford the pure cyclopentene **269a** and the minor cycloadduct **269b**. Compound **269a** was converted to acetate **270** for characterization of the structure. Dihydroxylation of **270** with OsO_4 favored *syn* addition, and subsequent acetylation gave compound **271a** selectively and quantitatively. The next key point in



Scheme 38

the synthesis was the introduction of a quaternary stereocenter. Hydrogenolysis of both benzylic ether and Ac groups of **271a** using $Pd(OH)_2$ on carbon afforded the alcohol **272**, and nitrophenylselenation followed by in situ oxidative elimination according to the method of Grieco et al. [195] cleanly converted **272** into alkene **273**. Flanked by two allylic substituents shielding the top face of the 5-membered ring, the exocyclic alkene increment in **273** underwent vicinal hydroxylation exclusively from the opposite face and subsequent acetylation furnished acetate **274**. Exhaustive acid hydrolysis of **274** provided the aminocyclitol **275** required for the synthesis of the C6-epimer of trehazolin (**253**). This aminocyclitol hydrochloride **275** was converted into the C6 epimer of trehazolin (**253**) in analogy to the syntheses of trehazolin (**223**) and its stereoisomers **224**, **252**, and **253** reported by Kobayashi and Shiozaki et al. [172,173,174,187,188,189,190] and Ogawa's group [182,183,184,185,186] (*Scheme 39*).



Scheme 39

Moreover, these authors prepared the aminocyclitol **226** needed for the synthesis of trehazolin (**223**) from the allyl alcohol **269a**. Epoxidation of **269a** with mCPBA gave the desired epoxide **276** exclusively. The epoxide **276** was exposed to 2:1 H_2O-TFA to open the epoxy ring, and afforded the alcohols **277**. They were transformed to peracetates **278a** and **278b**,

Trehazolin (223)

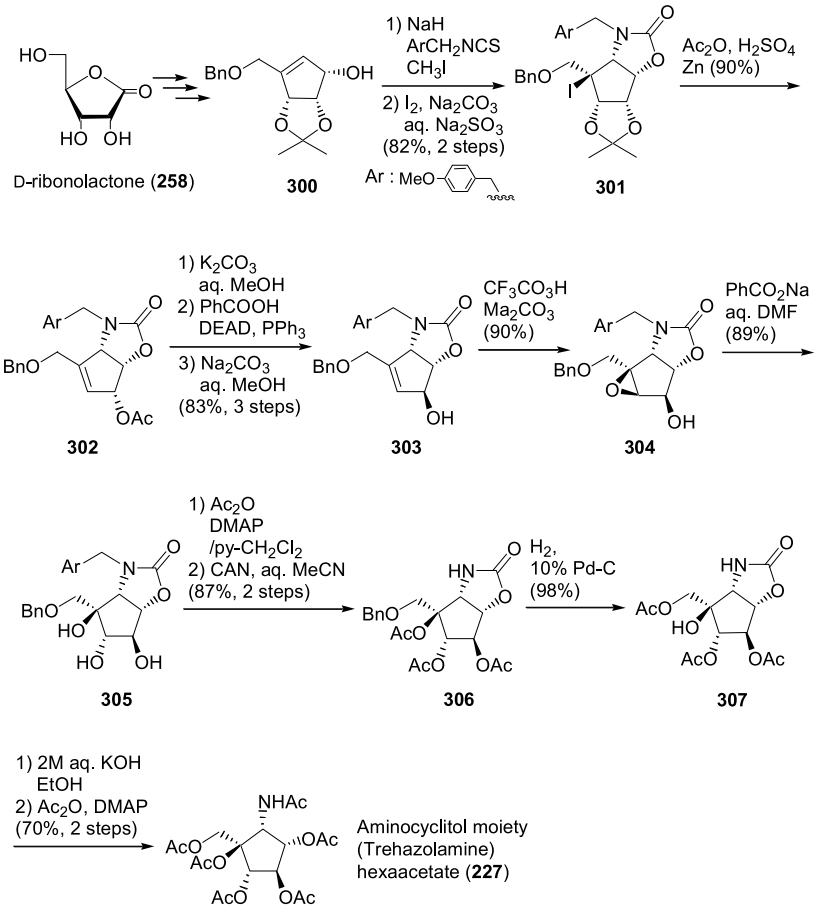
Scheme 41



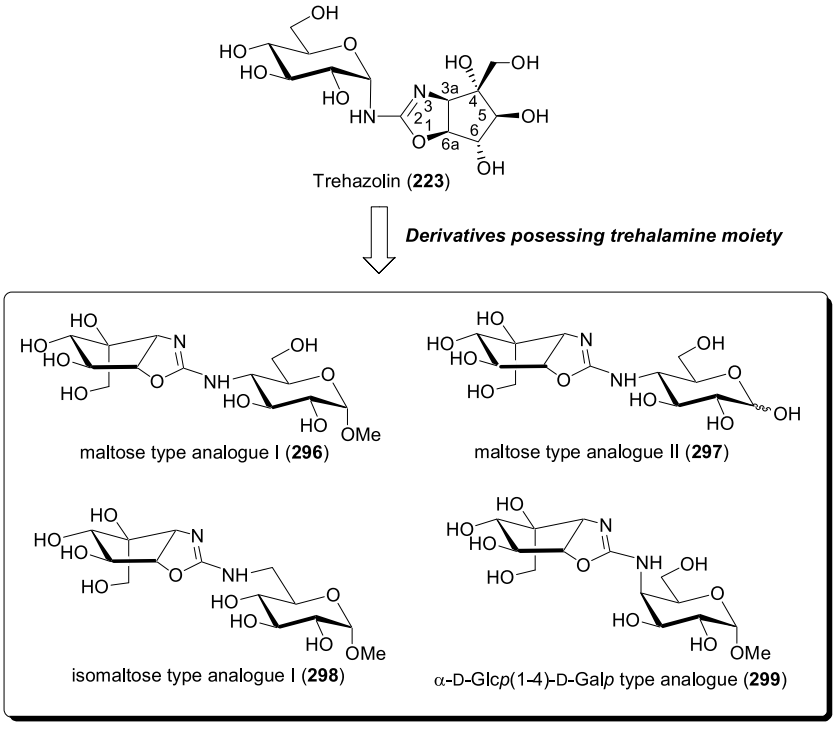
Scheme 42

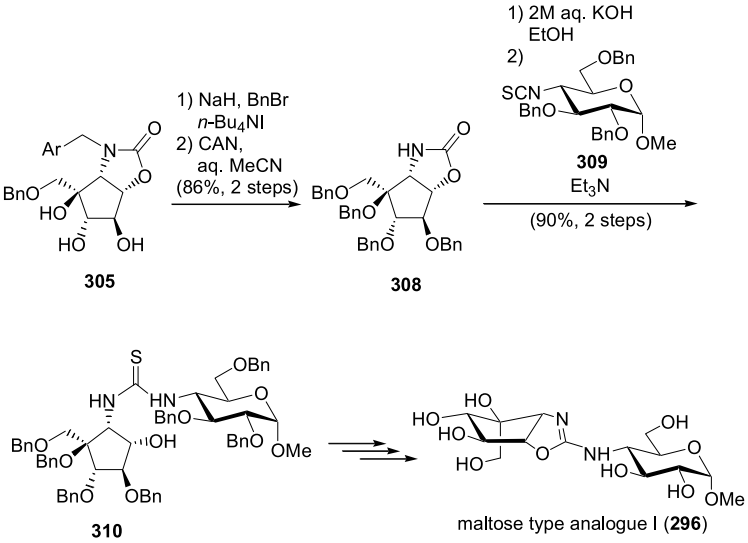
respectively, for further characterization of the structure of the alcohols **277**. The desired peracetate **278a** was converted into the aminocyclitol **226** necessary for the synthesis of trehazolin (**223**), according to the synthetic procedure for the C-6 epimer of trehazolin (**253**), and thus completed the formal total synthesis of trehazolin (**223**) (*Scheme 40*).

On the other hand, Carreira et al. also reported the total synthesis of trehazolin from the optically active spirocycloheptadiene [196], which was prepared from the (*R*)-epichlorohydrin **282** and lithium cyclopentadienide, shown in *Scheme 41*. Treatment of lithium cyclopentadienide (CpH+BuLi) with (*R*)-epichlorohydrin **282** afforded the optically active spirocycloheptadiene **283** in 91% ee. Compound **283** was converted into trichloroacetimidate **284** by treatment of NaH and Cl_3CCN [197], and subsequent treatment of **284** with I(*syn*-collidine)$_2ClO_4$ gave the alcohol **287** via the unstable intermediates **285** and **286**. After silylation of the secondary hydroxy group of **287**, the imidate underwent nucleophilic opening upon treatment of the corresponding silyl-protected imidate with Li_2NiBr_4 to yield the cyclopropylcarbinyl bro-

mide **288** [198]. The alkene moiety in **288** was converted into the epoxide **289** with dimethoxydioxorane [199], and subsequent treatment of the resulting epoxide **289** with $BF_3 \cdot Et_2O$ afforded the alcohol **290**. Conversion of **290** to **291** was performed under free radical conditions, which also resulted in partial reduction of the trichloromethyl moiety. Oxazoline **291** was directly converted into **292** by treatment with aqueous PPTS, followed by acetylation. Hydroboration of the terminal olefin unit in **292**, followed by Swern oxidation of the resulting primary alcohol, provided aldehyde **293** [200,201]. Conversion of **293** to the corresponding phenyl ketone **294** was achieved by treatment of **293** with PhMgBr and oxidation of the resulting secondary alcohol. The aryl ketone **294** underwent Norrish type II cleavage upon irradiation through a Pyrex filter in degassed PhH, giving the corresponding alkene, which, without purification, was reacted with catalytic OsO_4 to yield diol **295** as a single diastereomer. Exhaustive acid hydrolysis of **295** provided the aminocyclitol hydrochloride **226** necessary for the synthesis of trehazolin (**223**), and this corresponding aminocyclitol **226** was transformed to trehazolin (**223**) according to the preceding synthesis (*Scheme 41*).

After the total synthesis of trehazolin (**223**) and its stereoisomers, the further focus of synthetic studies on trehazolins was directed to the design and exploration of the other glucosidase-specific inhibitors possessing the trehalamine moiety, because trehalamine is considered to be a kind of pseudo-D-glucose. Compound **296** was designed by Knapp et al. as a pseudo-maltose and it was expected to have a potential for maltase inhibition [202]. On the other hand, compound **296** and its related compounds **297**, **298** and **299** were independently designed by Kobayashi and Shiozaki et al. [203].





Scheme 43

Knapp et al. achieved the synthesis of the trehazolin aminocyclitol moiety (trehazolamine) as the hexaacetate **227** in the process of the synthesis of a maltose-type of trehazolin derivative **296**. The allylic alcohol **300**, available from D-ribonolactone **258** in several steps according to the method of Marquez [204], was converted to its thiocarbamate derivative by condensation with *p*-methoxybenzyl isothiocyanate, which in turn was cyclized with I_2 to afford the iodooxazolidinone **301**. This is a rare example of formal anti-Markovnikov iodocyclization and may result from the kinetic preference for 5-membered (rather than 6-membered) and fused (rather than bridged) ring formation. One-pot treatment of **301** with Ac_2O and H_2SO_4 followed by activated Zn provided allylic acetate **302**, whose configuration was inverted at the C3 position (trehazolin aminocyclitol numbering), by the Mitsunobu procedure [205], and the allyl alcohol **303** was obtained. Epoxidation of the resulting alcohol **303** gave the desired epoxide **304** as a single stereoisomer detected, and then hydrolysis of **304** at the less substituted position (C2 position, trehazolin aminocyclitol numbering) led to the triol **305**. The stereochemistry of the cyclitol chemistry was proven by the conversion of **305** to the aminocyclitol hexaacetate **227** (*Scheme 42*).

Moreover, the triol **305** was converted into the *O*-benzylated compound **308**, which was transformed to compound **296** via coupling with D-glucopyranosyl isothiocyanate **309** [206], formation of aminooxazoline ring, and complete removal of protecting groups (*Scheme 43*).

Kobayashi and Shiozaki et al. synthesized the trehazolin-related compounds **296**–**299** from aminocyclitol **226** degraded from natural intact trehazolin (**223**) [203]. The purpose of the synthesis was to discover the pseudosaccharides with interesting α-glucosidase inhibitory activities, and especially, compounds **296** and **297** were designed as intestinal maltase inhibitors and **298** was designed as an intestinal isomaltase inhibitor, and these inhibitors were directed towards potent therapies for noninsulin-dependent diabetes. The general synthetic route is summarized in *Fig. 11*, and this route was established, based on the experience that cycliza-

tion of compound **[IV]** proceeded through path A to form thermodynamically stable [3, 3, 0] bicyclic structure in their synthesis of trehazolin C-6 epimer (**253**) [189,190].

Compounds **296**–**299** were synthesized according to this general synthetic route successfully and inhibitory activities of these compounds are shown in *Table 3*.

Interestingly, the structure-activity relationships of these compounds based on structural similarities couldn't be found. Compound **298**, which was designed as a pseudo-isomaltose, inhibited maltase and sucrase more potently than trehazolin (**223**); whereas compounds **296**, **297**, and **299** did not exhibit inhibitory activities toward maltase, isomaltase, and sucrase, compared to trehazolin (**223**). On the other hand, while none of the derivatives inhibited silkworm trehalase at a concentration of 100 μg/ml, only compound **297** possessed inhibitory activity toward porcine trehalase, with an IC_{50} value of 0.245 μg/ml. These results suggest that the interaction between an α-glucosidase and a glucose unit would be rather diverse among various glucosidases even though they can catalyze common substrates, and particularly, in the case of α-glucosidase reacting to disaccharide specifically, it was concluded that accurate structural analyses of the complexes consisting of the inhibitors and target enzymes are necessary for the design of the inhibitors with specific α-glucosidase inhibitory activity.

4 New Methods for Conversion of Sugars to Carbasugars

The definition of carbasugars can be described as highly oxygenated and functionalized carbocycles. Also, these types of carbocycle components are included in the biologically significant molecules, such as a variety of enzyme inhibitors represented by glycosidase inhibitors, nucleoside mimetics, and natural products. Therefore, the methodologies of carbocycle formation should be designed to be applied to a wide range of the synthesis.
In general, as mentioned earlier, the Ferrie reaction, intramolecular [3 + 2] cycloaddition of nitrile oxide and cyclization of the diene with Grubbs' catalysts are powerful methods as the key reactions for conversion of sugars to carbasugars. In addition to these, regarding the synthesis of 6-membered carbasugars, transformation of furanolactones to carbasugars via C1 unit prolongation and Lewis acid-mediated aldol-like cyclization, is also a useful synthetic method [207,208,209]. Also, regarding the transformation of a 6-membered to a 5-memberd ring, the development of methodologies has received much attention. Most of the methodologies involve a free-radical approach in which Bu_3SnH mediated a well-known 5-hexenyl-type radical cyclization from bromide, iodide, or thiocarbonyl imidazole precursors [210,211,212]. In the meantime, the chemical characters of Sm and Zr have been a topic of interest and their utility in synthetic chemistry continues to be examined. In particular, synthetic exploitation of the reagent SmI_2 has rapidly become one of the most significant fields in organic chemistry [213], and a great number of important synthetic transformations with SmI_2 involve the one-electron reduction of ketones and aldehydes to a samariumketyl radical anion which can promote cyclizations, deoxygenations, and reductions. In fact, during this decade, some new methodologies for the transformation of pyranose derivatives to 5-memberd carbasugars using Sm and Zr reagents have been reported. In this section, novel synthetic methodologies for conversion of sugars to carbasugars will be introduced.

4.1 Carbasugar Formation via $SnCl_4$-Promoted Intramolecular Aldol Condensation

Tatsuta et al. developed the method of carbasugar formation using $SnCl_4$-promoted intramolecular aldol condensation as a key step. The methodology is shown in ❯ *Fig. 12*, and a key precursor of carbasugar, α-hydroxymethyl enone **[XI]** was achieved according to the following steps: (1) 1,2-addition of lithiated $MeSO_2Ph$ to furanolactones containing a dimethyl acetal **[VII]**, (2) transformation of compound **[VIII]** to linear silyl enol ether **[IX]**, (3) $SnCl_4$-promoted aldol-like cyclization of **[IX]** to α-phenylsulfonyl cyclohexenone **[X]** and (4) conversion of the corresponding α-phenylsulfonyl cyclohexenone **[X]** to α-hydroxymethyl cyclohexenone **[XI]** through the Michael-type addition of tributylstannyl-lithium followed by trapping with formaldehyde and desulfonylation. This transformation is ideally suited to the synthesis of carbocycle-containing natural products and carbasugars, since the core skeleton arises after appropriate replacement of the phenylsulfonyl group, and, in practice, this method was applied to total synthesis of progesterone receptor ligands, (–)-PF1092A, B, and C [207], and (–)-glyoxalase inhibitor and its precursor (–)-KD16-U1 (❯ *Fig. 12*) [208].
As shown in ❯ *Scheme 44*, this method was also applied to total synthesis of (+)-valienamine (**320**) and (+)-validamine (**324**) [209]. Silyl enol ether **314** derived from D-xylose in nine steps

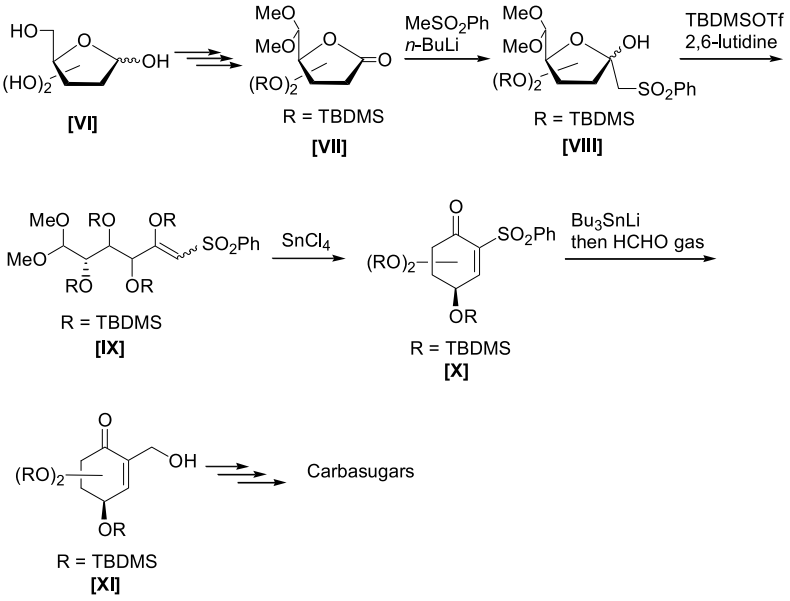

Figure 12
Key steps of the synthesis of the 6-membered carbasugar using $SnCl_4$-promoted intramolecular aldol condensation

was converted to α-hydrixymethyl cyclohexenone **316** via $SnCl_4$-promoted intramolecular aldol condensation and Michael-aldol reaction with tributylstannyl-lithium and formaldehyde in good yield. Cyclohexenone **316** was converted to (+)-valienamine (**320**) and (+)-validamine (**324**) via the common intermediate, azide **318** in good yield (*Scheme 44*).
It can be expected that this transformation would be one of the methods useful for the synthesis of 6-membered carbasugars.

4.2 SmI_2-Mediated Carbasugar Formation

First, the intramolecular cyclizations between carbonyl compounds and olefins will be described. This field can be classified into three types as illustrated in *Fig. 13*. One is a type of cyclization between carbonyl compounds and α, β-unsaturated esters (type [A]), the next is a type of cyclization between carbonyl compounds and simple olefins (type [B]), and the last is a type of cyclization between carbonyl compounds and oximes (type [C]) (*Fig. 13*).
The general feature of these reactions is as follows: When treated with SmI_2, a reductive cyclization between the carbonyl compound and the β-carbon of the olefin of **[XIII]** derived from sugars **[XII]** gives the desired polyhydroxylated cyclopentane **[XIV]**, in which a new C1/C5 bond (carbohydrate numbering) is formed between sp^2 centers. In the overall sequence, the sp^3 alcohol stereocenter at C5 is destroyed when oxidation occurs to form the carbonyl moieties and subsequently reinstated, upon treatment with SmI_2, to form a new hydroxy-

bearing stereocenter. In contrast, the existing 5-hexenyl free radical methods for the cyclization of carbohydrates do not allow for the incorporation of this additional sp^3 alcohol center which provides further functionality for subsequent synthetic manipulations. This is a general difference between the traditional radical cyclization and the SmI_2-mediated radical cyclization [214].

4.2.1 Cyclization between Carbonyl Compounds and α, β-Unsaturated Esters

Enholm et al. reported the SmI_2-mediated construction of carbocycles from carbohydrate templates in 1989 [214]. This is the example of the type [A] reaction in *Fig. 13*. This strategy, which permits the conversion of pyranose sugars into highly oxygenated cyclopetanes, is illustrated in *Fig. 14* (Eq. (1)). Treatment of carbohydrate templates **[XVI]**, which are derived from sugars **[XV]** via Wittig reaction with stabilized ylides and subsequent PDC oxidation, with the one-electron reducing reagent SmI_2 prompts the intramolecular coupling of two sp^2-hybridized carbon centers and finally constructs a highly oxygenated cyclopentane

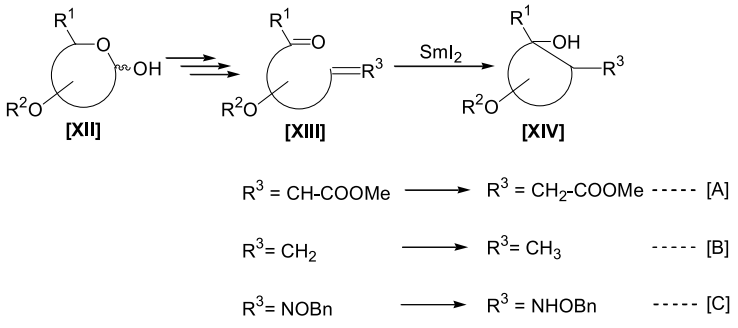

Figure 13
SmI_2-mediated carbasugar formation

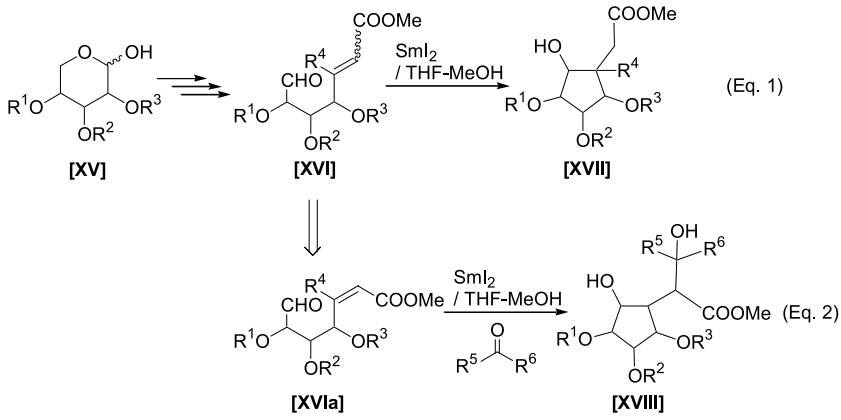

Figure 14
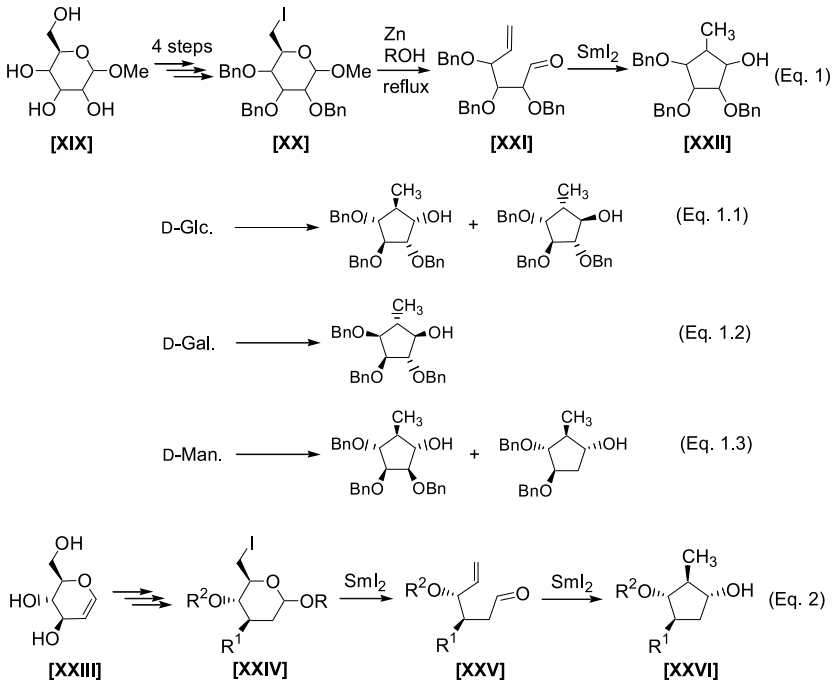
Cyclization between carbonyl compounds and α, β-unsaturated esters

ring **[XVII]**. Interestingly, the geometry of the olefin unit of the substrates influences the stereochemistry at C1 and C5 (carbohydrate numbering) of the products, and there is the tendency that *Z*-olefins give the *anti*-alcohols and *E*-olefins provide the *syn*-alcohols exclusively. Also, this method was applied to the synthesis of the natural product, anguidine [215]. Moreover, Enholm also reported the sequential SmI_2-promoted one- and two-electron reactions as an application of this concept (● *Fig. 14*, Eq. (2)) [216]. Treatment of the compounds **[XVIa]** and carbonyl compounds with SmI_2 afforded a highly modified carbocycle. In the domino key step, SmI_2 promoted a sequential one-electron (radical) cyclization of an aldehyde and an alkene, followed by a two-electron intermolecular carbonyl addition reaction to afford compounds **[XVIII]** (● *Fig. 14*).

4.2.2 Cyclization between Carbonyl Compounds and Simple Olefins

As the example of the type [B] reaction, the reports by Holzapfel et al. and Chiara et al. who independently reported this type of reaction are described. Initially, Holzapfel et al. reported the SmI_2-mediated radical cyclization of the ring-opened hex-5-enals **[XXI]** derived from pyranoses **[XIX]** via the step of the reductive elimination of C6 iodopyranose derivatives **[XX]** with active Zn [217] (● *Fig. 15*, Eq. (1)). Afterwards, they also reported the one-pot SmI_2-



● Figure 15
Cyclization between carbonyl compounds and simple olefins (1)

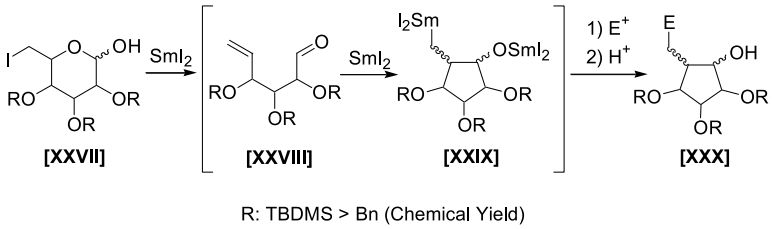


Figure 16
Cyclization between carbonyl compounds and simple olefins (2)

mediated radical cyclization of 6-deoxy-6-iodohexopyranose derivatives **[XXIV]** which were derived from glycals **[XXIII]** [218] (*Fig. 15*, Eq. (2)).
In each case, the cyclization itself proceeds typically with above 65% efficiency, and the stereochemistry of C1 and C5 (carbohydrate numbering) of the products shows an *anti*-configuration. However, as an exception, in case of the *manno*-type derivative of **[XXI]**, the compound arises via initial SmI_2-mediated elimination of the α-substituent (benzyloxy group) to the carbonyl (*Fig. 15*, Eq. (1.3)).
On the other hand, Chiara et al. also reported outcomes similar to Holzapfel's results [219]. They attempted the one-pot, SmI_2-mediated cyclization of fully functionalized 6-deoxy-6 iodohexopyranose derivatives and investigated the influence of the stereochemistry of the substrates as well as the effects of the protecting groups in this type of reaction (*Fig. 16*).
Basically, their results are consistent with those of Holzapfel et al., especially with respect to the stereochemical arguments given above and the chemical yield of the products. According to these studies, the TBDMS group is suitable for the reaction from the viewpoints of the ease of separation of the products and the avoidance of the β-elimination seen in the reports of Holzapfel et al. Also, they reported that 6-deoxy-hexopyranose derivatives were obtained as the by-products in the range of yields of 10–50%.

4.2.3 Cyclization between Carbonyl Compounds and Oximes

Chiara et al. also reported the type [C] reaction, the cyclization between carbonyl compounds and oximes [220,221]. As illustrated in *Fig. 17*, three types of substrate were synthesized from hexopyranoses and pentopyranoses, and the terminal *O*-benzylformaldoxime-ketones and the terminal *O*-benzylformaldoxime-α, β-unsaturated esters were synthesized from a series of hexopyranoses, and meanwhile the terminal *O*-benzylformaldoxime-aldehydes were derived from a series of pentopyranoses (*Fig. 17*).
The goal of this attempt is the stereochemistry of the hydroxy group and amino group generated after cyclization. In cases of cyclization of the terminal *O*-benzylformaldoxime-ketones and the terminal *O*-benzylformaldoxime-α, β-unsaturated esters, the stereochemistry is mainly the *anti*-configuration as is also the case for the cyclization described above.
However, in contrast to the latter substrates, in the case of cyclization of the terminal *O*-benzylformaldoxime-aldehydes, the realized stereochemistry depends on the configuration or the protecting groups.

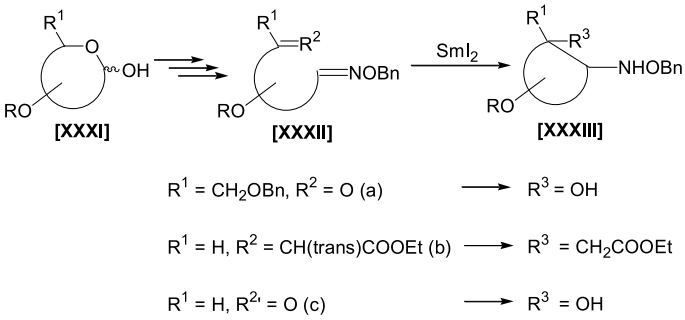

Figure 17
Cyclization between carbonyl compounds and oximes

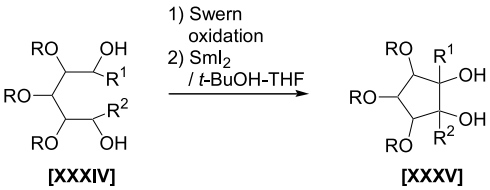

Figure 18
SmI_2-mediated Pinacol coupling

4.3 SmI_2-Mediated Pinacol Coupling

SmI_2-mediated pinacol coupling is also a useful synthetic method to form carbasugars possessing a *cis*-diol moiety from sugars. In fact, as mentioned above, Nakata et al. utilized this method in the synthesis of cyclophelitols, and it is one of the good examples to verify the synthetic utility of SmI_2-mediated pinacol coupling [20]. This coupling reaction has also been utilized in the field of the transformation of sugars to highly functionalized 5-membered carbocycles (*Fig. 18*).

Initially, application of this method to the formation of 5-membered carbocycles was reported by Sinäy et al. [222]. In their case, a dialdehyde was used as the substrate, and cyclization occurred with a comparable overall yield of carbocyclic *cis*-diols but with much lower diastereoselectivity. Later, Iadonisi et al. reported the results of the application using keto-aldehydes as the substrates [223]. Compared to Sinay's results, cyclization of the keto-aldehydes occurred with a relatively high stereoselectivity, and it should be suggested that, in particular, electrostatic interactions play an important role in the stereocontrol of this reaction.

4.4 SmI_2- or Zirconium-Mediated Ring Contraction of Hexapyranoside Derivatives to 5-Membered Carbosugar

As mentioned in the above sections on the syntheses of natural glycosidase inhibitors, the ring contraction reaction of a 6-membered ring system to a 5-membered ring system is definitely

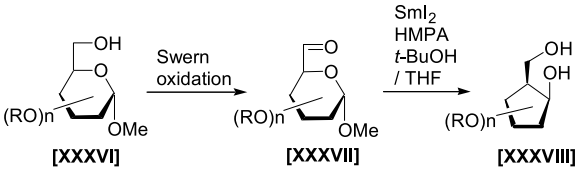

Figure 19
SmI_2-mediated ring contraction of hexapyranoside derivatives to 5-membered carbasugars

a significant aspect in synthetic chemistry, and the further development of this type of method should pave the way to the syntheses of the complex natural products and artificial chemicals including clinical drugs as well as a series of glycosidase inhibitors.

Here, the SmI_2- or zirconium-mediated ring contraction of hexapyranoside derivatives to 5-membered ring carbosugars will be described.

Sinäy et al. presented the SmI_2-mediated ring contraction of methyl 6-unprotected-hexopyranoside derivatives to fully functionalized 5-membered carbosugars via the intermediate aldehyde shown in *Fig. 19* [224]. The aldehyde **[XXXVII]**, which was derived from the methyl 6-unprotected-hexopyranoside derivative **[XXXVI]** via Swern oxidation, was treated with SmI_2 (5 equiv.) in THF in the presence of HMPA and *t*-BuOH to afford the *cis*-cyclopentane **[XXXVIII]** exclusively. Interestingly, the *cis*-configuration between C1 and C5 (carbohydrate numbering), which is the new stereocenter generated in this reaction, does not depend on the substrates, and each compound can be obtained in moderate yield (*Fig. 19*).

Sinäy et al. anticipated the mechanism of the reaction illustrated in *Fig. 20*. The first equivalent of SmI_2 reduces the aldehyde **326**, which was derived from **325**, to the samariumketyl **327**. The second equivalent of SmI_2 reduces the corresponding ketyl **327** to disamarium species **328**, which then undergoes ring opening followed by methoxide elimination to give the key intermediate **330**. Subsequently, this reaction uniquely generates a system which is ideally suited for a following aldol cyclization reaction involving intramolecular nucleophilic attack of the samarium enolate onto aldehyde through a 5-enol *exo-exo-trig* process. With respect to the stereoselectivity of this reaction, they concluded that it was expected to ensue from a samarium-linked, medium-sized chelate, from which the carbon–carbon bond formation would take place as a ring contraction (*Fig. 20*).

Recently, Aurrecoechea et al. reported the synthesis of 2-vinylcyclopentanols by SmI_2/Pd(0)-promoted carbohydrate ring-contraction [225]. On the other hand, Ito and Taguchi et al. independently presented the $Cp_2Zr/BF_3{\cdot}Et_2O$-mediated carbohydrate ring-contraction [226,227]. The contrast regarding the stereochemistry of products in each methodology is interesting as illustrated in *Fig. 21*.

First, the SmI_2/Pd(0)-promoted carbohydrate ring-contraction will be described. As illustrated in *Fig. 21*, substrates **[XXXIX]**, which were derived from methyl 6-unprotected hexapyranoside derivatives via Swern oxidation followed by Wittig olefination, were treated with SmI_2 and a catalytic amount of $Pd(PPh_3)_4$ to afford the 2-vinylcyclopentanols **[XXXX]** possessing the *trans*-stereochemistry between the vinyl and the newly generated hydroxyl group. The authors speculated on the mechanism of this reaction and the cause of the predominant *trans*-stereoselectivity of the resulting compounds as illustrated in *Fig. 22*. The for-

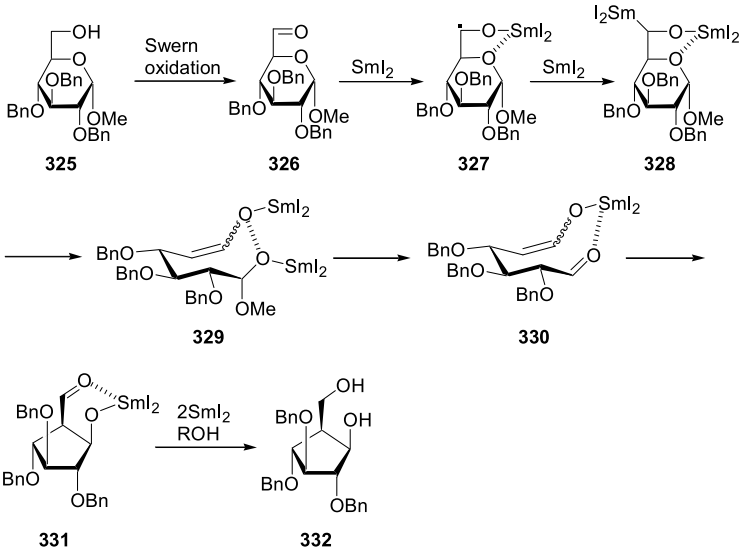

Figure 20
Proposed mechanism of SmI_2-mediated ring contraction

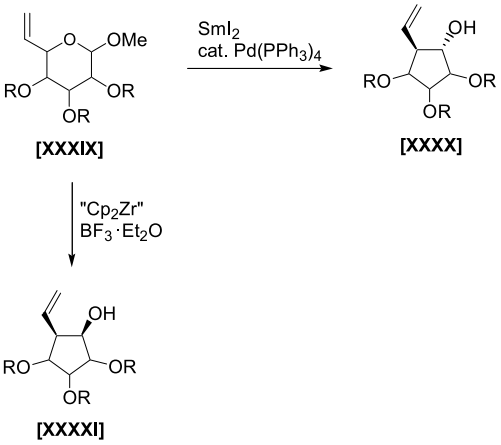

Figure 21
SmI_2-Pd(0)- or Zr-mediated ring contraction of hexapyranoside derivatives to 5-membered carbasugars

mation of cyclopentane products can be rationalized by a Pd(0)-promoted ring-opening of **[XXXIX]** leading to an intermediate **[XXXXII]** that contains both a *p*-allylpalladium complex and an aldehyde moiety. Reduction of the palladium complex by SmI_2 and carbonyl addition of the resulting allylsamarium species **[XXXXIII]** would then lead to the observed products **[XXXX]**. With respect to the stereochemistry of the products observed in these cyclizations, the predominant *trans*-stereoselectivity is surprising when compared to the relat-

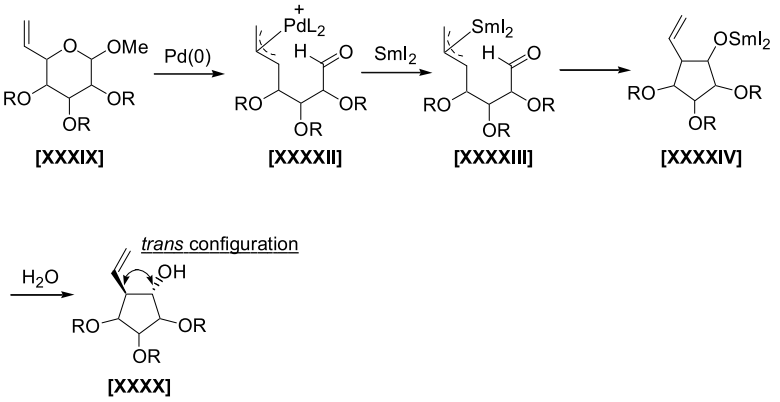

Figure 22
Proposed mechanism of SmI_2-Pd(0)-mediated ring contraction

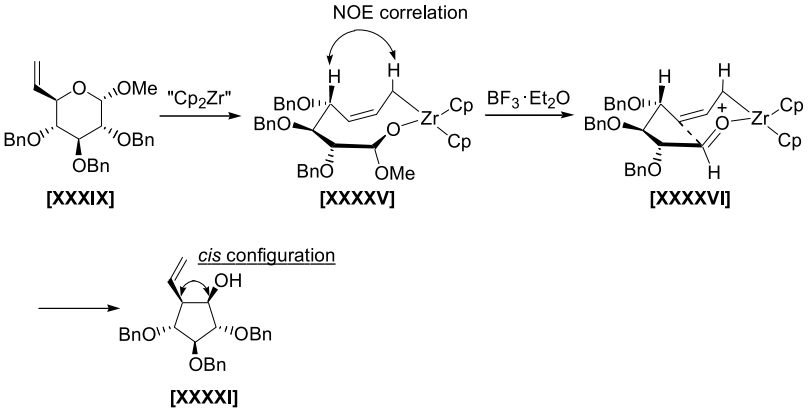

Figure 23
Proposed mechanism of Zr-mediated ring contraction

ed SmI_2/Pd(0)-promoted intramolecular cyclization of a ketone containing a pendent vinyloxirane moiety. This latter case is also assumed to proceed through allylsamarium intermediates, but affords preferentially a *cis*-product, presumably through a chelated cyclic transition structure. If a similar mechanism is indeed operating, the different stereochemical outcomes described above could be due to a combination of factors derived from differences in reaction conditions and substrate structures. Interestingly, in addition to the preferred *trans*-relationship observed between the vinyl and hydroxyl groups, the glucose- and mannose-derived substrates also displayed preference for a *trans*-relationship between the hydroxyl group and the adjacent benzyloxy group. Whereas for the more selective galacto derivatives, the opposite *cis*-relationship was found (*Fig. 22*).

On the other hand, the zirconium-mediated ring contraction of hexapyranoside derivatives, which was reported by Ito and Taguchi et al. afforded the 2-vinylcyclopentanols, and the

resulting 2-vinylcyclopentanols possess *cis*-stereochemistry between the vinyl group and the newly generated hydroxyl group. They explained that the derived stereochemistry would be induced through the intermediates illustrated in Fig. 23. Treatment of **[XXXIX]** with Cp_2Zr in THF provided intermediate **[XXXXV]**, which was confirmed by NMR analysis. The proof of **[XXXXV]** as an intermediate in the reaction was further confirmed by the conversion of **[XXXXV]** to **[XXXXI]** upon addition of $BF_3{\cdot}Et_2O$. It is probable that $BF_3{\cdot}Et_2O$ accelerates the elimination of the methoxy group through coordination to the methoxy oxygen of **[XXXXV]** to form the sterically favored oxocarbenium ion **[XXXXVI]**. Finally, this intermediate was cyclized to afford the resulting *cis*-2-vinylcyclopentaol **[XXXXI]** (Fig. 23).

5 Conclusion

As mentioned above, a variety of natural glycosidase inhibitors have been isolated, and they show interesting, strong, and enzyme-specific inhibitory activities. Recently, it was recognized that these compounds are important molecules to elaborate the pivotal roles of glycoconjugates in living systems, and have potential use as clinical drugs, and, in the field of biochemistry, the synthesis and supply of the glycosidase inhibitors and their analogues occupies a quite significant position. In this chapter, a variety of syntheses of glycosidase inhibitors were described, and also applications and developments of the new synthetic methodologies for transformation of sugars to carbasugars, ranging from the typical Ferrier reaction to the recent SmI_2/Pd(0)-mediated ring-contraction, could be introduced through the synthesis of a variety of glycosidase inhibitors. I hope that a variety of studies in glycoscience using carbasugars will pave the way to further elucidation of the functions of glycosidases and glycoconjugates in living systems.

Acknowledgements

Finally, I thank Dr. Masao Shiozaki, currently at RIKEN, for helpful discussions and suggestions during the preparation of this chapter.

Abstract

Sugars with heteroatoms other than oxygen in the ring are unusual but highly interesting relatives of "normal" sugars. In particular, 4-thiofuranoses as well as 5-thiopyranoses have attracted considerable attention. Side by side with their counterparts with nitrogen in the ring,

the iminosugars, these thiosugars feature exciting challenges for both the chemists synthesizing them and the biologists investigating their biological properties as glycomimetics. This chapter is aimed at giving an introduction to the world of sugars with sulfur in the ring, their syntheses as well as their chemical and biochemical properties as known to date.

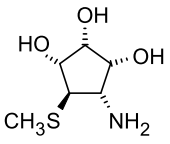
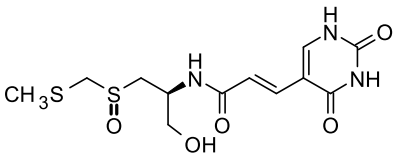
1 Introduction

Displacement of the ring oxygen in a sugar by other heteroatoms such as nitrogen or sulfur leads to pronounced changes of the physico-chemical properties and, thus, in the "information content" of the modified carbohydrate towards biochemical systems. Consequently, the altered biological properties of such a derivative with sugar-modifying enzymes, for example glycosidases or glycosyl transferases, as well as other carbohydrate recognizing biological entities can lead to useful applications as a diagnostic or therapeutic agent. Sugar analogs with nitrogen instead of oxygen in the ring have attracted considerable attention due to their pronounced biological activities as inhibitors of glycosidases. Similar effects have been found with carbohydrates bearing sulfur in the ring. Other elements introduced into this position, for example phosphorus or selenium, have had lesser impact on carbohydrate chemistry and glycomimetics research.

In the periodic table, sulfur is positioned in the same group next to oxygen. Despite such a close resemblance of the outer shell orbitals, sulfur can also occur in oxidation states other than −2, namely +2, +4 as well as +6. Thus, a large variety of organo-sulfur compounds exhibiting a wide range of different properties is found in nature.



1



2

In addition to quite a few sulfur-containing amino acids, many sulfur containing organic natural products exhibiting notable biological activities are known to date, such as the vitamin biotin, the *Allium* components which are responsible for the characteristic taste and smell of onion, garlic, and related plants, the antibiotic penicillins and lincomycins as well as the

powerful mannosidase inhibitor mannostatin (**1**) [1]. Compounds with sulfur in a higher oxidation state include, the antiviral agent sparsomycin (**2**) [2], a sulfoxide as well as taurin (2-aminoethanesulfonic acid, the sulfonic acid equivalent of glycine) just to mention a few well-known examples. Consequently, sugars, sugar analogs, as well as carbohydrate-related natural products with sulfur in the ring have attracted considerable interest, both in terms of synthetic challenges as well as potential biological activities.

2 Thiosugars

2.1 Physico-Chemical Properties

A sulfur-containing hemiacetal ring is more stable [3,4,5] as was concluded from the distinctly reduced mutarotation exhibited by 5-thioaldoses when compared to their oxygenated parent compounds. On the other hand, it was discovered that glycosides of such thiosugars are more prone to hydrolysis than their natural counterparts [6].

Because of the higher nucleophilicity of sulfur as compared to oxygen, the ring size is generally dependent on the position of the thiol group. In 5-thiosugars the pyranoid tautomers prevail over five-membered ring systems whereas in 4-thiosugars the furanoid form is found to be preferred over the pyranoid ring containing O-5. As with natural sugars, for thermodynamic reasons, pyranoid 5-thiosugars have been found to be more stable than furanoid 4-thiosugars [7]. As a consequence of the smaller C–S–C bond angle in 5-thio-D-glucopyranose as compared to the C–O–C bond angle in D-glucopyranose, the former was found to be more puckered [8].

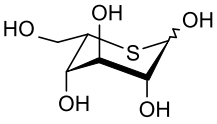
Anchimeric assistance by the ring sulfur during nucleophilic displacement reactions at various ring positions have frequently been reported and could also be exploited for defined and desired structural alterations.

Sulfoxides and sulfones have been prepared by oxidation of thiosugars but have only found very limited use as carbohydrate mimics.

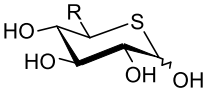
On the other hand, biologically active sulfonium-containing species have been discovered and will be discussed in the following.

2.2 Early Developments

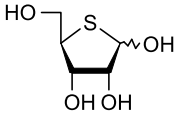
As early as 1961/62 the first examples of 5-thiopyranoses were reported in the literature. Adley and Owen [4] described the synthesis of 5-thio-L-idopyranose (**3**) by thiirane ring opening of 5,6-dideoxy-5,6-epithio-1,2-*O*-isopropylidene-β-L-idofuranose with potassium acetate in a mixture of glacial acetic acid and acetic anhydride and subsequent deprotection.



3

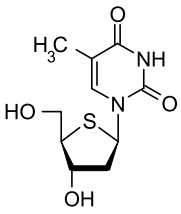


4 R = H
5 R = CH_2OH

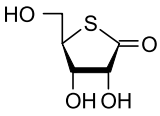


6

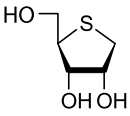
5-Thio-D-xylopyranose (**4**) was prepared by the same group and also by Schwarz and Yule [5] as well as by Whistler and co-workers [9,10]. 5-Thio-D-glucopyranose (**5**) was first synthesized by Feather and Whistler [11].



7



8



9

The first sulfur-containing furanose rings were described by Reist and co-workers [12,13], who prepared 4-thio-D- (**6**) and -L-ribofuranose via nucleophilic displacement of the tosylate in 2,3-*O*-isopropylidene-4-*O*-toluenesulfonyl-α-D- and -α-L-lyxopyranosides, respectively, with potassium thiobenzoate in DMF. Subsequently, several nucleosides of 4-thiofuranoses were synthesized, for example, the 4′-thio analogue [14] of natural thymidine (**7**) or the corresponding derivative of cytidine [14].

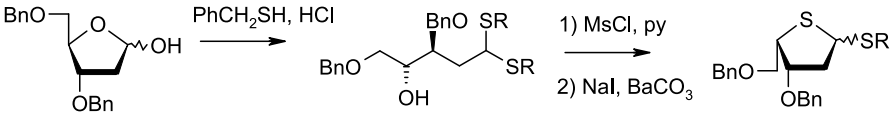
2.3 Furanoid Systems

Replacement of the ring oxygen in naturally occurring as well as synthetic nucleosides for potentially useful therapeutic reasons has been a major task of carbohydrate chemistry in context with the topic under consideration. Thus, starting in the early 1960s, all diastereomeric 4-thio analogs of natural pentofuranoses as well as some of their enantiomers were prepared and based on these approaches a wide range of synthetic 4′-thionuclosides has been reported.

2.3.1 4-Thioaldopentoses and Derivatives

4-Thio-D- as well as -L-ribofuranosides, synthesized by Reist and co-workers [12,13], were amongst the first furanoid thiosugars with sulfur in the ring. The synthesis of methyl 4-thio-D-ribofuranoside from α-L-lyxose was also reported by Whistler and co-workers [15]. The corresponding per-*O*-acetylated sugar served as an intermediate in the preparation of various purine and pyrimidine nucleosides [14]. A synthesis of free 4-thio-D-ribofuranose was achieved by Imbach and co-workers [16] who also prepared protected derivatives suitable for nucleoside syntheses [17]. Protected 4-thio-D-arabinofuranose as well as the corresponding D-*xylo* configured sugar were prepared by the Reist group [18]. Nayak and Whistler [19] reported the synthesis of methyl 4-thio-β-D-arabinofuranoside and subsequently employed this compound for nucleoside syntheses [20].

4-Thio analogs of D-ribono- (**8**) as well as L-lyxonolactones were synthesized by Varela and Zunszain [21]. Syntheses of 1,4-anhydro-4-thio-D- (**9**) and -L-ribitol were recently described by Altenbach and Merhof [22,23]. 1,4-Anhydro-4-thio-D-arabinitol was employed in the synthesis of a potential inhibitor of glycosyl transferases [24]. Thiofuranosides



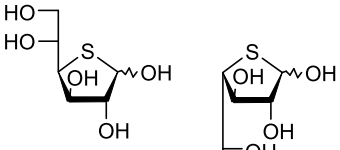
10

Scheme 1

of 4-thiopentofuranoses [25], prepared by intramolecular displacement of a sulfonate by a C-1 thioacetal sulfur atom, as well as the corresponding 2-deoxyderivatives such as **10** [26], including epimers thereof and C-3-branched analogues [27] as well as an O-glycoside [28] have been employed mainly en route to 4-thionucleosides.

2.3.2 4-Thioaldohexoses and Derivatives

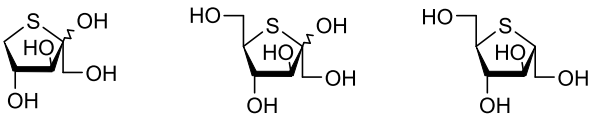
In the series of the aldohexoses, 4-thio derivatives of D-glucose, **11** [29], D-mannose [30] and, more recently, D-galactose **12** [31] have been synthesized. In addition, the 6-deoxy analogs of D-*gluco* [32], D-*gulo* [33] as well as D-*ido* [34] configured 4-thioaldohexoses have been prepared. Per-*O*-acetylated 6-deoxy-4-thio-D-galactofuranose was obtained by acetolysis of methyl 6-deoxy-4-thio-D-galactopyranoside [35]. The synthesis of methyl α-D-talofuranoside was reported by Garegg and co-workers [36]. 4-Thiofuranoside derivatives of D-galactosamine are also known [37].



11 **12**

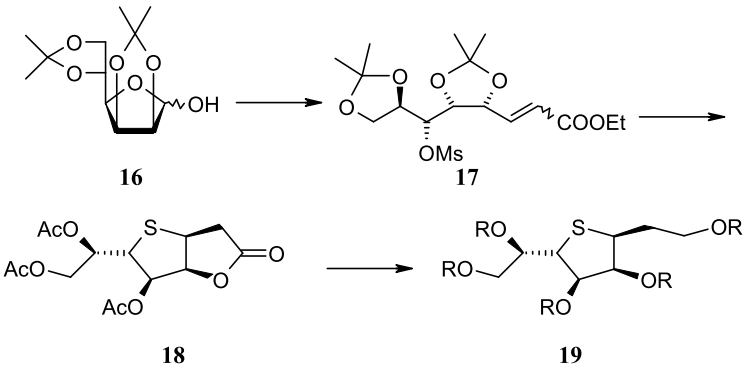
2.3.3 5-Thioketopentoses, 5-Thioketohexoses, and Derivatives

A de novo approach to 5-thio-D-*threo*-2-pentulofuranose (5-thio-D-xylulose, **13**) from 2-mercaptoacetaldehyde with the aid of rabbit muscle aldolase (RAMA, EC 4.1.2.13) as well as yeast transketolase (EC 2.2.1.1) was reported by Effenberger and co-workers [38]. This approach was recently extended in combination with the glucose isomerase (EC 5.3.1.5) catalyzed isomerization of compound **13** in an interesting synthesis [39] of 5-thio-D-xylose (**4**), a precursor for antithrombotic drugs [40].



13 **14** **15**

5-Thio-D-fructofuranose (**14**) was synthesized by Chmielewski and Whistler. The 2-deoxy derivative of 5-thio-β-D-fructofuranose, 2,5-anhydro-5-thio-D-mannitol (**15**), as well as the corresponding L-*ido* configured compound were prepared by ring-opening reactions of D-mannitol derived 1,2:5,6-diepoxides and were found to be poor inhibitors of D-glucosidases [41]. Various protected bicyclic 2,5-anhydro derivatives of 5-thio-D-mannitol were obtained by ring opening of trans-annular thiiranium ring-opening reactions of methyl 2,3,4-tri-*O*-acetyl-6-*O*-mesyl-5-thio-α-D-glucopyranoside [42].



16 **17** **18** **19**

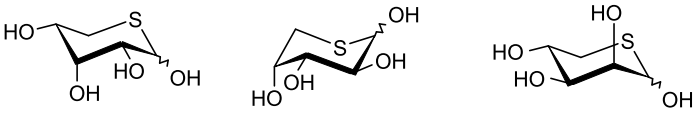
Scheme 2

Starting from 2,3:5,6-di-*O*-isopropylidene-D-mannose (**16**, *Scheme 2*), by chain elongation to enoate **17** and subsequent thiol introduction and ring closure, 6,3-anhydro-6-thio-octanoates **18** as well as the corresponding 6-thioanhydrooctitols **19** could be prepared [43]. Not unexpectedly, they proved ineffective in the attempted inhibition of a range of standard glycosidases.

2.4 Pyranoid Systems

2.4.1 5-Thioaldopentoses, 5-Thioaldohexoses, 6-Thioketohexoses, and Derivatives

5-Thio-D-xylose (**4**) was prepared by Adley and Owen [4], Scharz and Yule [5], as well as by Whistler and co-workers [9,10].

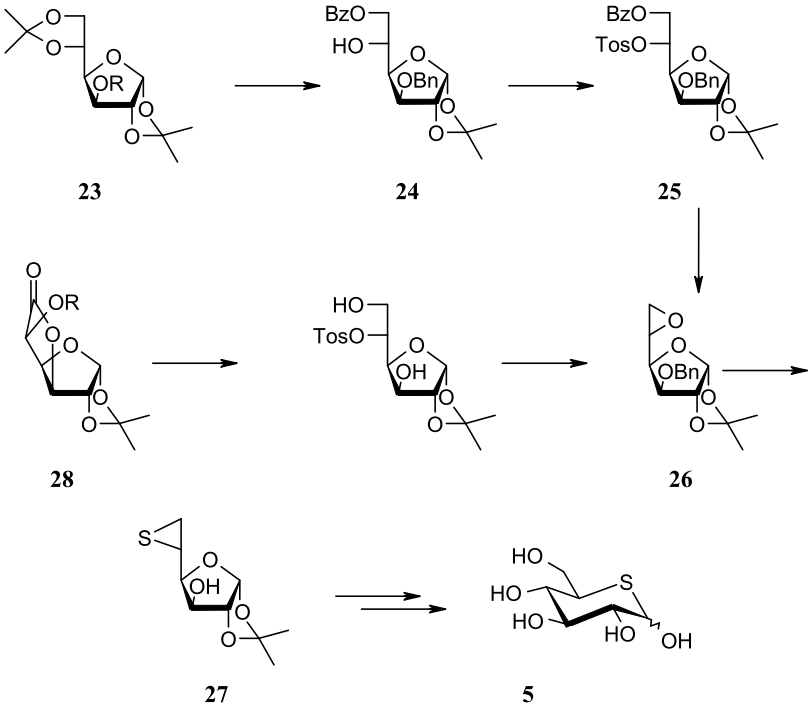


20 **21** **22**

5-Thio-D-ribose (**20**) was first reported by Clayton and Hughes [44,45], an improved synthesis from D-ribono-1,4-lactone was published in 2002 [46]. Isopropylidene acetals [47] as well as 1,4-anhydro derivatives thereof [48] have also been made available.

5-Thio-D-arabinose (**21**) as well as 5-thio-D-lyxose (**22**) were made by Hughes and Munkombwe [49] from 1,2-*O*-isopropylidene-5-*O*-tosyl-D-arabinofuranose by reaction with thioacetate and subsequent deprotection. A synthesis from 5-*O*-trityl-D-arabinofuranose was reported in 1996 [50].

5-Thio-D-glucose (**5**) was one of the first examples of sugars with sulfur in the ring [11].



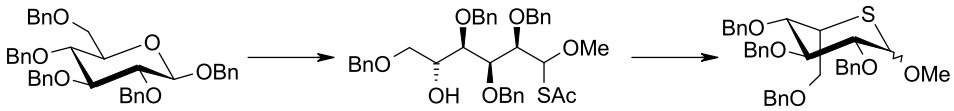
Scheme 3

In a typical synthetic approach (*Scheme 3*) [51], 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**23**) was employed as the starting material.

By a sequence of standard protecting group manipulations, O-3 was protected as the benzyl ether, the 5,6-acetal was removed by acid hydrolysis and O-6 was subsequently regioselectively protected with a benzoyl group to give **24**. Activation of C-5 was achieved by *O*-tosylation to give compound **25**. Upon base treatment, this intermediate was converted into the corresponding L-*ido* configured 5,6-oxirane **26** by intramolecular nucleophilic displacement of the tosylate. Thiourea treatment of **26** gave the corresponding thiirane derivative **27** with inversion of configuration at C-5. This was regioselectively opened at C-6 with acetate. Removal of the protecting groups gave 5-thio-D-glucose (**5**) in good overall yields after ten steps.

An improved synthesis based on the same strategy was devised by Driguez and Henrissat [52]. These workers took advantage of the regiospecifically available position C-5 in 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone (**28**). This easily accessible starting material was O-sulfonylated with tosyl chloride followed by reduction of the lactone moiety and

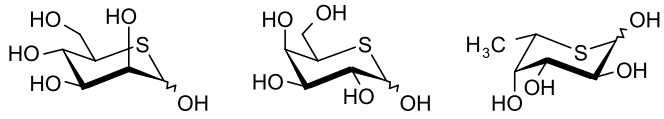
subsequent 5,6-oxirane formation, the remaining steps to compound **5** being the same as in Whistler's approach. Recently, Uenishi and Ohmiya provided an interesting threose-based approach featuring a two-carbons chain extension followed by Sharpless epoxidation of the primary allylic alcohol thus obtained and conversion of the oxirane into a 5-thio 5,6-cyclic xanthate intermediate from which – depending on the configuration of the threose – 5-thio-D- and L-glucose as well as the corresponding L-altro epimers and their 1,6-anhydro derivatives could be made available in enantiomerically pure forms [53].



29 **30** **31**

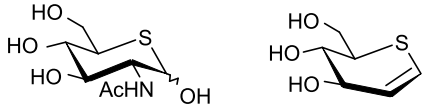
Scheme 4

Another chemical method for the preparation of 5-thioaldopyranosides was chosen by Hashimoto and co-workers [54]. They converted per-*O*-benzylated methyl β-D-glucopyranoside **29** into the open-chain mixed acetal **30** which, in turn, was treated with the Mitsunobu system, triphenylphosphine and diethyl azodicarboxylate, in the presence of benzoic acid to yield protected 5-thio-L-idopyranosides **31**.



32 **33** **34**

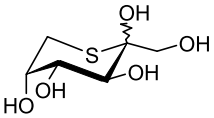
Most of the other important 5-thiopyranoses such as 5-thio-D-mannose (**32**) [55], 5-thio-D-galactose (**33**) [56], and 5-thio-D-allose [57] have been synthesized.
5-Thio-L-fucopyranose (**34**) was synthesized by Hashimoto and co-workers [58,59] combining the synthetic approach depicted in *Scheme 3* with a reductive thiirane ring-opening procedure previously reported in the synthesis of 6-deoxy-5-thio-D-glucose [42].
The 5-thio analogue of *N*-acetyl-D-glucosamine (**35**) was synthesized from suitably protected furanoid [60,61,62] or open-chain [63] D-glucosamine derivatives employing the general approach via the thiirane route as well as from 5-thio-D-glucal (**36**) [64] via azidonitration [65,66].



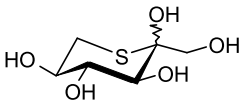
35 **36**

Access to thioketoses with sulfur in the ring could also conveniently be provided by an aldolase-based strategy. This involves rabbit muscle aldolase catalyzed carbon–carbon bond

formation of a 3-thioglyceraldehyde with dihydroxyacetone phosphate leading, for example, to compounds such as 6-thio-D-fructose (**37**) [38] or 6-thio-L-sorbose (**38**) [38,67].



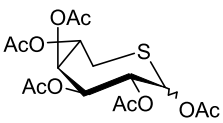
37



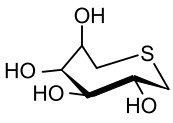
38

2.5 Septanoses and Derivatives

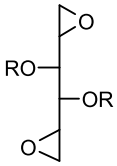
Despite the strong nucleophilicity of the thiol substituent, septanoses have not been found to generally form spontaneously from 6-thiosugars [7]. As with their natural counterparts, in cases where the formation of a pyranoid ring is not possible, the 6-thiofuranose is favored over the 6-thioseptanose system [18,68].



39



40



41

Early synthetic approaches to the 6-thioseptanose system were provided by Cox and Owen [68] as well as by Whistler and Campbell [69]. The latter workers prepared a protected open-chain 6-thio dithioacetal of D-galactose which upon deprotection at C-1 and S-6 could be cyclized to form the corresponding 1,2,3,4,5-penta-*O*-acetyl-D-galacto-6-thioseptanose (**39**) from which several derivatives such as both anomers of the thioseptanosyl chloride as well as the methyl thioseptanosides were synthesized. It was found that the methyl thioseptanoside is more prone to hydrolysis than the corresponding sulfur-containing pyranoid glycoside.
1,6-Anhydroalditol derivatives such as **40** were recently obtained by Le Merrer from D-mannitol via di-oxiranes such as **41** [41].

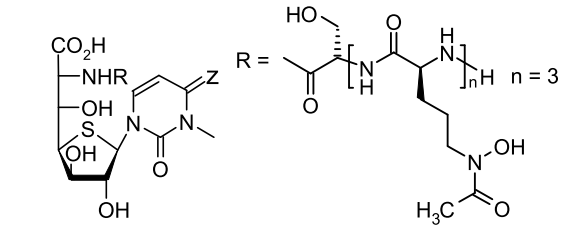
2.6 Summary

From the selected examples mentioned, it is clearly evident that sufficiently versatile methodology has been made available to allow for the synthesis of practically any sugar analog with sulfur in the ring. On this sound basis, a range of interesting and potentially valuable sophisticated natural products and synthetic analogs have recently been targeted.

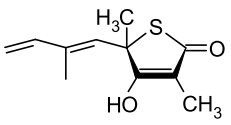
3 Examples of Glycomimetics with Sulfur in the Sugar Ring

3.1 Natural Products

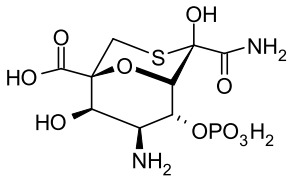
Only a few sugars and related compounds with sulfur in the ring have been reported as natural products to date. In the following, some selected, structurally quite dissimilar examples will be discussed.



42



43



44

3.1.1 Albomycin

As early as 1952, the antibiotic albomycin (**42**) was reported in a Polish journal [70]. It was found to be an iron-binding siderophore whose structure was determined by a Bayer group in collaboration with Paulsen and co-workers more than 30 years later [71]. Novobiocin is a synonym also found in the literature [72].

3.1.2 Thiolactomycin

The antibiotic thiolactomycin (**43**), a fermentation product from a *Nocardia* species containing an unusual thiolactone moiety was patented as antibiotic "no. 2-200" and subsequently reported in the literature in 1982 [73,74]. It resembles a sugar-derived α,β-unsaturated 4-thioglycono-1,4-lactone and was found to be a broad-spectrum antibiotic [75] by interference with the fatty acid metabolism of bacteria and also inhibited inducible β-lactamases [76]. A de novo synthesis of the racemate was reported by a Du Pont group in 1984 [77]. Chambers and Thomas [78] reported the synthesis of the (5*S*)-enantiomer in 1989 and concluded from its optical rotation that the natural product is the (5*R*)-enantiomer.

As an inhibitor of mycolic acid biosynthesis, compound **43** exhibits activity against strains of *Mycobacterium tuberculosis*, the causative agent of tuberculosis [79,80,81]. Furthermore,

thiolactomycin was also found to be active against various parasites including Trypanosoma [82]. Structure-activity considerations have recently been reported [83].
Structurally closely related is the antibiotic thiotetromycin [84,85].

3.1.3 Tagetitoxin

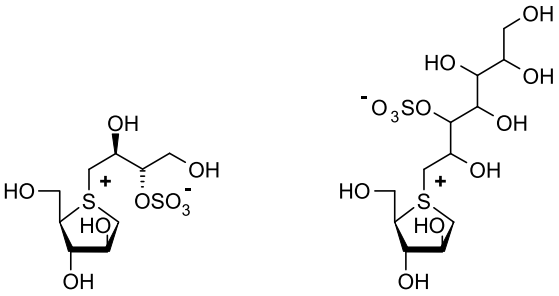
Tagetitoxin (**44**) is a metabolite of *Pseudomonas syringae*, first reported in 1981 [86] and, based on NMR investigations, was assumed to be a highly functionalized eight-membered ring system resembling a sulfur-containing keto-octonic amide [87]. A revised structure was published in 1989 [88] suggesting a 9-oxa-3-thiabicyclo[3.3.1]nonane core. Early synthetic studies providing simplified analogs were conducted by Furneaux and co-workers [89]. Recently, successful completion of a partially protected intermediate en route to the bicyclic system was reported [90].
It was noted that this compound is an inhibitor of RNA synthesis in plants by specifically interfering with RNA polymerases of chloroplasts [91] suggesting tagetitoxin as a novel herbicidal agent.
Moreover, tagetitoxin was found to inhibit RNA polymerase III by a unique, as yet not fully clarified mechanism [92] thus providing interesting biochemical and medicinal aspects for this compound.

3.1.4 5-Thio-D-Mannose

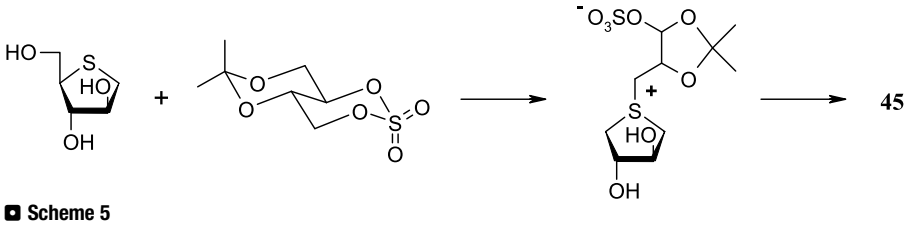
5-Thio-D-mannose (**32**), discovered as a metabolite of the marine sponge *Clathria pyramida* (Lendenfeld) is still unique representing the only example of a free 5-thioaldopyranose in nature [93]. Shortly after this discovery a synthesis from methyl 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranoside was reported [55] which essentially followed the principle of the approach depicted in *Scheme 3*. Before, 5-thio-D-mannose had been available by molybdate-catalyzed epimerization [94,95] of 5-thio-D-glucose [51].

3.1.5 Salacinol and Kotalanol

An interesting thiosugar, salacinol **45**, containing sulfur atoms in two different oxidation states was isolated and found to be the active principle of the Indian plant *Salacia reticulata* which is used in local traditional medicine for treatment of diabetes [96]. The compound was shown to be a potent inhibitor of intestinal α-glucosidases comparable in its activity with the powerful aminosugar derivative acarbose [97]. Kotalanol (**46**), a chain-extended homolog of salacinol, was discovered around the same time [98].
Triggered by their novel structures and consequential synthetic challenges as well as by their interesting biological properties, synthetic efforts were made to make salacinol and kotalanol as well as numerous synthetic derivatives available. Two teams of researchers, Yoshikawa and co-workers as well as Pinto and his group have provided significant contributions to aspects of synthesis as well as biological activities and structure-activity relationships in this area.
Apparently, the combination of both the sulfonium as well as the sulfate moieties is vital for the biological properties of salacinol and kotalanol [96].



45 46



Scheme 5

The first synthesis of salacinol by a multi-step procedure featuring the reaction of 1,4-anhydro-4-thio-D-arabinitol with the cyclic sulfate derived from 1,3-isopropylidene D-erythritol was reported in 2000 [99]. A similar approach was taken advantage of by Pinto and co-workers shortly thereafter [100]. Exploiting hexafluoroisopropanol as the solvent, the efficacy of the method could be further improved [101]. Improvements and extensions to other configurations of the five-membered ring system were also provided [102,103]. Other modifications include deoxy derivatives [104], chain extended analogues [105,106] as well as 2,5-anhydro-5-thio-L-iditol containing [107] and ring-enlarged [108,109] relatives whose inhibitory properties towards maltase-glucoamylase were screened as potential anti-Diabetes type II agents [110,111] and with a view to active-site mapping of this enzyme [111]. Some of the analogs prepared exhibit excellent inhibitory activities in the single figure micromolar range and below.

Employing *Drosophila* retaining Golgi α-mannosidase II, the binding mode of salacinol was compared with the interactions of swainsonine and kifunensine with the active site [112,113]. To date, to the best of our knowledge, the configuration of the heptitol moiety in kotalanol is still not elucidated.

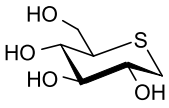
Salacinol derivatives with selenium instead of sulfur in the ring have also been prepared and will be discussed in *Section 4*.

3.2 Synthetic Glycomimetics

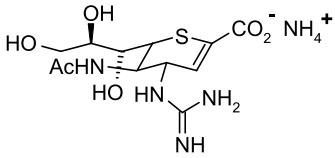
A wide variety of synthetic sugar and nucleoside mimicking compounds with sulfur in the ring have been prepared for basic research as well as with a view to biologically active compounds with improved biochemical properties.

3.2.1 Glycosidase Inhibitors

*5-Thio-*D*-Xylose, 5-Thio-*D*-Glucose* As early as 1965 the inhibitory activity of 5-thio-D-xylopyranose (**4**) against β-D-xylosidases was observed and a fairly high K_i value of 2 mM was reported for this reversible inhibition [114].



47



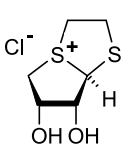
48

In-depth investigations [115,116,117] into the biological properties of 5-thio-D-glucose (**5**) rapidly led to the conclusion that the replacement of the ring oxygen with sulfur has a pronounced influence on the sugar metabolism. Despite being non-toxic with an LD_{50} of 14 g/kg, diabetogenic effects of **5** were reported by Hoffman and Whistler [115]. These workers found rapidly developing glucosuria and hyperglycemia in rats which had received this D-glucose mimic. Other effects observed were diminished glycogen contents in the liver and reduced membrane transport of D-glucose. Furthermore, inhibition of spermatogenesis in mice [118] and rats [119,120] as well as reduction of proliferation of trypanosoma [121] by this compound were observed. Biological activities included inhibition of growth of cancer cells [122]. 5-Thio-D-glucose was also found to inhibit yeast α-glucosidase with a K_i value of 750 µM but is a poor inhibitor of the β-specific enzyme from sweet al.monds [123].
Weak inhibitory effects on the former enzyme have also been observed with the corresponding methyl α-pyranoside [123] as well as the 1-deoxy derivative **47** [41,124]. None of these sugars or related derivatives [123,124,125] have significant effects on β-glucosidases. No pronounced biological effects were reported for 6-thio-D-fructopyranose (**37**). Instead, this compound is unusually sweet and essentially non-toxic in mice [126]. In addition to the chemical synthesis [127], an enzymatic preparation from 6-thio-D-glucose employing glucose isomerase (EC 5.3.1.5) was reported [128]. In keeping with the general properties of sulfur-containing pyranoid ring systems, the 6-thiofructopyranose is strongly favored in the equilibrium allowing the isolation of this product in over 90% yield.

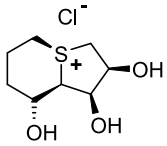
*5-Thio-*L*-Fucose* 5-Thio-L-fucose (**34**) was characterized as a fairly potent α-L-fucosidase inhibitor with K_i values of 42 µM and 84 µM against the enzymes from bovine epididymis and kidneys, respectively. Nevertheless, it is about five orders of magnitude less powerful than 1-deoxy-L-fuconojirimycin [129], the corresponding iminoalditol featuring a basic nitrogen instead of sulfur in the ring. Recently, the same group reported the chemical synthesis of fucosidase inhibiting disaccharides containing the 5-thio-α-L-fucopyranosyl moiety [130]. These were found to exhibit similar inhibitory power as **34**.

Neuraminic Acid Analogs Non-natural mimics of neuraminic acids which inhibit viral sialidase have recently emerged as interesting anti-influenza drugs [131]. In this context, 6-thio analogs have been targeted by von Itzstein and co-workers [132] based on the chain exten-

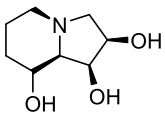
sion of suitably protected 3-thio-*N*-acetyl-D-glucosamine derivatives as outlined by Mack and Brossmer [133,134]. Gratifyingly, one of the derivatives with sulfur in the ring, **48**, inhibited influenza virus sialidase with an IC_{50} value in the low nanomolar range.



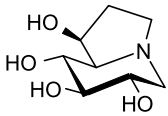
49



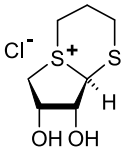
50



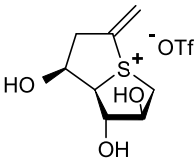
51



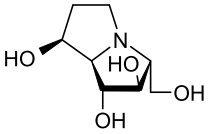
52



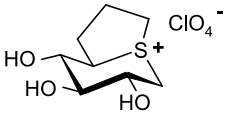
56



55



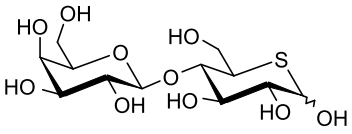
54



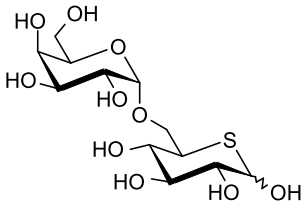
53

Analogs of Glycosidase Inhibiting Polyhydroxyindolizidine and Pyrrolizidine Alkaloids On the basis of an early finding by a French-British team of workers [135] who discovered that bicyclic D-erythrose-derived dithioacetal **49** is a selective inhibitor of human liver α-mannosidases, and supported by synthetic technology developed for the preparation of salacinol analogs, Pinto and co-workers have also provided access to the thio analog **50** of the powerful mannosidase-inhibiting alkaloid swainsonine (**51**) and related structures [136,137]. Furthermore, amongst others, some variations on the basic structure of the glucosidase inhibitors castanospermine **52** such as **53** [138,139] and australine **54**, for example **55** [140] have been synthesized by the same workers.

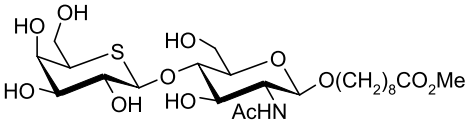
Another swainsonine-related compound (**56**) was also reported by Siriwardena and his group [141] in an extension of their seminal publication [135].



57

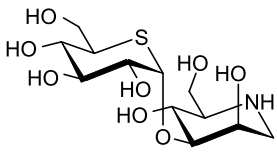


58

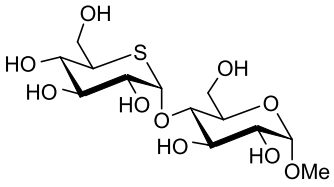


59

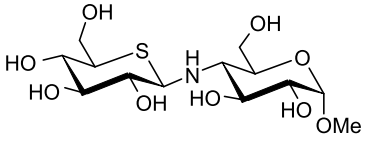
5-Thiodisaccharides and Oligosaccharides The first examples of disaccharides containing a 5-thiopyranosyl unit were reported between 1991 and 1993 by Wong and his group [142] for lactose analogs **57** and **58** featuring the thiosugar at the reducing end, the Thiem team [143] for a 1,1′-linked disaccharide containing 5-thiogentosamine (3-aminodeoxy-D-xylose) and galactose as well as Hindsgaul and co-workers [144] for a 5′-thiolactosamine analog **59** with the thiosugar as the non-reducing sub-unit. Such 5′-thiolactosaminides were observed to exhibit increased stability towards β-galactosidase from *E. coli* [144].
Interestingly, all these workers exploited biocatalytic approaches taking advantage of galactosyltransferase-mediated glycosyl transfer.
Chemical 5-thioglycosylation has largely relied on the trichloroacetimidate procedure as exemplified by Pinto and co-workers of 1,2- as well as 1,6-connected gluco-disaccharides with the thiosugar at the non-reducing end [145]. Several examples of classical Koenigs–Knorr methodology have also been reported, just to mention the most frequently employed approaches.
Targeted compounds include analogs of the H-type 2 [146,147] and Lewis^X [148,149] antigens as well as a wide range of potential endo-glycosidase inhibitors.



60

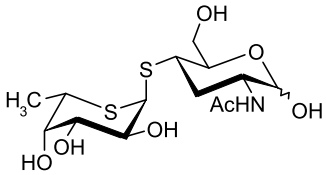


61

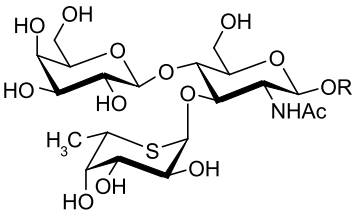


62

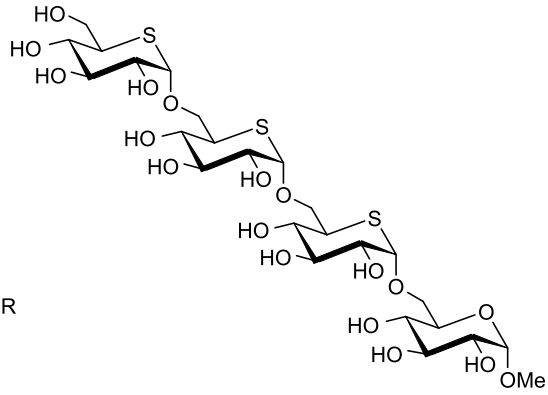
For example, the 3-*O*-(5-thio-α-D-glucopyranosyl) derivative of 1-deoxymannojirimycin (**60**), a powerful D-mannosidase inhibitor, was synthesized as a potential inhibitor of *endo*-α-D-mannosidase of glycoprotein trimming [150].
The weak glycosidase inhibitory activities usually observed for monosaccharides with sulfur in the ring when compared to the corresponding natural substrates have frequently also been found with di- and oligosaccharides.
Maltose analogs **61** featuring the thiosugar at the non-reducing end are only weakly inhibiting glucoamylase G2 [151], whereas disaccharides with sulfur in the ring of the non-reducing sugar and a basic nitrogen as interglycosidic linkage such as **62** were potent glucoamylase inhibitors [152]. Because of the sensitivity of fucosidases, 5-thiofucose containing thio-bridged disaccharides, for example **63**, inhibit fucosidase from bovine epididymis with K_i-values in the low micromolar range [153].



63

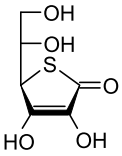


64

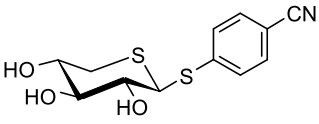


65

Trisaccharides such as compound **64** featuring a 5-thiopyranosidic linkage were successfully synthesized with a view to sulfur-containing Lewis^X analogues [154].
A maltotetraoside **65** containing three 5-thioglucose units in the non-reducing positions was prepared by the Hashimoto group who exploited the trichloroacetimidate approach in a linear sequence of glycosylation steps [155].

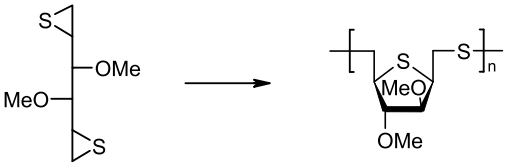


66



67

Others 4-Thioascorbic acid (**66**) was prepared by Stachel and co-workers who could demonstrate that this analogue is a stronger reducing agent than the parent compound [156].
Orally administered 4-cyanophenyl 1,5-dithio-β-D-xylopyranoside (**67**) was recently reported to exhibit powerful antithrombotic activity [157]. Consequently, syntheses of several related sugar derivatives of various chain lengths and configurations have been reported since [158,159,160].



68 **69**

Scheme 6

Polymers An interesting new concept for the synthesis of thiosugar oligo- and polymers was recently introduced taking advantage of open-chain meso alditol derived *O*-methyl protected 1,2;5,6-bisthiiranes (**68**) which upon cationic as well as anionic polymerization gave polymers containing 2,5-anhydro-1,5-dithioalditol subunits (**69**) as the main components [161,162]. Regio- and stereoselectivities of the processes have recently been discussed [163].

3.2.2 Nucleosides

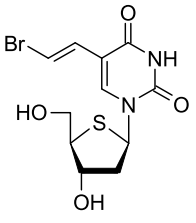
Early synthetic approaches to nucleosides with sulfur in the furanose ring were reported by Reist and co-workers [13,18] as well as Whistler and his group [14,20,164], mainly aiming at antibacterial agents [165,166]. In the early 1990s, Walker and co-workers synthesized, amongst others, 4′-thio derivatives of BVDU [*E*-5-(2-bromoethenyl)-2′-deoxyuridine] such as **70** as anti-viral compounds [167,168]. 4′-Thio-AZT (**71**) and other thio analogs of antiviral nucleosides were prepared by Secrist [169] and other workers [170] but subsequently were found to be toxic [171].

This was also the case with 2′-deoxy-4′-thio analogs of purine nucleosides [172]. On the other hand, the United States Food and Drug Administration has approved the 3′-thia analogue of L-cytidine (**72**) [173] as an anti-HIV agent. This was the first example of an L-enantiomer being more potent than the naturally configured compound. 4′-Thioarabinonucleosides have been discovered to exhibit high activity against herpes and cytomegalo viruses [174].

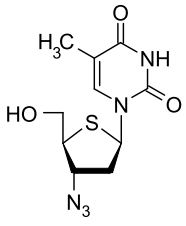
Amongst others, both enantiomers of the 4′-thio analog **73** of the powerful anti-herpes agent L-FMAU ("2′-fluoro-5-methyl-β-L-arabinofuranosyluracil") have been prepared in this context [175,176].

A variety of nucleosides have been prepared by Wirsching and co-workers [177] as well as other groups. Activities, albeit, were found not suitable for further development.

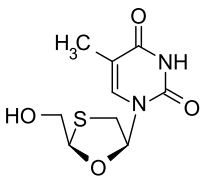
Thionucleotides have also been prepared to be incorporated into oligonucleotides [178].



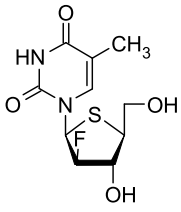
70



71



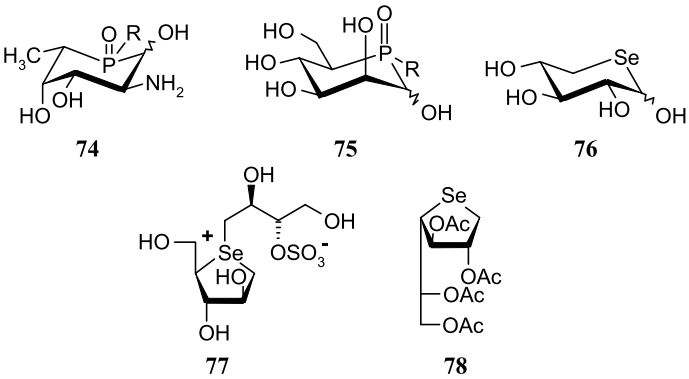
72



73

4 Other Changes in the Ring

Sugar analogs with ring heteroatoms other than nitrogen and sulfur have only raised limited interest due to their lack [179] of noteworthy biological properties. Sugars with phosphorus in the ring have been reviewed by Yamamoto and Inokawa [179], by Witczak and Whistler [180], who have also treated selenosugars [181], as well as by Yamamoto and Hanaya [182].



Some examples in the phosphahexose series include synthetic approaches to analogs of L-fucosamine (**74**) [183] and D-mannopyranose (**75**) [184]. Selenosugars such as **76** have been found to be highly sensitive [7,185] to air oxidation and, thus, are strongly limited in their potential as carbohydrate mimics. An interesting exception to this statement has been provided by Pinto and co-workers who synthesized blintol **77** [186,187], the seleno analog of salacinol which turned out to be stable and to exhibit, albeit mediocre glucosidase inhibiting properties [186]. Other compounds including fully protected selenogalactofuranose derivative **78** featuring selenium species in the ring have also been investigated by this group [188,189].

5 Further Reading

Many aspects of synthesis as well as biological activities and drug design associated with thiosugars of the structural types under consideration here have been competently and extensively reviewed. Amongst others, noteworthy reviews have recently been provided by Witczak [190], Carvalho [191] as well as by Robina and Vogel [192] which will provide additional pieces of information adding more "color" to the selected examples and outlines presented above.

Abstract

This chapter covers the synthesis of a large collection of "*C*-oligosaccharides", synthetic analogs of naturally occurring oligosaccharides in which a carbon atom replaces the anomeric, interglycosidic oxygen atom. These non-natural constructs are stable to chemical and enzymatic degradation, and are primarily devised to probe carbohydrate-based biological processes. These mainly target carbohydrate-protein interactions such as the modulation of glycoenzyme (glycosylhydrolases and transferases) activities or the design of ligands for lectin Carbohydrate Recognition Domains. The discussion is based on the key carbon–carbon bond assembling steps on carbohydrate templates: ionic (anionic and cationic chemistries, sigmatropic rearrangements) or radical assemblage, and olefin metathesis. Synthetic schemes in which at least one of the monosaccharide units is constructed by total synthesis or by cyclization of acyclic

Chapter-DOI 10-1007/978-3-540-30429-6_51:

chiral chains are presented separately in a "partial de novo synthesis" section. The review also provides comments, when they are known, on the conformational and binding properties of these synthetic analogs, as well as their biological behavior when tested.

Keywords

C-Glycosyl compounds; *C*-Linked oligosaccharides; Sugar organometallic; Glycosyl lithium; Glycosyl samarium; Glycosyl radical; Radical cyclization; Nitro sugars; Olefin metathesis

Abbreviations

9-BBN	9-borabicyclo[3.3.1]nonane

TMS	trimethylsilyl

1 Introduction

1-C-Linked glycosyl compounds are carbohydrate analogs in which a carbon atom replaces the anomeric oxygen atom or nitrogen atom of glycosides (simple glycosides, oligosaccharides, nucleosides, *O*- or *N*-glycosyl amino acids and peptides, or glycolipids). In recent years, much effort has been devoted to developing efficient methods for their syntheses. Chap. 3.8 in Vol. 1 as well as numerous reviews [1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23] present the wide range of methodologies currently available.

Historically, the synthesis of *C*-glycosyl compounds was confined to the preparation of naturally occurring carbon-linked nucleosides [1,2,5] or *C*-glycosyl arenes [2,13]. More recently this field has expanded enormously into the construction of mimics of glycostructures that are relevant to glycobiology such as oligomers, glycopeptides, glycolipids, metabolic intermediates [11], or "clustered" structures of various kinds. The main idea is to create molecular species, stable to chemical and enzymic degradation, which conserve the configurational and conformational features of the naturally occurring parents. These analogs may serve as glycoenzyme regulators (glycosylhydrolases and transferases) or artificial ligands that can be useful in probing cellular interactions.

Due to space limitations, we have restricted this overview to the synthesis of carbon-linked mimics of natural oligosaccharides that contain the correct number of linking carbons. This, of course, does not presuppose that the chemistry or the potential usefulness of these mimics is more interesting than the ones associated with other types of *C*-linked analogs (*pseudo-C*-glycosyl analogs). Because of this necessary limitation, one should also realize that a good deal of important chemistry relevant to the field of functionalized tetrahydropyrans or tetrahydrofurans will not appear in this chapter, as for example, the precursory work of Vasella on the condensation of anomeric nitro sugars [24] or the chemistry developed for the total synthesis of a variety of natural products containing cyclic ether fragments. Four very representative examples are the total syntheses of palytoxin-carboxylic acid [25], tunicamycin V [26], brevetoxin B [27], or altohyrtin C [28] among many others. The *C*-glycosyl compounds, including C-dimers, associated with carbasugars or imino sugars ("aza" sugars) have been reviewed in two preceding chapters.

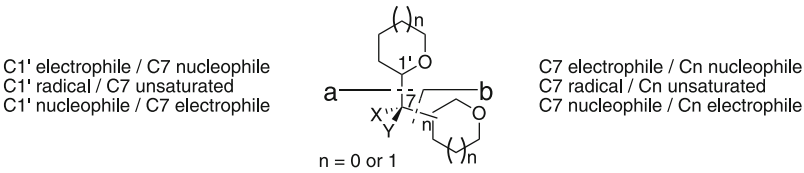
In the following, we have divided the discussion, mostly centered on synthetic approaches, according to the key carbon–carbon bond-forming steps (ionic or radical assemblage, olefin metathesis). Syntheses of oligosaccharide mimics in which one of the monosaccharide units is constructed by total synthesis or by cyclization of acyclic chiral chains are presented separately (partial de novo synthesis). Where appropriate, brief comments on the conformational and binding properties of these synthetic constructs will be specified, as well as the biological

behavior when tested. Finally, we have systematically used the chair conformational drawings of the tetrahydropyranyl ring systems although it is well recognized that a great many synthetic intermediates adopt a conformation very different from the chair. Most of the final deprotected forms of the C-analogs will however adopt a conformation identical or very close to the naturally occurring glycoside in the cyclic substructures.

2 The Ionic Assemblage

The desired stereochemical features of a mimic, e. g., a glycopyranosyl or a glycofuranosyl dimer, may be most attractively derived from the parent monomers if they are readily available. To add the missing carbon, all possible key assembling steps have been employed which are summarized in *Scheme 1*.

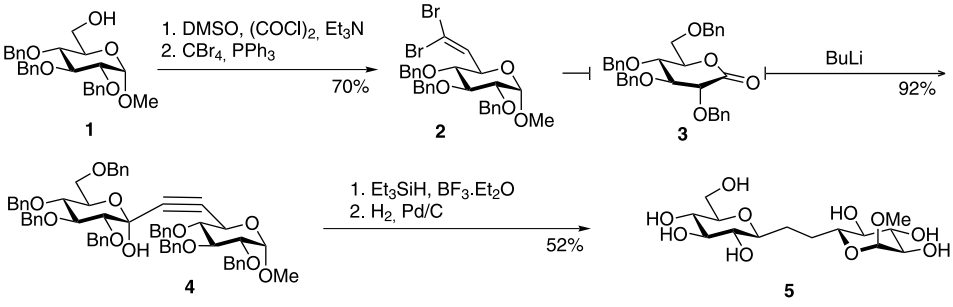
Disconnection **a** implies that a stereoselective carbon–carbon bond formation at the anomeric center of the "non-reducing" unit has to be identified (C1′ electrophile, radical, or nucleophile) using the appropriate "reducing" unit carrying the additional carbon. A simple, one-carbon *C*-glycosyl compound is rather utilized in disconnection **b**, having as a coupling "reducing" partner a nucleophilic, an electrophilic, or an unsaturated species.



Scheme 1

2.1 C5 (or C4) and C1 Alkynyl Anions

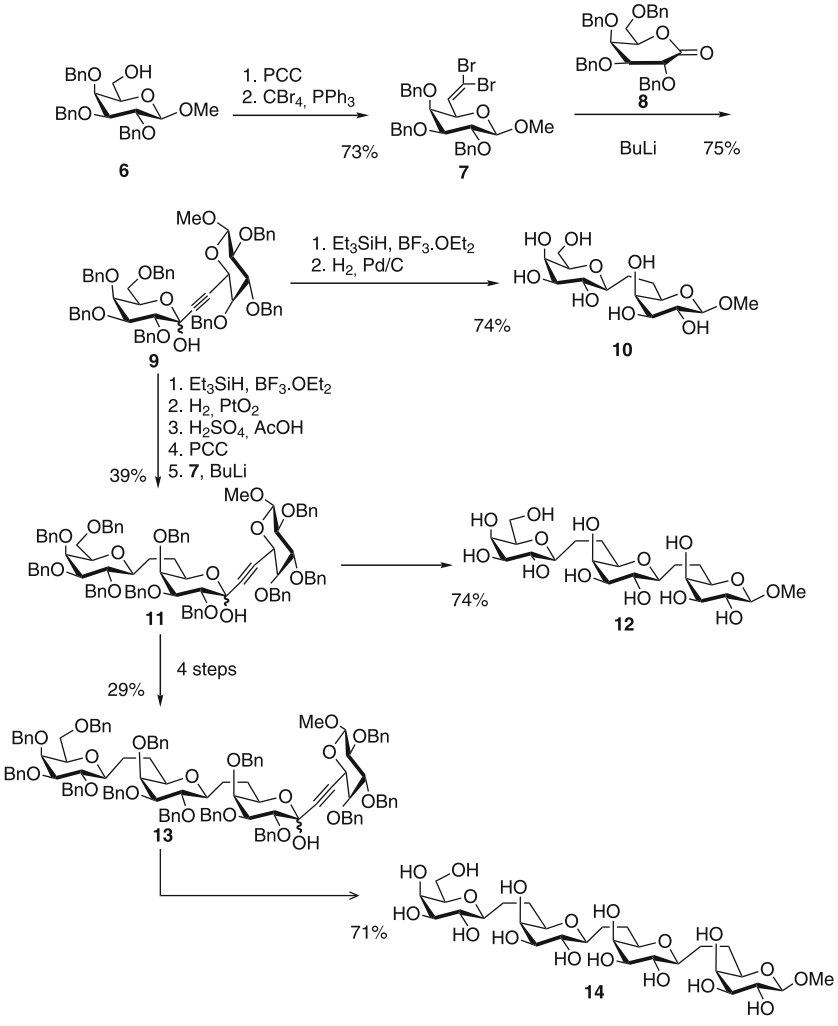
As briefly discussed above, every synthesis that will be described involves the addition of one linking carbon between two cyclic carbohydrate structures in order to replace the anomeric oxygen. The easiest route to accomplishing this task is to target a (1→6) linkage because the



Scheme 2

organometallic partner can be built up in a simple way and only one asymmetric center has to be created. It is then no surprise that the first synthesis of a *C*-analog of a natural disaccharide was reported by Rouzaud and Sinaÿ in 1983 following this route [29] (*Scheme 2*).

In their work they took advantage of the previously reported syntheses of *C*-alkenyl- and *C*-alkynyl-β-D-glycosides by Kishi [30] and Sinaÿ [31], using vinyl dibromide **2** easily prepared in two steps from glucose derivative **1**. Conversion of dibromide **2** to the acetylenic lithium reagent with BuLi, followed by treatment with glucopyranolactone **3** leads to hemiacetal **4** in a high yield. Stereospecific reduction of **4** by hydride delivery on the α-face of



Scheme 3

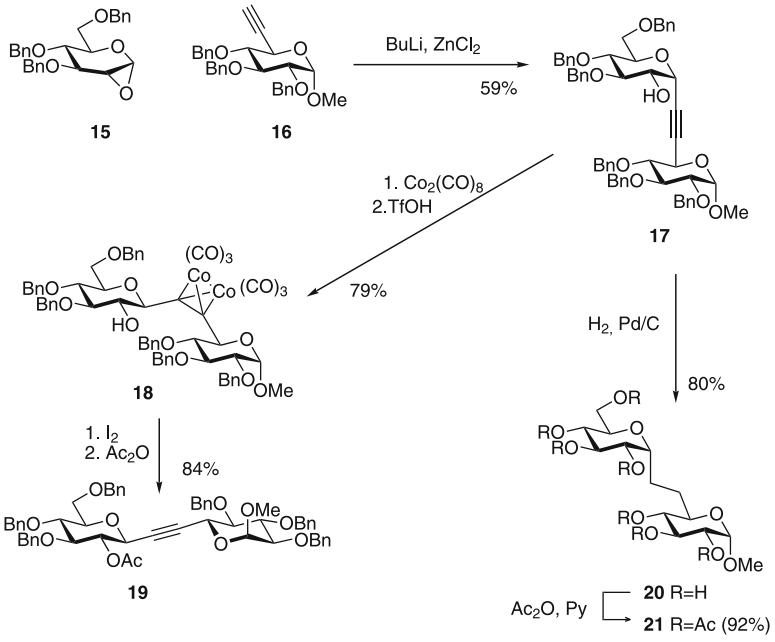
a cyclic oxycarbenium ion using the $Et_3SiH/BF_3{\cdot}Et_2O$ system affords the β-D-Glc(1→6)-D-Glc *C*-disaccharidic mimic **5** after catalytic hydrogenolysis. The efficiency of this approach led the Sinaÿ group to integrate this reaction sequence in an iterative process for the construction of the β-(1→6) *C*-oligomers **10**, **12**, and **14** through dimer **9**, trimer **11**, and tetramer **13** by an elongation through the reducing end [32] (*Scheme 3*).

These *C*-analogs show behaviors identical to the natural haptens in their binding to monoclonal antigalactan immunoglobulins [33], indicating the absence of hydrogen bonds in the carbohydrate-protein interaction involving the interunit oxygen atoms of the natural ligands.

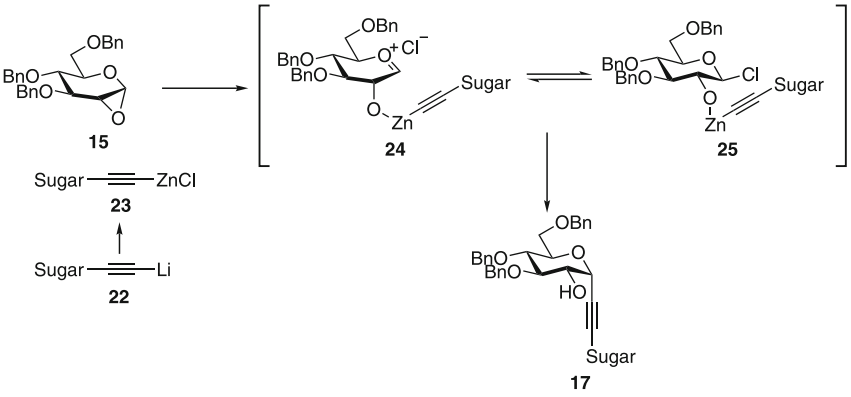
With the same acetylenic lithium reagent derived from the C6-alkynyl D-glucopyranose derivative **16**, van Boom and Sinaÿ developed a stereoselective $ZnCl_2$-assisted ring-opening of 1,2-epoxide **15**, establishing a ready access to *C*-isomaltoside **20** [34] by the route shown in *Scheme 4*.

This interesting result may be rationalized by transmetallation with $ZnCl_2$ of the lithium acetylide to **23** and formation of an alkynyl-zinc complex **24** with the 1,2-epoxide **15** (*Scheme 5*).

Intramolecular delivery of the alkynyl moiety in ion pair **24** or β-chloride **25** via the Zn tether would lead stereoselectively to α-*C*-glycosyl compound **17**. The Nicholas reaction [35] with triflic acid-induced isomerization [36] of the dicobaltohexacarbonyl complex of alkyne **17** provides cleanly the corresponding β-*C*-glucoside complex **18** (*Scheme 4*). Decomplexation with iodine and acetylation then gives β-*C*-disaccharide **19**.



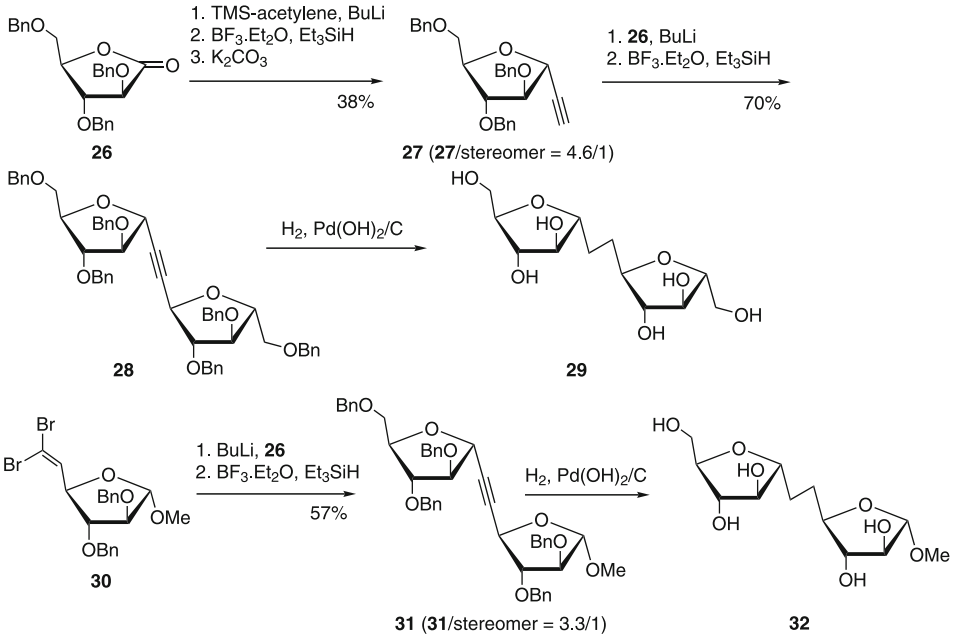
Scheme 4



Scheme 5

Different synthetic approaches to *C*-analogs related to the important α-D-arabinofuranosyl-(1→5)-α-D-arabinofuranose structural motif of mycobacterial arabinan will be discussed in this chapter. Routes involving acetylenic intermediates were reported by Wightman et al. [37] (*Scheme 6*).

The strategy is based on the pseudo C_2-symmetric feature of the target. Lactone **26** prepared from D-arabinose, serves as the precursor of acetylenic derivative **27** and as the substrate in the



Scheme 6

coupling reaction to furnish symmetric dimer **29** after selective silane reduction and protecting group removal. The other alternative in preparing methyl glycoside **32** is to start from dibromoalkene **30**, available from methyl α-D-arabinofuranoside. Reaction of the lithio derivative with lactone **26** and reduction with $Et_3SiH/BF_3{\cdot}Et_2O$ provide acetylenic derivative **31** as the major product, transformed to *C*-disaccharidic mimic **32** after catalytic hydrogenolysis and triple bond reduction.

2.2 C5 (or C4) and C1 Methylenephosphonium Ylides

Another route to generate (1→6) linkages, reported by Dondoni in 1996 [38], is to exploit the Wittig olefination between 1-*C*-glycopyrano(or furano)syl formaldehydes, available through the thiazole-based formylation of glyconolactones [39], and phosphonium ylides at position 6 of glycopyranosides. A representative example is the construction of the *C*-analog of the β-D-Gal(1→6)-D-Gal disaccharide (*Scheme 7*).

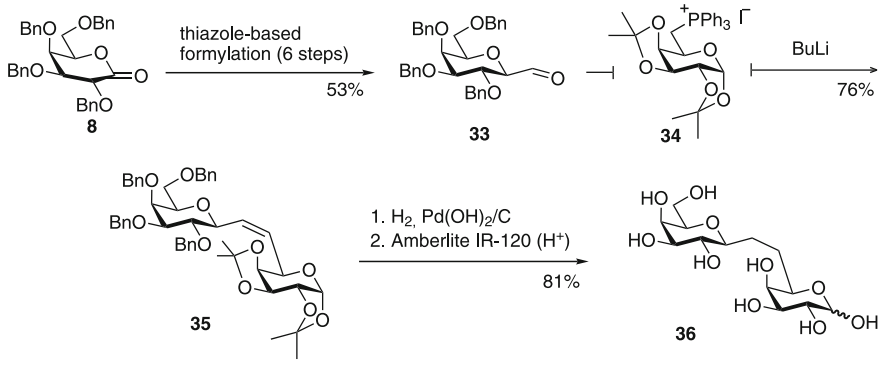
Condensation of the phosphonium ylide derived from the galactose phosphonium salt **34** and aldehyde **33** affords alkene **35** which, by reduction and removal of protecting groups, leads to the final *C*-dimer **36**.

A similar sequence of reactions starting from aldehyde **37** provides efficiently the *C*-pentamer **40** in a 33% overall yield from **37** [40] (*Scheme 8*).

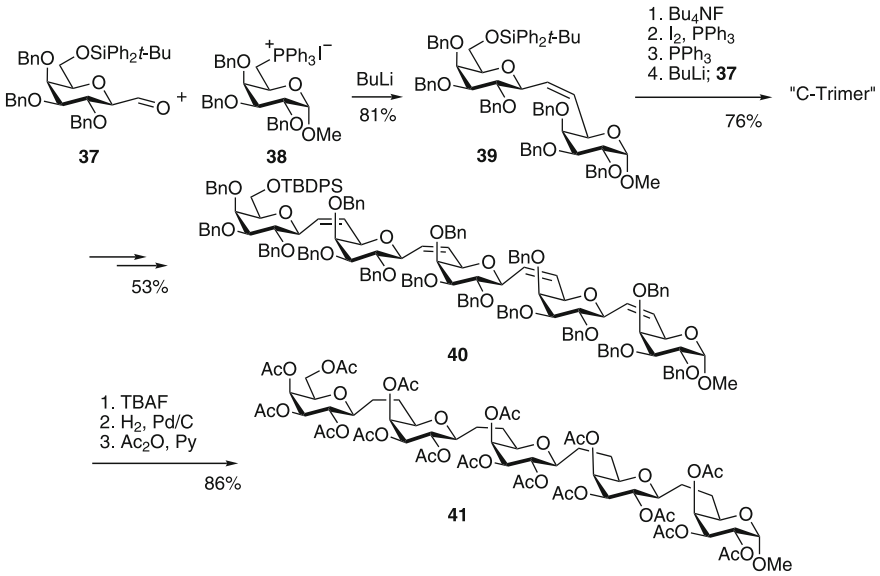
Protecting group removal and hydrogenation of the carbon–carbon double bonds furnish a *C*-mimic of the β-(1→6) pentagalactoside, characterized as the corresponding *O*-acetyl derivative **41**.

A set of ten carbon-linked (1→6) dimers was prepared in this way, starting from the *C*-glycosyl formaldehydes **33** and **42–47** and the phosphonium salts **34** and **48** [41] (*Scheme 9*).

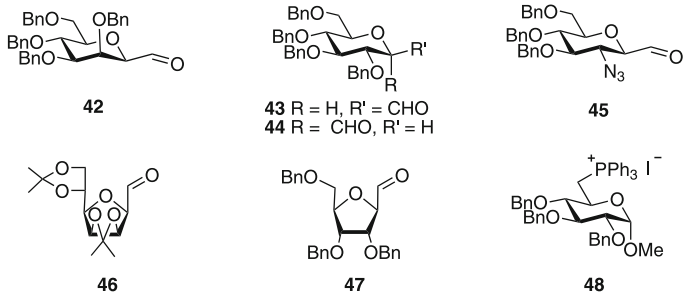
This route requires, however, the use of the thermodynamically more stable aldehydes; α-*C*-glucosyl precursor **44** will provide, for example, the corresponding β-*C*-dimer by isomerization under the basic conditions of the Wittig reaction. An exception is the use of aldehyde **50** obtained selectively from the corresponding thiazolyl α-*C*-glycoside **49**, provid-



Scheme 7



Scheme 8



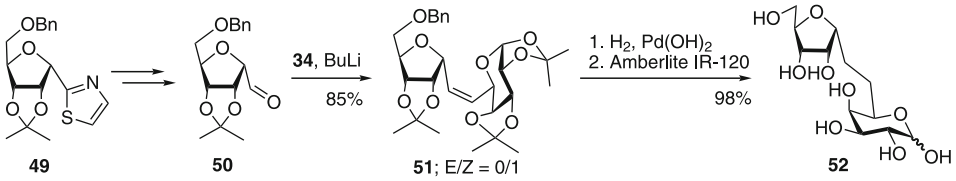
Scheme 9

ed by deoxygenation of the thiazolylketose acetate using TMSOTf-triethylsilane [42]. Having such a compound, α-(1→6)-*C*-disaccharide **52** was then synthesized (*Scheme 10*).

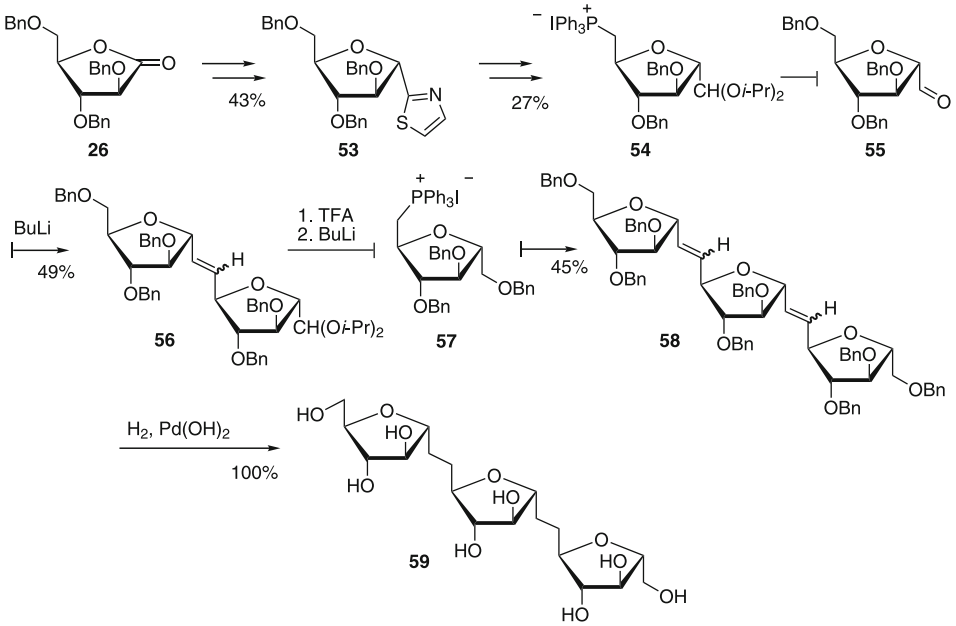
Aldehyde **50** is stable in the course of the Wittig olefination with phosphonium salt **34** and provides only the *Z*-alkene **51**. Reduction of the double bond and benzyl group removal, followed by an acidic treatment then afford α-(1→6)-*C*-disaccharide **52**.

C-analogs of the α-(1→5)-arabinofuranosyl repeating motifs found in the polysaccharidic chains of mycobacterial cell wall were also prepared using this approach by Dondoni and Marra [43]. This route is based on the use of a bifunctional unit **54** with regeneration of the formyl group in one step after the Wittig coupling reaction (*Scheme 11*).

Both partners **54** and **55** of the Wittig reaction are derived from the same thiazolyl intermediate **53**, itself prepared following the thiazole-based formylation of lactone **26**. The resulting



Scheme 10

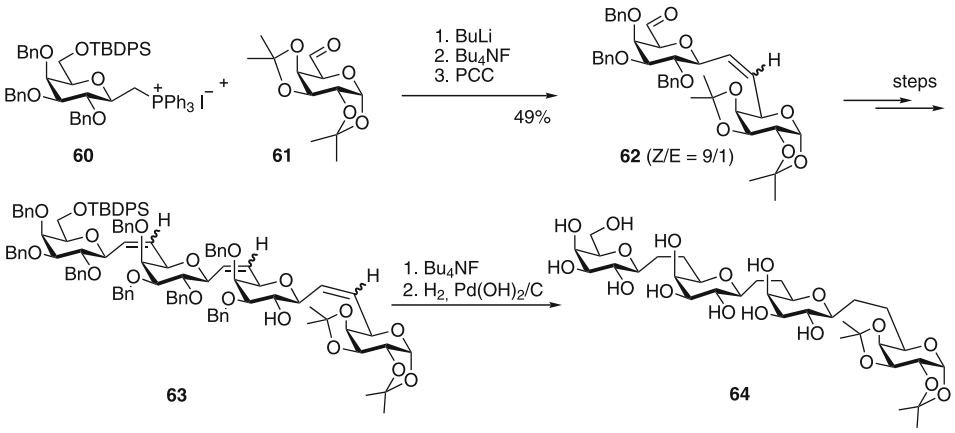


Scheme 11

alkenes **56** are then subjected to acidic treatment leading to the corresponding aldehydes, electrophilic partners in a second Wittig reaction. Hydrogenation of the double bonds provides the *C*-analog of α-(1→5)-*C*-arabinofuranotriose **59**. In this synthesis the α-configuration is also maintained during the elongation of the chain.

The reversed strategy has also been reported by condensation of C6 aldehydo sugars with β-linked methylenephosphonium ylides [44] (*Scheme 12*).

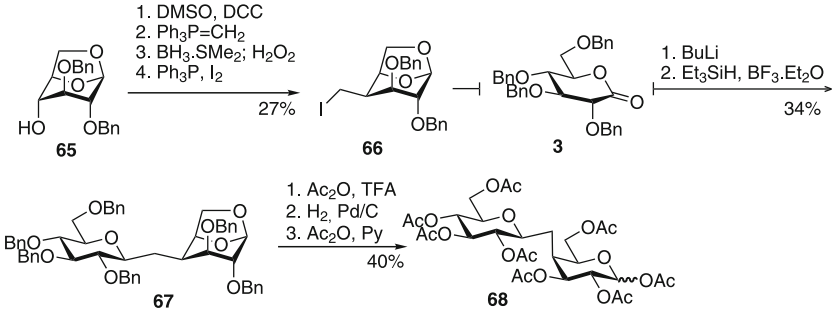
Condensation of the D-galactopyranosyl-derived phosphonium salt **60** and aldehyde **61** provides the unsaturated dimer **62** after desilylation and oxidation. Iteration of the sequence twice with phosphonium salt **60** leads to tetramer **63** with, however, low coupling efficiencies (36% for the trimer and 11% for the tetramer) mostly due to the base-induced α,β-unsaturation of the aldehydic substrates. Protecting group removal and hydrogenation of the carbon–carbon double bonds furnish tetramer **64**, a *C*-mimetic of the β-(1→6) tetragalactoside similar to the one shown in *Scheme 3*.



Scheme 12

2.3 C4 Lithiomethyl Sugars

Sequences similar to the ones detailed in *Sect. 2.1* in which the anionic carbon is present at positions other than C6 have also been described such as the C4-branched lithium species derived from iodide **66** reported by Preuss and Schmidt [45] (*Scheme 13*).
Stereoselective hydroboration-oxidation of the olefin obtained in two steps from the 1,6-anhydroglucose **65** followed by iodination and lithium-halogen exchange generates a lithio reagent that adds to gluconolactone **3** to give a hemiketal, which is stereoselectively reduced to the *C*-linked disaccharide **67**. Opening of the 1,6-anhydro ring and deprotection provides the *C*-linked β-D-Glc(1→4)-D-Gal disaccharide **68**, after acetylation. The same sequence using galactonolactone **8** leads to the *C*-linked β-D-Gal(1→4)-D-Gal dimer.

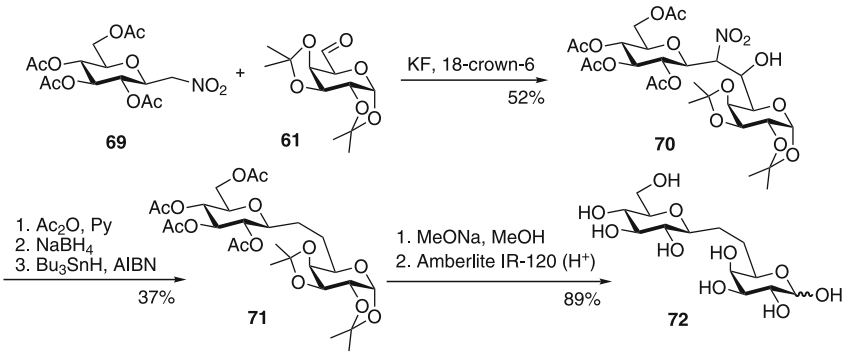


Scheme 13

2.4 C1 Nitromethyl Sugars

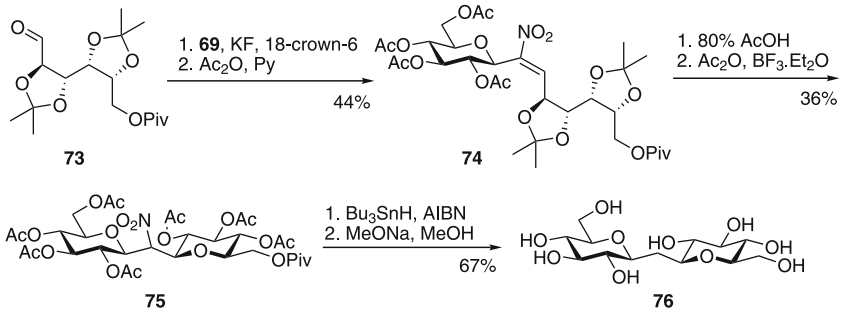
One way to generate *C*-linked dimers is to start from a preformed *C*-linked monomer in which the "missing" carbon is carried as either the electrophilic partner (for example, C1-aldehydo sugars, see *Sect. 2.2*, or the nucleophilic partner. In the latter case β-elimination must be controlled. The nitronate anions derived from *C*-glycosyl nitromethanes are species of the latter kind, and Martin and Lai [46] reported a short preparation of the *C*-analogs of β-D-Glc(1→6)-D-Gal and non-natural β,β-trehalose [β-D-Glc(1→1)-β-D-Glc] using as a key assembling step, a nitroaldol condensation (Henry reaction), a well-known method for chain extension of carbohydrates [24,47]. Fluoride-mediated condensation of *C*-glucosyl nitromethane **69**, obtained in two steps from glucose, with the D-galactose-derived aldehyde **61**, provides nitroaldols **70**. Acetylation-elimination to nitroalkene, reduction of the double bond, and radical denitration readily afford the protected *C*-linked disaccharide **71**, deprotected in two steps to the *C*-linked β-D-Glc(1→6)-D-Gal mimetic **72** (*Scheme 14*).

Extension of the same methodology to the aldehydo-glucose derivative **73** yields, after the elimination step, the nitroalkene **74** (*Scheme 15*).



69 **61** **70** **71** **72**

Scheme 14



73 **74** **75** **76**

Scheme 15

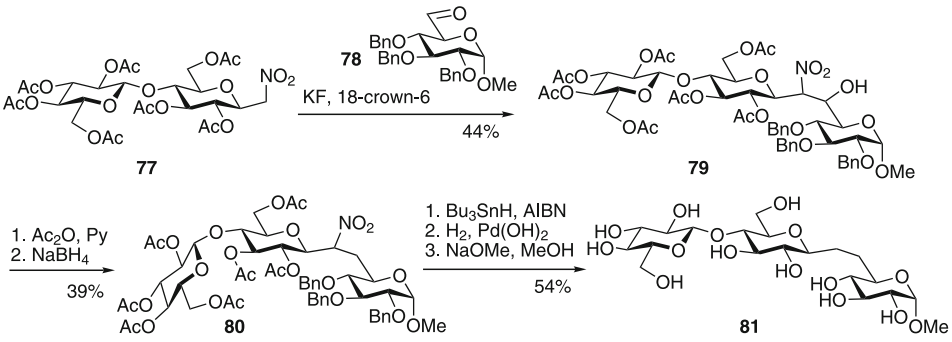
Upon removal of the isopropylidene groups, Michael addition occurs providing the *C*-linked disaccharide **75** after acetylation, together with the tetrahydrofuranyl isomer (25% yield). Radical denitration and deacylation afford the *C*-linked β,β-trehalose **76**.

The same fluoride condensation was used for the synthesis of a mixed *O*,*C*-trisaccharide analog of methyl β-D-glucopyranosyl-(1→4)-β-D-glucopyranosyl-(1→6)-α-D-glucopyranoside [48] (*Scheme 16*).

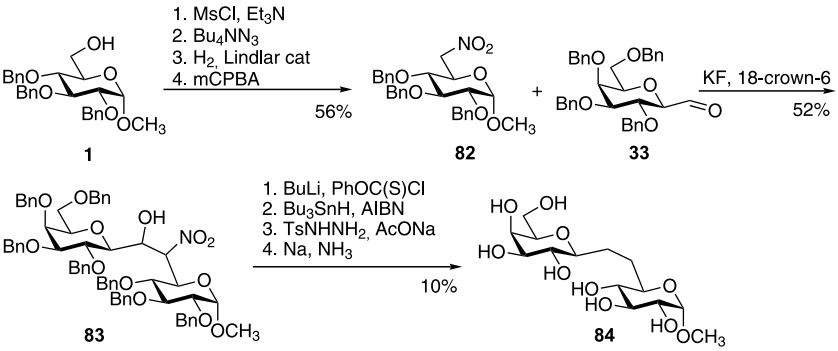
Reaction of the nitromethyl derivative **77** obtained in four steps from cellobiose peracetate, with the glucose-derived aldehyde **78** and potassium fluoride/18-crown-6 leads to the expected condensation product **79**. The acetylation-elimination-reduction sequence (→**80**) followed by reductive denitration and total deprotection affords the *O*,*C*-trimer mimic **81**.

A reverse option of the nitro-aldol condensation is available, as in the synthesis of the *C*-analog of β-D-Gal-(1→6)-D-Glc, also called allolactose, viewed by the authors as a potential inducer of the Lac repressor protein that is not susceptible to β-galactosidase cleavage [49] (*Scheme 17*).

The nitronate anion derived from nitro sugar **82**, available from glucopyranoside **1** using standard methods, condenses with aldehyde **33** to afford adduct **83**. Reduction with diimide of the *E*-olefin, produced in low yield by radical elimination of the nitroaldol, and removal of the



Scheme 16

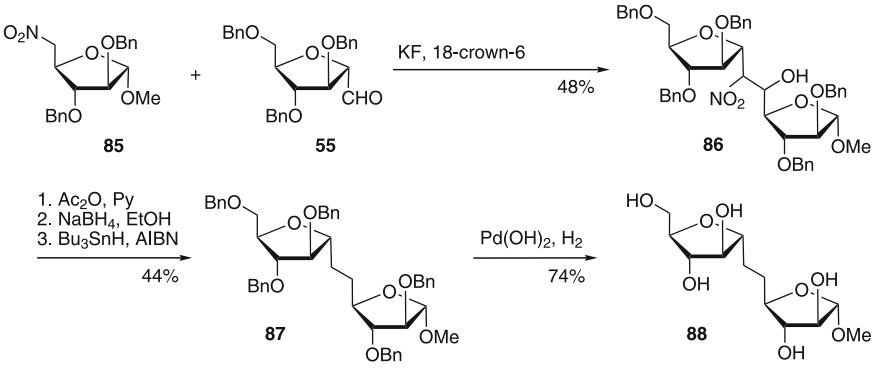


Scheme 17

benzyl groups provide the *C*-analog **84** of methyl allolactoside. 6-Deoxy-6-nitro sugars are also good substrates in intramolecular radical reactions for the preparation of *C*-linked dimers (see *Sect. 3.1*).

Using a similar approach, Gurjar described the synthesis of *C*-analog **88** of the disaccharide α-ara*f*-(1→5)-ara*f* present in motif C of the arabino-galactan portion of *Mycobacterium tuberculosis* [50] (*Scheme 18*).

Fluoride-induced condensation of the 5-deoxy-5-nitro furanoside **85** with the α-*C*-furanosyl formaldehyde **55** obtained by ring contraction of glucosamine and subsequent functional group manipulation lead to a diastereomeric mixture of the nitroaldols **86**. An acetylation-elimination sequence followed by reduction of the alkene, denitration and hydrogenolysis provide the *C*-disaccharide **88**.

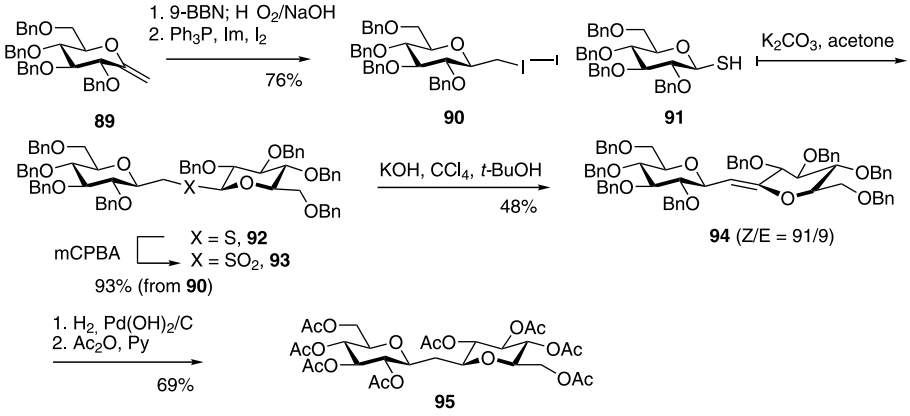


Scheme 18

2.5 The Ramberg–Bäcklund Route

The groups of Taylor [51a] and Franck [51b] independently reported in 1998 the interesting use of the Ramberg–Bäcklund rearrangement for preparing substituted exo-glycals (1-exomethylene sugars) from anomeric sulfones. In this reaction, α-halogenated sulfones are transformed to regio-defined olefins on treatment with base. The potential of this approach in synthetic applications has been reviewed [51c]. This procedure for preparing *C*-linked disaccharides has mainly been developed by the Taylor group. They took advantage of their initial studies on the exo-glycal preparation using this rearrangement [51a,52,53]. In their strategy the two monosaccharides are coupled through a thioetherification reaction and the resulting *S*-linked disaccharide is oxidized to the required sulfone for the Ramberg–Bäcklund rearrangement. This was successfully applied to the synthesis of a carba analog of isotrehalose (β-D-glucopyranosyl-(1→1)-β-D-glucopyranose), a disaccharide in which residues are linked through their anomeric center [54,55] (*Scheme 19*).

Exoglycal **89**, obtained by either methylenation of the gluconolactone using (Cp_2TiMe_2) [56] or the Ramberg–Bäcklund rearrangement of the anomeric methylsulfone [51a], is converted to iodomethylglucoside **90** in a two-step procedure: stereoselective hydroboration-oxida-

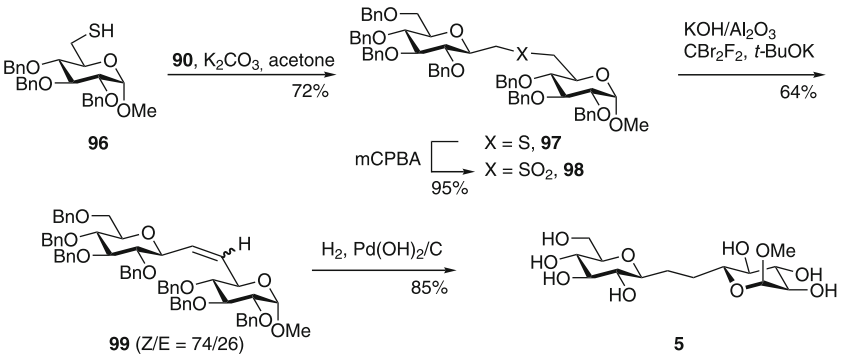


Scheme 19

tion and iodination using the Garegg protocol. Thioetherification with the protected thioglucose **91**, followed by oxidation of the resulting sulfide with mCPBA, provides sulfone **93** in 93% yield. The Ramberg–Bäcklund rearrangement under the Meyer's conditions [57] affords enol ether **94** predominantly as the Z-isomer (Z/E = 91/9). Hydrogenolysis-hydrogenation in a methanol/ethanol mixture and acetylation provide selectively the β,β-*C*-dimer **95**.

The same approach was used for the synthesis of the β-(1→6) *C*-disaccharide **5**, analog of methylgentiobioside [54,55] (*Scheme 20*).

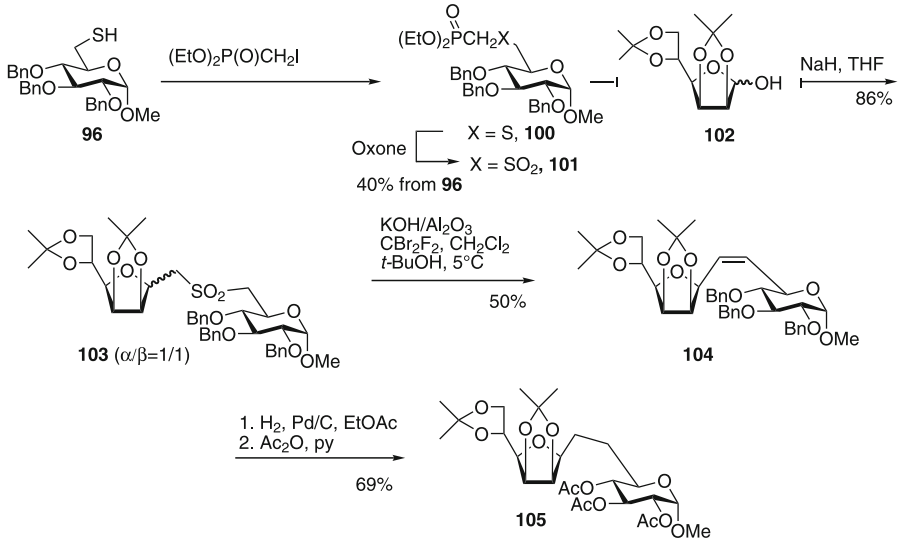
The thioetherification-oxidation sequence from thiol **96** delivers sulfone **98** in 68% yield. The sulfone functionality of this substrate is centrally positioned and displays, on both sides, a methylene linked to a monosaccharide. The Ramberg–Bäcklund rearrangement under the Chan's halogenation conditions [58] (KOH/Al_2O_3 and CBr_2F_2) provides the unsaturated *C*-disaccharide **99** in 64% yield as a mixture of isomers (Z/E = 70/30). Hydrogenation-hydrogenolysis finally gives the methyl-*C*-gentiobioside **5**.



Scheme 20

Taylor's group also showed that the Horner–Wadsworth–Emmons (HWE)/conjugate-addition sequence can be an efficient alternative to the thioetherification-oxidation reactions for the preparation of the required sulfones [59]. This was illustrated in the synthesis of the β-(1→6)-mannofuranose-α-Glu *C*-dimer [60] (Scheme 21).

Alkylation of thiol **96** with diethyliodomethylphosphonate followed by oxidation produces the HWE reagent **101**. The HWE-conjugate addition sequence with diisopropylidene mannofuranose **102** proceeds in 86% yield to sulfone **103** as a α/β mixture (1/1). The Ramberg–Bäcklund rearrangement under Chan's conditions applied to this mixture provides the *E*-alkene **104** in 50% yield, with total β selectivity. Hydrogenolysis and concomitant hydrogenation of the alkene give, after acetylation, *C*-disaccharide **105** in 69% yield.

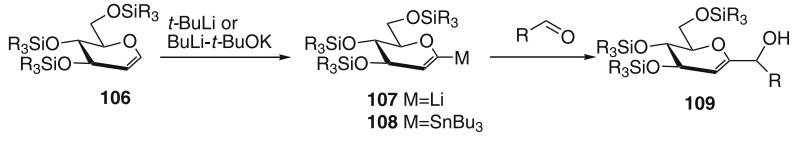


Scheme 21

2.6 C1-Lithiated Glycals

Three independent reports in 1986 showed that glycals are deprotonated by *tert*-butyllithium [61,62] or butyllithium/potassium *tert*-butoxide [63] when silyl ethers are used as protecting groups (Scheme 22).

Vinylic lithium reagents **107** or the corresponding 1-tributylstannyl glycals **108** have provided useful routes to C1-substituted glycals and *C*-glycosyl compounds [10]. The procedure has



Scheme 22

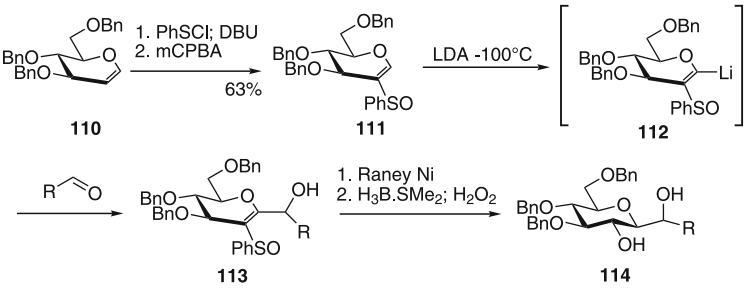
not yet been applied, however, to the synthesis of true mimics of oligosaccharides. A phenylsulfinyl substituent at C2, as shown by Schmidt and coworkers, facilitates deprotonation at C1 of glycals so that LDA is a base strong enough for C1-lithiation [64] (Scheme 23).

The 2-phenylsulfinyl glucal **111** is available from glucal **110** by addition of phenylsulfenyl chloride, DBU elimination and oxidation. The C1-substituted glycal **113**, obtained by addition of the lithium reagent **112** to aldehydes, is transformed to a β-D-*C*-glucosyl derivative **114** by reductive removal of the phenylsulfinyl group with Raney nickel and stereoselective hydration of the C/C double bond by hydroboration-oxidation.

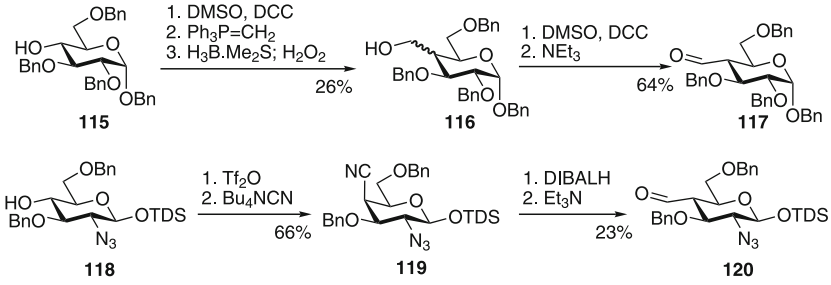
The linking carbon in the aldehydo-sugar partner is usually introduced by a Wittig reaction (or Tebbe's reaction) using a sequence of reactions starting from the appropriate glycoside as exemplified by glucoside **117** [65,66] (Scheme 24).

When this route is inefficient, as with the 2-azido-2-deoxy-D-gluco derivative **118**, the hydroxy group may be replaced by a cyano group (as in **119**), which is reduced by a diisobutylaluminum hydride treatment and isomerized with triethylamine to produce the C4-formyl glucoside **120**. Similar one-carbon homologation of uloses has also been reported by Armstrong [68] and Vasella [69].

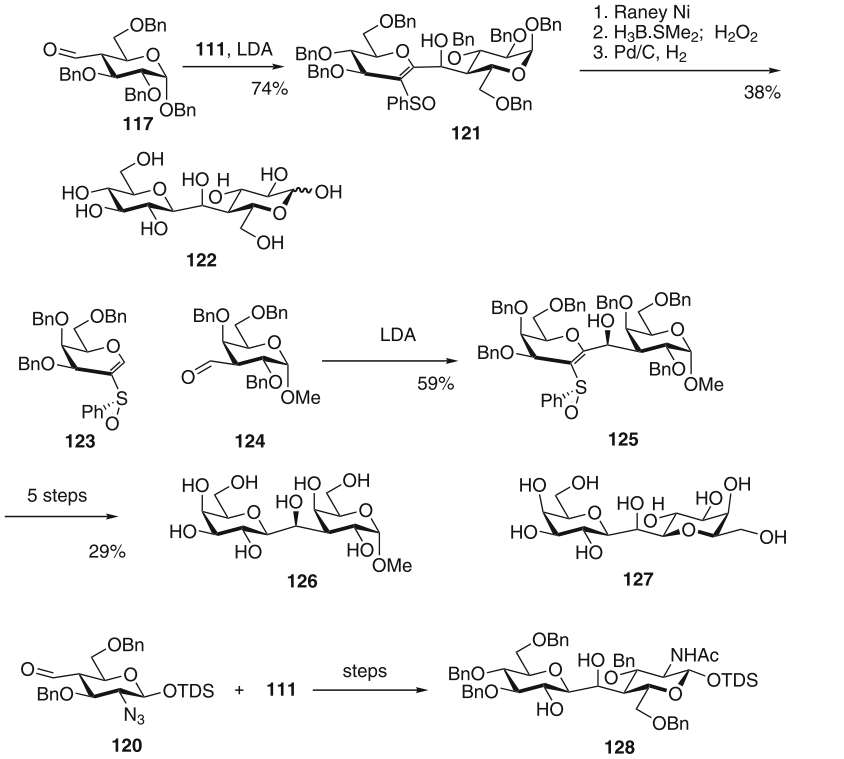
Several hydroxymethylene *C*-linked disaccharides have been prepared using this approach including the *C*-linked mimics of cellobiose **122** [65], β-D-Gal-(1→3)-D-Gal **126** [66], "galacto-β,β-trehalose" [β-D-Gal-(1→1)-β-D-Gal] **127** [70], and *N*-acetyllactosamine **128** [67] (Scheme 25).



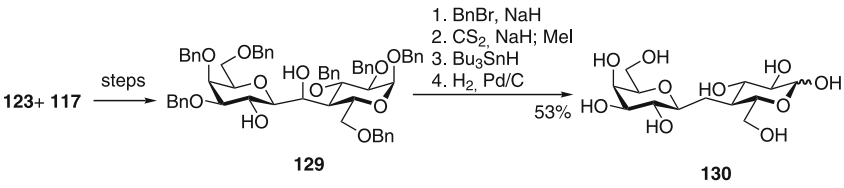
Scheme 23



Scheme 24



Scheme 25



Scheme 26

There is one report of the hydroxymethylene bridge being deoxygenated using the Barton procedure, leading to the *C*-analog of lactose **130** [71] (*Scheme 26*).

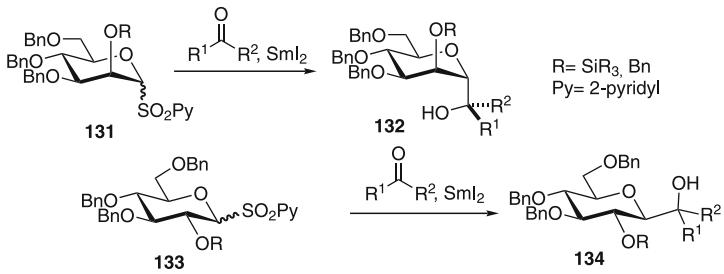
2.7 Glycosyl Samarium Reagents or Related Species

Tetrahedral anomeric lithium reagents are [10], initially restricted to the 2-deoxy sugar series in order to avoid the facile β-elimination of the substituent at position 2, is usable if a protective metallation at the C2-substituent is carried out before the metallation event at C1 by reductive lithiation or transmetallation of the corresponding stannanes [10]. This process has

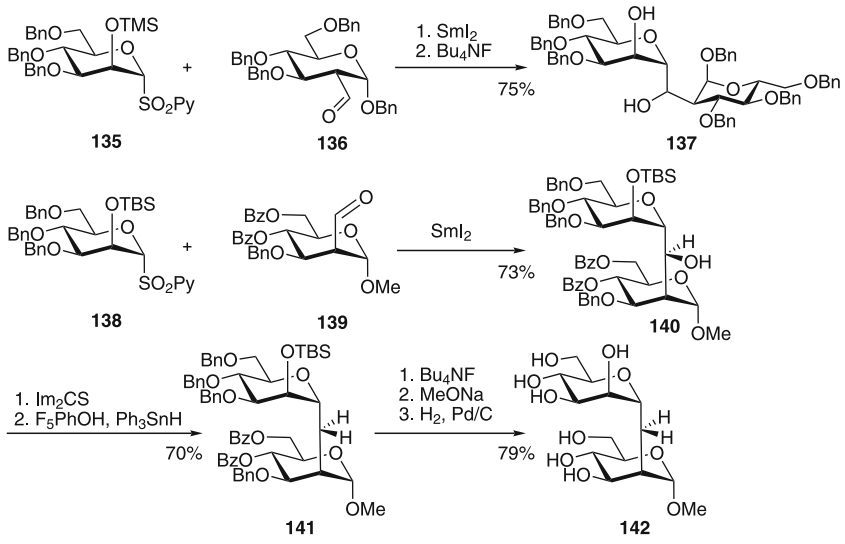
not been applied to the construction of *C*-analogs of disaccharides. An unexpected solution to this problem reported by Skrydstrup and Beau in 1995 [72] showed that reductive samariation (SmI_2, THF without an additive) of manno (and gluco) pyranosyl 2-pyridyl sulfones **131** and **133**, respectively, produces stereospecifically and instantaneously, in the presence of carbonyl compounds under Barbier conditions, the corresponding 1,2-*trans*-*C*-glycosyl compounds in good (*manno* series, **132**) to fair (*gluco* series, **134**) yields (*Scheme 27*).

This mild and simple procedure has been extended to the synthesis of *C*-linked disaccharides such as the *C*-linked mimic **137** of the α-D-mannopyranosyl(1→2)-D-glucopyranoside from sulfone **135** and aldehyde **136** [72,73] and the methyl α(1→2)-*C*-mannobioside **142** from sulfone **138** and aldehyde **139** [74,75] (*Scheme 28*).

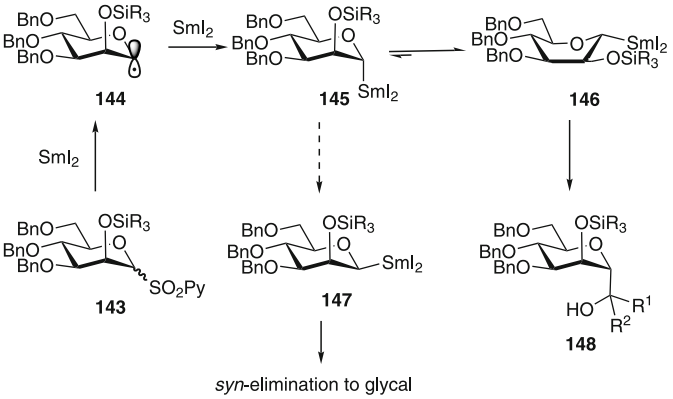
The production of a kinetic α-organosamarium(III) species **145** by reductive samariation of the corresponding anomeric radical **144** explains the stereospecific formation of α-*C*-mannosyl compounds (*Scheme 29*).



Scheme 27



Scheme 28

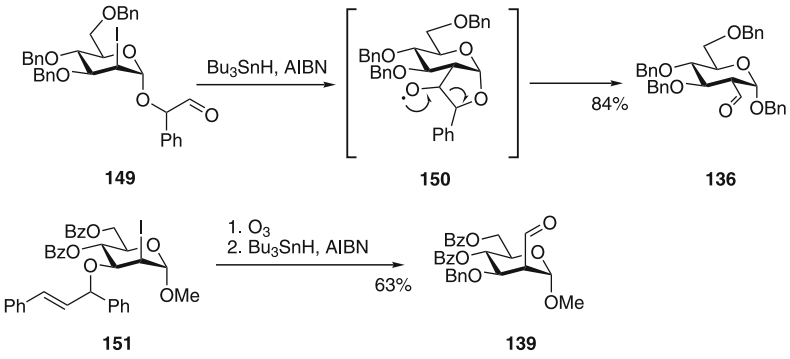


Scheme 29

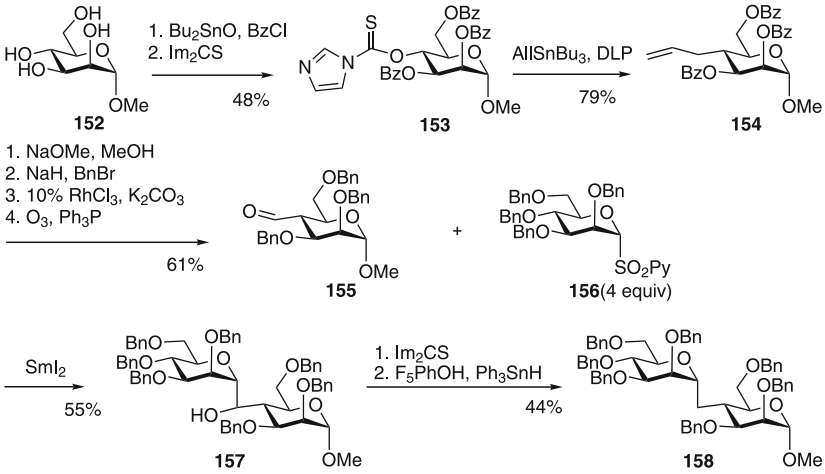
Rather than isomerization to β-samarium species **147**, reagent **145** probably undergoes a facile conformational change in which the C1 and C2 substituents are placed in more stable equatorial orientations. The isomerized species **147**, if any, apparently undergoes a *syn* β-elimination at room temperature. The synthesis of aldehydes **136** and **139** merits a special comment because a versatile formyl group transfer originally proposed by Jung and Choe [76] is used (*Scheme 30*).

The authors showed that iodo-glycoside **149** undergoes, under Bu_3SnH treatment, a 5-*exo* radical cyclization-fragmentation to the more stable benzyl radical resulting in a stereospecific formyl group transfer to C2, leaving a standard benzyl protecting group at the anomeric position. Delivery of the formyl group from the C3 position, as with iodo glycoside **151**, produces rather the isomeric axial C2-formyl manno derivative **139** as shown by Skrydstrup and Beau [74,75].

For the assembly of the *C*-linked disaccharide α-D-Man-(1→4)-D-Man, Mikkelsen and Skrydstrup followed the same route using this SmI_2-mediated coupling of pyridyl sulfone **156** with



Scheme 30



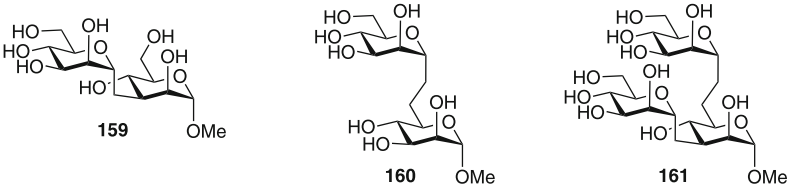
Scheme 31

aldehyde **155**, affording the *C*-disaccharide derivative **157** with complete stereocontrol at the two new stereogenic centers (*Scheme 31*) [77].

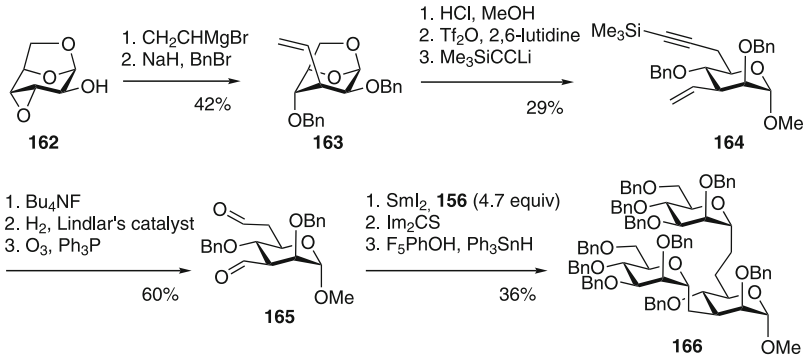
In this synthesis, the C4-formyl monosaccharide **155** was prepared from the benzoylated thionocarbamate **153** using a stereoselective radical based allylation. The exclusive equatorial selectivity observed in the *manno* series is remarkable and can probably be explained by the unfavorable axial approach of the incoming allyl group due to steric interactions with the axially oriented C2-substituent. Exchange of the protecting groups, rhodium-catalyzed double bond migration and reductive ozonolysis then produced the aldehyde **155**.

Methyl α-1,3- and α-1,6-*C*-mannobiosides **159** and **160**, as well as the branched *C*-trimannose analog **161** of the common core structure of asparagine-linked oligosaccharides have also been synthesized using the same sulfone **156** and, for the *C*-trimer, the monosaccharide dialdehyde **165** (*Scheme 32* and *Scheme 33*) [78,79,80].

The conformational preferences of these *C*-linked dimers and trimer have been analyzed by comparing with their natural counterparts, using a combination of NMR spectroscopy and time-averaged restrained molecular dynamics [81]. It was notably found that a major conformational distinction between the natural trisaccharide and the glycomimetics concerns the ω-(1,6) torsion angle around the α-(1,6)-linkage, with a unique *gt* rotamer for the *C*-trimer **161**. The *C*-glycosyl trimer analog is recognized by three mannose-binding lectins, as shown



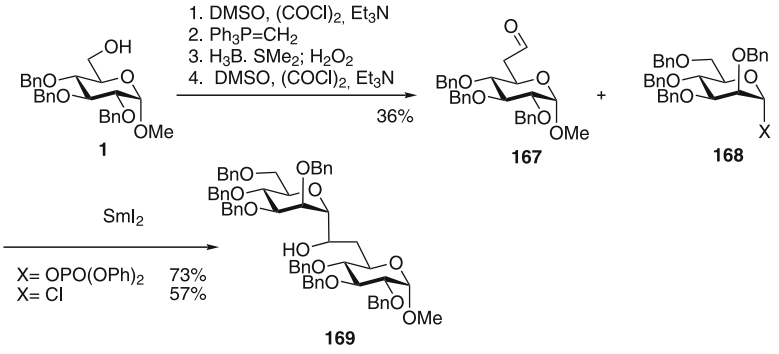
Scheme 32



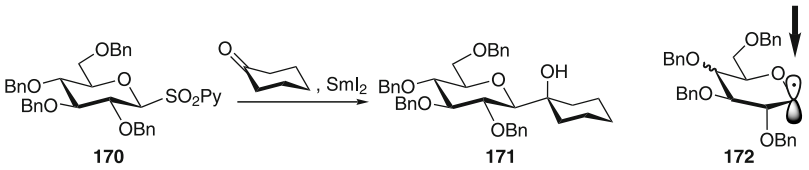
Scheme 33

by NMR (line broadening, TR-NOE, and STD) and surface plasmon resonance (SPR) methods, in a binding mode similar to the one whereby the lectins recognize the natural compound. Anomeric chlorides or phosphates may also be used as reducible groups in the reaction as shown in the synthesis of the $\alpha(1\rightarrow2)$ *C*-linked disaccharide **169** of mannose [82,83] (*Scheme 34*).

For the synthesis of 1,2-trans *diequatorial* *C*-glycosyl compounds (e. g., with the glucopyranosyl series), this *C*-glycosylation procedure was not efficient enough to be used in the construction of complex *C*-oligomers. The major drawback was a too high level of the competing β-elimination (an elimination/C–C bond formation ratio of approximately 1/1) that could be minimized only by using a bulky protecting group at O2 (R in **133** = *t*-butyldimethylsilyl, *Scheme 27*) [72,73]. An unpredicted solution was reported in 2000 by incorporating catalytic amounts of nickel(II) iodide (1 mol%) with the reducing samarium salt [84]. Catalysis by transition metals of some reactions mediated by samarium diiodide was introduced by Namy and Kagan [85]. This dramatic effect of catalytic nickel is seen in the high coupling efficiency of sulfone **170** and cyclohexanone at 0 °C with a solution of SmI_2 containing 1 mol% of nickel(II) iodide (*Scheme 35*).



Scheme 34



Scheme 35

These results suggest a possible mechanism in which, during the samariation step, the intermediate anomeric radical **172** is primarily reduced under the control of steric factors by a bulky catalytic species containing low valent nickel.

This procedure provides a fast synthesis of *C*-glycosyl disaccharides with the anomeric sulfones derived from the D-gluco, D-galacto and L-fuco series and this is presented using aldehyde **175**, obtained by the five-step sequence of reactions shown in *Scheme 36*.

The *C*-linked $\beta(1\rightarrow6)$-disaccharides **176**, **178** and **180** are all obtained in good yields (83 to 89%). The addition of the organosamarium reagents to the carbonyl group of aldehyde **175** also occurred with a high facial selectivity (diastereomeric ratio of about 95:5), exclusively controlled by the asymmetry of the *C*-glycosyl donor.

This chemistry is also possible with per-*O*-trimethylsilyl glycosyl iodides [86] or, if a multistep construction of more complex *C*-glycosyl compounds is considered, with the more practical per-*O*-benzyl iodides derived from D-glucose, D-galactose or L-fucose [87] (*Scheme 37*).

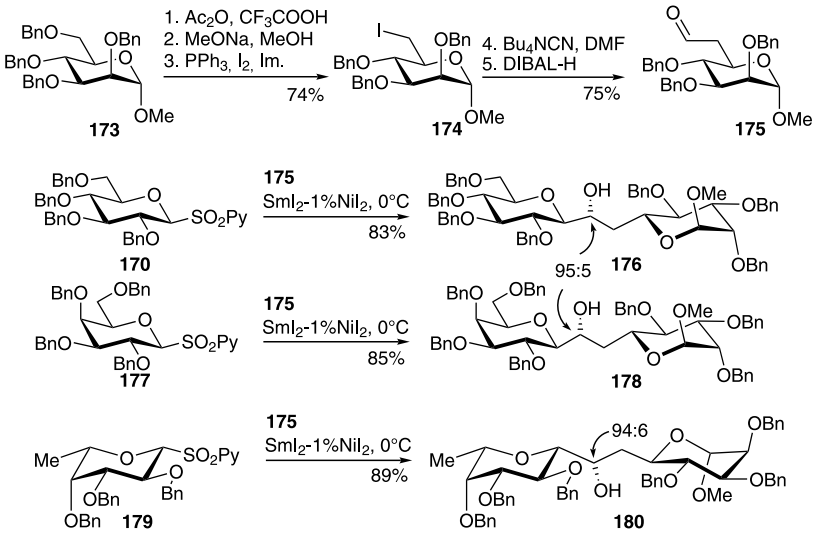
For example, reductive samariation of benzyl glycopyranosyl iodide **182** in the presence of aldehyde **175** provides the corresponding 1,2-*trans* *C*-glycosyl disaccharide **176**, transformed to the methylene-linked dimer **183**. A striking difference from the results obtained with the anomeric 2-pyridyl sulfones is the decrease or the absence of the β-elimination reaction when using SmI_2 alone, with the efficiency marginally improved by incorporating catalytic amounts of NiI_2 with SmI_2. This is not yet explained but it is possible that there is a change in the electron transfer mechanism ongoing from anomeric pyridyl sulfones to anomeric iodides inducing a change in the product distribution (C–C bond formation versus elimination).

This SmI_2-induced *C*-glycosylation was extended to the synthesis of *C*-linked glycosides of 2-acetamido-2-deoxy sugars [88,89,90]. Reductive samariation of the 2-pyridyl sulfone of *N*-acetylglucosamine **184** in the presence of aldehyde **167** leads selectively to the α-*C*-glycosyl dimer **185** [90] (*Scheme 38*).

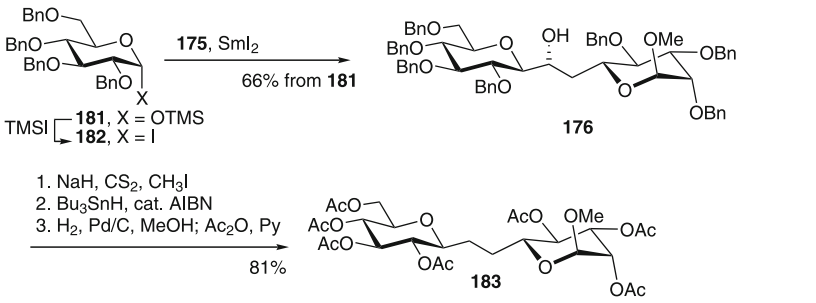
The transformation is only moderately stereoselective in this situation and the stereochemical outcome of the reaction is explained by a complexation of the samarium atom by the acetamido group in the kinetic α-Sm(III) species **186**, slowing down the isomerization to the β-species. The anomeric selectivity is completely lost when operating with the acetylated sulfone **187**.

A solution to restore a selective reaction and to access to *C*-glycosides mimicking the biologically ubiquitous β-GlcNAc motif, relies on this intermolecular samarium-Barbier reaction followed by an oxidation-isomerization sequence [91] (*Scheme 39*).

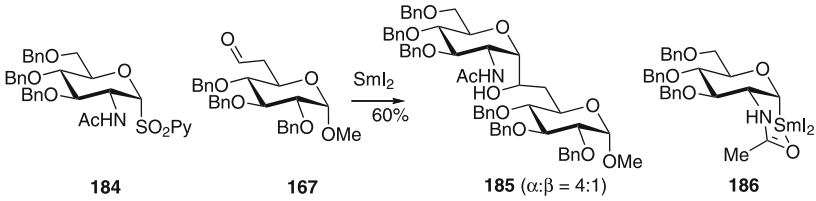
Coupling of sulfone **187** with aldehyde **175** provides a mixture of four isomers which, after oxidation, epimerization and reacetylation produce the β-linked *C*-disaccharide **188**, a protected analog of the β-D-GlcNAc-$(1\rightarrow6)$-D-Man motif of *tri*- and *tetra*-antennary complex-type



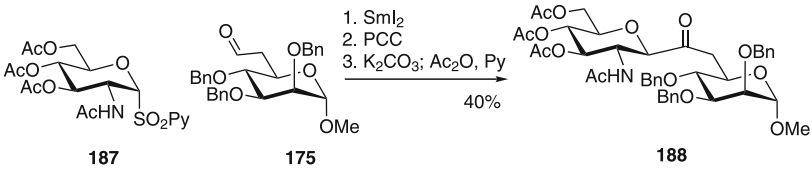
Scheme 36



Scheme 37



Scheme 38



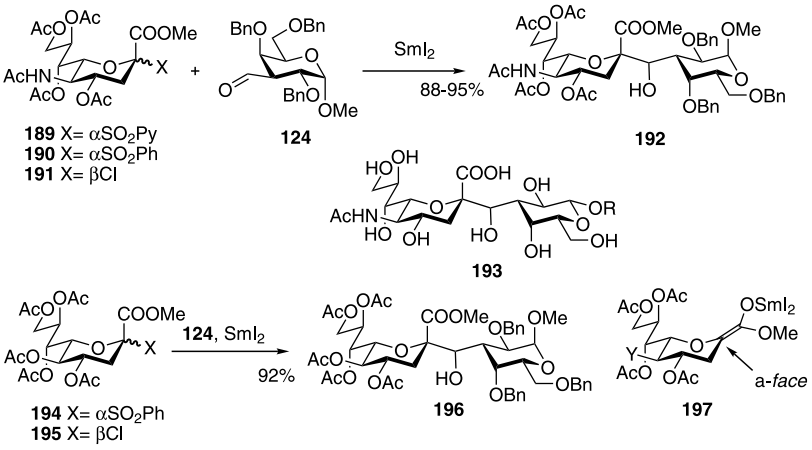
Scheme 39

N-glycans. The procedure also capitalizes on the observation that these anionic conditions remarkably tolerate the presence of standard *O*-acetyl protecting groups as noted previously [72], as well as acidic protons in acetamido groups.

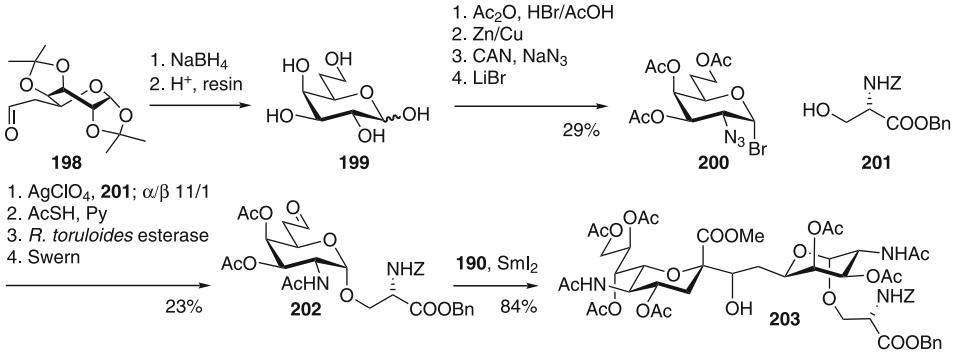
This method has also been applied to a high-yielding stereoselective synthesis of *C*-linked *N*-acetylneuraminic acid (Neu5Ac)-containing disaccharides [92] starting from either the 2-pyridyl (phenyl) sulfones **189** and **190** or the anomeric chloride **191** (*Scheme 40*).

The reductive samariation of phenyl sulfone **190** or chloride **191** is possible without HMPA because the initial homolytic cleavage of the C–S bond, leading to a radical stabilized by the carbomethoxy group, is easier. We note again the exceptional efficiency of this coupling process with acetyl protecting groups. The high α-stereoselectivity can certainly be explained by the formation of a samarium enolate intermediate **197**, which accepts the electrophile from the less sterically hindered α-face. Similar results were reported with other ulosonic acids such as KDN (3-deoxy-D-glycero-D-galacto-2-nonulopyranosylonic acid), a natural analog of NeuAc in which the acetamido group is replaced by a hydroxy group, using phenyl sulfone **194** or chloride **195** [93] (*Scheme 40*).

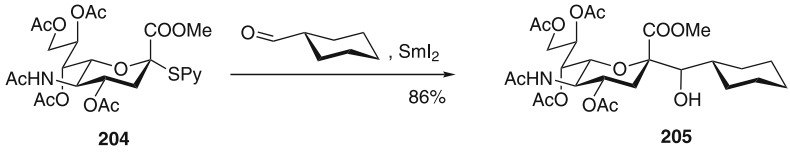
The conformational analysis of deprotected *C*-glycosyl analog of sialyl-α-(2→3)-D-galactose **193** show that the population distribution of conformers around the pseudo-glycosidic linkages is mainly controlled by steric interactions [94].



Scheme 40



Scheme 41



Scheme 42

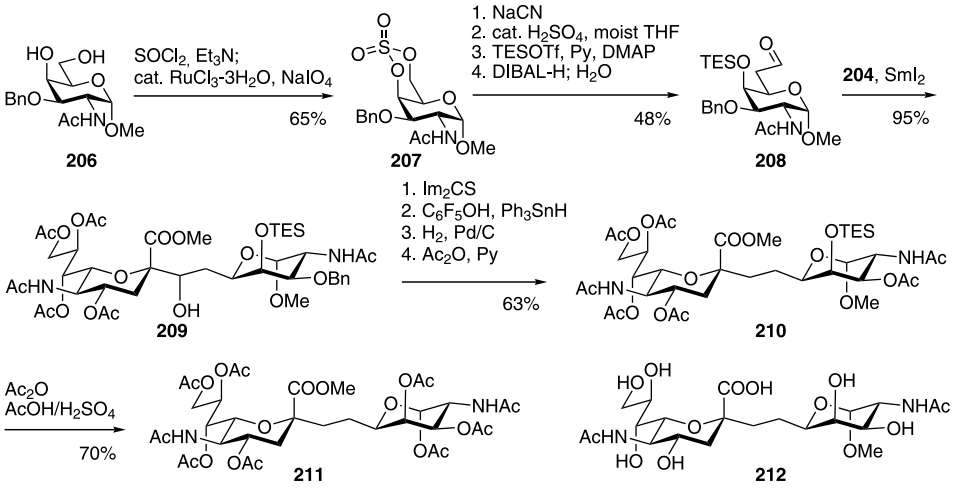
Phenyl sulfone **190** was also the *C*-glycosyl donor used in a synthesis of a *C*-linked mimic **203** of the sialylTn antigen [Neu5Ac-α(2→6)-GalNAc-α(1→*O*)Ser] [95] (*Scheme 41*).

Aldehyde **198**, available in four steps from D-galactose, is the starting point of a ten-step synthesis of the key α-glycosyl-serine aldehyde **202**, partner in the reductive samariation procedure with sulfone **190**. This provides efficiently the expected fully protected *C*-analog **203** of this important antigen that could not, however, be deoxygenated to the methylene-linked analog [95].

It was more recently shown that the stable and crystalline 2-pyridyl sulfide of Neu5Ac derivative **204** is also an excellent precursor of the anomeric organometallic species, in this samarium-Reformatsky procedure [96] (*Scheme 42*).

The efficiency of this approach is seen in a prompt reductive coupling of sulfide **204** with cyclohexane carbaldehyde to afford *C*-glycosyl derivative **205**. This was applied to a fast synthesis of the same disaccharidic component of the sialylTn antigen [96] (*Scheme 43*).

The synthesis was designed in such a way that an activated disaccharidic block would be available for modular attachment to a wide variety of acceptors aiming at its incorporation into a synthetic vaccine. The preparation of the required aldehyde **208** started from *N*-acetylgalactosamine derivative **206**, obtained from the inexpensive *N*-acetyl-D-glucosamine. It was converted to 4,6-cyclic sulfate **207**, following the procedure of Gao and Sharpless [97]. Regioselective ring opening of cyclic sulfate **207** at C-6 [98] by sodium cyanide provided in high yield a cyanide sulfate, which was transformed in three steps into aldehyde **208**. The samarium-Reformatsky key-coupling step proceeds in high yield to afford the *C*-linked dimer **209**, transformed to the methylene-bridge analog **210**. The high stability of these *C*-linked mimics



Scheme 43

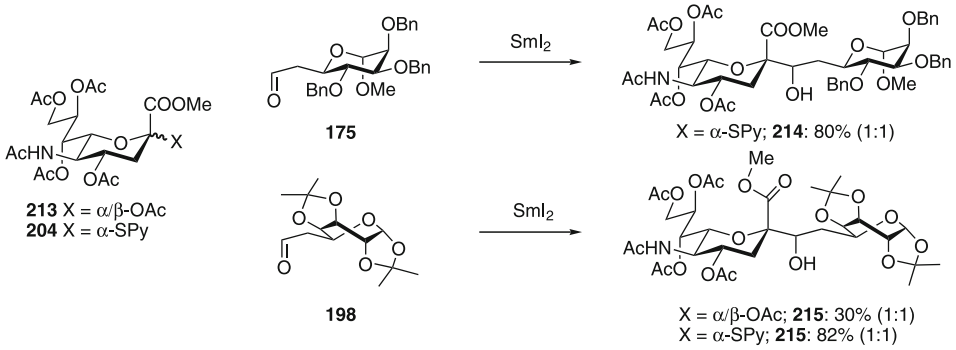
allows for modifications under conditions unacceptable with a native *O*-linkage. Thus, acetolysis of the methyl glycoside in dimer **210** provides anomeric acetate **211**, easily exchangeable to other anomeric substituents usable in a block synthesis.

The clear advantage in using the 2-pyridyl motif (sulfone or sulfide here) over the phenyl sulfonyl anomeric substituent reported in the work of Linhardt [95] concerns the amount of the reducing agent. While 2.5 equiv. are needed with the SPy (or SO_2Py) substituent (theoretical amount, 2 equiv.), a large excess (more than 5–8 equiv.) is necessary with the SO_2Ph substituent because of the competitive deoxygenation of the leaving phenylsulfinate as was previously pointed out [116].

The conformational analysis of the deprotected analog **212**, performed by using NMR and molecular mechanics, indicates a drastic difference from the major conformation found with the natural compound present in solution, especially around the Φ and ω angles [99]. The low energy barriers for conformer interconversion might nevertheless allow easy access to other conformers that can bind to natural receptors without major entropy penalties.

In an even more simple approach, the reductive samariation of the readily available anomeric acetates **213** is possible in the absence of any additive that increases the reducing power of the samarium salt [100] (*Scheme 44*).

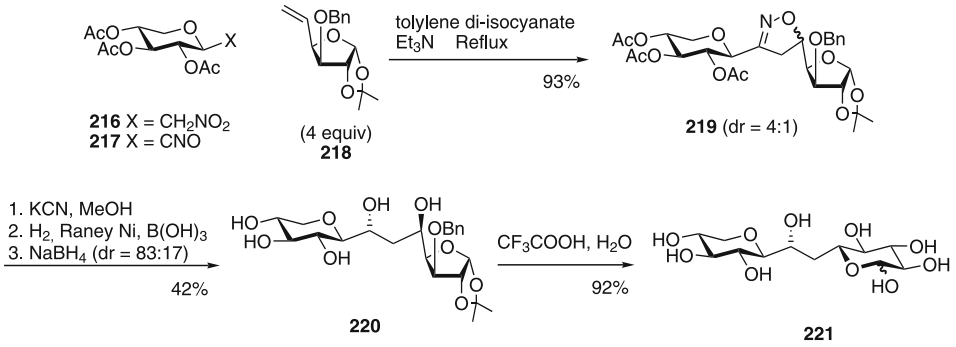
The procedure is remarkably effective for the coupling with cyclic ketones and provides a fast access to α-*C*-ketosides of Neu5Ac. The coupling efficiency is however moderate in the synthesis of *C*-disaccharides, as shown with the D-galactose-derived aldehyde **198** (*Scheme 44*). Acetates **213** provide the expected compound **215** but much less efficiently than sulfide **204** (30 versus 82% yield, respectively). The moderate yield using acetates **213** is due to the competitive pinacol coupling of aldehyde **198** because the rate of the reductive metallation of the anomeric acetates is too slow.



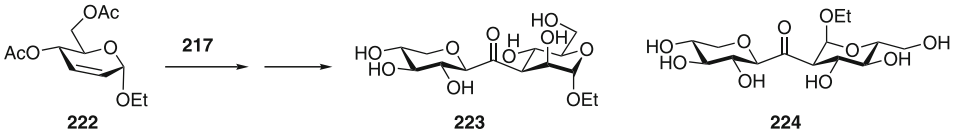
Scheme 44

2.8 Dipolar Cycloaddition

The key carbon–carbon bond formation may be carried out under very different conditions using pericyclic reactions. Paton used the 1,3-dipolar cycloaddition of nitrile oxides derived from pyranoses with unsaturated sugars [15]. Nitrile oxide **217**, generated in situ by dehydration of the nitromethyl derivative **216** in the presence of an excess of alkene **218** at reflux provides regioselectively isoxazoline cycloadducts **219** (dr = 4:1) [101] (*Scheme 45*).
Deacetylation, reductive hydrolysis, and carbonyl reduction of the major isomer yield diastereomers, with one (**220**) being hydrolyzed to the hydroxymethylene-bridged analog of the β-D-Xyl(1→6)-D-Glc dimer **221**. Another example starting from an excess of 2,3-unsaturated sugar **222** and nitrile oxide **217** generates, after similar steps, an equimolar mixture of β-(1→3) and β-(1→2) mimics **223** and **224**, respectively [102] (*Scheme 46*). One should notice that *C*-dimer analog **224** arises from the isomerization of the bulky acyl substituent at C2 to the more stable equatorial position.
The substituents of the eno-pyranoside control well the facial selectivity, however without regiocontrol. With a terminal, non-cyclic alkene such as **218** (*Scheme 45*), the controlling features are reversed (good regioselectivity with lower facial selectivity).



Scheme 45



Scheme 46

3 The Radical Assemblage

3.1 Intermolecular Reactions

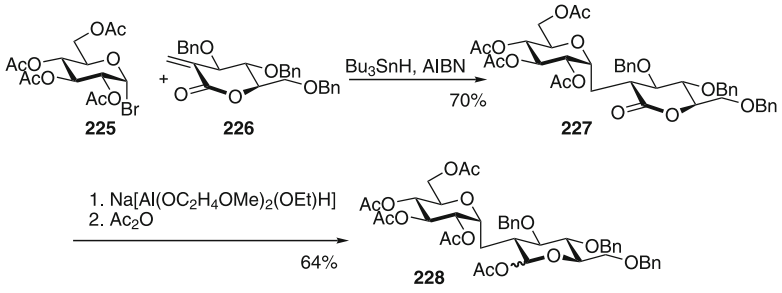
Instead of relying on ionic reactions to execute the crucial assembling of two glycosidic units, one may profitably consider radical reactions [12,16]. An anomeric radical, being an alkoxyalkyl radical, will behave as a nucleophile, and its high-lying SOMO will better interact with the LUMO of an electron-poor alkene, typically α,β-unsaturated carbonyl compounds or similar derivatives. In other words, in intermolecular reactions, the radical acceptor should be activated enough to compete efficiently with an H-donor.

Giese showed that an anomeric radical, obtained by reaction of acetobromoglucose **225** with tributyltin hydride, adds to sugar-derived α-methylene-γ-lactones such as **226** with good yields and high α stereoselectivity [103] (*Scheme 47*).

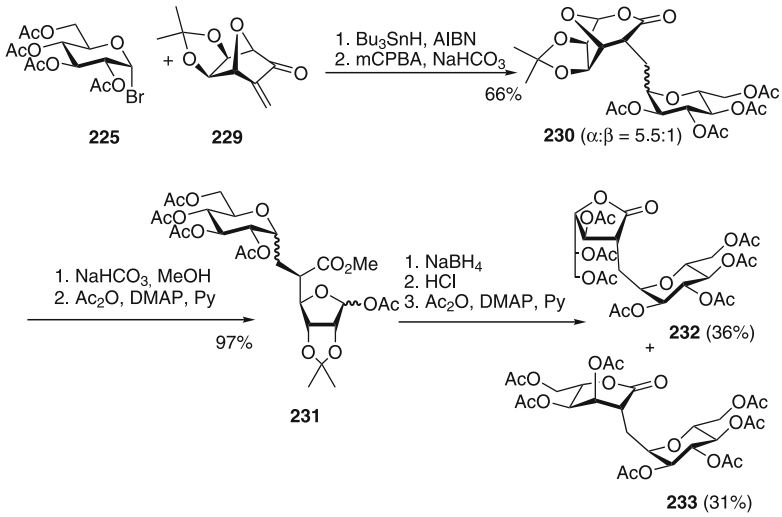
The resulting lactone is further modified to the corresponding *C*-linked disaccharide **228** (*C*-kojibiose).

Similar reactions were described by Vogel, using a "naked sugar" as a radical acceptor. The resulting product has to be further elaborated before it becomes a "true" *C*-linked disaccharide, with the key-step being a Baeyer–Villiger ring expansion [104,105] (*Scheme 48*).

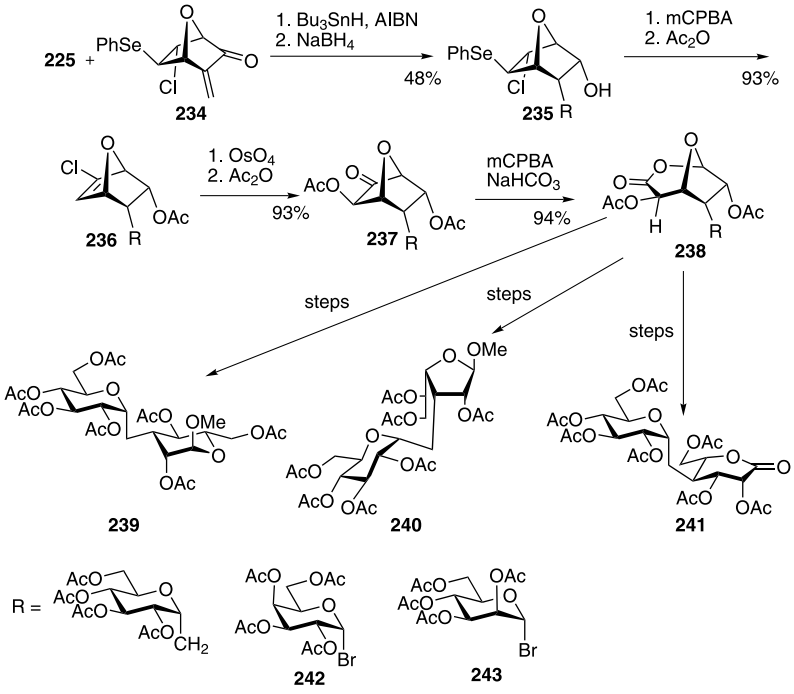
Variations of the radical acceptor substitution pattern and use of acetobromogalactose **242** [106] or acetobromomannose **243** [107,108] as a radical precursor has resulted in the synthesis of various *C*-dimers including the *C*-linked analog of Man-α(1→3)-GalNAc, which proved to be an inhibitor of several glycosidases, as well as human α-1,3-fucosyltransferase VI [108] (*Scheme 49*).



Scheme 47

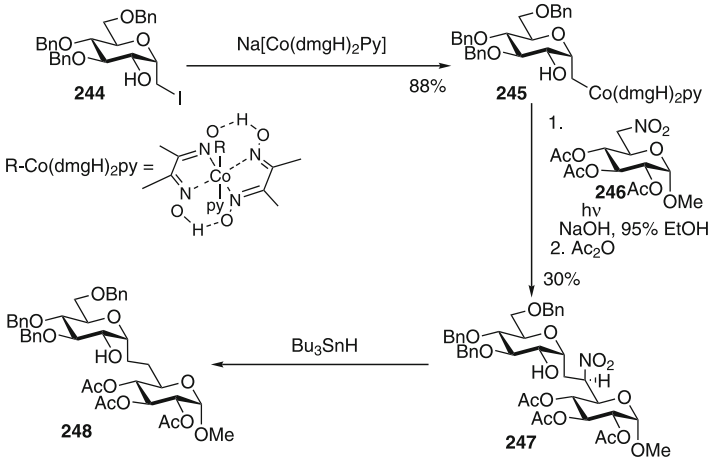


Scheme 48

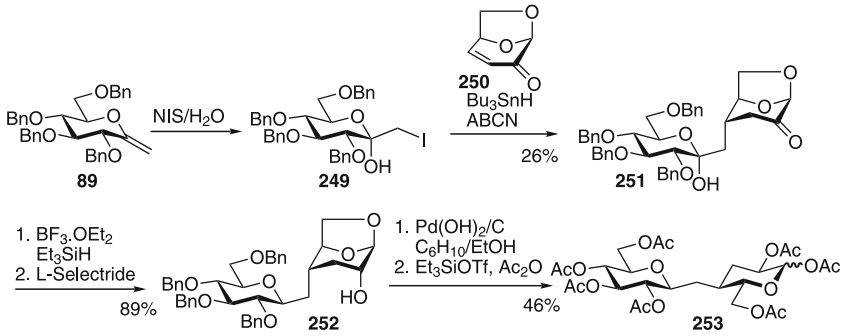


Scheme 49

In a very different approach, Martin used an α-glycosylmethyl cobaloxime **245**, prepared from iodide **244**, to photochemically generate the corresponding radical [109] (*Scheme 50*).
This radical adds to the nitronate ion derived from 6-nitro sugar **246**. Tin-hydride mediated denitration leads to an α-(1→6) *C*-linked disaccharide **248**.
Witczak also used a methylene "extended" glucose derivative **249** as a radical precursor [110] (*Scheme 51*).
Stereoselective radical addition on the *exo*-face of levoglucosenone **250** leads to the *C*-linked dimer **251** in a modest 26% yield. The expected competing reaction is the direct hydrogen abstraction by the initial radical species. Stereoselective hemiketal and ketone reductions afford the 1,6-anhydro derivative **252**, which is deprotected and opened to give the final *C*-analog of a β-(1→4) disaccharide **253**.



Scheme 50



Scheme 51

3.2 Intramolecular Reactions

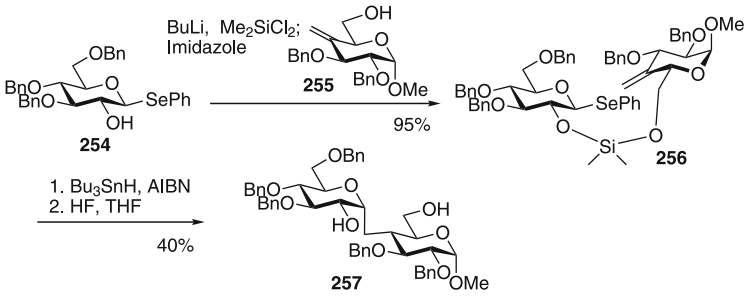
Olefin activation by electron-withdrawing groups is no longer necessary when an intramolecular trapping is programmed because radical cyclizations occur faster than do intermolecular additions. In such cases, the stereoselectivity of the cyclization and its efficiency will depend on several parameters such as ring size, the type of atoms, and the nature of asymmetric centers present in the ring.

This strategy was mostly exploited by Sinaÿ and his coworkers, enabling them to prepare various *C*-linked disaccharides in an expeditious fashion, via radical cyclization of temporarily tethered monosaccharidic precursors [111]. Medium-sized ring intermediates are obtained in reasonable yields, leading to the desired compounds after removal of the tether. The prototype of this approach is described below [112a] (*Scheme 52*).

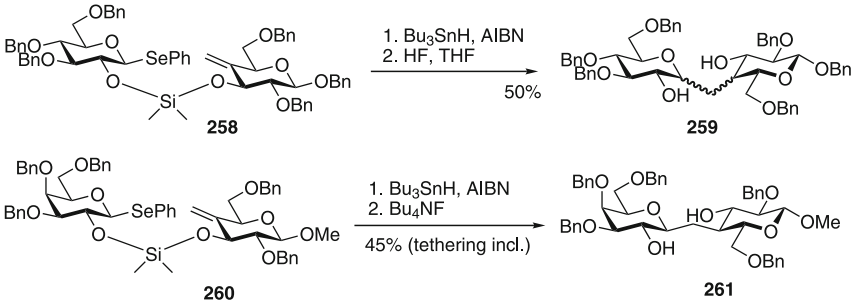
The two glucose derivatives **254** and **255** are linked via a silaketal function. Radical 9-*endo*-trig cyclization of intermediate **256** leads, after removal of the tether, to a single *C*-dimer **257** isolated in 40% yield. Anomeric radical trapping occurs exclusively from the α side of the initial species, while H-abstraction by the resulting intermediate radical leads to the equatorially substituted product. As a result, the isolated compound is the *C*-linked analog of methyl maltoside **257**. When this methodology was extended to the *galacto* series, the cyclization yield increased to 60%, although three different *C*-dimers were obtained via the 9-*endo*-trig cyclization [112b].

The nature of the attacking sugar radical, the size of the intermediate ring, and the choice of the tethering positions have a great influence on selectivities, and consequently on product distributions. For example, while the 8-*endo*-trig cyclization of the gluco compound **258** yields an inseparable mixture of all four possible products [112a], the same reaction performed in the *galacto* series leads, in 45% yield, to the *C*-linked analog of methyl β-lactoside **261** [113] (*Scheme 53*).

It is noteworthy that this is an exceptional reported situation where the major isolated compound resulted from an attack of the anomeric radical on its β face, leading to a β-*C*-linked dimer. This unique behavior is probably caused by a strong conformational bias in the intermediate species.

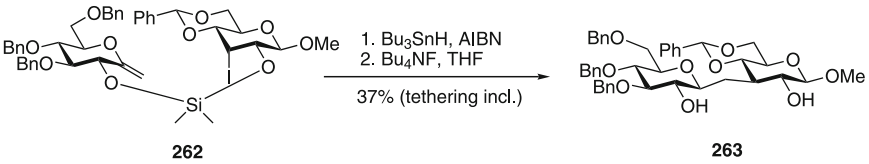


Scheme 52



258 **259** **260** **261**

Scheme 53



262 **263**

Scheme 54

Interestingly, when the role of the partners is reversed, e. g., when the radical is formed on a non-anomeric position of one of the sugars as in **262** (Scheme 54), the addition occurs equatorially to an anomeric exomethylene, resulting in an anomeric radical that abstracts hydrogen from the α face.

Consequently, the β-*C*-linked disaccharide **263**, analog of a methyl laminaribioside derivative, is isolated [114]. Other β-*C*-linked disaccharides, namely analogs of cellobiose, Gal-β-(1→3)-Glu, β,β and α,β trehaloses have been prepared using this strategy.

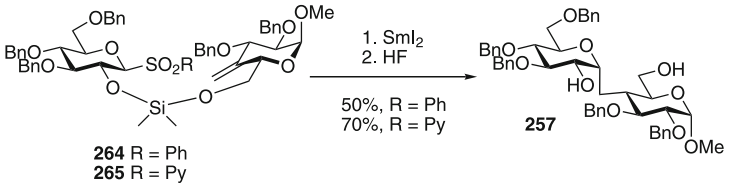
As an alternative to the Bu_3SnH-phenylseleno glycoside chemistry, radicals may also be generated by samarium diiodide reduction of anomeric arylsulfonyl groups [115], (R=Ph) (Scheme 55).

The use of the 2-pyridylsulfonyl group introduced by Skrydstrup and Beau [116], more easily reduced than the phenylsulfonyl group, allows a significant increase in the cyclization yield [117].

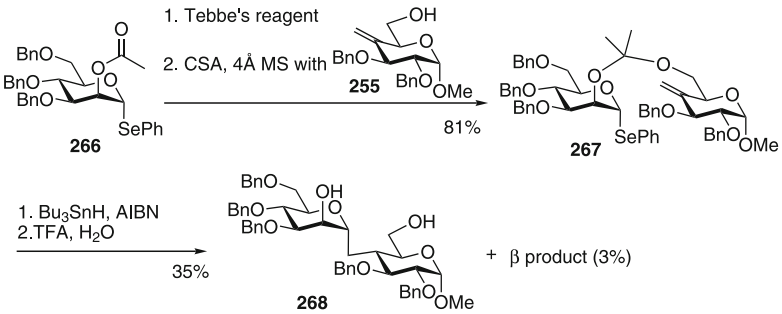
Other temporary connections, such as ketal tethers were also tested. Tebbe olefination of acetate **266** and ketal formation with sugar alcohol **255** lead to tethered intermediate **267**, which is cyclized to a *C*-analog derivative **268** of the α-D-Man(1→4)-D-Glc disaccharide after ketal cleavage [118] (Scheme 56).

Similarly, DDQ oxidation of the *p*-methoxybenzyl group of **269** in the presence of alcohol **270**, a strategy reported by Ito and Ogawa [119] in *O*-glycoside synthesis, provides benzylidene acetal **271** [120] (Scheme 57).

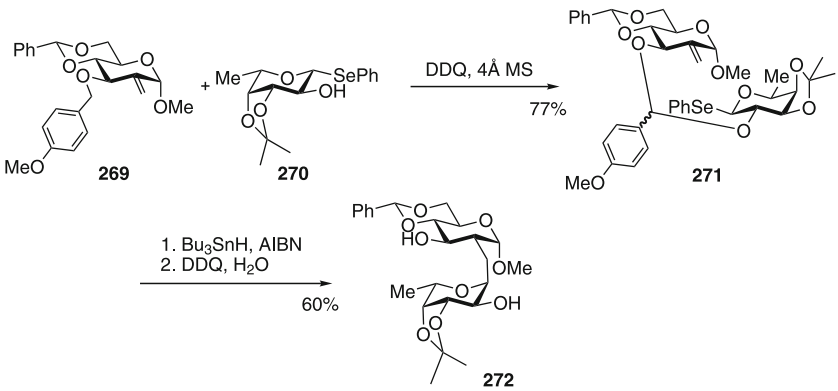
8-*Endo* radical cyclization and removal of the acetal generate a *C*-linked derivative **272** of the α-L-Fuc(1→2)-D-Glc dimer.



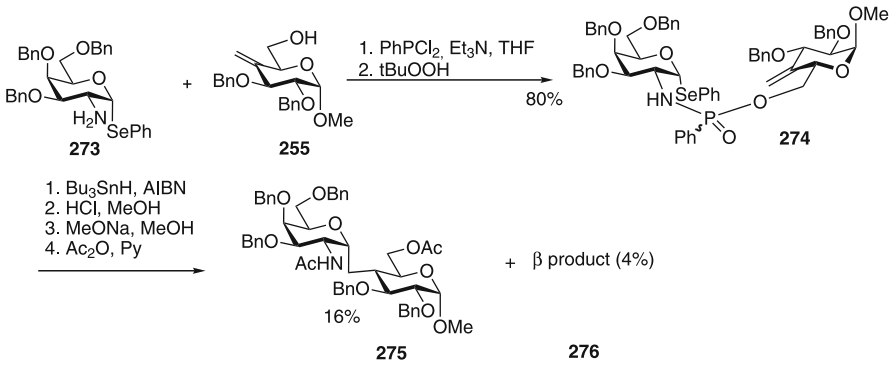
Scheme 55



Scheme 56



Scheme 57



Scheme 58

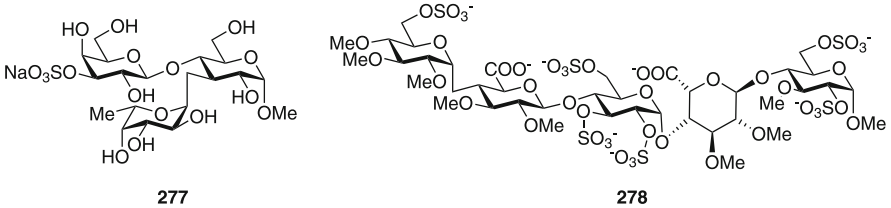
A phosphoramidic linker was also used for tethering via the amino group of a 2-amino-2-deoxy sugar [121] (*Scheme 58*).

Once again, 9-*endo* cyclization of intermediate **274**, obtained in two steps from galactosamine derivative **273** and unsaturated alcohol **255**, followed by detethering and acetylation of the amino group leads to *C*-dimers **275** and **276** in an expeditious way.

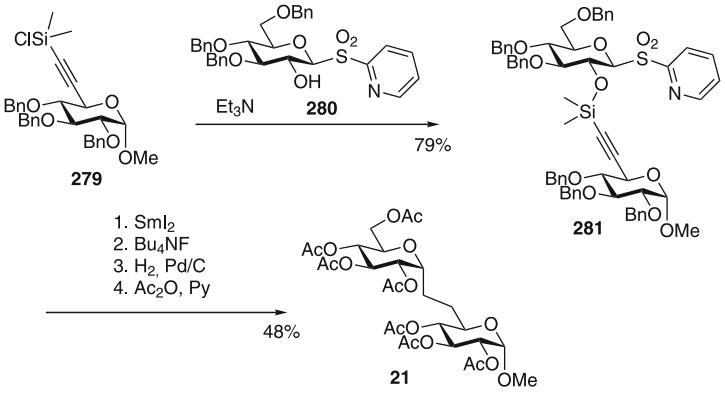
We have seen in the preceding examples the efficiency and potential generality of this type of *C*-glycosylation procedure. The monosaccharidic precursors are relatively easy to obtain, allowing these reactions to be performed on a multigram scale. The resulting *C*-linked disaccharides can consequently be incorporated in more complex structures, like mixed C/O-linked oligosaccharides. This approach has been successfully used in the synthesis of several *C*-linked glycosides of potential biological interest such as a sialyl Lewis^x analog **277** [122], and a "C/O-linked pentasaccharidic" analog of the antithrombin III binding region of heparin **278** [123] (*Scheme 59*).

Another intramolecular approach to *C*-linked disaccharides has been described by Skrydstrup and Beau [116] using 2-pyridyl sulfones to generate anomeric radicals. Tethering sulfone **280** with chlorosilane **279** provides silyl ether **281** (*Scheme 60*).

Samarium diiodide-promoted 5-*exo* radical cyclization and further transformation lead only to the *C*-analog derivative **21** of methyl isomaltoside.



Scheme 59

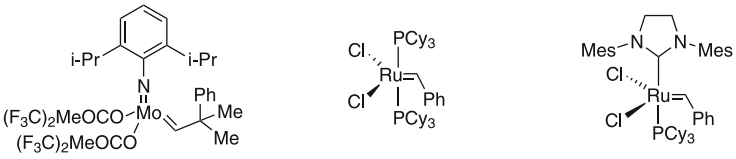


Scheme 60

4 The Olefin Metathesis Route

In the last decade, olefin metathesis has emerged as a powerful method for the formation of carbon–carbon bonds under mild conditions. This reaction can be defined as the exchange of alkylidene fragments between two olefins promoted by metal–carbene complexes. The synthetic development in this field happened with the discovery of catalysts of high activity and functional group tolerance. Initial use of the air-sensitive Schrock's molybdenum catalyst **282** [124], was followed by the use of Grubbs first generation ruthenium carbene **283** (Grubbs I), which is more stable to air and moisture [125]. Metathesis protocols now rely heavily upon the utilization of the highly stable second generation Grubbs catalyst **284** (Grubbs II) bearing *N*-heterocyclic carbene ligands [126] or similar catalysts (*Scheme 61*).

The potential of this reaction with polyfunctional substrates has provided new synthetic solutions in carbohydrate chemistry. Among the three main metathesis versions (cross metathesis, ring-opening or closing metathesis and enyne metathesis), the ring-closing metathesis (RCM) is widespread because, in this case, intramolecular reaction shows an entropic advantage compared to cross metathesis. The Postema group illustrated the value of RCM in the synthesis of *C*-analogs of natural structures [23]. In an initial study, they showed that esterification of an appropriate olefin alcohol followed by a methylenation reaction and ring-closing metathe-



Scheme 61

sis allowed the preparation of C1-substituted glycals in reasonable yields [127]. Selective hydroboration-oxidation of the C–C double bond of these substrates delivers the *C*-glycosides [128] (Scheme 62).

In the example shown in Scheme 62, the C4-allylated sugar **286** is prepared by a radical allylation from the C4-iodide. Exchange of protecting groups, oxidative cleavage of the alkene and Pinnick oxidation of the major aldehyde provide the corresponding acid **288**, which is esterified with olefin alcohol **289** to ester **290**. Takai's methylenation furnishes the acyclic enol ether, substrate for the RCM in presence of Schrock or Grubbs II catalysts. Hydroboration-oxidative quench provides selectively the β-*C*-*gluco* disaccharide isomer **291**. The overall yield of the three-step sequence (methylenation-RCM-hydroboration) is largely improved (56%) using a one-pot procedure with the Grubbs II catalyst.

This approach was extended to the synthesis of $\beta(1\rightarrow1)$,$\beta(1\rightarrow2)$,$\beta(1\rightarrow3)$ and $\beta(1\rightarrow6)$, [129] linked *C*-disaccharides in good overall yield (Scheme 63).

All these *C*-disaccharides were deprotected and tested against various glycosidase enzymes. Only the $\beta(1\rightarrow1)$-linked *C*-disaccharide derived from **292** showed a modest inhibitory activity with a K_i of 126 µM against almond β-glucosidase.

More recently, the same methodology was applied to the synthesis of β-*C*-trisaccharide **298** [130] and tetrasaccharide **301** [131] from diacid **296** and triacid **299**, respectively (Scheme 64).

In contrast to RCM, cross metathesis is more challenging to implement because undesired homodimerization of olefins can occur. However, Lowary and co-workers took advantage of this side-reaction to access to potential arabinosyltransferase inhibitors. They reported the synthesis of a *C*-analog of α-D-Ara*f*-(1→5)-α-D-Ara*f*, a motif present in the mycobacteria cell wall [132] (Scheme 65).

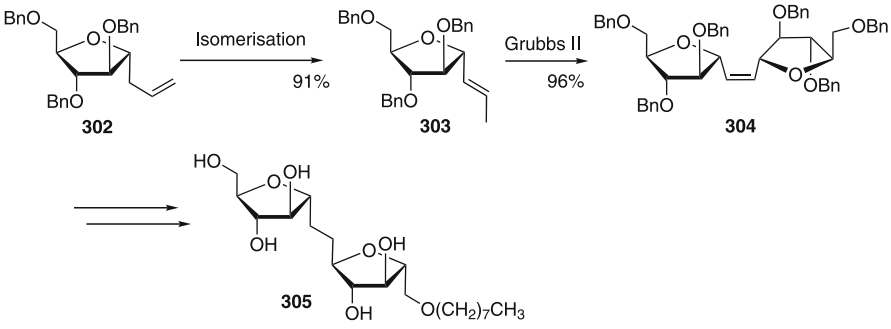
Scheme 64



302 **303** **304** **305**

Scheme 65

Isomerization of the *C*-allyl glycoside **302** provides the corresponding *C*-(1-propenyl) derivative **303** as a major *E*-isomer. Cross metathesis proceeds in high yield only with the Grubbs II catalyst to deliver the homodimer **304**, transformed to *C*-disaccharide analog **305** of the mycobacterial motif.

5 Partial de Novo Synthesis

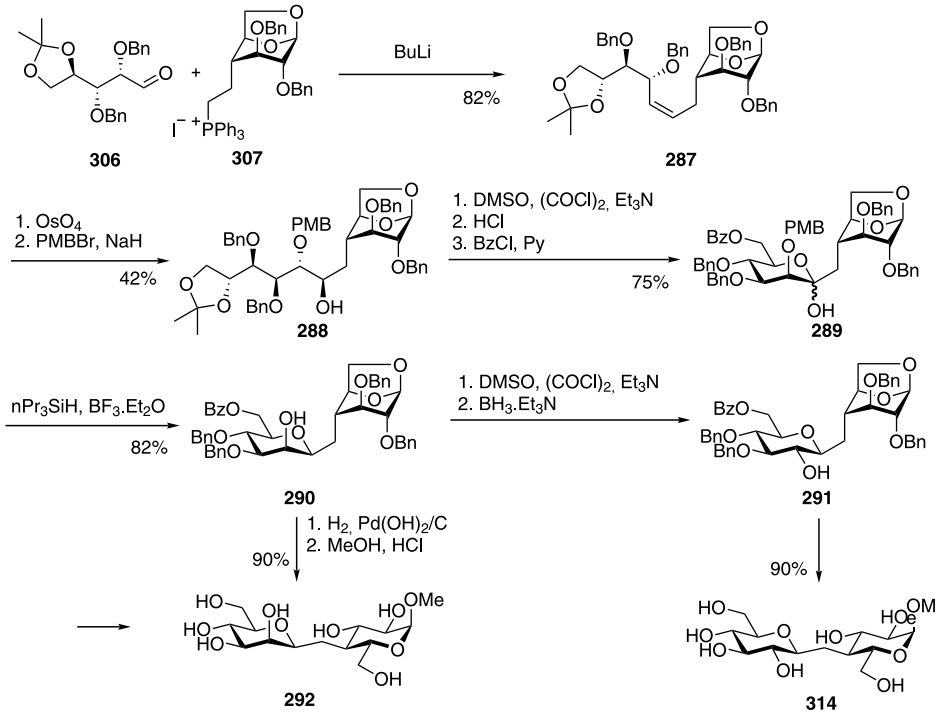
Instead of using a readily accessible natural sugar that can ultimately be transformed to a sugar analog, a de novo synthesis of one or several carbohydrate units in the oligomer can be programmed. One of the advantages of the de novo design is that a given synthetic plan towards a particular target can easily be redesigned to accommodate stereostructural variants using the appropriate diastereo(or enantio-)selective transformations currently available, particularly in acyclic systems. Much of the work in this area was pioneered by Kishi and his coworkers who prepared a collection of *C*-glycosides and *C*-oligomers, a synthetic program primarily designed to probe their solution conformation for purposes of comparison with the corresponding parent glycosides. This work was also closely connected to the stereochemical assignment and total synthesis of palytoxin [25], a polyhydroxylated marine natural product containing no less than seven functionalized tetrahydrofurans and tetrahydropyrans which can be considered as substructural *C*-glycosyl motifs. One should note the various facets of the synthetic technology developed by Kishi and coworkers including, to name only a few, axial and equatorial nucleophilic *C*-allylation (allenylation) of electrophilic sugars, $CrCl_2$/$NiCl_2$-mediated coupling of vinylic halides and aldehydes, stereo-directed *cis*-dihydroxylation of olefins, cyclization strategies to stereo-defined tetrahydropyranyl units, that have been a rich source of inspiration to many other investigators in this field.

A common feature of these partial de novo syntheses of *C*-linked dimers or oligomers is that an intact (or slightly modified) sugar unit is used while the other is being appended and constructed by total (or partial) synthesis.

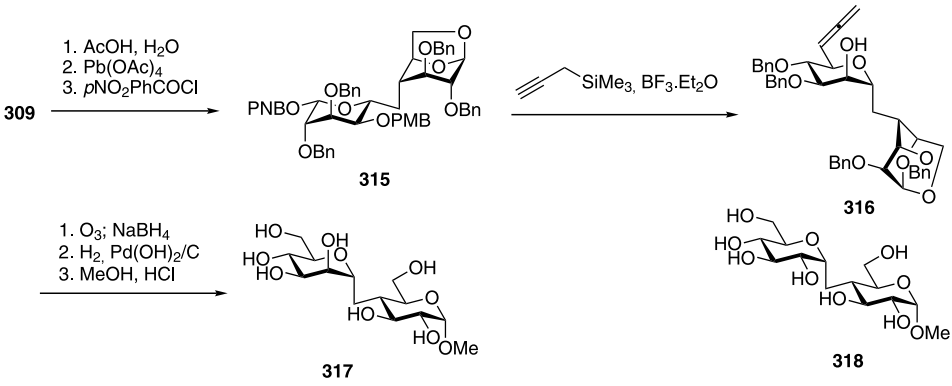
The first example of the Kishi series reported in 1987 [133] involved a stereocontrolled synthesis of four *C*-dimers which include the *C*-analogs of cellobiose and maltobiose. Construction of the *C*-disaccharides starts by the exclusive *cis*-olefination of aldehyde **306**, available from D-arabinose and the ylide generated from phosphonium salt **307** (*Scheme 66*).

Stereoselective dihydroxylation, monoprotection of the diol (→**309**), oxidation, and cleavage of the isopropylidene group lead to a cyclic hemiacetal which is benzoylated on the primary hydroxy group (→**310**). Hemiacetal reduction to the *C*-disaccharidic derivative **311** is stereoselective only with the *n*-Pr_3SiH reagent. Deprotection and methyl glycoside formation provides the *C*-analog of the β-D-Man-(1→4)-D-Glc disaccharide **313**. High yield conversion of the *manno* series **311** to the *gluco* series **312** is feasible using an oxidation-reduction sequence as shown, leading ultimately to the *C*-analog of methyl cellobioside **314**. The isomeric axially substituted α-*C*-disaccharides are also available from the same intermediate **309** by inversion of the hydroxy-carbonyl functions in the acyclic segment (*Scheme 67*).

This is readily done by isopropylidene removal, diol cleavage, and formation of the anomeric *p*-nitrobenzoate **315**. Axial introduction of the allenyl moiety yields stereoselectively, as predicted, the α-*C*-manno derivative **316** after chair inversion. Degradation of the allenyl group to



Scheme 66



Scheme 67

a primary hydroxy group, deprotection, and methyl glycoside formation provides the *C*-mimic of the α-D-Man-(1→4)-D-Glc disaccharide **317**. A similar sequence of reactions also provides methyl *C*-maltobioside **318**.

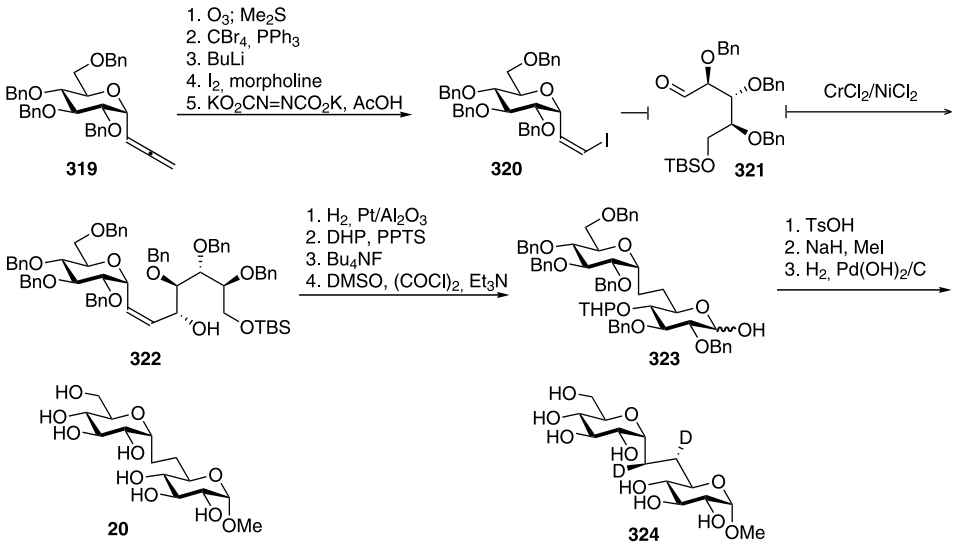
The stereoselective formation of allylic alcohol **322** (15:1 ratio) by the $CrCl_2/NiCl_2$-mediated coupling reaction [134] of vinyl iodide **320**, generated from *C*-allenyl glucoside **319**, and aldehyde **321**, available in six steps from L-xylose, is the key assembling step in the synthesis of methyl *C*-isomaltoside **20** [135] (● *Scheme 68*).

The remaining sequence includes a four-step transformation of the acyclic segment to a D-glucopyranosyl unit in **323** that was deprotected to the final *C*-analog **20**. The unsaturated intermediate **322** is also very useful to stereoselectively deuterate the analog (*cis*-deuteration by D_2, Pt on Al_2O_3) as in the d_2-derivative **324**, for conformational studies.

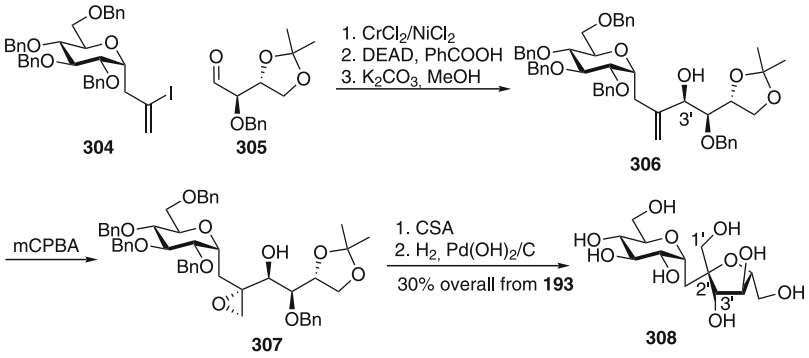
The same strategy was used in a concise synthesis of the *C*-analog of sucrose (and ultimately its C2′, C3′ diastereomers) starting from iodide **325** and aldehyde **326** [136] (● *Scheme 69*).

The anti-selective (10:1 ratio) $CrCl_2/NiCl_2$ coupling reaction produces an allylic alcohol (C3′-diastereomer of **327**) that is inverted to the desired allylic alcohol **327** by a Mitsunobu procedure. *m*CPBA oxidation of **327** gives selectively the *anti*-epoxy alcohol **328** that cyclizes stereospecifically in a 5-*exo* fashion under acid catalysis, by exclusive attack of the secondary hydroxy group at the quaternary center of the epoxide. Hydrogenolysis of the protecting groups completes this efficient synthesis of *C*-sucrose **329** in an overall yield of 30% from vinyl iodide **325**.

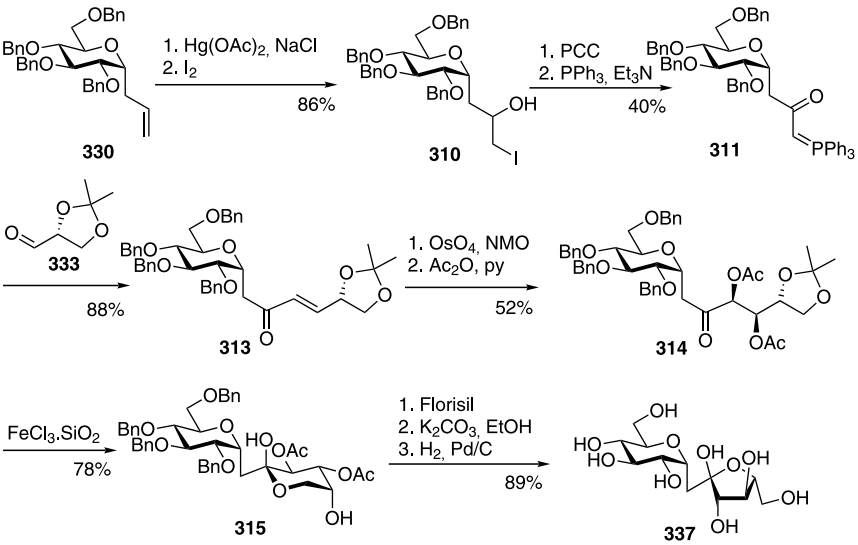
Another synthesis of a *C*-sucrose analog, missing however C1′, was reported by Nicotra from stabilized ylide **332**, generated in four steps from *C*-allyl glucose **330** [137] (● *Scheme 70*).



Scheme 68



Scheme 69

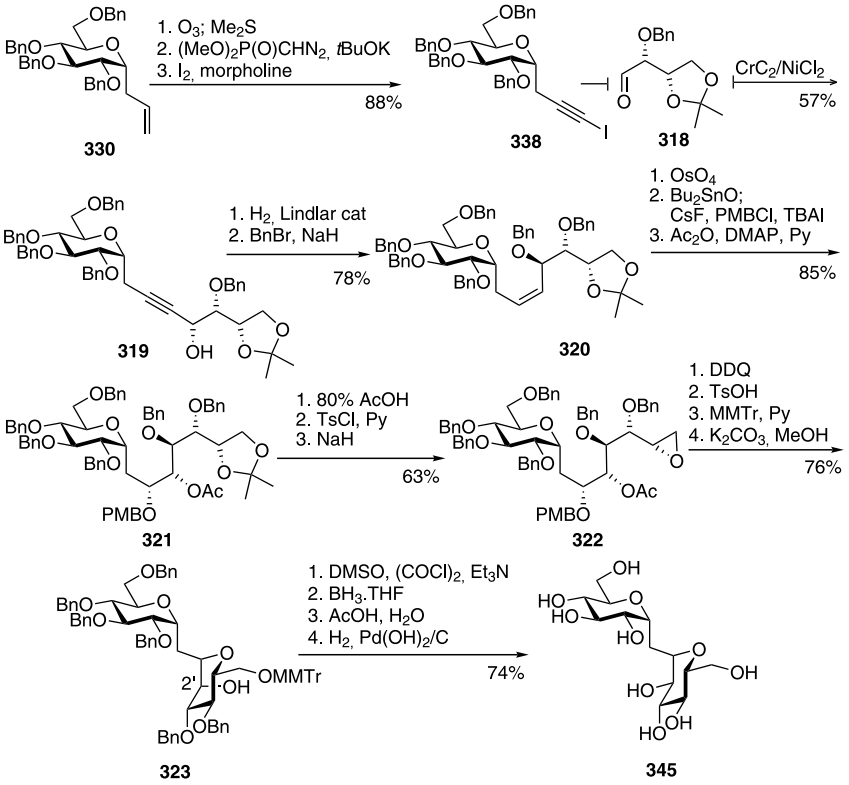


Scheme 70

Condensation of **332** with the D-glyceraldehyde derivative **333**, stereoselective dihydroxylation (60% de) and acetylation afford diacetate **335**. Acidic treatment provides rather the pyranose form **336** which isomerizes to the furanose form upon Florisil treatment. Deprotection in two steps leads to the *C*-analog of sucrose **337**, in equilibrium with the pyranose form.

Another synthesis including a Cr(II)/Ni(II)-mediated coupling reaction as a key coupling step was proposed by Wei and Kishi in 1994 [138]. They reported a single strategy for the stereocontrolled synthesis of the *C*-analog of α,α-trehalose **345** [α-D-glucopyranosyl $(1\rightarrow1')$-α-D-glucopyranoside] as well as its α,β- and β,β-diastereomers (*Scheme 71*).

Coupling of alkynyl iodide **338**, obtained in three steps from allyl glucose **330** with aldehyde **339**, prepared from L-xylose, furnishes the *anti*-propargylic alcohol **340** (stereoselectivity of 4 to 1) which can be reduced to either the *E*-olefin with bis(methoxyethoxy)aluminum hydride

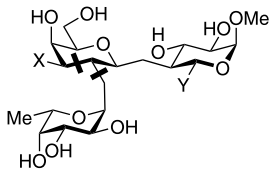


Scheme 71

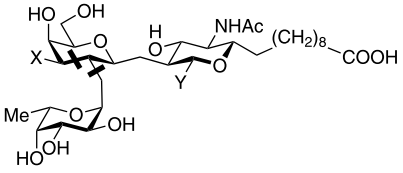
(Red-Al) or the *Z*-olefin **341** after benzylation. Stereoselective dihydroxylation and regioselective protection of the diol provides protected polyol **342** that is transformed in three steps to terminal epoxide **343**. Removal of the *p*-methoxybenzyl group followed by acid-catalyzed epoxide opening yields exclusively tetrahydropyran **344** after protection of the primary alcohol and deacetylation. Inversion of the C2′ stereocenter by an oxidation-reduction sequence and deprotection furnishes the *C*-mimic of α,α-trehalose **345**.

An aldol route was rather adopted by Kishi [139,140] for the construction of the central unit of trimer analogs **346–353** of the type II(H) cellular antigen trisaccharide α-L-Fuc-(1→2)-β-D-Gal-(1→4)-β-D-GlcNAc (*Scheme 72*).

This strategy is flexible enough to accommodate specific structural modifications. The aldol disconnections, presented in *Scheme 72*, call for a glucosamine (or glucose) unit with a three-carbon appendage at position-4 and a C1-formyl fucose unit connected by a four-carbon acyclic segment carrying two asymmetric centers of the future central galactose unit. The synthesis of the glucosamine unit **358**, used in the construction of *C*-analog **350**, starts with epoxide **354** transformed to the C4-branched epoxide **355** by a Cu(I)-catalyzed Grignard reaction followed by base treatment [140] (*Scheme 73*).

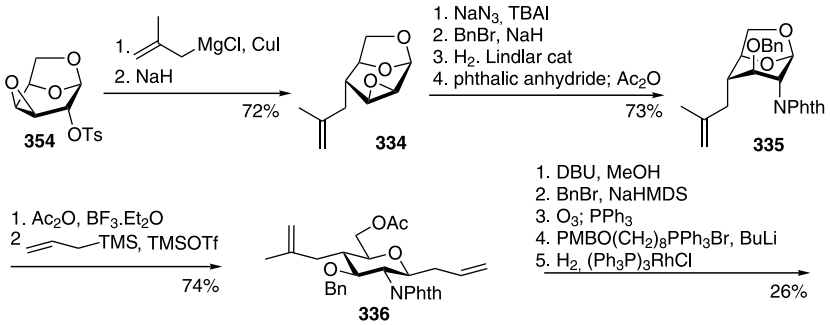


346 X = OH, Y = CH_2OH
326 X = H, Y = CH_2OH
327 X = OH, Y = H
328 X = Y = H



329 X = OH, Y = CH_2OH
330 X = H, Y = CH_2OH
331 X = OH, Y = H
353 X = Y = H

Scheme 72

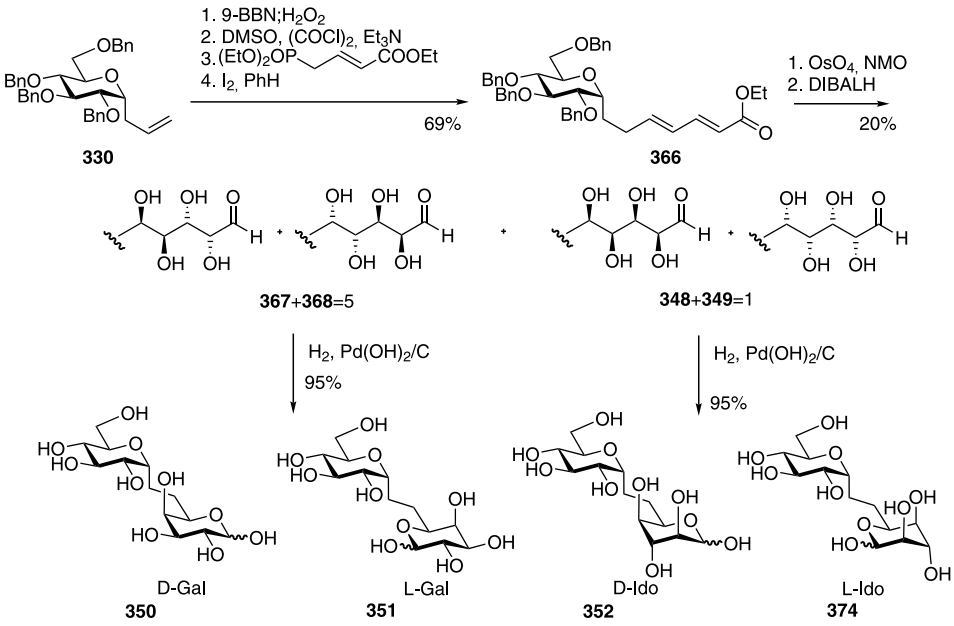


Scheme 73

Azide opening of epoxide **355**, benzylation, azide reduction, and phthalimide formation provide the 1,6-anhydro derivative **356** that is opened and stereoselectively β-allylated to **357**, an interesting stereochemical outcome, probably directed by the C2-phthalimido group. The first aldol condensation between methyl ketone **358**, generated in five steps from **357** and aldehyde **359**, provides smoothly aldol products **360**, converted to the *C*-disaccharide ketone **361** by silyl removal, hemithioketal formation/tin hydride reduction, and oxidation. The second aldol reaction between **361** and 1-*C*-fucopyranosyl formaldehyde **362** needs optimal equilibrating conditions (LHDMS, TMEDA, $MgBr_2$) to produce the equatorial aldols **363**. Conjugate and ketone reductions of enones **364**, generated by mesylation and base elimination on **363**, lead to *C*-trimer **365** transformed to the final polyol **350** in the form of a lithium carboxylate by a five-step sequence of routine transformations.

Armstrong and Sutherlin applied a combinatorial concept, by keeping one sugar unit constant while varying the structure of others to include all possible stereomers. This is exemplified by the synthesis of four *C*-linked D-glucopyranosyl α-(1→6) hexopyranoses [141] (*Scheme 74*).

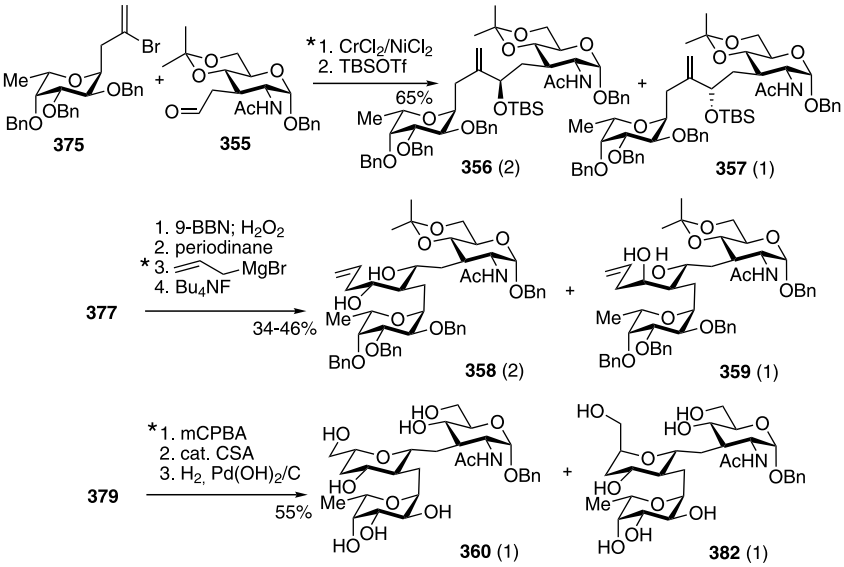
Elaboration of *C*-allyl glucose **330** to diene ester **366** by the four steps shown followed by a dihydroxylation-reduction sequence affords a mixture of the lactols **367–370** (represented in acyclic forms) having the D/L-galacto and the D/L-ido configurations in a 5:1 ratio. Hydrogenolysis provides the corresponding *C*-dimers **371–374**, four out of the sixteen possible diastereomers.



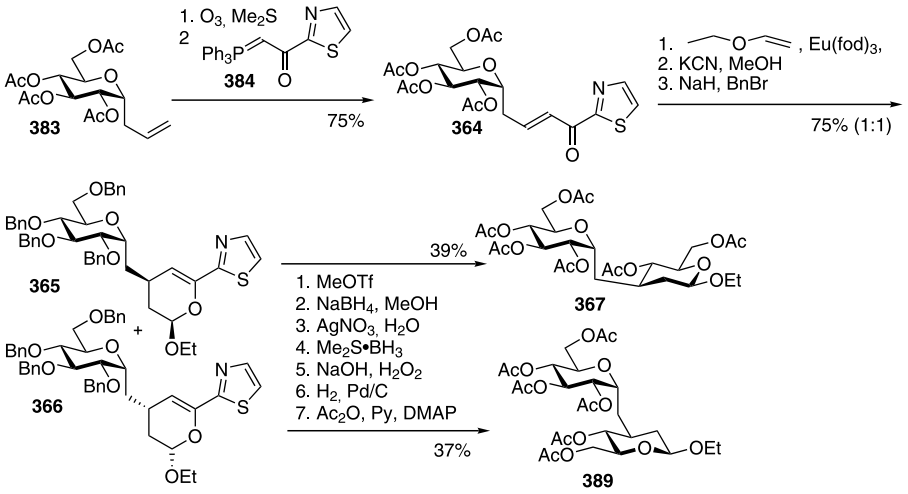
Scheme 74

Another example is the synthesis of *C*-trimer analogs of the Lewis type I blood group determinant having the general formula α-L-Fuc-(1→2)-hexose-(1→3)-D-GlcNAc in which the structural diversity in the central hexose unit is achieved by performing either non-selective transformations to create a mixture of diastereomers, or predictably selective transformations to construct a single diastereomer [142]. The approach begins with a $CrCl_2/NiCl_2$ coupling [134] of vinyl bromide **375**, available in three steps from L-fucose, and aldehyde **376**, generated in four steps from *N*-acetylglucosamine, leading after silylation to diastereomers **377** and **378** (2:1 ratio) [142] (● *Scheme 75*).

Diastereoselective hydroboration-oxidation and periodinane oxidation on major isomer **377** give an aldehyde which is homologated by the addition of allylmagnesium bromide and desilylation to diols **379** and **380** (2:1 ratio). The major isomer **379** is in turn unselectively oxidized with *m*CPBA and subsequently cyclized under acid catalysis providing the two *C*-trisaccharide analogs **381** and **382** (1:1 ratio) after removal of all protecting groups with the exception of the anomeric benzyl group on GlcNAc. This strategy has resulted in the synthesis of eleven *C*-analogs of a hexose trimer. In the case where inseparable diastereomeric mixtures are generated by this type of synthetic sequence, access to a single component of the mixture is possible by replacing a non-selective step (marked by asterisks in ● *Scheme 75*) with a selective option, an operation referred to as a "recursive stereochemical deconvolution" strategy by the authors. Kniezo and collaborators developed [143] a short and efficient de novo synthesis of α-(1→3) *C*-linked disaccharides starting from *C*-allyl glucose **383**, which, subjected to ozonolysis prior to direct reaction of the resulting ozonide with a stabilized phosphorus ylide **384**, leads to **385** (● *Scheme 76*).



● **Scheme 75**



Scheme 76

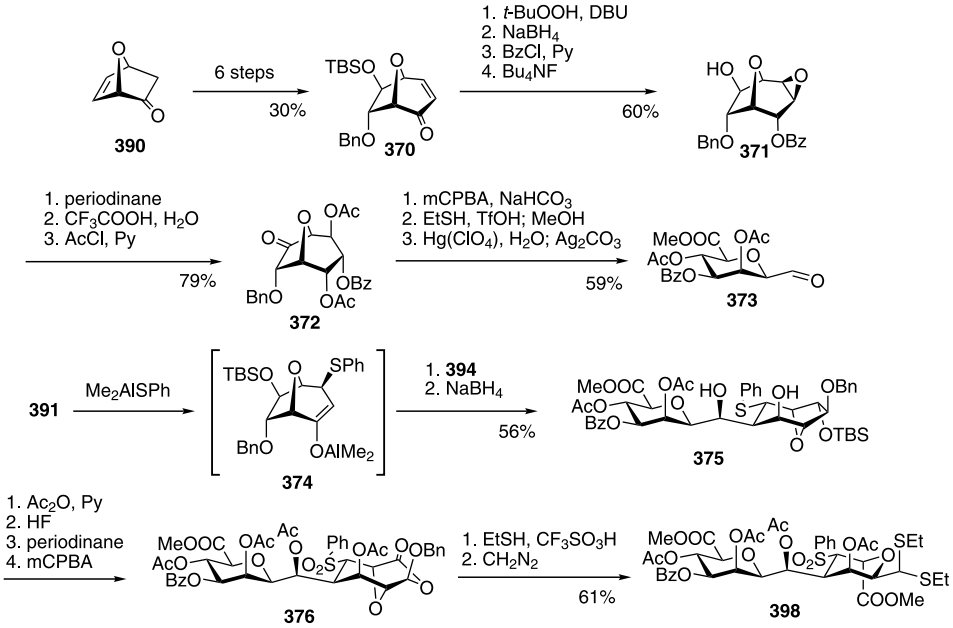
Compound **385** undergoes a $Eu(fod)_3$ catalyzed hetero-Diels–Alder cycloaddition with ethyl vinyl ether, leading to an equimolar mixture of the two *endo*-cycloadducts which prove chromatographically separable after deacetylation and benzylation. Each of the resulting products (**386** and **387**) was subjected to the same series of transformations (conversion of the thiazole ring into a formyl group [144], simultaneous reduction of the aldehyde and hydroboration-oxidation of the alkene from the less hindered face) with a final protecting group exchange (Bn → Ac), leading to two *C*-linked disaccharides **388** and **389**.

Another very different conceptual de novo design was developed by Vogel and coworkers [14], which is based on stereoselective transformations of the rigid oxanorbornane bicyclic system leading to *C*-linked sugar units. Some illustrations are given in *Sect. 3.1.*.

In addition, Gerber and Vogel have described an ionic assemblage of a dimer using optically pure ketone **390** [145] (*Scheme 77*).

Enone **391**, precursor of both units of the dimer and containing the future tetrahydropyranyl ring, is stereoselectively transformed in seven steps to highly oxygenated intermediates **392** and **393**. Regioselective Baeyer–Villiger oxidation, opening of the uronolactone, and dithioacetal hydrolysis provide uronic acid derivative **394**, the electrophilic partner of the coupling step. The aldol condensation between the aluminum enolate **395** derived from enone **391** and aldehyde **394** furnishes the precursor of the *C*-linked dimer **396** after carbonyl reduction. Transformation of **396** by a six-step sequence similar to the sequence leading to **394** provides a protected form of a *C*-linked β-D-mannuronic-(1→3) dimer **398**, a starting point towards *C*-linked oligomers, obtainable by an iterative process.

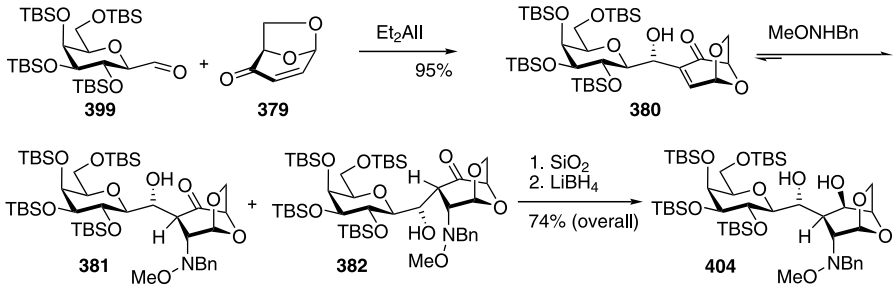
Vogel and coworkers also developed entries into a variety of *C*-linked disaccharides and analogs based on the *Oshima–Nozaki* condensation of levoglucosenone and isolevoglucosenone with monosaccharide derived aldehydes [146]. For instance, a series of *C*-linked β-(1→3)-glucopyranosides of 2- and 4-deoxy-D-hexoses were prepared by elaboration of the



Scheme 77

condensation products obtained by Me_2AlSPh or Et_2AlI induced coupling of glucose-derived aldehyde **43** and isolevoglucosenone or levoglucosenone [147].

This strategy recently culminated in the preparation of a *C*-linked disaccharide analog of the tumor-associated Thomson–Friedereich (T) epitope α-*O*-conjugated to L-serine [148]. Interestingly, final elaboration and coupling to serine proved to be a challenge since the *C*-linked disaccharide did not behave as expected based on the chemistry known for simpler galactose derivatives and *O*-linked disaccharides [149,150]. The final, successful synthetic route is depicted in *Scheme 78*.



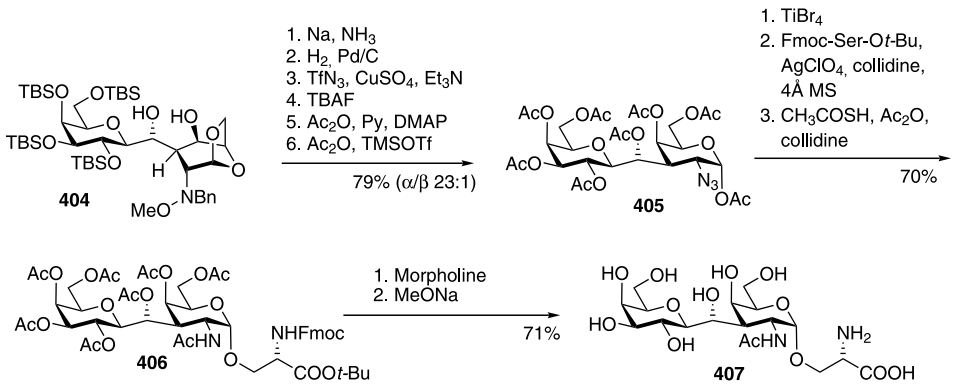
Scheme 78

In the initial C–C bond-forming step, *Oshima–Nozaki* condensation of the persilylated galactose-derived aldehyde **399** with isolevoglucosenone **400**, in the presence of diethylaluminum iodide, leads to enone **401** with 95% yield. Conjugate addition of the highly nucleophilic MeONHBn without solvent or catalyst gives a 1:1 mixture of diastereomeric adducts **402** and **403**, which are isomerized on silica gel allowing the recovery of pure **403** in 82% yield. Diol **404** is finally isolated in 90% yield following hydride addition ($LiBH_4$) on the *exo* face of the bicyclic system. It then proved necessary to transform the methoxy(benzyl)amino group since attempts to pursue the synthesis in its presence led exclusively to β-selective glycosylation of the protected serine derivative. Birch reduction followed by catalytic hydrogenolysis liberates the free amine which is converted into the corresponding azide in 81% yield, with trifluoromethanesulfonyl azide in the presence of cupric sulfate [151] (*Scheme 79*).

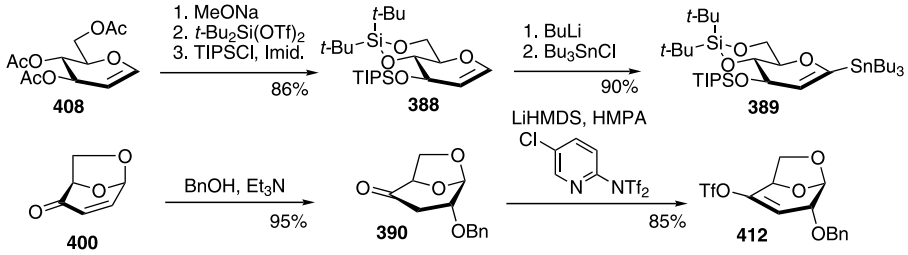
The synthesis was further conducted by desilylation, peracetylation, ring-opening of the 1,6-anhydrogalac-

tose moiety, conversion into the anomeric bromide, and Königs–Knorr glycosylation with the protected serine derivative, under the control of the kinetic anomeric effect (α/β selectivity, 5/1). Final deprotection leads to **407**.

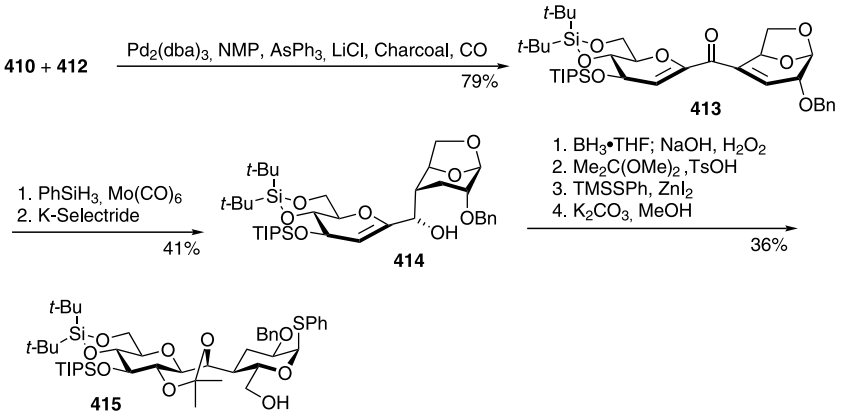
Another approach developed by the Vogel group relies on a carbonylative Stille cross-coupling between stannylated glucal derivative **410** and enol triflate **412** derived from isolevoglucosenone [152] (*Scheme 80*).



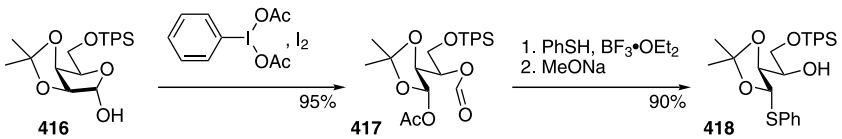
Scheme 79



Scheme 80



Scheme 81



Scheme 82

Coupling of these two readily available precursors leads to bis-enone **413** elaborated to **414** by *chemo-* and *stereo*selective hydrogenation of the more strained, bicyclic alkene with $PhSiH_3$ in the presence of catalytic $Mo(CO)_6$, and K-selectride diastereoselective reduction (*Scheme 81*).

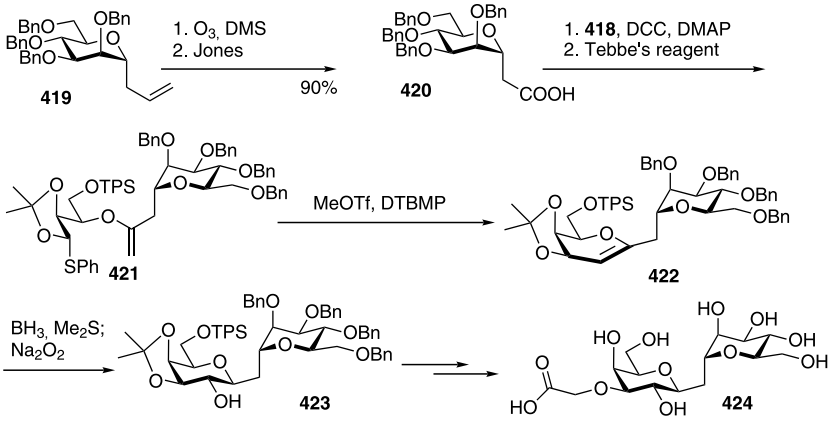
Hydroboration-oxidation occurs on the probably less hindered α-face of the glucal, leading to a diol which is protected as an acetonide prior to conversion of the 1,6-anhydrohexose ring into the corresponding thioglycoside **415**, a potential glycosyl donor.

Thioacetal **418** was used by Mootoo to access several *C*-linked disaccharides [153,154] including the *C*-linked analog of a Sialyl Lewis x mimetic [155] (*Scheme 82*).

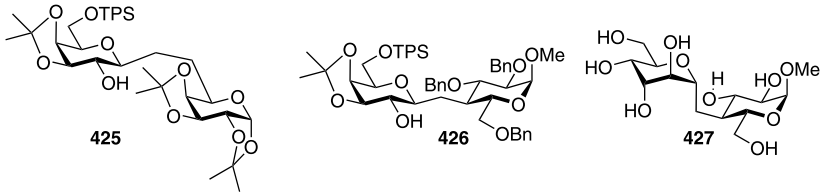
Thioacetal **418** can easily be prepared on a large scale from D-lyxose via intermediate **416**, which is oxidized into **417** by the diacetoxy-iodobenzene/I_2 system [156]. Treatment of **417** with thiophenol and $BF_3{\cdot}OEt_2$ affords **418** after methanolysis of the formate group.

Oxidative cleavage of *C*-allyl mannose **419** [157] following Wong's procedure [158] leads to acid **420** which is esterified with **418** prior to methylenation with Tebbe's reagent (*Scheme 83*).

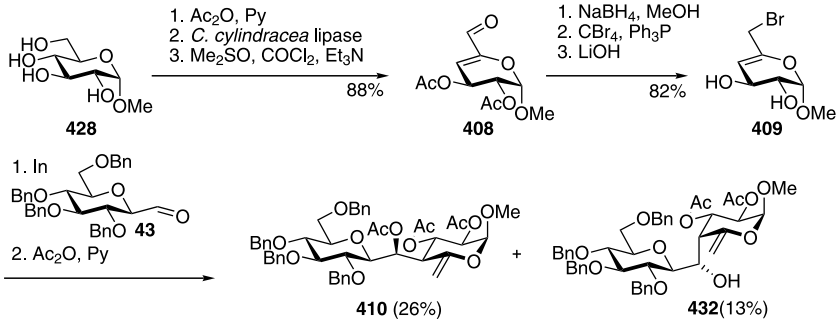
The resulting enol ether intramolecularly traps the oxycarbenium ion obtained by treatment of the thioacetal with TMSOTf, leading after regioselective deprotonation, to the substituted glycal **422**, which gives, after hydroboration-oxidation, *C*-linked glycoside **423**. Further elaboration leads to the desired molecule **424**. This derivative, as well as its *O*-linked counterpart (and more constrained *C*-linked analogs) were tested for P-selectin binding, but they did not show significant variations in activity [159].



Scheme 83

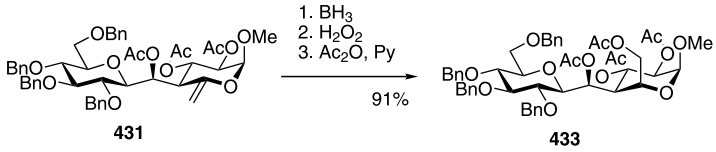


Scheme 84

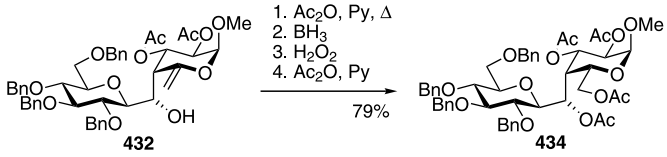


Scheme 85

Other *C*-linked disaccharides have been obtained using this strategy, including Gal-$\beta(1\rightarrow6)$-Gal **425**, Gal-$\beta(1\rightarrow4)$-Glc **426** [153] and Alt-$\alpha(1\rightarrow4)$-Glc [154] **427** (*Scheme 84*).
Lubineau et al. prepared two (1→4) *C*-linked disaccharides via an indium promoted allylation in aqueous medium [160] (*Scheme 85*).
The starting glucose-derived allylic bromide **430** is obtained in 6 steps (acetylation, lipase-catalyzed selective deacetylation of the primary position, Swern oxidation leading directly to



Scheme 86



Scheme 87

the 4,5-unsaturated aldehyde, reduction, bromination and final saponification) from α-methyl glucoside **428** in 72% overall yield. Allylation of aldehyde **43** in the presence of indium in a THF/phosphate buffer (2/1) leads to a mixture of *C*-linked disaccharide precursors which can be separated after acetylation (**432** proved to be only partially acetylated). After complete acetylation of **432**, requiring more demanding conditions, the two derivatives were subjected to the same series of transformations, leading after hydroboration-oxidation and acetylation to two *C*-linked disaccharides **433** and **434** (*Scheme 86* and *Scheme 87*).

The same group described the $Yb(OTf)_3$ catalyzed Mukaiyama aldol reaction of aldehyde **43** with silyl enol ether **435** in an aqueous medium [161] (*Scheme 88*). This results in the formation of two non-separable diastereomeric aldols **436** and **437** in a 95% combined yield. Finally, $NaBH_4$ reduction leads to isolation of pure **440** and a mixture of **438** and **439**.

Instead of using "Neu5Ac-*C*-glycosyl donors" as reported in *Sect. 2.7* for the synthesis of *C*-linked *N*-acetylneuraminic acid-containing disaccharides, another alternative, described by Schmidt's group, is a de novo construction of the Neu5Ac moiety. This is exemplified by the synthesis of a *C*-glycosyl analog of sialyl-α-(2→3)-D-galactose starting from D-gluconolactone [162] (*Scheme 89*).

The key step of the strategy is a low temperature phenylselenyl-mediated 6-*exo-trig* electrophilic cyclization of acyclic precursor **446**, elaborated by the coupling between the lithium reagent derived from iodide **444** and aldehyde **443**, itself produced from D-glucono-δ-lactone **441**. A selena-Pummerer rearrangement, oxidation and esterification sequence delivers methyl ester **448** which, after deacetylation, is regioselectively benzoylated with benzoyl cyanide. Triflate activation and nucleophilic displacement by azide ion afforded azide **449**, which was reduced with hydrogen and Pearlman's catalyst with simultaneous removal of the benzyl ethers. The following three steps successfully complete this de novo synthesis of the *C*-linked Neu5Ac-α-(2→3)-D-Gal disaccharide.

9.5 Oligosaccharide Mimetics

Hans Peter Wessel, *Susana Dias Lucas*

hans_p.wessel@roche.com

Abstract

The important roles of oligosaccharides in physiological and pathophysiological processes have spurred the development of mimetics. Oligosaccharide mimetics discussed in this chapter may possess a linker of two or more atoms such as amide or urea groups that may lead to isosteric linkage replacements but mostly do not. Larger groups that replace a full sugar unit we refer to as spacers and have grouped molecules with flexible acyclic spacers and more rigid cyclic spacers. The employment of pharmacophore models has led to oligosaccharide mimetics with only one sugar unit left or finally without any saccharide unit as exemplified in mimotopes.

Keywords

Glycomimetics; Linked sugars; Spaced sugars; Functional mimetics; Saccharide-peptide hybrids; Sugar amino acids; Solid phase synthesis; Sialyl Lewis^x; Carbohydrate medicinal chemistry

Abbreviations

CDMT 2-chloro-4,6-dimethoxy-1,3,5-triazine
Gum glucosyl–uronic acid–methyl amine
M6P mannose 6-phosphate

1 Introduction

In this chapter mainly molecules will be discussed that contain a sugar linking unit which deviates from the usual linking pattern, the one-atom linkage via oxygen, or in which sugars

In: *Glycoscience*. Fraser-Reid B, Tatsuta K, Thiem J (eds)
Chapter-DOI 10-1007/978-3-540-30429-6_52:

Scheme 1

have been replaced by a non-sugar structural unit. In a simplified representation (*Scheme 1*) these are sugar molecules containing a linker consisting of more than one atom or a spacer group.

Not discussed in this but in previous chapters are the *structural* mimetics: sugars, in which formally minor changes have been made, such as replacement of the ring oxygen by a nitrogen atom (imino sugars), a sulfur atom or carbon atom (carbasugars) or the replacement of the glycosidic oxygen by a carbon atom (*C*-glycosides) or sulfur atom (thioglycosides). In contrast, the mimetics under discussion here, such as the "spaced sugars", are usually planned to be *functional* oligosaccharide mimetics, i. e., molecules which typically display the activity or property of a carbohydrate.

Many natural products will essentially not be regarded here although bis-glycosides may be viewed as spaced sugars in which the aglycone is the spacer. Interestingly, it is in most cases not clear which role the aglycone plays and whether this non-sugar moiety is possibly a sugar mimetic. Examples may be the saponins from medicinal foodstuffs [1] or the triterpenoid glycosides from medicinal plants [2].

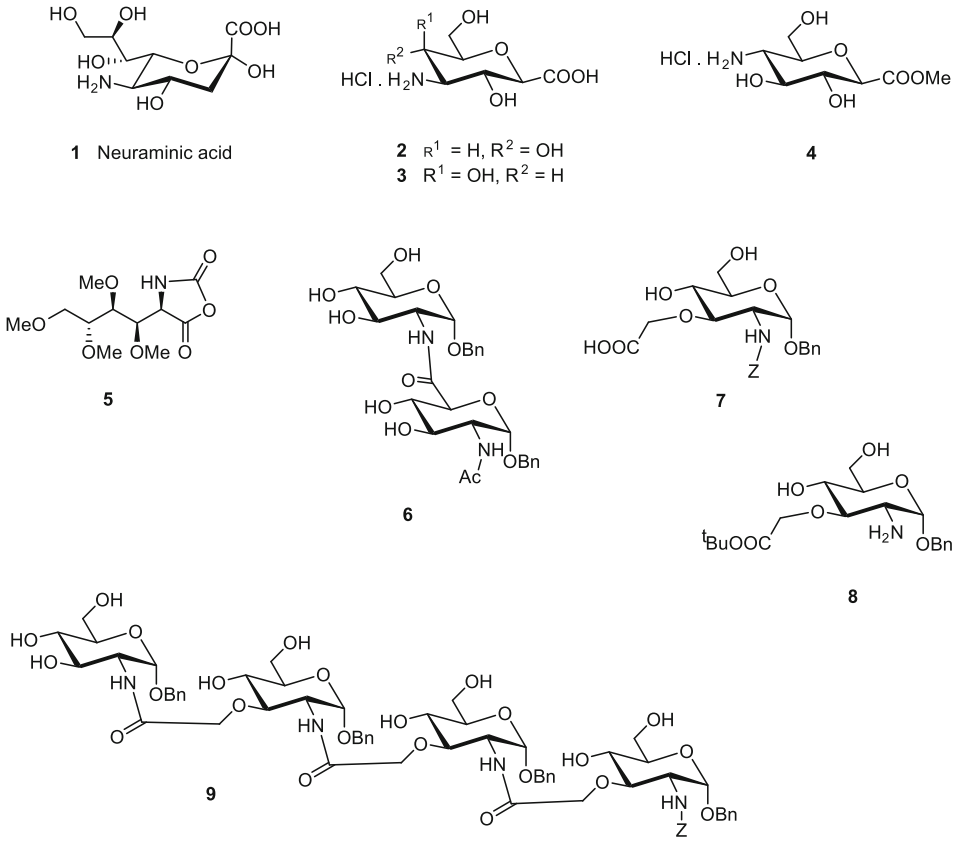
2 More-Atom Linked Sugars

A linker we call a relatively small group of at least two atoms between two sugar units. A "more-atom linked sugar" is thus a spaced saccharide in which the spacer is different in length from the interglycosidic oxygen or its isosteric replacements as in *C*- or *S*-glycosides and definitely smaller than a sugar unit. Phosphate-linked will not be in the scope of this review.

2.1 Amide-Linked Sugars

A formal replacement of the interglycosidic oxygen atom by an amide group leads to amide-linked sugars (*Scheme 2*). This type of structure is suited to build up oligomers or polymers as oligosaccharide or polysaccharide mimetics, respectively, the monomer unit being a sugar amino acid. Sugar amino acids occur in Nature; one example is neuraminic acid **1**

Scheme 2



Scheme 3

(*Scheme 3*) abundant on glycoproteins or certain complex nucleoside antibiotics such as ezomycin [3].

First synthetic reports on amide-linked sugars stem from the mid-1970s. Fuchs and Lehmann [4] prepared the amino-D-*glycero*-L-*manno*- and -D-*glycero*-D-*gulo*- heptonic acids **2** and **3** (*Scheme 3*) and pointed out their potential for polymerization. The isomeric 5-amino-2,6-anhydro-5-deoxy-D-*glycero*-D-*gulo*-heptonic acid methyl ester **4** [5] was submitted to oligomerization under basic conditions and resulted, depending on the reaction time, in oligomers or polymers which, however, were not individually characterized. At about the same time, Yoshimura et al. [6] synthesized amide-linked disaccharides such as **6** as analogues of cell wall components or certain antibiotics. 3,4-Di-*O*-acetyl-6-*O*-carboxymethylglucosaminyl bromide was polymerized with diphenylphosphoryl azide and trimethylamine to give, after deblocking and hydrolysis of the bromide, a water-soluble reducing polymer with a mean molecular mass of 150 kD [7], and the *N*-carboxyanhydride derivative of a methylated 2-amino-2-deoxy-gluconic acid **5** was polymerized in the presence of triethylamine to give polyamides of an average molecular mass of 10 kD [8].

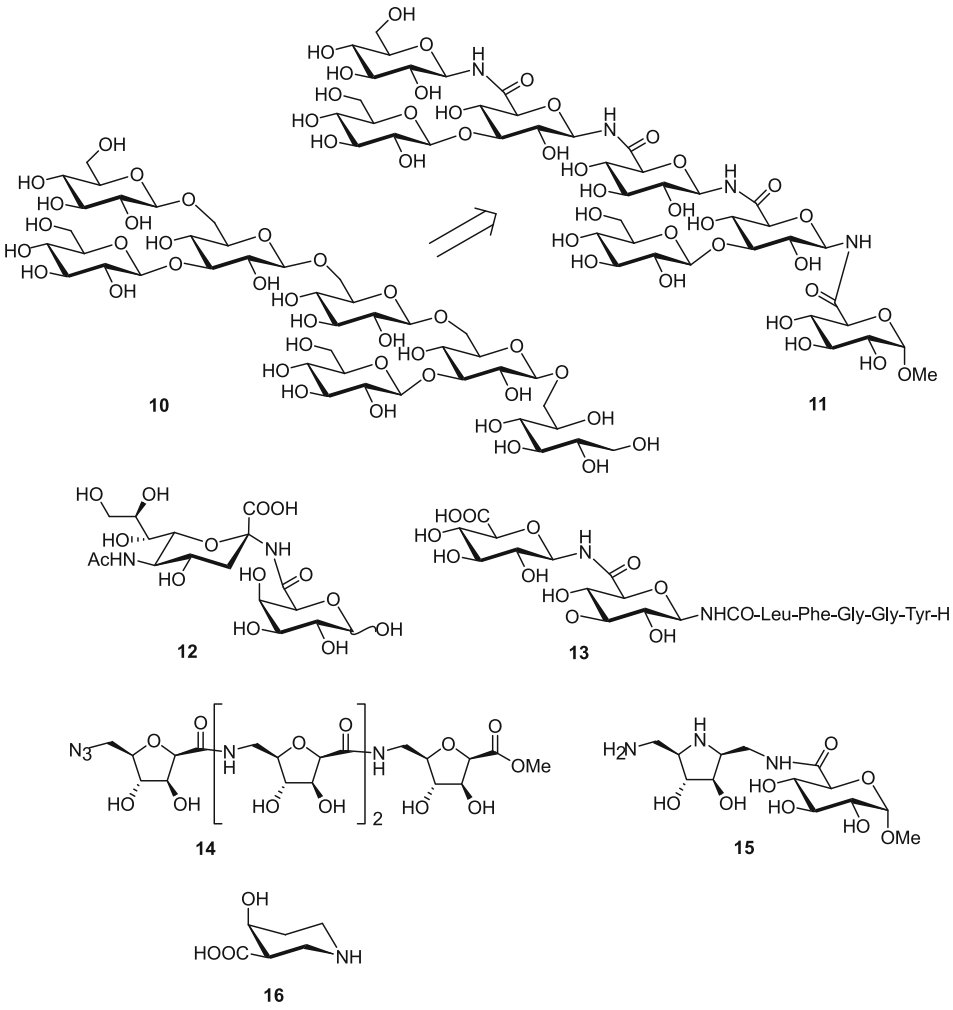
With an interest in oligosaccharide mimetics for pharmaceutical applications, a Roche group prepared the first amide-linked oligomers in a controlled fashion from suitably protected sugar amino acids to construct a tetramer in a [2 + 2] block synthesis. A standard peptide synthesis strategy in solution was applied in which **7** and **8** (*Scheme 3*), both equipped with an acetic acid linker and prepared in five steps from readily available glucosamine, were coupled using a mixed anhydride. The tetramer **9** with four-atom linkers was obtained after activation of a dimer with CDMT [9]. Notably, no protection of hydroxyl groups was required employing this approach.

This type of carbohydrate mimetic was coined "saccharide-peptide hybrid" to point out that carbohydrate properties as well as peptide properties are represented. The mimetics still retain the carbohydrate epitopes available for binding, the pyranose or furanose ring plus hydroxy groups, as well as the peptide function.

A number of groups became interested in this class of compounds, and the saccharide-peptide hybrids were coined "carbopeptoids" [10], "glycotides" [11], "peptidosaccharides" [12], or "saccharopeptides" [13]. In comparison to the formation of oligosaccharides, the complexity in the synthesis of saccharide-peptide hybrids is reduced since no α/β-anomers can be formed. In addition, the oligomerization can be carried out without protecting the hydroxy groups [14] since the amino function is more nucleophilic. We have demonstrated that the oligomerization can also be carried out on a solid phase [14], which opened the way to combinatorial approaches [15,16,17].

If the sugar amino acid is a glycuronopyranosylamine, the oligomers are isosters of (1→6)-linked sugars. This type of mimetic has been investigated in various contexts. A very interesting example has been contributed by van Boom's group [18] who have prepared a branched saccharide-peptide hybrid **11** analogous to the natural phytoalexin elicitor **10** (*Scheme 4*). Disappointingly, this mimetic did not display biological activity, which was attributed to the decreased flexibility at the amide bonds. Sabesan [12] targeted the α-D-Neu5Ac-(2→6)-β-D-Gal*p* disaccharide, which occurs naturally in glycoproteins and glycolipids and mimics of which may be neuraminidase inhibitors. He prepared the amide-linked sialoside **12** as well as analogues replacing the galactose unit. With a view to more selective analgesics, Drouillat et al. [19] worked on glucuronic acid modified enkephalins; a solid-phase synthesis yielded an amide-linked glucuronic acid disaccharide mimetic and its peptide conjugate **13**. In a mouse model, this sugar dimer modified leucin enkephalinamide was slightly more active than the Leu- enkephalinamide standard. D'Onofrio et al. [20] prepared by solid-phase synthesis a tetrasaccharide mimetic composed of two (1→6)-amide-linked lactose units conjugated to an oligonucleotide; the presence of this mimetic at the 3′-end of antisense 18-mer sequences enhanced the stability of the oligonucleotides in bovine fetal serum without negatively interfering with their ability to form stable duplexes with complementary DNA strands. The Fleet group has investigated various saccharide-peptide hybrids based on furanoid sugars; their tetramer **14** [21] can be seen as an analogue of (1→6)-linked hexofuranosides. An analogue of glycosidase inhibitors of the imino sugar family, the (1→6)-amide-linked pyrrolidine disaccharide mimetic **15**, was reported [22].

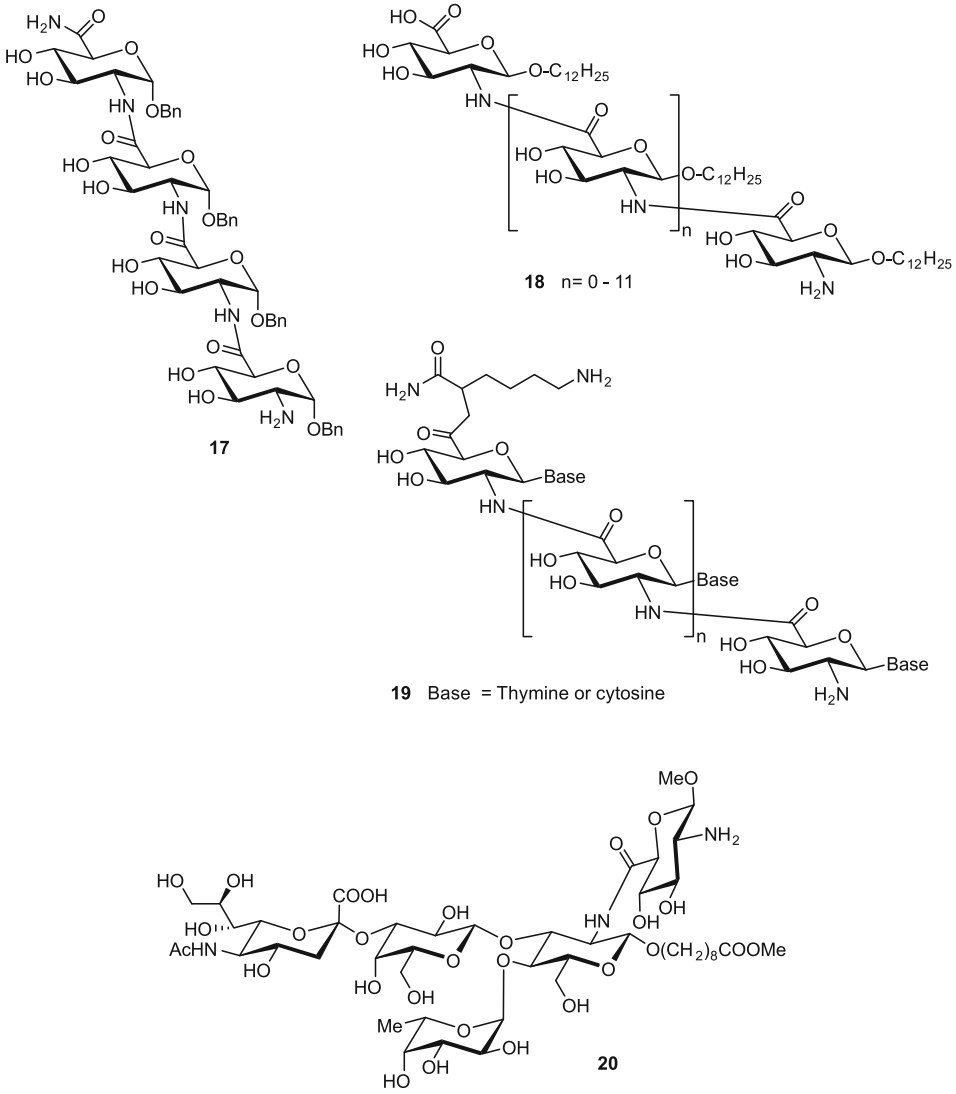
Also, piperidines have been employed for oligomerization, notably 4-hydroxypiperidine-3-carboxylic acid **16** [23] (*Scheme 4*); the ring nitrogen has been used as the amine component, and amide linkage led to mimetics of (1→3)-linked sugars with a one-atom linker (the carbonyl carbon atom). Reacting quinic acid derivatives with sugar amines, analogues



Scheme 4

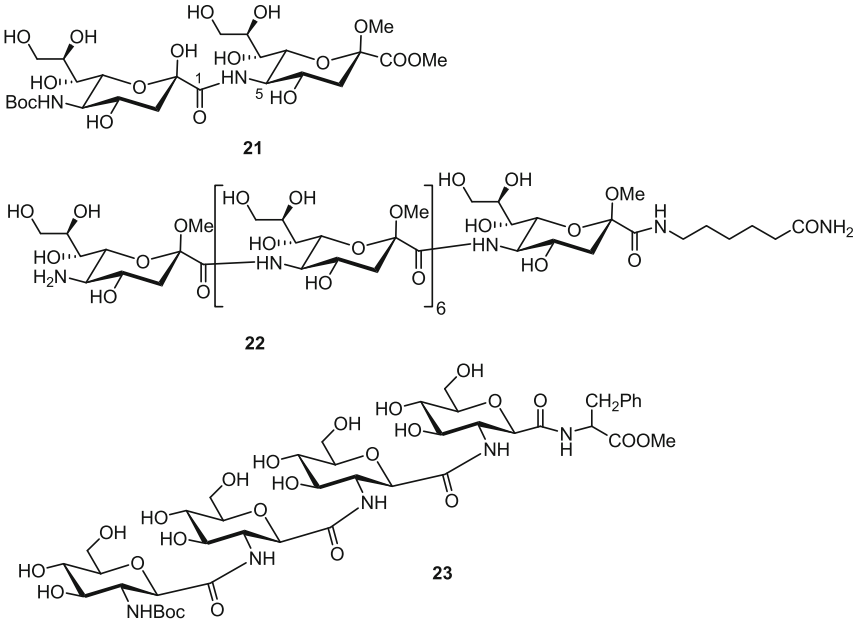
of cardiac glycoside disaccharide moieties with a three-atom amide linker were synthesized [24].

Glucosamine as a readily available and inexpensive sugar is an obvious starting point to prepare sugar amino acids. Amide coupling of 2-amino-2-deoxy-glucuronic acids leads to a (2→6)-linkage with a two-atom linker, i. e. one atom more than in the usual interglycosidic linkage, as in disaccharide mimetic **6** (*Scheme 3*) and the tetramer **17** [14] (*Scheme 5*), the latter was prepared by solid phase synthesis. As a consequence of this (2→6)-linkage, the anomeric center is free and can be employed for further derivatization, e. g., to increase the hydrophobic character as in **17** with the benzyl groups. Another application has been the glycosylation of the sugar amino acid with long chain alcohols to pre-orient the alkyl groups in an oligomer **18** which was synthesized as a mixture of compounds with differing degrees of poly-



Scheme 5

merization [25]. With a nucleo-base at the anomeric center [26], polymers were synthesized on a solid phase as pyranose-based antisense agents [27]. A 13-mer **19** is depicted in *Scheme 5*. Analogues of the natural oligosaccharides sialyl Lewis^a and sialyl Lewis^x have been prepared [28,29], replacing the acetamido group of the central glucosamine by a methyl glycopyranosiduronamido group. This replacement still allowed the construction of these molecules using the enzymes 2,3-sialyltransferase, $\beta(1\rightarrow4)$-galactosyltransferase [29] and fucosyltransferase III and IV. Compound **20** is the glucuronamide analogue of sialyl Lewis^a, the biological properties of these derivatives have not been reported.



Scheme 6

With neuraminic acid, a sugar amino acid widely occurring naturally as *N*-acetylneuraminic acid, an amide-linked (1→5)-dimer **21** (*Scheme 6*) and the corresponding 2,3-ene analogue were prepared [30]. On a solid phase, even an octamer **22** was available [31].

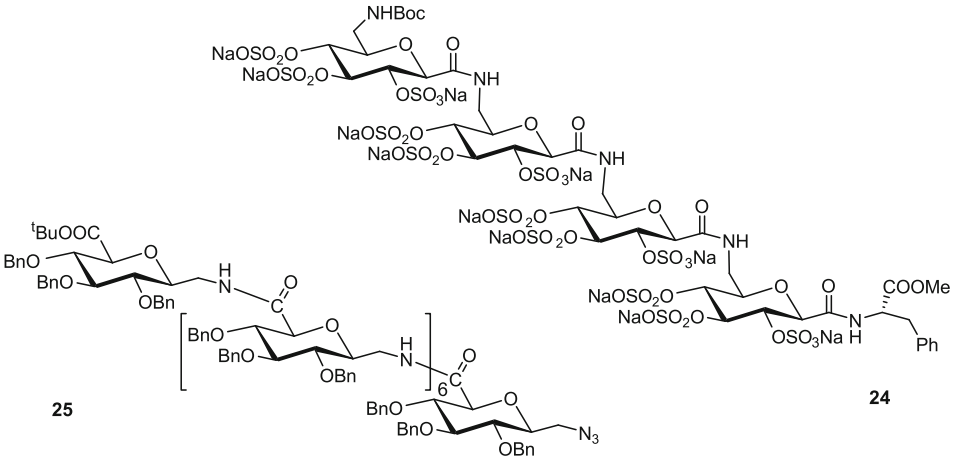
A mimetic of a (1→2)-linked glycoside was devised by Ichikawa's group [32] using a 3-amino-2,6-anhydro-3-deoxy-heptonic acid building block to arrive at tetramer **23**. A two-atom linker replacing the interglycosidic oxygen also characterizes this saccharide-peptide hybrid. A sulfated derivative of **23** blocked syncytium formation caused by HIV infection to CD4 cells at 50 µM concentration.

Oligomerization of a 7-amino-2,6-anhydro-7-deoxy-heptonic acid results in mimetics of (1→6)-linked sugars with a three-atom instead of a two-atom linker. The sulfated tetramer **24** (*Scheme 7*) turned out to exhibit μ-molar activity in the protection of MT2 cells from HIV infection [33], and was also shown to provide heparanase inhibitory activity [34]. With different location of the amide bond, a still benzyl protected β(1→6)-linked octamer of glucosyl–uronic acid–methyl amine (Gum [35]) **25** was synthesized [36].

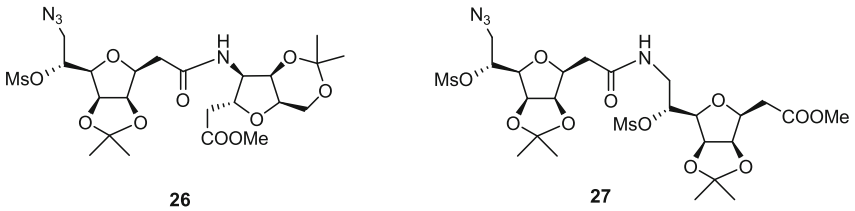
Using a *C*-glycosidic furanoid sugar amino acid, McDevitt and Lansbury [11] prepared a saccharide-peptide hybrid with a three-atom linker, the dimer **26**. The homodimer of this *C*-glycosidic sugar amino acid gave rise to a five-atom spacer as in compound **27** (*Scheme 7*); these derivatives have not been reported in deprotected form.

An interesting example of a branched trimer containing β(1→6)- and β(1→2)-amide-linked sugars was supplied by Sicherl and Wittmann who devised mimetics of amino glycosides [37].

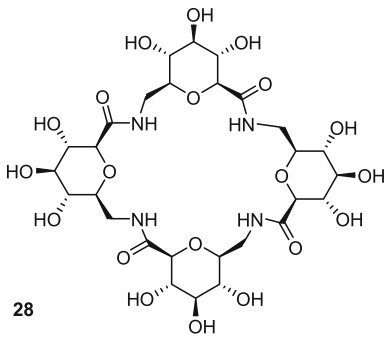
Pioneered by the group of Kessler [38] pyranoid sugar amino acid templates were described to represent turn mimetics and model peptides [39,40] including cyclic peptides [41,42]. As



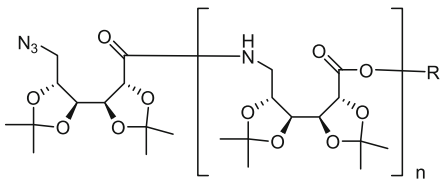
25 24



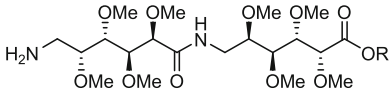
26 27



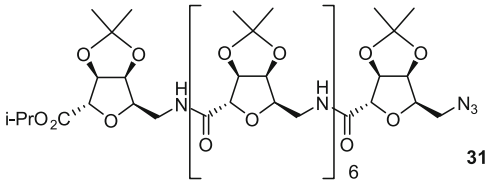
28



29 n = 1, 3, 5, 7



30



31

Scheme 7

a logical extension, also cyclic homooligomers of sugar amino acids were devised, first using Gum (see above) as a monomeric unit thus creating three-atom linkages as in cyclic tetramer **28** (*Scheme 7*) [43]. Further examples of cyclodextrin analogues based on furanoid sugar amino acids with three-atom [44] or four-atom linkers [45] as well as oxetane based cyclic homooligomers with three-atom linker [46] were described.

More recently, also oligomers of open chain sugar amino acids were described such as galactonates **29** (*Scheme 7*) of which also cyclic analogues were prepared [47,48,49,50]. This is an extension of work directed at polymers composed completely of amide-linked open chain sugars as hydroxylated analogues of polyamides (nylon) with the main goal to achieve biodegradability [51,52,53]. Instead of starting from monomers, also amide-linked dimers such as **30** have been employed to arrive at well-defined, enantiomerically pure and stereoregular polyhydroxylated polymers [54,55].

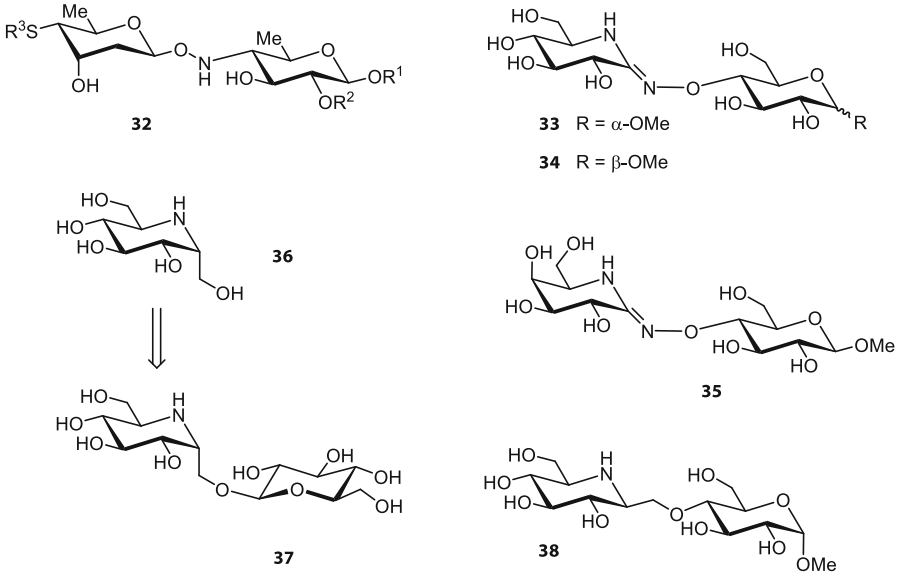
Saccharide-peptide hybrids have attracted particular attention because of their conformational properties. Oligomers of sugar amino acids have a tendency to adopt a compact conformation, a type of oligomer termed "foldamer" by Gellman [56]. Kessler's group [38] had already demonstrated that sugar amino acids may induce specific peptide conformations. Combined ^{1}H-NMR and CD spectroscopic evidence suggested that (1→5)-amide linked sialic acid oligomers in water adopt a defined secondary structure from the size of a tetramer on [31]. Similarly, a β(1→2)-amide-linked pyranoid sugar, a decamer of compound **23**, formed a right-handed helix [57]. The acyl-protected furanoid oligomer **14** prepared by Fleet's group [58] was shown by calculation and ^{1}H-NMR spectroscopy in organic solvents to exhibit a β-turn secondary structure. The investigation of further analogues showed that most higher oligomers with a 2,5-*cis* stereochemistry across the tetrahydrofuran ring adopt a right-handed helix conformation composed of repeating β-turns and with NH_i-O_{i-2} hydrogen bonds [59,60]. A secondary structure was however not found in the D-*galacto*-configured analogues [61].

For the 2,5-*trans* furanoid octamer **31** with D-*talo* building block a left-handed helix with NH_i-O_{i-3} interresidue hydrogen bonds was described [62] while the corresponding tetramer adopts a rigid but not hydrogen bonded conformation [63]. The van Gunsteren group, based on molecular dynamics simulations, has cautioned that NOEs can not be interpreted for single conformations but that clusters of various stable conformations are to be expected [64,65]. A conformation classification system based on various spectroscopic parameters including chiroptical spectroscopy was proposed [66].

In the D-*manno* series, an unprotected octamer showed an ordered structure in solution based on circular dichroism [67], but not the lower unprotected [67] or protected homooligomers [68]. Initial X-ray and NMR evidence for a secondary structure was found in a new series of tetrafuran based L-*ribo* configured γ-amino acids [69]. The conformational investigation of oxetane based oligomers revealed that a β-amino acid hexamer formed a left-handed helix [70], but δ-amino acid hexamers did not exhibit hydrogen bonded interactions but some regularity on steric grounds [71].

2.2 Non-Amide-Linked Sugars

There are numerous interglycosidic linkers other than amide linkers known in also natural products—Nature has already invented saccharide mimetics! One example are the calicheam-

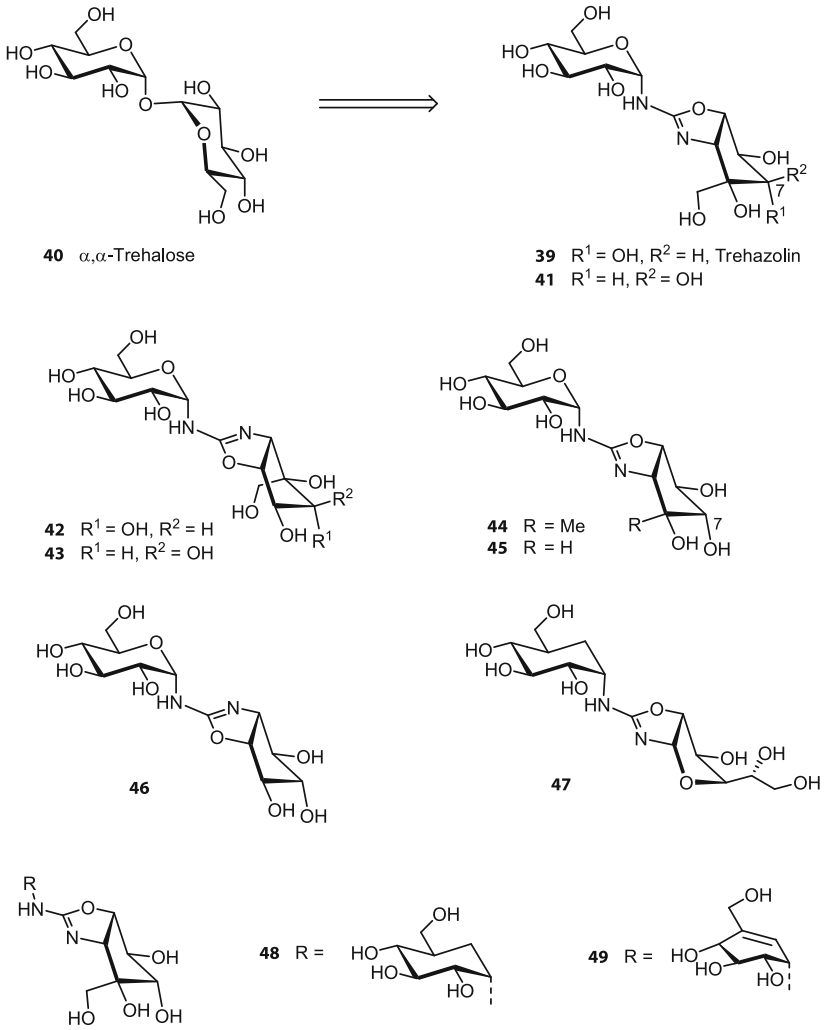


Scheme 8

icin [72,73] and esperamycin [74,75] endiine antibiotics sharing the characteristic disaccharide unit **32** (*Scheme 8*) with its two-atom *N*,*O*-interglycosidic bond [76]. Several groups have approached this interesting structure synthetically [77,78,79,80,81]. With a similar two-carbon linker, glycosides of sugar lactam oximes were prepared as selective glycosidase inhibitors [82]; both anomeric disaccharide mimetics **33** and **34** are good inhibitors of the β-glucosidase from *C. saccarolyticum*, the lactoside analogue **35** is a strong inhibitor of the *E. coli* β-galactosidase with an inhibition constant of $K_i = 0.1$ µMol.

Homo-*aza*-sugars such as α-homonojirimycin **36** have been devised to mimic the lengthening of the glycosidic bond in the transition-state in a glycosidase [83]. Interestingly, this mimetic **36** has also been isolated from a moth (*Urania fulgens*) and from its larval food plant. The β-D-glucoside of **36**, the disaccharide mimetic **37** (MDL 25,637 [84]), turned out to be a potent inhibitor of rat intestinal sucrase in vitro and had in vivo activity in a mouse hyperglycemia model. This mimetic is a homo-analogue of a trehalose mimetic, i. e. (1→1)-linked. A corresponding (1→4)-linked mimetic, the homo-*aza* analogue **38** of methyl α-cellobioside, was synthesized by Martin's group [85].

Trehazolin (**39**, *Scheme 9*) is a natural compound with a cyclic urea three-atom linker which has been first isolated only in 1991 [86], before the proof of identity it was also called trehalostatin [87]. Trehazolin is an inhibitor of the enzyme α,α-trehalose glucosidase which cleaves trehalose, the blood sugar and reserve carbohydrate of many insects. The aminocyclopentitol oxazoline thus mimics one glucosyl unit of α,α-trehalose (**40**), or, more likely, the postulated glucopyranosyl cation intermediate. The synthesis of trehazolin was first achieved by S. Ogawa et al. [88], other groups offered synthetic alternatives [89,90,91]. To ascertain the structure of trehazolin, the Ogawa group has also prepared the 7-epimer **41** and the diastereomers **42** and **43** of trehazolin with inverted stereochemistry



Scheme 9

in the aminocyclopentitol moiety [92]; these derivatives were, however, not active against trehalase. The deoxy- and dehydroxymethyl trehazolin derivatives **44** and **45** were clearly less active against silkworm trehalase than trehazolin, but the dehydroxymethyl derivative of **42** with the inverted configuration, compound **46**, lost activity only by a factor of about three [93]. The glucofuranosyl analogue **44** [93] with a carbasugar moiety replacing one glucosyl unit had sacrificed its trehalase activity. Simple oxazoline derivatives, i. e. fragments of trehazolin and analogues missing the cyclitol moiety, had no trehalase activity [94].

Replacements of the α-glucosyl moiety of trehazolin by α-mannopyranosyl, 3-deoxy-*ribo*-hexopyranosyl, α-galactopyranosyl, and 6-deoxy-glucopyranosyl [95] residues abolished

the trehalase activity demonstrating that the glucosyl moiety is sensitive towards variation. Changes in stereochemistry, particularly at the anomeric center, are not tolerated, and the hydroxyl groups in positions 3 and 6 seem to be involved in trehalase binding as judged by the deoxy derivatives. In contrast, the α-carbaglucosyl analogue **48** gave the same activity towards silkworm trehalase as trehazolin. The unsaturated valienamine derivative **46** had again no activity [95].

Modifications in the attachment of the glucosyl amine moiety have been devised by a Sankyo group [96]: they prepared the isomaltose analogue **50** (◉ *Scheme 10*), the maltose analogues **51** and **52**, and aminogalactosyl derivative **53**. Derivatives **51**–**53** were inactive towards maltase, isomaltase, and sucrase demonstrating that the aminocyclopentitol oxazoline does not generally replace glucose. Compound **52** displayed weak activity against porcine trehalase ($IC_{50} = 245$ ng/ml). Interestingly, compound **50** had some inhibitory activity against maltase and sucrase. Compound **51** was also independently synthesized by Knapp et al. [97] and shown to display weak yeast α-glucosidase activity. Another interesting member of this imidazol family of compounds is the 1-deoxynojirimycin (**54**) derivative formally fused with trehalamine (**55**) resulting in dimer **56** [98], a blend of two different types of glycosyl mimetics. During the last deprotection step (removal of benzyl groups from the deoxynojirimycin moiety with $Pd(OH)_2$ on carbon in methanol) also the rearranged product **57** was obtained. Both products **56** and **57** come with two-carbon linkers.

Formal opening of the oxazoline ring leads to urea or the analogous thiourea derivatives. Glycosyl thiourea **58** [89] or differently protected species [90,92] and analogues [95,96,97] have been prepared as precursors of trehazolin. These derivatives may be viewed as sugar mimetics with a three-atom linker or, in the case of the 1-deoxynojirimycin analogue **59** with one of the thiourea nitrogens in the ring, with a two-carbon linker. The amino glycoside antibiotic glycocinnasperimicin D (**60**) [99] family isolated from *Nocardia* strains contains urea linked aminodeoxy sugars, and urea and thiourea linked sugars have received increasing attention as oligosaccharide mimetics. Glycosyl ureas (as well as thioureas and guanidines) have been built up e. g. from carbodiimide-linked glycosides [100,101,102,103]. Those are themselves oligosaccharide mimetics with a three-carbon linker, and can be obtained via an *aza*-Wittig reaction such as compound **61** [104]. Following that methodology urea-linked nojirimycin glycosides such as **62** [105] and related Calystegine B analogues [106] were synthesized as glycosidase inhibitors (◉ *Scheme 10*). Urea-linked α- and β-glycosides have been synthesized from glycosyl isocyanates [107,108,109,110,111] or by oxazolidinone opening reaction with amines [112]. We have obtained unsymmetrical urea-linked sugars like **63** (◉ *Scheme 10*) in the lithium aluminum hydride reduction of *N*-benzyloxycarbonyl-protected glucosamine derivatives which are thought to be formed also via an intermediate 2-isocyanato derivative [113].

Urea-, thiourea- and guanidine-linked sugars have been investigated as phosphate binders, the guanidine-linked sugars showing the most favorable association constants [114]. In the nucleotide area, the research on antisense oligonucleotides has led to non-phosphorous phosphate replacements to modify parameters like RNA binding affinity, stability, especially against nucleases, or uptake into cells [115,116]. In this context, formacetal, thioformacetal, *N*-methylhydroxylamine, guanidino, sulfamate, urea, thiourea [117], carbamate, thiocarbamate [118], as well as different amide or thioamide [119] groups have been applied as linkers between 2-deoxyribofuranosyl derivatives.

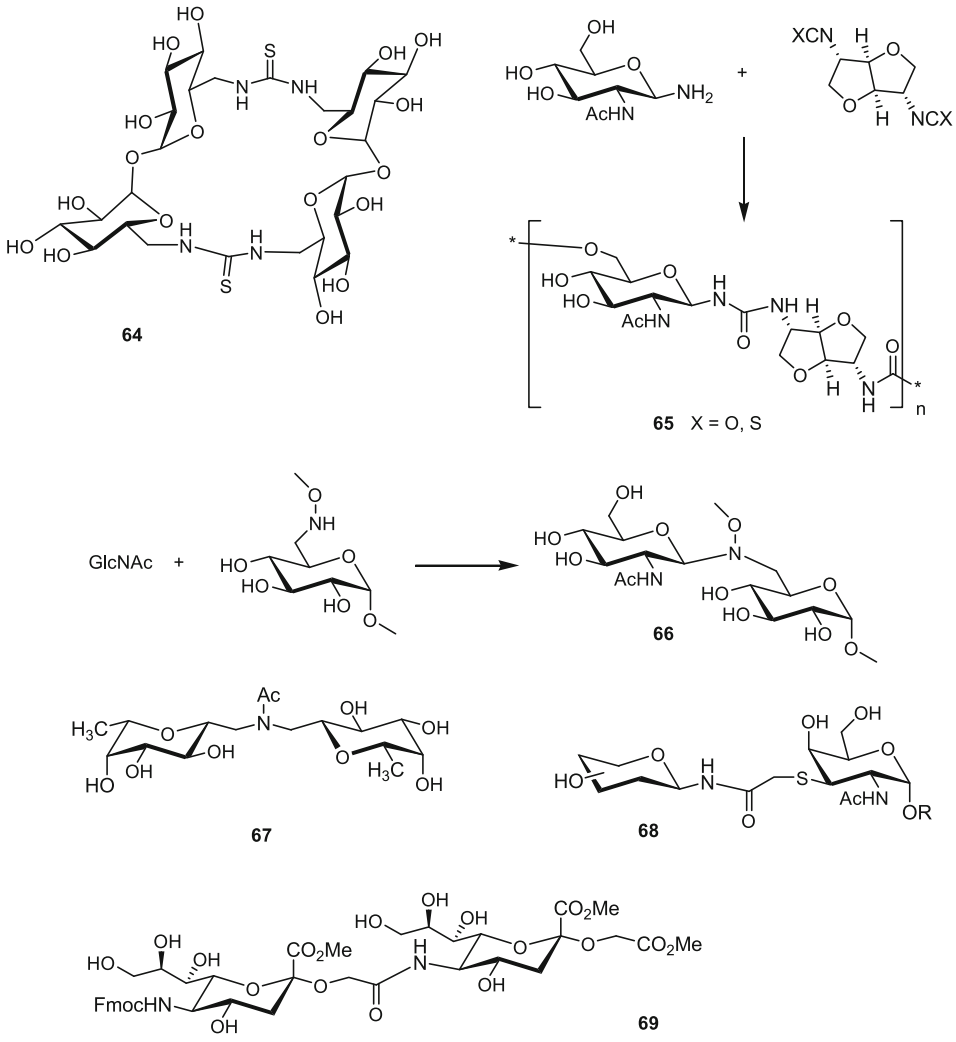


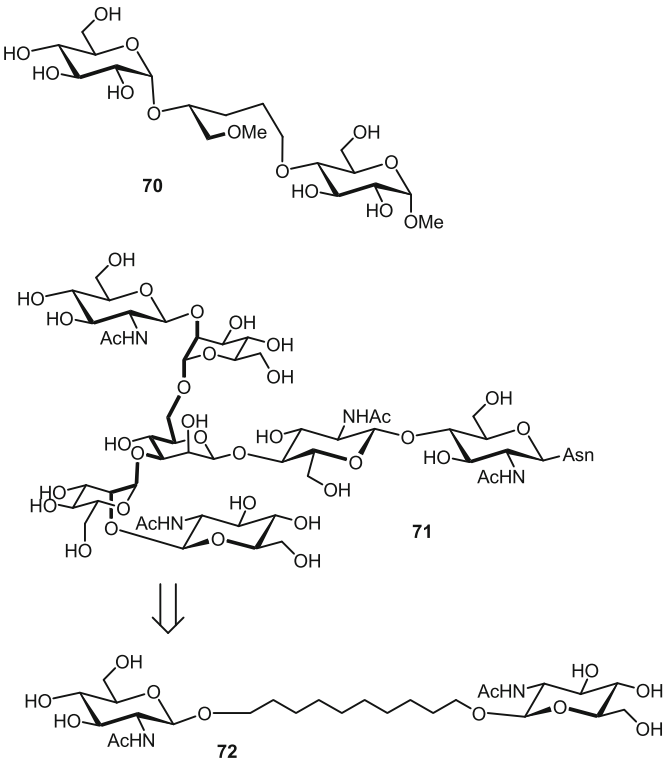
Scheme 11

Thiourea (6→6)-linked sugars were prepared [120] to arrive at a macrocycle **64** with alternating (1→1) and (6→6)-linkages which binds Cs^+ ions and forms strong complexes with Cu^{2+} ions. Urea linkers have also been employed to bridge cyclodextrins [121,122] (*Scheme 11*) and to build up template structures for the construction of glycoclusters [123]. Remarkable carbohydrate-based polyurethanes such as **65** (*Scheme 11*) containing urea- or thiourea-linked sugars as well as carbamate linkages were synthesized from diisocyanates or dithioisocyanates and amino sugars [124]. Defined glycosyl carbamates were synthesized starting from glycosyl isocyanides followed by oxidation and reaction with alcohols [125].

Condensation of methoxyamino sugars with free sugars resulted in the interesting oxyamino linked sugars **66** as mimetics of (1→6)-linked sugars [126]. While these di- and trisaccharide mimetics [127] are isosteric to the natural saccharides the conformational behavior was however found to be different [128].
A tail-to-tail, thus not C-glycosidically, acetylene linked pseudodisaccharide was described by the Beaupère group [129]. The Gross group [130] found a new *C*-glycosidic three-atom methylene amino linker in the course of the catalytic reduction of glycosyl cyanides (see compound **67**). 3-Thiogalactosamine was coupled with *N*-bromoacetamido sugars to result in **68** with a four-atom linker to mimic mucin-type oligosaccharides [131]. The Hindsgaul group employed an acetic acid linker amide coupled to neuraminic acids, a motif **69** that was found in marine sources and is thought to mediate sperm-egg recognition [132]. The same linker was utilized to tether C-6 and C-2′ of lactosamine thus constraining the conformation [133]. Acetic acid extended glycosides were used as building block in Ugi multicomponent reactions [134,135]. A new synthetic approach to this linker was devised by Queneau through opening of carboxymethylglycosyl lactones with amines [136]. An analogous *C*-glycosidic spacer was built up by oxidation of allyl *C*-glycosides, amide coupling furnished linear and cyclic homooligomers [137]; the amides were also reduced to the corresponding amino-linked compounds.

3 Spaced Sugars with Acyclic Spacers

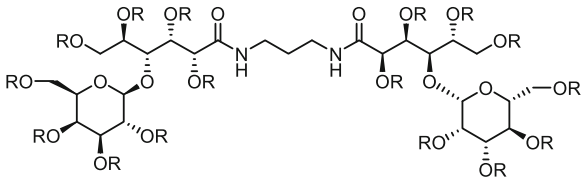
Acyclic spacers have been used to replace sugar units in a rather flexible way. In a first report by Jegge and Lehmann [138], an alkyl spacer-linked mimetic **70** (*Scheme 12*) of methyl α-maltotrioside was prepared, the six-carbon spacer would mimic one (1→4)-linked glycosyl residue. One motivation at that time was to enable with the spacer the introduction of a reactive group for photoaffinity labeling of enzymes [139]. Mimetic **70** turned out to be an inhibitor of porcine α-amylase. As a mimetic of the biantennary core structure **71** of *N*-linked glycoconjugates, the compound **72** with a long ten-carbon alkyl spacer replacing the three central mannose residues was devised [140]. This substrate could still be galactosylated with a membrane-bound galactosyl transferase from a microsomal fraction of liver cells. A binding model with two separate binding sites for the outer GlcNAc residues was supported by the lower activity of analogues with shorter alkyl spacers than in **72** [141] (*Scheme 12*).
Penta- and hexasaccharide mimetics related to fragments of the capsular polysaccharide of *Streptococcus pneumoniae* type 14, {6)-[β-D-Gal*p*-(1→4)]-β-D-GlcNAc*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-Glc*p*-(1}$_n$, were synthesized in which one or two galactosyl units were replaced by a three-carbon alkyl spacer. These linear oligosaccharide mimetics served as good acceptor substrates for bovine milk β-1,4-galactosyltransferase to enzymatically introduce the galactosyl branches resulting in hexa- and octasaccharide mimetics, respectively [142].
Head-to-head β,β-linked spaced galactosides were obtained by glycosylation of 1,3-propanediol, 1,6-hexanediol, and of 1,4-butynediol [143]. Roy's group [144,145] presented an approach to alkenyl-spaced (and with that implicitly alkyl-spaced) saccharides employing homodimerization of suitable glycosides such as allyl galactosides by olefin metathesis, similarly *C*-glycosidically (1→1)-linked β-galactosides with an alkenyl spacer were obtained. Also employing olefin metathesis, head-to-head linked [146], tail-to-tail linked [147] or



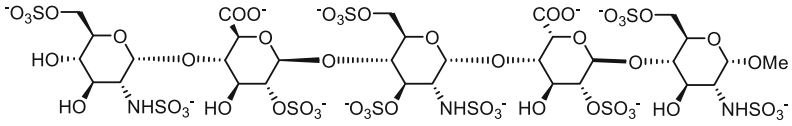
Scheme 12

macrocyclic [148] alk(en)yl spaced amino and other [149,150] glycosides were prepared. Alkenyl spaced sugars were further synthesized by Stille coupling of halo-*exo*-glycals [151] and by palladium-catalyzed glycosylation with allylic biscarbonates [152]. Spacers were also attached via amides [153,154,155,156] or ureas [103,157].

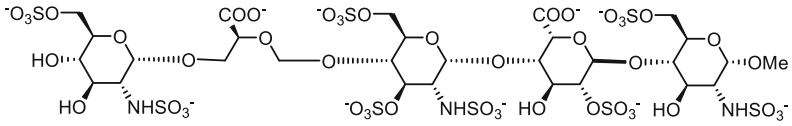
A prominent example of a spaced saccharide is Aprosulate **73** (*Scheme 13*), a symmetrical sulfated lactobionic acid amide. This compound was developed as an antithrombotic agent to mimic heparin, a glucosaminoglycan which is employed clinically as an anticoagulant since decades. Different spacer lengths were studied varying from five to eleven atoms, as well as a branched four-atom *N*,*N*′-dimethylethylenediamine spacer [158]. The five-atom propylenediamine spacer compound yielded the most promising anticoagulant profile. This spacer may replace one glycosyl unit so that **73** may mimic a yet unknown natural pentasaccharide. Aprosulate sodium probably acts by catalyzing thrombin inhibition by heparin cofactor II [159]. Aprosulate had reached phase I clinical trials and was efficacious, but being associated with increased transaminase levels [160,161], the further clinical development has been suspended. On a more rational basis, open-chain analogues of the heparin pentasaccharide **74** have been prepared. This heparin pentasaccharide [162] was identified as the unit which binds to antithrombin (AT) with high affinity resulting in the acceleration of the inhibition of coagulation factor Xa (AT-mediated anti- Xa activity: 700 U/mg). As a reference compound,



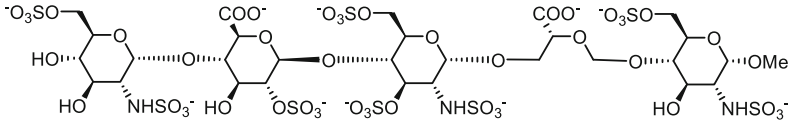
73 R = SO_3Na



74



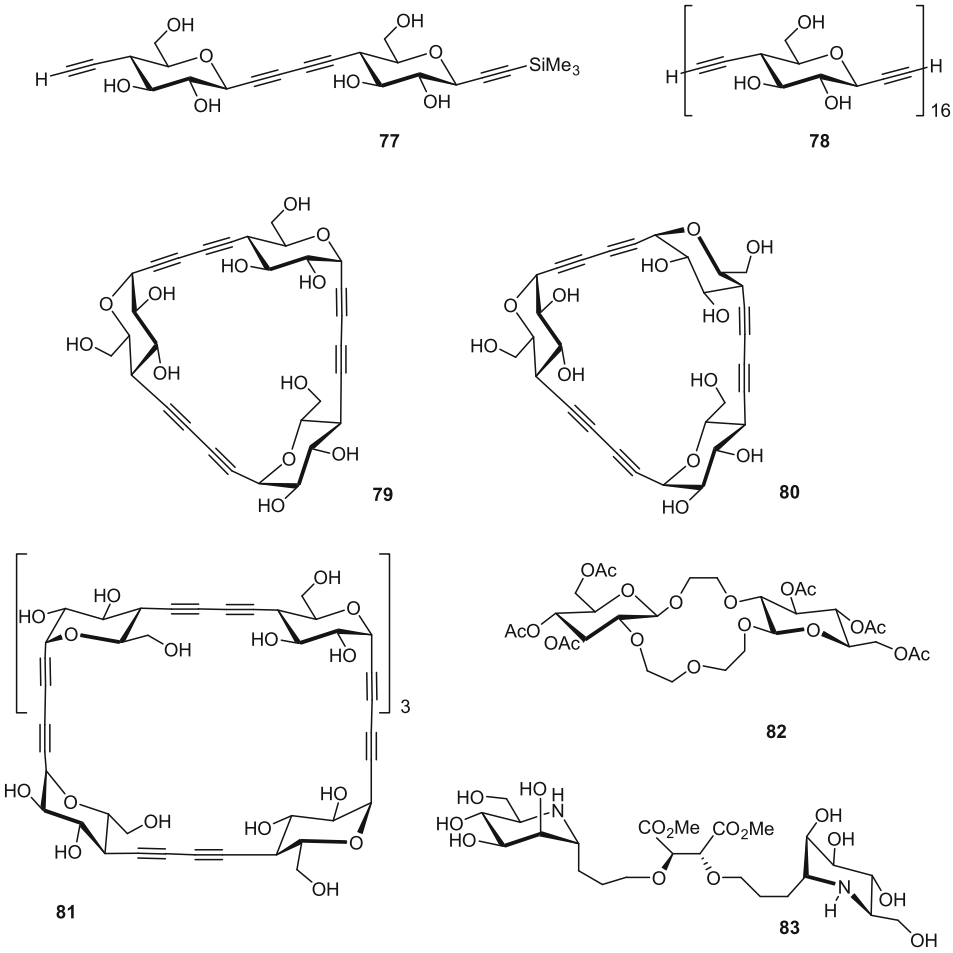
75



76

Scheme 13

a derivative additionally sulfated at the 3-position of the glucosamine unit at the reducing end was chosen with even higher activity (AT-mediated anti-Xa activity: 1250 U/mg) [163]. Both uronic acids of this pentasaccharide were replaced by open chain fragments, the D-glucuronic acid by an (*S*)-glyceric acid oxymethylene residue to give **75** [163], and the L-iduronic acid by an (*R*)-glyceric acid oxymethylene residue to give **76** [164]. These are six-atom spacers with the same atom count as the (1→4)-linked pyranuronic acid. While **75** was inactive, pentasaccharide **76** (AT-mediated anti- Xa activity: 150 U/mg) retained some 12% of the activity of the reference compound. The methylene acetal in **76** adopted a linear conformation [165]. Since the conformational flexibility of L-iduronic acid is well documented, the pyranoside exists in a chair/skew boat equilibrium, it is not surprising that a more flexible unit is tolerated. In contrast, a flexible replacement of the rigid D-glucuronic acid seems to be not allowed. Accordingly, the pentasaccharide in which both the D-glucuronic acid unit and the L-iduronic acid unit have been replaced by glyceric acid oxymethylene residues (structure not shown here) was inactive.



Scheme 14

Heparan sulfate and hyaluronan pentenyl disaccharides were coupled by metathesis or reductive amination reactions resulting in 8- or 12-atom spacers [166,167].

Vasella et al. developed the concept of acetylenosaccharides as oligo- and polysaccharide analogues to study intra- and intermolecular interactions [168]. A first representative was the dimer **77** (*Scheme 14*) [169] with a rigid four-carbon butadiynyl spacer. Higher oligomers up to the β-*C*-glucosyl hexadecamer **78** were assembled [170]. The same spacer concept was applied to devise cyclic acetylenosaccharides as analogues of cyclodextrins. Starting with an α-*C*-linked building block, two different cyclotrimers were synthesized, the C_3-symmetric **79** with (1→4)-linkages exclusively [171], and **80** with one (1→1)-linkage [172]. In addition, syntheses of larger rings like several cyclotetramers and, of bigger ring sizes, up to the cyclooctamer **81** were achieved [173]. Other acetyleno cyclodextrins contained mannose [174] or glu-

cosamine [175] units, or only one butadiynyl [176], pentadiynyl or hexadiynyl spacer [177]. By intramolecular attack of the butadyine triple bonds the spacer could be shortened to three- or two-carbon length [178]. In the context of a study on oligonucleoside foldamers ethynyl-linked nucleosides were investigated [179]. Cyclic dinucleosides were prepared by bridging with butylene spacers thus creating a 24-membered ring [180].

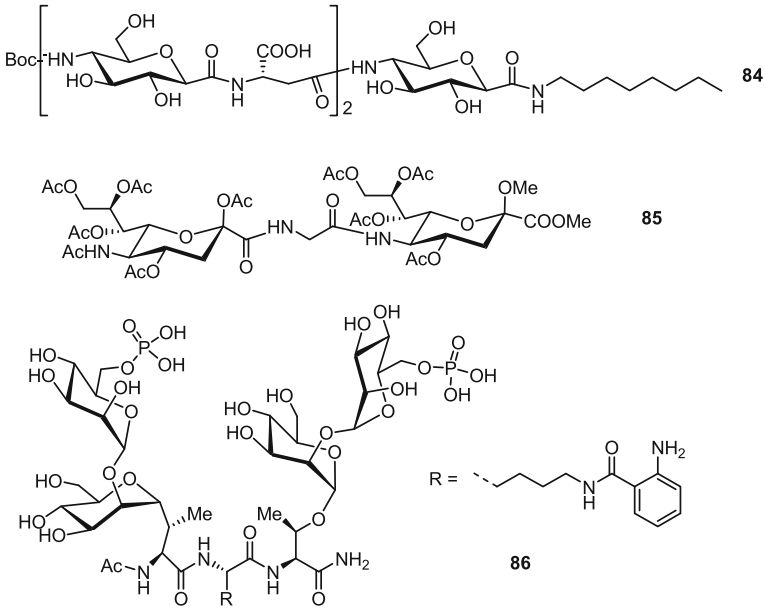
Carbohydrate crown ethers were obtained with ethylene spacers; from a crown ether point of view, the carbohydrate vicinal diols are replacing one ethylene glycol unit [181,182]. Cyclic compounds synthesized include bis-gluco-15-crown-5 **82**, bis-gluco-21-crown-7, and tetra-gluco-24-crown-8 (❯ *Scheme 14*). These chiral macrocycles could serve as catalysts in the asymmetric Michael addition of methyl α-phenylacetate to methyl acrylate. With the goal to study molecular interactions, β,β-, β,α-, and α,α-bis-maltosides with aliphatic two-, three-, or four-carbon spacers were synthesized [183]. Spaced cyclodextrins were prepared to study their supramolecular properties [184,185].

Also spaced glycoside mimetics have been described, e. g., analogues of trehazolin **39** (cf. ❯ *Sect. 2.2*, ❯ *Scheme 9*) with two- and three-carbon alkyl spacers [186]; they turned out to be inactive as yeast α-glucosidase inhibitors [187]. Further examples are head-to-head β,β- or α,α-linked 1-deoxymannojirimycins with eight carbon alkyl spacers or those with more polar centers like dipropylamine (seven atoms) or a ten-atom spacer as in **83** [188] (❯ *Scheme 14*). Glycosyltransferase inhibitors (reviewed in [189]) with micromolar activity were obtained with iminosugars spaced to other sugars or nucleosides with the spacer acting as phosphate mimetic.

Glycoproteins (cf. ❯ Chap. 8) and natural or synthetic glycopeptides as well as glycoconjugates can be viewed as "spaced sugars" but in their entity are not in the scope of this chapter; only a limited number of oligosaccharide mimetics are discussed here. Suhara et al. [190] have synthesized alternating sugar amino acids and α-amino acids, and the oligomers were examined in two in vitro systems measuring inhibition of chemotaxis and invasion in highly metastatic tumor cell lines. A trimer containing D-aspartate and a pentamer **84** (❯ *Scheme 15*) containing L-aspartate showed considerable activity. Molecular dynamics calculations of these oligomers indicated stable conformations due to intramolecular hydrogen bonding. Ramamoorthy and Gervay [13] described an acetyl protected neuraminic acid-glycine-neuraminic acid trimer **85**.

Mannosyl oligosaccharides with two terminal mannose 6-phosphate (M6P) residues have been suggested to be the natural ligand for the mannose-6-phosphate receptor, which is involved in inflammatory processes. Bidentate structures with 6-*O*-phosphorylated mannose disaccharides on a peptide template with three to five amino acids have been created. A compound with a tripeptide spacer **86** was distinctly more active in a binding inhibition assay than a suggested natural ligand oligosaccharide [191]. A much simplified mimetic with a four-carbon alkyl spacer between two mannose units with phosphate replacements showed appreciable affinity for the M6P/insulin-like growth factor II receptor [192]. Glycopeptide mimetics of mammalian Man_9NAc_2 were designed and tested for their ability to inhibit binding of mannan-binding protein to mannan from *Saccharomyces cerevisiae* [193]. Further linear [194] and cyclic [195,196,197,198,199] alternating sugar amino acids/amino acids were studied [200].

Another group of spaced sugars is found in the growing class of glycodendrimers [201,202,203,204], prepared as neoglycoconjugates [205,206] or cluster glycosides [207,208,209,210] and to address the issue of multivalency [211,212]—this topic is covered in detail in



Scheme 15

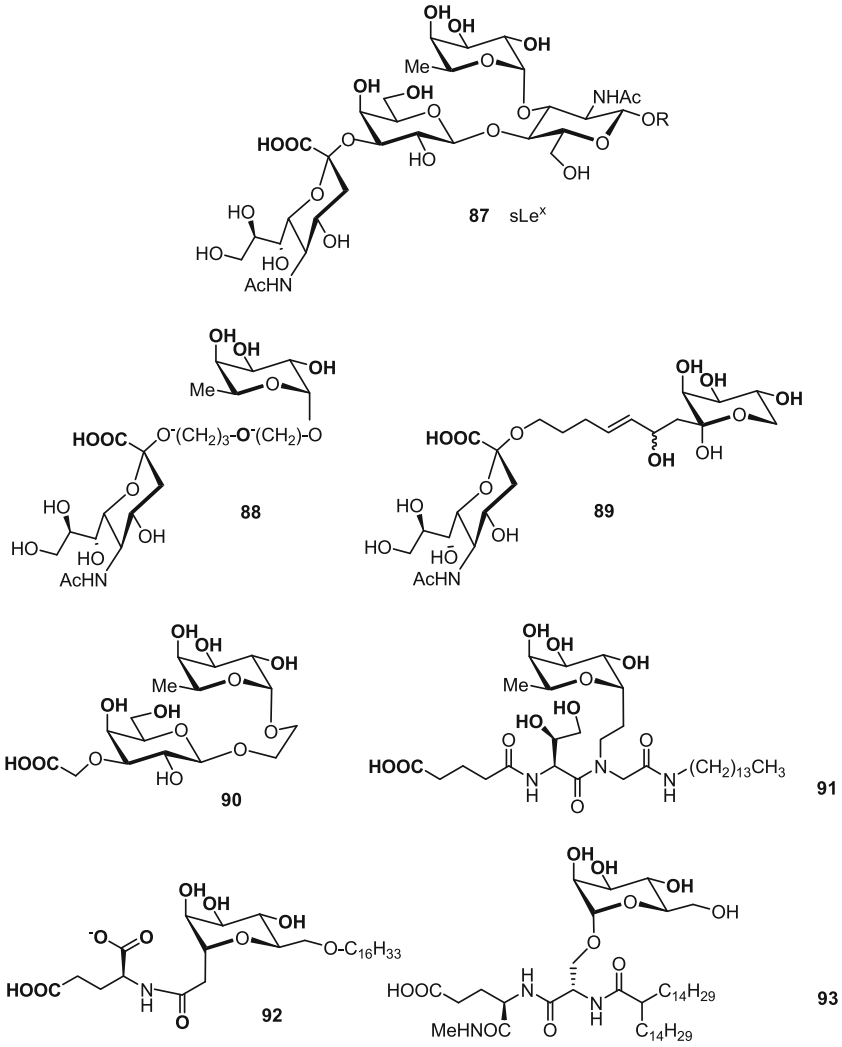
Chap. 12.4. Also in these cases sugars have been linked "unnaturally" as amides [213, 214,215,216] or thioureas [217,218].

Early examples of neoglycoconjugates are sulfated heparin oligosaccharides linked by a more than 50-atom spacer to replace ten or more glycosyl units and to inhibit the coagulation factor thrombin [219] or the head-to-head linked *N*-acetylglucosamines with linear spacers with up to 66 atoms which have been prepared as model compounds for more complex sugars [220].

With respect to physicochemical properties, sugars with sufficiently long spacers, such as bolaamphiphiles [221] or gemini molecules [222], may form supramolecular structures and have surfactant character.

Active research programs in a number of pharmaceutical companies and academic laboratories have been devoted to the identification of mimetics of sialyl Lewis x (sLe^x, **87**) [223,224], cf. *Scheme 16*. sLe^x glycosides are found on the outer surface of glycolipids and glycoproteins and are the key recognition elements of the selectins, a group of cell surface proteins with carbohydrate recognition domains classified as E-, P-, and L-selectins according to their occurrence on endothelial cell, platelets, and lymphocytes [225]. Selectin-carbohydrate interactions occur at an early stage of inflammatory reactions or metastasis. The hope is that with sLe^x mimetics it would be possible to intervene in acute and chronic inflammatory diseases (asthma, arthritis, myocardial infarction, lung injury) and to find new anticancer agents [226,227]. Towards this goal the full knowledge on carbohydrate mimetics described above has been employed in this practical exercise of carbohydrate medicinal chemistry to simplify the complex sLe^x saccharidic structure.

As indicated in the structural representation of **87** (*Scheme 16*) some groups (marked in bold print) are important groups in the binding to E-selectin. In early examples, the galactose



Scheme 16

residue was substituted by alkyl or hydroxylated alkyl chains [228,229]. Both the galactose and glucosamine residues have been replaced by non-cyclic spacers as shown in fucoside **88** [230] or branched fucoside **89** [231]. Other spacers were simple alkyl chains [230], pentaerythritol [232], or higher hydroxylated or keto analogues of **89** [231]. These extensive flexible sugar replacements abolished, however, the biological activity.

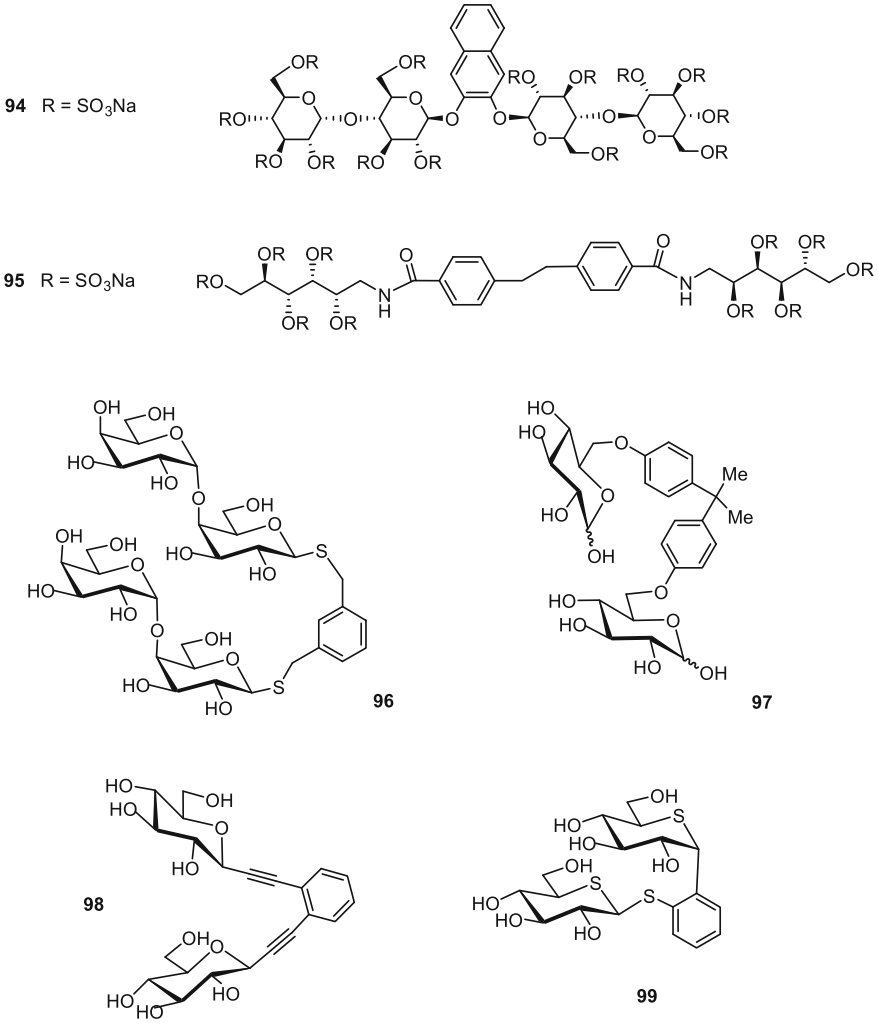
Once it was realized that the most important group of the neuraminic acid is the carboxylate, this saccharide was frequently replaced by a, in some cases substituted, hydroxyacetic acid group. The glucosamine unit was substituted by a simple glycol as in **90** [233] or a substituted glycol, e. g., the C_2-symmetrical 2,3- butanediol group [234,235], also *C*-glycosidic mimetics

were prepared [236,237]. Among these, the glycol derivative **90** retained the highest activity (0.8 mM against E-selectin) being ca. three times less active than sLe^x itself. An alternative substitution of the Neu5Ac-(1→3)-Gal disaccharide was brought about by alkylated malonic acid derivatives giving rise to sLe^x-like activities [238], 2- and 3-malonate substituted galactosides were designed resulting in lead compounds more potent than sLe^x for P-selectin [239]. Further trimming of the inhibitors by replacement of also the galactosyl unit derivatives with only one saccharide unit were devised. *O*- and *C*-glycosidically linked fucosyl peptides with hydroxylic or peptidic side chains were synthesized [240,241,242,243,244], and a marked increase in activity was observed with the attachment of lipid moieties as in **91** ($IC_{50} = 37\,\mu M$, E-selectin) [241]. Similarly, 6-amino-6-deoxy-L-galactose [245] and mannose [246] with the same arrangement of hydroxy groups as in fucose have been employed; it was found that the essential hydroxy groups of the galactose moiety can be replaced by a carboxylate: compound **92** had an $IC_{50} = 40\,\mu M$ against E-selectin [247]. sLe^x mimetics with glycosylated β-turn dipeptides showed to be potent but unselective selectin antagonists, for instance mannosylated compound **93** had $IC_{50} = 3.5$, 0.45 and 4.0 µM for E-, P- and L-selectin, respectively [249,249]. Combinatorial approaches have been chosen to build up peptidic sLe^x mimetics employing either the four-component Ugi condensation with a *C*-fucosyl, -mannosyl, or -galactosyl building block [250,251] or parallel chemistry on a solid phase [252].

The synthesis of polymers containing carbohydrate monomers has received attention to enhance their hydrophilicity and biodegradability [253], the synthesis of chiral polyamides has been reviewed [254]. Thiem and coworkers synthesized various polymers with aliphatic spacers from dianhydro sugars [255,256] or sugar diamino derivatives [257], the Kiely group started from various aldaric acids to synthesize polyhydroxy nylons [258,259,260,261]. On the basis of aldaric acids, novel carbohydrate-segmented silicone polyamides were synthesized [262]. Stereoregular polyamides with monomers of D-*manno* or L-*ido* configurations [263,264] and other AABB-type polymers [265,266] were prepared. The Fleet group built up macrocyclic lactams from open chain sugars spaced with alkyl groups [267].

4 Spaced Sugars with Cyclic Spacers

Cyclic spacers are more rigid than acyclic ones and present the attached sugar molecules at more defined exit vectors. Early example are the sulfated spaced oligosaccharides described by Wessel et al. [268] that were developed as heparinoid mimetics from sulfated trehalose oligosaccharides [269,270] with heparin-like antiproliferative activity. Contrary to the oligosaccharides, the spaced disaccharides could be completely sulfated to arrive at chemically well defined compounds. The spacer compound **94** (*Scheme 17*) had a 20% higher antiproliferative activity than the polysaccharide heparin itself along with good selectivity against antithrombin-mediated anticoagulant effects [271]. A number of other aromatic spacers could be used advantageously, but non-aromatic and particularly acyclic spacers gave distinctly lower activities; the aromatic spacer contributed to the binding and thus increased the activity. In an extension of that work, the disaccharides were replaced by open-chain sugars that were attached to aromatic spacers via an amide, sulfonamide, ether, amine, urea, or thiourea linker. This type of heparinoid mimetic was readily accessible; in the simplest case glucamine (1-amino-1-deoxy-glucitol) was coupled to aromatic bis-carboxylic acids



Scheme 17

followed by sulfation to furnish, e. g. **95**. This specific sulfated mimetic had a 50% higher antiproliferative activity than heparin in a smooth muscle cell growth assay with concomitant high selectivity with regard to its anticoagulant effects in a clotting assay.

Sulfated heparin oligosaccharides were coupled to aromatic spacers by reductive amination to investigate their binding to platelets [272,273].

Structurally similar bis-*O*- and *S*-glycosides were prepared to study the mode of presentation of the sugar binding epitopes in carbohydrate-protein recognition, galabiose (α-D-Gal*p*-(1→4)-D-Gal*p*) as in **96** (*Scheme 17*) and globotriose (α-D-Gal*p*-(1→4)-β-D-Gal*p*-(1→4)-D-Glc*p*) were employed as saccharide units [274]. Replacement of the core disaccharide

βGal(1→3)GalNAc of the GQ1bα ganglioside by a biphenyl spacer as in **97** led to antagonists of the myelin-associated glycoprotein [275]. C_2-Symmetric phenylene bridged glycosyl ureides were reported to display good Leishmanicidal activity [276]. Divalent aromatically spaced tetragalloylglucoses inhibited lipopolysaccharide-induced tumor necrosis facor-α secretion by more than 50% [277]. Other divalent structures, glycosyl amides with restricted conformations, were prepared to influence receptor clustering [278,279].

Bis-*C*-aryl- and bis-*C*-alkynylaryl-glycosides such as **98** were introduced by Vasella and collaborators [168,280]. Aromatic ethynyl spacers have been built up by Sonogashira coupling [281,282].

Bicyclic aromatic [283,284] or triazole [285] spacers were used to arrange oligosaccharides in a parallel fashion to investigate mimicry of cellulose I and II. Interesting aryl *C*,*S*-bisglycosides of type **89** (● *Scheme 17*) have been obtained during the work on antithrombotic 1,5-dithiopyranosides [286].

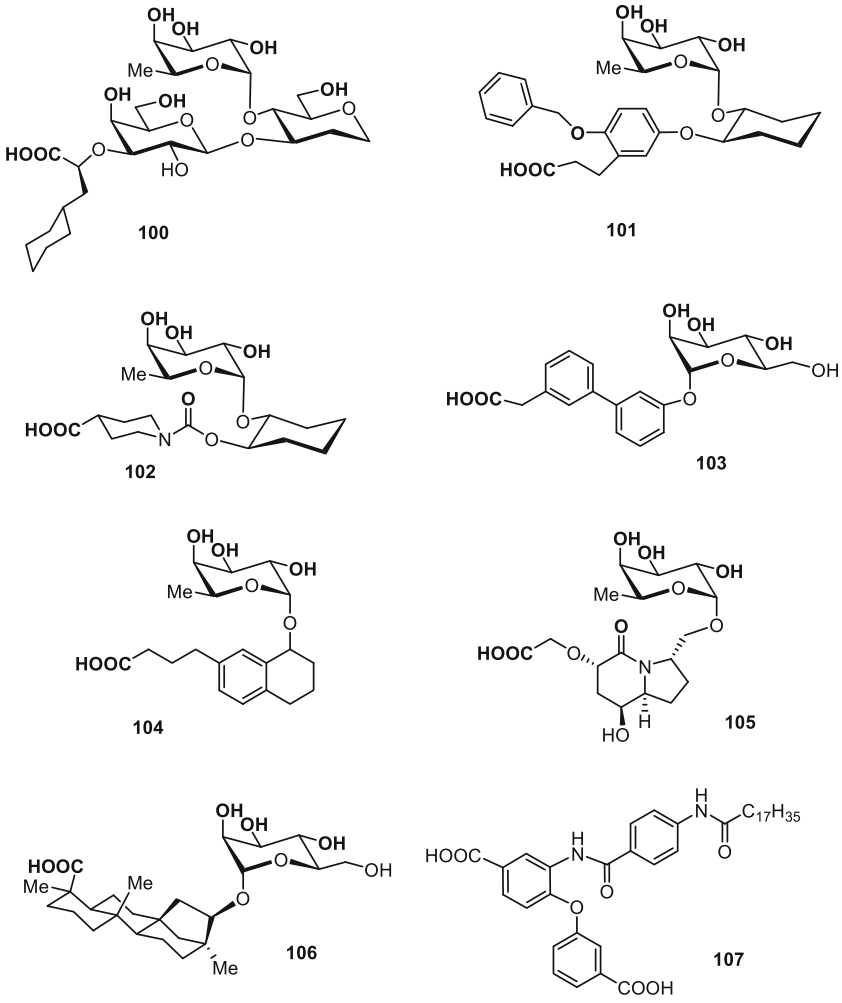
In the area of glycosidase inhibitors, a cyclic analogue of the spaced imino sugar **83** (● *Scheme 14*) was reported with replacement of the tartaric acid element by a cyclohexanediol [188]. Triazole spaced saccharides were devised as glycosidase inhibitors in which the trizole mimicked a valienamine unit [287]. Thanks to the ready access via 1,3-dipolar addition—the copper-catalyzed Huisgen reaction is the basis of the so-called "click chemistry"—triazoles have become popular to construct linear [288,289,290] or cyclic [177,291] spaced saccharides, likewise oxazole spacers were constructed [292]. Other ways to construct a cyclic spacer from glycosyl building blocks was by yne-ene cross metathesis followed by Diels–Alder reaction [293] or by Biginelli polycondensation [294].

Carboranes are particular cyclic spacers that have been introduced for boron neutron capture therapy to be taken up by tumor cells [295,296,297]. Aromatic spacers have been integrated in cyclodextrin analogues to modify the guest binding properties [298,299,300]. Also amide-linked polymeric open chain sugars with aromatic spacers were prepared [257,264,301].

Sugars with cyclic spacers are also found in Nature [302], well known examples are antibiotics such as calicheamicin [303,304] or vancomicin [305].

The last paragraphs of this chapter shall be devoted again to mimetics of the sLe^x tetrasaccharide **87** (● *Scheme 16*). Since it was realized that the glucosamine moiety of **87** does not considerably contribute to the selectin binding, this sugar was replaced by a cyclohexyl group without loss of affinity towards E- and P-selectin [228]. Cyclic analogues of the glycol derivative **90**, in which the neuraminic acid was reduced to a hydroxyacetic acid, were synthesized using, for example, a cyclohexyl, phenyl [235], or pyrrolidine [236,306] spacer. While these replacements alone were disappointing, a derivative with a cyclohexylmethyl-substituted hydroxyacetic acid replacing the neuraminic acid had good activity against E-selectin [307,308], the hydroxymethylated analogue **100** (● *Scheme 18*) was 30 times more active than **87** and showed to be efficient in a murine model of acute inflammation ($ED_{50} = 15$ mg/kg) [309,310].

In the series of peptidic fucosyl derivatives, Wong's group also presented analogues of sLe^x with a cyclohexyl group replacing the glucosamine unit [311,312]. The galactose and glucosamine units have also been substituted individually by carbocycles derived from D-quinic acid [313]. Mimicking the Gal-GlcNAc disaccharide with xylene derivatives [314] or a rigid spiroketal [315] did not improve the activity, the use of bis-*C*-glycosylated diphenylmethane to mimic the same units led to low micromolar L- and P-selectin antagonistic activity [316].



Scheme 18

Finally, three glycosyl units were replaced by a carboxylic acid and a suitable spacer, leaving only a fucosyl unit. In **101**, the spacer is an aryl cyclohexyl ether [317]; similar structures were prepared by the groups at Hoechst [318], and, incorporating their cyclohexylmethyl-substituted hydroxyacetic acid, Novartis [319]. Toepfer and Kretschmar with, e. g., **102** have presented [318,320] piperidine carbamates as a galactose replacement. Kogan et al. [321,322] employed various biphenyl derivatives as disaccharide mimetics as exemplified in **103** with a seven-fold higher activity towards E-selectin than sLe^x. Murphy et al. [323,324] incorporated tetralin and naphthalene ring systems as in **104** to obtain sLe^x-like activity. Hanessian et al. [325] introduced γ-lactams and indolizidinones as β-turn mimetics to achieve with for example **105** activity against P-selectin in the low µM range. With activities in µM range

β-linked aryl *C*-glycosides [326] and also the interesting α-mannosyl terpenoid **106** [327] proved to be P-selectin antagonists.

More recently, multivalent approaches [328,329,330] were reported. Based on molecular modeling approaches, non-sugar sLe^x mimetics [331,332,333] such as **107** ($IC_{50} = 86$, 6.1, and 30 µM for E-, P- and L-selectins respectively) [331] were created. A peptide mimicking the sialyl $Lewis^a$ oligosaccharide has been identified [334], this concept is discussed in more detail the next chapter.

5 Peptides as Carbohydrate Mimetics

As discussed in *Sect. 3*, peptides have been employed successfully as spacers in carbohydrate mimetics. Here we cover cases where peptides alone are able to mimic oligosaccharides and particularly carbohydrate antigens on the surface of cells. This parallels the finding that anti-idiotypic antibodies could act as immunogens and thus mimic carbohydrates [335,336]. Carbohydrates are T cell-independent and thus only weakly immunogenic, a problem which had been addressed by the formation of carbohydrate-protein conjugates. Now it has been demonstrated that peptides can mimic the meningococcal group C capsular polysaccharide, carbohydrate epitopes on breast adenocarcinoma cell lines [337,338], and those expressed on the envelope protein of the human immunodeficiency virus [339,340] and the Galα1→3Gal epitope which is of importance in hyperacute rejection [341]. The screening of suitable peptides has been greatly facilitated by the phage display technology [342,343]. Using this approach, peptides mimicking the bacterial saccharide *O*-antigen [344] of the *Shigella flexneri* serotype 5a lipopolysaccharide [345], the polysaccharide capsule of *Cryptococcus neoformans* [346] or glycosphingolipids [347] were prepared. Also peptide ligands for endogenous galactose-specific lectins (galectins) that are involved in various physiological and pathophysiological pathways including tumor growth regulation were identified [348,349,350].

Peptidic oligosaccharide mimetics that not only compete with the native protein for antibody binding but are also able to induce antibodies with the same biological activity were coined mimotopes [351]. Early hopes that this concept will lead to new vaccines directed against carbohydrate epitopes were supported by successful immunization of tumor bearing mice leading to complete elimination of tumor cells with co-administration of interleukin 12 [352].

Structural knowledge has been derived from X-ray structures of protein–carbohydrate complexes [353]; conformational preferences of carbohydrate mimicking peptides were studied by NMR [354]. The computer program LUDI [355] has been employed to epitope map the anti-Lewis Y antibody combining site, correlating peptide reactivity patterns [356]. The mimicry of specific carbohydrates or carbohydrate sequences was found to be associated with specific peptide sequences, for example, glucose with trypsin-arginine-tyrosine, α(2→9)sialic acid with tyrosine-tyrosine-arginine-tyrosine-aspartic acid, and the Lewis Y antigen [Fucα1→2Galβ1→4(Fucα1→3)GlcNAc] with proline-trypsin-leucine-tyrosine [337]. Mainly aromatic-aromatic and hydrophobic interactions were found to drive the peptide–protein binding.

1 Overview: New Tools for Glycobiology

Various glycans that are located at the cellular surfaces as glycosphingolipids, glycoproteins, and proteoglycans, deposited in the extracellular matrices and bound to secretory proteins have a variety of crucial roles in the phenotypic expression of cellular genotypes. General technologies such as chemical synthesis, spectrometric analysis using UV, fluorescence, CD, NMR,

In: *Glycoscience*. Fraser-Reid B, Tatsuta K, Thiem J (eds)
Chapter-DOI 10-1007/978-3-540-30429-6_53:

and SPR have greatly contributed to the insight into the molecular basis of structural features and functional roles of many glycoconjugates. Although there have been substantial advances in our understanding of the effects of glycosylation on some biological systems, we still do not fully understand the significance and mechanism of glycoform alteration observed widely in many human diseases. As a result, the therapeutic potential of complex glycans has not been well exploited with a few notable exceptions. This chapter describes background and provides a brief introduction of recent advances in new technologies and tools for glycomic approaches that should greatly accelerate functional glycobiology and their clinical applications.

2 Proteomics and Glycomics: Glycan Expression is not Template-Driven

Glycosylation is one of the most important posttranslational modifications of proteins in eukaryotes. This step is essential to modulate a wide range of protein (and lipid) functions both on the cellular surfaces and within the cells [1]. Therefore, the long-term challenge of glycomics is enormous; to define the identities, quantities, relationship between glycoforms and functions of the glycoconjugates, and to characterize how these properties vary in different cellular contexts. Proteomics, the analysis of genomic complements of proteins, has burst onto the broad scientific fields over the past few years, perhaps befitting a discipline that can enjoy the virtually instantaneous conversion of the genome sequence into a set of predicted proteins [2]. The development of method for parallel proteomics has relied on the rapid identification of open reading frames (ORFs) and their facile cloning and expression protocols. Cloning of a genomic set of ORFs and the chemical synthesis of gene-specific primers that are suitable for amplification by the polymerase chain reaction (PCR) and for subsequent insertion of the PCR products into appropriate plasmids permits a widespread use of recombination-based biotechnologies. Genomic-scale PCR amplification using mouse and human ORFs has also been carried out towards large-scale mammalian proteomics. Herein, it must be noted that primers can be made by high-throughput synthetic methods with high fidelity, at reasonable cost, and in 96-well format amenable for robotic manipulation.

Glycomics, a term defining the sequence analysis or profiling of glycome, must be integrated with the results (database) obtained by proteomics because the glycosylation (glycoforms) greatly influences protein functions and structures. However, it should be emphasized that individual glycoforms (profiled glycan structures or carbohydrate structures) of the glycoconjugates of interest are impossible to predict based on gene expression patterns as described above because the biosynthetic process of the glycans is not template-driven and is subject to multiple sequential and competitive enzymatic pathways [3]. There is no PCR-like glycan amplification technology for glycomics. While proteomics can use satisfactory amounts of the proteins of interest by means of the above-mentioned ORF-PCR-based recombination technology, glycomics need an enrichment process of glycans from highly complicated mixtures such as serum, cells, and tissues. One of the key bottlenecks in structural and functional glycomics is on the difficulty that the purification of trace amounts of oligosaccharides requires extremely tedious and time-consuming multi-step processes. This is because crude sample mixtures prepared by enzymatic digestion from cells, organs, serum, etc., usually contain large amounts of impurities such as peptides, lipids, and salts. These technical problems in the sequenc-

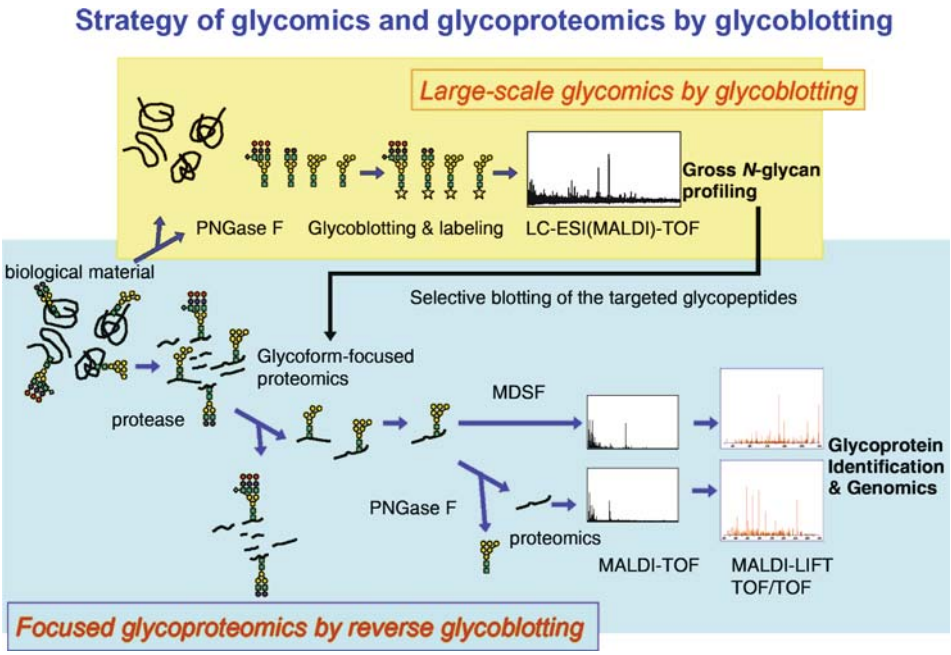

Figure 1
Strategy of glycomics and glycoproteomics by glycoblotting

ing of carbohydrates make it impossible to achieve high-throughput protein glycomics. Our recent efforts have been directed to the establishment of practical methods for glycan enrichment, namely "glycoblotting" [4,5,6,7,8]. The optimized protocol needs only 5–20 microliter of human serum for the quantitative profiling of 30–40 kinds of major glycoforms within 5–8 hours [9]. This novel technology will allow for large-scale glycomics and the clinical glycomic/glycoproteomic approach toward discovery research of new biomarkers (*Fig. 1*).

3 Emerging Glycomics Technologies

3.1 Mass Spectrometry (MS)

Mass spectrometry (MS) has become an indispensable tool for proteomics that in general deals with the large-scale determination of gene and cellular function directly at the protein level. It seems that the ability of MS to identify and to precisely quantify thousands of proteins from complex samples can be expected to impact broadly on cell biology and medicine. As in proteomics and metabolomics, MS-based analytical methods have come to the fore as a powerful tool for highly sensitive and definitive glycan analysis. Ann Dell (Imperial College, London) describes (Chap. 10.4) the state of the art in modern MS applications in the structural glycomics.

3.2 Microarrays

Microarrays of glycans (glycoarrays) displayed on solid surfaces are expected to be a convenient tool for advancing the glycomics field because these arrays will greatly facilitate high-throughput analysis and determination of the glycan-protein interactions. Ten Feizi (Imperial College, London) describes designer arrays for deciphering the glycocode that are based on an established platform of glycolipids and neoglycolipids arrayed on nitrocellulose-coated glass slides [10]. This technique permits the construction of a microarray displaying a library of 300 diverse sequence-defined glycans and the investigation of the binding of various glycan-binding proteins at femto mole levels of sensitivity.

3.3 Chemical Probes and Monitoring

Rapid and efficient methods for probing and identifying cell surface glycans in living animals are of growing importance because dynamic structural changes in glycosylation are known to accompany cell differentiation and disease progression. A metabolic glycan engineering strategy based on ManNAc analogs has been recognized as a promising approach for allowing the glycocalyx of living cells to be remodeled [11]. Kevin J. Yarema (Johns Hopkins University, Baltimore) focuses on recent advances in the metabolic installation of versatile thiol functional groups into cell surface glycans in order to modulate stem cell adhesion [12].

3.4 Bioinformatical Tools

Posttranslational glycosylations of proteins dramatically enhance their structural and functional diversity. Glycome provides vast information space at minimum genetic cost, because biosynthesis of glycans is not encoded through a template-driven system in the information flow from the genome to the glycome. With a goal of building a systems biology approach to glycan structure-function relationships, diverse datasets generated from different glycomics technologies should be integrated into versatile bioinformatics platforms. Claus-Wilhelm von der Lieth (Chap. 10.5) (German Cancer Research Center) describes the importance of relational bioinformatics databases and international plans to establish a federated network of distributed databases for glycobiology.

t.feizi@imeprial.ac.uk

Abstract

Carbohydrate chains of glycoproteins, glycolipids, and proteoglycans can mediate processes of biological and medical importance through their interactions with complementary proteins. The unraveling of these interactions is a priority therefore in biomedical sciences. Carbohydrate microarray technology is a new development at the frontiers of glycomics that has revolutionized the study of carbohydrate-protein interactions and the elucidation of their specificities in endogenous biological processes, immune defense mechanisms, and microbe-host interactions. In this chapter we briefly touch upon the principles of numerous platforms since the introduction of carbohydrate microarrays in 2002, and we highlight platforms that are beyond proof-of-concept, and have provided new biological information.

Keywords

Carbohydrate-binding proteins; Glycolipid; Microarray; Neoglycolipid; Oligosaccharide

Abbreviations

AO-NGLs	NGLs prepared *via* oxime ligation with lipid tag AOPE
AOPE	*N*-aminooxyacetyl-1,2-dihexadecyl-*sn*-glycero-3-phosphoethanolamine
CFG	Consortium for Functional Glycomics
DH-NGLs	NGLs prepared *via* reductive amination with lipid tag DHPE
DHPE	1,2-dihexadecyl-*sn*-glycero-3-phosphoethanolamine
HA	hemagglutinin
HIV	human immunodeficiency virus
MIC-1	micronemal protein-1

1 Overview of Carbohydrate Microarray Technologies

The diverse oligosaccharides that 'decorate' glycoproteins, glycolipids, proteoglycans, and polysaccharides are potentially a vast source of information, and could harbor a 'glycocode' that is waiting to be deciphered in various contexts of biological and medical importance [16,45]. It is desirable therefore to develop a knowledge base of biological systems that operate through oligosaccharide recognition. However, detailed analyses of carbohydrate-protein interactions has been a challenging area due to the structural complexities of oligosaccharides, the limited amounts that can be isolated, the difficulties in their characterization, and in general, the low affinities of their interactions with cognate proteins. Oligosaccharides cannot be cloned and the diverse repertoire of oligosaccharides is difficult to access by chemical synthesis. For all these reasons, the advent of carbohydrate microarrays is a welcome development for elucidating carbohydrate-binding specificities in a wide variety of contexts: cell-cell, cell-protein, and host pathogen interactions. The main advantage of microarray analysis is that a broad range of sugars (tens or hundreds, eventually thousands) can be immobilized and simultaneously interrogated. The multivalent display of arrayed ligands can usually mimic cell surface display and is ideal for detecting the generally very low affinities of interactions that involve carbohydrates. The miniaturization in microarrays is particularly well suited for investigations in glycomics, as the amounts of oligosaccharide probes arrayed are relatively small and thousands of binding events can be assessed in parallel on a single microarray slide. A number of recent reviews have covered in some depth different methodologies for constructing carbohydrate microarrays [11,17,37,40]. With the exception of polysaccharides [41,46,48] and natural glycolipids [16], chemical derivatizations are required for immobilizing carbohydrates for microarrays, as hydrophilicities of oligosaccharides preclude their direct noncovalent immobilization on solid matrices. One principle is to conjugate natural or chemically synthesized oligosaccharides to lipid by reductive amination to generate neoglycolipid (NGL) probes with amphipathic properties for arraying [20]. The use of reductive amination has also been described for preparing fluorescent oligosaccharide derivatives which contain a primary amine for array generation [49]. Most other mono- or oligosaccharide probes generated for printing have been de-novo synthesized chemically or chemoenzymatically, requiring substantial chemical expertise for access to defined structures that incorporate specific functional groups, e. g. thiol [1,7,36], maleimide [34], amine [4,12,14], azide [15], and cylcopentadiene [22] functionalities, or proteins as tags [1,31] for covalent attachment to solid matrices. Oligosaccharides with lipid [8] or fluorous tags [30] for noncovalent immobilization have also been described. These methods are promising due to compatibilities with advanced chemical or enzymatic synthesis of oligosaccharides [24,25,35]. However, relatively few structures can be obtained by current synthetic approaches [39]. Moreover, multi-step manipulations limit applications to the small quantities of oligosaccharides that can be isolated from natural sources. As natural oligosaccharides are crucial for discoveries of hitherto unknown oligosaccharide ligands [16,17], carbohydrate microarrays should ideally encompass oligosaccharides from both synthetic and natural sources. Approaches

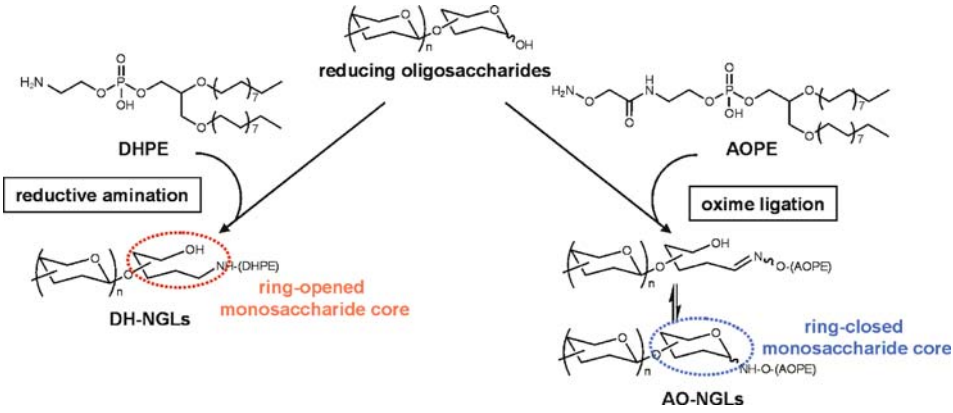
have been described for printing and covalent attachment of unmodified mono and short oligosaccharides onto aminooxy- or hydrazide-modified glass slides [26,53] and heparin-derived sulfated oligosaccharides onto hydrazide-modified gold surfaces [52]. Disadvantages of direct covalent surface immobilization methods are the high concentrations of the saccharides required and the potential variation of the immobilization efficiencies depending on the nature of saccharides. In most cases there is no way of knowing how much sample is attached at each spot. Fluorescence-based measurement is, to date, the prevalent detection principle for detecting binding to carbohydrate microarrays. An alternative approach described recently is the use of surface plasmon resonance (SPR) imaging for real-time, label-free analysis of protein interactions with microarrays of biotinylated glycans (printed onto neutravidin-coated gold chips) [23].

Many of the aforementioned carbohydrate microarray strategies have been used for observations on proteins of known specificities and their interactions with sugars. We highlight below several oligosaccharide microarray systems that are beyond proof-of-concept and have provided new biological insights. We dwell, in some detail, on the NGL-based oligosaccharide microarray platform with which we have first hand experience.

2 Sequence Defined Carbohydrate Microarrays

Encouraged by the observations of Wang and colleagues [46] that polysaccharides and glycoproteins can be satisfactorily immobilized on nitrocellulose by noncovalent interaction, Feizi and colleagues adapted their long established [44] and validated NGL technology [19] to generate microarrays of lipid-linked oligosaccharide probes using nitrocellulose as the matrix [16,20,21,38]. The NGL technology involves conjugating oligosaccharides by microscale reductive amination to an aminolipid, 1,2-dihexadecyl-*sn*-glycero-3-phosphoethanolamine (DHPE), as depicted in ❯ *Scheme 1*. This allows minute amounts (nmol scale) of oligosaccharides released from *O*- and *N*-glycosylated proteins, glycosaminoglycans, and polysaccharides to be converted into lipid-linked probes (DH-NGLs). The amphipathic property conferred by introduction of the lipid tag enables immobilization in clustered display on solid matrices such as silica-gel plates, plastic microtiter wells, and nitrocellulose. This mode of display is optimal for detecting binding signals with the majority of carbohydrate-binding antibodies and receptors, as the affinities of binding are low. In addition, the NGL technology provides a way to resolve, by high performance (HP) TLC, mixtures of oligosaccharide probes, and to perform carbohydrate-binding experiments on TLC plates in conjunction with oligosaccharide sequence determination by mass spectrometry in situ [10]. The NGL principle has led to discoveries of unsuspected oligosaccharide sequences on glycoproteins [50], as well as new oligosaccharide ligands for carbohydrate-binding proteins [51] (other examples are reviewed in [18]).

Other than ring-opening of the monosaccharide residues at the reducing ends, oligosaccharides remain intact in DH-NGLs. Those derived from tri- or larger oligosaccharides have performed well for the majority of carbohydrate-recognition systems which have the peripheral or backbone regions of oligosaccharides as recognition motifs [16]. However, ring-opening of the monosaccharides at the reducing-end may affect biological activities of short oligosaccharides. For instance, the DH-NGL of Lewis^x (Le^x) trisaccharide is not bound by anti-Le^x



Scheme 1
Principles of the preparation of NGL probes from reducing oligosaccharides by reductive amination and oxime ligation

antibodies [43], and that of sialyl-Le^x tetrasaccharide is not bound by the selectins [27]. To overcome this limitation and enhance the applicabilities of NGL probes derived from short oligosaccharides which are the most accessible via chemical synthesis, a novel type of NGLs with ring-closed monosaccharide cores has been introduced [28,29]. These are prepared from a variety of reducing sugars by conjugation with an aminooxy-functionalized DHPE (AOPE) via microscale oxime ligation (without reduction). The key features of these NGLs (AO-NGLs) have been demonstrated by microarray analyses: there is efficient presentation of short oligosaccharides, such as Le^x trisaccharide to anti-Le^x-antibodies and sialyllactose analogs to receptors of the immune system known as siglecs; the core-monosaccharide of a fucosylated *N*-glycan is also preserved as a ligand for the plant lectin from *Pisum sativum* (pea lectin) which recognizes the unmodified core.

The NGL-based microarray platform schematically presented in *Fig. 1*, currently has over 300 robotically arrayed, sequence-defined saccharide probes, which comprise NGLs from both natural and synthetic oligosaccharides, as well as natural and synthetic glycolipids, and are expanding in number. Included are: *N*-glycans (neutral and acidic, high-mannose and complex types), *O*-glycans and blood group-related sequences (A, B, H, Le^a, Le^b, Le^x, and Le^y) on linear or branched backbones, and their sialylated and/or sulfated analogs, gangliosides, glycosaminoglycans, homo-oligomers of sialic acid and oligosaccharide fragments of other polysaccharides, ranging in size from 2 to 20 monosaccharide units. This platform has all the attributes of the NGL technology with provision for generating 'designer' microarrays from targeted tissues and macromolecules [20,32,33]. It is advantageous that there is the provision for 'deconvolution', by resolving arrays of NGL mixtures by HPTLC before ligand-binding experiments in conjunction with mass spectrometry in situ for sequence assignment. This platform shows considerable promise as a novel approach to surveying entire glycomes and proteomes for the molecular definition of recognition systems.

The first generation NGL-based microarray system using nitrocellulose membranes provided insights to the specificity of an antibody (CS-56) to chondroitin sulfates A and C [20], and

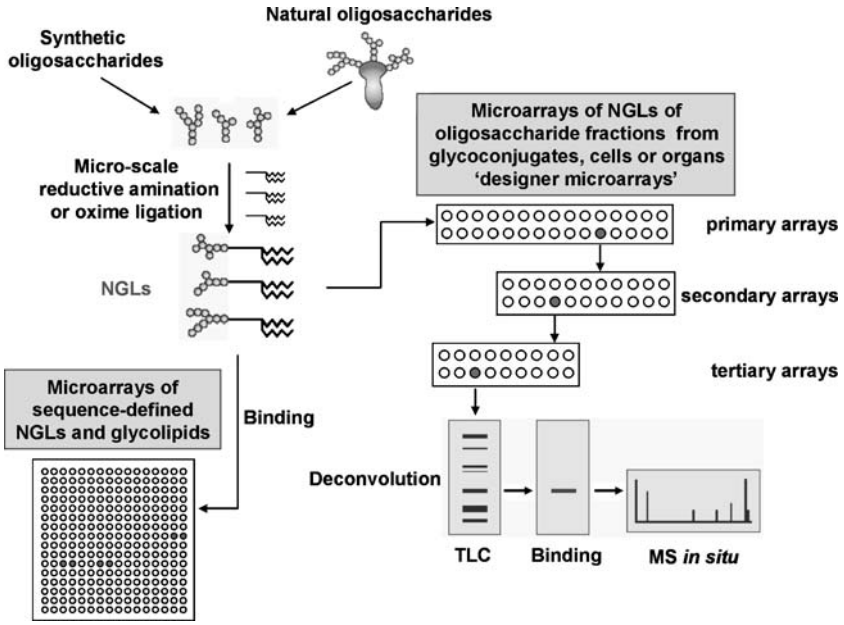


Figure 1
The NGL-based oligosaccharide microarray platform

enabled the identification of ligands for receptors of the immune system known as SIGN-R1, SIGN-R3, and langerin [21]. Assignment could also be made of a carbohydrate-binding function to domain 5 of the cation-independent mannose 6-phosphate receptor [38]. In addition, the applicability of NGL-based microarray to mixtures of oligosaccharides obtained from biological sources such as cells and whole organs has been shown [20,32].

With the second generation advanced NGL-based microarrays, using nitrocellulose-coated glass slides, the influence of sulfation on carbohydrate recognition by the siglecs has been shown [9]. Recent carbohydrate ligand assignments made by this microarray system have revealed, at one extreme a broad range of sialyl motifs, among *N*- and *O*-glycans and glycolipids to be recognized by the micronemal protein-1 (MIC-1) of *Toxoplasma gondii* (*Fig. 2* and *Fig. 3*) [5]. This accounts for the unique adaptation of this protozoan parasite to infect a wide range of hosts, including virtually all warm-blooded animals and up to 50% of the world population. At the other extreme, the ligands for Decin-1, a receptor of the innate immune system, were found to be highly restricted, and could be identified only by generating designer microarrays from the fungal and bacterial polysaccharide glycomes that the receptor targets (*Fig. 4*) [33].

Seeberger and colleagues have applied microarrays containing synthetic oligosaccharides to address several biological problems. Mainly two surface chemistries have been adopted for the preparation of the microarrays. The first involves maleimide-functionalized surfaces to form a covalent bond between the slides and the thiol containing synthetic carbohydrates (*Fig. 5a*). By this means, high-mannose microarrays were constructed using a panel of

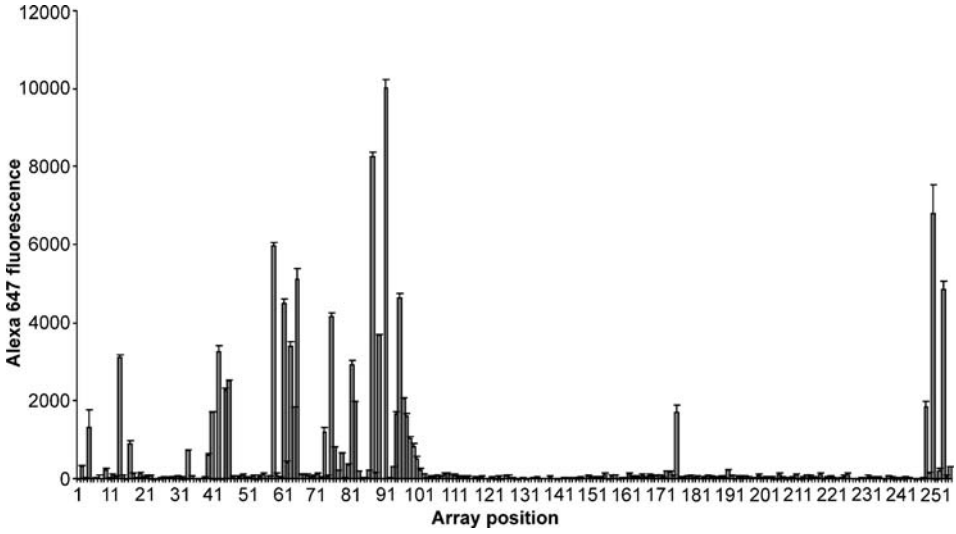

Figure 2

Microarray analyses of the binding of the *T.gondii* protein MIC-1. Two hundred and eighteen sequence-defined lipid-linked oligosaccharide probes were printed on nitrocellulose-coated slides [5]. A total of 256 oligosaccharide positions are shown, as some probes were arrayed at more than one position. Binding is plotted as relative fluorescence, means, with error bars, of duplicate spots minus backgrounds, at 7 fmol/spot. Binding was observed only to sialylated probes, which are described in *Fig. 3* below

synthetic mannose-containing oligosaccharides for identification of human immunodeficiency virus (HIV) vaccine candidate antigens [1]. The binding profiles were described for several proteins that bind to gp120 of HIV. These include the receptor of immune system known as DC-SIGN, the antibody 2G-12, and the bacterial proteins Cyanovirin-N and Scytovirin. Microarrays of natural or chemically modified glycoproteins were also included in this study and provided additional information regarding the importance of the underlying peptide context in which glycans are presented to their binding partners. A microwave-assisted two-step procedure was recently reported to introduce a thiol linker at the reducing end of carbohydrates for the construction of arrays on maleimide-functionalized surfaces [7]. For the second surface chemistry, amine linkers were employed to covalently attach the sugars onto amine-reactive slides (*Fig. 5b*). By this approach, monosaccharide microarrays were assembled and applied for adhesion studies on pathogenic bacteria [14], and microarrays displaying synthetic heparin oligosaccharides were used to study the binding profiles of heparin-binding proteins [12,47]. Microarrays of aminoglycosides were similarly constructed by random covalent immobilization onto amine-reactive glass for the evaluation of aminoglycoside antibiotics [13].

The Consortium for Functional Glycomics (CFG, http://www.functionalglycomics.org) has developed two generations of oligosaccharide microarrays [2]. The first is built on streptavidin-coated microtiter plates to which a library of biotinylated synthetic or natural glycans is attached [3]. This has now been replaced by the second generation, which is built using microarray printing technology to spot amine-terminating glycans on commercially available NHS-activated glass slides [4]. The key features in the construction of the printed arrays are

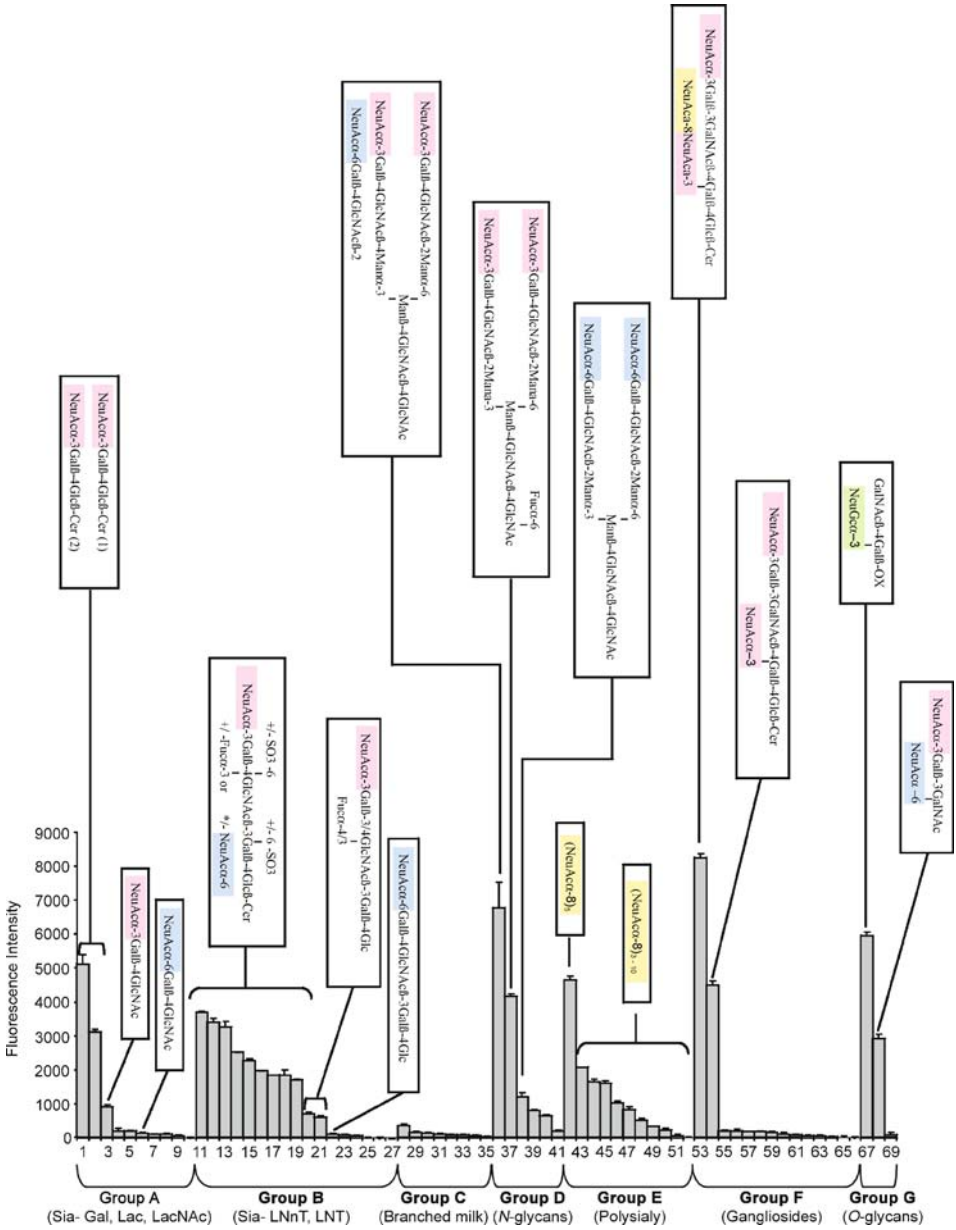

Figure 3

Numerical scores are shown of the binding signals with the *T.gondii* protein MIC-1: means of duplicate spots at 7 fmol/spot (with error bars) for the 59 sialyl oligosaccharide probes examined. These are classified into seven groups according to back-bone sequence. Sixty-nine positions are shown as ten of the probes were printed at two positions. Twenty-two selected probes are annotated, with designations of Neu5Acα2–3Gal linkage as pink; Neu5Acα2–6Gal, blue and Neu5Acα2–8 linkage yellow. The scores for the non-sialylated probes in the microarray are not shown; none gave binding signals above 150. Reprinted from ref. [5] with permission from the EMBO Journal

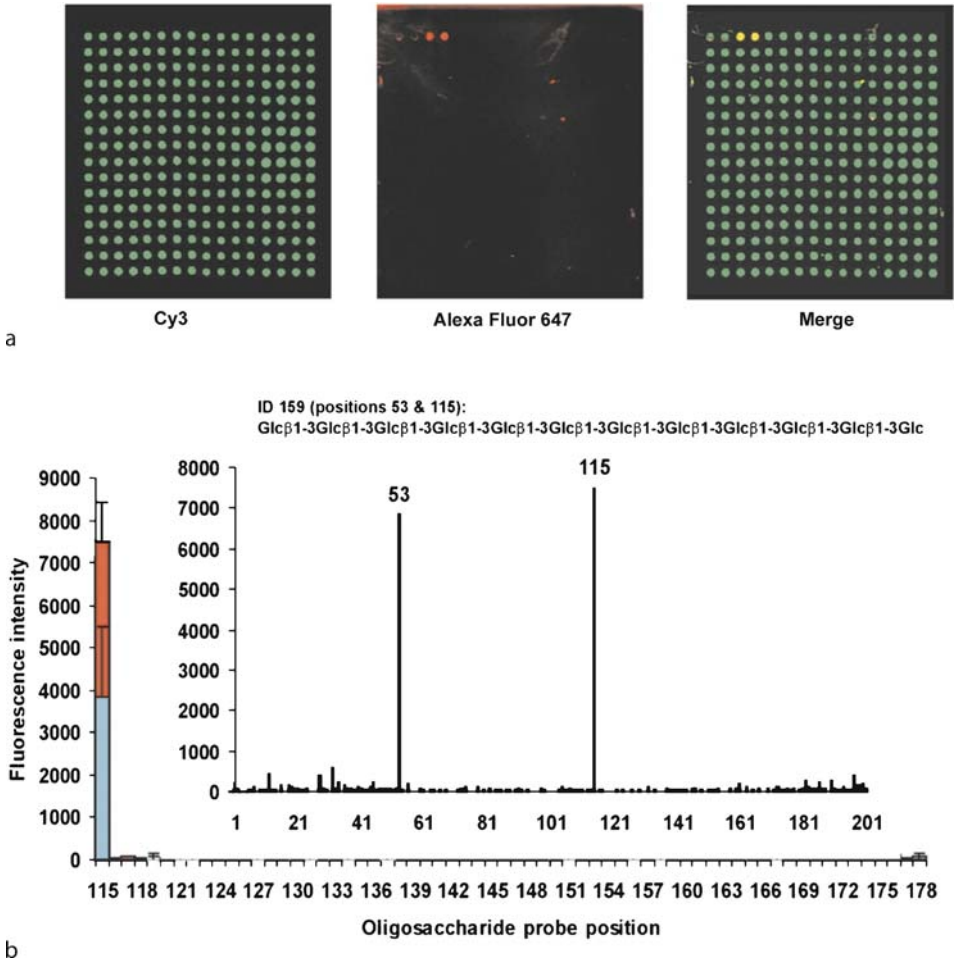

Figure 4

Microarrays of lipid-linked oligosaccharide probes showing Dectin-1 binding exclusively to the 'designer' NGL probe derived from the bacterial polysaccharide curdlan. (a) Oligosaccharide probes were printed in duplicate on nitrocellulose-coated glass slides at 2 and 7 fmol/spot with Cy3 dye included as a marker (green emission). Binding was detected with Alexa Fluor 647-labeled streptavidin (red emission). The image is that of a subset of 256 arrayed spots of 64 oligosaccharide probes. (b) Numerical scores are shown of the binding signals (means of duplicate spots) at 2 (blue) and 7 fmol/spot (red) with error bars for the 64 probes at positions 115–178. The inset shows numerical scores of the binding signals at 7 fmol/spot for all of the oligosaccharide probes arrayed. The signals at positions 53 and 115 correspond to those elicited by a probe derived from curdlan (β1,3-linked glucose 12mer). Reprinted from ref. [33] with permission from Journal of Biological Chemistry

introduction of short neutral azido-linkers or *N*-Fmoc protected amino acids chemically to the monosaccharides, chemical or enzymatic elongation of these monosaccharides to obtain various oligosaccharide structures and conversion of the azido group of the linkers and the amino acid-moiety into amine functionality for covalent immobilization on NHS activated slides

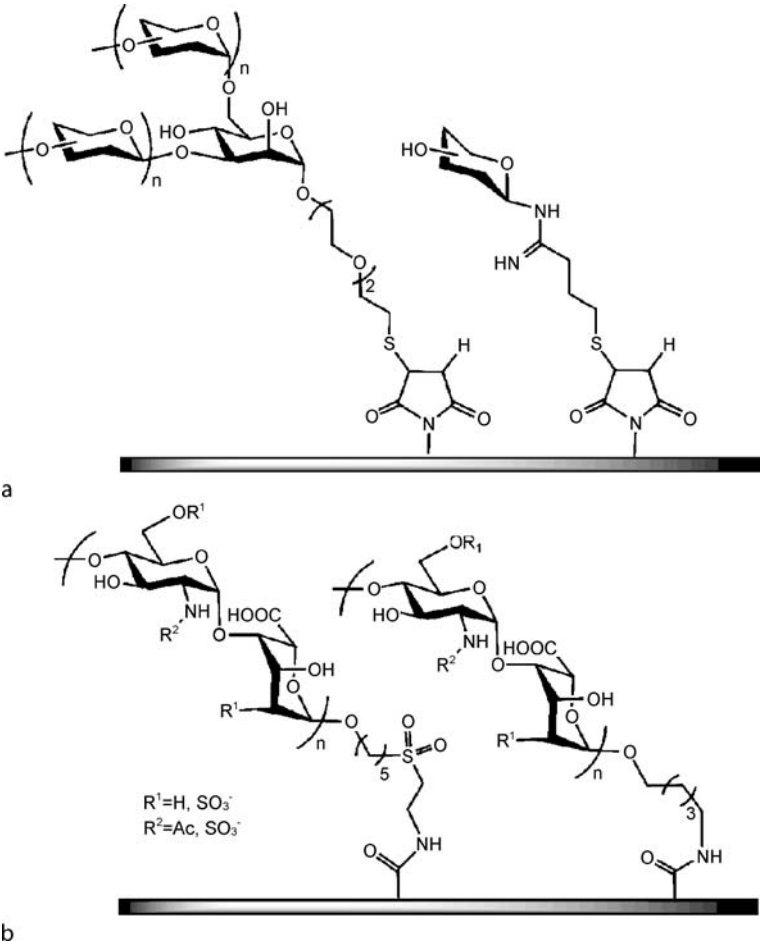

Figure 5
Covalent immobilization of chemically synthesized carbohydrates onto derivatized surfaces by Seeberger group. (a) Attachment of thiol containing carbohydrates to maleimide-functionalized glass slides; (b) attachment of amine-terminated heparin oligosaccharides onto amine-reactive glass slides

(*Fig. 6*). A growing library of more than 300 structurally defined glycans, predominantly synthetic, ranging in size from monosaccharides to undecasaccharides is included in the current microarrays. A recent development in this microarray platform is the preparation of glycan probes by one-step derivatization of free reducing glycans using a bi-functional spacer which contains both an aminooxy functionality and an amino group [6]. The binding specificities of a wide variety of carbohydrate-binding proteins, including C type lectins, siglecs, galectins, anti-carbohydrate antibodies, and lectins from plants, have been examined [4]. This system has also been applied to detect anti-carbohydrate antibody specificities in human serum [4]. In addition, glycan array analyses have been carried out on hemagglutinin (HA) from the

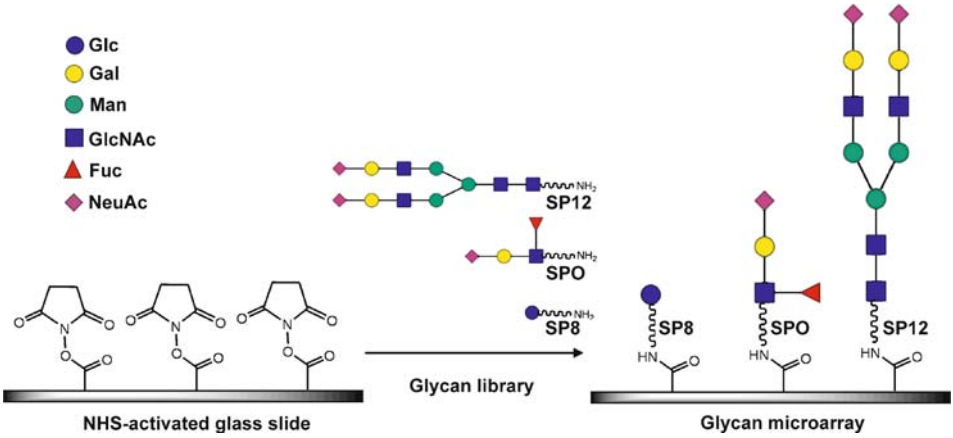

Figure 6
Covalent immobilization of glycans printed onto NHS-activated glass slides. Linkers SP0 = -$(CH_2)_2NH_2$, SP8 = -$(CH_2)_3NH_2$, and SP12 = Asparagine. Symbols for presentation of monosaccharides in glycans are as designated by CFG

1918 pandemic human influenza virus and the HA mutants with changed carbohydrate-binding specificities [42]. Microarray analysis with whole influenza virus was also shown to be possible [4].

3 Comments

Carbohydrate microarrays are coming of age. Their advent has transformed the studies of carbohydrate-protein interactions, leading to high throughput analyses of biomedically important systems that operate through carbohydrate recognition. It can be anticipated that many new and hitherto unsuspected carbohydrate-binding proteins and their ligands will be identified by these approaches.

Abstract

Metabolic oligosaccharide engineering (MOE) is a rapidly growing technology emerging from the field of chemical biology that allows novel chemical functionalities to be biosynthetically installed into the carbohydrates of living cells and animals. Since pioneering efforts to modulate sialic acid display through the use of non-natural *N*-acetyl-D-mannosamine (ManNAc) analogues were reported 15 years ago, monosaccharide probes have been developed to manipulate *N*-acetyl-D-galactosamine (GalNAc), *N*-acetyl-D-glucosamine (GlcNAc), and fucose-containing glycans. The 'first generation' of analogues, comprised of a series of ManNAc derivatives with elongated *N*-acyl chains, demonstrated pathway permissivity and the ability of this methodology to impinge on biological processes ranging from pathogen binding to gene expression and cell adhesion. Later analogues have incorporated chemical function groups including ketones, azides, thiols, and alkyne not normally found in carbohydrates. These groups serve as 'tags' for the subsequent use of chemoselective ligation reactions to further elaborate the chemical properties of the cell surface and thereby greatly expand the potential of MOE technology to offer control over biological processes.

Keywords

Carbohydrates; Chemoselective ligation; Neoglycoconjugates

Abbreviations

Ac acetyl
AFM atomic force microscopy
BSA bovine serum albumin
CDG congenital disorder of glycosylation
CMP cytidine monophosphate,
DLT dose limiting toxicity
FITC fluorescein isothiocyante
GAG glycosylaminoglycan
GNE UDP-GlcNAc 2-epimerase/ManNAc 6-kinase
GDP guanidine diphosphate
hEBD human embryoid body-derived
MB (+)-biotinyl-3-maleimidopropionamidyl-3,6-dioxaoctanediamine
MOE metabolic oligosaccharide engineering
NMR nuclear magnetic resonance
OGT *O*-glycosyltransferase
PCR polymerase chain reaction
PSA polysialic acid
RNA ribonucleic acid
Ser serine
SCFA short chain fatty acid
SPPS solid phase synthesis
TCEP tris-(2-carboxyethyl) phosphine hydrochloride
Thr threonine
UDP uridine diphosphate

1 Introduction

Carbohydrates are the most abundant organic molecules found in Nature. By mass, polysaccharides such as cellulose in plant walls and chitosan in the shells of marine organisms vastly outweigh other biological polymers. These polysaccharides are typically assembled from homopolymers of monosaccharides or repeating disaccharides units that can be several hundred residues in length. They play major structural roles in fungi, crustaceans, and plants but are also often subject to post-synthetic modifications, especially in animals, that greatly increase their chemical diversity and biological activities. In higher organisms, carbohydrates are quantitatively less abundant and also of smaller size, often occurring as oligosaccharide structures of only 20 or fewer—sometimes only one or two—residues. Despite their relatively small size, mammalian oligosaccharides have critical biological functions that derive from two fundamental differences compared to the other three major classes of biomacromolecules (nucleic acids, proteins, and lipids); carbohydrates can be highly branched molecules and their monomeric units may be connected to one another by many different linkage types. For example, four different amino acids can be combined to form 24 different tetrapeptides while four different monosaccharides can be combined to give 35,560 distinct tetrasaccharides [1,2]. This complexity allows even relatively small oligosaccharides to exist in a profuse number of structural variations with immense information carrying capacity so that, even when they are present in vanishingly small quantities, they have a profound impact on modulating the structure and function of the proteins and lipids.

Although they can be present without being attached to other molecules, most mammalian carbohydrates are attached to proteins or lipids and are generically referred to as 'glycoconjugates' or 'glycans'. According to the survey performed by Spiro, a wealth of sugar–protein linkages are known, involving 13 different monosaccharides and eight amino acids leading to a total of at least 41 bonds [3]. These diverse glycans, when present on the cell surface, largely determine the interactions of the host cell with other cells or with its environment. These functional roles, initiated by protein–carbohydrate or carbohydrate–carbohydrate interactions, include numerous biological recognition processes including, viral and bacterial infection, cancer metastasis, inflammatory response, innate and adaptive immunity, and many other receptor-mediated signaling processes [4,5,6,7]. In addition to serving as a surface 'sugar code' [8] that identifies a cell to the outside world, oligosaccharides can also modify the intrinsic properties of the specific proteins and lipids to which they are conjugated. For proteins, these properties include catalytic activity, resistance to proteolytic attack, solubility and conformational aspects including folding [9,10,11]. For lipids, an outstanding example of the role of sugar is the dramatic differences in biological activities exhibited by small differences, the acetylation status, of the sialic acid residue of ganglioside GD3 in sensitizing or providing resistance to apoptosis [12]. Of note, although glycosylation has long been regarded as an extracellular phenomenon, carbohydrate-specific biological activities—exemplified by the nuclear and cytosolic *O*-GlcNAc protein modification [13,14,15]—are gaining in importance. On the basis of the ever-growing list of biological processes influenced by glycosylation, there is intense interest in modulating glycan display for purposes ranging from study of function, cell engineering, to treatment of disease. Methods akin to the techniques for nucleic acid and proteins have been hindered by the fact that glycans are not primary gene products and there is not a one-to-one correspondence between a template and the ultimate structure the way

that a nucleic acid sequence specifies the primary amino acid structure of a protein. Moreover, because glycans are not template-based, methods similar to PCR for amplification of minor components do not exist. As a consequence, structure-function correlation is a difficult problem because glycan chains of glycoproteins are complex, flexible, and microheterogenous in nature making simple structural characterization challenging. However, with the advent of sophisticated analytical, spectral, and biological techniques, the 'glycomics' analyses of cellular glycans is becoming possible [16]. Even when glycoconjugate structures are identified, however, in situ regulation of glycan production remains difficult with few methods available to precisely up- or down-regulate the biosynthesis of a targeted oligosaccharide structure. In some cases, elegant chemical or enzymatic methods are available for the synthesis of glycoconjugates of biological interest that allow glycans to be produced outside a cell. Rarely, however, can exogenous glycans be added to a cell to reproduce the effects seen upon endogenous production (an important exception is glycosphingolipids that can be synthesized and added exogenously).

Considering the immense challenges confronting the glycobiologist seeking to manipulate glycans in living cells, a technology developed over the past decade by the chemical biology community now generally referred to as 'metabolic oligosaccharide engineering' (MOE) offers a major advance. MOE technology—wherein non-natural, exogenously supplied metabolic precursors intercept biosynthetic pathways and are incorporated into cellular glycans—was largely pioneered by Reutter and colleagues for sialic acid [17,18] and is now proving to be remarkably versatile, having now been demonstrated for several different monosaccharides. ❯ *Sect. 2* of this report will provide a general overview of MOE technology giving information on the basic technology, limitations and opportunities, and scope in living systems. Then, ❯ *Sect. 3* will give a detailed analysis of the specific glycosylation pathways that have been targeted successfully and will describe the monosaccharide analogues that serve as chemical probes for specific pathways. After that, ❯ *Sect. 4* will describe how, after the glycosylation machinery of a cell has been exploited for metabolic incorporation of the analogues into mature glycans, further chemical manipulation of the cell surface is possible via chemoselective ligation reactions. Overall, the focus of this chapter is on the use of 'chemical biology' methods to manipulate glycosylation with a detailed discussion given to the chemical intermediates used to intercept metabolic pathways. In addition, examples of changes to 'downstream' biological processes altered by MOE—either directly or after further chemical manipulation of cell surface displayed sugars—are provided throughout, along with relevant references for the interested reader who seeks in depth information.

2 Basics of Metabolic Oligosaccharide Engineering

2.1 MOE—the Incorporation of Non-Natural Monosaccharides into Glycans

The basic technology behind MOE involves the uptake of the building blocks of glycan biosynthesis—i. e., monosaccharides—followed by interception of the targeted biosynthetic pathway and ultimate incorporation into cellular glycans in the place of endogenously supplied metabolic substrates. MOE has proven to be remarkably broad-based, with metabolic incor-

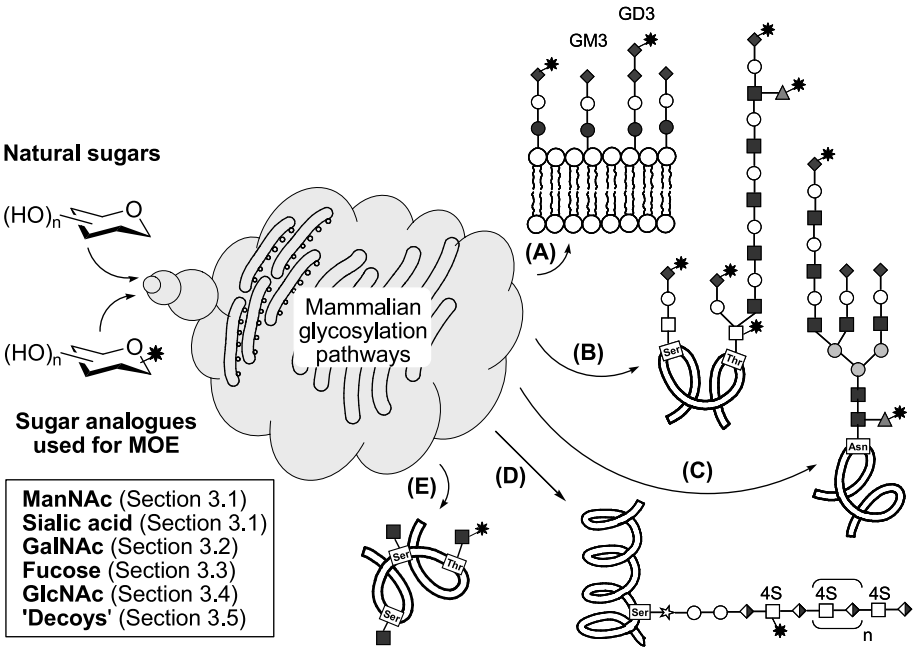

Figure 1

MOE in mammalian cells. Non-natural analogues of monosaccharides intercept glycosylation pathways in place of the natural sugars and are biosynthetically incorporated into various classes of carbohydrates including (A) glycosphingolipids, (B) *O*-linked glycoproteins, (C) *N*-linked glycoproteins, (D) glycosoaminoglycans, and (E) *O*-GlcNAc-modified nuclear and cytosolic proteins. Non-natural residues incorporated into these glycans are indicated with a *starburst* and the *symbols* used to represent sugars are given in *Fig. 2*

poration of non-natural sugar residues already demonstrated for several of the major classes of mammalian carbohydrates (*Fig. 1*). These include *N*-linked glycoproteins [19,20], mucins (*O*-linked glycoproteins) [21,22,23], glycosphingolipids [24,25], glycosoaminoglycans (GAGs) [26], and *O*-GlcNAc-modified nuclear and cytosolic proteins [27]. In addition to the well-studied mammalian systems, pilot studies have shown incorporation of carbohydrate analogues into bacterial lipooligosaccharides [28,29] and cell wall components [30,31].

2.2 Glycosylation—a Catalogue of 'Building Blocks' and Biosynthetic Elements

Despite the complexity of glycan production, the biosynthetic components that comprise the 'glycosylation machinery' have become well defined and the resulting knowledge is critical for ongoing progress in MOE. Basic information needed for MOE includes information on the genes responsible for the metabolic processing of the nine common monosaccharides found in mammalian oligosaccharides (Glc, Gal, Man, Xyl, GlcNAc, GalNAc, GlcN, Fuc and sialic acid, **1–9**). In addition, GlcA and IdoA (**10** and **11**) residues found in GAGs and certain sugars, exemplified by ManNAc (**12**) in sialic acid-based MOE, play important roles as metabolic

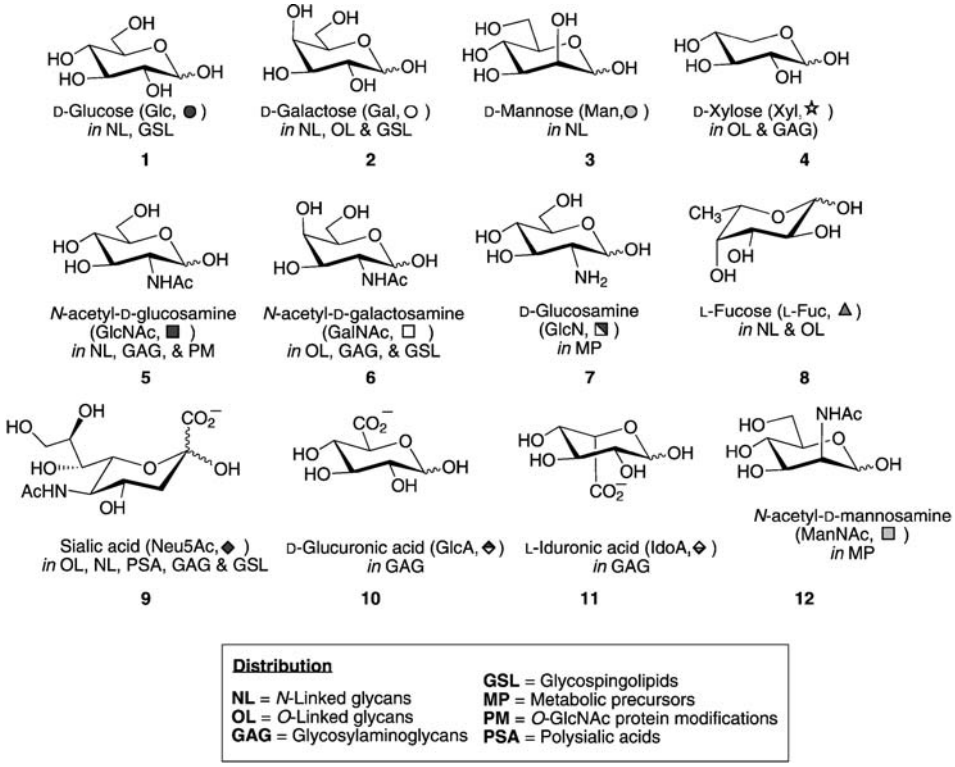

Figure 2
Monosaccharide structures. The chemical structures, symbols specified in "Essentials of Glycobiology" (http://grtc.ucsd.edu/symbol.html), and predominant glycan distribution of common mammalian sugars is given

intermediates [32]. These monosaccharides, shown in *Fig. 2*, are converted to nucleotide sugar 'building blocks' and assembled into glycoconjugates by the sequential and concerted actions of cytosolic processing enzymes, membrane transporters, glycosyltransferases, and glycosidases. Current estimates are that the protein components of the 'glycosylation machinery' collectively comprise 1 to 3% of the human genome [33] resulting in a complex set of metabolic networks [32].

Next, a detailed knowledge of the sequential metabolic intermediates found along the biosynthetic pathways responsible for glycan production is critical in MOE undertakings to ensure that the intended pathway is successfully targeted. From a historical perspective, in many cases the characterization of pathway metabolites significantly predated recently obtained genomic information on the proteins responsible for enzyme and transporter activities. Much of the biochemistry of the sialic acid pathway, for example, was determined in the 1960s by Roseman and colleagues [34,35,36,37] and even earlier for GlcN [38]. As described in detail in *Sect. 3*, a thorough knowledge of metabolic networks allows intelligent choices to be made when deciding where to intercept a biosynthetic pathway for the targeted replacement of a sugar. This decision process is exemplified by MOE manipulation of sialic acid where the

biosynthetic process can be directly modulated by sialic acid analogues but is more commonly controlled through ManNAc derivatives and less frequently by GlcNAc or CMP-sialic acid analogues; as discussed in *Sect. 3.1*, the biochemistry of the pathway stipulates efficient and rationale selection of one of these four possible interception points.

2.3 Overcoming the Plasma Membrane Barrier to Analogue Up-Take by Cells

2.3.1 Non-Natural Sugars Are not Membrane Permeable

A common problem that plagues MOE experiments is the slow initial uptake of the sugar analogues by a cell. Although families of transporters exist for common dietary sugars such as Glc [39], they are usually refractory to modified derivatives such as the GlcNAc analogues (*Sect. 3.4*) now used in MOE. A similar uptake problem exists for ManNAc as no membrane transporters have been reported for even the natural form of this sugar [40] thereby posing a significant hindrance to sialic acid pathway intervention. Consequently, millimolar quantities of mannosamine analogs such as ManNProp (**13**) [17] or ManNLev (**14**) [20], which are presumably taken into cells primarily by diffusion or pinocytosis, are required to maximize metabolic incorporation into sialic acids.

Non-receptor mediated uptake of carbohydrates into a cell by diffusion is severely hampered by the ubiquitous hydroxyl groups of sugars and experimental evidence suggests that the number of hydroxyl groups in the glycan determines the rate and extent of uptake. Because a strong correlation exists between membrane permeability and partitioning of solutes into an organic solvent, one strategy for improving the cellular uptake of monosaccharides has been to increase the hydrophobicity of the sugar by appending lipophilic groups. The difficulty of passing the polar hydroxyl groups through the interior of a membrane, which resembles a low dielectric solvent, was illustrated by the pentoside Xyl-β-*O*-2-naphthol (**15**), which diffuses into CHO cells more readily than the hexoside Gal-β-*O*-2-naphthol (**16**), containing the same aglycone (*Fig. 3A*) [41]. The comparison of these compounds showed that even one additional hydroxyl group creates an obstacle to uptake and the multiple hydroxyl groups of a disaccharide constitute an even larger energy barrier to membrane diffusion. Consequently, naphthol-derivatization successfully used for monosaccharides did not improve the uptake of the Gal-β-1,3-Gal-β-*O*-2-naphthol disaccharide (**17**) [41]. In theory, a further increase in the size and hydrophobicity of the aglycon moiety should enhance uptake but in practice strongly amphipathic compounds act like detergents. Thus, pyrene derivatives of glycosides such as **18** [42] or sugars containing alkyl chains of 15 carbons (**19**) result in cell lysis (*Fig. 3B*).

2.3.2 Short Chain Fatty Acids Increase Cellular Uptake and Modulate Biological Function

To circumvent problems encountered when attaching a single, highly lipophilic moiety to ferry a sugar across a cellular membrane (*Fig. 3B*), modified analogues containing short chain fatty acids (SCFAs) were developed to increased cellular uptake. SCFAs represent a compromise between extremely lipophilic groups that damage the membrane and hydrophilic nature of the sugar that prevents membrane uptake. Moreover, SCFAs, most often acetates, have been

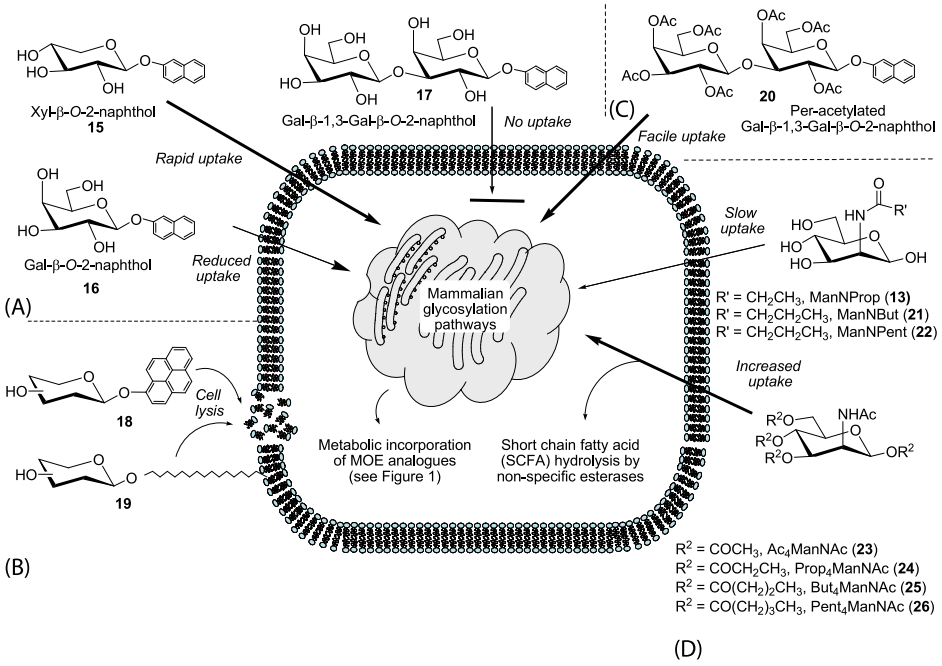

Figure 3
Strategies to improve membrane permeability of MOE analogues. The use of (A) naphthol derivatives or (B) highly lipophilic groups has been attempted to increase cellular uptake of small carbohydrates. (C) Peracetylation of 17 (to form 20) dramatically facilitated uptake leading to the general strategy of using SCFAs for the delivery of MOE substrates including ManNAc analogues (D). Inside a cell, the SCFAs are hydrolyzed by esterases, regenerating the parent monosaccharide that in turn intercepts the targeted glycosylation pathway

used to improve bioavailability of drugs (e. g., acetylsalicylic acid), second messengers (e. g., dibutyryl cAMP), and glycosidase inhibitors (e. g., carbonoyloxy analog of swainsonine) [41]. Cells have numerous esterases, some of which have broad substrate specificity, that can remove the acetates and convert the pro-drugs into their active forms. On the basis of this precedent, it was proposed that the cellular uptake of MOE analogues would be improved by the addition of acetyl esters to the hydroxyl groups of sugars. This hypothesis was demonstrated over a decade ago when the Esko group showed that peracetylation enhanced the uptake of Gal-β-1,3-Gal-β-*O*-2-naphthol (**20**) [41,43] (● *Fig. 3C*). This strategy was then applied to the 'first generation' MOE analogues ManNProp (**13**), ManNBut (**21**), and ManNPent (**22**) where per-acetylation increased metabolic utilization by an estimated ~200-fold in the Jurkat cell line [44] (● *Fig. 3D*); a similar increase upon peracetylation was subsequently observed for ManNLev (**14**) and several other ManNAc analogues (see ● *Table 1* for ManNAc analogues) [45]. In a separate study, a thorough quantitative comparison of peracetylated ManNAc compared to its free monosaccharide counterpart revealed from 300- to 900-fold increased efficiency across cell lines [46]. Together, these studies established that the strategy of using SCFAs to increase cellular uptake applied for multiple analogues across various cell types and can therefore be regarded as generally useful for MOE experiments.

Table 1

ManNAc analogues used in MOE are categorized as having (A) unbranched alkyl substituents, (B) glycolyl or thiolglycolyl groups, (C) branched or bulky groups, (D) ketone groups, and (E) azides at the *N*-acyl position. Representative references are provided for each compound; in most cases additional citations are provided in the text

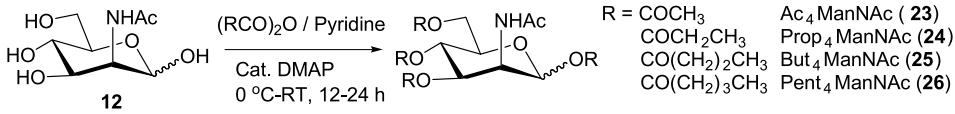
Because the increase in metabolic efficiency observed upon peracetylation of a mono- or disaccharide analogue is attributed to enhanced membrane diffusion due to increased lipophilicity, our laboratory tested whether SCFAs longer than acetate would further improve cellular uptake. Upon the synthesis of a series of SCFA-ManNAc hybrid molecules (*Scheme 1*), we found additional increases in metabolic efficiency for propionate-derivatized ManNAc (**24**) (~1,800 fold compared to the free hydroxyl form of this sugar) as well as for fully butyrate-derivatized ManNAc (**25**) (~2,100) [47]. These analogues also provided an opportunity to investigate a potential downside of SCFA-derivatized sugars; which is their tendency to be toxic. Although toxicity is not a major concern because it usually occurs at concentrations greater than required for robust metabolic incorporation [46,48], and has not been reported to be significant in several in vivo studies [49,50], its mechanistic basis is nevertheless of interest. One possibility—with scant experimental evidence to date—is that the increased analogue uptake exacerbates latent sugar effects. A second possibility—supported by several studies—is that toxic effects are due to the short chain fatty acid itself.

Experimental evidence that acetates are not silent moieties that only function as delivery vehicles to increase membrane uptake came from a comparison of the effects of ManNAc and Ac_4ManNAc (**23**) on mRNA levels for the enzymes involved in sialic acid biosynthesis. In these studies, the addition of exogenous ManNAc to the culture medium had no effect on these enzymes [51] whereas supplementation with **23** at levels that increased metabolic flux



Scheme 1
Synthesis of SCFA-derivatized ManNAc

through the pathway to a similar level changed the expression of several genes [52]. The ability of SCFAs, including acetate [53], to function as histone deacetylase inhibitors (HDCAi) and thereby influence gene expression [54] provided a tentative mechanistic explanation for these results. To confirm that sugar-delivered SCFAs had the widely observed biological activities expected from these compounds, we evaluated the effects of But_4ManNAc (**25**)—a hybrid molecule consisting of butyrate and ManNAc—on HDAC inhibition and gene expression. In these experiments we substituted butyrate for the acetate to exacerbate SCFA-specific cellular responses because this 4-carbon SCFA has the highest level of biological activity. The ability of **25** to function as an HDACi was tested in several human cancer cells lines and the expected suite of SCFA responses including inhibition of proliferation, induction of apoptosis, alteration of histone acetylation, and up-regulation of $P21^{WAF1/Cip1}$ expression were observed [55].
Several important implications arose from the finding that SCFA 'protecting groups' influence biological activity. First, until the complex interactions between SCFAs and sugar metabolism are more thoroughly understood, the use of these protecting groups in MOE experiments may give rise to unanticipated biological activities that complicate the interpretation of the results. Second, once these responses are adequately understood, SCFA-derivatization will prove a design opportunity to extend the sugar-specific effects of MOE analogues over biological systems. Such opportunities were vividly illustrated by experiments that compared fully butyrated ManNAc (But_4ManNAc, **25**) and mannose (But_5Man, **27**) and demonstrated that the core sugar had a powerful ability to tune the activity of the SCFA moiety. In particular, although both compounds exhibited canonical SCFA activities such as modulation of histone acetylation status, **25** elicited significantly different patterns of gene expression than **27**. The former compound also induced apoptosis in cancer cell lines at concentrations where **27**, as well as the stereoisomer But_4GlcNAc (**28**), only provided transient cell cycle arrest [55]. Together, these experiments demonstrate that acetate and butyrate are necessary but not sufficient for toxicity and that biological responses to SCFAs are exquisitely tuned by the core sugar.

2.4 Monitoring Surface and Metabolic Flux Responses to MOE Analogues

2.4.1 Measurement of Surface Display of Non-Natural Sugar Residues

The surface display of non-natural sugar residues requires methods to assess the degree of replacement of natural sugars with the corresponding non-natural residues. The characterization of analogues with inert alkyl chains, exemplified by the original set of MOE analogues ManNProp (**13**), ManNBut (**21**), and ManNPent (**22**) developed by the Reutter group

(see ❯ *Sect. 3.1*) for surface display as modified sialic acids, is relatively time consuming, laborious, and generally cannot be performed on live cells. Glycosidases often do not function on the modified sugars, eliminating a straightforward route to analysis wherein these enzymes are used to remove modified residues from the surfaces of intact cells. In some cases, lectins can be used to detect surface changes upon analogue incorporation [56]; other times antibodies can be generated [57] that can be used—at least in theory—as imaging agents [58]. While neither lectins nor antibodies have yet proved to be highly quantitative and reproducible for probing modified glycan display, they remain valuable because they can provide conclusive qualitative evidence for metabolic incorporation of an analogue.

Radiolabeled probes constituted an early strategy to quantify analogue incorporation into cellular glycans and follow incorporation into membrane fractions [17]. Rigorous determination of analogue incorporation into glycans, however, required isolation of the carbohydrate-containing components by methods not compatible with physiological conditions such as acid hydrolysis followed by chromatographic analysis [50]. Similarly, separation methods including thin layer chromatography that have been employed for detection of sialic acids found in gangliosides [59] can not be performed on living cells. Consequently, the tandem development of analogues with orthogonal chemistries not naturally found in the glycocalyx, including ketones [20], azides [60], and thiols [61] along with complementary chemoselective ligation strategies compatible with physiological conditions have greatly facilitated the detection and quantification of surface displayed non-natural sugars (this topic is discussed in detail in ❯ *Sect. 4*).

2.4.2 Measurement of Intracellular Flux and Metabolite Levels

Several factors have motivated the development of methods to quantify intracellular metabolites to complement measurements of surface display of non-natural sugars. First, in cases when the detection of modified sugars such as Sia5Prop (**29**) on the cell surface is difficult, the monitoring of intracellular flux provides a rough measure of metabolic utilization of the precursor analogue. For example, it is relatively straightforward to measure the production of sugar intermediates by colorimetric assays, especially for the sialic acid pathway where the periodate-resorcinol assay [62] has been widely applied. Consequently, the metabolic uptake and pathway incorporation of analogues such as ManNProp (**13**) or ManNBut (**21**) that support a large increase in flux can be monitored easily by such colorimetric assays [48,63]. By contrast certain analogues that lead to surface modifications, such as ManNHex (**30**) or ManNOxoHex (**31**), do not measurably change intracellular metabolite levels. In these cases the flux of non-natural intermediates through the pathway is real but quantitatively small compared to endogenous metabolites and simple colorimetric assays are not informative.

In situations where both the surface display and intracellular metabolites resulting from analogue metabolism are refractory to rapid analysis, a benchmark of utilization can be obtained by analysis of analogue uptake from the medium. Although uptake occurs in advance of pathway incorporation and may not always directly correspond to metabolic utilization, the analysis of conditioned media by functional assays as described by Jones and coworkers is valuable for probing early steps (i. e., cell uptake) in the MOE process [46]. This method is mainly of value for SCFA-derivatized sugars where a large proportion (> 50%) of total analogue is removed from the culture medium compared. By contrast, the margin of error in this analy-

sis of +/− ~5% can mask uptake of free hydroxyl monosaccharides where a much smaller fraction (often less than 1%) of total analogue is removed from the culture medium by the cells. Although requiring significantly more effort, detailed analytical characterization of intracellular metabolites or media components, to test pathway interception or membrane transit, respectively, is possible by chromatographic methods [64] or by using radioactive tracers [63]. In conclusion, monitoring intracellular metabolic intermediates serves the dual purposes of verifying intake into the targeted glycosylation pathway as well as identifying 'bottlenecks' that hinder efficient metabolic processing, a topic that will be discussed at more length in Sect. 3.1.7.

2.5 Scope of MOE in Living Systems

2.5.1 Mammalian Cell Lines

To date, MOE technology been most extensively applied to mammalian cells; Jurkat cells in particular have been employed in many experiments and HeLa and HL-60 cells have also been well studied. Although analogue utilization appears to be a universal feature of human cells, the extent of incorporation varies several-fold based on several factors. In some cases, size differences between cells can largely explain differences in surface display; this situation is exemplified by the Jurkat and HeLa lines where the 3- to 4- fold difference in total surface display of Sia5Lev (**32**) upon ManNLev (**14**) exposure roughly corresponded to the relative surface areas of these lines [65]. In other cases, exemplified by human chondrocytes, lower incorporation is hypothesized to result from the copious secretion of extracellular matrix components that sequester the analogue and hinder its up-take by the cells (K. J. Yarema, unpublished results). In addition, analogues are utilized differently based on subtle differences in their chemical structures; this topic is discussed in depth in Sect. 3.1.7. Finally, species-specific differences in analogue metabolism can be particularly pronounced, with rodent cells showing dramatically lower (e. g., ~20-fold) surface display of ketones when incubated with **14** [65] and azides when incubated with ManNAz (**33**) [23] compared to human lines.

On the basis of these considerations, as a general guideline for initial experiments where novel analogues undergo evaluation in untested cell lines, peracetylated analogs should be tested over the range of 0 to ~250 μM. Metabolic incorporation usually does not increase significantly above 250 μM for peracetylated analogues but the 'real' upper limit for media supplementation is typically determined by dose limiting toxicity (DLT), which can range between 50 to > 700 μM depending on the cell line [48], the *N*-acyl substituent [47], and cell density [46]. Generally, DLT is not observed for free hydroxyl monosaccharides and concentrations up to 50 mM [65] or higher [55] result in increasing surface display and intracellular metabolite production. When analogue concentrations approach 100 mM, however, further maximization of metabolic uptake is not possible due to the deleterious effects of such high levels of solute.

2.5.2 Animal Tests

The evaluation of MOE technology in vivo has taken place almost entirely in rodent models with several mouse and rat studies having been reported. A striking feature shared amongst many studies is that analogue metabolization is highly organ- and tissue-specific for analogs

ranging from ManNProp (**13**), ManNBut (**21**), and ManNPent (**22**) [17,66] to Ac_4ManNAz (**34**) [67]. It remains unclear if pharmacokinetic factors are primarily responsible for differences in incorporation where organs that simply receive more analogue experience higher levels of metabolic replacement. For example, the heart receives high levels of blood flow suggesting it would be exposed to high levels of analogue, which is consistent with the high levels of sialic acid replacement observed for this organ in a recent study by Gagiannis and coworkers [50]. In this study the brain—hypothesized to have low incorporation because it is a privileged compartment due to the blood brain barrier [22,67]—had very low incorporation of Sia5Prop (**29**). This study, however, revealed the complexity of analogue metabolism in vivo by showing that PSA production was down-regulated in brain Ac_4ManNProp (**35**), thereby indicating that the analogue was not excluded from this organ after all. Instead, the brain was able to avoid the most common biological response to this analogue [i. e., glycan incorporation of Sia5Prop (**29**)] while directing a less common outcome (i. e., inhibition of PSA production [68]). As more information becomes available, including the ability of rodent B cell glycoproteins to become robustly labeled with Ac_4GalNAz (**36**) exposure while T cell glycoproteins were not [22], it is becoming clear that fundamental differences in the glycosylation machinery or metabolism exist between even very similar cell types.

2.5.3 Bacteria, Plants, Insects, and Yeast

Bacteria, yeast, plants, or insect cells have not been extensively investigated as hosts for MOE. However, there are hints—and in some cases pilot studies—that each of these cell types may be amenable to incorporation of non-natural sugars. For example efforts to 'humanize' glycoprotein production in yeast [69] and insect cells [70], to metabolically engineer carbohydrate production in bacteria [71], and to investigate sialic acid production in plants [72] delve in depth into pathway analysis of the type required to design analogues to intercept specific pathways at defined points (see *Sect. 3*). Already there have been reports that sialylation of recombinant proteins can be increased in insect cells through supplementation with ManNAc analogs [73]. The manipulation of carbohydrates in bacteria has also been achieved through the ingenious use of MOE. To briefly highlight two prokaryotic results, Schilling and coworkers demonstrated the biosynthesis of lipooligosaccharides in *Haemophilus ducreyi* with modified sialosides bearing extended *N*-acyl moieties. In *H. ducreyi*, unlike mammalian cells, analogue incorporation was dependent on exogenous sialic acids and could not be achieved with modified mannosamines [28,29]. In a second pilot study targeting oligosaccharide display on the surfaces of bacteria, Nishimura's group synthesized UDP-MurNAc pentapeptide derivatives that were incorporated into cell wall components of *Lactobacilli plantarum* [30,31,74].

3 Glycosylation Pathways and Analogues Used in MOE

This section will systematically discuss the various glycosylation pathways that have been targeted by MOE to date, using the well-studied sialic acid pathway to illustrate several aspects of analogue design and utilization. After that, efforts to extend MOE to GalNAc, fucose, and GlcNAc will be summarized followed by a brief discussion of glycosylation inhibitors that share mechanistic similarities with 'conventional' MOE analogues.

3.1 Metabolic Precursors for the Biosynthesis of Cell Surface Sialosides

3.1.1 Overview of Sialic Acid Biosynthesis and Biological Function

The sialic acid biosynthetic pathway, which consists of the enzymes, transporters, and metabolites shown in *Fig. 4* and described in detail elsewhere [18,75], was exploited to pioneer both the basic concept of MOE [17] as described in *Sect. 3* as well as the subsequent development of the cell surface chemoselective ligation technology [20,76] described in *Sect. 4*. As a brief background, sialic acids are attractive candidates for MOE for several reasons. First, these sugars are usually terminal residues situated at the non-reducing ends of oligosaccharides. Consequently, they are located at the outer periphery of the glycocalyx and are ideally positioned to interact with other cells, signaling molecules such as Siglecs or cytokines, pathogens, or exogenously supplied chemoselective ligation reagents. The sialic acid biosynthetic pathway is also attractive for MOE because it is unusually permissive to substrate alterations, perhaps because Nature already exploits sialic acid biosynthesis with a type of MOE where over 50 different naturally occurring structural variations are introduced into this sugar (*Fig. 5*) [77]. The most abundant sialic acid in man is 5-acetamido-D-*glycero*-D-*galacto*-2-nonulosonic acid (Neu5Ac, **9**). The 5-glycolylamido derivative *N*-glycolyl-D-neuraminic acid (Neu5Gc, **37**) is common in most other animals and the non-aminated 3-deoxy-D-*glycero*-D-*galacto*-2-nonulosonic acid (KDN, **38**) is found in many other biological systems [78,79]. Besides of these three common sialic acids, additional natural modifications typically involve mono-acetylation of hydroxyl groups, most often at the C-9 position, although di- and tri-*O*-acetylated derivatives also occur along with other variations that range from lactoylation or phosphorylation at C-9 to methylation or sulfation at C-8 [80].

Several functional consequences of Nature's MOE of sialic acid are already well known; in particular, biological responses to the selective display of Neu5Ac (**9**) and Neu5Gc (**37**) are profound. Differential incorporation of these two sugars, which vary only by the absence or presence of a hydroxyl group appended to the *N*-acyl chain, have been suggested to play roles in human evolution both far in the past by affecting brain development [81] and more recently through persistently changing patterns of Siglec recognition [82]. MOE technology extends the repertoire of chemical changes that Nature uses to tune the chemical and functional properties of sialic acid. For example, in the early experiments, ManNProp (**13**) was used to substitute the hydroxyl of **37** with a methyl group [17]. Even though the resulting structural change to sialic acid structure was modest, **13** elicits a gamut of biological responses not found with natural sialic acids (as discussed below in *Sect. 3.1.4*).

A second layer of complexity that both confounds and increases the potential ability of MOE experiments to modulate biological responses lies in the various glycosidic linkages of sialic acid (*Fig. 6*). In humans, which only express a subset of these linkages (α-2,3-, α-2,6-, and α-2,8-), 20 sialyltransferases (STs [51]) work in parallel to install sialic acids onto glycoproteins and lipids. The structural importance of each linkage is illustrated by binding preference

of influenza viruses that show exquisite discrimination between α-2,3- and α-2,6-linked sialic acids [83,84] and can rapidly evolve binding specificity for one linkage over the other [85]. Because of the biological repercussion of sialic acid display in these different linkages, it is likely that certain MOE applications will require careful control to partition metabolic analogues between the various glycosidic linkages. Achieving this objective will be challenging

Figure 6
Glycosidic linkages of sialic acid. In mammals the nucleotide sugar donors 52 and 53 are used to supply sialic acids 9 and 37 that either α-2,3- or α-2-6-linked to Gal and GalNAc or α-2-8-linked to an underlying sialic acid. The human sialyltransferases responsible for each linkage are listed with detailed information given elsewhere [51]. Linear homopolymers of 9 and 37, either α-2,8-, α-2,9-, or alternating α-2,8-/α-2,9-linked, have been found in glycoproteins of embryonic neural membranes and neural cell adhesion molecule, fish eggs, and certain bacteria. Polymers of 37 have also been found in sea urchin eggs linked through the glycolyl hydroxyl group resulting in α-2,5-linkages

because of several factors that could, in theory, skew analogue distribution. For example, the SCFA groups used to increase metabolic uptake of ManNAc alter patterns of ST expression [52]. In addition, the Km of each ST for various nucleotide sugar donors (i. e., for CMP-Neu5Ac (**52**) vs. CMP-Neu5Gc (**53**) vs. CMP-Neu5Prop (**54**), or for the other sialosides shown in ❯ *Table 2*) may be different resulting in predominant or disproportional display of a non-natural sialic acid in a particular linkage or on a subset of proteins or lipids. In the future, once these complex effects are better understood, it may be possible to exploit them to gain exquisite control over biological function. At present, in the absence of definitive information, we include this discussion as a cautionary note if MOE results in otherwise inexplicable biological outcomes.

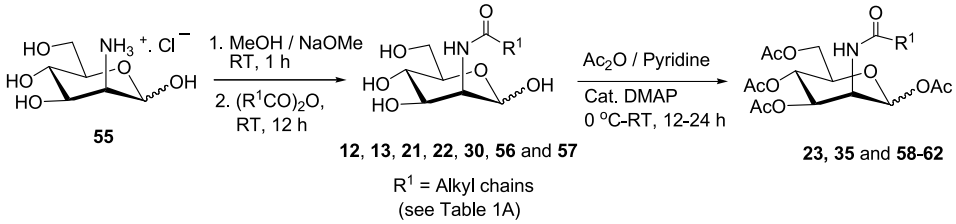
3.1.2 ManNAc Analogues Exploit Feedback Inhibition of GNE for Efficient Sialoside Display

The epimerization of UDP-GlcNAc to ManNAc (**12**) by UDP-GlcNAc 2-epimerase/ManNAc 6-kinase (GNE) is the first committed step in sialic acid biosynthesis (❯ *Fig. 4*) [86]. Because there are no other known fates for **12** (with the possible exception of conversion to GlcNAc in cells over-expressing recombinant renin-binding protein [87] that was later found to have C-2 epimerase activity for hexosamines [88]), sialic acid biosynthesis is uniquely targeted by ManNAc analogues. Importantly from a practical perspective, ManNAc analogues feed into the biosynthetic pathway directly downstream of the point of feedback inhibition, allowing

incorporation with reduced competition from the incoming flux of natural **12**. The importance of diminished metabolic competition is illustrated by experiments where exogenously added **12** effectively out-competed non-natural analogues for transit through the pathway [65]. Similarly, the sialuria form of GNE [89], which is not subject to stringent feedback inhibition and therefore allows a high level of UDP-GlcNAc to be converted to **12** [90], ablates surface expression of sialic acid analogues from non-natural ManNAc precursors [91]. Conversely, cells with inactive forms of GNE that are consequently unable to produce endogenous **12** are superior hosts for replacement of surface sialic acids with their non-natural counterparts [92,93].

3.1.3 The 'First Generation' ManNAc Analogues had Elongated *N*-Acyl Alkyl Chains

The application of MOE to sialic acid was pioneered by Reutter and coworkers who synthesized ManNProp (**13**), ManNBut (**21**), and ManNPent (**22**), the three, four, and five carbon homologues of ManNAc, respectively (*Scheme 2* and *Table 1*A) [17,24]. These compounds were converted into their respective sialic acids by living cells without affecting their growth rate or viability and into the sialosides of rodents without any notable toxicity [50]. In subsequent experiments, limits to the permissivity of the sialic acid pathway in mammalian cells were probed by using the extended *N*-acyl chain analogues ManNHex (**30**), ManNHept (**56**), and ManNOct (**57**) (analogues with longer alkyl chains than **57** tend to form micelles under aqueous conditions). In human cells, longer chain derivatives beyond the straight chain 'Hex' substituent, as well as analogues with branching side chains [25,63], show negligible flux through the sialic acid pathway [47] or incorporation into sialoglycoconjugates [63]. Interestingly, however, the bulky *N*-phenylacetyl form of ManNAc (**72**) was efficiently used by human cancer cells and incorporated into ganglioside GM3 [25].



Scheme 2

3.1.4 Biological Responses Supported by ManNProp, ManNBut, and ManNPent

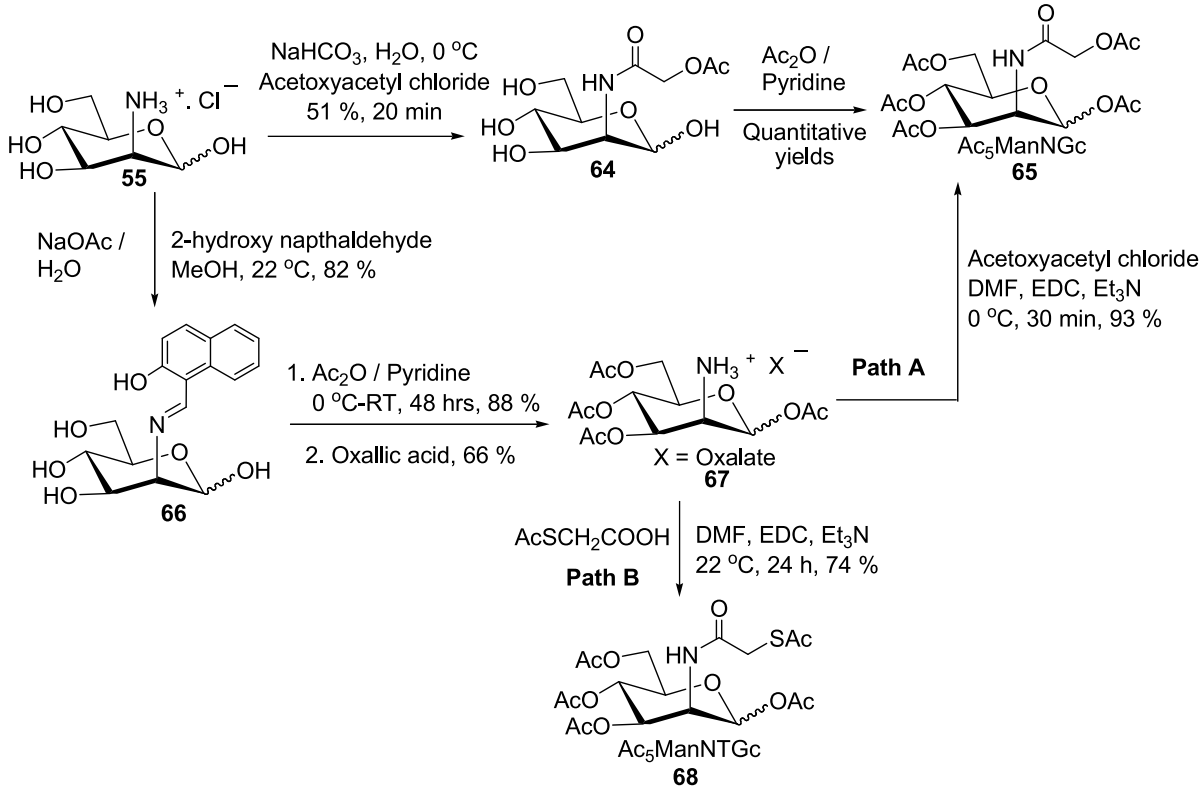
Although the primary focus of this paper is not to provide an in depth analysis of the surfeit of biological responses to analogues, the ability of these compounds to intervene in many aspects of cell biology is critical to propelling the field forward and to justifying continued research in this area. Consequently, by using the seminal ManNProp (**13**), ManNBut (**21**), and ManNPent (**22**) analogs as exemplars, we briefly survey biological responses to these compounds.

First, considering that many viruses, including HIV and influenza, have binding specificities determined by sialic acid, **13**, **21**, and **22** offer broad—and usually inhibitory—perturbation of viral binding and infectivity that may provide therapeutic options against the looming threat of global pandemics [18,94]. Certain analogs, for example **13**, have also shown potential as anticancer drugs through their incorporation into polysialic acid [95] or gangliosides [25], where they function as tumor-specific antigens [57]. Analogues **21** and **22**, by virtue of their ability to inhibit PSA production [96] by incorporation of non-natural sialosides into the nascent polymer that in turn terminates further elongation [68], may also find roles in cancer therapy. Although these therapeutic applications remain in the early stages of development, ManNAc analogues have already become valuable research tools. For example, the reversible inhibition of PSA expression with these small molecules [68] is a powerful tool for studying the role of this epitope in neuronal development [96,97,98] and tumor-related processes [95]. Similarly, fibroblasts cultured in the presence of **13** experienced suppression of contact-dependent growth inhibition [99] providing early evidence of sialic acid's role in linking cell adhesion with signaling.

Many of the profound biological consequences of *N*-acyl modification of sialic acids are anticipated. For example, the snug fit of the *N*-acyl side chain into the binding pocket of hemagluttin of influenza virus [100] portended the results—predicted by thermodynamic considerations [18]—where increased steric bulk at this submolecular site inhibited influenza A virus infection by as much as 80% [101]. In other cases, biological responses to MOE analogues have been unanticipated; for example, **13**, **21**, or **22** sometimes increased viral binding or infectivity. Even more puzzling have been reports that **13** can alter the expression of genes such as integrins at the mRNA level [102]. One possible explanation is that the transit of non-natural metabolites through the nucleus affects transcription. A second possibility is that cross-talk between sialic acid on the cell surface and signaling pathways upstream of gene expression are modulated by this analogue. Either way, solving this puzzle is sure to provide added insights into the biological roles of sialic acid and may provide novel methods to control the relevant molecular systems.

3.1.5 Introduction of Neu5Gc and Neu5TGc into Glycans

As mentioned earlier, every day Nature in effect uses MOE technology in humans who consume meat or animal products to restore man's lost ability [82] to biosynthetically install the Neu5Gc (**37**) form of sialic acid into human glycans. The cell surface display of dietary **37** demonstrates that the substitution of a hydroxyl group on the *N*-acyl side chain is tolerated by late steps in the pathway. In the laboratory, MOE experiments show that the installation of **37** onto human cells can also be accomplished with Ac_5ManNGc (**65**), a compound that can be synthesized by the route shown by Path A in ❯ *Scheme 3* [52]. In neurons, the presence of **37** abrogated binding of the myelin-associated glycoprotein [103], an event implicated in the inhibition of nerve regeneration after injury, thereby opening the door to new approaches for the regeneration of damaged nerve tissue. On the basis of the precedent established by dietary **37** as well as by **65** for pathway permissivity for hydrophilic groups located at the termini of the *N*-acyl chain, our laboratory synthesized the *N*-thioglycolyl counterpart Ac_5ManNTGc (**68**) (❯ *Scheme 3*, Path B) [52,104]. A key feature of Neu5TGc (**69**), the surface product of **69** is that, unlike the alkyl chain and hydroxyl analogues discussed above, an orthogonal chemical



Scheme 3
Synthesis of glycol- and thiol-containing ManNAc analogues

reactivity—the thiol group—is installed in the unique location of the glycocalyx. As such, **68** builds on the work initiated by the Bertozzi lab and described below in more detail to introduce new chemical functionalities onto the cell surface that can be exploited via chemoselective ligation reactions.

3.1.6 Introduction of Orthogonal Chemical Functional Groups into ManNAc Analogues

The 'first generation' ManNAc analogues used in MOE displayed relatively simple alkyl chain extensions devoid of chemical reactivity. In follow-up experiments, structural diversity was increased by the use of branching and ring structures (● *Table 1*C), as well as chemical functional groups already common in sugars such as the hydroxyl of Neu5Gc (**37**). While these compounds were valuable for diverse purposes ranging from cancer immunotargeting [25,57] to altering receptor-binding interactions [56,103], the efforts of the Bertozzi group to exploit metabolic processes to incorporate orthogonal, reactive functionality into cell-surface glycoproteins added an important new dimension to MOE. In the groundbreaking experiments, a mannosamine analogue derivatized with a levulinoyl side chain (ManNLev, **14**) was synthesized from the commercially available mannosamine hydrochloride (● *Scheme 4*) [20]. The key feature of ManNLev was the presence of the ketone group in the *N*-acyl levulinoyl ('Lev') moiety that is foreign to the cell surface and will readily undergo selective reaction with chemoselective ligation agents such as aminooxy, hydrazide, or related functional groups to form stable covalent adducts. Following the synthesis of ManNLev, several additional ketone-derivatized ManNAc analogues (**31**, **82–91**, shown in ● *Table 1*D) have been reported.

In the continuing expansion of MOE, additional ManNAc analogues containing orthogonal functional groups for glycocalyx display include the aforementioned thiol groups of Neu5TGc and the azide groups of ManNAz (**33**) and the peracetylated counterpart Ac_4ManNAz (**34**) (● *Scheme 5*). The display of azides via the analogues shown in ● *Table 1*E is particularly attractive from a chemical standpoint because unlike ketones (that exist inside a cell) or thiols (that occur ubiquitously in a cell with the exception of the glycocalyx) these groups are completely abiotic and can be exploited for orthogonal reactions intracellularly, on the cell surface, or even in the extracellular matrix. To recap, the display of ketones, azides, or thiols is fundamentally different than alkyl chains or hydroxyl groups. While the latter groups have the remarkable ability to influence sialic acid-specific biological activities, the analogues containing functional groups not naturally present in sugars install new chemical reactivity onto the cell surface.

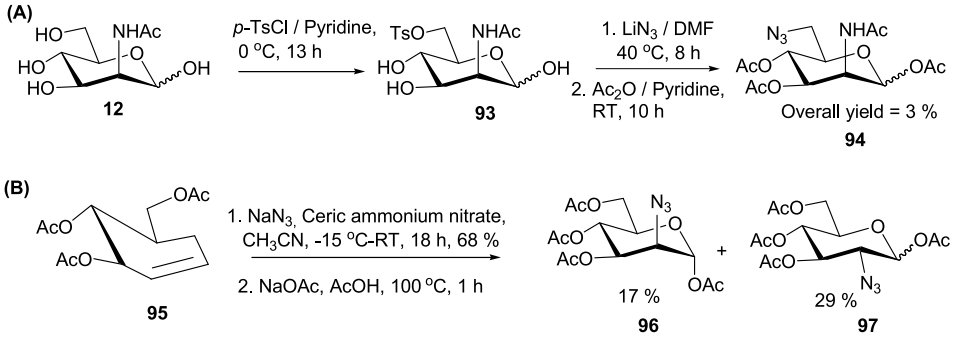
Synthesis of Ac_4ManNAz (34)

3.1.7 Structural and Biochemical Considerations that Determine Flux Through the Pathway

As briefly discussed above, and as described in more detail in our publications where a panel of analogues with ketone-containing *N*-acyl groups that varied in length or steric bulk were evaluated [47,63], the sialic acid pathway has an impressive but ultimately limited ability to accommodate non-natural metabolic intermediates. As a consequence of these limitations, analogue design requires careful consideration; to illustrate this point, when installing orthogonal functional groups, azide groups at the *N*-acyl position of ManNAc (i. e., ManNAz, **33**) are more efficiently accommodated by the pathway than the ketone groups of ManNLev (**14**). Another critical aspect of analogue design is that the functional groups can only be accommodated at certain positions on the monosaccharide backbone. This point is illustrated by comparing the effects of an azide group attached to the C-6 carbon of ManNAc or directly appended to the C-2 carbon instead of being displayed on the *N*-acyl chain of **33**. The two former compounds, 6-azido ManNAc (**94**) and 2-azido mannose (**96**), were synthesized by Saxon and coworkers as shown in *Scheme 6*, A and B, respectively [23] and resulted in greatly reduced or negligible surface display of azide groups compared to **33** [23].

An understanding of the biochemical conversions imposed on each metabolite along a biosynthetic pathway can lend insight into the mechanism of inhibition and suggest alternative strategies to bypass problematic steps. For example, after UDP-GlcNAc is converted to ManNAc, phosphate is installed on the C-6 hydroxyl group by GNE. Analogues such as



Scheme 6
Synthesis of C-6 and C-2 azide-modified mannose derivatives

6-azido ManNAc cannot undergo this reaction because of a lack of a C-6 hydroxyl, and combined with the enhanced conversion of phosphorylated intermediates to sialic acid (non-phosphorylated analogs have ~30-fold lower conversion rates to sialic acid [105]), it is not surprising that overall flux of such compounds through the pathway is low. Of note, Jacobs and coworkers showed that even when the C-6 hydroxyl is present, phosphorylation of this group remains the rate limiting step of the pathway [63]. Identification of ManNAc 6-kinase processing as a bottleneck for the sialic acid pathway provides options, discussed next and outlined in *Fig. 4*, for intercepting the pathway at other points to increase overall flux.

3.1.8 Sialic Acid Analogues—Bypassing Metabolic Pathway Bottlenecks

Once early steps in sialic acid biosynthesis were implicated as rate-limiting bottlenecks in the metabolic pathway, an obvious strategy to increase the flux of recalcitrant analogues was to intercept the pathway downstream of these chokepoints. Taking advantage of the ability of sialyltransferases to utilize CMP-9-fluoresceinyl-Neu5Ac (**103**) [106] and other modified CMP-Neu5Ac groups including those with photoactivatable appendages (*Table 2*) [107,108,109,110], interception of the pathway at the nucleotide sugar stage (*Fig. 4*) allowed highly permissive substitutions to be made in living cells [111,112]. Importantly, the use of CMP-sialic acid analogues bypassed the C-6 phosphorylation requirement of ManNAc analogues, allowing metabolic engineering of the C-9 position of sialic acids. A serious drawback to the use of nucleotide sugars for MOE was the membrane impermeability of these compounds that limited initial uptake into a cell as well as the subsequent subcellular localization to the lumen of the ER or Golgi where glycosyltransferases reside. The requirement for Golgi localization necessitated the use of permeabilized cells for experiments with non-natural CMP-sialic acids [111,112], which severely compromised cell viability and precluded in vivo applications.

Scheme 7
Synthesis of C-5 modified sialic acids

To avoid the difficulties inherent in using CMP-sialic acids for MOE, sialic acid analogues that can be synthesized with modifications at the C-5 (› *Scheme 7*, [57]) or other (› *Table 3*) positions, were tested. Because sialic acids including both **9** [113] and **37** [114] are efficiently taken up by cells [56], the introduction of analogues at the sialic acid stage of the pathway (see › *Fig. 4*) offered the dual advantages of bypassing rate limiting steps early in the pathway and avoiding the need to permeabilize cells for uptake. Illustrating the metabolic advantages of sialic acid analogues a specific example, the ability of Ac_4ManNLev (**87**) to inhibit sialic acid production in human cells [47] implied that the use of keto sialic acids would result in a higher

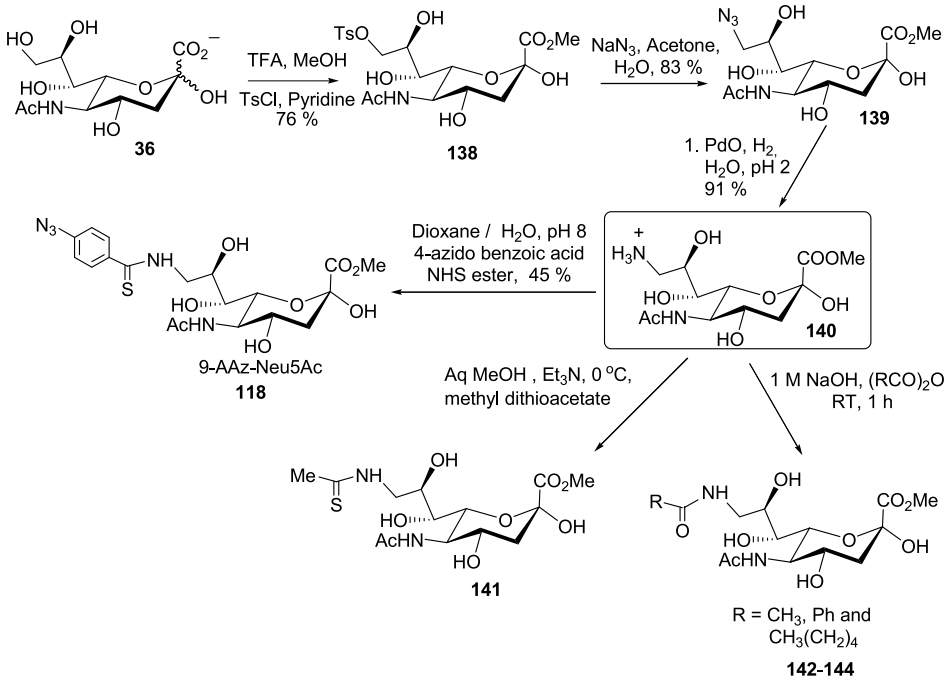
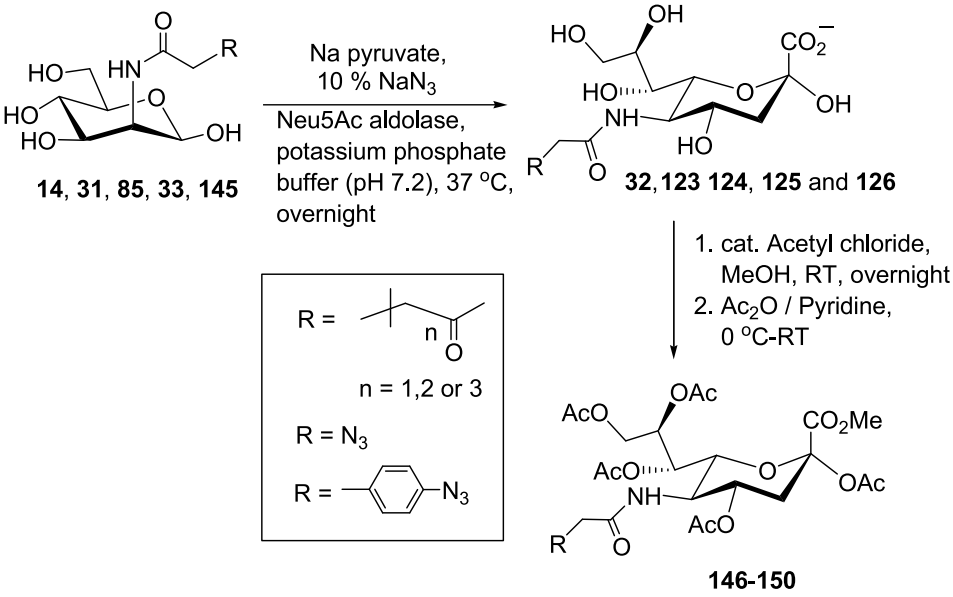
level of cell-surface ketones than the corresponding keto mannosamine analogues. Upon testing of the levulinoyl analogues, the sialic acid derivatives **32**, **123**, and **124** produced three times more cell-surface ketones than the corresponding ManNAc analogues **14**, **31**, and **84**. In contrast to the trend observed with these ketone derivatives, the azido-bearing mannosamine and sialic acid compounds (**125** and **126**) showed similar metabolic efficiency. This finding might derive from the fact that ManNAz is processed by sialoside biosynthetic enzymes considerably more efficiently than ManNLev [23] thereby masking any further gains realized by pathway interception at the sialic acid stage. Finally, even though sialic acid analogues are taken up by cells with reasonable efficiency [56], peracetylated sialic acids are utilized by cells between eight- and 20-fold more efficiently than their unprotected counterparts [115], suggesting that SCFA-derivatization (*Sect. 2.3*) is valuable for MOE experiments with this class of compounds.

3.1.9 ManNAc vs. Sialic Acid Analogues—Practical Considerations Prefer ManNAc Usage

As discussed above, the interception of the sialic acid pathway at the CMP-sialic acid stage offers tremendous versatility for functional group incorporation but is not compatible with living cells. By contrast, sialic acid analogues are efficiently taken up by cells and generally offer superior flux compared to the corresponding ManNAc analogues (although in some cases, such



Scheme 8
Synthesis of C-9 modified sialic acids



Scheme 9
Synthesis of modified sialic acids by aldolase-catalyzed condensation

as the azido derivatives, rates of metabolic processing are similar). Despite the apparent superiority of sialic acid analogues, a perusal of the literature reveals that ManNAc analogues have been used more often in MOE experiments. One answer for this apparent disparity between theory and practice is the ready availability and facile chemical synthesis of ManNAc analogs (as shown by examples given in Schemes 1 to 6) compared to the relatively difficult de novo chemical synthesis of the corresponding sialic acids.

In some cases, the direct synthesis of sialic acid analogs, such as that of 9-AAz-Neu5Ac (**117**) is fairly straight-forward (*Scheme 8*) [116]. More often, however, the synthesis of sialic acids is laborious, as exemplified by the 16-step synthesis required to produce modified forms of this sugar from the readily available starting material D-Glc [117]. Not surprisingly, the difficulty of purely synthetic approaches spurred efforts to obtain sialic acid analogues by neuraminic acid (Neu5Ac) aldolase-catalyzed condensation of pyruvate and the corresponding ManNAc analogue (*Scheme 9*) [118]; many of the mannosamine derivatives shown in *Table 1*D and *Table 1*E [119] were derived by this route. A difficulty with chemoenzymatic syntheses of sialic acid analogues, however, is the limited substrate permissivity of Neu5Ac aldolase as illustrated in attempts to prepare nitrogen isosteres, such as **152**, of Neu5Ac [117] from a series of C-3 nitrogen-functionalized ManNAc derivatives (e. g., **151**) [120]. In these experiments, as well as in other studies [121], C-3-substituted ManNAc derivatives did not serve as substrates for Neu5Ac aldolase. In summary, unless sialic acid analogues are required for organisms such as *H. ducreyi* that do not convert ManNAc into sialic acids [28,29], the modest gain in metabolic efficiency generally does not justify the extra effort required for the production of modified sialic acids.

3.2 Metabolic Precursors for the Substitution of GalNAc in Mucins and GAGs

3.2.1 Overview of Mucin Biology

N-Acetyl-D-galactosamine (GalNAc, **6**) is abundant in many natural glycoconjugates including those from higher eukaryotes where this sugar is attached to the hydroxyl group of Ser/Thr side chains by α-linkage and provides the foundation for 'mucin-type' glycoproteins. 'Muco-proteins' and 'mucopolysaccharides' have been studied since the early 1800s when the term 'mucin' was first used by Nicolas Theodore de Saussure in 1835 to describe substances isolated from mucus [122]. By 1865 Eichwald had determined that mucins were a combination of protein and carbohydrate with the sugar components often encompassing more than 50% of total mass. More recently, in 1969 Weissman and Hinrichsen reported that the carbohydrates of mucins were attached to the peptide by an α-GalNAc linkage by analyzing purified α-*N*-acetylgalactosaminidase from bovine liver [123]. Subsequent structural studies using atomic force microscopy (AFM) [124], light scattering [125], and nuclear magnetic resonance (NMR) spectroscopy [126] have demonstrated that clustered *O*-linked glycosylation results in extended protein structures up to hundreds of nanometers in length [127]. In the past three decades, more than 150 different mucin-type *O*-linked glycans have been isolated and identified [128].

3.2.2 Metabolic Pathways Responsible for Replacement of GalNAc with Analogues

An ever-increasing number of biological processes are now attributed to *O*-linked glycans ranging from lymphocyte homing [129,130] to roles in diseases from Wiskott–Aldrich syndrome [127], to hematological disorders [131] and cancer [132]. Considering the biological importance of *O*-linked glycans, together with the limited specificity of lectins for binding the diverse array of *O*-linked glycan produced by mammalian cells, proteomic analysis of *O*-linked glycosylation remains difficult. Consequently, the metabolic incorporation of non-natural monosaccharides that bear unique functional group handles such as ketones or azides has gained tremendous attention as a method to analyze *O*-linked glycans. In order to accomplish this objective through MOE, a detailed knowledge of the metabolic pathways that process GalNAc, similar to the considerations discussed above for sialic acid modulation, is of value when planning the point of pathway interception.

Mucin-type *O*-linked glycoproteins result from the biosynthetic efforts of a family of GalNAc transferases (ppGalNAcTs) that use UDP-GalNAc as the nucleotide donor for attachment of the sugar to a protein substrates [133]. UDP-GalNAc can be obtained for use in glycan assembly through epimerization from UDP-GlcNAc as well as via salvage pathways (*Fig. 7*). Consequently, two options exist for exogenous supplementation with GalNAc-targeting analogues. The first, and poorer, option is to feed analogues into the hexosamine (see *Fig. 9*, below) or salvage pathways that lead to UDP-GlcNAc production. This alternative, however, may not be desired because UDP-GlcNAc has multiple metabolic fates in addition to epimerization to UDP-GalNAc which include sialic acid biosynthesis (*Sect. 3.2*) and *O*-GlcNAc protein modification (*Sect. 3.5*). The second option is to target GalNAc salvage pathways

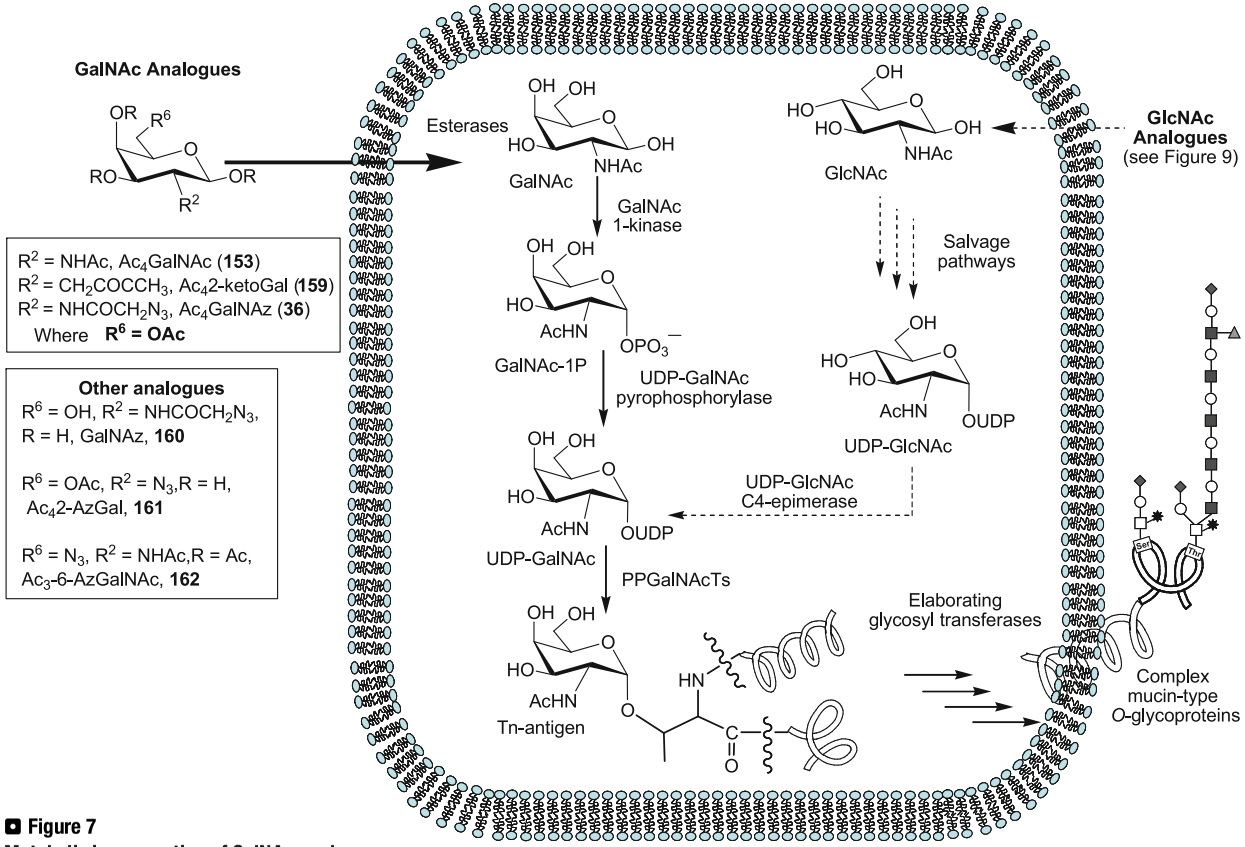


Figure 7
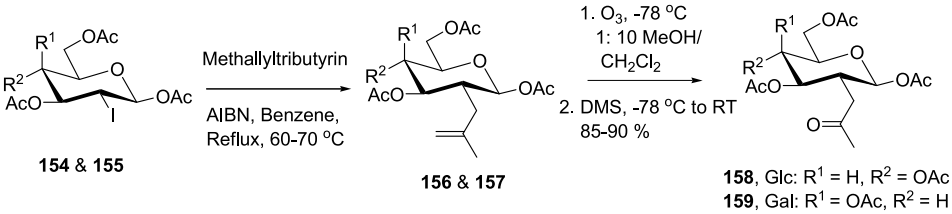
Metabolic incorporation of GalNAc analogues



Scheme 10
Synthesis of '2-ketosugars'

directly. Using this strategy, Hang and Bertozzi synthesized (*Scheme 10*) '2-ketosugars', which are C2-carbon isosterates of the 2-acetamidosugars of GlcNAc (**158**) and GalNAc (**159**), and demonstrated incorporation into *O*-linked glycans, and possibly into GalNAc-containing GAGs (*Fig. 1*) [26]. These analogues possessed a ketone group, similar to keto ManNAc analogues that target sialic acid for metabolic replacement (*Sect. 3.1.6*), that allows chemoselective reactions with aminooxy- or hydrazide-bearing reagents (*Sect. 4.2*). In addition, the GalNAc analogues discussed in the next section can be exploited for tagging mucin-type *O*-linked glycans with azides, which then can be selectively reacted with phosphine reagents for proteomic analysis (*Sect. 4.3*).

3.2.3 Optimizing GalNAc Analogue Structure

Although fewer studies have been done to optimize GalNAc analogue metabolism compared to the detailed exploration of the substrate specificity of the ManNAc pathway outlined above, a rudimentary indication of pathway permissivity has been gained from a comparison of azido GalNAc analogues. In particular, the metabolic incorporation of *N*-azidoacetyl-D-galactosamine (GalNAz, **160**) or the peracetylated counterpart 1,3,4,6-tetra-*O*-acetyl-*N*-azidoacetylgalactosamine (Ac_4GalNAz, **35**), into mucin-type *O*-linked glycans in a variety of mammalian cell lines has been demonstrated in vitro and in animals [22]. By comparison, 1,3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-D-galactose ($Ac_4$2-AzGal, **161**), and 1,3,4-tri-*O*-acetyl-6-azido-6-deoxy-*N*-acetyl-D-galactosamine (Ac_3-6-AzGalNAc, **162**) were synthesized and their metabolic incorporation was compared with the former compounds in CHO cells. In these studies, cells treated with **35** demonstrated a 30-fold higher fluorescence than untreated cells whereas **161**- and **162**-treated cells did not exhibit fluorescence above the level of untreated cells suggesting that these two analogues are not effective substrates for the GalNAc salvage pathway.

3.3 L-Fucose Analogues

3.3.1 Overview of Fucose Pathways and Biology

Similar to sialic acid, L-fucose is usually displayed as a terminal sugar in glycans allowing it to readily participate in cell–cell interactions and modulate cell motility and migration processes connected with fertilization, embryogenesis, lymphocyte trafficking, immune responses, and cancer metastasis [134,135,136]. To date, many of the specific roles of fucose have been traced

to the fact that it is a critical component of the Lewis X (Le^X) trisaccharide epitope as well as the tetrasaccharide sialyl Lewis X (sLe^X) [137]. Over-expression of sLe^X is characteristic of many cancers [138] and this structure is also a determinant of the selectin ligands that mediate leukocyte-endothelial interactions at sites of inflammation [139]. Glycoproteins displaying Le^X promote embryonic cell adhesion and have important roles in neurogenesis [134]. Fucose is also a terminal sugar of many tumor-associated antigens and the multitude of fucosylated antigens up-regulated in cancerous tissue provides an opportunity to exploit these glycans as potential cancer biomarkers [140]. On the basis of these, and many additional, biological activities, the investigation of fucosylated glycans in health and disease is of great interest and the development of specific tagging methods to visualize and quantify fucosylated glycoconjugates in situ has become a subject of keen interest [16,141,142,143].

3.3.2 Targeting Fucose for Metabolic Replacement

Akin to the incorporation of dietary Neu5Gc sialic acid into cellular sialoglycans that presaged the use of sialic acid analogues in MOE, the finding that the congenital disorder of glycosylation (CDG) leukocyte adhesion deficiency II (LADII) could be corrected by oral supplementation [144] provided a foundation for applying MOE to fucose. An analysis of glycosylation pathways responsible for fucose display indicates two possibilities for the introduction of L-fucose analogues into glycoconjugates (*Fig. 8*). First, mannose can be converted to GDP-D-mannose and subsequently to GDP-L-fucose, suggesting that mannose derivatives have the potential to serve as fucose precursors. This possibility, however, was discounted by the lack of surface display of the 2-azido form of mannose (**96**) discussed in *Sect. 3.1.7*. The second option was the direct supply of fucose analogues, an approach that has now been successfully demonstrated by two laboratories. In one set of experiments, Bertozzi's group synthesized fully acetylated 6-azido (**164**), 2-azido (**165**), and 4-azido (**166**) analogues of peracetylated fucose [145]. All three compounds were evaluated for incorporation into glycoproteins in the human T lymphoma cell line Jurkat by labeling the analogue-treated cells with phosphine-bearing FLAG peptide [146] followed by staining with a FITC-conjugated α-FLAG antibody and analysis by flow cytometry. In these experiments significant fluorescence was only observed after treatment with **164** while compounds **165** and **166** did not label cell surface glycans. In a second set of experiments reported by the Wong laboratory [147], the 6-azido analogue was successfully incorporated along with the alkyne-bearing analogue **167**; in these studies new fluorescent probes were utilized to detect surface display in a one-step procedure as described in more detail in *Sect. 4.6*.

3.4 GlcNAc Analogues as Tools to Study *O*-GlcNAc Protein Modification

3.4.1 Surface GlcNAc Residues Are Refractory to Metabolic Replacement

Of the three common hexosamines found in mammalian cells, analogues of ManNAc and GalNAc are readily incorporated into surface glycans (as discussed in *Sect. 3.2* and *Sect. 3.3*, respectively). By contrast, GlcNAc analogues are largely refractory to incorporation into glycoconjugates with GlcNProp (**168**) [17], GlcNLev, **169** [65], and GlcNAz (**170**) [23] all showing dramatically lower surface display than the corresponding mannosamines (*Fig. 9*).

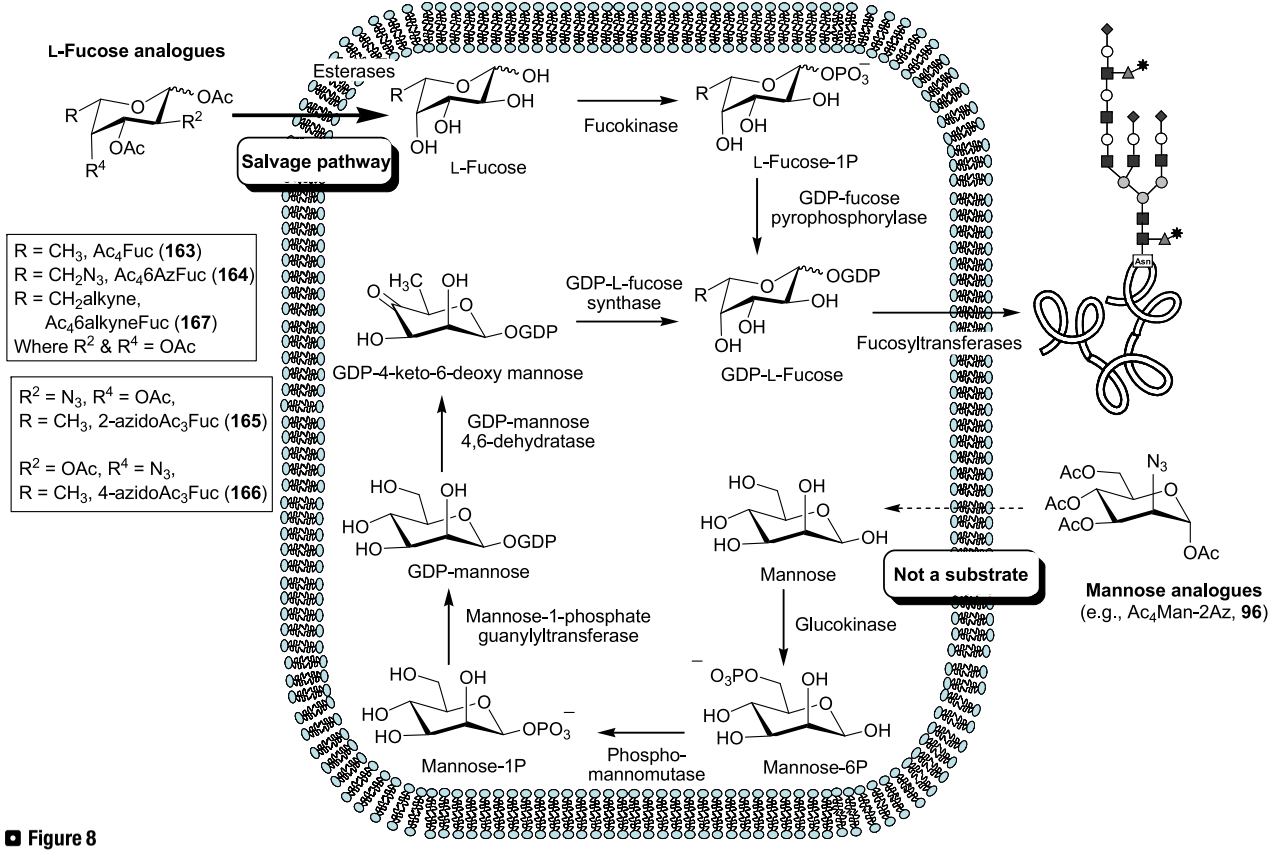


Figure 8
Metabolic incorporation of fucose analogues

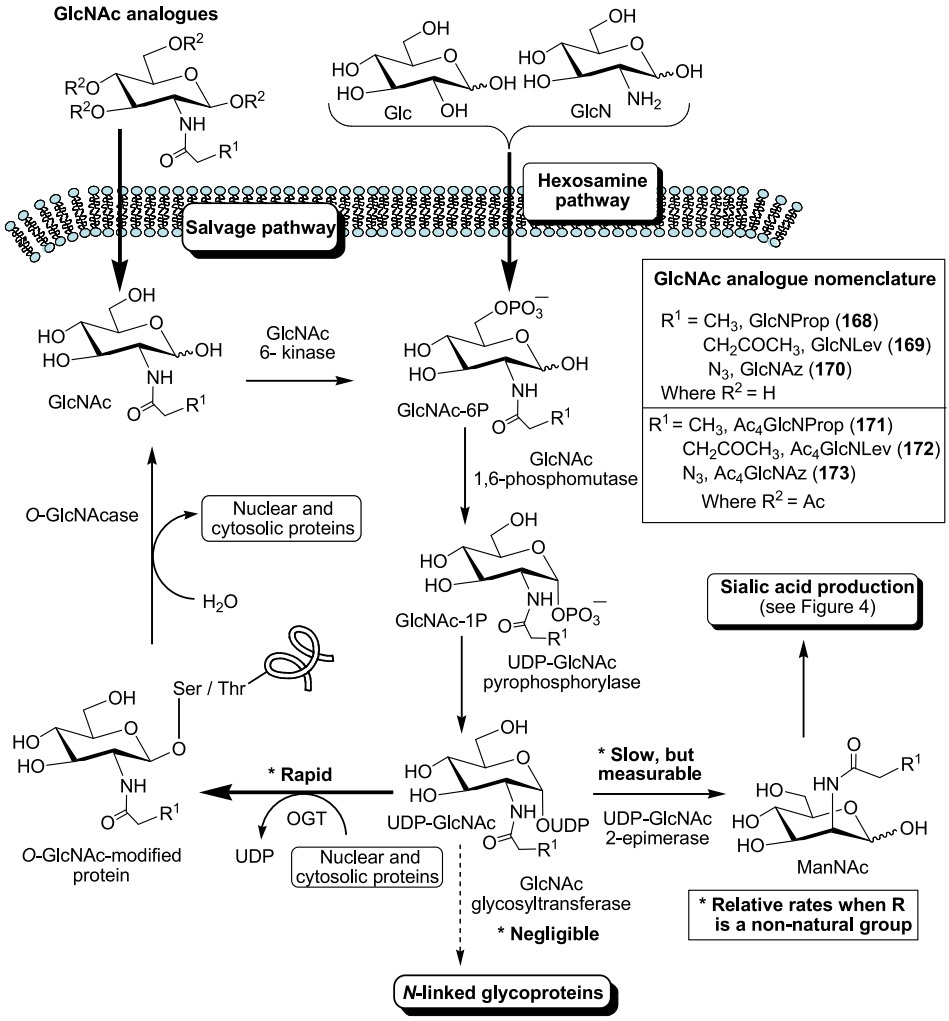

Figure 9
Metabolic incorporation of GlcNAc analogues

One possibility for the incorporation of GlcNAc analogues into glycans can be envisaged by considering the ability of the renin binding protein/GlcNAc 2-epimerase to interconvert GlcNAc to ManNAc [88] as shown in *Fig. 4*; in this case, the surface display of GlcNAc analogues would occur via incorporation into the sialic acid pathway. Evidence for surface display by this route has been shown for Ac_4GlcNAz (**173**), which was thought to be converted to ManNAz (**33**) after deacetylation followed by further conversion to Sia5Az (**125**) [23]. The relatively low level surface display of azide groups upon exposure to exogenous **173** compared to Ac_4ManNAz (**34**) suggested that the epimerization of **170** to ManNAz **33** was severely rate limiting. In theory, a second route to surface display of GlcNAc analogues is through the

salvage pathway after phosphorylation at the C-6 position [148] that, if amenable to non-natural substitutions, would produce UDP-GlcNAc analogues that could be incorporated into *N*-linked glycans directly or epimerized to UDP-GalNAc analogues for *O*-glycan display as diagrammed in ❯ *Fig. 9*.

The lack of incorporation of metabolites of **173** into cell surface glycoproteins via UDP-GlcNAc intermediates established that the GlcNAc salvage pathway was refractory to MOE [23]. Several explanations can be offered why a UDP-GlcNAc analogue such as UDP-GlcNAz (**174**) is not incorporated into surface glycans: (*i*) **174** may not be efficiently transported into the lumen of organelles of the secretory pathway, (*ii*) GlcNAc transferases may not tolerate the *N*-acyl modification of **174**, or (*iii*) **174** may be diverted into other pathways. Considering the latter possibility, UDP-GlcNAc can be converted to UDP-GalNAc or to ManNAc (❯ *Fig. 9*), thereby offering alternative routes to surface display. With the exception of possible conversion to ManNAc and glycan incorporation as sialosides, these options have been largely eliminated as efficient routes to the surface display of GlcNAc analogues. Interestingly, the surface inaccessibility of GlcNAc analogues has prompted the exploration of alternative uses for these MOE agents and they are now gaining acceptance as probes for *O*-GlcNAc protein modification. The significance of this emerging application is given below by briefly describing *O*-GlcNAc protein modification (❯ *Sect. 3.4.2*) and relevant analogue probes (❯ *Sect. 3.4.3*).

3.4.2 UDP-GlcNAc Is Used for *O*-Glycosylation of Cytosolic and Nuclear Proteins

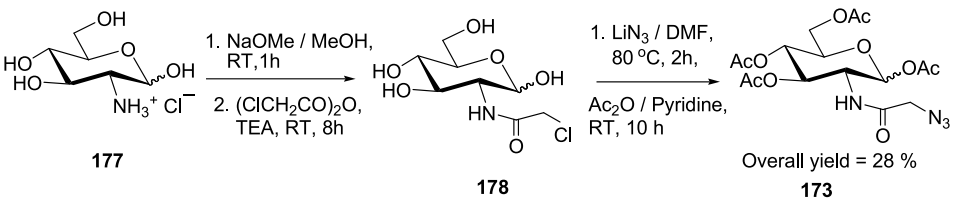
In 1984, Torres and Hart described a post-translational modification where Ser and Thr residues found in nuclear and cytoplasmic proteins were *O*-linked to GlcNAc through β-linkage [149,150]. *O*-GlcNAc was novel for two reasons: first, *O*-GlcNAc was not elongated into a more complex structure, with the possible exception of plant nuclear pore proteins [151]; second, it had a nucleocytoplasmic distribution, whereas 'traditional' glycoproteins had been localized to the cell surface and topologically equivalent intracellular compartments, such as the lumens of the endoplasmic reticulum and Golgi apparatus [152]. *O*-GlcNAc shares many similarities with protein phosphorylation in cellular regulation; for example, like phosphorylation, *O*-GlcNAc is highly dynamic with rapid cycling in response to cellular signals or cellular stages and often occurs at the same sites on the protein backbone that are modified by protein kinases [14]. Unlike protein phosphorylation, however, where 650 genetically distinct enzymes regulate the addition and removal of phosphate, just two catalytic polypeptides catalyze the turnover of *O*-GlcNAc; the uridine diphospho-*N*-acetyl-D-glucosamine: peptide β-*N*-acetylglucosaminyl transferase (OGT) adds the sugar residue to proteins and *O*-β-*N*-acetylglucosaminidase hexosaminidase (*O*-GlcNAcase) reverses the modification [15] (❯ *Fig. 9*).

In most organisms, *O*-GlcNAc protein modification is vital for life. It occurs ubiquitously across species with only the yeasts *Saccharomyces* and *Pombe* lacking biochemical or genetic evidence for *O*-GlcNAc protein modification [15]. Clues to *O*-GlcNAc function come from estimates that hundreds of proteins are subject to this modification, with substrates including cytoskeletal proteins, nuclear pore proteins, chromatin associated proteins, RNA polymerase II (RNA Pol II) and its transcription factors, hnRNPs, proto-oncogenes, tumor suppressors, hormone receptors, phosphatases, and kinases [14]. In essence, *O*-GlcNAc acts as a glucose

sensor, through the conversion of glucose to glucosamine and then to UDP-GlcNAc via the hexosamine biosynthetic pathway [13], that tune the activities of this diverse set of cellular players to environment conditions of the cell.

3.4.3 Chemically Tagged GlcNAc Analogues Can Be Used to Probe *O*-GlcNAc Modification

Despite numerous studies implicating *O*-GlcNAc modification of proteins as a modulator of cellular processes of critical importance to diseases such as diabetes [153], many aspects of *O*-GlcNAc modification including the complete repertoire of modified proteins and the specific sites of modification remain largely unknown. Indeed, although hundreds or even thousands of proteins are *O*-GlcNAc modified, relatively few have been identified and fewer still have had the specific glycosylated residues identified. Furthermore, no consensus sequence directing the *O*-GlcNAc modification of proteins to a particular Ser or Thr residue has been established on the basis of known modification sites. To help overcome these limitations, MOE methods based on bioorthogonal non-natural GlcNAc analogues are now proving to be important tools to assist in the characterization of *O*-GlcNAc and to study these protein modifications in cells. In particular, based on observations that compounds such as *p*-nitrophenyl 2-acetamido-2-deoxy-β-D-glucopyranoside (*p*NP-GlcNAc, **175**) act as a substrate for OGT with only a 35% decrease in the value of the apparent second-order rate constant and a 2-fold decrease in the value of *V*max relative to the native substrate, Vocadlo and coworkers synthesized peracetylated GlcNAz (Ac_4GlcNAz, **173**, ❯ *Scheme 11*) and the control compound *p*-nitrophenyl 2-azidoacetamido-2-deoxy-β-D-glucopyranoside (PNP-GlcNAz, **176**) [27]. The ability of OGT to tolerate the azido group remarkably well allowed the identification of specific proteins by the chemoselective ligation strategies discussed in ❯ *Sect. 4.3.2* that are undergoing continued development in a variety of 'tagging via-substrate' (TAS) methods [141,154,155,156] that complement more conventional proteomics tagging schemes used to identify *O*-GlcNAc modifications [157].



Scheme 11
Synthesis of GlcNAc analogues

3.5 MOE Offers Opportunities for Inhibition of Glycan Biosynthesis

MOE technology—which has been described so far as a method to provide alternative flux options through metabolic pathways and incorporate new sugar residues into cellular glycans—can also provide opportunities to *inhibit* glycan biosynthesis via three distinct mechanisms. The first is 'conventional' inhibition, wherein the activities of one or more path-

way elements are reduced. The second is the incorporation of non-natural sugar residues into a nascent glycan structure, which then terminates or retards subsequent biosynthesis. Finally, non-natural sugars can function as 'decoys' for synthesis. Each of these strategies is discussed next.

3.5.1 MOE Grew Out of Attempts to Inhibit Glycosylation Pathways

Taking a historical perspective, one foundation of today's MOE technologies grew from the efforts by Brossmer and colleagues about two decades ago, as discussed in *Sect. 3.1.8*, to exploit the substrate permissivity of sialyltransferases. Interestingly, another basis for MOE had already been established in living cells at that time from efforts to inhibit glycosylation pathways that date back to the 1970s. Even then it was clear that abnormal glycan production, most often over-expression, was associated with the transformed and malignant cells, leading to efforts to block oligosaccharide biosynthesis as a potential cancer therapy. Early attempts to use fluorine-modified and acetylated ManNAc analogues to block sialic acid production, however, resulted in the unplanned metabolic conversion of these non-natural compounds into the corresponding sialic acids [158,159]. As described in *Sect. 3.1*, Reutter and colleagues built on these findings by deliberately exploiting the substrate permissivity of sialic acid enzymes to achieve surface display on non-natural sugars [17]. The ketone-containing analog ManNLev (**14**) however, which was the prototype analogue used to install new chemical functionalities onto the cell surface [20], actually inhibits flux through the sialic acid pathway when used in its peracetylated form [47]. On the basis of these connections between MOE technologies and efforts to inhibit glycosylation, we will briefly describe ongoing developments in this area.

3.5.2 Inhibition of PSA via Metabolic Incorporation of ManNAc Analogues

As mentioned above, the Sartorelli group attempted sialic acid pathway inhibition over two decades ago by the conventional strategy of substituting protons and hydroxyl groups of the metabolic substrate, in this case ManNAc, with fluorine [158,159]. Even if these original attempts to inhibit flux through the sialic acid pathway had met their objective, they may not have translated into useful cancer therapies due to the many critical roles of sialic acid in healthy cells that would have been affected adversely. Consequently, subsequent efforts have attempted to achieve highly targeted effects on glycan production, not through inhibition of flux through the linear portion of the sialic acid pathway (*Fig. 4*), but rather by targeting a subset of sialyltransferases (*Fig. 6*). The strategy of targeting specific glycan epitopes is a daunting task but is reaching fruition for the fetal-oncogenic marker polysialic acid (PSA). In this case, incorporation of a run of up to five consecutive Sia5But (**127**) or Sia5Pent (**128**) residues into a nascent PSA chain as a consequence of ManNBut (**21**) or ManNPent (**22**) uptake, respectively, blocks further chain extension [68,96] (*Fig. 10A*). These analogues

have already served as important research tools for the discovery of the function of PSA in neuronal development [97,98]; in the future ablation of PSA expression in cancer [160] may prove equally significant.

3.5.3 Inhibition with Decoys

The concept of a 'decoy' inhibitor shares the basic similarity with MOE in that a non-natural sugar derivative introduced to a cell intercepts the glycosylation process. Glycan decoys were first demonstrated in 1973 when Okayama and coworkers showed that β-D-xylosides act as substrates for the assembly of glycosaminoglycans and thereby stimulate the synthesis of free GAG [161]. Subsequently, D-xylose, β-D-xylosides, and β-D-galactosides have been used as artificial initiators of chondroitin sulfate synthesis that enable polysaccharide-chain synthesis to be studied as an event separate from the synthesis of intact proteoglycan [162]. As a consequence of the biosynthetic efforts of a cell being diverted to non-naturally-primed glycan synthesis, these 'decoys' competitively inhibit the biosynthesis of glycosaminoglycan chains on their usual substrates, the endogenous proteoglycan core proteins (*Fig. 10B*). Interestingly, α- and β-xylosides can also prime the production of GM3-like compounds and thereby inhibit glycolipid biosynthesis [163]. In a similar way, aryl-*N*-acetyl-α-galactosaminides were later discovered to prime mucin-like oligosaccharides and alter the assembly of *O*-linked oligosaccharides on glycoproteins resulting in 1-benzyl-2-acetamido-2-deoxy-α-D-galactopyranoside (GalNAc-α-*O*-Bn, **179**) now being arguably the most well-known and most-utilized inhibitor of glycosylation [164].

Recently, efforts in decoy development have turned to the inhibition of specific glycoepitopes, such as the sLe^X ligand involved in key steps of inflammation and tumor metastasis. In the past, GalNAc-α-*O*-Bn (**179**) was used to inhibit the sialic acid or fucose components of sLe^X but, while this compound had the desired effect of suppressing both α-2,3-sialylation and α-1,3-fucosylation, it also dramatically increased α-2,6-sialylation and led to massive accumulations of truncated oligosaccharides [165] indicating an unacceptable lack of specificity. In subsequent experiments, increased specificity was achieved through the use of peracetylated disaccharides including Gal-β-1,3-GlcNAc (**180** and **181**), Gal-β-1,4-GlcNAc (**182** and **183**), GlcNAc-β-1,3-Gal (**184** and **185**), and Gal-β-1,3-GalNAc (**186** and **187**) with naphthyl or naphthyl-methene aglycons [41]. Later, peracetylated GlcNAc-β-1–3Gal-naphthalenemethanol (GlcNAcβ1–3Gal-NM, **188**) was found to have even greater potency and will inhibit sLe^X-dependent cell adhesion [43]. Thus, peracetylated disaccharides have distinct advantages over monosaccharide primers such as **179**, including greater specificity and efficacy at lower concentration that derives from the ability of these derivatives to efficiently cross the hydrophobic barrier of the cell and Golgi membranes and down regulate the expression of sLe^X ligands. Moreover, the ability of these compounds to suppress cellular adhesion events implicated in chronic inflammation and metastatic cancer eventually could be useful for treating immune disorders and ameliorating tumor progression.

4 Cell Surface Chemistry—Chemoselective Ligation Reactions

Section 3 of this chapter described strategies based on the metabolic engineering of several monosaccharides to achieve cell surface display of chemical functional groups including

ketones, azides, and thiols that are not normally found in the glycocalyx. Once situated in this novel cellular location, these functionalities can be exploited via the chemoselective ligation strategies described here in ❯ *Sect. 4* for an ever-expanding complement of purposes. On the basis of the growing number of chemoselective coupling strategies, including a recent proliferation of bioorthogonal reactions designated for azides [166], this discussion is intended to be a guide to assist the non-specialist in selecting appropriate ligation chemistry.

4.1 Requirements of Chemoselective Ligation, Previous Applications, and Use in MOE

Chemoselective ligation reactions are designed to allow the selective reaction of two complementary chemical functional groups even in a complex milieu of a biological system such as a living cell [76,167]. Ideally, the two reactive partners are abiotic, undergo non-reversible covalent bond formation under physiological conditions, and recognize only each other while remaining impervious to their cellular surroundings [60]. An early example of ketone- and aldehyde-based chemoselective ligation is the work of Rideout and colleagues who reported the self-assembly of inactive prodrugs into cytotoxic agents inside cells [168,169].

The chemoselective ligation strategy was soon applied to the synthesis of neoglycoconjugates because bioorthogonal coupling provided an attractive alternative to previous methods. For example, in a common synthetic strategy used for glycopeptides, sugars were attached to the peptide backbone during solid phase synthesis (SPPS) by means of glycosyl amino acid building blocks. This 'linear' synthetic approach was laborious, required extensive use of protecting groups, and only allowed the preparation of one glycoform per synthesis. A second, convergent approach that suffered from similar limitations was based on either the enzymatic elongation of the oligosaccharide chain of a pre-synthesized glycopeptide or glycosyl amino acid or on the conjugation of a fully elaborated, complex saccharide to short synthetic peptides. As reviewed in detail elsewhere [170,171,172,173], chemoselective ligation reactions provide attractive alternative strategies that overcomes several synthetic stumbling blocks to neoglycoconjugate synthesis. An example of this strategy is shown in ❯ *Fig. 11A* where neoglycoconjugates are synthesized through the coupling of a thiol-derivatized peptide to thiol-specific reactants conjugated to glycans. Similar technology is also proving to be of great utility in the construction of oligosaccharide microarrays (❯ *Fig. 11B*), which are finding various uses in emerging high-throughput 'glycomics' technologies [16,142,174,175].

To date, several chemoselective coupling strategies have been exploited in MOE. In this chapter five different bioorthogonal ligation reactions that have been applied to surface carbohydrates on living cells or in animals will be discussed briefly. The first one is the reaction of carbonyl groups (ketones or aldehydes) with strong nucleophiles, the second is the addition of sulfur nucleophiles to other electrophiles, the third is the modified Staudinger ligation of azides with phosphines, the fourth is photo-activated functional groups, and finally, the fifth example is provided by the cycloaddition between diene and dienophiles or the (3+2) cycloaddition between azides and alkynes. In addition to the chemistry involved, a sampling of applications will be given to provide the reader with a small window into the enormous potential of this emerging technology to modulate biology.

4.2 Glycan-Displayed Ketones and Aldehydes: Establishing Chemoselective Ligation for MOE

4.2.1 ManNLev, keto2Gal, and GlcNLev are Ketone-Derivatized Metabolic Precursors

Mild periodate treatment of mammalian cells introduces aldehydes into surface sialic acids. The chemical reactivity of periodate-produced aldehydes has been exploited for purposes ranging from investigation of sLe^X-mediated lymphocyte homing [176] to the development of new modes of carbohydrate-based cell attachment [177]. Although periodate treatment of surface

sugars provided an important precedent for MOE because of the similar chemical properties of aldehydes and ketones found in sugar analogues, limitations to the periodate method included transient surface display of modified sugars due to membrane recycling, significant loss of cell viability, and incompatibility with in vivo conditions. By comparison, glycan-displayed ketones installed by MOE can be maintained indefinitely on the cell surface [65], harm to the host cells—even for toxic analogues—can be avoided by controlled delivery rates and control of cell density [46], and MOE methodology can be used in animals [17].

The Bertozzi group pioneered the introduction of orthogonal chemical functionalities onto the cell surface with a spate of monosaccharides derivatized with ketone groups. The first such compound, ManNLev (**14**), was a precursor for sialic acid biosynthesis as have been several later ManNAc analogues that include the peracetylated forms of ManNLev (Ac_4ManNLev, **87**), ManNHomoLev (Ac_4ManNHomoLev, **88**) [47], and ManNOxoHex (Ac_4ManNOxoHex, **89**) [63]. In follow-up experiments Hang and coworkers showed that a ketone-containing GalNAc mimic (*Sect. 3.2*) could also be used to install ketones into *O*-linked glycans and possibly GAGs, although fewer ketones were expressed relative to ManNLev [26]. Treatment of mammalian cells with a ketone-containing GlcNAc analogue GlcNLev (**169**) resulted in the incorporation of ketones into *O*-GlcNAc-modified nuclear and cytosolic proteins (*Sect. 3.4*). Finally, ketones have been incorporated into the cell walls of lactic acid bacteria via metabolic substrate-based engineering [30,31].

4.2.2 Exploitation of Ketone-Bearing Glycans

After the metabolic installation of a ketone group into a cellular glycan, chemoselective ligation reactions can be used towards several ends. In particular, there are two complementary chemical functional groups—the aminooxy and hydrazide—that selectively reactive with ketones to the exclusion of other surface components (*Fig. 12*). The choice of reactant depends on several factors including expense (hydrazide conjugation reagents are commercially available at lower costs), reaction kinetics (aminooxy ligation occurs more rapidly at physiological pH), or the desired stability of the bond. To expound on the last point, hydrazide-coupling reactions result in hydrazone linkages, which are pH sensitive and upon internalization to low pH endosomal vesicles can be reversed. By this process, ‘cargo’ attached to the hydrazide group can be released in an internal compartment and the ketone ‘tag’ can return to the cell surface to be reused; this method in effect results in the shuttling of agents such as drugs into a cell [178]. By contrast, the oxime linkage that results from aminooxy ligation is pH insensitive and preferred when stable conjugation products are desired, such as the delivery of MRI contrast agents to non-natural sialosides [44].

In addition to drug delivery, surface ketones installed via MOE have been exploited for the development of MRI contrast reagents [44], for gene transfer [179], for glycan remodeling [65], and for the targeting of cancer cells with toxic proteins [20] (*Fig. 13*). Probably the most commonly utilized ketone-based reactions have been to quantify surface expression of non-natural sialic acids. A facile method for quantification of surface-displayed functional groups has been developed for ketones and involves a two-step process [20,65]. The first step involves covalent conjugation with one of many commercially available hydrazide- or aminooxy-biotin probes. In the second step, the biotinylated cells are stained with FITC-avidin followed by flow cytometry quantification. A drawback of this methodology is that detection

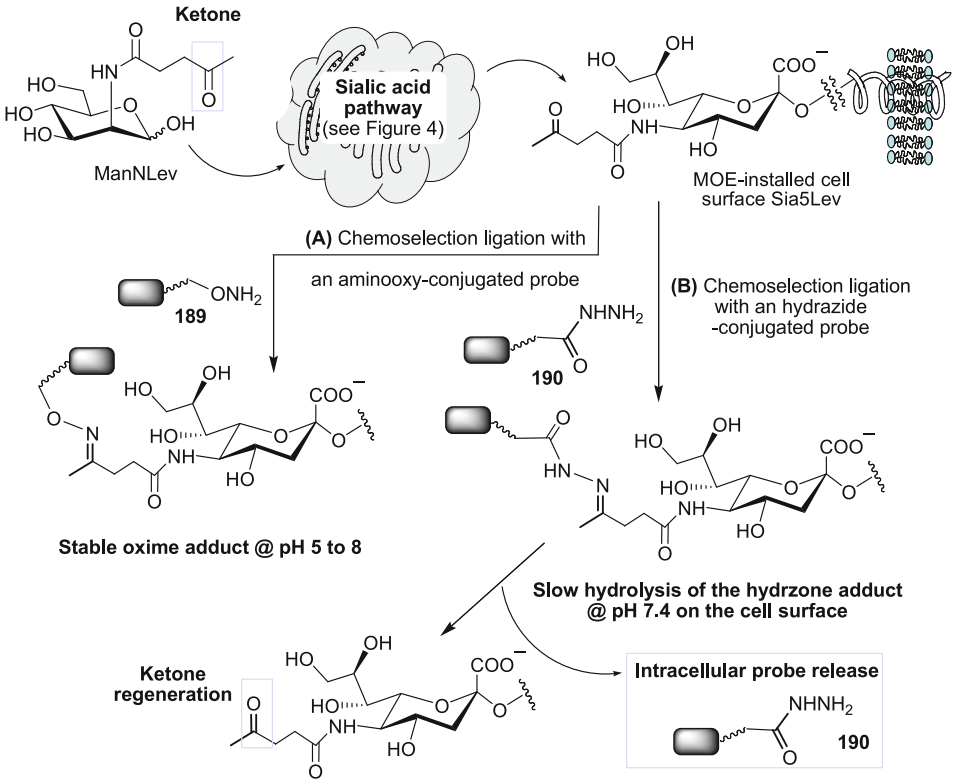

Figure 12
Ketone-based chemoselective ligation reactions that exploit cell surface displayed Sia5Lev (32)

is not quantitative insofar as the labeling efficiency depends on pH and biotin hydrazide concentration; for hydrazides, pH ranges where fast conjugation occurs with (i. e., at ~pH 5) are not compatible with cell survival. Another limiting factor is that biotin hydrazide is not soluble above ~5 mM whereas labeling increases throughout the soluble range, indicating that if higher concentrations were possible, additional conjugation would occur [180]. Nonetheless, this labeling method—contingent upon reagent concentrations and reaction times being maintained constant from experiment to experiment—provides a rapid means to compare cell lines, concentrations, time of incubation with analogue, and so on. Further, even with these limitations, up to 10^7 surface functionalities can be ligated under physiological conditions [180], a number that compares favorably with tumor-associated antigens targeted in immunotherapy where only ~10^4 to 10^5 surface epitopes are present, which is often not sufficient to achieve adequate levels of drug delivery [181].

4.2.3 Shortcomings of Ketone-Based Ligation Strategies

The ketone-based chemoselective ligation reactions described above initially demonstrated the versatility and potential of MOE to modulate biology through changes in cell surface

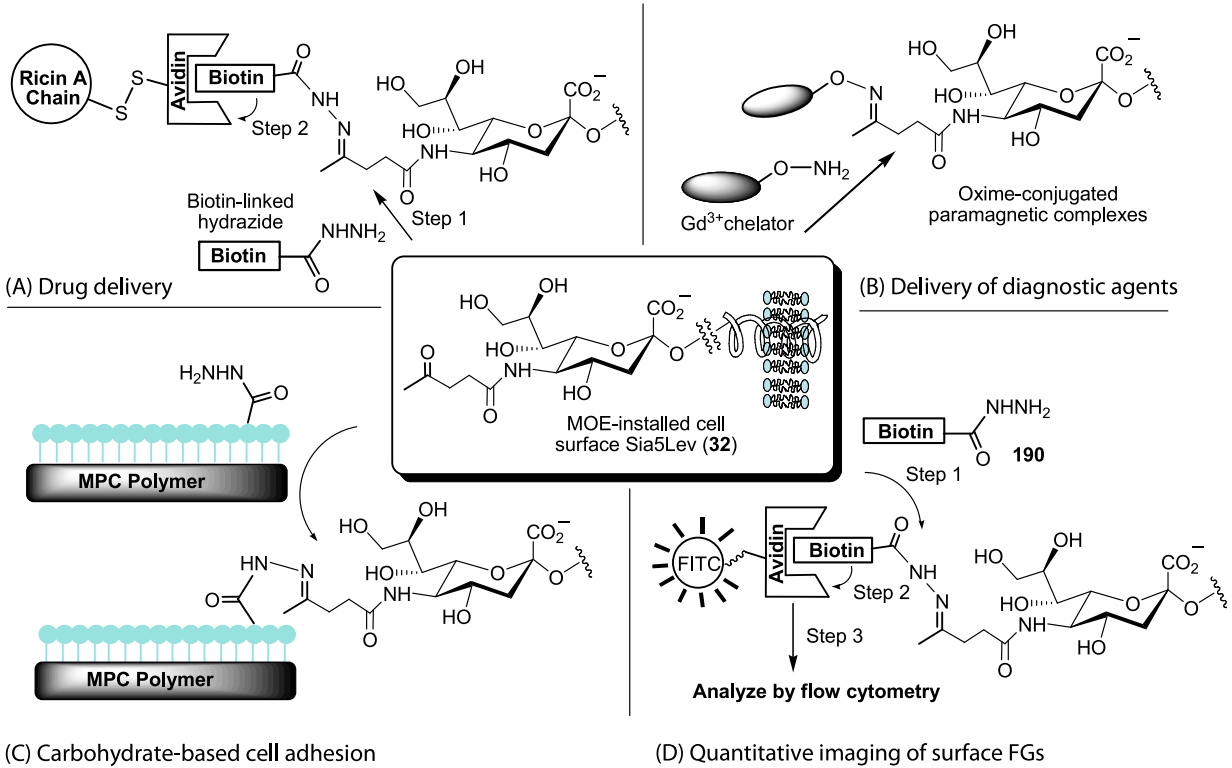

Figure 13
Applications of chemoselective ligation reactions that exploit Sia5Lev

chemistry. These reactions, however, have limited intracellular use owing to competition with endogenous keto-metabolites and they can be compromised by pH requirements that do not match physiological conditions. In addition, keto-analogs, exemplified by ManNLev, do not transit metabolic pathways efficiently (in fact, Ac_4ManNLev inhibits flux through the sialic acid pathway [47]). Therefore, to augment the potential of these pioneering analogues in the study and manipulation of cellular components, the ongoing development of additional cell-compatible chemoselective ligation reactions is of fundamental importance and has led in several directions outlined below in ❯ *Sect. 4.3* to ❯ *Sect. 4.6*.

4.3 Glycan-Displayed Azides

4.3.1 Azides and the Modified Staudinger Reaction

An exciting chemoselective ligation technique based on the conjugation between an azide and a phosphine was developed when the Bertozzi group modified the Staudinger ligation to be compatible with physiological conditions. The conventional Staudinger reaction is hydrolyzed under aqueous conditions (❯ *Fig. 14A*) whereas the physiological reaction forms a stable amide bond by coupling of an azide and a specifically engineered triarylphosphine [60]. This 'second generation' MOE chemical functional group is superior to ketones in that azides are completely abiotic and can be exploited for chemoselective ligation reactions inside a cell as well as on the surface, furthermore they do not suffer from the pH limitations of ketone-hydrazide coupling. As an added benefit, the bevy of azide-bearing monosaccharide analogues now includes ManNAc, GlcNAc, GalNAc, and fucose derivative that typically are metabolized by glycosylation pathways more efficiently than their keto counterparts (as discussed in ❯ *Sect. 3.1*.).

4.3.2 Azide-Derivatized Analogues Are Being Used in Proteomics

Similar to the labeling scheme shown in ❯ *Fig. 13* for ketones, the azide group provides a convenient handle for quantification of metabolic incorporation (❯ *Fig. 14C*) [60]. In ongoing efforts to move beyond whole cell analysis by flow cytometry to the identification of individual molecules, azide-modified analogues are gaining extensive use in emerging 'glycoproteomics' efforts. Particularly fruitful have been GlcNAz analogues that, upon incorporation into *O*-GlcNAc-modified nuclear and cytoplasmic proteins (❯ *Sect. 3.4*), allow facile detection by biotin- or pFLAG-based probes (❯ *Fig. 15*). Metabolic incorporation of GlcNAz analogues also enables rapid enrichment, analysis, and identification of modified proteins as demonstrated by a recent study where more than 199 putative *O*-GlcNAc-modified proteins were isolated from analogue-treated HeLa cells. Among the first proteins identified in this experiment, 10 were previously reported and 13 were newly identified as bearing the *O*-GlcNAc modification [156]. In a variation of this method, enzymatic tagging of *O*-GlcNAc with keto-analogues allowed the identification of modified proteins from the brain [141]. Although the methodology is not yet as well developed, similar proteomics approaches are under development for the metabolic tagging, isolation, and characterization of GalNAc- and fucose-bearing glycans. Finally, it is worth noting that azide detection methods apply to bacteria [182], potentially opening the door to similar glycomics approaches to prokaryotes where nascent MOE experiments have been reported [28,30].

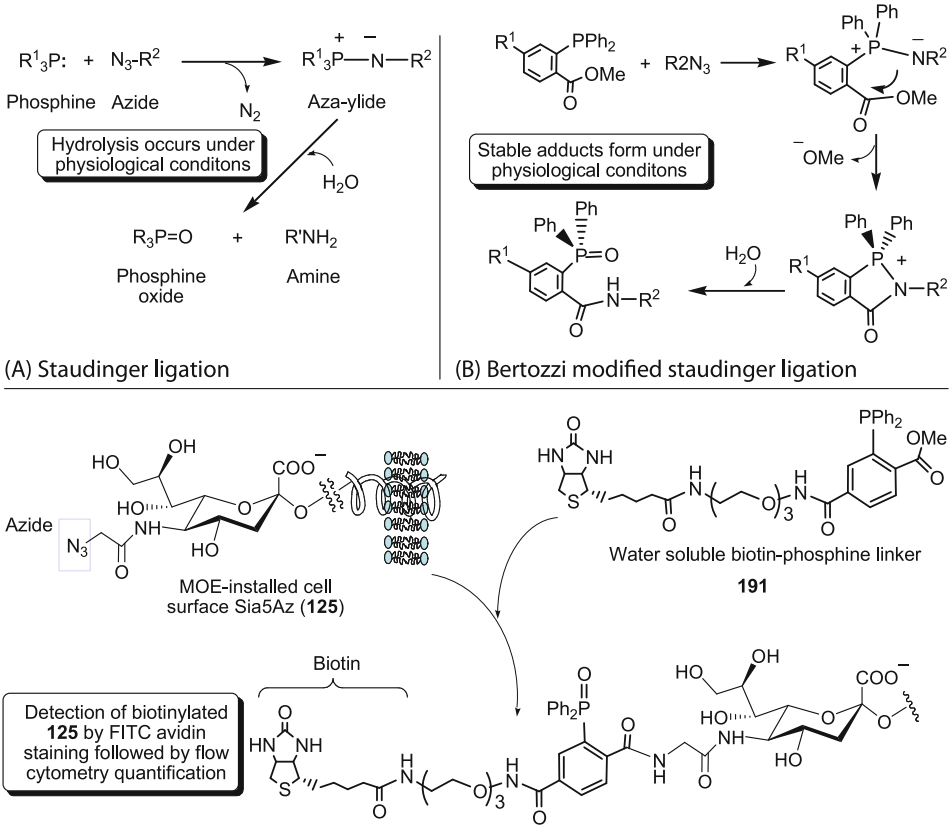

Figure 14
Use of the Staudinger ligation in MOE. (A) The original ligation product of the original Staudinger reaction undergoes hydrolysis under physiological conditions. (B) The Bertozzi modification of the Staudinger ligation [60] produces stable adducts in water thereby adapting this reaction for MOE and rendering it appropriate for applications including quantification of surface display of Sia5Az (C)

4.4 Glycan-Displayed Thiols

4.4.1 Thiols Have Versatile Chemistry but Are not Unique to the Cell Surface

Recently, our laboratory synthesized thiol-derivatized ManNAc analogues [52] corresponding to the glycolyl sugars used by the Schnaar group to install Neu5Gc (**37**) onto human cells [103]. The impetus behind the production of the thiol-derivatized ManNAc analogue Ac_5ManNTGc (*Fig. 16A*, **68**) used to install Sia5TGc on the cell surface was the versatile chemistry of thiol groups, along with the wealth of commercial reagents available for conjugation, that would extend the possibilities of ketone and azide groups. A potential downside to thiol display is that these groups are not unique to a cell. They occur in small molecules such

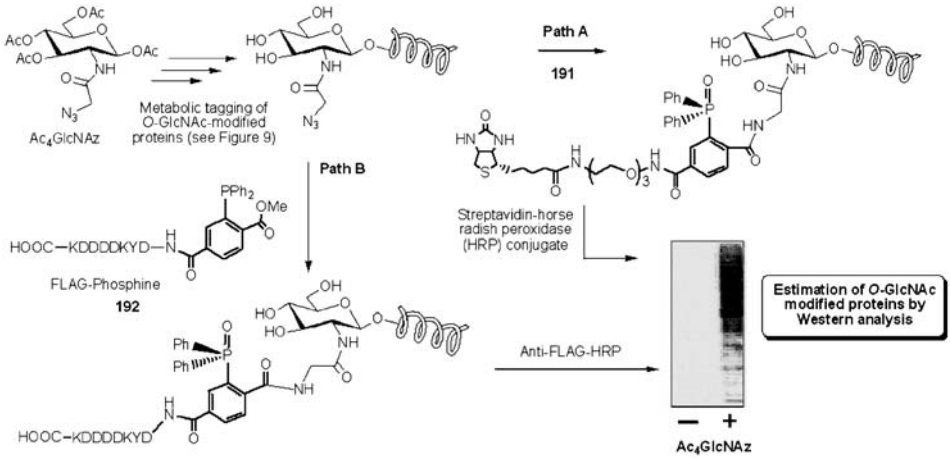

Figure 15

GlcNAc analogues can be exploited for proteomics. The GlcNAc analogue Ac_4GlcNAz tags *O*-GlcNAc-modified proteins with an azide group that can then be analyzed through Western analysis after visualization by strategies shown in either Path A or Path B

as glutathione and cysteine inside a cell as well as on proteins both inside a cell and on the surface. However, the bulk of surface thiols participate in disulfide bonds, are complexed with metals, or are shielded by the glycocalyx (*Fig. 16*), providing sialic acid-displayed thiols with unique accessibility to chemical reagents and growth surfaces in the cell's microenvironment.

4.4.2 Sialic Acid Displayed Thiols Are Highly Accessible to Outside Reactions

The first indication that sialic acid-displayed thiols endowed the cell surface with unique properties was the clustering of Jurkat cells upon incubation with **68** [104]. Typically, Jurkat cells grow in suspension as single cells but the presence of thiols on the cell surface apparently led to disulfide formation between adjacent cells creating cell aggregates containing a few thousand cells reminiscent of hepatocyte spheroids created for use in bioartificial livers. The expression of sialic acid-displayed thiols was confirmed by adapting the chemoselective labeling strategy used for ketone detection shown in *Fig. 13D* and for sialic acid-displayed azides shown in *Fig. 14C*. In this case, because maleimide is a chemoselective ligation partner for thiols, the analogue-treated cells were incubated with (+)-biotinyl-3-maleimidopropionamidyl-3,6-dioxaoctanediamine (MB) followed by staining with FITC-conjugated avidin and flow cytometric quantification. In these experiments, cells directly labeled with MB after exposure to **68** (*Fig. 16B*) showed at least an order of magnitude greater staining than controls, confirming that glycocalyx-displayed thiols were able to interact with the exogenous labeling reagents much better than sulfurs located in membrane proteins [104]. When the cells incubated with **68** were treated with tris-(2-carboxyethyl) phosphine hydrochloride (TCEP) a reducing agent for disulfide bonds prior to MB labeling (*Fig. 16C*), the fluorescent signal increased by another order of magnitude, indicating that Sia5TGc-displayed thiols predomi-

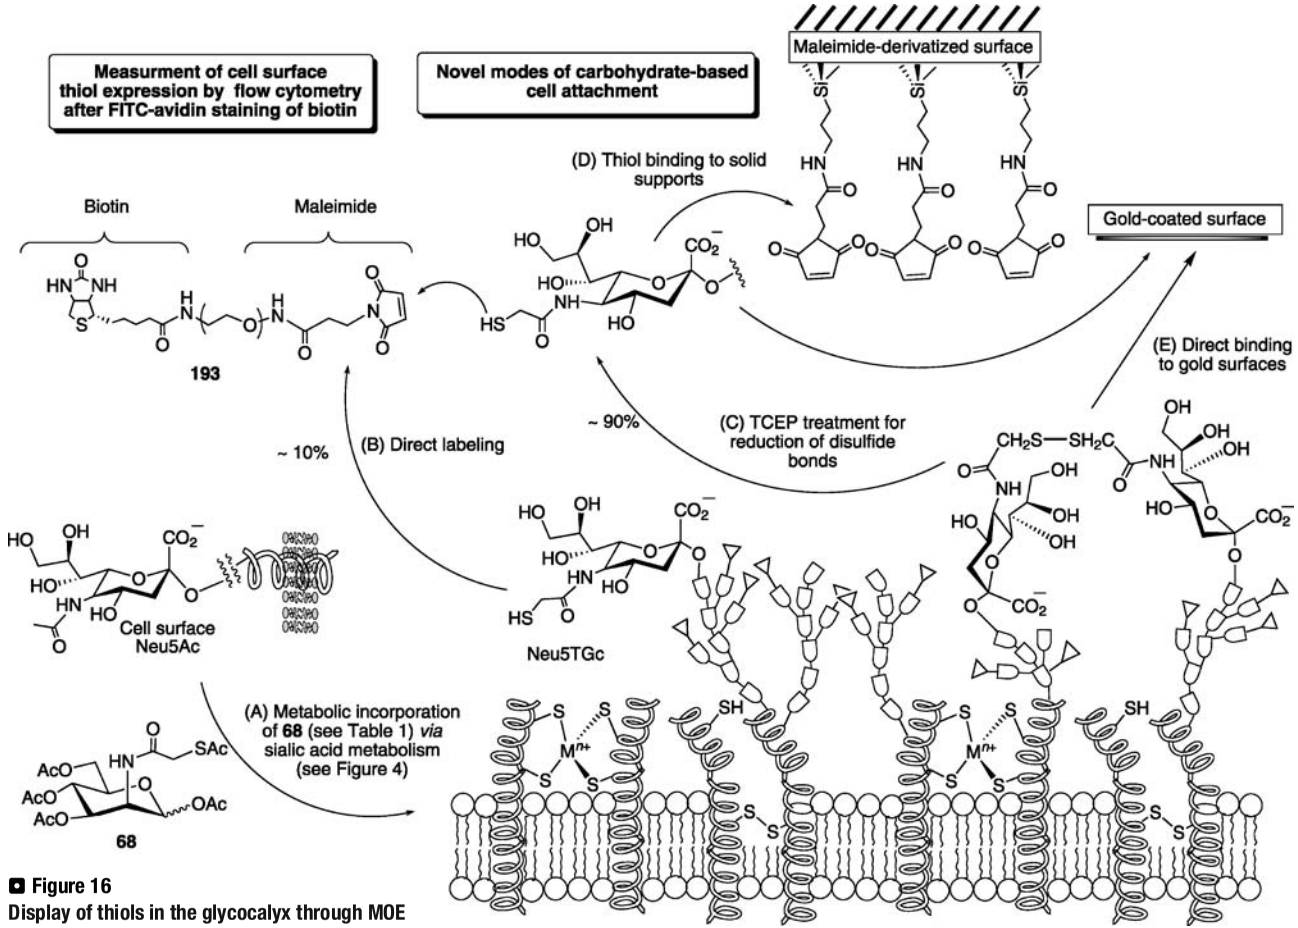

Figure 16
Display of thiols in the glycocalyx through MOE

nantly exist as disulfides, an observation consistent with the slightly oxidative nature of tissue culture medium.

4.4.3 Sialic Acid Displayed Thiols Are Useful for the Control of Stem Cell Fate

Similar to sugar-displayed aldehydes and ketones that have been exploited to attach cells to chemically compatible growth surfaces or polymers [177,183], Sia5TGc has proven useful for novel modes of carbohydrate-based cell adhesion. In one set of experiments, Jurkat cells treated with **68** selectively attached to a maleimide functionalized surface [104] **68** (*Fig. 16D*). In follow-up experiments, the human embryoid body-derived (hEBD) LVEC cell line was incubated **68** and grown on gold to take advantage of the high-affinity interaction expected from glycocalyx-displayed thiols with this metal (*Fig. 16E*). These growth conditions activated the Wnt signaling pathway, led to β-catenin accumulation, distinct changes in cellular morphology, nestin staining, and re-organization of the cytoskeleton indicative of differentiation to a neural cell lineage [104]. By contrast, only negligible changes in morphology were seen for cells treated with Ac_5ManNGc, the oxy-analogue of **68**, or the solvent vehicle ethanol, indicating that the thiol moiety of **68**, or an intracellular metabolic intermediate arising from this compound, had a critical role in the analogue-mediated differentiation to neurons.

4.5 The Use of Photo-Affinity Cross-Linkers in MOE

The Paulson group devised an ingenious method to exploit MOE analogues derivatized with photo-activated crosslinkers to identify the in situ binding partners of CD22 [116]. In these experiments the sialic acid analogue 9-AAz-NeuAc, which was synthesized as shown in *Scheme 9* and bears an aryl-azide moiety at the C-9 position, was incubated with B-cells. Surface display of the aryl-azide functionality was verified by labeling the cells with a biotin probe that was ligated by the Bertozzi–Staudinger reaction and visualized by FITC-avidin staining. Interestingly, despite the bulk of the 9-AAz group, the modified glycan remained a binding partner for CD22, allowing in situ interactions to be captured by photo-activated cross-linking (*Fig. 17*). The importance of devising new methods for probing biological function, such as this approach to understanding CD22, was illustrated by the outcome of this experiment wherein CD22 was found to assemble into homo-multimeric complexes—a result that differed from previous experiments that used more highly invasive methods to explore CD22 interactions.

4.6 Cycloaddition Ligation Reactions

4.6.1 Cycloaddition Reactions Are Compatible with Carbohydrates Under Physiological Conditions

Cycloaddition reactions between azides and alkynes—exemplified by the Huisgen 1,3-dipolar cycloaddition—have tremendous potential for the development of biomolecules and have been employed for conjugation of sugars to peptides [184]. Drawbacks of the Huisgen cycloadditions, however, are poor regioselectivity and incompatibility with physiological conditions. These limitations, which hinder MOE applications in living cells, were first overcome by cop-

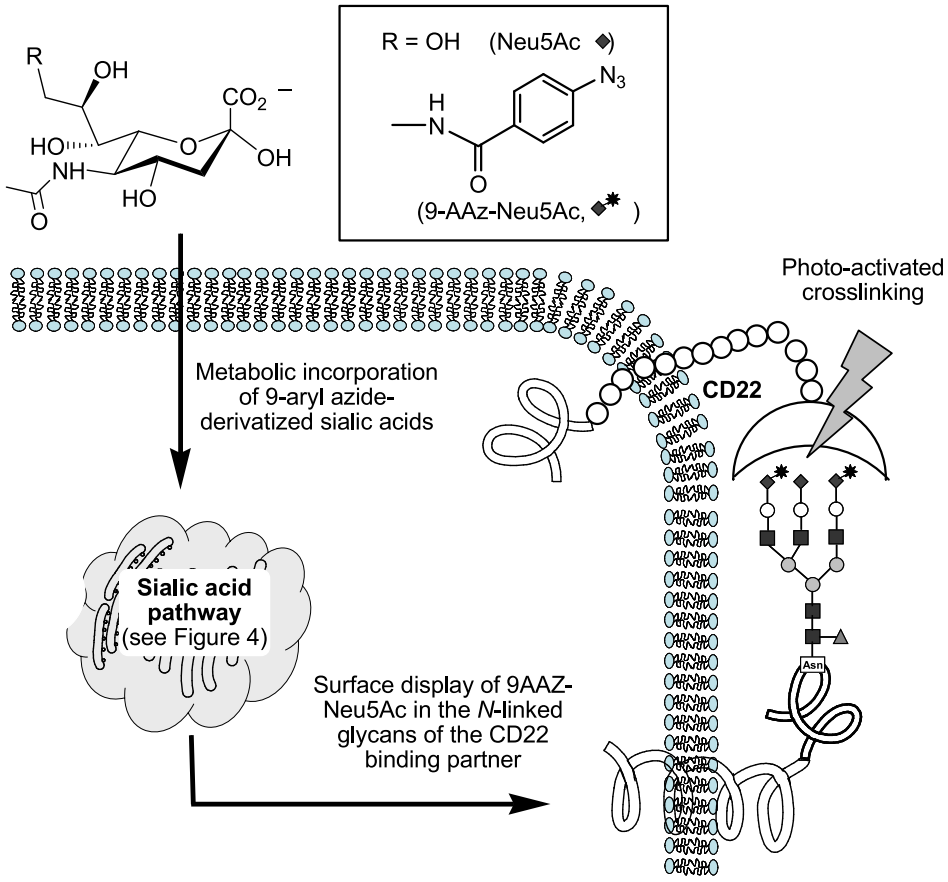

Figure 17
Photo-activated cross-linking of MOE sialic acids to identify CD22 binding partners

per [Cu (I)] catalyzed versions of the Huisgen 1,3-dipolar cycloaddition of azides and terminal alkynes reported independently by the Sharpless and Meldal groups (*Fig. 18A*) [184,185]. In the first experiments, grafting of protected and unprotected carbohydrates onto a polymer was demonstrated via an azide located at either the C-6 or anomeric position by Cu(I)-catalyzed 'click chemistry', providing a simple and efficient route to synthetic glycopolymers. The (3+2) cycloaddition chemistry has now been extended to MOE applications by using non-natural L-Fuc derivatives derivatized with azide or alkyne groups for direct ligation of fluorescent tags [147] (*Fig. 18B*). Although compatible with physiological conditions, considerable copper-attributed toxicity has been reported in azide-alkyne coupling, which suggests this chemistry will be more appropriate for proteomics rather than live cell applications. To avoid copper toxicity, Agard and coworkers have recently reported a family of cyclooctynes that were effective for tagging azides on live cells in the absence of copper through strain-promoted [3+2] cycloaddition [166] (*Fig. 18C*) that may find roles in MOE-proteomics (*Fig. 18D*).

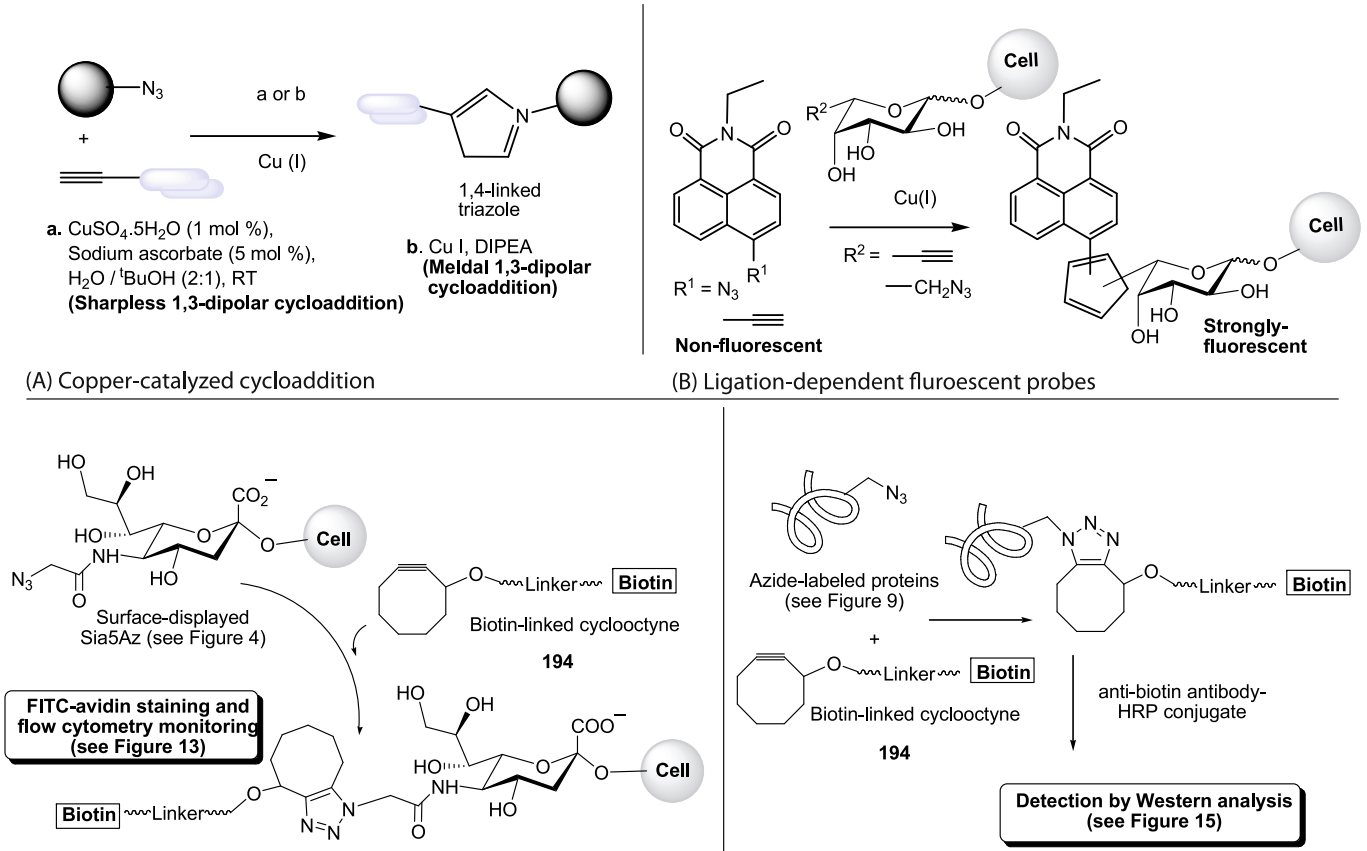

Figure 18
Cycloaddition ligation reactions used in MOE

4.6.2 Development of Fluorogenic Reactions for Azide-Derivatized Glycans

To date, the quantification of MOE functional groups on the cell surface has generally used secondary fluorescent dyes for visualization. This strategy can be compromised by difficult-to-eliminate background noise making attractive the use of fluorogenic reactions, where the ligated product generates a strong detectable signal while the unreacted reagent remains traceless. On the basis of this concept, two click-activated fluorescent probes based on 1,8-naphthalimide (*Fig. 18B*) that can selectively label azido- or acetylene-modified L-fucose analogs by a Cu(I)-catalyzed azide-alkyne ligation, which triggers their fluorescence, were used in a fluorogenic labeling technique sufficiently sensitive to visualize fucosylated glycoproteins in intact cells [147].

4.6.3 Extending the Use of Cycloaddition Reactions in MOE

Cycloaddition reactions between dienes and dienophiles provide a versatile method in synthetic organic chemistry for converting simple molecules to structures of increased complexity. In 2002, Pozsgay and coworkers developed a method for chemoselective bioconjugation of carbohydrates to proteins by using Diels–Alder cycloaddition [186]. Of potential relevance to MOE, maleimidoyl-conjugated BSA (**196**) was coupled with L-rhamnose containing oligosaccharides (particularly the *O*-specific polysaccharide of *Shigella dysenteriae* type 1, **195** that contain a diene) under physiological conditions (*Fig. 19*). These investigators found that the Diels–Alder conjugation methods—while favored at pH 5.7 in phosphate-borate buffer—proceeded with equal efficiency at neutral pH in ion-exchanged water. Prospects of extending this chemistry to metabolically installed dienes—although to our knowledge not yet demonstrated—should be possible based on the transit of a single alkene though the sialic acid pathway (ManNCrot, *Table 1*C) [18], combined with the use of alkyl chains of sufficient length, such as ManNHex or ManNHept (*Table 1*A) [63], to accommodate a diene.

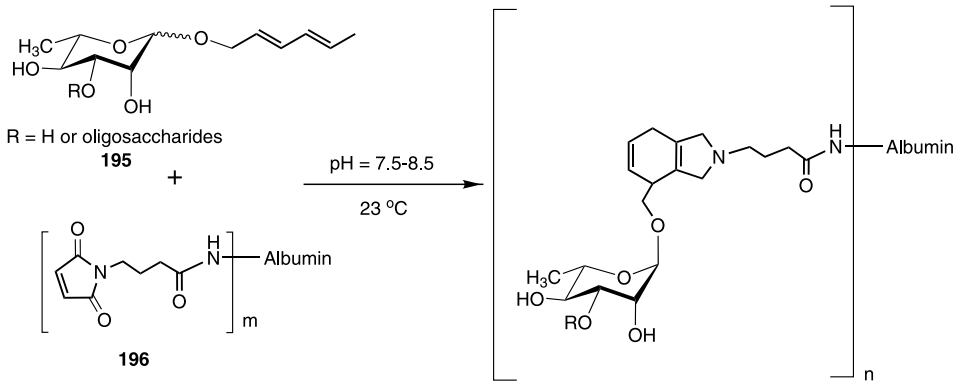

Figure 19
Chemoselective bioconjugation of carbohydrates to proteins by using Diels–Alder cycloaddition chemistry

5 Concluding Comments and Future Prospects

In conclusion, this report has provided an overview of MOE technology by outlining the various biological systems that accept non-natural sugar analogues and metabolically incorporate them into cellular glycoconjugates. Although novel analogues are constantly under development, the lists of compounds described in *Sect. 3* designed to target sialic acid, GalNAc, GlcNAc, and fucose metabolism provide a broad-based 'tool-kit' to manipulate cell surface display on oligosaccharides in living cells and animals. An especially exciting aspect of MOE technology is the seamless merging of chemistry and biology, wherein novel chemical functionalities introduced into cellular components can be further exploited by a growing list of chemoselective ligation reactions. As can be deduced from the brief sampling of applications of MOE referenced in this report, the potential impact of MOE on biological research and medicine has already been significant and is expected to gain in importance as it becomes widely adopted by the research community.

Chapter-DOI 10-1007/978-3-540-30429-6_56:

Abstract

There is an increasing body of evidence indicating that glycans are implicated in numerous biological processes such as cell–cell interactions, intracellular signaling, and immune response. Glycomics emerges from the necessity to understand the mechanisms underlying the interactions responsible for these activities. The term glycomics is used to describe experimental approaches to studying the structure and function of the glycomes of fluids, cells, tissues, organs etc. Glycomics embraces a variety of technologies amongst which mass spectrometry (MS) plays a pivotal role because it is the method of choice for defining the primary structures of glycopolymers. This chapter provides an insight into MS-based structural strategies that are best suited to studying complex glycomes.

Keywords

Glycomics; Glycopeptides; Glycoproteomics; Mass spectrometry; Nano liquid chromatography; *N*-glycans; *O*-glycans; Profiling; Structural analysis; Tandem mass spectrometry

Abbreviations

Asn	asparagine
CAD	collisionally activated decomposition
CAD ESI-MS/MS	collisionally activated decomposition tandem MS
CID	collisionally induced decomposition
CHCA	α-cyano-4-hydroxycinnamic acid
Da	Dalton
DE	delayed extraction
DHB	2,5-dihydroxybenzoic acid / gentisic acid
ECD	electron capture dissociation
EI	electron impact/ionization
ESI	electrospray ionization
ESI-MS	electrospray ionization mass spectrometry
eV	electron volt
FAB	fast atom bombardment
FAB-MS	fast atom bombardment mass spectrometry
FT-ICR	Fourier transform ion cyclotron resonance
Fuc	fucose
Gal	galactose
GalNAc	*N*-acetylgalactosamine
GC-MS	gaschromatography–mass spectrometry
Glc	glucose
GlcNAc	*N*-acetylglucosamine
Hex	hexose
HexNAc	*N*-acetylhexosamine
HF	hydrofluoric acid
Hz	Hertz
kDa	kilo-Dalton

kV	kilo-Volt
LC	liquid chromatography
LC (ESI)-MS	liquid chromatography (electrospray ionization) mass spectrometry
m/z	mass / charge
MALDI	matrix-assisted laser desorption ionization
MALDI-MS	matrix-assisted laser desorption ionization mass spectrometry
MALDI-TOFMS	matrix-assisted laser desorption ionization– time-of-flight mass spectrometry
Man	mannose
MS	mass spectrometry
MS/MS	tandem mass spectrometry
MS^n	multiple-stage mass spectrometry
µl	micro-Liter
NeuAc	*N*-acetylneuraminic acid
NeuGc	*N*-glycolylneuraminic acid
Nd-YAG	neodymium-doped yttrium aluminum garnet
PNGase F	peptide: *N*-glycosidase F / *N*-glycanase
ppm	part per million
Q-TOF	quadrupole/orthogonal acceleration time-of-flight
Ser	serine
TFA	trifluoroacetic acid
Thr	threonine
TOF	time-of-flight

1 Overview

The repertoire of glycans in an organism or part thereof constitutes its glycome. The term glycomics is used to describe experimental approaches to studying the structure and function of the glycomes of fluids, cells, tissues, organs etc. Glycomics embraces a variety of technologies amongst which mass spectrometry (MS) plays a pivotal role because it is the method of choice for defining the primary structures of glycopolymers. Ultra-high sensitivity, coupled with the ability to characterize individual components within a complex mixture, are key features of mass spectrometry that are especially advantageous in glycomic research. The first part of this chapter provides an overview of the MS techniques that are widely used in glycan analysis. Subsequent sections provide an insight into MS-based structural strategies that are best suited to studying complex glycomes. Informatic tools that are being developed to support glycomic research are described in the following chapter.

1.1 Components of a Mass Spectrometer

At a fundamental level, mass spectrometers generate ions, separate them according to their mass to charge ratio, and measure their abundance. Hence, the three main components of mass spectrometers are (i) an ionization source, where samples are ionized, (ii) one or more

mass analyzers, where ions are separated according to their mass to charge ratio (m/z), and (iii) a detector, where signals are recorded, generating a mass spectrum consisting of the relative abundance and m/z ratio. Additionally, the instruments may include collision cells for producing fragment ions from selected parent ions.

1.2 Ionization Techniques

From as far back as the 1960s, structural studies on glycans were carried out using electron impact (EI) and chemical ionization (CI) techniques. Limitations of these techniques were that they are largely restricted to the analysis of volatile, low molecular weight molecules (less than 1000 Da). Nevertheless, the EI method coupled with gas chromatography remains an indispensable tool for compositional and linkage analyses [1] and is an integral component of many glycomic strategies.

During the 1970s, the development of field desorption (FD) ionization [2], allowed scientists to study non-volatile compounds by mass spectrometry for the first time. Moreover, the coupling of this ionization technique with a new generation of high mass analyzers [3] allowed the analyses of biological compounds, including glycoconjugates, whose masses were significantly in excess of 1000 Da [4]. However, FD was a very challenging technique and very few laboratories had the necessary expertise for its successful exploitation. Not surprisingly, therefore, FD rapidly became obsolete when more tractable methods for ionizing non-volatile substances were developed. The first of these was fast atom bombardment (FAB) which was developed at the end of the 1970s [5] and soon revolutionized the structural analyses of complex glycans [6,7,8,9]. MS sequencing of large glycans was feasible for the first time leading to an exponential increase in the knowledge of glycan structures. Subsequently matrix-assisted laser desorption ionization (MALDI) [10,11] and electrospray ionization (ESI) [12,13] became the ionization methods of choice for analyzing glycans. The principles of FAB, MALDI, and ESI are outlined in the following sections.

1.2.1 Fast Atom Bombardment (FAB)

In the FAB experiment the sample is suspended in a non-volatile, viscous liquid such as glycerol or thioglycerol referred to as the matrix, and is bombarded with a high energy atom or ion beam. The purpose of the matrix is (i) to replenish the surface and thereby minimize rapid destruction of the sample, and (ii) to dissipate excess energy from the atom or ion beam preventing extensive fragmentation of the sample. The sample-matrix mixture is loaded on a metal target that is attached on a probe tip and inserted directly into the FAB source, which is held at high vacuum. A beam of accelerated atoms (argon or xenon) or ions (cesium) is fired at the target from an atom or ion gun. This impact transfers energy to the sample molecules in the matrix allowing them to sputter into the high vacuum of the ion source. During this process, the majority of the molecules couple with ions such as H^+, Na^+, and K^+ generating singly charged species, e. g., $[M+H]^+$ and $[M+Na]^+$. FAB-MS is capable of analyzing glycans of up to about 6000 Da yielding both molecular and fragment ions in a single experiment. Thus, it affords an efficient and rapid method for mapping both terminal epitopes and molecular ions within a complex mixture of glycans. In recent years, due to advances in MALDI and ESI instrumentation (see below), FAB-MS has been phased out in many laboratories.

Nevertheless an appreciation of FAB research is very helpful because the fragmentation pathways observed in FAB spectra are recapitulated in MALDI and ESI experiments. Moreover, many current glycomic protocols have been adapted from FAB-based methodologies developed in the 1980s and 1990s to study complex mixtures of glycans isolated from cells and tissues [14,15,16,17,18].

1.2.2 Matrix-Assisted Laser Desorption Ionization (MALDI)

In MALDI-MS, the sample is co-crystallized with a low molecular weight ultraviolet-absorbing matrix on a metal target which is introduced into the high-vacuum MALDI source. The sample/matrix mixture is irradiated by laser pulses that result in the accumulation of energy in the condensed phase and cause desorption of ionized molecules. The ionization process is still poorly understood. However, it is widely believed that the matrix allows the energy from the laser to be dissipated and assists the formation of ions by proton transfer and chemical processes between the photo-excited matrix and the analyte [19]. Commonly used matrices include 2,5-dihydroxybenzoic acid (DHB) which is ideal for native and derivatized glycans, α-cyano-4-hydroxy cinnamic acid (CHCA) for peptides/glycopeptides, and sinapinic acid for the analysis of larger proteins and for glycoprotein analysis. Most commercial MALDI-MS instruments use ultraviolet lasers, with the nitrogen laser, which has a wavelength of 337 nm and pulse rates of 2–20 Hz [20], being the most widely used due to its low cost and effectiveness. More recently, a diode-pumped neodymium-doped yttrium aluminum garnet (Nd-YAG) laser operating at 355 nm between 20 Hz and 2 kHz [21] has been introduced in MALDI instruments.

MALDI-MS is now a firmly established and highly sensitive ionization technique used in the study of glycans. It is a "softer" ionization method than FAB and yields a series of singly charged molecular ions with minimal fragmentation, making it an ideal method for obtaining an overall glycan profile, i. e., a fingerprint of glycans in a sample mixture. The upper mass limit for successful analysis by MALDI is considerably higher than for FAB and glycopolymers well in excess of 10,000 Da are amenable to this technology [22,23].

1.2.3 Electrospray Ionization (ESI)

The electrospray ionization (ESI) method was originally described by Malcolm Dole and co-workers [24] but it took another 20 years to develop a practical system. Yamashita and Fenn [25,26] and Alexandrov and co-workers [12] pioneered these later developments. The ESI technique is based on producing a spray by applying a high electrical field, under atmospheric pressure, to a liquid passing through a capillary tube. Applying a potential difference of 3–6 kV between the capillary and the counter electrode generates an electric field, which induces a charge accumulation at the liquid surface situated at the end of the capillary. This causes the surface to break and form an aerosol of highly charged micro droplets. These droplets then traverse a series of skimmers where they encounter a drying gas. As the solvent evaporates, the charged micro droplets decrease in size whilst the charge density at the surface of the droplet increases until they reach the Raleigh stability limit (1.1×10^5 charges). At this point, droplets explode due to the mutual repulsion of charges. This process is repeated until the net effect is the production of gaseous ions devoid of solvent. In contrast to the singly

charged molecular ions that are formed in FAB and MALDI experiments, the charge status of ESI-generated ions mirror charges prior to spraying. Consequently multiply charged molecular ions are observed in ESI spectra of most biological molecules.

The nano-electrospray (nanoES) source is essentially a miniaturized version of the ES source. This technique allows very small amounts of sample to be ionized efficiently at nanoliters per minute flow rates and it involves loading sample volumes of 1–2 µl into a gold-coated capillary needle, which is introduced to the ion source. Alternatively for on-line nanoLC-MS experiments the end of the nanoLC column serves as the nanospray needle. The nanoES source disperses the liquid analyte entirely by electrostatic means [27] and does not require assistance such as solvent pumps or nebulizing gas. This improves sample desolvation and ionization and sample loading can be made to last 30 minutes or more. Also, the creation of nanodroplets means a high surface area to volume ratio allowing the efficient use of the sample without losses. Additionally, the introduction of the Z-spray ion source on some instruments has enabled an increase in sensitivity. In a Z-spray ion source, the analyte ions follow a Z-shaped trajectory between the inlet tube to the final skimmer which differs from the linear trajectory of a conventional inlet. This allows ions to be diverted from neutral molecules such as solvents and buffers, resulting in enhanced sensitivity.

1.3 Mass Analyzers

Once ions are formed, mass analyzers are required to separate the ions according to their mass to charge ratio. A number of mass analyzers are commonly used in biopolymer mass spectrometry including double focusing analyzers, quadrupoles, time-of-flight (TOF), quadrupole ion traps, and Fourier transform ion cyclotron resonance (FT-ICR). The majority of FAB research was carried out on instrumentation employing double focusing analyzers which consist of a magnetic sector, which separates ions according to their mass to charge ratio, and an electrostatic analyzer that focuses ions according to their kinetic energy. These analyzers provided excellent mass accuracy and resolution but, like FAB, they have been largely superseded by instrumentation described in the following sections which is cheaper and/or more sensitive and/or more versatile.

1.3.1 Time-of-Flight (TOF) Analyzers

In time-of-flight (TOF) analyzers, as the name implies, the separation and measurement of ions is based on the fact that ions of different mass and the same kinetic energy will travel through a field-free region at different velocities. Most MALDI instruments have TOF analyzers because the pulsed method of ionization is ideally suited to TOF analysis. Ions formed in the source are simultaneously accelerated and extracted into a linear, field-free flight tube. The mass-to-charge ratios are determined by the time that ions take to travel through this field-free region. A major drawback of a linear TOF instrument is its poor mass resolution due to the flight time variations of molecules with the same m/z ratio. There are several factors contributing to this phenomenon; one of them is the inherent length of the ion formation process resulting in ions being introduced in the TOF tube at various times and thus introducing a significant variability on the time of flight measurement. In addition, the ionization process also adds an initial kinetic energy before acceleration leading to a variation of the final kinetic

energy of the ions. Moreover, the varying spatial positions of each ion within the ionization chamber can also lead to errors in the time of flight calculation. To ameliorate the problem of poor resolution "Delayed Extraction (DE)" of ions from the MALDI source was introduced. Under DE conditions a delay between hundreds of nanoseconds and several microseconds is allowed after the laser pulse, prior to applying a voltage pulse to extract the ions from the source. Applying the pulse after a delay transmits more energy to ions that have remained for a longer period of time in the source allowing them to catch up with the more energetic ions at the entry to the flight tube.

Another great improvement of TOF analyzers is the use of a series of electrostatic mirrors, also called a reflectron. The reflectron is used to focus ions of the same m/z but with different kinetic energies, thus acting as an ion "retarding field". Ions with the same m/z ratio but a higher kinetic energy arrive at the reflectron earlier, penetrate more deeply, and leave later than ions of the same m/z ratio but less kinetic energy. The result is ions of the same m/z but different kinetic energies reach the detector simultaneously, therefore significantly improving the mass resolution. High mass, slow moving ions cannot penetrate the reflectron so the high resolution reflectron mode of a TOF analyzer is restricted to analyses below masses of about 10,000 Da.

The main strengths of the TOF are its almost unlimited mass range, and its very high sensitivity achieved because scanning of the analyzer is not required for m/z selection. Also hundreds of samples can be robotically loaded on each MALDI plate thus enabling high throughput analysis. Indeed, MALDI-TOF is an indispensable tool in glycomic analyses. More recently, tandem MALDI-TOF/TOF mass spectrometers have been developed which are proving to be enormously powerful for glycomics because of their sequencing capabilities.

1.3.2 Quadrupole Analyzers

In quadrupole analyzers the ions are separated according to their m/z ratio using the stability of their trajectories in oscillating electrical fields. A quadrupole analyzer consists of four rods with circular or hyperbolic cross-section arranged perfectly in parallel to each other. A direct current voltage (U) and an oscillating radio-frequency (V) are applied to each pair of diagonally opposite rods creating an electric field. Rods adjacent to each other have opposite current polarity. Scanning the voltages allows ions of successively higher or lower m/z to follow a stable path through the analyzer. Therefore, the rods in a quadrupole mass analyzer act as mass filters. Quadrupole mass analyzers have several advantages including fast scanning speed, high robustness, and low cost. They can be operated at relatively high pressure and are therefore especially suitable for ESI instrumentation. Also, EI sources for GC-MS analysis are usually coupled with quadrupole analyzers. A potential weakness of quadrupole mass analyzers is their upper m/z limit of about 4000. Fortunately this is not usually a problem for ESI-MS because larger molecules tend to carry more charges allowing their m/z values to fall within this range.

1.3.3 Quadrupole Ion Traps

The operating principle of a quadrupole ion trap mass analyzer is similar to that of a standard quadruople but the geometry is different. A trap consists of three hyperbolic electrodes comprising a ring and two endcap electrodes. Applying voltages to these electrodes, results

in a 3D quadrupole within the trap. As the name implies, ions are held or "trapped" in the small area between the end caps and the center of the ring electrode. Ions pass into the trap, are stored for a period of time (usually μsec), and are ejected out to the detector by varying the voltages on the entrance and exit of the trap electrodes. The ability to "trap" ions means that a sufficient number of ions can be stored for subsequent MS/MS analysis with high detection sensitivity. However, in practice, the volume in which ions are trapped tends to be small and storage of an excessive number of ions can cause them to leave the trap without being detected. Recent developments in ion trap technology are helping to overcome this problem by the incorporation of linear ion traps [28,29]. The linear geometry provides a larger space in which ions can be accumulated. An increased space decreases the charge-state effect, thus allowing significant gain of sensitivity. Recent studies using linear ion trap instrumentation are clearly demonstrating its potential importance for glycomic research [30].

1.3.4 Fourier Transform Ion Cyclotron Resonance (FT-ICR)

The Fourier transform ion cyclotron resonance analyzer is the most powerful ion trap employed in mass spectrometry. It determines *m*/*z* of ions based on the cyclotron frequency of ions trapped within the magnetic field of a static superconducting high field magnet (typically 4.7 to 13 Tesla). When the ions pass from the source into the ICR cell (also called a Penning trap) they are bent by the Lorentz Force into a circular motion in a plane perpendicular to the field. They are prevented from processing out of the cell by trapping plates at each end. Trapped ions are then excited to a large and coherent cyclotron orbit by an oscillating electric field perpendicular to the magnetic field. An image current generated by the ions as they drop back to their natural orbit can be measured and a Fourier transform is applied to give a mass spectrum. FT-ICR instruments can achieve higher resolution and higher mass accuracy than any other mass spectrometers and, like ion traps, multiple stages of MS can be achieved. However they are hugely expensive and the maintenance of the high magnetic field can be difficult. Therefore this technology has been limited to only a few specialist laboratories and is not yet widely exploited for the structural analyses of glycans.

1.4 Tandem Mass Spectrometry (MS/MS)

MALDI-MS and ESI-MS experiments yield very few fragment ions because the ionization process is very gentle. Although this means they are highly suited to mass fingerprinting of glycan mixtures which is very valuable for initial stages of glycomic analysis, a lack of fragment ions can be a problem for rigorous sequencing. Fortunately, this can be solved with appropriate instrumentation by making the molecular ions more energetic thereby inducing fragmentation. This is achieved by employing two mass analyzers in tandem (MS/MS) or by using ion trap instruments. In the former case, molecular ions are selected by the first analyzer and passed into a pressurized collision cell containing an inert gas such as argon or xenon. The selected ions undergo collision induced dissociation (CID) [also known as collisionally activated decomposition (CAD)]. This promotes fragmentation of the ion of interest and the resulting fragments are subsequently separated by the second mass analyzer. A great variety of tandem instruments have been employed in biopolymer research including triple quadrupoles [31], quadrupole/orthogonal acceleration time-of-flight (Q-TOF) [3], and TOF/TOF instrumenta-

tion [32]. The latter two are currently the analyzers of choice for ESI- and MALDI- MS/MS, respectively.

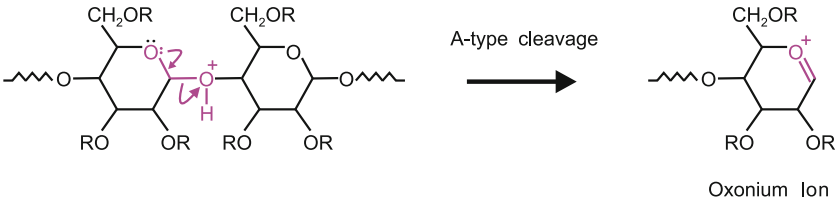
When ion trap instrumentation is used for MS/MS analysis a second mass analyzer is not required since the trap serves as the analyzer for both the parent and fragment ions and as the collision chamber. After selection of the parent ion the trap is pressurized with an inert gas, typically helium. Fragment ions produced by CID are trapped and then sequentially ejected from the trap to produce a mass spectrum. One of the advantages of the ion trap is that the nature of trapping and ejecting allows fragment ions to be selectively isolated and further fragmented allowing so called MS^n experiments. This can be helpful for the assignment of linkages and branching patterns of glycans. Another advantage of ion trap instrumentation for MS/MS experiments is the applicability of alternative methods to CID for energizing the parent ions. These include irradiating trapped ions with an infra-red multi-photon laser, and electron capture dissociation (ECD) in which one of the positive charges on a multiply charged ion is quenched by an electron beam resulting in an energetic radical cation. These methods often produce different fragment ions from those afforded by CID which is helpful for certain structural studies. A limitation of many ion traps is that a low-mass cut-off point is created according to the different parameters used. No ions below that cut-off point will be trapped and therefore important fragment ions at low mass may not be observed. Ions above the cut-off point will be trapped but with a decrease in trapping efficiency for larger *m*/*z* values. In addition, traditional ion traps have a limited space, hence a low ion capacity, which results in poor sensitivity compared to tandem instruments like the Q-TOF. However, the geometry of the new generation of linear ion traps (see above) eliminates this cut-off problem and this instrumentation is therefore promising for future glycomic research.

1.5 Derivatization of Glycans for Structural Analyses

Purified, intact glycans can be analyzed directly by MS, but, because they do not ionize as efficiently as other molecules such as peptides [33], derivatization prior to MS analysis is the preferred strategy in glycomic analysis due to the enhanced sensitivity achievable with suitable derivatives [34,35,36,37]. Permethylation gives the smallest increase in molecular weight of the sample, and the greatest enhancement in sensitivity. In addition, permethylated glycans fragment very selectively resulting in a limited number of structurally diagnostic fragment ions which are relatively easy to interpret [38], and ions arising from single and multiple cleavage events can be readily discriminated. Moreover, permethylation of glycans is a prerequisite for linkage analysis [1]. Hence permethylation steps are integral to many glycomic investigations.

1.6 Fragmentation of Carbohydrates

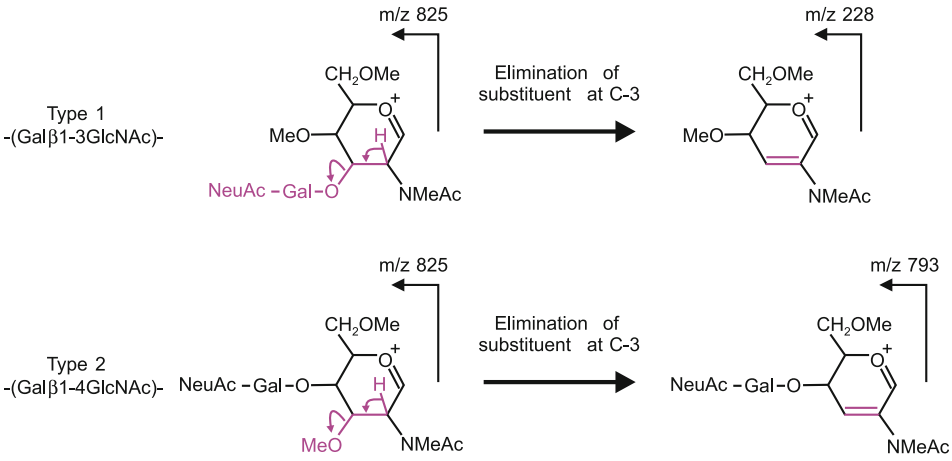
To interpret spectra produced in MS/MS experiments, it is necessary to understand the fragmentation behavior of glycans. The majority of fragment ions are produced by cleavage on either side of glycosidic bonds to yield non-reducing and reducing-end fragment ions, respectively. These ions provide sequence and branching information. Ring fragmentation can also occur especially for smaller glycans, provided that MS/MS experiments are carried out under conditions that impart sufficient internal energy, for example by high energy collisional acti-



Scheme 1
Glycosidic cleavage to form an oxonium ion

vation. Ring cleavages are helpful for assigning linkages. The most common fragmentation pathways are:

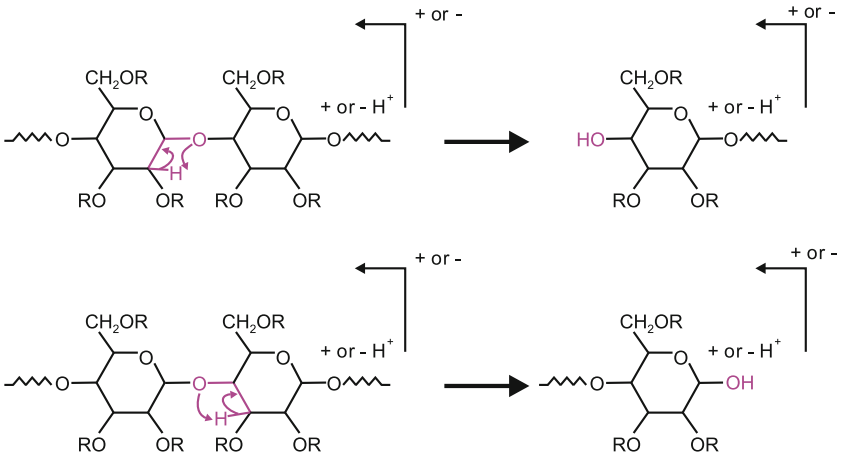
(1) Cleavage of positively charged parent ions on the non-reducing side of the glycosidic bond to form an oxonium ion which may carry sodium if the parent ion was sodiated prior to cleavage (*Scheme 1*). This type of fragmentation is often referred to as A-type cleavage. A-type cleavage is favored at HexNAc residues and is often accompanied by secondary fragmentation involving β-elimination of the substituent at position three on the ring (*Scheme 1.1*).



Scheme 1.1
***β*-Elimination from the 3-position of oxonium ions**

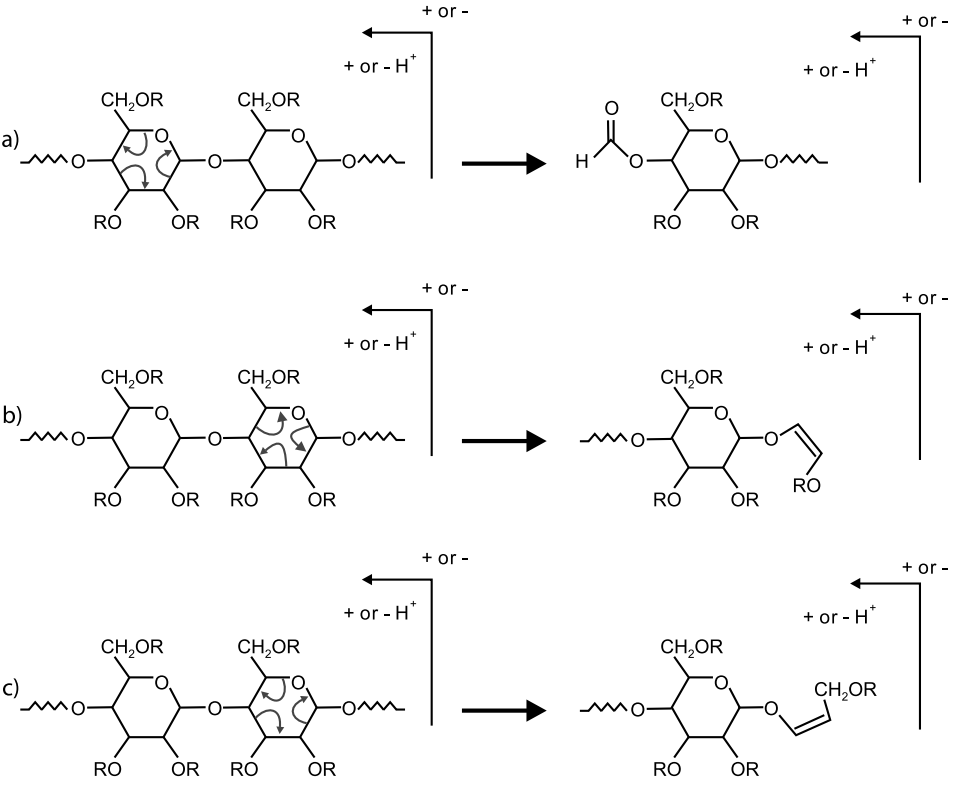
(2) Glycosidic cleavage accompanied by a hydrogen transfer with charge residing on either the reducing or non-reducing ends depending on which bond to the glycosidic oxygen is cleaved. This fragmentation is often referred to as β-cleavage and occurs in both positive and negative modes (*Scheme 2*).

(3) Ring cleavage. The charge can remain on either the reducing or the non-reducing end, depending on the nature of the sample and whether positive or negative ions are being detected (*Scheme 3*).



Scheme 2

Glycosidic cleavages with hydrogen transfer, charge retained on the reducing end (upper) or non-reducing end (lower); sometimes called β-cleavages. In the positive mode, the ions may be protonated as shown or sodiated



Scheme 3

Examples of ring cleavages

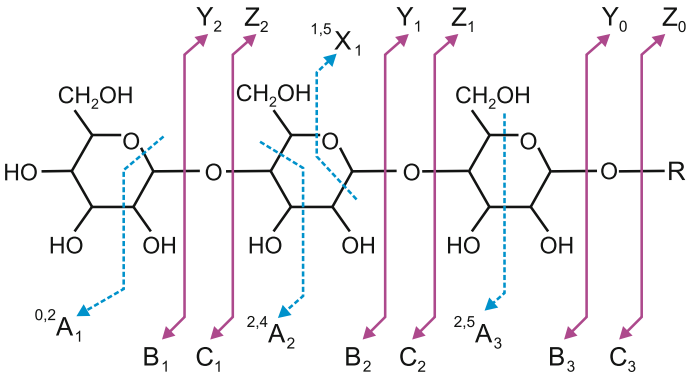


Figure 1
The systematic nomenclature introduced by Domon and Costello [39]. A, B, and C refer to non-reducing terminal fragments whereas X, Y and Z represent reducing terminal fragments

Systematic nomenclature for the fragment ions shown in the above Schemes is depicted in *Fig. 1* [39].

1.7 Enzymatic and Chemical Treatments of Glycans

Another important tool in the structural analyses of glycans is the use of enzymatic and chemical treatments in addition to MS screening and MS/MS sequencing experiments. These treatments provide important information on structural features such as the stereochemistry, monosaccharide unit identity, and linkage. Prior to carrying out these experiments, data derived from glycan profiling and MS/MS analyses are used as a guide for the choice of the appropriate enzyme(s) and/or chemical treatment(s).

Enzymatic degradations are relatively simple experiments from which a significant amount of structural information is obtained. There are various enzymes available. These include exo-glycosidases that remove non-reducing end terminal sugar residues, endoglycosidases which can cleave internal sugar residues, and glycosyltransferases that add sugars to non-reducing positions. These enzymes are usually specific in terms of sugar type, linkages, and anomeric conformation of the sugars they remove or extend. Thus, comparing glycan profiles before and after enzymatic reactions will identify components with specified terminal sugars, or defined internal sequences in the case of endoglycosidases. Chemical treatments compatible with facile MS analysis include hydrofluoric (HF) acid and trifluoroacetic (TFA) acid treatments. HF removes $\alpha 1 \rightarrow 3$ linked fucose residues rapidly whereas $\alpha 1 \rightarrow 2$, 4 and 6 linked fucose are released at a slower rate [40]. Treatment with TFA releases acid labile sugars including sialic acids.

Although some commercially available enzymes are linkage specific, the majority of linkages cannot be defined solely using this approach and/or using the chemical approaches. Hence, linkage analysis experiments are often necessary for rigorous structure analysis.

1.8 Linkage Analyses by Gas Chromatography Mass Spectrometry (GC-MS)

Linkage analysis of partially methylated alditol acetates by GC-MS, coupled with the techniques described earlier, facilitates the assignment of all aspects of the primary structure of glycans. Most importantly, it allows the identification of monosaccharide constituents and glycosidic bond positions. In this technique, glycans are first permethylated in order to derivatize hydroxyl and amide groups. The methyl groups act as permanent tags for hydroxyl groups that are not involved in ring formation or linkage with another sugar residue. The derivatized glycans are then subjected to acid hydrolysis releasing the partially methylated monosaccharides which are subsequently converted to alditols. Hydroxyl groups are then *O*-acetylated thereby providing labels that indicate the positions of the former linkages. The partially methylated alditol acetate (PMAA) sugar derivatives are then analyzed by GC-MS. Monosaccharides can be identified by comparison of their retention times on the GC column and the EI-MS spectra with those of known standards, and quantitation is achieved by comparing peak areas in the ion chromatograms. Linkage analysis is an ideal experiment to carry out after MS and MS/MS analyses of permethylated glycans providing enough material is available.

2 MS Strategies for Glycomics

As pointed out at the beginning of this chapter, the term "glycome" is used to denote the complement of glycans in a cell line, organism etc. Thus, strictly speaking, the term "glycomics" should mean the study of the full complement of glycans from a defined source. In practice, because glycomic investigations are still in their infancy, they are usually confined to studies of subsets of glycans, for example the neutral and sialylated *N*-, *O*-, or lipid-linked glycans present in a particular cell-type or tissue. Over the past decade high sensitivity MS strategies have been devised for screening populations of *N*- and *O*-glycans isolated from a diverse range of biological material, including body fluids, secretions, organs and cultured cell lines. More recently these protocols have been adapted to include glycolipid glycans [41,42]. These glycomic strategies are delineated in ❯ *Fig. 2*. First, glycolipids and glycoproteins are extracted from the biological sample and separately partitioned. Glycans are liberated from the glycolipid fraction using ceramide glycanase, and *N*- and *O*-glycans are released sequentially from the glycoprotein fraction by PNGase F and reductive elimination, respectively. A portion of each glycan pool is then analyzed by MS after permethylation. Putative structures are assigned to each molecular ion based on the usually unique glycan composition for a given mass and prior knowledge of biosynthetic pathways. This is referred to as "mass mapping" and is most conveniently carried out using MALDI ionization because of its very high sensitivity. An algorithm called Cartoonist has been developed to assist data interpretation ([43]; see ❯ Chap. 10.5). Assignments are confirmed and further refined by MS/MS experiments in which molecular ions are selected for collisional activation. Further structural information is provided by linkage analyses and by MS and MS/MS experiments on chemical and enzymatic degradations, the choice of which is guided by the sequence information provided by the initial mass mapping and MS/MS experiments.

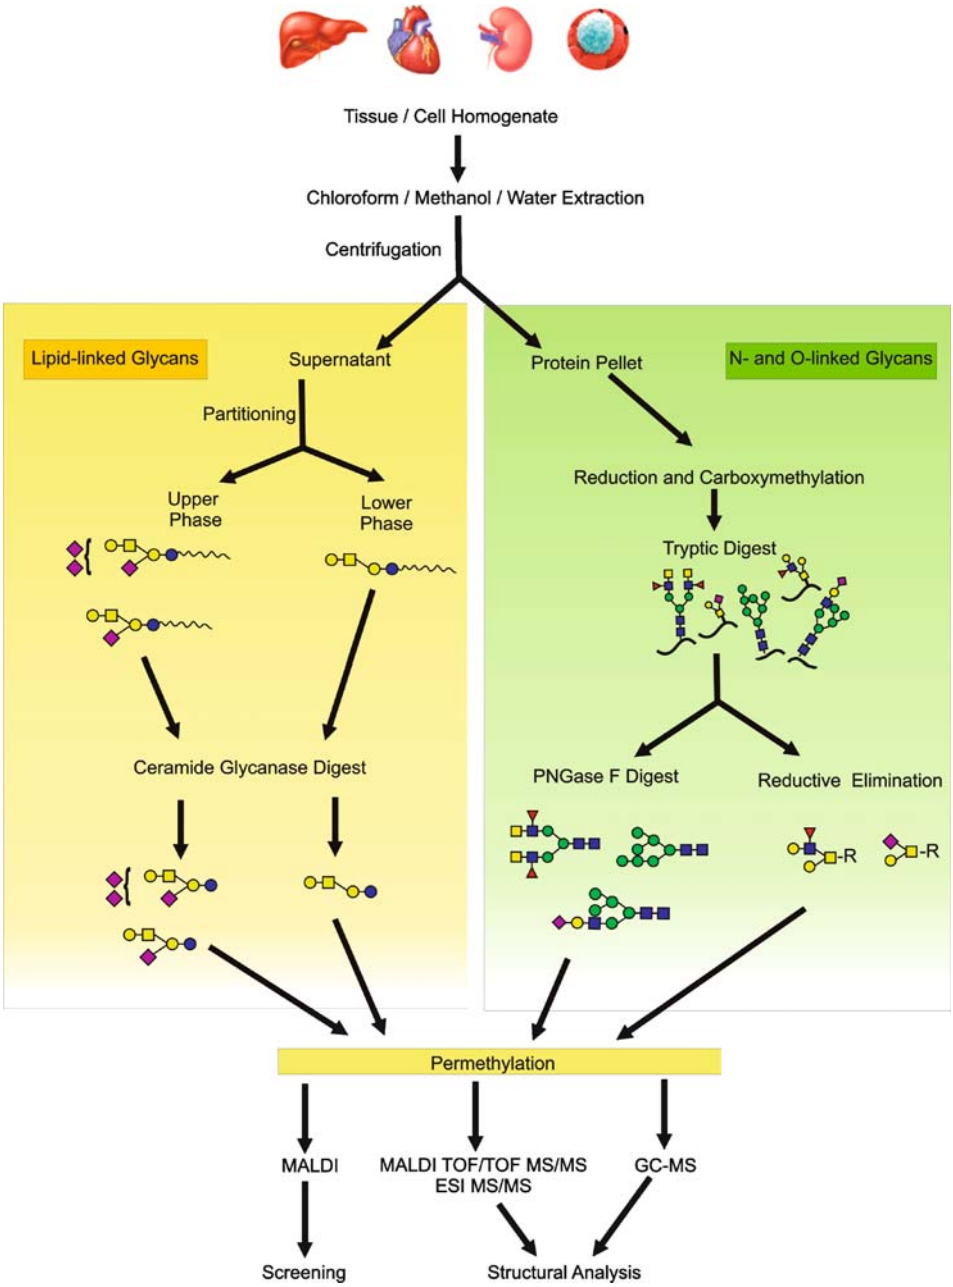

Figure 2

Schematic representation of MS strategies for glycomics. Glycosphingolipids and glycoproteins are extracted from homogenates of biological samples. Glycans are released from the glycosphingolipid fraction using ceramide glycanase and *N*- and *O*-glycans are released from the glycoprotein fraction by PNGase F digestion and reductive elimination, respectively. An aliquot of each glycan pool is permethylated and initially screened by MALDI-TOF MS. R: reduced

These methodologies are illustrated by data from a glycomics analysis of the mouse spleen which is described below.

2.1 Example 1: Characterization of Spleens from Wild-Type and Mgat4a Knock-Out Mice

2.1.1 MALDI-TOF MS Profile

The gene *Mgat4a* encodes the enzyme GlcNAcT-IVa. This enzyme transfers a GlcNAc residue via a $\beta 1 \rightarrow 4$ linkage to the 3-arm of the *N*-glycan trimannosyl core subsequently generating tri- and tetra-antennary *N*-glycans. Knocking out this gene is thought to preclude the formation of tri- and tetra-antennary structures. The MALDI-TOF profiles of the *N*-glycans derived from wild-type and *Mgat4a* knockout mouse spleens are shown in ❯ *Fig. 3* (key symbols are shown in ❯ *Table 1*). In both cases, the molecular ions observed are consistent with high mannose and bi-, tri-, and tetra-antennary complex *N*-glycans. The complex *N*-glycans are predominantly core fucosylated and their terminal structures contain NeuAc/NeuGc residues and Gal-α-Gal epitopes. The most abundant complex structure is a bi-antennary core fucosylated *N*-glycan carrying NeuGc residues on both of the antennae (*m/z* 3026, $NeuGc_2Fuc_1Hex_5HexNAc_4$). On the basis of the MALDI-TOF profiles, the gene that has been knocked out, *Mgat4a*, appears to be compensated for by at least one other gene leading to the very similar *N*-glycan fingerprints.

2.1.2 MALDI-TOF/TOF MS/MS Experiment (*m/z* 2489)

To further characterize the tentative structures predicted from MALDI-MS data, components observed in the wild-type and knockout mouse spleen were subjected to MS/MS analyses using MALDI-TOF/TOF instrumentation. These experiments provide information on features like branching patterns, non-reducing end terminal structures, and sometimes linkage positions. ❯ *Figure 4* illustrates the MALDI-TOF/TOF spectrum of the molecular ion at *m/z* 2489. Major assignments are annotated and fragmentation patterns are shown schematically.
The main signals observed following fragmentation of this molecular ion correspond to independent β-cleavages of HexNAc (*m/z* 2230), HexHexNAc (*m/z* 2026), and $Hex_2HexNAc$ (*m/z* 1822) illustrating the main non-reducing end terminal epitopes. These assignments are further corroborated by the observation of the non-reducing end fragment ions at *m/z* 486 (HexHexNAc) and *m/z* 690 ($Hex_2HexNAc$). Furthermore, the fragment ion at *m/z* 1577 corresponds to the single β-cleavage of $Hex_2HexNAc_2$, confirming a tandem HexHexNAc repeat. The signal at *m/z* 472 indicates that the terminal Hex residue on the $Hex_2HexNAc$ non-reducing epitope is linked to a sub-terminal Hex residue. This is consistent with the presence of Gal$\alpha 1 \rightarrow$ 3Gal$\beta 1 \rightarrow$ 4GlcNAc epitopes. Overall, the data indicate the presence of a mixture of different isomers, as shown in ❯ *Fig. 4*. Diagnostic signals for each isomer are indicated.

2.1.3 ESI-MS/MS Experiment (*m/z* 2651)

ESI-MS/MS is another powerful tool for performing tandem mass spectrometry experiments. To get sequence information on the *N*-glycan at *m/z* 2651 ($FucHex_7HexNAc_4$; ❯ *Fig. 2*), the

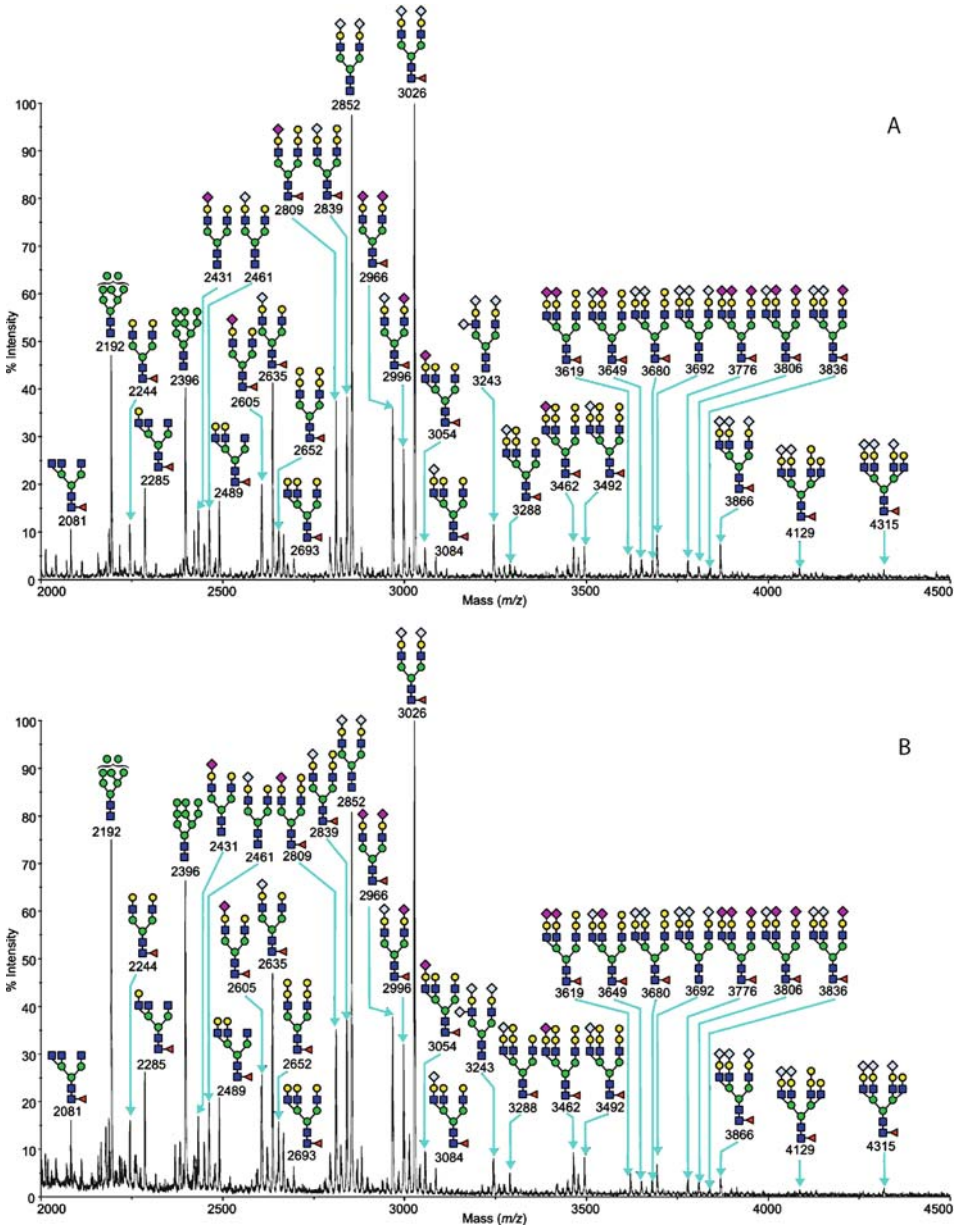

Figure 3

MALDI-MS profiles of the wildtype (panel A) and knockout (panel B) mouse spleen. Putative structures based on knowledge of *N*-glycan biosynthetic pathways and glycan composition are shown. For convenience only one branching pattern for tri-antennary structures is shown. Monosaccharide symbols are shown in *Table 1*

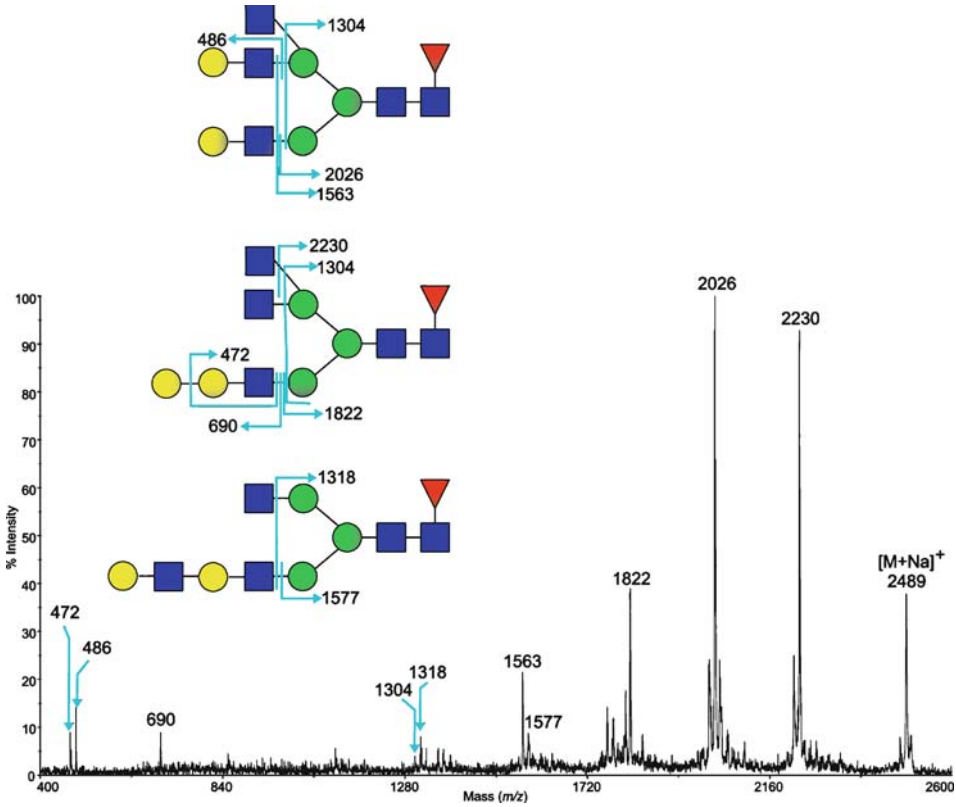

Figure 4

doubly charged sodiated molecular ion $[M+2Na]^{2+}$ (m/z 1337^{2+}) was chosen for MS/MS analyses (*Fig. 5*).

Following fragmentation of the molecular ion, a major signal at m/z 690 corresponding to the non-reducing end structure $Hex_2HexNAc$ established that this is the major non-reducing end epitope of the *N*-glycan. Additionally, the presence of m/z 463 (Hex_2) indicates that the two Hex residues are present in tandem. The signal at m/z 533 represents a cross-ring cleavage and is indicative of a 4-linkage between the sub-terminal Hex and the HexNAc residue. The data therefore provide good evidence for Galα1 → 3Galβ1 → 4GlcNAc epitopes.

Major signals corresponding to a single β-cleavage of $Hex_2HexNAc_1$ (m/z 1984 and 1003^{2+}) were observed. Additionally, a fragment ion produced as a result of a double β-cleavage of two $Hex_2HexNAc_1$ (m/z 1318) epitopes was detected indicating that this is a bi-antennary *N*-glycan carrying $Hex_2HexNAc_1$ on each antenna. Hence, it can be concluded that this *N*-glycan has a core fucose (shown by m/z 474) and two antennae, each carrying a Galα1 → 3Galβ1 → 4GlcNAc epitope.

2.1.4 Enzyme Digest—α-Galactosidase Digestion

To confirm anomeric configurations and the nature of monosaccharide constituents, enzymatic digestions were carried out. In this case an α-Galactosidase digestion was performed. α-Galactosidase is an exoglycosidase that removes terminal α-linked Gal residues from the non-reducing end of glycans. After α-Galactosidase treatment, an aliquot of the digested sample was permethylated and analyzed by MALDI-MS. *Figure 6* illustrates the spectra before (panel A) and after (panel B) digestion.

The signals at *m/z* 2448, 2652, 2665, 2809, 2839, 2897, and 3101, which were present in the glycan mixture before digestion, were absent in the spectrum of the digestion products. These results confirmed the presence of terminal α-linked Gal residue(s) in the structures corresponding to these signals. The remaining complex type structures were insensitive to digestion consistent with their tentative assignments.

2.1.5 Linkage Analysis

Partially methylated alditol acetates were prepared from the permethylated *N*-glycans of the wild-type and knockout mouse spleens, and subsequently analyzed by GC-MS (*Table 2*). The data shows both samples are composed of similar components and are consistent with the structural assignments shown in *Fig. 3*. In particular, 2-linked Man is present at high levels, consistent with the high abundance of bi-antennary *N*-glycans whereas 2,4- and 2,6-linked Man support the presence of tri- and tetra-antennary *N*-glycans. Bisected *N*-glycans are minor components of the mouse spleen, corroborated by the low levels of 3,4,6-linked GlcNAc. The absence of Le^x structures is further supported by the absence of 3,4-linked GlcNAc, while the 3-linked Gal is attributed to Gal$\alpha 1 \rightarrow$ 3Gal epitopes as well as sialylated glycans. The presence of 6-linked Gal indicates that some of the sialic acids are $\alpha 2 \rightarrow 6$ linked to subterminal galactose.

2.1.6 Summary

The strategy described above demonstrates the power of mass spectrometry as a tool for glycomics. From a single mouse spleen, *N*-glycans can be purified, derivatized, and profiled by MALDI-MS to gain information on their compositions. Based on these compositions and the well-defined biosynthetic pathways of *N*-glycans putative structures can be proposed for each molecular ion. Further evidence from linkage analysis (GC-MS), tandem mass spectrometry (MALDI-TOF/TOF MS/MS and/or ESI-MS/MS), and enzyme digests can be used to further refine these putative assignments. The example above is a comparison between a spleen from a wild-type mouse and a spleen from a mouse which has had the *Mgat4a* gene knocked out. The strategy outlined here quickly demonstrated that the *N*-glycans derived from the two spleens were very similar, leading to the conclusion that other genes can compensate for the action of *Mgat4a* in spleen.

3 Glycoproteomics

Whereas glycomics creates an inventory of all the glycans present in a tissue or an organ with no respect to the molecules carrying these glycans, glycoproteomics determines the position and the structure of each glycan carried by a specific protein. In order to achieve this level of structural characterization several experiments are required. The glycoprotein of interest is first isolated from a cell lysate, tissue or a protein mixture by methods such as affinity or lectin chromatography, immunoprecipitation, or electrophoresis. If sufficient material is available, direct MALDI-MS or ESI-MS profiling of the intact glycoprotein can be performed to determine the level of glycosylation. However, this profiling may require a lot of sample and the quality of the results largely depends on factors such as the molecular weight and heterogeneity of the glycoprotein and its ability to ionize efficiently. Therefore digestion to form glycopeptides of manageable size is the preferred route for analysis.

Putative *N*- and *O*-glycosylation sites of a protein of interest can be determined from the amino acid sequence. *N*-glycosylation sites can be identified by the consensus sequences Asn-Xaa-Ser/Thr (where Xaa cannot be Pro), whereas prediction of likely *O*-glycosylation sites is possible in favorable cases using specialist NetOGlyc software (http://www.cbs.dtu.dk/services/NetOGlyc/). Once these putative sites have been identified, a convenient enzyme digestion strategy is designed to produce glycopeptides with molecular weights that are convenient for mass spectrometric analyses (approximately 2000–5000 Da). Once the enzymatic strategy has been decided, the glycoprotein is digested and glycopeptides are analyzed using online

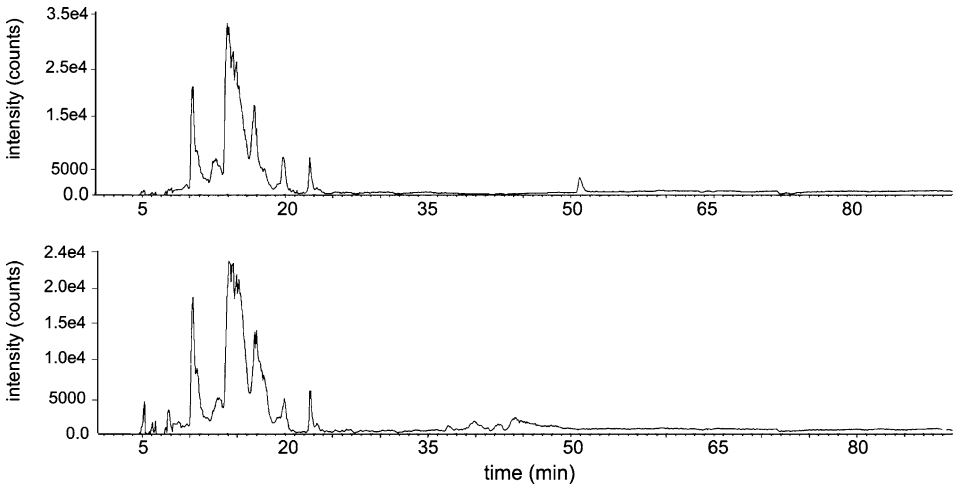

Figure 7

NanoLC-ESI-MS of tryptically digested human IgG. Extracted chromatograms for the two main diagnostic glycan ions, HexHexNAc (*m/z* 366; upper panel) and HexNAc (*m/z* 204; lower panel) are shown. The chromatograms of both ions indicate that most of the glycopeptides elute between 10 and 18 minutes

nano-LC chromatography coupled to ESI-MS and ESI-MS/MS instrumentation. This type of experiment allows the determination of:

- the occupancy of each of the predicted sites;
- the molecular composition of each glycan at each occupied site and consequently the heterogeneity of glycosylation;
- the complete or partial mapping of the glycoprotein sequence.

Although these methodologies are highly sophisticated, they cannot rigorously define glycan features such as stereochemistry, linkage, and branching patterns. To achieve this detail, the glycans must be released from the purified protein and glycomic analyses such as those described in the previous section must be undertaken. To illustrate a typical glycoproteomic strategy, an analysis of human immunoglobulin G (IgG) is detailed below.

3.1 Example 2: Glycoproteomics Analysis of Human IgG

The putative *N*-glycosylation sites of IgG were determined by searching the amino acid sequence for Asn-Xaa-Ser/Thr motifs. Because of the convenient location of lysine and arginine residues in the regions flanking these sites, trypsin was chosen as the most amenable enzyme for producing glycopeptides that are a convenient size for mass spectrometry. Accordingly, the IgG sample was reduced and carboxymethylated to protect S–S bridges, digested by trypsin and analyzed by nanoLC-ESI-MS(/MS). When glycopeptides are subjected to ESI, partial fragmentation of the glycan moiety results in high abundance $[M+H]^+$ fragment ions at *m/z* 204 (HexNAc) and *m/z* 366 (HexHexNAc). This particular feature is extremely useful for the determination of the time window during which glycopeptides are eluted. *Figure 7* shows the extracted ion chromatograms of *m/z* 204 (HexNAc) and 366 (HexHexNAc) of the nanoLC-ESI-MS experiment.

The region in the chromatogram where the diagnostic fragment ions were observed (between 10 and 18 minutes) was then manually searched for glycopeptides and two major species were detected. A signal at *m/z* 1398^{2+} corresponds to the peptide EEQYNSTYR carrying an *N*-glycan with a molecular composition of $FucHex_4HexNAc_4$, whereas the signal found at *m/z* 1479^{2+} (*Fig. 8*) corresponds to the same peptide carrying an *N*-glycan with a molecular composition of $FucHex_5HexNAc_4$.

To confirm the structure of the peptide carrying the two different glycans, nanoLC-ESI-MS/MS experiments were performed. *Figure 9* shows magnification of the regions of the ESI-MS/MS spectrum where series of y″ and b-ions corresponding to peptide fragments were observed. By combining the information gained from the y″-type ions at *m/z* 175, 338, 439, and 526, and the b-type ions at *m/z* 259, 387, and 550 the peptide backbone of the glycopeptide was determined.

To complement the glycoproteomics data, the IgG *N*-glycans were released, and profiled by MALDI-TOF MS using the glycomics strategy described above (*Fig. 10*).

The most abundant molecular ions were detected at *m/z* 1836, 2040, and 2244 corresponding to core-fucosylated bisected glycans with compositions of $FucHex_3HexNAc_4$, $FucHex_4HexNAc_4$, and $FucHex_5HexNAc_4$, respectively. The high abundance of the glycans at *m/z* 2040 and 2244 correlates with the data obtained from the glycoproteomics study.

MALDI-MS spectrum of released *N*-glycans from human IgG. Monosaccharide symbols are shown in *Table 1*

4 Conclusion

Over the past decade, mass spectrometry has revolutionized our knowledge of biological macromolecules. Our understanding of the structures and diversity of glycans present in cells and tissues has increased enormously due to the high sensitivity and versatility of these instruments. Today, mass spectrometers are smaller and more user-friendly than ever before and are becoming de rigueur in university departments and pharmaceutical companies throughout the world. This surge in structural information has been enormously beneficial to the glycobiological community, but has created a new problem. The challenge in the future will be how to interpret and present the huge volumes of mass spectrometric data in a useful and timely fashion. Already, the Consortium for Functional Glycomics has begun to catalogue some of this data (http://www.functionalglycomics.org/), and the following chapter will deal with the role of bioinformatic tools in glycomic analysis.

Abstract

Recent years have seen an increase in both the development and use of informatics tools and databases in glycobiology-based research. Mass spectrometric methods, which are capable of detecting oligosaccharides in the low pico- to femtomole range, are fundamental technologies used in glycan analysis. The availability of robust and reliable algorithms to automatically interpret MS spectra is critical to many glycomic projects. Unfortunately, the current state-of-the-art in glycoinformatics is characterized by the existence of disconnected and incompatible islands of experimental data, resources, and proprietary applications. The development of tools for the robust automatic assignment of glycans on the basis of MS measurements is often hampered by the paucity of available MS data. Here, we review the methodologies for semi-automatic interpretation of MS spectra of glycans, based upon current technology. Three promising approaches are highlighted: (a) combinatorial approaches to the automatic assignment of possible monosaccharide superclass composition—*Glyco-Peakfinder*, (b) the scoring of a set of identified structures with theoretically calculated fragments–*GlycoWorkbench* and (c) the correlation of experimental masses to a database of theoretical fragment masses, in a technique known as Glycofragment Mass Fingerprinting.

1 Introduction

1.1 Definitions

The term '*glycomics*' describes the scientific endeavor to identify, characterize, and study all glycan molecules [1,2,3]. Functional glycomics is defined as the systematic study of glycan interaction with other biological macromolecules, often using modern array technologies [2,4,5,6]. More formally, the term '*glycome*' encompasses the molecular families of glycoproteins, proteoglycans, glycolipids, peptidoglycans, lipopolysaccharides, and any other glycoconjugates synthesized by an organism over its lifetime. '*Glycoproteomics*'—the study of the carbohydrates attached to proteins—is regarded as a branch of proteomics, and is often discussed in combination with other post-translational modifications [7,8]. The analytical techniques to analyze glycans are fundamentally similar to those found in proteomics: electrophoresis and chromatography, mass spectrometry, NMR, and bioinformatics.

1.2 Analytical Techniques

Several intrinsic factors have hampered the development of techniques for the structural analysis of carbohydrates. As the biosynthesis of glycans is not a template-driven process, no biological amplification methods exist. Consequently, carbohydrates either have to be analyzed at their physiological concentration, or time-consuming enrichment procedures such as electrophoresis and HPLC have to be applied. MS methods capable of detecting oligosaccharides in the low pico- to femtomole range are currently the workhorse technologies used in glycan profiling and detailed sequencing [7,9,10,11,12,13,14,15,16,17].
NMR methods enable a complete and unambiguous assignment of all structural features of glycans—from the stereochemistry of monosaccharide units, to the type of linkage between connected units and even down to conformational preferences. However, the large amount of purified material required normally excludes NMR from being used in glycomics projects, where only a low amount of material is available [18].

1.3 Implications of the Structural Complexity of Carbohydrates for the Development of Informatics for Glycomics

The buildings blocks of complex carbohydrates consist of monosaccharides, which often have the same molecular weight and chemical constitution (superclasses), differing only in the stereochemistry of the attached hydroxyl groups. MS techniques are not able to distinguish between different stereoisomers like galactose, glucose, and mannose, which manifest the same residue mass. Consequently, seven main mass constituents of glycoprotein oligosaccharides need to be considered in the majority of mammalian analyses for mammals: Hex (mannose, glucose, galactose), HexNAc (*N*-acetylglucosamine, *N*-acetylgalactosamine), dHex (fucose, rhamnose), NeuAc (*N*-acetyl neuraminic acid), NeuGc (*N*-glycolyl neuraminic acid), HexA (glucuronic, galacturonic, and iduronic acids), and S (sulfate).

This intrinsic property of carbohydrates considerably limits the success of any de novo assignment of monosaccharide composition, although such a technique is feasible for amino acids in proteins (contingent on accurate mass values of the peptide precursor ion and a small number of accurate fragment ion mass values) [19].

In proteomics, 19 of the 20 different naturally occurring amino acids can be identified by their mass. Additionally, the diversity of atoms which constitute monosaccharides is restricted such that C-, O-, and H-atoms occur more frequently, while *N*- and *S*-atoms only rarely occur. This further limits the diversity in elemental composition of glycan fragments when viewed in comparison to those of peptides.

The detection of linkages between monomeric units is a cumbersome process, dependent on the presence of key data points, and so other sources of information such as biosynthetic pathways are incorporated in a structural assignment.

Nevertheless, MS-based studies analyzing the *N*-glycan repertoire often provide a list of fully characterized *N*-glycan structures [9,10], where data from other analytical techniques are included as justification for the assignment.

Supplemental information involved in this detailed assignment is the knowledge of *N*-glycosylation pathways in mammalian systems, from which a number of inferences can be made on the unknown structure.

Therefore, the assignment of explicit *N*-glycan structures can be justified when these two independent sources of information are taken into consideration in parallel.

The structural heterogeneity seen in glycans, for example attached to proteins (glycoforms), is enormous. Although the same glycosylation machinery is available to all proteins in a given cell, most glycoproteins emerge with characteristic glycosylation patterns and heterogeneous populations of glycans at each glycosylation site. More than 100 glycoforms have been reported for a single glycosylation site on a protein, and more than glycoforms are often reported [20,21].

1.4 Structural Diversity of Glycans

Since the biosynthesis of glycans is a non-template-driven process, the catalogue of carbohydrate structures is dependent on the activity of the glycosylation machinery at any point of time. Consequently, all glycans existing in a given species can currently only be coarsely estimated. Hence, the only way to describe the range of expressed glycans is to curate collections of previously characterized structures. In contrast to the genomic and proteomic areas, no comprehensive, currently maintained collections summarizing results from literature have been compiled so far [4,22].

2 (Semi)-Automatic Interpretation of Mass Spectra

Interpretation of glycan mass spectrometric data is still an emerging field. Bioinformatic scientists all over the world are attempting to develop a tool to provide complete structural information (i. e. composition, sequence, branching, linkage, and anomeric state) from mass spectra, without the requirement for additional information derived from specific structural experiments. Up till now, several tools have been developed in different laboratories, mostly with the

aim to solve the specific problems of the working group, thus limiting the type of structures that can be resolved. Additionally, the tools often lack user-friendly interfaces and therefore require expert knowledge to be utilised. The tools summarized in this section are categorized into two families—one which uses data from single mass spectrometry measurements and the other which additionally uses information from fragmentation experiments (*Table 1*).

2.1 Compositional Analysis

Elucidation of glycan composition is a combinatorial problem where the number of compositions that must be tested scales exponentially with the number of different monomers that can form the solution. Therefore, the composition for molecules of high mass can take a very long time to be derived. The number of solutions will also grow at a similar ratio, thus offering an enormously large amount of alternatives to the user. Furthermore, when adducts and other mass spectrometric losses are taken into account, a number of compositions may be indistinguishable within a relatively low mass delta threshold (less than 0.05 Da). Therefore, it is often

useful to introduce constraints to the calculations to make the problem tractable. Taxonomic and biosynthetic information can be used to limit the compositional searches, eliminating any residue classes that are known not to occur in the system or requiring the presence of essential saccharides in any solution composition.

Several tools capable of calculating the sugar composition corresponding to a target mass have been developed. These tools usually employ a combination of dynamic programming and greedy algorithms to solve the combinatorial problem and adopt different approaches for restricting the number of displayed results, showing only relevant data. *GlycoComp* is a commercial software tool developed by Proteome Systems. In *GlycoComp* the derived composition is used in tandem with statistical information from *GlycoSuiteDB* [23] (also from Proteome Systems) to rank compositions, thus presenting solutions deemed to be biologically likely. *GlycoMod* [24] is a web-based tool for compositional analysis. Composition can be restricted by selecting the type of monomers present and the type of glycan (*N*- or *O*-linked). Also, several derivatizations and reducing-end modifications can be taken into account, and the tool is able to compute glycopeptide composition—given a protein sequence and the type of enzymatic digestion. In addition, the derived composition can be used to search for matching structures in *GlycoSuiteDB* [23]. *Glyco-Peakfinder* [25] is the most recent addition to this category of algorithms. Composition can by derived by taking into account a comprehensive list of saccharides, reducing-end modifications, derivatizations, and glycoconjugates (peptides and lipids). The biological relevance of fragments derived with *Glyco-Peakfinder* can be checked by searching if such a composition exits in a structure database. *Glyco-Peakfinder* supports such a search in an open access database. In contrast to other tools, *Glyco-Peakfinder* can also estimate the composition of fragment ions from their masses, giving useful information for sequence analysis. *Glyco-Peakfinder* is described in detail in a following section.

A different paradigm to composition prediction is adopted by the *Cartoonist* tool [26]. *Cartoonist* generates all the *N*- and *O*-linked glycans that could be possibly synthesized by mammalian cells using a set of archetypal structures, and a set of rules for the modification of said structures. The archetypes and rules have been compiled by a group of experts, and represent the current knowledge about biosynthetic pathways in mammalian organisms. By incorporating this pathway information, and using constructive techniques in building structures, the numbers of matching structures are greatly reduced, and only biologically feasible molecules are suggested.

2.2 Sequence Analysis

In contrast to compositional analysis, sequence analysis requires further data derived from additional experiments. Modern MS techniques are capable of producing mass spectra of fragmented carbohydrate molecules, and suitable algorithms have been developed to exploit this information to resolve glycan structure. Unfortunately, even MS^n spectra can be populated by isobaric ions with distinct structures, given that fragments with equal composition share the same mass. However, cross-ring fragmentation can be useful to distinguish among different branching and linkage positions. Sequencing tools can be divided into three categories: semi-automatic, library based, and de novo.

2.2.1 Semi-Automatic Sequencing

Semi-automatic sequencing tools assist the interpretation of a mass spectrum by evaluating a set of structures proposed by the user against a spectrum. Each structure is used to generate a theoretical peak list from its theoretical fragments. The theoretical peak list is then matched with the real peak list obtained from the mass spectra. A number of semi-automatic sequencing tools exist. *GlycoFrag* is one such tool produced by Proteome Systems. Similarly, *GlycoFragments* [27] is a tool that computes all the theoretical fragments of a given structure. Like *GlycoFrag*, *GlycoFragment* displays all the fragments with their associated masses and allows for derivatized structures. Away from web-based tools, *Sweet Substitute* [28] is a Windows-based software package, complete with a graphical interface for building glycan structures. The software is restricted to consider only mammalian *N*-glycans, with no derivatization and reducing-end modifications. Matching of fragments with the given peak list is done automatically. Finally, *GlycoWorkbench* has an easy to use interface for building glycans that displays the structure using symbolic notations. The tool features a complete list of glycan types, derivatizations, monosaccharides, substituents and reducing-end modifications. Raw spectra can be directly loaded into the tool so the user can pick the interesting peaks directly on the graph. The fragments are automatically matched with the given peak list, allowing for multiple cleavages and cross-ring fragments. More details will be given about the tool in later sections.

2.2.2 Library-Based Sequencing Tools

Library-based sequencing tools identify the glycan sequence by matching the unassigned spectra with data derived from known glycan structures. In mass fingerprinting approaches, a database of known structures is used to generate synthetic peak lists which are then matched to the unassigned spectra. This approach is conceptually similar to the peptide mass fingerprinting (PMF) procedures for protein sequencing. Thus far, a single tool has been proposed that automatically evaluates all the glycans from a structure database on the given MS^n spectra, *GlycosidIQ* [29]. The main feature of *GlycosidIQ* is a proprietary scoring function that intelligently ranks the candidate structures. More details about the algorithm and its scoring function are given in the following sections. A restriction of structure library-based methods is that the structures found by mass fingerprinting methods are limited to those already contained in databases. As mentioned, this can be problematic since no exhaustive collection of experimentally derived glycan sequences exists. A different approach to library-based sequencing is through matching against a library of experimentally determined fragment spectra, instead of synthetic peak lists, as described in detail in [30]. Essential to this method is a comprehensive library of experimental MS^2 and MS^3 spectra—which are obtained in a meticulous fashion. A search algorithm is used to identify structures whose library MS^2 spectrum exhibits high similarity to the unassigned spectrum. Afterwards, the unassigned spectrum is analyzed concerning the potential of its MS^3 ions to function as diagnostic ions between candidate structures. The most promising MS^2 ion is selected for additional fragmentation, and the resulting MS^3 spectrum is matched with the library. This approach is highly dependent on experimentally derived data, and since no public collection of assigned MS^n spectra of pure glycans exists, the general availability of this technique is limited. Furthermore, since experimental conditions must be very similar to those under which the library of spectra was recorded, experimental flexibility is limited.

2.2.3 De Novo Glycan Sequencing

De novo glycan sequencing tools are not restricted to previously characterized structures, and thus represent the most promising family of techniques. Unfortunately, many approaches have been proposed, but no single one has demonstrated the capability to deliver the desired accuracy and flexibility. *STAT* [31] prompts the user to select a composition from amongst the alternatives compatible with the precursor mass. The algorithm then calculates all the possible structural topologies having the given composition. The structures thus produced are evaluated against the given peak list, and ranked accordingly. Like *STAT*, *Oscar* [32] generates candidate structures from an estimated composition. *Oscar* uses the information contained in fragmentation pathways derived from MS analysis of permethylated oligosaccharides as a basis for restriction of the set of possible results. All possible result structures must contain the common *N*-glycan mammalian core. For each peak in the provided MS^n fragmentation pathways, a series of structural inference rules are applied to filter the candidate glycan set by eliminating structurally infeasible results, thus retaining only those candidates that are consistent with all input pathways. *StrOligo* [33] proceeds in the opposite way: the differences between fragment masses are used to estimate the loss of known moieties and to produce a candidate composition for the precursor ion. Only glycosidic cleavages are considered, and the structure must not be derivatized. Given the estimated composition of the precursor, *StrOligo* generates a set of structures by applying biosynthetic rules specific to mammalian *N*-glycans. The topology of the proposed structures is limited by the type of terminals that are tested (lactosamine repeats, capping sialic acid, terminal and core fucosylation). *GLYCH* [34] is a dynamic programming algorithm derived from de novo peptide sequencing programs, modified to allow branching in the polymer structure (only binary branching is considered). The *GLYCH* algorithm performs a maximization of the number of assigned peaks by generating a series of b-ions starting from the leaves of the glycan tree structure. The complete structure is generated from the top-level b-ion. In a final re-evaluation phase, the top scoring results from the optimization procedure are re-ranked according to double cleavages. Lastly, Kameyama and co-workers [35] describe a method for matching the unassigned spectra with simulated fragment mass spectra of arbitrary non-characterized *N*-glycan structures. This method is an improvement over library-based spectral matching algorithms and is not limited by the availability of experimentally derived spectra. The simulated fragment spectra are generated from the observation of characteristic fragmentation patterns for every possible branch type of *N*-linked oligosaccharides. The fragmentation patterns have been previously derived by performing collision-induced dissociation experiments of sets of oligosaccharides complementarily labeled with $^{13}C_6$-D-galactose.

3 Approaches with a Potentially Broad Appeal

In the previous section we have given an overview of approaches and tools for assisted interpretation of MS spectra of glycans. It is obvious that unlike for proteomics, currently no widely available and accepted solution exists for the rapid identification of glycans. Here, we describe in more detail three approaches to assisted interpretation and their implementation in more detail. In the opinion of the authors, these three techniques have the promise to become widely adopted. Two of the techniques, embodied in *Glyco-PeakFinder* and *GlycoWorkbench*, are

freely accessible through the Internet. MS technique agnostic, they provide support for the basic daily work needs of scientists when annotating MS spectra of glycans. The glycan fragment mass fingerprinting (GMF) approach, although unable to demonstrate its full potential because of the lack of comprehensive glycan structure databases, seems also to have a high potential to be broadly, and routinely used as soon as free services will become available. An important prerequisite for the success of these tools is that an efficient and user-friendly integration of the currently independent tools is realized.

3.1 Automatic Compositional Analysis of Glycan MS Spectra

All the necessary information to calculate compositions of glycans (i. e. masses of the residues, mechanisms of bond cleavages, ion masses, etc.) is well known. However, as mentioned earlier, efficient solutions to deal with the combinatorial problems are required. The knowledge of the sequence of the underlying glycan in question is not mandatory for performing a compositional analysis. This can easily be understood by comparing the structure of carbohydrates to those of hydrocarbons. For hydrocarbons, although the number of isomers increases with the number of carbon atoms, all structural isomers of one hydrocarbon have the same atomic composition. Accordingly, carbohydrate structures can be treated as linear sequences of monomers, which allows the calculation of their masses by simple incremental addition of the masses of the residues (mass of monosaccharides minus mass of water molecule, i. e. Hex m = 162 u, HexNAc m = 203 u, dHex m = 146 u, etc.). On the basis of this "core", the masses of whole glycans for MS profiles, different fragment types (A, B, C, X, Y, Z: for definition see ❯ *Fig. 1*) in fragment spectra, reducing-end modifications, derivatized structures can be calculated by adding or subtracting further incremental masses.

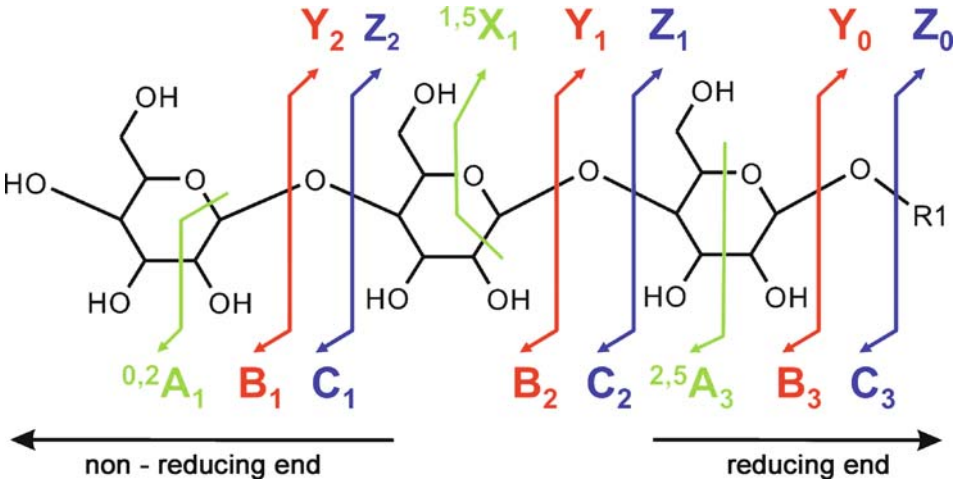

Figure 1
Nomenclature of fragments of carbohydrates as defined by Domon and Costello [47]

Modern MS techniques, such as ESI-MS, often result in multiply charged ions, mostly with ions of different charge states. A fully fledged de novo compositional analysis algorithm should be able to analyze the whole set of signals given from a mixed-stage MS spectra without charge deconvolution in the preprocessing steps.

3.1.1 Glyco-Peakfinder

Glyco-Peakfinder is able to determine the composition for a mass signal independent to the source of spectral data (MALDI, ESI) or fragmentation technique (no fragmentation, LID, CID, ion-trap, etc). This program is able to take into account multiple charges (−4 to +4), multiple cleavages (up to four), all known fragmentation schemes (B-, C-, Y-, Z- and cross ring cleavages A, X: see *Fig. 1*) and modifications (either at the reducing end, or for the whole structure, such as permethylation). The whole calculation is a complete de novo concept and does not need the support of structural databases or any precalculated mass values from (sub-) structures.

Peak lists from mass spectrometric experiments can be uploaded to the web interface of *Glyco-Peakfinder* in several data formats. To decrease the calculation time and number of solutions for each mass value, further options can be set before calculation. The estimated accuracy of the mass signals—representing the experimental technique used—can be given, as well as a choice between monoisotopic and average mass calculation. Depending on the experimental conditions, *Glyco-Peakfinder* can optimize its calculations towards a selection of either glycan profile or fragment spectrum data. Further inputs allow the specification of monosaccharide quantities, including their proposed minimum and maximum occurrence in the structure. As well as the default residues (*Table 2*), up to three new user-specified residues can be used in the calculation.

Advanced settings for the calculation can also be specified in further dialogs. The "ion/charge" settings (see *Fig. 2*, example data were taken from a pyridylamino-oligosaccharide $Hex_3HexNAc_5dHex$-PA fraction obtained from batroxobin of *Bothrops moojeni* venom [36]) refer to experimental technique and fragmentation style: for example, for experimental techniques other than MALDI, ions bearing multiple combinations of charges have to be calculated. Different fragmentation techniques result in different choices for the fragment types and maximum number of cleavages used in the calculation. Finally, the modifications settings enable the calculation of either manually modified structures (i. e. permethylation, reduction, pyridylamination, etc.) or of naturally occurring glycoconjugates, such as glycolipids or glycopeptides.

Table 2
***Glyco-Peakfinder*, a selection of residues**

Classification	Superclasses
Unsubstituted sugars	hexose (galactose, glucose, mannose), pentose (xylose), heptose
Amino sugars	2-aminohexose, 2-*N*-acetylaminohexose (GalNac, GlcNAc)
Desoxy sugars	6-desoxyhexose (fucose), 5-desoxypentose, 4,6-didesoxyhexose (tyvelose)
Others	3-methylhexose, 4-methylhexose, 6-hexuronic acid
Sialic acids	*N*-acetyl sialic acid, *N*-glycolyl sialic acid, KDN, KDO, muramic acid
Substituents	sulfate, phosphate, phosphocholine, pyruvate, acetate

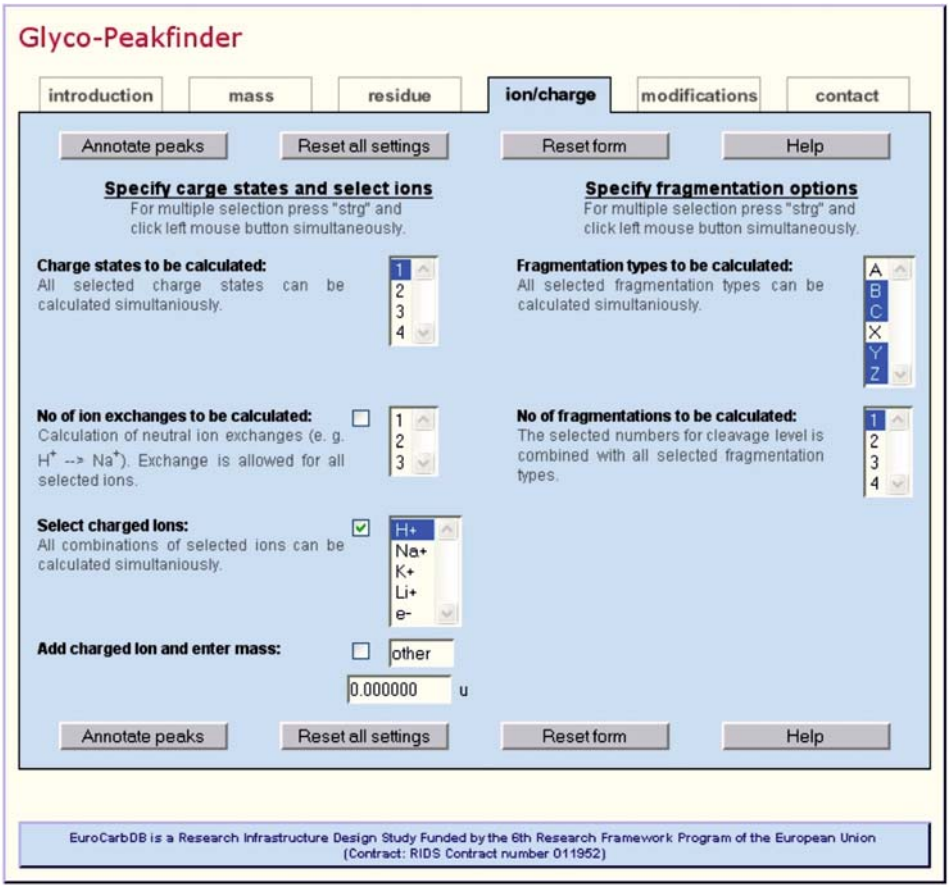

Figure 2

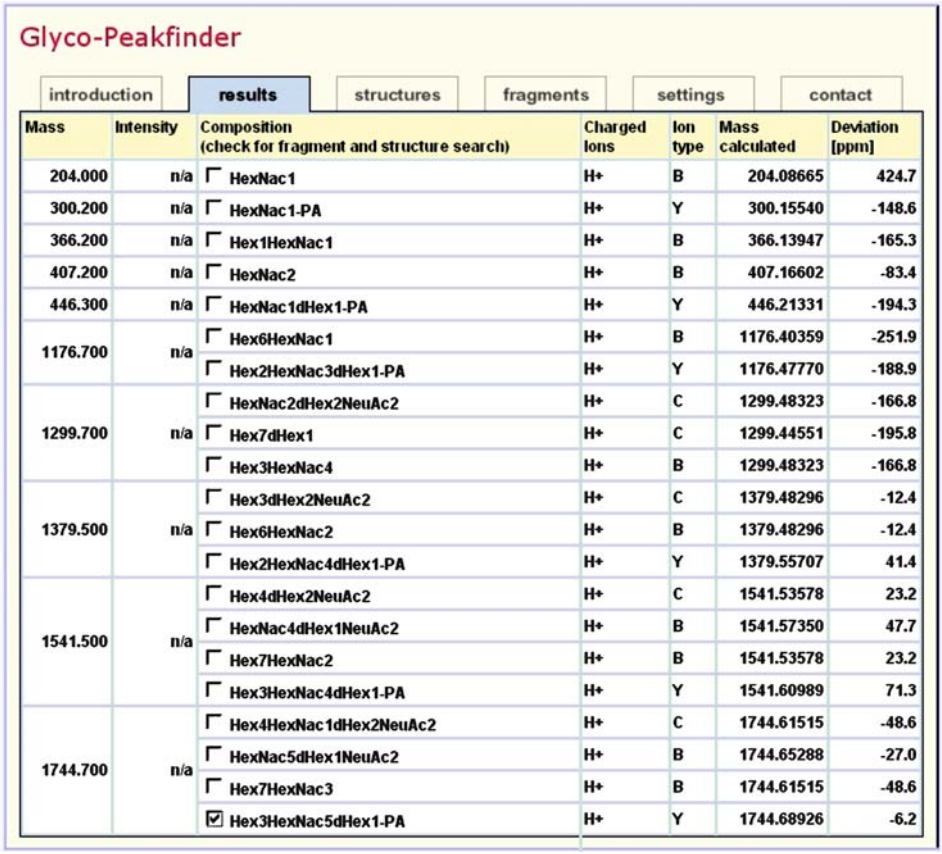
***Glyco-Peakfinder*, ion/charge window. *Glyco-Peakfinder* is a web-based tool for automatic composition analysis of glycan MS spectra. The *Glyco-Peakfinder* ion/charge window allows the specification of parameters, such as charge state or fragment types, to be used for the calculation of possible compositions from the given mass list. The settings in the example were used to calculate compositions from a mass spectrum of a pyridylamino-oligosaccharide $Hex_3HexNAc_5dHex$-PA fraction obtained from batroxobin of *Bothrops moojeni* venom [36]. *Glyco-Peakfinder* can be accessed through the URL: http://www.eurocarbdb.org/applications/ms-tools/**

Starting the calculation leads to a catalogue of possible compositions for all peaks in the mass list according to the specified parameters. Within the results, composition, charged ions, fragment type, and the agreement between measured and calculated masses are displayed (see *Fig. 3*, for example data see [36]).

All calculations up to this point were performed without a structural database. To receive an idea of possible structures belonging to the derived compositions a database search is available (see *Fig. 4*, example data see [36]). The retrieved results from the database can be used for further investigations in *GlycoWorkbench*.



Mass	Intensity	Composition (check for fragment and structure search)	Charged Ions	Ion type	Mass calculated	Deviation [ppm]

Figure 3
***Glyco-Peakfinder* results window. The *Glyco-Peakfinder* results window shows the calculated compositions for mass signals from a mass spectrum of a pyridylamino-oligosaccharide $Hex_3HexNAc_5dHex$-PA fraction obtained from batroxobin of *Bothrops moojeni* venom**

3.2 *GlycoWorkbench*: Assisted Annotation of Fragment Mass Spectra

The previous sections have explained that completely automated annotation of generic glycan mass spectra is still unfeasible. Expert knowledge is fundamental for the correct interpretation of spectra but this is not yet available in the form of machine readable data collections. Tools like *Glyco-Peakfinder* can help to determine the possible candidates for a certain mass value but these hypothetical structures must then be assessed by MS^n fragmentation experiments. Manual annotation of fragment spectra comprises a series of tedious and repetitive steps whose automation is straightforward, and can result in a substantial decrease in the time needed for sequencing a structure. The *GlycoWorkbench* is a suite of software tools designed to assist the experts during the annotation of glycan fragment spectra. The graphical interface of *Glyco-*

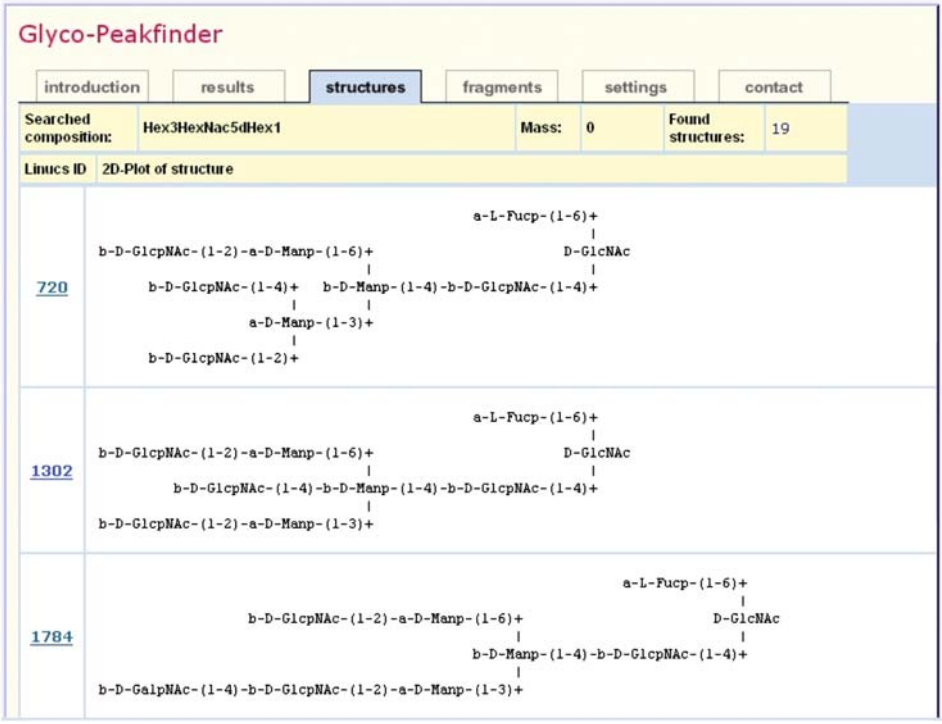

Figure 4
***Glyco-Peakfinder* structures window. The *Glyco-Peakfinder* structures window shows structures in *GLYCOSCIENCES.de* [48] stored for the $Hex_3HexNAc_5dHex$ composition. The retrieved structures are displayed as a 2D graph using an IUPAC-CarbBank-like encoding for complex carbohydrates. LINUCS-ID [49] is an identifier for unique descriptions of glycan structures as used in the *GLYCOSCIENCES.de* portal**

Workbench (see *Fig. 5*) provides an environment in which structure models can be rapidly assembled, automatically matched with MS^n data, and compared to assess the best candidate. The screenshots of *GlycoWorkbench* shown in this chapter are taken from a semi-automatic assignment of a pyridylamino-oligosaccharide $Hex_3HexNAc_5dHex$-PA fraction obtained from batroxobin of *Bothrops moojeni* venom [36], the same experimental setup used for demonstrating the *Glyco-Peakfinder* tool. The three structural models have been retrieved from the result of a composition search with *Glyco-Peakfinder* in a structure database. This demonstrates a possible complete workflow for semi-automatic assignment involving the two tools.

3.2.1 *GlycanBuilder*

The main component of *GlycoWorkbench* is the *GlycanBuilder* [37], a rapid and flexible visual editor of glycan structures (see *Fig. 5*). Carbohydrates mostly present tree-like non-sequential structures, and their constituents exhibit great diversity. Therefore, the input of a structure in a computer readable format is not as straightforward as writing a sequence of characters, as

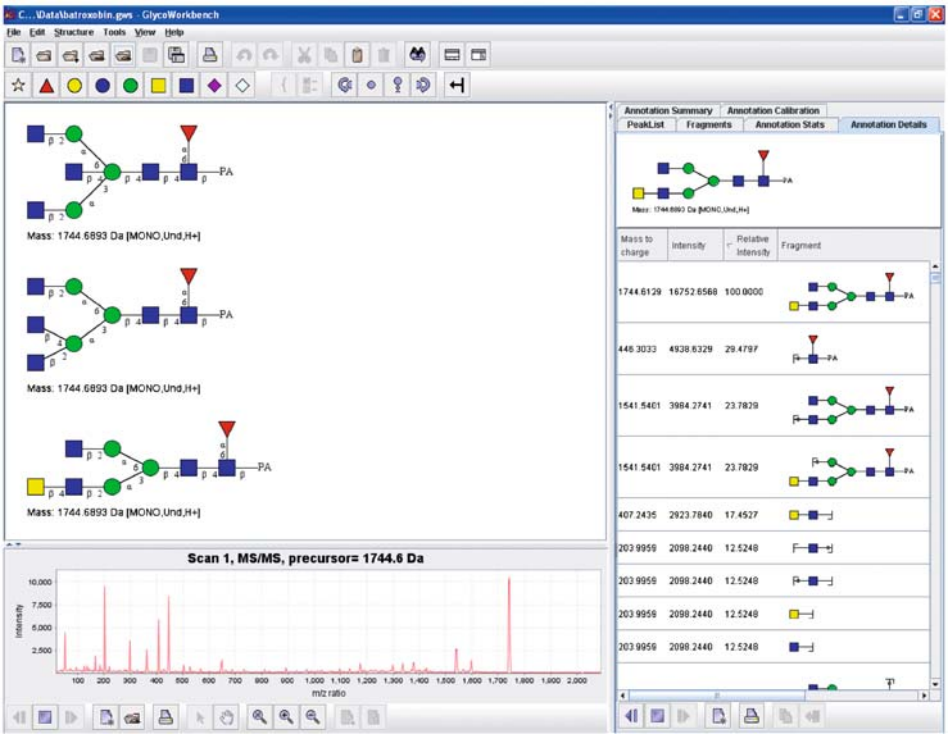

Figure 5

***GlycoWorkbench*, main window. *GlycoWorkbench* is an integrated suite of software tools for assisting the annotation of glycan fragment mass spectra. All the tools are accessible from a common user interface. Here the *GlycoWorkbench* interface with the *GlycanBuilder* (*left top*), the "spectra viewer" (*left bottom*), and the "fragmentation tool" (*right*) are shown. The commonly used cartoon-like representation as recommended by the US Consortium for Functional Glycomics is used to display the oligosaccharide structures. The three structures shown here have been identified with the help of the *Glyco-Peakfinder* structures window (*Fig. 4*) from the *GLYCOSCIENCES.de* database. *GlycoWorkbench* can be downloaded from the URL: http://www.eurocarbdb.org/applications/ms-tools/**

for DNA, RNA, and peptide sequences. Additionally, numerous alternative notations are commonly adopted to graphically represent glycan structures. Two types of structure builders have been developed so far, mainly for searching databases: template-based editors, where the user can only choose among a fixed set of templates and extensions (e. g. Consortium for Functional Glycomics [38], Bacterial Carbohydrate Structure Data Base [39]) and totally graphical editors, where the user can freely position the residues on a drawing board, often manually adjusting the image for optimal layout [40,41]. In the *GlycoWorkbench* editor, the structure is assembled simply by selecting the point of attachment of the residue to add. The spatial placement of the new residue is automatically determined according to the rules for the given notation. Therefore, the display of a glycan is dependent only on its structure and the chosen notation: the software always knows how to represent a structure, and a new notation can

be applied without the need for user intervention. The structure is directly available for use both in bioinformatics computations and for publication purposes. In addition, the structure can be exported into standard encoding formats like *GlycoCT*, or *GLYDE-II* (see *Table 1*) or graphical formats like SVG, PDF, or BMP. The popular notations for glycan representation from the Consortium for Functional Glycomics and the Oxford Glycobiology Institute [42] are available as notation styles. The available constituents comprise an exhaustive list of saccharides, substituents, reducing-end markers, and saccharide modifications. All the stereo-chemical information about a saccharide, like anomeric conformation, chirality, ring configuration, and linkage position, can be specified.

3.2.2 *In Silico* Fragmentation

After a set of structures has been created with the *GlycanBuilder*, the remaining tools can be used to derive their fragments, compute the fragment masses, build a peak-list, and annotate it. Computation of fragments and their masses from the intact structure is a central step for the annotation of CID MS^n spectra. The "fragmentation tool" creates all topologically possible fragmentations of the precursor molecular ion, applying both multiple glycosidic cleavages and cross-ring fragments. The list of possible ring fragments is exhaustive, and is available for all the residues supported by *GlycoWorkbench*. Partial or total loss of labile substituents such as sulfates and phosphates is automatically taken into account. Alternatively, a fragment editor is available where the user can specify which positions the cleavages are occurring on the displayed structure in order to reproduce an already known fragment molecule. Given a fragment structure, m/z values resulting from several types and quantities of charges can be calculated both for native and derivatized structures (permethylated / peracetylated).

3.2.3 Annotation of Peaks

The next step in the annotation process is the definition of a peaklist. In *GlycoWorkbench* a peaklist can either be loaded from a tab-separated text file, thus allowing for import from peak-picking software, or it can be created by typing mass and intensity values directly into the application (see *Fig. 6* and *Fig. 7*). Alternatively, the whole spectrum can be loaded from several standard XML or vendor-specific data formats (supported through the use of the ProteomeCommons IO library [43]). The raw mass spectrum is displayed and can be panned or zoomed as in a normal spectrum viewer. The user can then select mass values directly from the curve, add them to the peak-list or check them on-the-fly for matching against fragment masses. Once the peak-list is ready, the fragmentation tool is used to generate all the possible fragments of each input structure and their m/z values are tested for matches against every peak given the desired accuracy. The resulting annotated peak-list can then be viewed using various panels that show its different aspects. Each panel is based around a spreadsheet-like table view, whose cell values can be sorted by each column, and can be copied into spreadsheet software. The detailed view (see *Fig. 7*) lets the user check a comprehensive list of fragment-peak matches for each of the structures, showing the fragment structure, mass, m/z value, distribution of charges, and annotation accuracy. The annotation can also be reviewed by removing the matches that are not satisfactory. The summary view (see *Fig. 6*) lets the user compare the annotations for the different structures back-to-back in the same table. The

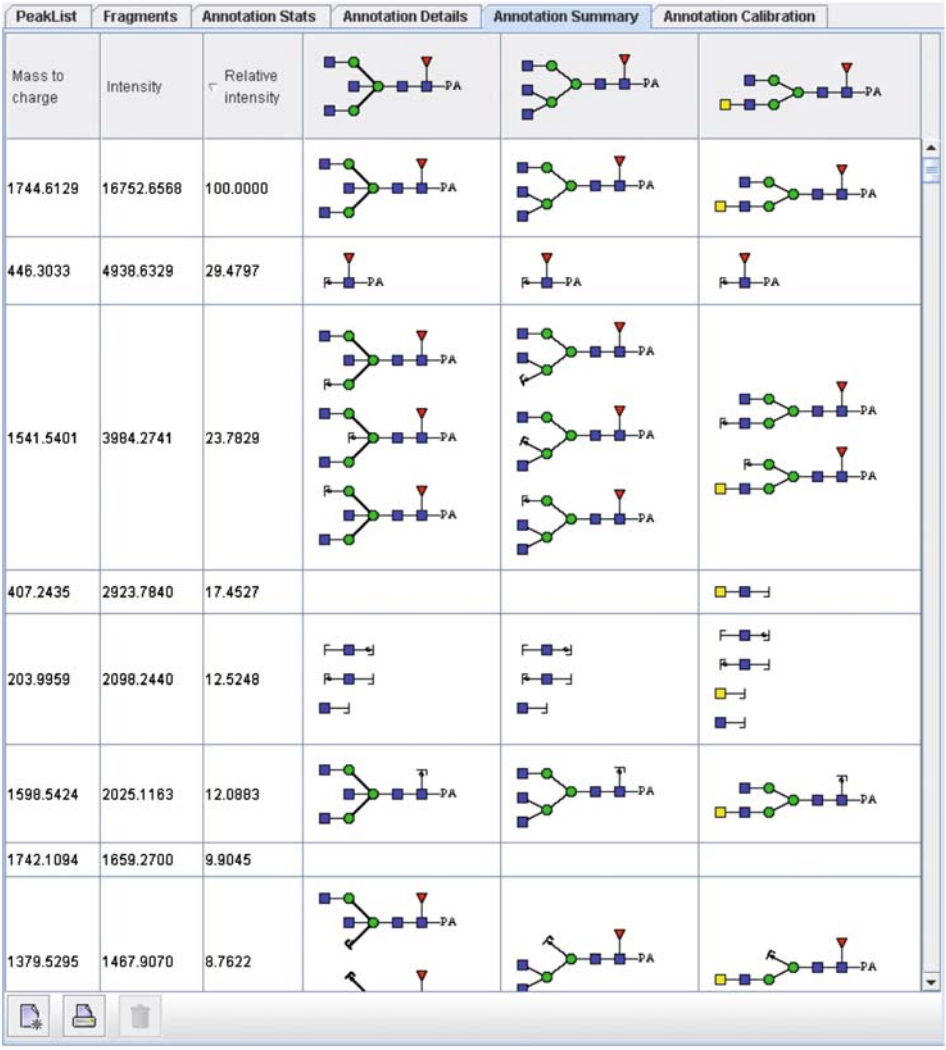

Figure 6

***GlycoWorkbench*, annotation summary view. The *summary* view enables a direct comparison of peak assignments to fragments for various user-selected structures back-to-back in the same table. The matching fragments from different structures are shown in adjacent columns, with each row corresponding to a single peak. The user can thus identify signals which clearly distinguish the correct annotation from the other hypothetical models**

matching fragments from different structures are shown in adjacent columns, with each row corresponding to a single peak. In this way, signals that clearly distinguish the correct annotation from the other hypothetical models can be identified. The statistics view lets the user perform a quantitative comparison between the annotations, by showing the number of assigned

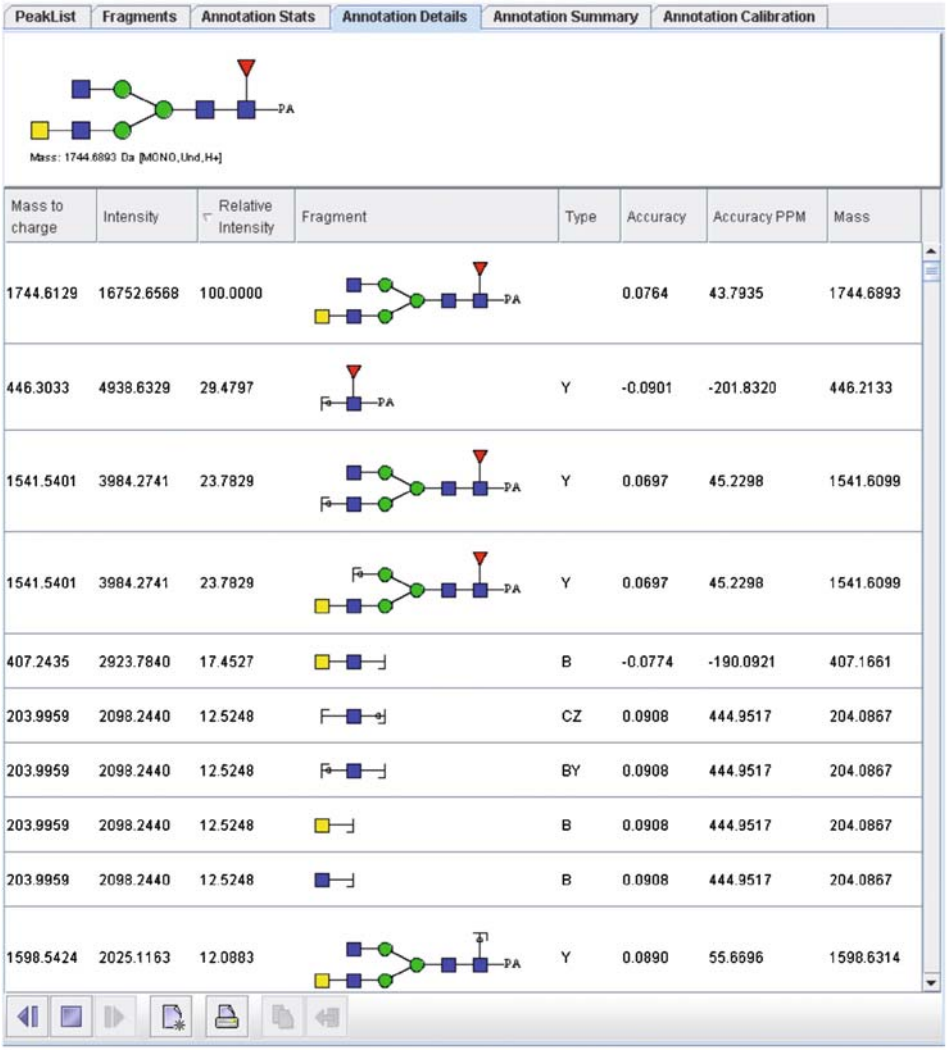

Figure 7

***GlycoWorkbench*, annotation detailed view. The *detailed* view enables users to check for each individual structure all the fragments that match at least one measured peak, showing the associated fragment structure, theoretical mass, m/z value, distribution of charges, and annotation accuracy. In this panel, the annotation can also be reviewed by removing the matches that are not satisfactory**

peaks at different thresholds of relative peak intensity, the root mean square deviation between peak and fragment *m*/*z* values and the average intensity of assigned peaks. Finally, a calibration graph shows the annotation accuracies at the various *m*/*z* values, allowing the user to check the correct calibration of the mass spectra.

3.3 Glycofragment Mass Fingerprinting

Glycofragment Mass Fingerprinting [27,29] is a bioinformatic technique analogous to Peptide Mass Fingerprinting [44,45], suggesting structures for a particular glycan fragmentation mass spectrum. In GMF, experimental masses are matched up against a database of theoretical fragment masses, and the best matches are presented as results.

Fundamental to GMF, a comprehensive library of structures serves as the source of theoretical fragmentation data. Each of the structures within the library is transformed into a set of fragments by performing a virtual cleavage of bonds. This produces a set of fragmentations for each structure that is representative of all possible fragmentations that could occur on the glycan. Each fragment has a mass associated with it that can be considered as a virtual peak mass for the fragment.

The underlying GMF technique can be split into two stages—with the first being the matching of spectra against the library of known fragmentations, and the second being the scoring and ranking of candidate structures.

3.3.1 Matching of Spectra

An important preprocessing step in performing the search is to ensure that all spectra being used in the algorithms are normalized, and no mass spectrometric or experimentally specific modifications to the spectrum are reflected in the data used in the algorithm execution. To achieve this, many GMF tools normalize all m/z values by resolving the charge state and removing any adducts. This functionality is controlled through the setting of various experimental parameters (such as charge state, adducts, and derivatizations). Certain tools can also accept spectral data in XML format allowing for automatic normalization of spectra.

Structures which match up with the input structure are then selected using a voting algorithm, where each fragment derived from a structure will count as a vote for that structure if the virtual peak mass matches with a normalized peak mass. Those structures having at least one vote (or matched fragment) are candidate structures for the match. Each normalized peak mass may not necessarily match up with a single fragment mass from a structure, as many fragmentations from a structure can share the same mass.

3.3.2 Scoring of Candidate Structures

The scoring stage of GMF is the most important part of the matching process whereby candidate structures are ranked according to the suitability of match to the input spectrum. A number of approaches can be taken in this stage, from simple counting of matched peaks to algorithms that perform an analysis of the evidence presented by the matched peaks.

There are no standard sets of scoring methods, so the methods available in each tool differ, however, it is generally accurate to say that current scoring algorithms do not provide a single reliable quantitative measure for the match. Instead, combinations of scores are used as an aid to the further interpretation of data using expert knowledge.

GMF excels at distinguishing between structural isomers, as match information from a search can be important in identifying diagnostic ions that support one structure over another. Important diagnostic ions are often related to cross-ring fragmentation, which will yield information related to the linkages on a structure.

3.3.3 Limitations of GMF

Limitations of GMF approaches are related to the data that comes in to the algorithms. Since tandem MS data is not as information rich as a set of multiple-stage MS spectra, it may not be possible to distinguish between two structures based on the one spectrum alone. In fact, it is often the case that supplemental evidence is required to make a confident assertion that structures have been assigned correctly.

The quality of the GMF match that occurs is dependent on the quality of the library of structures. When the library of structures is incomplete, there may be a chance that the structure in question may not be part of the library, and an incomplete or incorrect assignment may result. This can be mitigated in part through the use of intelligent scoring algorithms that can rank structures that are similar to the actual (unknown) structure highly.

The term mass fingerprinting is a slight misnomer when applied to glycan fragmentation, as the structures do not necessarily yield unique "fingerprint" spectra when fragmented. In fact, due to the nature of the fragmentation of some structures, many spectra are isobaric. This problem is in fact inherent to tandem MS spectra where high levels of fragmentation are desired. Although it is possible to deduce the combination of fragmentations that have occurred to produce a fragment in optimal experimental conditions, you often cannot discern the order of fragmentation, or the pathway of fragmentation needed to produce that fragment. It is for this reason that one-off spectral matching will not work well for larger glycan structures. However, spectral matching has been shown to work well when used to identify smaller structures, working well enough to even distinguish the stereochemistry for residues. Used in combination with multiple-stage mass spectrometry, it is possible to control the fragmentation pathway so that all fragmentations are well characterized. This MS^n [32,35,46] approach to analysis is a fundamentally different approach to GMF, yielding significantly richer data, and obviating the need for sophisticated scoring algorithms. The key to the success of MS^n approaches is the ability to select ions for further fragmentation.

For spectra where it is not possible to distinguish between two structural isomers, clarification of structure can be found through the further fragmentation of the structure. To do this, algorithms pick out the peaks corresponding to the glycan fragments containing the sub-structures in question. This is a recursive approach to sequencing, where ion selection and further fragmentation occurs until the structure is fully elucidated. Coupled with technologies to control the ion selection on the mass spectrometer, this technique shows promise for fully automated identification and sequencing of structures.

4 Summary and Conclusion

Investigations into the analytical techniques of glycans showed clearly that mass spectrometry is still the key technology for research involving the analysis of carbohydrate structure. Despite its popularity, the automatic interpretation of MS spectra is an analytical bottleneck in the rapid and reliable interpretation of MS data in high-throughput glycomics projects, and robust solutions are of critical importance. Given the importance of establishing such solutions, it is not surprising that various experimentally oriented groups have been developing software solutions and algorithms to bypass this bottleneck.

A side-effect of the multiple efforts being put into place to solve this bottleneck is that the current situation in glycoinformatics can be characterized by the existence of multiple disconnected and incompatible islands of experimental data, data resources, and specific applications, each managed by various consortia, institutions, or local groups. This is in no small part due to the closed nature of much of the software—only a limited amount of software is freely available to be shared by various projects.

The coverage and capability of existing tools is somewhat varied—compositional analysis is well served by the current number of tools available, encompassing a number of approaches to the analysis. For MS tools, the existing software serves the needs less well for general researchers, primarily due to the availability of the programs. However, with respect to functionality, the tools are capable of performing semi-automatic interpretation, functioning as an additional source of information in the elucidation of structure.

Recent developments have raised the hope that in the near future freely available software suites for compositional analysis as well as for annotation of spectra (such as *Glyco-Peakfinder* and *GlycoWorkbench*) will form the basis of software which can support easy and reliable semi-automatic assignment of complete MS spectra to glycans.

Other library-based approaches (such as GMF) would benefit from free availability of databases, containing structural information as well as spectrometric data. The use of widely available free databases would enhance the use of informatics in glycomics to a level comparable to proteomics, where the use of databases is part of daily work in nearly all laboratories.

A long-term goal of informatics for glycomics is to enable high-throughput analysis of data. To do this, each piece of software must be able to automatically interact, functioning as an analysis pipeline. The issue of interoperability is not only important between tools, but is a crucial issue with respect to databases also. Maturity in the glycomic software area will allow for data to freely move between databases and software, providing maximum flexibility in analysis workflows. With the agreement to accept *GLYDE-II* (see NIH White Paper: "*Urgent requirements for the development of informatics for glycomics and glycobiology*") as the central format to exchange structural data, a fundamental issue surrounding interoperability has been solved.

It is becoming clear that the optimal way to provide semi-automatic, and even wholly automatic sequencing of structures is through a pluralistic methodology, using multiple analytical techniques such as HPLC, NMR, glycan arrays, and GC MS. This multi-technique approach to analysis, including the automated integration of data from multiple sources yields the best possibility for achieving a fully automatic unambiguous structural determination.

Acknowledgement

Glyco-Peakfinder and *GlycoWorkbench* are developed as part of the EUROCarbDB project, a Research Infrastructure Design Study Funded by the 6th Research Framework Program of the European Union (Contract: RIDS Contract number 011952). The development of the *GLYCOSCIENCES.de* portal at the DKFZ (German Cancer Research Center) was supported by a Research Grant from the German Research Foundation (DFG BIB 46 HDdkz 01–01) within the digital library program as well as the president fond of the Helmholtz society.

Part 11
Biosynthesis and Degradation

11.1 Biosynthesis and Degradation of Mono-, Oligo-, and Polysaccharides: Introduction

Iain B. H. Wilson
Department für Chemie, Universität für Bodenkultur
(University of Natural Resources and Applied Life Sciences),
Muthgasse 18, 1190 Wien, Austria
iain.wilson@boku.ac.at

Abstract

Glycomolecules, whether they be mono-, oligo-, or polysaccharides or simple glycosides, are—as any biological molecules—the products of biosynthetic processes; on the other hand, at the end of their lifespan, they are also subject to degradation. The beginning point, biochemically, is the fixation of carbon by photosynthesis; subsequent metabolism in plants and other organisms results in the generation of the various monosaccharides. These must be activated—typically as nucleotide sugars or lipid-phosphosugars—before transfer by glycosyltransferases can take place in order to produce the wide variety of oligo- and polysaccharides seen in Nature; complicated remodelling processes may take place—depending on the pathway—which result in partial trimming of a precursor by glycosidases prior to the addition of further monosaccharide units. Upon completion of the 'life' of a glycoconjugate, glycosidases will degrade the macromolecule finally into monosaccharide units which can be metabolized

Chapter-DOI 10-1007/978-3-540-30429-6_58:

or salvaged for incorporation into new glycan chains. In modern glycoscience, a wide variety of methods—genetic, biochemical, analytical—are being employed in order to understand these various pathways and to place them within their biological and medical context. In this chapter, these processes and relevant concepts and methods are introduced, prior to elaboration in the subsequent more specialized chapters on biosynthesis and degradation of mono-, oligo-, and polysaccharides.

ATP	adenosine triphosphate
CDG	congenital disorder of glycosylation
CDP	cytidine 5′-diphospho-
CMP	cytidine 5′-monophospho-
Dol-P	dolichol phosphate
dTDP	deoxythymidine 5′-diphospho-
EGF	epidermal growth factor
$EtNPO_4$	ethanolamine phosphate
GDP	guanosine 5′-diphospho-
GlcNAc-T	*N*-acetylglucosaminyltransferase
GPI	glycosylphosphatidylinositol
NAD	nicotinamide adenine dinucleotide
NADP	nicotinamide adenine dinucleotide phosphate
NDP	nucleoside diphosphate
PAPS	3′-phosphoadenosine 5′-phosphosulfate
PEP	phosphoenolpyruvate.
TSR	thrombospondin type 1 repeat
UDP	uridine 5′-diphosphate

1 General Principles

The term ‘glycoconjugate’ encompasses a wide range of biological molecules containing at least one monosaccharide unit combined with other moieties, which can be either glycosidic or non-glycosidic in nature. Correspondingly, the breadth of molecular transformations of these molecules—leading to their formation or degradation—is also large and great strides have been made in the past two or three decades as regards our understanding of the structures themselves and the various biochemical pathways in which they are involved. Most recently, molecular biology has revolutionized the study of the enzymes responsible for these biotransformations and has made larger quantities of protein available for enzymatic and structural characterizations. These enzymes fall into a number of categories—those involved in synthesizing the building blocks of glycoconjugates (i. e., a variety of enzymes required for

monosaccharide synthesis and modification), those involved in generating glycosides (glycosyltransferases, which transfer one or more sugars to another molecule) and those involved in breaking the bonds made by glycosyltransferases (primarily glycosidases). Furthermore, transporters and flippases necessary for transferring glycomolecules across biological membranes are also important in completing the vast biochemical network required for the biosynthesis and degradation of mono-, oligo-, and polysaccharides.

The starting point for this biochemical journey from monosaccharide to glycoconjugate and back again is photosynthesis and, indeed, glucose is a central player in the ability of cells to generate glycoconjugates. Although knowledge about glycoconjugates has increased vastly in the last century, it is still of interest, in this context, to quote Armstrong from his 1919 monograph [1]:

"The interest attaching to the [carbohydrates] may be said to centre around glucose, this carbohydrate being the first to arise in the plant and the unit group from which substances such as cane sugar, maltose, starch and cellulose are derived; it is also of primary importance in animal metabolism, as the main bulk of the carbohydrate in our food materials enters the circulation in the form of glucose."

It is not the intention here to discuss the synthesis of glucose and glucosidic polymers such as starch or glycogen and their central role in energy storage and production. However, every monosaccharide is 'descended' in some way from glucose; thus, any discussion of biosynthesis and degradation of glycoconjugates must give some attention to the transformation of glucose into other sugars and, thereby, Armstrong's comment is still relevant. A number of steps including epimerization, decarboxylation, dehydration and reduction are necessary to turn glucose into the range of monosaccharides observed as components of glycoproteins with their *N*- and *O*-linked glycans, proteoglycans, glycolipids, peptidoglycans, lipophosphoglycans, simple glycosides, nucleic acids and other sugar-containing molecules and polymers.

Another important general principle is that, prior to the joining of a sugar to the 'acceptor', which can be another sugar or another type of molecule, the monosaccharide must be activated (other than in the case of transglycosylation). This reflects the requirement for energy in the formation of glycosidic bonds; this energy originates from ATP (the synthesis of which is itself driven by the oxidative phosphorylation of glucose). In turn, this means that, in general, sugars are present in the form of nucleoside mono- or diphosphosugars or lipid-linked phosphosugars; it is these activated forms which are the 'donors' for the reactions catalysed by glycosyltransferases (EC 2.4.1.-, 2.4.2.- and 2.4.99.-). In some cases, glycosidases can be used to also generate glycosidic bonds, but these reactions are often transglycosylations resulting from the use of these enzymes under very artificial conditions or of genetically engineered forms ('glycosynthases'); although enzymes which naturally transglycosylate do exist, e. g., the *trans*-sialidase of *Trypanosoma cruzi* or plant xyloglucan endo-transglycosylases [2,3], the vast majority of enzymes of glycoconjugate biosynthesis are glycosyltransferases requiring nucleotide sugars and it is these which are the focus of much attention in glycobiology.

In 'opposition' to the enzymes forming glycosidic bonds are those that degrade them, primarily members of the vast families of glycosidases (EC 3.2.1.-). In contrast to the glycosyltransferase reaction, the hydrolysis of a glycosidic bond is thermodynamically favourable, with ΔG° values of approximately –10 kJ mol^{-1} [4]; at the same time, activation energies of perhaps +40–80 kJ mol^{-1}, as in the case of mammalian lysosomal hexosaminidases [5], indicate that these reactions require a catalyst. It is also interesting that glycosidases are often chemically and structurally well-described, due to the relative ease of purification, recombinant expression,

assaying and handling of these enzymes as compared to glycosyltransferases which are considered 'finicky' to purify or express and expensive to assay. Despite this 'advantage', the biological role of catabolic glycosidases in higher organisms is often neglected as compared to the glycosyltransferases, particularly those involved in *N*-linked glycan biosynthesis. However, their clinical relevance is shown particularly well by the various 'storage' diseases which result from mutations in the genes encoding either lysosomal glycosidases themselves or the proteins required for their targeting [6]. Indeed, many 'knock-outs' (natural or artificial) demonstrate that the proper biosynthesis and degradation of a range of mono- and oligosaccharides is a prerequisite for biological viability.

2 Components and Types of Glycoconjugates in Mammals

A major focus of modern glycoscience is on the oligosaccharides of mammalian glycoconjugates. Mammals express a range of these macromolecules—proteins with either *N*-linked, *O*-linked or *C*-linked oligosaccharides, glycosylphosphatidylinositol membrane anchors, glycolipids and glycosaminoglycans (*Fig. 1*) as well as the storage polymer glycogen [7,8]. The *N*-linked oligosaccharides or *N*-glycans all share a common pentasaccharide core consisting of two *N*-acetylglucosamine and three mannose residues; this core is elaborated in a number of ways depending on the class of oligosaccharide. The categories of oligomannosidic (or 'high mannose'), hybrid and complex oligosaccharides have been known for many years and will be discussed in more detail in Chap. 11.2; it is sufficient to say that the range of structures is very broad and that, for mammalian *N*-glycans, the most important monosaccharides are *N*-acetylglucosamine, mannose, galactose, glucose, *N*-acetylgalactosamine, glucuronic acid, fucose and sialic acids. Modifications with sulfate and phosphate are also known.

The *O*-glycans, on the other hand, have a wide range of possible core structures—not only should the typical 'mucin-type' *O*-linked sugars (*N*-acetylgalactosamine linked to serine or threonine) be considered; furthermore, as recently reviewed by Spiro [8], other linkages of fucose, galactose, glucose, xylose, mannose and *N*-acetylglucosamine are also present. Some of these have important biological functions. For example, cytosolic/nuclear '*O*-GlcNAc' is an element, 'competing' with phosphorylation, in controlling protein function [9], while *O*-fucose functions as a modifier of Notch signalling in development [10]. Furthermore, *O*-mannose is a form of glycosylation of dystroglycan with roles in certain forms of muscular dystrophy [11] and *O*-linked xylose is the first sugar in chondroitin and heparan sulfate glycosaminoglycan chains [12]. Whereas 'mucin-type' *O*-glycans contain monosaccharides familiar as modifications of *N*-glycans (*N*-acetylgalactosamine, *N*-acetylglucosamine, galactose, fucose and sialic acids), the chondroitin and heparan sulfates contain a core of GlcAβ1,3Galβ1,3Galβ1,4-Xylβ1-O-Ser which is then modified by either GalNAcβ1,4GlcAβ1,3 (chondroitin) or GlcNAcα1,4GlcAβ1,4 (heparan) repeats. These sugars can then be modified by sulfation or, in the case of glucuronic acid, epimerization to iduronic acid. In the case of epidermal growth factor-like (EGF) and thrombospondin type 1 repeat (TSR) domains of, e. g., blood clotting factors, the modifications by Xylα1,3Glcβ-O-Ser and *O*-fucose must also be considered [13], whereas hydroxylysine residues of collagen and collagen-like domains can carry Glcα1,2Gal structures [14]. A more unusual modification is the *C*-mannosylation of tryptophan also present on thrombospondin repeats of certain proteins [15].

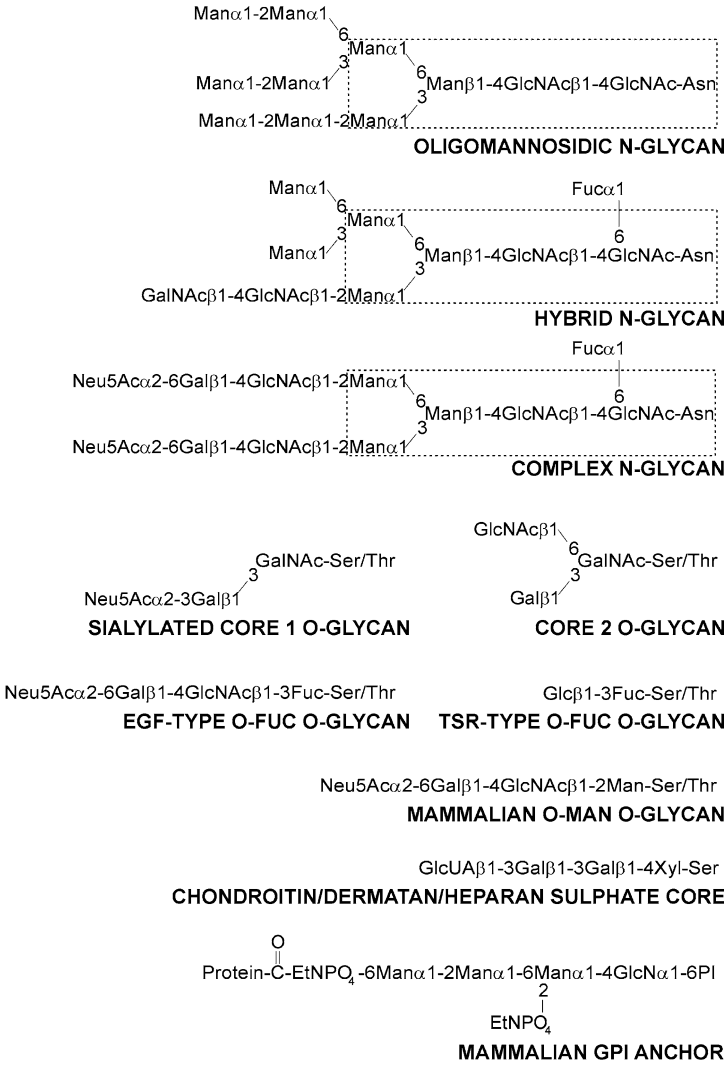

Figure 1

The main types of mammalian protein-linked glycoconjugate. A selection of typical mammalian protein-linked glycans (*N*- and *O*-linked), as well as a glycosylphosphatidylinositol (GPI) anchor, are shown. As typical *N*-glycans, an oligomannosidic structure ('Man9'), a hybrid structure found in a mannosidase double-knockout mouse and a sialylated core fucosylated biantennary structure are depicted; the common pentasaccharide core is boxed. 'Mucin-type' core 1 and core 2 *O*-glycans, the *O*-fucose-type glycans of EGF and TSR repeats, the *O*-mannose-type glycan of, e. g., dystroglycan and the core tetrasaccharide region of chondroitin, dermatan and heparan sulfate glycosaminoglycan chains are also shown. In the case of mammalian GPI anchors, the inositol portion of the phosphatidylinositol (PI) moiety is typically acylated; other side chains on the glycan moiety are possible. Other modifications such as cytoplasmic *O*-GlcNAc, collagen-type *O*-glycans, *O*-glucosylation of EGF domains and *C*-mannosylation of tryptophan are not included. See text for references

Figure 2
Major categories of glycosphingolipid. The six basic cores of mammalian glucosylceramides, two types of mammalian galactosylceramide and the core of an insect/nematode *arthro*-type glycosphingolipid are shown [7,17]

In the case of glycosylated lipids, the glycosylphosphatidylinositol (GPI) membrane anchors and the glycosphingolipids represent distinct categories of glycoconjugate. The GPI anchors replace traditional *C*-terminal transmembrane domains on a number of proteins such as decay accelerating factor (DAF) and a form of the neural cell adhesion molecule (N-CAM-120); they are based, as the name suggests, on a phosphatidylinositol lipid moiety elongated with a $GlcNMan_3EtNPO_4$ structure; the *C*-terminus of the mature protein is linked through the ethanolamine moiety via an amide bond [16]. Glycosphingolipids, on the other hand, are not covalently linked to protein, contain a core glucose or galactose residue linked to ceramide and often act as receptors for bacteria or their toxins. These two monosaccharyl lipids are modified by a variety of structures—the mammalian glucosylceramides fall into six categories (*lacto*-, *lactoneo*-, *globo*-, *isoglobo*-, *ganglio*- and *muco*-series; *Fig. 2*), whereas the generally simpler galactosylceramides contain a *gala*-core or are sulfatides (sulfatoglycosphingolipids) [7,17]. Another mammalian sulfoglycolipid is, on the other hand, a glycerolipid: the seminolipid sulfo-3-monogalactosylalkylacylglycerol [18]. Finally, polysaccharides also occur in mammals—glycogen, which indeed can be seen as being a tyrosine-linked *O*-glycan [19], and the glycosaminoglycan hyaluronic acid, a 'free' glycosaminoglycan [20].

3 Components and Types of Glycoconjugates in Other Eukaryotes

It is obvious that much glycan-related research has centred on mammals; however, the glycosylation of many other eukaryotes has been studied, either due to curiosity or due to the clinical and biotechnological relevance of these systems. One major point is that the glycosylation of unicellular organisms, plants, fungi and invertebrates often shows significant differences to that of mammals and of vertebrates in general. These differences are then considered 'foreign' by mammalian immune systems and result in immune reactions to these glycans. A classic instance is the antiserum raised against the plant glycoprotein horseradish peroxidase; the antiserum recognizes predominantly the xylose and core α1,3-fucose residues on plant *N*-glycans [21]. These features are shared with many other plants and invertebrates—thus resulting in cross-reactivity; for instance, this same antiserum recognizes the neural tissue of

many invertebrates and this is also due to the presence of core α1,3-fucose in, e. g., fruitfly and nematode glycoproteins [22]. Furthermore, this same structural motif is often an epitope for the immunoglobulin E (IgE) from patients with plant food, pollen or insect venom allergies [23].

The example of anti-horseradish peroxidase highlights the significance of the presence, in plant and invertebrate *N*-glycans, of residues or linkages not found in the *N*-glycans of mammals; conversely, there are residues in mammalian *N*-glycans which are not, or perhaps only rarely, found in plant, fungal and invertebrate glycans—sialic acids being a prime example [24]. Indeed, the 'complex' *N*-glycans found in vertebrates (e. g., those with up to five outer antennae with sialic acids, bisecting GlcNAc and possibly core α1,6-fucose) are not found in 'lower' species. Although the pentasaccharide core is conserved, the tendency is that the *N*-glycans are simpler than in mammals, with many truncated 'paucimannosidic' structures being present, and that the most 'complex' *N*-glycans carry fucose residues (core and outer arm) as well as, sometimes, galactose and *N*-acetylgalactosamine (❯ *Fig. 3*). Indeed, some of the structures are 'complex' in the sense of having a 'complicated' structure, even if the modifications do not resemble those of complex glycans found in vertebrates. For instance, in plants, the most complex *N*-glycans carry Lewis a epitopes in addition to core fucose and xylose [25], in the trematode parasite *Schistosoma* species Lewis x, core fucose and xylose are present [26], whereas the fruitfly *Drosophila melanogaster* and the honeybee *Apis mellifera* have glycans with two core fucose residues [27,28] and the nematode worm *Caenorhabditis elegans* expresses *N*-glycans carrying up to four fucose residues and methyl groups [29]. Further modifications with phosphorylcholine in nematodes [30] and phosphorylethanolamine in an insect species [31] have also been reported. All these species also express the oligomannosidic *N*-linked glycans found in mammals.

In fungi, the tendency is to have *N*-glycans containing mainly mannose residues, which are sometimes phosphorylated. 'Hypermannosylation', as well as phosphomannosylation, is a common feature in yeasts [32], which limits the biotechnological potential of fungal species such as *Saccharomyces cerevisiae* and *Pichia pastoris* as regards the production of glycoprotein pharmaceuticals—although re-engineering of glycosylation pathways has emerged as a technology to circumvent such problems [33]. Occasionally, residues such as galactose and pyruvate are also found in yeast, such as in *Schizosaccharomyces pombe* [34]; furthermore, antigenic galactofuranose and β1,2-linked mannose residues, respectively, are found on the *N*-glycans of the pathogens *Aspergillus fumigatus* and *Candida* spp [35,36]. In unicellular organisms, such as trypanosomatids, both oligomannosidic and complex structures are found [37], whereas in the slime mould (or social amoeba) *Dictyostelium discoideum*, core fucose and 'intersecting' GlcNAc residues are also present [38].

In the case of *O*-glycans, the situation is more variable—*O*-linked mannosylation being a typical feature of yeasts and fungi [39]; insects possess short 'mucin-type' *O*-glycans [40], whereas the *O*-fucosylation and *O*-mannosylation pathways have been shown to be developmentally important in the fruitfly [41,42]. Nematodes also have 'mucin-type' *O*-glycans [43], with some unusual modifications with glucose, fucose and glucuronic acid being reported. Also, *O*-linked chondroitin and heparan sulfate glycosaminoglycan chains are present in the proteoglycans of invertebrates [44].

More unusual forms of *O*-glycosylation, such as linkages of fucose and GlcNAc via phosphate to serine and of a pentasaccharide to a hydroxyproline of the cytoplasmic Skp1 protein,

***N*-glycans from non-mammalian eukaryotic species. Selected *N*-linked oligosaccharides are shown from plants (vacuolar-type as found on, e. g., horseradish peroxidase and a 'Lewis-type' found on, e. g., laccase; Ref. [25]), insects (a 'paucimannosidic-type', the most common *N*-glycan in *Drosophila melanogaster*, and the most complex structure found on bee venom phospholipase A_2; Refs. [27] and [28]), the trematode parasite *Schistosoma mansoni* (a structure with Lewis x, core fucose and xylose modifications; Ref. [26]), nematodes (a phosphorylcholine-containing structure of the type found in many nematodes and a putative structure with incompletely characterized modifications from *Caenorhabditis elegans*; Refs. [29] and [30]), the slime mould *Dictyostelium discoideum* (a putative structure with bisecting and intersecting GlcNAc and core fucose; based on Ref. [38] and unpublished data) and the yeast *Saccharomyces cerevisiae* (the outer chain is absent from *S. cerevisiae* intracellular glycoproteins such as invertase, but in other cases can contain up to n = 200 residues [32]; similar structures with different numbers of mannose residues sometimes in different linkages are found in other yeast species). Oligomannosidic *N*-glycans of the same type as in mammals (see *Fig. 1*) are also present in a range of 'lower' eukaryotes**

have been found in the slime mould [45,46,47]; various novel *O*-glycan types have also been observed in trypanosomatids—such as the 'mucins' of *Trypanosoma cruzi* containing *O*-linked GlcNAc (rather than GalNAc) [48] and the phosphoglycans of *Leishmania* [49]. In plants, quite different *O*-glycans are found which contain arabinose and galactose residues [50]. Plants are also a rich source of various simple glycosides, including glucosylated and rhamnosylated forms of flavonoids and hormones, which are products of the large family of UDP-glycosyltransferases [51].

Glycolipids of 'lower' eukaryotes, too, display major differences as compared to mammals. In insects and nematodes, the *arthro*-series of glycosphingolipids possess a GalNAc-β1,4GlcNAcβ1,3Manβ1,4Glc core attached to ceramide [52,53] and can act as 'receptors' for bacterial toxins [54]; fungi have glycoinositolphosphosphingolipids containing mannose and sometimes other sugars [55]; plants have galactosyldiacylglycerols and sulfoquinovosyldiacylglycerol in chloroplast membranes [56,57]; trypanosomatids have a wide-range of species-specific GPI-like glycolipids [58]. Those protein-bound GPI anchors from 'lower' eukaryotes have, regardless of source, the same core as in mammals, although the decorations are different [16]. Finally, the picture is completed by the vast world of polysaccharides: chitins (poly-GlcNAc) and glucans in some invertebrates and yeasts [59,60], the glucuronoxylomannan of the pathogenic fungus *Cryptococcus neoformans* [61], starch [62] and the various cell wall components of plants, such as cellulose (also a feature of amoebae), hemicelluloses (e. g., xyloglucans) and pectins (e. g., rhamnogalacturonans), which contain a very wide range of monosaccharides not found elsewhere [63]. Probably, very many other oligo- and polysaccharides remain to be discovered or be fully characterized.

4 Components and Types of Glycoconjugates in Prokaryotes

The glycoworld of prokaryotes (bacteria and archaea) is quite different from that of eukaryotes. The cell walls of prokaryotes contain a bewildering number of monosaccharide components—indeed, peptidoglycans, lipopolysaccharides, capsular polysaccharides, *S*-layer glycoproteins, mycobacterial lipoglycans and arabinogalactans as well as Gram-positive bacterial secondary cell wall polymers contain many novel sugar residues: therefore, there are also many unusual donor substrates found in prokaryotes, with the CDP-glucose [64] and dTDP-glu-

cose [65] pathways being important in the synthesis of various bacterial antigens containing residues such as tyvelose (a 3,6-dideoxyhexose) and rhamnose (6-deoxy-L-mannose). Another interesting feature is that the prokaryotic genes required for biosynthesis of donor substrates, as well as those encoding the glycosyltransferases themselves, are often grouped into gene clusters [66].

What has also become very obvious in the past few years is that bacteria can indeed glycosylate proteins, even if this is not the case in standard laboratory strains of *Escherichia coli*: the sugar-protein linkages are often unlike those of eukaryotes. For instance, in the case of the pathogen *Campylobacter jejuni*, a glycan containing bacillosamine (2,4-diacetamido-2,4,6-trideoxyglucose) with further *N*-acetylgalactosamine residues is transferred to asparagine [67], whereas the archaeal species *Methanococcus voltae* has an *N*-glycan of the form Man*p*NAcA6Thr-β1,4Glc*p*NAc3NAcAβ1,3Glc*p*NAc [68]. Various *O*-glycans with different novel linkages to protein are also known, including addition of heptoses to specific proteins in wild-type strains of *E. coli* [69], of FucNAc to the pilin of *Pseudomonas aeruginosa* [70], of glucose to tyrosine in the *S*-layer glycoprotein of *Thermoanaerobacterium thermosaccharolyticum* [71] and of *O*-linked mannose (just as in eukaryotes) to mycobacterial proteins [72]. Furthermore, the glycosylation of eukaryotic proteins by prokaryotic enzymes (e. g., glucosylation and ADP-ribosylation) is important in the mechanism of some bacterial toxins [73,74]. The reader is directed to specialist reviews on the various classes of prokaryotic glycoconjugates [75,76,77,78,79,80,81,82,83,84].

5 The Biosynthesis of Activated Monosaccharides

The pre-requisites for the formation of a glycosidic bond are a relevant glycosyltransferase, an acceptor and an activated donor sugar. These glycosyltransferase donors are most commonly nucleotide sugars (NDP-sugars) such as UDP-Glc, GDP-Fuc or CMP-NeuAc [7,85]; however, also important are the lipid-linked (dolichol-linked in eukaryotes) donors such as Dol-P-Man and Dol-P-Glc [86]. Furthermore, some glycosyltransfer reactions require an oligosaccharyl donor: in eukaryotes, a dolicholpyrophosphoryloligosaccharide is the donor for *N*-glycosylation [87,88,89,90] and similar lipid-linked (polyisoprenyl) donors are a feature of glycoconjugate biosynthesis in bacteria [91,92]. However, the oligosaccharide donors themselves contain residues which originated as nucleotide sugars.

In order for a monosaccharide to be biosynthetically active, it is generally phosphorylated. In the case of glucose, the free sugar obtained by hydrolysis of various polymers is brought into the hexose phosphate pool by the action of hexokinase [7,93]. The resulting glucose-6-phosphate can be converted into fructose-6-phosphate, which can then enter the glycolysis pathway. Other fates of these hexose-6-phosphates exist: fructose-6-phosphate can be acted upon by phosphomannose isomerase to form mannose-6-phosphate, thus beginning the pathway necessary for formation of mannose and fucose donors [94]; an amidotransferase and an acetyltransferase, using glutamine and acetyl coenzyme A as the respective 'donors', facilitate the formation of GlcNAc [95] and, indirectly, GalNAc [96] and sialic acid [97] donors; glucose-1-phosphate is also required for UDP-Glc synthesis and the latter can be epimerized to form UDP-Gal [98] or oxidized to UDP-GlcA, which can then be decarboxylated to form UDP-Xyl [99]. Thus, we can account for the formation of the typical monosaccharide com-

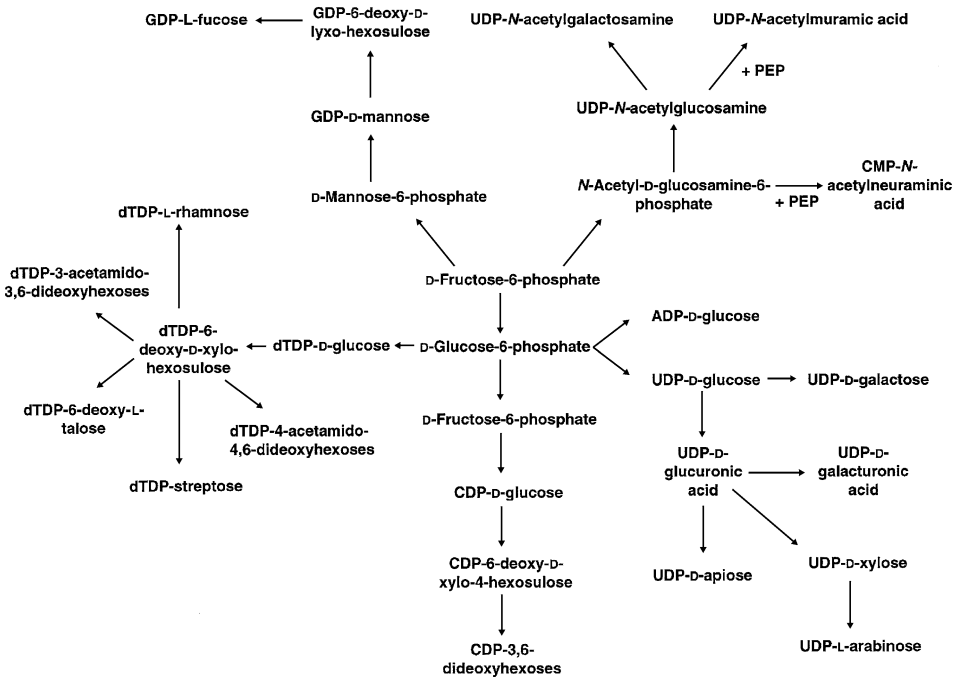

Figure 4

Pathways in the formation of NDP-sugars. A selection of monosaccharide conversions occurring at the phosphate ester and nucleotide-monosaccharide level in animals, plants and bacteria are shown; all pathways radiate from fructose-6-phosphate, indicating the central role of this metabolite. The dTDP, CDP and UDP-*N*-acetylmuramic pathways are peculiar to bacteria, whereas ADP-D-glucose, UDP-D-apiose and UDP-L-arabinose are found in plants. For reasons of simplicity, other pathways, e. g., to UDP-L-rhamnose in plants, GDP-D-rhamnose in *Pseudomonas aeroginosa* and GDP-D-arabinose in trypanosomatids are not included. The figure is reproduced from Chap. 6.4 of the first edition of this book

ponents of glycoconjugates found in mammals: *N*-acetylglucosamine, mannose, galactose, glucose, *N*-acetylgalactosamine, glucuronic acid, fucose, sialic acids and xylose (see *Fig. 4* for a selection of NDP-sugar biosynthetic pathways). Similar pathways are obviously necessary in invertebrates, whereas the large number of cell wall modifications in plants require formation of other donors, such as those for arabinosyl-, rhamnosyl- and galacturonyltransferases [100]. As mentioned above, a wide range of monosaccharides and relevant NDP-sugar biosynthesis pathways are present in bacteria [66]. Many of the enzymes involved in the formation of NDP-sugars, such as the two enzymes converting GDP-Man to GDP-Fuc or the UDP-hexose-4-epimerases, are members of the short-chain dehydrogenase/reductase family, whose *N*-terminal regions bind the cofactors NAD(H) or NADP(H) [101]. Any substitutions, such as methylation (e. g., in plants, nematodes, gastropods and some bacteria), sulfation and phosphorylation of non-reducing termini, are assumed to be a result of modification of the completed glycans by relevant transferases using activated donors such as *S*-adenosylmethionine [102], 3′-phosphoadenosine 5′-phosphosulfate [103] or NDP-donors.

In addition to the various de novo pathways for activated monosaccharide formation, 'salvage' pathways exist in which monosaccharides, present in the bloodstream or released by lysosomal degradation of macromolecules, can re-enter the biosynthetic pathways via phosphorylation [104,105,106,107]; thus, various monosaccharide kinases exist to facilitate the synthesis of new activated sugars from 'old' components. These salvage pathways are of interest since they can be used to 'rescue' defects in de novo biosynthesis, such as the mutation in phosphomannose isomerase in the Congenital Disorder of Glycosylation, or CDG, Type Ib [108] or a fucosylation defect in the slime mould *Dictyostelium discoideum* [109]. Finally, as reviewed in the next chapter, a large number of other monosaccharides (such as the ribose present in nucleotides and nucleic acids) can be derived from routes related to photosynthesis and glycolysis via the hexose and pentose interconversion pathways; in 'lower' organisms, a wide range of secondary metabolic pathways can also be based upon free monosaccharides.

6 The Transport of Activated Monosaccharides

Activated monosaccharides are generally, but not always, synthesized in the cytoplasm. This means that they are normally in the 'wrong' compartment as compared to the localization, in the ER or Golgi, of most of the glycosyltransferases which utilize them as donor substrates [110]. Thus, either transport or flipping is necessary for them to cross the endomembranes (in eukaryotes) of the endoplasmic reticulum and Golgi apparatus. In the case of dolichol-linked monosaccharides (Dol-P-Glc and Dol-P-Man), a flipping event occurs whose exact nature is still uncertain; for nucleotide sugars as well as the sulfate donor 3′-phosphoadenosine 5′-phosphosulfate (PAPS), though, there exist a number of transporters which facilitate the entry of the donor substrates in exchange for the relevant nucleoside monophosphate (e. g., GMP or UMP), which 'returns' to the cytoplasm [111]. A number of these transporters have been characterized recently—in all cases thus far, they contain multiple transmembrane domains and all are members of the solute carrier family 35 (SLC35) [112]. A number of defects in man and in model organisms (as well as farm animals) have been found to be due to mutations in SLC35 gene family members; examples include human Leukocyte Adhesion Deficiency II (also known as CDG IIc), which is caused by a defect in GDP-Fuc transport and, so, results in a lack of the fucosylated structures required for lymphocyte homing [113], and bovine Complex Vertebral Malformation syndrome, which correlates with a defective UDP-GlcNAc transporter gene in descendents of a single elite bull [114].

7 Heterogeneity of Oligo- and Polysaccharides

The pathways for the biosynthesis of the various glycoconjugates in prokaryotes and eukaryotes are often complex—furthermore, these pathways are, unlike nucleic acid or protein biosynthesis, not template-driven. Indeed, most "purified" glycoconjugates are mixtures—resulting in so-called microheterogeneity; in the case of glycoproteins, the native isolated material consists of a series of glycoforms [115]. Even a simple glycoprotein such as bovine pancreatic ribonuclease B can carry, on its single *N*-glycosylation site, structures with anything between five and nine mannose residues [116]; even ignoring the potential isomers of oligomannosidic *N*-glycans, this means that a population of ribonuclease molecules is

a mixture of at least five isoforms (i. e., glycoforms), with some molecules bearing *N*-glycans with five mannose residues, some with six, and so on. Thus, the potential for a high degree of heterogeneity becomes very large in the case of proteins with many glycosylation sites and, in the whole population of molecules, a variety of glycan structures. For proteoglycans and plant polysaccharides, the potential for microheterogeneity is even larger due to the sheer size of the glycan chains.

The glycoforms observed in any mixture purified from a natural eukaryotic source are the products of the interplay between the various enzymes (whether these are glycosyltransferases or 'processing' glycosidases) localized, except when we think of nucleocytoplasmic glycosylation, within the secretory pathway—the relative amounts expressed, their localization, their exact substrate specificities—and the accessibility and availability of the substrates whether acceptor or donor [117,118]. On a glycoprotein, the folding of the peptide backbone can affect the outcome of the various glycomodification steps due to steric effects [119] or the presence, in some special cases, of sequence or structural motifs [120]. Therefore, it is no wonder that the biosynthesis of these molecules results in heterogeneous products. It may be that this is 'desired', in order that not all glycoproteins have the same glycosylation—the addition of variation beyond that directly encoded by the genome may confer advantages in terms of having a spectrum of activities and binding specificities. Certainly, though, the lack of a template means that glycoscientists have a major challenge not just in determining the structures present, but also as to the metabolic routes necessary for their synthesis.

The major 'workhorses' in the various biosynthetic pathways are, of course, the glycosyltransferases [7]. However, in some pathways (e. g., *N*-glycosylation), selective trimming of glycans opens up new routes—thus, the $Glc_3Man_9GlcNAc_2$ structure transferred by eukaryotic oligosaccharyltransferases (with the exception of some protists which transfer shorter glycans to protein) from a dolichol-linked precursor to Asn-Xaa-Ser/Thr/Cys motifs of nascent polypeptides (i. e., those still being synthesized by ribosomes bound to the endoplasmic reticulum) is initially not the substrate for glycosyltransferases, but for glucosidases, mannosidases and sometimes an endomannosidase [121]. Indeed, it is only when the *N*-glycan is trimmed down by 'processing' (rather than 'degradative') glycosidases to $Man_5GlcNAc_2$ that we come to a point at which glycosyltransferases in most eukaryotes (but not yeasts) begin to add more residues to this core structure [89].

Even the description so far of these biochemical reactions indicates that just a single glycosylation pathway (*N*-glycosylation in eukaryotes) is highly complex. This impression is even more pronounced when one considers that different species, different cell types or different developmental, pathogenic or activation states may result in different glycosylation patterns even of the same polypeptide. This fact explains the concept of 'glycotype' [115], which was first described to account for the glycosylation patterns of Thy-1, a protein expressed in both brain and thymocytes found to carry different *N*-glycans when isolated from different tissues in the same species [122]. This concept becomes more complicated when considering that different species do not have the same numbers of genes encoding glycosyltransferases and glycosidases, although the overall number is generally about 1% of the identified genes in a species [123]. Therefore, the glycosylation potential of a mouse is different from that of a human or a worm, never mind that changes in sialic acid metabolism have the consequence that our own sialylation is different even from that of a chimpanzee [124]. These differences also have an impact on our ability to make conclusions from the use of model organisms in gly-

cobiological research or in the use of heterologous systems for the production of recombinant glycoproteins.

8 Glycosyltransferases and Glycosidases in Biosynthesis of Glycans in Eukaryotes

All the heterogeneity observed in glycoconjugates results from the different abilities of glycosyltransferases and 'processing' glycosidases to modify glycan substrates. In the case of *N*-glycosylation, the process in most eukaryotes begins with the synthesis of a dolichol-linked tetradecasaccharide (the aforementioned $Glc_3Man_9GlcNAc_2$ structure; see *Fig. 5*). The first steps in the synthesis of this structure are the result of the action of two *N*-acetylglucosaminyltransferases and five mannosyltransferases which utilize UDP-GlcNAc and GDP-Man as donor substrates and whose catalytic domains are on the cytoplasmic face of the endoplasmic reticulum [89]; then in a process seemingly mediated by a protein encoded by the so-called *RFT1* gene [125], the resulting heptasaccharide, still linked to dolichol, is flipped from the cytoplasmic to the lumenal face of the endoplasmic reticulum. The final four mannose and three glucose residues are 'donated' by Dol-P-Man and Dol-P-Glc; thereafter, oligosaccharyltransferase catalyses the transfer to protein [87,89]. In higher eukaryotes, the majority of protein-linked *N*-glycans are trimmed, by a series of glycosidases in the endoplasmic reticulum and early Golgi, down to $Man_5GlcNAc_2$ [121], which is then the substrate for an *N*-acetylglucosaminyltransferase (GlcNAc-TI or GnTI; EC 2.4.1.101) in the Golgi apparatus, with UDP-GlcNAc being the donor substrate [126]. In yeast, though, trimming does not progress beyond the $Man_8GlcNAc_2$ stage [127]; however, this decasaccharide is the substrate for subsequent mannosylation reactions in the yeast Golgi apparatus, commencing with transfer of an α1,6-linked mannose by the Och1p '**o**uter **ch**ain' mannosyltransferase [32,128,129]. In other unicellular organisms, other trimming and decoration events can occur, although oligomannosidic structures may predominate.

In mammals, the action of GlcNAc-TI 'heralds' the beginning of all the routes leading to hybrid and complex oligosaccharides [117,130]. First the two outer mannose residues from the hybrid oligosaccharide $Man_5GlcNAc_3$ (sometimes called Man5Gn) are trimmed by Golgi mannosidases II or II^x [130,131]; the remaining non-substituted α1,6-linked mannose is then the target for the next *N*-acetylglucosaminyltransferase known as GlcNAc-TII or GnTII [126], whose action generates a complex *N*-glycan. A wide variety of other modifications by branching and bisecting *N*-acetylglucosaminyltransferases (GlcNAc-TIII-VI) are subsequently possible [117,130], depending on the tissue, species and protein; then, most commonly, galactosyltransferases, fucosyltransferases and sialyltransferases may act, with sulfation, glu-

Figure 5

An outline of *N*-glycan biosynthesis in mammals. The summarized progression of the biosynthetic pathway of *N*-glycans in mammals is shown, starting with the formation of the dolichol-linked $Glc_3Man_9GlcNAc_2$ precursor in the endoplasmic reticulum (ER) and ending with the formation of complex *N*-glycans in the Golgi apparatus. The steps as far as the transfer to protein by oligosaccharyltransferase are generally conserved also in eukaryotic micro-organisms, plants and animals. For reasons of clarity, the whole multitude of potential pathways, by-pass reactions and branching and elongation events are not included. See text for references

curonylation or addition of *N*-acetylgalactosamine also occurring. This means that mammalian cells require also transporters capable of facilitating the import of UDP-GlcNAc, UDP-Gal, GDP-Fuc, CMP-Sia, UDP-GlcUA, UDP-GalNAc and PAPS into the Golgi lumen [110]. In some cases, though, it is the oligomannosidic structures which are modified in mammals—the addition of GlcNAc-1-phosphate to the C6-hydroxyl of certain non-reducing terminal mannose residues is a pre-requisite for the formation of the 'mannose-6-phosphate' marker for lysosomal enzymes [132]. The entire process of *N*-glycan maturation may, according to pulse-chase experiments, take about 30 minutes, prior to final delivery of a glycoprotein to the cell surface [90].

In plants and invertebrates, the *N*-glycome (i. e., the sum of different *N*-glycan structures) tends to be simpler—dominated by either oligomannosidic structures or oligosaccharides carrying fucose residues. However, the range of possibilities is huge and it is remarkable that some 'small' organisms such as the nematode *Caenorhabditis elegans* seemingly have a more complex *N*-glycome [29,133,134] than a 'larger' animal such as the fruitfly *Drosophila melanogaster* [27,135]. In invertebrate species, the processing of *N*-glycans first requires the transfer of one GlcNAc residue by GlcNAc-TI; then mannosidase II, core α1,6-fucosyltransferase and, optionally, core α1,3-fucosyltransferase can act [24,136]. Subsequently, the GlcNAc residue originally transferred by GlcNAc-TI is often removed by a processing hexosaminidase present in the secretory pathway [137,138]. In plants, the action of GlcNAc-TI is also important for the modification of the core by fucose and xylose [139,140]; however, the common plant-type glycan structure lacking non-reducing terminal GlcNAc residues results from the action of vacuolar hexosaminidases [141]. Alternatively, a β1,3-galactosyltransferase and an α1,4-fucosyltransferase generate Lewis a epitopes on the proteins secreted by plant cells [24].

For *O*-glycosylation, the overall concept of modification is different from that of *N*-glycans; in this case, regardless of the type of *O*-glycan formed, the residues are transferred to the protein one-at-a-time. There is no lipid-linked oligosaccharide precursor: the transfer of the first sugar to the peptide is followed by sequential addition of the subsequent residues. Furthermore, since there is no larger precursor, there are probably no '*O*-glycan-processing' glycosidases; only a wide variety of glycosyltransferases are involved in *O*-glycan biosynthesis. Since there are a number of different types of *O*-glycosylation, a large number of enzymes can initiate the process (again in contrast to the 'single' oligosaccharyltransferase in *N*-glycan biosynthesis). Indeed, even for one type of linkage, there may be multiple initiating enzymes; for instance, in the case of mucin-type *O*-glycosylation in vertebrates and invertebrates, there are about twenty polypeptide-modifying *N*-acetylgalactosaminyltransferases (EC 2.4.1.41) encoded by the human genome [142]; thereafter 'core 1' β1,3-galactosyltransferase and various β-*N*-acetylglucosaminyltransferases may act to form the different *O*-glycan cores known in mammals [117,130].

In the case of *O*-fucose, there are two types of *O*-fucosyltransferase (EC 2.4.1.221), specific for either EGF or TSR domains, whose action is followed by, respectively, the β1,3-*N*-acetylglucosaminyltransferase known as Fringe or a β1,3-glucosyltransferase [143]. In mammals, there are two polypeptide-modifying xylosyltransferases (EC 2.4.2.26) which are the first of a series of glycosyltransferases required for the synthesis of the chondroitin and heparan sulfates [144]. The first residue of *O*-mannosyl glycans is transferred by a heterodimeric peptide-*O*-mannosyltransferase in mammals [145], whereas in yeast there are a number of

potential mannosyltransferase subunits [146]. The glycosphingolipids are also built up one glycosyl residue at a time [147,148]; in contrast, the GPI anchors are 'pre-assembled' prior to the transamidation reaction which results in the formation of the bond to the new *C*-terminus of the acceptor protein [16,149]. Some further details about these reactions will be discussed in Chap. 11.2.

Obviously, all these various glycosylation events require an enzymatic machinery, but our understanding of it has grown only relatively slowly. The beginnings of glycosyltransferase research were in the 1960s with the first activities being detected and the first enzyme purifications being attempted. The basic problem was the low amounts in which the majority of glycosyltransferases are expressed. Bovine β1,4-galactosyltransferase (which acts as lactose synthase when complexed with α-lactalbumin; EC 2.4.1.22) was one of the first glycosyltransferases to be partially purified [150] and was for many years the most studied due to the large amounts present in milk; this was an advantage that the vast majority of glycosyltransferases did not have. Another problem is that biological extracts may contain a mixture of activities with overlapping specificities: this is something which we realize only in retrospect. Indeed, the 'one linkage, one enzyme' hypothesis of Hagopian and Eylar [151] has to be modified in the light of the use of molecular biology, which has revealed a higher degree of complexity, than was first imagined, as regards the glycogenomic capacities of various organisms. Often, in the case of the terminal modifications, multiple genes encode enzymes with subtly different activities. The cloning of glycosyltransferase cDNAs, which began in the 1980s also with the β1,4-galactosyltransferase [152,153], has proved most valuable in gaining large amounts of recombinant enzymes for characterization in terms of substrate specificities and crystal structures. Most recently, the revolution in molecular glycobiology has been in terms of reverse genetics—targeted knock-outs and knock-downs have yielded new perspectives as to the biological function of glycosylation [154,155].

9 The Degradation of Oligo- and Polysaccharides

Biological macromolecules such as proteins and carbohydrates are rarely long-lasting, but are subject to turnover; thus, degradation is an integral part of the 'life' of an oligosaccharide (see also Chap. 11.3). Indeed, a deficiency in degradation can be as problematic as a mutation in a biosynthetic pathway: this is particularly obvious with the lysosomal storage diseases of humans and domesticated animals, for which the defective genes in a relatively long list of diseases correspond to a number of steps in glycosaminoglycan and glycolipid catabolism [6,7,156]. The degradation of many glycoconjugates is not, though, a simple reversal of their biosynthesis. Furthermore, the enzymes responsible, primarily the glycosidases, are highly numerous, although normally not showing perhaps the same exact linkage and substrate specificities displayed by glycosyltransferases.

In the case of *N*-glycans, degradation in the mammalian lysosome involves the peptide being subject to proteolysis and the release of the glycan by a peptide:*N*-glycosidase, followed by an endo-β-*N*-acetylglucosaminidase in some species, then by removal of the non-reducing terminal sugars [157]. There are also pathways to degrade glycans from glycoproteins which have failed the 'quality control process' in the endoplasmic reticulum [158,159] or from dolichyl-linked oligosaccharides [158]. For glycolipids, there are some unique glycosidases includ-

ing an enzyme releasing the reducing-terminal residue from ceramide and, in some cases, the glycosidases require 'sphingolipid activator proteins' (saposins) in order to cleave their substrate [148,160]; in the case of glycosaminoglycan chains, endoglycosidases, exoglycosidases and sulfatases are important in the degradation process [161].

Plants, particularly their vacuoles, are a rich source of glycan-degrading enzymes: examples, used in laboratories to determine glycan structure, include the peptide:*N*-glycosidase A from almonds [162] and the various jack bean exoglycosidases [163,164,165]. For microorganisms and fungi, on the other hand, it is not just the turnover of the endogenous glycans or the ability to degrade glycoconjugates for purposes of gaining nutrients which are to be considered: glycosidases also play roles in pathogenicity. For instance, the influenza virus has a neuraminidase, which is a drug target and is important for movement and release of viruses [166].

Finally, two other groups of glycan-degrading enzymes are the polysaccharide lyases (E.C. 4.2.2.-) and the phosphorylases. Examples of the first are the pectate lyases, which generate unsaturated galacturonosyl residues at their non-reducing ends: these enzymes are produced by both plants and micro-organisms and have roles, respectively, in fruit ripening and pathological cell wall damage [167]. Other lyases from bacteria, specific for glycosaminoglycans and, therefore, known as chondroitinases or heparinases [168,169], are used in structural determination studies. The phosphorylases, though, are primarily of interest due to their roles in metabolism: phosphorolysis of starch or glycogen within cells results in the production of glucose-1-phosphate, which can then directly be used in hexose metabolism; although the importance of starch phosphorylase (EC 2.4.1.7) in plants is currently not clear [170], human glycogen phosphorylase (EC 2.4.1.1) is a potential therapeutic target in diabetes [171].

10 Concluding Remarks

In the previous pages I have sought to summarize a number of basic concepts as regards the biosynthesis and degradation of mono-, oligo- and polysaccharides, with an emphasis on those pathways involved in the formation of eukaryotic glycoconjugates. In the next two chapters on 'Molecular Basis for the Biosynthesis of Oligo-, and Polysaccharides' and 'Polysaccharide Degradation', each of these areas will be discussed in more depth. It is sufficient to state that glycoconjugate metabolism is a complex web of biochemical reactions with a large number of species- and tissue-specific factors and that modern methods of molecular and structural biology have in recent years greatly expanded our knowledge of these pathways. This knowledge, which still needs to be supplemented, is certain to have a major impact in biotechnology and biomedicine in the future.

Acknowledgement

I thank Drs. Paul Messner and Christina Schäffer (Universität für Bodenkultur Wien) for updating me on aspects of prokaryotic glycosylation and Drs. Frank Unger (Universität Wien), Harry Schachter (Hospital for Sick Children, Toronto), Erika Staudacher, Katharina Paschinger and Dubravko Rendić (Universität für Bodenkultur Wien) for their comments on the chapter as a whole.

Abstract

The oligo- and polysaccharide structures observed in samples of biological origin represent the products of a large number of enzymes: the workhorses of the biosynthetic pathways involved are the glycosyltransferases, although some steps necessary for the final glycoconjugate structures result from glycosidase or transglycosylase activities. Glycosyltransferases are, as the name suggests, enzymes which transfer sugars from an activated donor (normally a nucleotide sugar or lipid-linked phosphosugar) to an acceptor, which can be a polypeptide, a lipid or another saccharide. These enzymes have been studied by a wide variety of approaches—biochemical, genetic, chemical, crystallographic—in order to determine their occurrence, substrate specificity, biological function, mechanism and three-dimensional structure.

Keywords

Glycans; Glycosyltransferases; Crystallography; Mechanism

Abbreviations

alg	asparagine-linked glycosylation (mutant)
ALG	asparagine-linked glycosylation (gene)
Alg	asparagine-linked glycosylation (protein)
ATP	adenosine triphosphate
CAZy	carbohydrate active enzyme (database)
CDG	congenital disorder of glycosylation
CMP	cytidine 5′-monophospho-
Dol-P	dolichol phosphate
EDEM	ER degradation-enhancing α-mannosidase-like protein
EGF	epidermal growth factor
ER	endoplasmic reticulum
ERAD	ER-associated degradation
GDP	guanosine 5′-diphospho-
GlcNAc-T	*N*-acetylglucosaminyltransferase
GPI	glycosylphosphatidylinositol
GT(s)	glycosyltransferase(s)
LBHB	low-barrier hydrogen bond
NDP	nucleoside diphosphate
PAPS	3′-phosphoadenosine 5′-phosphosulfate
QM/MM	quantum mechanics/molecular mechanics
RNAi	RNA interference
siRNA	small interfering RNA
TSR	thrombospondin type 1 repeat
UDP	uridine 5′-diphospho-

1 Introduction

Glycosylation is quantitatively the most significant biochemical reaction on earth and the range of oligo- and polysaccharides observed in nature is the result of a large number of biochemical reactions catalyzed by a multitude of enzymes. The key players in the biosynthesis of these structures are the glycosyltransferases, although 'processing' glycosidases are also important in the *N*-glycosylation pathway. It is estimated that, normally, 1–3% of the genes of any organism are involved in synthesis and breakdown of glycoconjugates [1]; this figure includes glycosyltransferases and glycosidases, but excludes necessary 'accessory proteins' such as nucleotide sugar transporters or nucleotide sugar synthases and reductases. This indicates that organisms make a significant genomic investment in glycoconjugate biosynthesis, which in turn suggests that glycoconjugates have important biological roles.

As the name may suggest, glycosyltransferases are the major synthetic enzymes in glycoconjugate metabolism; they can be defined as enzymes which transfer glycomoieties from a donor substrate to an acceptor molecule. As mentioned in ❯ Chap. 11.1, the synthesis of glycosidic bonds requires a substantial input of energy; in biological systems, this means that phosphodiester bonds are cleaved. In the case of glycosyltransferases, the donor molecules are glycosides of either nucleotides or lipid phosphates (❯ *Eq. 1*):

$$XMP - Y + HO - R \rightarrow XMP + Y - O - R \tag{1}$$

In this generalised reaction, X can be a nucleotide (such as UMP, GMP), nucleoside (such as C) or polyprenol (such as dolichol), Y is the sugar linked through a phosphodiester bond destined to be transferred to the acceptor, and R is the lipid, protein or saccharide acceptor. Examples of this type of reaction include:

$$UDP - Xyl + Peptide \rightarrow UDP + Xyl - O - Peptide \tag{2}$$

which is the reaction catalyzed by peptide *O*-xylosyltransferase (EC 2.4.2.26), as the first step of chondroitin or heparan sulfate biosynthesis, and:

$$Dol - P - Man + Man_5GlcNAc_2 - PP - Dol \rightarrow Dol - P + Man_6GlcNAc_2 - PP - Dol \tag{3}$$

which is the reaction catalyzed by the sixth mannosyltransferase (Alg3p) during the biosynthesis of the lipid-linked precursor of *N*-linked oligosaccharides in most eukaryotes.

Other than the distinctions in terms of the types of donors and acceptors, glycosyltransferases fall into two basic categories: the inverting and retaining enzymes. In the case of an inverting enzyme, a monosaccharide α-linked to its donor is β-linked in the final product (or vice versa), whereas a retaining enzyme involves no change in the anomericity of the transferred sugar (see ❯ *Sect. 8*). Furthermore, glycosyltransferases fall into a number of categories based on primary sequence—the Carbohydrate-Active Enzyme Database [2] currently contains 86 families of glycosyltransferases (see ❯ *Sect. 7.1*). Biochemically, the Enzyme Commission has numbered many glycosylation reactions (with numbers of the form EC 2.4.-), but this list is highly incomplete and sometimes inaccurate; on the other hand, many proteins predicted to be glycosyltransferases on the basis of sequence homology are not yet proven to catalyse a specific

reaction. Certainly, the progress in cloning glycosyltransferase genes, primarily as a result of the many genome projects, has outpaced the ability to determine their biochemical and biological significance, never mind that the 3D-structural information on glycosyltransferases is based on a mere handful of crystal structures.

This chapter will concentrate on the biological, biochemical, molecular modelling and crystallographic approaches to the study of the glycosyltransferases, particularly those involved in the biosynthesis of the major classes of eukaryotic glycoconjugates: *N*-glycans, *O*-glycans, glycolipids (including glycosylphosphatidylinositols) and glycosaminoglycans. The biosynthesis of plant polysaccharides was well summarized in the previous edition of this book [3] and will only be briefly considered here, whereas the basics of biosynthesis of *N*-glycans in mammals has been well-reviewed over the years [4,5]; indeed, this chapter is not intended to be exhaustive, but, building upon ❯ Chap. 11.1, will concentrate on the aspects related to the most important modern methods in the field. For brief accounts of the major mammalian glycosyltransferases, the reader is referred to the relatively recent *Handbook of Glycosyltransferases and Related Genes* [6].

2 *N*-Glycan Biosynthesis in Eukaryotes

Probably the best-studied glycans are those linked to asparagine residues in eukaryotes (*N*-linked glycans), especially those of the yeast *Saccharomyces cerevisiae* and of mammals. As summarized in ❯ Chap. 11.1, the initial steps in *N*-glycan biosynthesis are those catalyzed by a series of glycosyltransferases (see ❯ *Fig. 1*) in the endoplasmic reticulum (ER) that lead to the synthesis of the tetradecasaccharide $Glc_3Man_9GlcNAc_2$ linked to dolichol through a pyrophosphate 'bridge' [4,5]; this type of glycosylation intermediate was first reported by Luis Leloir and his colleagues [7]. In some eukaryotes (seemingly mainly protozoan parasites), smaller dolichol-linked oligosaccharides are produced and efficiently transferred to protein: this is associated with the apparent loss of a number of the relevant *ALG* (asparagine-linked glycosylation) genes [8]. These genes have been well-studied in *S. cerevisiae* and are conserved between yeast and mammals; indeed the functional and sequence conservation is sufficient to allow mammalian *ALG* genes to rescue relevant *alg* mutants in yeast. This ability to transform mammalian genes into yeast has been valuable in the identification of mannosyl- and glucosyltransferases which are mutated in various Congenital Disorders of Glycosylation (Type I CDGs) [5,9]. The most recent advances in determining the molecular basis for the various reactions leading to the formation of $Glc_3Man_9GlcNAc_2$, thus leading to the identification of all the necessary glycosyltransferases, have been the discovery of the Alg13p/Alg14p complex required for the transfer of the second GlcNAc residue [10,11] and the demonstration of the dual activities of recombinant *Saccharomyces* Alg2p and Alg11p [12]. The formation of the lipid-linked oligosaccharide can be blocked by the action of tunicamycin, a transition-state analogue for the first reaction (the formation of GlcNAc-PP-Dol) catalyzed by Alg7p and this reagent can be used to inhibit *N*-glycosylation in cell culture [13]. Embryos with a homozygous deletion in the murine *ALG7* homologue die 4–5 days after fertilisation [14], which is an indication of the importance of *N*-glycosylation.

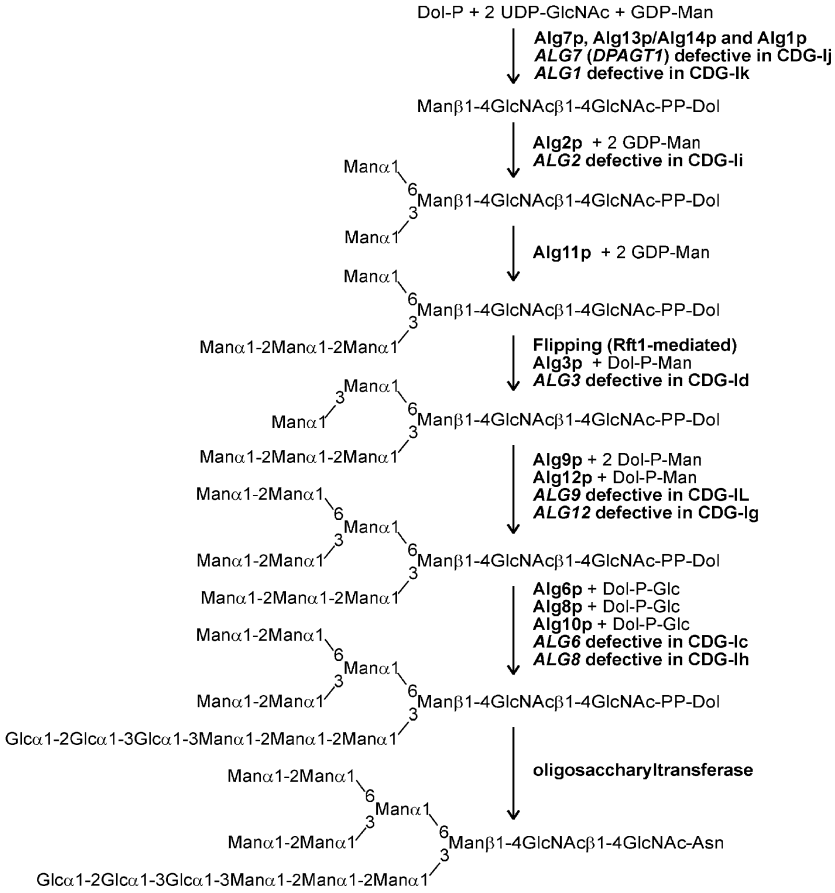

Figure 1

The formation of the dolichol-linked tetradecasaccharide in most eukaryotes. The series of GlcNAc-, Man- and Glc-transfer events (a total of 14 reactions catalyzed by 11 glycosyltransferases, each being in yeast an AlgXp protein) occur in the endoplasmic reticulum. Many of the relevant *ALG* genes are mutated in a corresponding human Type 1 Congenital Disorder of Glycosylation (CDG-I)

2.1 Post-Transfer Processing of Oligomannosidic *N*-Glycans

The completion of the lipid-linked $Glc_3Man_9GlcNAc_2$ is followed by transfer of this structure to nascent proteins (i. e., co-translationally), which is mediated by the multi-subunit complex known as oligosaccharyltransferase [15]. Subsequently, the $Glc_3Man_9GlcNAc_2$ structure is subject to a variety of trimming reactions (see *Fig. 2*), catalyzed by glycosidases such as glucosidases I and II, endoplasmic reticulum mannosidase I and endomannosidase [16,17,18]. The action of both glucosidases I and II can be inhibited by castanospermine or forms of deoxynojirimycin, whereas ER mannosidase I activity is blocked by deoxymannojirimycin [19]. This class I mannosidase (CAZy glycohydrolase family 47) is highly conserved

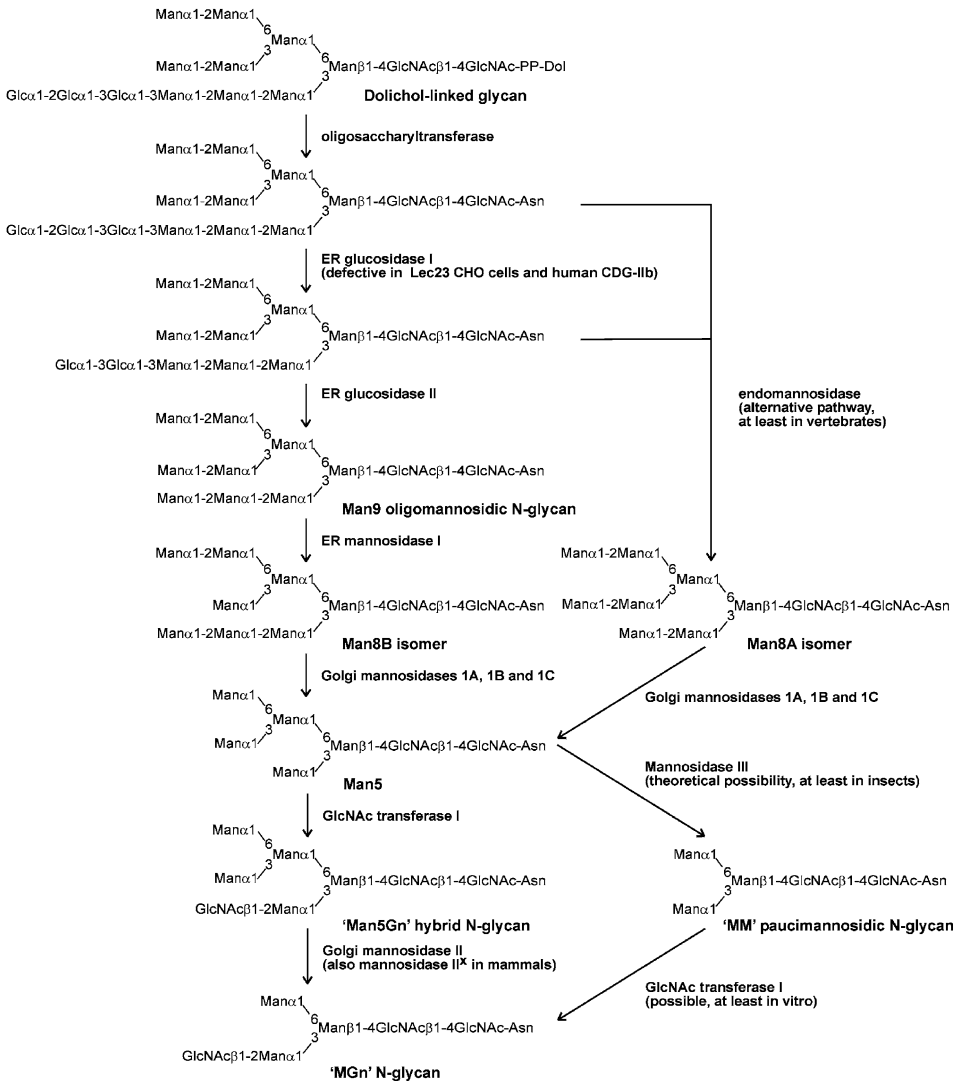

Figure 2

Post-transfer processing of oligomannosidic *N*-glycans. In general, eukaryotes transfer $Glc_3Man_9GlcNAc_2$ to proteins and this is the target of ER glucosidases I and II as well as of ER mannosidase. In yeast, the pathway is then continued by Golgi mannosyltransferases (not shown), whereas in multicellular eukaryotes, the classical pathway proceeds via the action of Golgi class I mannosidases, GlcNAc-TI and Golgi mannosidase II. However, alternative pathways exist or are hypothesised: the Golgi endomannosidase is known to operate in vertebrates and a route from Man5 to MGn via mannosidase III may exist in insects and potentially at a low level in nematodes, but, as judged by the most recent work with knockout organisms, is most probably not occurring in mammals and plants

in all eukaryotes and is the last trimming enzyme found in yeast; it catalyses the removal of a single mannose residue resulting in the formation of one isomer of $Man_8GlcNAc_2$ [20,21], whereas endomannosidase, found in vertebrates and molluscs, is a Golgi enzyme whose activity removes $Glc_{1-3}Man$ from *N*-glycans to form another isomer of $Man_8GlcNAc_2$ [18,22].

The trimming of the *N*-glycans in the endoplasmic reticulum is closely associated with the process of protein folding [23,24]: certainly, it is remarkable that most secreted proteins are glycosylated and this led, over 40 years ago, to Eylar proposing that glycosylation was a form of 'chemical passport' allowing proteins to exit cells [25]. This concept can now be re-considered in the light of the role of the lectins calnexin and calreticulin which recognise the glycans of unfolded proteins [23,24]; these may be reglucosylated in many eukaryotes by a UDP-Glc:glycoprotein glucosyltransferase in order that the proteins can re-enter the folding process [26]. If this fails, then the protein is recognised by lectins with homology to class I mannosidases (EDEMs) which direct the proteins towards ER-associated degradation (ERAD) [27,28], a process involving deglycosylation by a peptide:*N*-glycosidase and proteasome-mediated degradation of the polypeptide [29]. The free *N*-glycan is then, at least in vertebrates, the target of a cytosolic endo-β-*N*-acetylglucosaminidase [30] and a cytosolic mannosidase encoded by the *MAN2C1* gene [31].

If a glycoprotein, however, 'survives' the endoplasmic reticulum, it then enters the Golgi. In mammals, depending on the protein and cell-type, some further mannosidase-mediated trimming, specifically by class I mannosidases, takes place [32]. Many species have multiple Golgi mannosidase I isoforms; in mammals, mannosidases IA, IB and IC have subtly different activities, but can digest a $Man_9GlcNAc_2$ structure to $Man_5GlcNAc_2$ [33]; they display homology to the ER mannosidase I and indeed one amino acid substitution can alter the specificity of the ER enzyme so that it can also digest down to the $Man_5GlcNAc_2$ structure [34]. Mannosidase IB is essential for neonatal survival in mice, as shown by a recently published knock-out study [35].

Similar Golgi mannosidase-mediated processing probably takes place in all multicellular organisms; however, as mentioned above, in yeast only one mannose residue is removed in the endoplasmic reticulum and the maturation of *N*-glycans in the Golgi is, primarily, the result of addition of extra mannose residues [36]. Other 'destinies' occur in other species: for instance, the major *N*-glycan of the slime mould *Dictyostelium discoideum* is a $Man_8GlcNAc_2$ structure decorated with extra *N*-acetylglucosamine residues with or without a core fucose [37].

In mammals, if a glycan is not, or only partially, processed by mannosidases, then it remains oligomannosidic and is generally not subject to any further modification, unless the glycan is attached to an enzyme destined for the lysosome. Such glycans become phosphorylated in a two-stage process catalyzed by a GlcNAc-1-phosphotransferase and a specific 'uncovering' *N*-acetylglucosaminidase [38]; the result is the mannose-6-phosphate moiety recognised by receptors which enable correct targeting of lysosomal hydrolases. Indeed, defects in the two genes encoding the α/β and γ subunits of the GlcNAc-1-phosphotransferase are respectively associated with the lysosomal storage diseases mucolipidoses II and III (otherwise known as I-cell disease and pseudo-Hurler syndrome); the defective targeting resulting from these mutations causes a build-up of macromolecules in the lysosomes and hence to various pathogenic symptoms [39,40].

2.2 The Formation of Hybrid and Branched *N*-Glycans

On the other hand, if the glycan attains a $Man_5GlcNAc_2$ structure, then a major decision point in the 'life' of the glycan has been reached: it is then potentially the target of *N*-acetylglucosaminyltransferase I (GlcNAc-TI or GnTI; EC 2.4.1.101; see *Fig. 2* and *Fig. 3*), which is a resident of the *medial*-Golgi [41]. This enzyme appears to be a 'hallmark' of multicellular organisms and necessary for the formation of so-called 'complex', 'hybrid' and 'paucimannosidic' *N*-glycans (see Chap. 11.1 for an introduction). Certainly, the relevant *MGAT1* genes can be found in plant and animal species. GlcNAc-TI is essential for viability in mammals [42,43], although in plants and nematodes this enzyme is less important [44,45], but still probably required for 'normal' existence. For example, recent results indicate the knocking-out of GlcNAc-TI isoforms in the model nematode *Caenorhabditis elegans* results in differences in the pathogenic effects of bacteria on the worms [46]. In the case of the fruit fly *Drosophila melanogaster*, the effect of knocking-out GlcNAc-TI is a malformation of the fly brain and an unwillingness or incapability of male flies to reproduce, even though the sperm count is normal [47]. These results illustrate the importance of modern genetic methods in the determination of the function of glycans and glycosyltransferases, but also show the problems in extrapolating results from 'lower' to 'higher' organisms. They further indicate that complex *N*-glycans have acquired more and more important functions during evolution. On the other hand, the fact that cell-cell interactions are irrelevant to the survival of mammalian cells in culture may explain why they do not require GlcNAc-TI, as evidenced by the existence of, e. g., Lec1 (lectin resistant) Chinese hamster ovary cells that are null for GlcNAc-TI [48].

Analogously, knock-outs of the next enzyme in the series, Golgi mannosidase II (EC 3.2.1.114) show a similar 'problem' in inter-species comparisons: mutants of this enzyme in plants (*Arabidopsis*) and nematodes (*Caenorhabditis*) grow normally under standard laboratory conditions, even though significant changes in the *N*-glycome occur, which result in the appearance of non-wild-type hybrid structures [49,50]. However, in mammals there are two Golgi mannosidase II genes: one encoding the 'classical' mannosidase II [51] and one encoding mannosidase II^x [52]. The mouse mannosidase II-null mutant displayed an autoimmune phenotype and tissue-dependent loss of complex *N*-glycans, compatible with the known 'gatekeeper' role of mannosidase II [53,54]. However, in some tissues, the presence of complex glycans led to the suggestion that another mannosidase ('mannosidase III'; see *Fig. 2*) digested $Man_5GlcNAc_2$ directly to $Man_3GlcNAc_2$ without the need for the prior action of GlcNAc-TI; mammalian forms of GlcNAc-TI can accept $Man_3GlcNAc_2$, thus, theoretically (following the action of mannosidase III) facilitating the subsequent action of GlcNAc-TII (see *Fig. 3*) and, so, the formation of complex *N*-glycans [53]. Such an idea was built upon previous data suggesting that a Co^{2+}-stabilised mannosidase activity was present in the Golgi [55]; a recombinant enzyme with similar properties and a Golgi localisation has been studied in insects [56]. However, the results with the double mannosidase II/II^x knock-out mouse appear to have 'buried' the notion that a mannosidase III has any (significant) role in mammalian *N*-glycan biosynthesis or that mannosidase II^x is equivalent to mannosidase III: only hybrid *N*-glycans were found in the double mutant embryos [57]. Homozygous double knock-out offspring die either in utero or neonatally [58], whereas the single mannosidase II^x knock-out has an obvious defect 'only' in spermatogenesis [59]. It is interesting that hybrid *N*-glycans are relatively rare in mammals, but are plentiful on, e. g., chicken egg glycoproteins such as ovalbumin [60], suggesting either

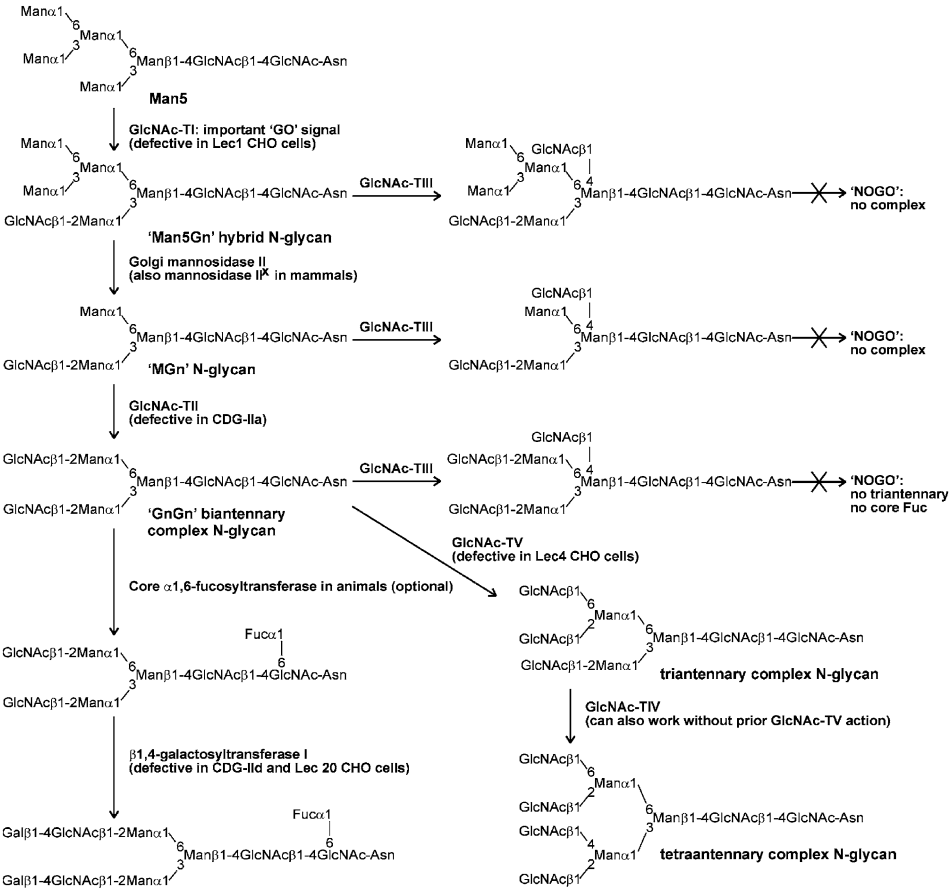

Figure 3

Processing of hybrid and complex branched or bisected *N*-glycans in vertebrates. The $Man_5GlcNAc_2$ structure which results from the action of Golgi class I mannosidases is the target of GlcNAc-TI; the action of this enzyme is a 'GO' signal for mannosidase II in multicellular eukaryotes and also for GlcNAc-TIII in vertebrates. If GlcNAc-TIII has modified an *N*-glycan, this is a 'NOGO' signal for mannosidase II, GlcNAc-TII, GlcNAc-TIV and GlcNAc-TV. In vertebrates chain elongation is generally initiated by β1,4-galactosyltransferase(s); such galactosylation, in turn, prevents or reduces subsequent modification by GlcNAc transferases. For simplicity not all possible core modifications, branching events and 'NOGO' signals are shown

a lack of mannosidase II in the chicken oviduct or that the glycan is poorly accessible to this enzyme or that high levels of GlcNAc-TIII (which transfers the 'bisecting' GlcNAc, thereby preventing mannosidase II action; see *Fig. 3*) or β1,4-galactosyltransferase compete for the same substrate [61].

Based on its primary sequence, mannosidase II is a member of the class II mannosidase family (CAZy glycohydrolase family 38, which includes also the lysosomal mannosidase involved in glycoprotein catabolism). Like the lysosomal enzyme, mannosidase II is inhibited by swainsonine [62], thus this reagent can be used to block the formation of complex *N*-glycans. The

structure of the *Drosophila* mannosidase II has been studied using enzyme crystallised in the presence and absence of this and other inhibitors [63,64]; the enzyme has also been shown to be a resident of the *medial*-Golgi [51,65] and it may form a complex with GlcNAc-TI [66].

Once mannosidase II has acted, the resulting $GlcNAcMan_3GlcNAc_2$ structure (sometimes known as 'MGn') is the substrate for GlcNAc-TII (EC 2.4.1.143; see ❯ *Fig. 3*). This is the key enzyme enabling cells to produce complex *N*-glycans and a mutation in the relevant *MGAT2* gene is associated with a Congenital Disorder of Glycosylation (CDG-IIa, formerly known as carbohydrate-deficient glycoprotein syndrome II) [67,68]. GlcNAc-TII can only act once GlcNAc-TI and mannosidase II have performed their task. Thus, as described by Harry Schachter [69], the action of GlcNAc-TI and mannosidase II constitute so-called 'GO' signals for this enzyme; in turn GlcNAc-TII is a 'GO' signal for the next 'branching' enzyme GlcNAc-TV (EC 2.4.1.155; encoded by the *MGAT5* gene). On the other hand, the prior action of GlcNAc-TIII (EC 2.4.1.144; encoded by the *MGAT3* gene) is a 'NOGO' signal, since the transfer of a bisecting GlcNAc to the core β1,4-linked mannose residue of *N*-glycans prevents the subsequent action of both GlcNAc-TII and GlcNAc-TV. Both these enzymes are also present in *C. elegans* [70,71], whereas GlcNAc-TII, but not GlcNAc-TIII and GlcNAc-TV, is found in plants and insects [72,73]. Novel 'intersecting' and 'bisecting' GlcNAc transferase activities, which take oligomannosidic oligosaccharides as acceptors, have been detected in the slime mould *Dictyostelium* [74]; the relevant genes may be amongst the various β1,4-GlcNAc transferase homologues in this organism. Two other 'branching' enzyme activities are also known: GlcNAc-TIV (EC 2.4.1.145) and the homologous GlcNAc-TVI, which are both β1,4-GlcNAc transferases acting respectively on the α1,3- and α1,6-antennae. The former apparently occurs in two isoforms in mammals [75], whereas the latter is found in birds [76] and its penta-antennary products are found particularly on proteins of chicken egg white [77]. Although potential products of GlcNAc-TIV are found in *Drosophila* [78], any enzymatic activity of the relevant homologues has not yet been described. On the other hand, as judged by glycan analyses, the many potential GlcNAc-TIII homologues in plants do not obviously modify *N*-glycans in vivo.

The role of the bisecting GlcNAc-TIII has attracted attention because of its 'NOGO' potential, particularly as regards the action of GlcNAc-TV [69,79]. The latter is often considered to be relevant to metastasis; certainly, the β1,6-branches initiated by the action of this enzyme are often the starting point for elongation into poly-*N*-acetyllactosaminoglycan chains [80]. Thus, once GlcNAc-TV has acted, there is an increased potential for the formation of very large *N*-glycans, the presence of which has long been considered to be correlated with transformation of cells; an accompanying increase in the average size of glycans was first noted by Warren and Glick [81] and a relationship between GlcNAc-TV levels and metastasis has been observed [82,83]. However, the evidence that that induction of increased GlcNAc-TIII activity (thereby inhibiting the action of GlcNAc-TV) may decrease metastasis has been contradictory, since GlcNAc-TIII is increased in some leukaemias [84]. Ablation of GlcNAc-TIII and GlcNAc-TV shows that neither gene is essential [85,86], but alterations in certain models of metastasis have been observed [84,86,87] and *mgat5* deficient mice display signs of an autoimmune phenotype [88]; interpretation of the apparent non-essential nature of GlcNAc-TV may, though, be complicated in some tissues by the identification of a second human enzyme (known as GnT-Vb or GlcNAc-TIX) with an overlapping in vitro activity [89]. Certainly, though, the 'NOGO' function of GlcNAc-TIII has potential in biotechnologically relevant

re-engineering of glycosylation - particularly since modifications of the core by fucosyltransferases in mammalian cells and plants (see below) are also inhibited by GlcNAc-TIII [90,91]. Two further GlcNAc transferases (VII and VIII) have been postulated to exist in mammals, due to the occurrence of a GlcNAc linked either α/β1,6 to the penultimate Man-linked core GlcNAc residue (LEC18) or β1,2 to the β-linked core mannose (LEC14) in two 'gain-of-function' Chinese hamster ovary cell lines [92].

2.3 Modification of the *N*-Glycan Core Region

Modifications of the core region of *N*-glycans are, in general, widespread: in plants, core α1,3-fucosylation of the reducing-terminal GlcNAc and β1,2-xylosylation of the core β1,4-linked mannose residue occur [93]. These modifications are immunogenic and are key epitopes for antisera generated in rabbits against plant glycoproteins, such as horseradish peroxidase [94]. 'Anti-HRP' is indeed an often-used reagent since it recognises neuronal glycans from invertebrate species [95,96,97]. Thus, this is an indication that xylose and/or α1,3-fucose are present in invertebrates. Interestingly, schistosomal and snail glycoproteins can have both types of modification [98,99], whereas insects and nematodes express core α1,3-fucosylated glycans [100,101]. Such a core α1,3-fucose residue is also present on honeybee venom glycoproteins [102] and constitutes an epitope for the IgE from allergic patients [103], a phenomenon also associated with other allergies [104]. Other modifications of the core involving fucose include the presence of this fucose on the second (or distal) GlcNAc residue of the core, as is the case in the parasite *Haemonchus contortus* [105] and galactosylation of the core fucose in octopus and in *Caenorhabditis* [106,107]; whether these are immunogenic is unknown.

In mammals, the core is not modified with α1,3-linked fucose; in contrast, α1,6-fucosylation is present on many glycoproteins, such as IgG. The relevant enzyme encoded by the *FUT8* gene (EC 2.4.1.68) is dependent on the prior action of GlcNAc-TI (see *Fig. 3*), but will not act if GlcNAc-TIII or β1,4-galactosyltransferase have already modified the *N*-glycan [69]. This type of fucosylation is indeed common throughout the animal kingdom and relevant genes have been cloned from mammals [108,109], *Caenorhabditis* and *Drosophila* [110]; double fucosylation of the core by both α1,3- and α1,6-fucosyltransferases (see *Fig. 4*) is a feature of nematodes and insects [100,101,102]. Knocking-out the α1,6-fucosyltransferase gene in mice has a number of effects, including semi-lethality and dysregulation of growth factor signalling [111,112]. In cell culture a true knock-out of the gene or the mere downregulation of its transcripts by siRNA enables the production of non-fucosylated IgG, which is more efficient in antibody-dependent cellular cytotoxicity (ADCC) assays [113,114].

Subsequent to the action of the various GlcNAc transferases and core fucosyltransferases, further modifications of *N*-glycans occur in a manner dependent on the type of organism. In plants, secreted glycoproteins such as sycamore cell laccase are modified by β1,3-galactosyltransferase(s) and α1,4-fucosyltransferase, thus resulting in formation of Le^a-structures [115]. The relevant α1,4-fucosyltransferase gene has been identified in a number of species [116,117], whereas an *Arabidopsis* β1,3-galactosyltransferase has only recently been identified, amongst twenty potential homologues, as having a role in *N*-glycan modification [118]. However, in plants there exists a different modification pathway for vacuolar glycoproteins; these have one

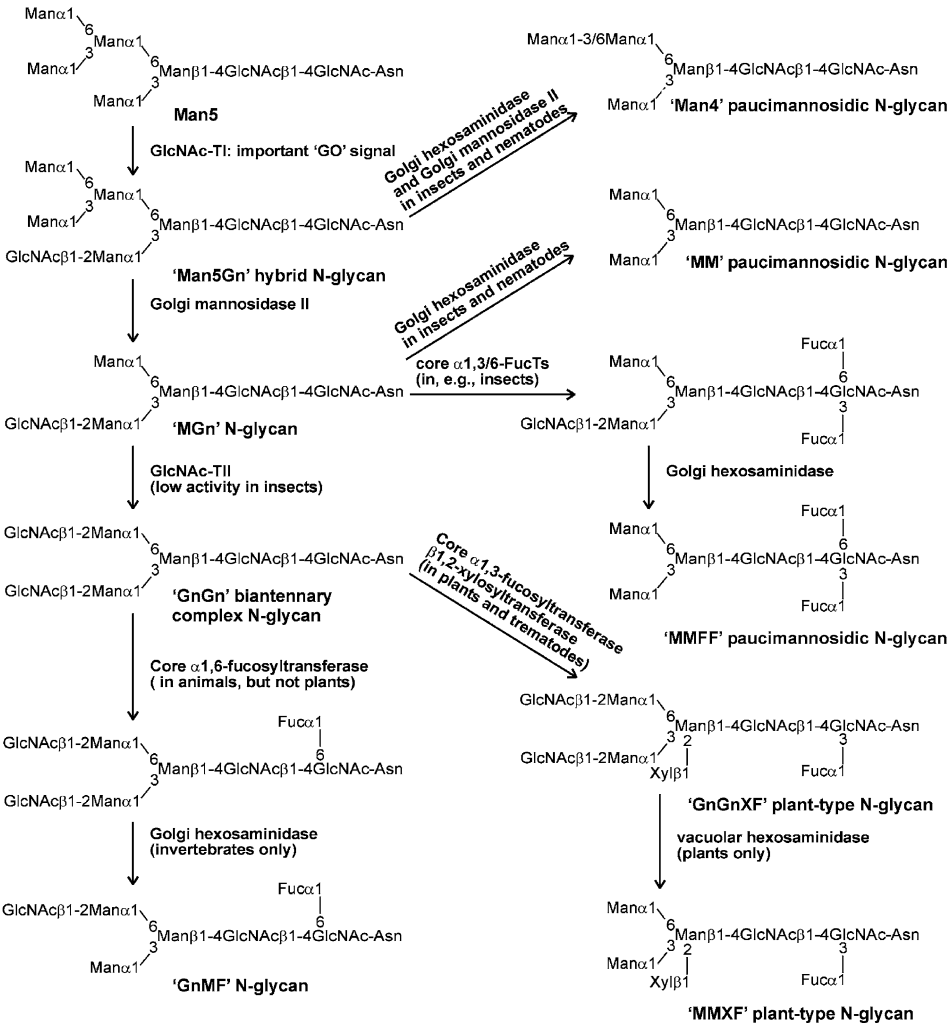

Figure 4

Selected *N*-glycan modification pathways in plants and invertebrates. The initial stages of *N*-glycan maturation in plants and invertebrates are akin to those of vertebrates (*Fig. 3*). However, after the action of GlcNAc-TI in invertebrates, a Golgi hexosaminidase may act which results in the formation of MM and Man4 paucimannosidic glycans. MGn may also be fucosylated (in nematodes only by the α1,6-fucosyltransferase, in insects and trematodes by α1,6- and/or α1,3-fucosyltransferases) prior to the action of this hexosaminidase. It is also possible that this removal of GlcNAc from the α1,3-antenna occurs after the action of GlcNAc-TII. In plants, though, the hexosaminidase acts putatively in the vacuole after the action of core α1,3-fucosyltransferase (EC 2.4.1.214) and β1,2-xylosyltransferase (EC 2.4.2.38); the latter type of enzyme is also present in trematodes and snails. For simplicity, the route in insects and nematodes to solely α1,6-fucosylated ('MMF') glycans, the pathways in nematodes including the GlcNAc-TI-independent core α1,3-fucosylation and the GlcNAc-TI-dependent transfer of phosphorylcholine as well as the addition of Lewis a (Le^a) epitopes in plants and less common antennal modifications in insects are not shown

or both of their non-reducing terminal GlcNAc residues removed by vacuolar hexosaminidases [119], thus resulting in the core-modified *N*-glycans terminating in mannose (see *Fig. 4*) which are familiar from plantproteins such as horseradish peroxidase [120].

A seemingly similar hexosaminidase-mediated modification of *N*-glycans occurs in nematodes and insects; however, there is a difference. The relevant enzyme (see *Fig. 4*) is postulated to occur in the Golgi and removes specifically the GlcNAc from the α1,3-antenna [121,122]; its action thus accounts for the fact that the most abundant glycans in these species are the so-called paucimannosidic structures with a trimannosyl core with and without fucose moieties [78,93,100,101]. Recently, the relevant *Drosophila* hexosaminidase has been identified and shown to be present throughout the secretory pathway [123]; genes encoding other enzymes with a similar specificity have been found in *Caenorhabditis* [124]. The significance of identifying hexosaminidase genes from invertebrates (especially insects) is that the presence of the encoded enzymes prevents elongation of the antennae of the *N*-glycans of these species, thus reducing their ability to produce, in a biotechnological context [125,126], proteins with 'human-like' glycosylation (i. e., with terminal galactose and sialic acid residues). Furthermore, cloning of these genes enables the examination of the biological significance of truncated *N*-glycans in these species and an unravelling of the 'mystery' as to how glycans can carry fucose residues (which generally, but not always, requires the prior action of GlcNAc-TI), yet lack any non-reducing terminal GlcNAc residues. Interestingly, in the fruit fly, the *fdl* hexosaminidase mutant has a 'fused lobes' phenotype [127] similar to that seen in the fly GlcNAc-TI mutant [47], suggesting that correct 'fly-type' glycosylation is required for normal neural development in *Drosophila*. However, only the GlcNAc-TI mutant lacks neural anti-HRP epitopes [47] and this result is compatible with the requirement of the fly core α1,3-fucosyltransferase (FucTA) for a non-reducing terminal GlcNAc on the α1,3-antenna [100,128]. The conclusion is that, in the fly, the *fdl* hexosaminidase acts subsequent to both core fucosyltransferases, thus accounting for the observed fucosylated paucimannosidic *N*-glycans; furthermore, although there are four potential α1,3-fucosyltransferase homologues in the fly, only the use of FucTA double-stranded RNA results in RNAi-mediated diminution of anti-HRP epitopes in a *Drosophila* neural cell line [128], indicating that a single fucosyltransferase gene is responsible for generation of these epitopes in the fly.

In *C. elegans*, the exact mechanisms for core α1,3-fucosylation are a bit different. Unlike the GlcNAc-TI-dependent fly core α1,3-fucosyltransferase (FucTA), the nematode core α1,3-fucosyltransferase (FUT-1) acts only on *N*-glycans that lack the GlcNAc-TI-dependent GlcNAcβ1,2Manα1,3 moiety [101]. It is concluded that, in the worm, the residue transferred by GlcNAc-TI must be removed by a hexosaminidase before FUT-1 can act. The worm core α1,6-fucosyltransferase (FUT-8), however, requires prior action of GlcNAc-TI and, therefore, the synthesis of difucosylated paucimannosidic *N*-glycans involves the sequential action of α1,6-fucosyltransferase, hexosaminidase and α1,3-fucosyltransferase. As expected, worms lacking an intact core α1,3-fucosyltransferase (*fut-1*) gene do not express anti-HRP epitopes; however, these epitopes are still observed in GlcNAc-TI-null worms lacking all three GlcNAc-TI isoforms [101] consistent with the presence of potentially anti-HRP antibody reactive fucosylated $Hex_{4-9}GlcNAc_2$ *N*-glycans in the GlcNAc-TI-null worm [45,46]. If a core fucosyltransferase does not act, the 'MGn' structure (*Fig. 4*) is processed primarily to the trimannosyl core [46]. MGn has, also, various other fates, e. g., incorporation of phosphorylcholine. This GlcNAc-TI-dependent modification is absent from GlcNAc-TI-null worms. In

the context of *N*-glycans, the phosphorylcholine epitope is seemingly nematode-specific and is associated with immunomodulation mediated by certain nematode glycoproteins [129].

2.4 Terminal Decorations of *N*-Glycans

In contrast to the hexosaminidase-mediated modification of *N*-glycans in 'lower' multicellular eukaryotes, the glycosylation pathways of mammals are, after the action of mannosidase II, based on addition, rather than further removal, of glycan moieties. The terminal GlcNAc residues are acceptors for β1,4- and β1,3-galactosyltransferases, although the former modification is the most familiar (see ❯ *Fig. 3*). There are a number of enzymes in mammals with β1,4-galactosyltransferase activity, but the major form is β4Gal-TI [130]. This enzyme is the same as the lactose synthase found in milk and is probably one of the most studied glycosyltransferases; it has a relatively broad substrate specificity and can tolerate even other nucleotide sugar donors, such as UDP-GalNAc [131], although it is most efficient with UDP-Gal. The enzyme displays an 'ordered sequential' mechanism by which UDP-Gal, in the presence of Mn(II) ions, first binds the enzyme; thereafter the acceptor substrate binds, the transition state forms, the saccharide product is released and finally the UDP 'by-product' dissociates [132]. In the Golgi, this UDP is cleaved to UMP [133], which is then returned to the cytoplasm via the UDP-Gal/UMP antiporter [134]. In the presence of α-lactalbumin, β4Gal-TI has a different acceptor specificity and prefers glucose over GlcNAc-terminating substrates [135]. Due to its role in producing the resulting disaccharide (lactose; Galβ1,4GlcNAc), the enzyme is, as a result of activation of a special transcription initiation site, overexpressed in the mammary gland; in most tissues, though, it is expressed constitutively and is considered to be a 'housekeeping' gene [136].

Knocking-out the β4GalT-I gene results in semi-lethality and other defects [137], but it is not absolutely essential, perhaps due to the possible compensatory action of five other β1,4-galactosyltransferases [130]. It is deficient in the human CDG-IId, which is characterised by hydrocephalus, myopathy, and blood-clotting defects [138]. Two major isoforms of β4Gal-TI are found and result from the use of alternative translation start sites: the longer form with an extended cytosolic domain is localised, for instance, in the plasma membrane of spermatozoa, where it may play a role in fertilisation perhaps acting as a lectin [139]; the function of this longer cytoplasmic tail in directing cell surface expression is apparently regulated by phosphorylation [140]. The shorter form is found in the Golgi, but is sometimes cleaved from the membrane and thereby secreted into the milk or into the serum [141,142].

The knowledge that this enzyme, like many Golgi glycosyltransferases, is active in the absence of its *N*-terminal cytoplasmic, transmembrane and stem regions (it is a typical Type II transmembrane protein with an uncleaved signal sequence) has facilitated its preparation as a soluble recombinant enzyme in *E. coli*, yeast (*S. cerevisiae* and *P. pastoris*) and insect systems [143,144,145,146,147,148,149]. β4Gal-TI was the first eukaryotic glycosyltransferase to have its cDNA cloned [150,151] and the first to be crystallised [152]. Its activity in the absence of its natural *N*-terminus does not mean that this region is without function: indeed, this region is required for the proper localisation of the membrane-bound form to the *trans*-Golgi [153].

When the β4Gal-TI gene is knocked-out, there is an increase in the amount of β1,3-galactosylated glycans [154]; in vitro data from two different laboratories implicate β3Gal-TI or

β3Gal-TII in the modification of *N*-glycans [155,156]. Another alternative form of modification of non-reducing terminal GlcNAc residues is the addition of β1,4-linked GalNAc, thus forming the GalNAcβ1,4GlcNAc moiety ('LacdiNAc'). β1,4-GalNAc-T activity has been associated with invertebrates due to a Tyr→Ile substitution found in insect homologues of β4Gal-TI [157]; GalNAc residues are found, for instance, on the *N*-glycans of honeybee venom phospholipase A_2 [102], although β1,4-galactosylation is also known in invertebrates such as the fruit fly *Drosophila* and the nematode *Ascaris suum* [78,158]. In the case of mammals, β1,4-GalNAc residues attached to GlcNAc are also found; in some cases, i. e., those of pituitary glycoprotein hormones, an amino acid sequence within the protein to which the *N*-glycan is attached acts as a signal for the relevant GalNAc transferase [159]. The GalNAc residues on these glycans are then sulfated, which is important for control of hormone levels in the bloodstream [160]. Another modification by β1,4-GalNAc is that observed in the CT antigen, which has the terminal structure GalNAcβ1,4(Siaα2,3)Gal-R also seen in the human Cad/Sd^a epitope (see *Fig. 5*); the transfer of GalNAc by the relevant enzyme to terminal galactose is dependent on prior α2,3-sialylation [161].

Sialylation is indeed a modification very familiar to those who study mammalian glycosylation. However, the levels of sialylation in non-vertebrates are in the range 'low' or 'no'; an absolute 'yes/no' is not possible since proving the absence of sialylation is as difficult as demonstrating conclusively that it is present at low levels. The relevant glycosyltransferases are all members of the sialyltransferase family, which utilise CMP-NeuAc or CMP-NeuGc as donors [162,163]; the latter cannot be made by humans de novo, due to an evolutionarily recent mutation in the relevant CMP-sialic acid hydroxylase gene [164]. The most familiar member of the sialyltransferase family is the α2,6-sialyltransferase, now known as ST6GalI, which modifies terminal galactose residues [165]; recently, a second such enzyme was found [166]. ST6GalI is an enzyme of the late Golgi [167], but can be cleaved by β-secretase, thus resulting in its secretion [168].

α2,3-Sialyltransferases may also transfer to terminal galactose with some preferring *N*-glycan substrates, whereas others modify *O*-glycans or glycolipids [169,170]. In special cases, the terminal sialic acid is then the target of up to six differentially expressed α2,8-sialyltransferases - thus initiating the formation of polysialic acid on *N*-glycans, *O*-glycans or on glycolipids [171,172]. Polysialic acid is particularly associated with embryonic development, during which the 'anti-adhesive' properties of this modification may aid the flexibility required during neurite migration; its expression is reduced in adults. A recent study indicates that induced expression of the relevant enzymes may be a promising approach to neural repair in later life [173]. Targeted ablation of different sialyltransferase genes results in immunological or neural defects [174,175,176]; a complete ablation of sialylation by knocking-out the UDP-GlcNAc 2-epimerase gene, required for CMP-sialic acid biosynthesis, indicates the overall essential role for sialic acid in mammalian development [177], whereas a defect in the Golgi CMP-sialic acid transporter is associated with human CDG-IIf [178].

Other terminal modifications of *N*-glycans include the poly-*N*-acetyllactosaminoglycans, the HNK-1 epitope and fucosylation (for examples, see *Fig. 5*). The first is a modification often associated, as mentioned above, with the branch initiated by GlcNAc-TV. Poly-*N*-acetyllactosaminoglycans (poly-LacNAc) are repeats of Galβ1,4GlcNAcβ1,3, i. e., LacNAc, hence the name. Their synthesis is initiated by a β1,3-GlcNAc transferase known as i-extension enzyme and the new GlcNAc terminus is then the target of 'standard' β1,4-galactosyltransferases; this

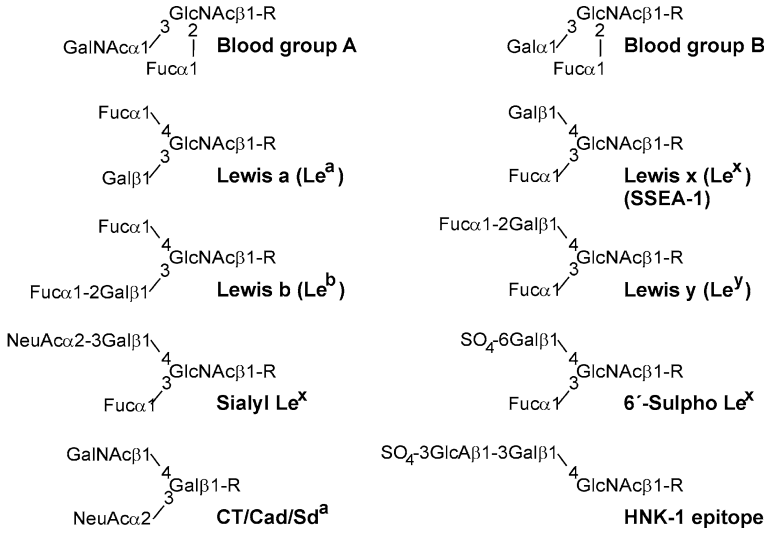

Figure 5
Examples of terminal modifications of mammalian glycans. Shown are the blood group A and B structures, variations of Lewis structures, CT/Cad/Sd^a antigen and the HNK-1 epitope

process can be repeated until the glycan chain is completed [179]. Branching of these chains, initiated by certain β1,6-GlcNAc transferases and thereby forming the so-called I antigen, is also possible [180,181]; the occurrence of poly-*N*-acetyllactosaminoglycans is not just confined to *N*-glycans - they are also present on some *O*-glycans and glycolipids.

Another modification which can be present regardless of the core is the addition of the HNK-1 epitope, SO_4-3GlcAβ1,3Galβ1,4GlcNAc (see *Fig. 5*), which is formed by the action of a glucuronyltransferase and a sulfotransferase [182,183]. Similarly, various blood Groups (Lewis and ABO) are also present on a range of glycoconjugates: the pre-requisite is a Galβ1,3GlcNAc ('type I') or Galβ1,4GlcNAc ('type II') non-reducing terminus. The H- and Se-type α1,2-fucosyltransferases, encoded in man by the *FUT1* and *FUT2* genes present on chromosome 19 [184], can modify these sequences, thus forming the O blood group. The further modification by the AB transferase then follows with the transfer of either an α1,3-linked GalNAc (blood group A; see *Fig. 5*) or a Gal (blood group B) depending on the sequence of the AB transferase gene. Four nucleotide differences alter the substrate specificity of the encoded enzyme and thus determine the blood group of the individual [185]; those with one A-type allele and one B-type have an AB phenotype, whereas individuals with an O blood group have a premature stop codon in both alleles of the ABO gene.

The Lewis-type blood groups have attracted attention, particularly in their sialylated or sulfated forms, due to their role in leukocyte homing, e. g., the selectin-mediated rolling associated with inflammation [186]. In mammals, a number of α1,3/4-fucosyltransferases can catalyse the formation of Lewis epitopes (Le^a, Le^b, Le^x, Le^y; see *Fig. 5*); Le^x is considered equivalent to the stage-specific embryonic antigen 1 (SSEA-1). The human *FUT3* gene encodes an enzyme which can accept Galβ1,3GlcNAc-R or Galβ1,4GlcNAc-R in order to form either

Galβ1,3(Fucα1,4)GlcNAc-R (Le^a) or Galβ1,4(Fucα1,3)GlcNAc-R (Le^x) [187], whereas the products of the *FUT4*, *FUT5*, *FUT6*, *FUT7* and *FUT9* genes are solely or primarily acting as α1,3-fucosyltransferases with subtly different substrate specificities [186,188]. Particularly, Fuc-TVII (i. e., the enzyme encoded by the *FUT7* gene) is involved in synthesis of sulfo- and sialyl-Le^x and is associated with the formation of selectin ligands necessary for normal leukocyte trafficking [189]; a further indication of the role of fucose in such processes is that human leukocyte adhesion deficiency II (or CDG-IIc) is a result of a defect in the GDP-Fuc transporter [190].

Not all mammals possess as many fucosyltransferase genes as are present in the human genome: indeed, *FUT3, FUT5* and *FUT6* are evolutionarily relatively new genes. Cattle only possess one such gene [191]; on the other hand, two mammalian fucosyltransferase homologues (Fuc-TX and Fuc-TXI) have, as yet, no known enzymatic function [192]. Lewis-type fucosylation is also a feature of invertebrates, such as the honeybee [193] and the trematode parasite *Schistosoma* [110], as well as fish [194] and the pathogen *Helicobacter pylori* [195], although, in the honeybee and in trematodes, the Lewis-type structures are all/partly fucosylated LacdiNAc moieties, i. e., GalNAcβ1,4(Fucα1,3)GlcNAc-R. In the case of schistosomes, these structures may play a role in the immune response to the parasite [196].

Another terminal modification, in this case restricted to *N*-glycans, is the addition of α1,3-galactose, otherwise known as the Galili epitope: this occurs in many mammals and also in one nematode parasite which infects deer [197]. This epitope, though, is absent from 'old world' monkeys and apes, including ourselves and other primates [198,199]. The relevant α1,3-galactosyltransferase gene is a pseudogene in humans. This correlates with high levels of naturally occurring 'anti-α-Gal' antibodies and is one barrier (of many) to the use of, e. g., pigs as a source of organs for xenotransplantation; the recent knocking-out of the α1,3-galactosyltransferase gene in pigs is only one step of many necessary in this area [200].

3 *O*-Glycan Biosynthesis in Animals

The term *O*-glycan has often been considered to be synonymous with the presence of a GalNAc linked to a serine or threonine residue. However, this 'mucin-type' of glycosylation is only the tip of an iceberg (see also Chap. 11.1), which includes *O*-linked fucose, *O*-linked mannose and *O*-linked GlcNAc in mammals and a range of other linkages in non-vertebrates and prokaryotes [201]. *O*-linked fucose is associated with 'Notch' signalling during development [202], *O*-linked mannose is present on α-dystroglycan and defects in the *O*-mannosyl-oligosaccharide pathway are associated with forms of congenital muscular dystrophy [203], whereas *O*-linked GlcNAc in the cytoplasm is important for signal transduction and is essential for mammalian cells [204].

3.1 Mucin-Type *O*-Glycans

In animals, the typical 'mucin-type' glycosylation is initiated by the transfer of GalNAc by a number of different enzymes; about twenty polypeptide-modifying GalNAc transferases

(ppGalNAcT) are known with various exact substrate specificities [205]. Some accept 'naked' peptides, others will only act if another residue on the acceptor peptide is already modified by a GalNAc and a final examination of their enzymatic functions still requires large-scale screening of substrates in order to understand how densely glycosylated mucin sequences can arise [206]. This multitude of initiating enzymes may explain, in retrospect, the difficulty in defining a consensus sequence for *O*-glycosylation [207]. In fruit flies, one specific ppGalNAcT encoded by the *pgant35A* gene is essential [208] and, in humans, mutations in the *GALNT3* gene are associated with familial tumoural calcinosis [209]; however, the overlapping tissue expression and substrate specificities of the mammalian enzymes make it difficult to produce 'knock-out' mice with a clear phenotype [210].

The situation is different with the next major modification of peptide-linked GalNAc: the addition of a β1,3-linked galactose to form the so-called 'core 1' structure Galβ1,3GalNAc otherwise known as the T antigen (see ❯ *Fig. 6*). In mammals, there appears to be a single relevant enzyme [211] which has a potential role in IgA nephropathy [212] and, as judged by the results with a knock-out mouse, in angiogenesis [213]. For its expression as an active enzyme, the core 1 galactosyltransferase requires the presence of a specific chaperone [214]. The relevant chaperone gene, *COSMC*, is X-linked in mammals; a deficiency in this gene is associated with a number of diseases, such as the autoimmune disease Tn syndrome [215], so-called since the Tn antigen (unmodified GalNAc-α-Ser/Thr) is present. The corresponding enzyme, however, in insects and nematodes does not require such a chaperone [216,217].

The core 1 structure is the target of a number of enzymes in mammals, such as α2,3-sialyltransferases modifying the galactose residue [218], α2,6-sialyltransferases modifying the GalNAc [219], a 'core 1 extension' β1,3-GlcNAc transferase required for synthesis of the MECA-79 epitope [Galβ1,4(SO_4-6)GlcNAcβ1,3Galβ1,3GalNAc] which forms part of L-selectin ligands [220] and β1,6-GlcNAc transferases also modifying the GalNAc. The latter type of enzyme catalyses the formation of the 'core 2' *O*-glycan, which is one of eight mucin-type 'cores' identified in mammals (❯ *Fig. 6*). The human genome has three genes encoding β1,6-GlcNAc transferases forming the core 2 structure [181,221,222]. This structure can be modified by poly-*N*-acetyllactosaminoglycans, which may be fucosylated to create Lewis groups, such as the *O*-glycans of P-selectin glycoprotein ligand 1 (PSGL1) [223]; knock-out mice lacking one of the core 2 GlcNAc transferase genes have a partial deficiency in selectin ligands and reduced neutrophil recruitment to sites of inflammation [224]. Core 2 structures are also associated with control of the immune system and are a marker of activated T-cells; the abnormal expression of core 2 structures in AIDS and Wiskott–Aldrich syndrome results in T-cells which are not truly active also carrying the modification [225]. In the fruit fly, there are no core 2 structures, but in *Caenorhabditis elegans*, a putative β1,6-glucosyltransferase has been found [226], which is probably involved in the formation of the rather unusual *O*-glycans found in this nematode [227].

An alternative to the core 1 structure is the core 3 structure GlcNAcβ1,3GalNAc, present in a restricted range of tissues. The relevant β1,3-GlcNAc transferase is known as β3Gn-T6 and is a member of the large β1,3-glycosyltransferase family [228]; it apparently suppresses the metastatic potential of carcinoma cells [229]. Core 4 [GlcNAcβ1,6(GlcNAcβ1,3)GalNAc] is formed from core 3 by the action of the so-called 'mucin-type' core 2 synthesising enzyme (C2GnT-M) [181]. Four other mucin core structures are known (cores 5, 6, 7 and 8), but information as to the genetic basis for their formation is currently absent.

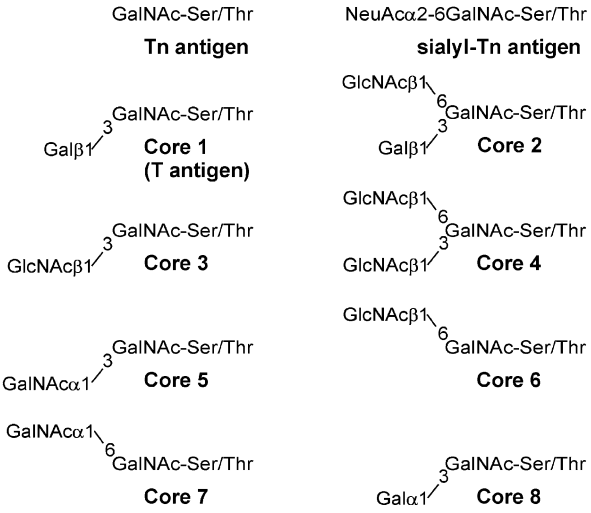

Figure 6
Core structures of mammalian mucin-type *O*-glycans

3.2 *O*-Fucosylation and *O*-Glucosylation

O-fucosylation of polypeptides is catalyzed by one of two E*R*-localised enzymes (the protein-*O*-fucosyltransferases encoded by the *POFUT1* and *POFUT2* genes), which modify, respectively, EGF (epidermal growth factor) or TSR (thrombospondin type 1 repeat) domains [230,231]. These enzymes recognise not just a peptide, but the actual 3D-structure of the relevant domain. Furthermore, the enzymes modifying the peptide-bound fucose residue (in the case of EGF domains Golgi-localised β1,3-GlcNAc transferase(s) and for TSR domains an ER-localised β1,3-glucosyltransferase) also recognise the domain structure [232,233,234,235]. Another modification specific for EGF-domains is *O*-glucosylation, which is associated with proteins such as clotting factors VII and IX and Notch receptor proteins [236]; the protein-bound glucose is, in turn, the acceptor for an α1,3-xylosyltransferase, which was recently purified from bovine liver [237].

Mutations in the *POFUT1* and *O*-linked fucose-modifying β1,3-GlcNAc transferase genes are associated with, for instance, mid-gestation lethality in mice [238] and abnormal wing development in the fruit fly [232,239]; indeed, the name of the β1,3-GlcNAc transferase mutant is *fringe*, reflects the nature of the morphogenetic defect in the fruit fly, which has similarities to the *notch* phenotype ('notched' wings in the fly). This is not surprising considering that *O*-fucosyltransferase I and Fringe modify the Notch protein and that this glycosylation pathway is important for Notch-mediated signalling required for embryonic development in animals [202]. The GlcNAc transferred by the Fringe enzymes is, in mammals, the target of β4Gal-TI [240] and the galactose can then be sialylated. Unlike flies, mammals have three *fringe* homologues encoding β1,3-GlcNAc transferases, specific for fucosylated EGF domains, known as lunatic fringe, manic fringe and radical fringe [233]; a mutation in

the human *lunatic fringe* gene has been found in one patient with spondylocostal dystosis, a disease associated with vertebral defects [241]. In zebrafish, use of antisense morpholino-oligonucleotides to target *lunatic fringe* transcripts indicates a role for the encoded enzyme in hypochord development [242].

3.3 *O*-Mannosylation

Another *O*-glycosylation event that has recently attracted attention is *O*-mannosylation, a modification once considered to be yeast-specific, but which is found also in mammals [203] and, most recently, in *Mycobacteria* [243]. In mammals and in fruit flies, two related proteins, POMT1 and POMT2 are required to be co-expressed in order for protein *O*-mannosylation to occur [244,245]; they require Dol-P-Man as the donor substrate. Defects in man result in a form of muscular dystrophy known as Walker–Warburg syndrome [246], whereas in flies the *twisted (tw)* and *rotated abdomen (rt)* mutations are associated with, as the names suggest, a twisted abdomen phenotype [247]. In yeast, the essential process of protein *O*-mannosylation [248] is followed by addition of further mannose residues in the Golgi [249], whereas in mammals, the *O*-mannose residue is then the acceptor for a GlcNAc residue transferred by protein *O*-mannose *N*-acetylglucosaminyltransferase I (POMGnTI), a homologue of GlcNAc-TI, which is defective in Muscle-Eye-Brain disease [250]. Indeed, the absence of correct *O*-glycosylation of α-dystroglycan is associated with a number of congenital neuromuscular diseases with mutations in glycosyltransferase-like genes (e. g., *LARGE*, *fukutin* and *FKRP*) encoding proteins of unknown activity [5,203,251].

4 Glycolipid Biosynthesis in Animals

In mammals, the term ‘glycolipid’ is often used to mean ganglioside - but these are only a subset of the glycolipids found in eukaryotes. As summarized in Chap. 11.1, gangliosides are a form of glycosphingolipid, which are glycosylated forms of ceramide. The first step in their biosynthesis is the transfer of glucose to ceramide to form glucosylceramide. This reaction takes place on the cytoplasmic face of the endomembrane system [252]; subsequent to flipping of glucosylceramide to the lumenal face of the endomembrane, a number of Golgi-localised glycosyltransferases act to make the range of gangliosides observed, with galactosyltransferases, GalNAc transferases and sialyltransferases being particularly important [253]. For mammalian glycolipids, the first modification of glucosylceramide is mediated by β1,4-galactosyltransferase VI [254]; the resulting lactosylceramide is then modified by either (i) sialylation with GM3 synthase (also known as ST3GalV) [255] and/or addition of GalNAc by GM2/GD2 synthase [256] to form members of the *ganglio*-series, (ii) α1,4-galactosylation yielding the P^k/Gb3/CD77 antigen of the *globo*-series [257], (iii) α1,3-galactosylation by the iGb3 synthase initiating the *isoglobo*-series [258] and (iv) transfer by β1,3GlcNAc-TV in the formation of the *lacto*- and *neolacto*-series [259]. In the case of the galactolipids, including sulfatide and seminolipid, the first step is catalyzed by galactosylceramide synthase [260] on the lumenal side of the endomembrane system.

Ablation of genes of glycolipid biosynthesis is often associated with neurological defects [253]. In humans, a loss-of-function mutation in the aforementioned ST3GalV/GM3 synthase

(encoded by the *SIAT9* gene) has been identified in Amish infantile epilepsy syndrome [261]; however, as an example of the problems of comparing mice and men, the corresponding knockout mouse shows no neurological symptoms, but displays insulin hypersensitivity [262]. As judged by recent tissue-specific knockout mice, the formation of glucosylceramide is also important for the maintenance of the barrier function of the epidermis and for brain maturation [263,264]. On the other hand, the relevant glucosylceramide synthase has attained increased interest due to it being a target for 'substrate reduction therapy' in lysosomal storage diseases. In this approach for treatment of type I Gaucher's disease, the intention is to reduce the pathological build-up of non-catabolised glucosylceramide in the lysosome; this is achieved by use of the glucosylceramide synthase inhibitor *N*-butyldeoxynojirimycin (also an ER glucosidase II inhibitor), which reduces the ability of cells to produce more glycolipids, including gangliosides, that are eventually catabolised to glucosylceramide during the normal physiological turnover of these compounds [265].

In invertebrates, different forms of glycosphingolipids are found; those of nematodes and insects, i. e., *arthro*-series lipids, are probably the best examined. Although the first reaction in their biosynthesis is the glucosylation of ceramide, the next enzymes to act are a β1,4-mannosyltransferase and a β1,3-GlcNAc transferase. Developmental defects in *Drosophila* are associated with defects in these two enzymes and this is reflected in the names of the corresponding mutants - *egghead* and *brainiac* [266,267]. The elongation of glycolipids in insects is not fully understood, but as judged by the structures observed [268,269] includes the action of a β1,4-GalNAc transferase [270], an α1,4-GalNAc transferase [271] and other enzymes such as a phosphoethanolamine transferase which is yet to be identified. Glycolipids often act as receptors for bacterial toxins and the series of *Caenorhabditis bre* (***B****acillus thuringiensis* toxin **re**sistant) mutants, displaying deletions in the glycolipid biosynthesis pathway, are associated with resistance to the Cry5B crystal toxin. The corresponding enzymes BRE-1, BRE-2, BRE-3, BRE-4 and BRE-5 are, respectively, a GDP-mannose dehydratase (required for GDP-Fuc biosynthesis), a β1,3-galactosyltransferase, an Egghead-like β1,4-mannosyltransferase, a β1,4-GalNAc transferase and a Brainiac-like β1,3-GlcNAc transferase [272,273,274] required for biosynthesis of fucosylated *arthro*-series glycolipids in the nematode. Some glycolipids in *C. elegans* and other nematodes (e. g., *Ascaris*), though, also carry phosphorylcholine residues and display immunomodulatory activity [275].

Another type of glycolipid is involved in anchoring some membrane proteins via a glycosylphosphatidylinositol (GPI). These types of membrane anchor were first found attached to the variant surface glycoprotein (VSG) of the African sleeping sickness parasite *Trypanosoma brucei* [276], but GPI-anchored proteins are widespread in other eukaryotes [277]; examples in mammals include various brush border enzymes, Thy-1 and decay accelerating factor (DAF). All GPI anchors consist of core based upon an inositol phospholipid modified by the sequential addition of an *N*-acetylglucosamine (which is then de-*N*-acetylated), three mannose residues, and an ethanolamine-phosphate which is linked to the mature *C*-terminus of the anchored protein. GPI biosynthesis begins on the cytoplasmic face of the endoplasmic reticulum; following a flipping event, similar to that during the formation of dolichyl-linked oligosaccharides, and final modifications of the core, the GPI-anchor is transferred in a transamidase-mediated reaction to the protein [277,278]. Obviously, a number of glycosyltransferases and auxiliary proteins are involved: these are encoded by *PIG* genes in mammals and *GPI* genes in yeast and trypanosomes. A somatic, rather than inherited, defect in the *PIG-A* gene in humans results in

the absence of decay accelerating factor from erythrocyte membranes and, thus, to paroxysmal nocturnal haemoglobinuria [279]. *GPI* genes are essential for the survival of the bloodstream form of *Trypanosoma brucei* [280] and subtle differences in the GPI-biosynthetic pathways of mammals and trypanosomatids have facilitated the development of inhibitors, which specifically target parasitic GPI biosynthesis [281]. GPI biosynthesis is also important for viability of the human fungal pathogen *Candida albicans* [282].

5 Glycosaminoglycan Biosynthesis

Animals synthesise several different types of glycosaminoglycans (GAGs) consisting of disaccharide repeats: (i) keratan sulfate in the form of sulfated poly-*N*-acetyllactosaminoglycans present on 'normal' *N*- and *O*-glycans [283], (ii) chondroitin, dermatan and heparan sulfate chains attached via xylose to serine residues of proteoglycan core proteins [284,285] and (iii) the free glycosaminoglycan known as hyaluronic acid [286]. These types of glycoconjugates have been known for some fifty or more years [287,288]; however, only recently has molecular biology made its impact on 'GAGobiology'. The biosynthesis of chondroitin, dermatan and heparan sulfates is initiated by the transfer of xylose to serine residues of a relevant core protein (see ❯ *Fig. 7*); generally, an acidic patch followed by a Ser-Gly sequence is required for xylosyltransferase to act [289]. Whereas most invertebrates have one xylosyltransferase gene [290,291], mammals have two such enzymes, XT-I and XT-II, which are functionally similar [292,293,294]; these xylosyltransferases display homology to the core 2 GlcNAc transferases involved in formation of some mammalian *O*-glycans. RNAi-feeding of *Caenorhabditis* with bacteria that express double-stranded RNA targeting the xylosyltransferase showed that embryonal cytokinesis depends on the presence of this protein [295].

Following xylosylation of the peptide core, the action of three other enzymes (Gal-TI, Gal-TII and GlcA-TI in the nomenclature of 'GAGolgists' and not to be confused with actual gene names) results in formation of the tetrasaccharide core (GlcAβ1,3Galβ1,3Galβ1,4Xyl-*O*-Ser) common to all chondroitin, dermatan and heparan sulfate chains; these enzymes are respectively encoded by the *B4GALT7, B3GALT6* and *B3GAT3* genes. The first are members of the familiar β1,4- and β1,3-glycosyltransferase families [296,297,298] and deficiencies of *B4GALT7* gene are associated with some cases of Ehlers–Danlos syndrome [299].

After the action of the β1,3-glucuronyltransferase, a 'decision' must be made: the action of an α1,4-GlcNAc transferase is required for initiation of heparan sulfate [300], whereas the transfer of a β1,4-GalNAc determines the beginning of chondroitin sulfate synthesis (dermatan sulfate being a modification of a chondroitin-type backbone) [301]. The subsequent formation of GlcAβ1,3GalNAcβ1,4- and GlcAβ1,4GlcNAcα1,4-disaccharide repeats is dependent on the actions of multiple enzymes. Some of these have two active sites and may form 'co-polymerases'. In mammals, the genetic basis is particularly complex, since five genes (*EXT1*, *EXT2*, *EXTL1*, *EXTL2* and *EXTL3*) are involved in the initiation and polymerisation of heparan sulfate [302]. The gene names reflect the role of mutations in heparan sulfate biosynthesis in the formation of exostoses, a benign bone tumour. Interestingly, exostoses patients only ever have one defective allele; in mice, homozygous mutants do not survive [303]. In the case of chondroitin sulfate, various 'chondroitin synthases' or 'chondroitin polymerisation factors' have been identified and combinations of these proteins may be involved in chondroitin poly-

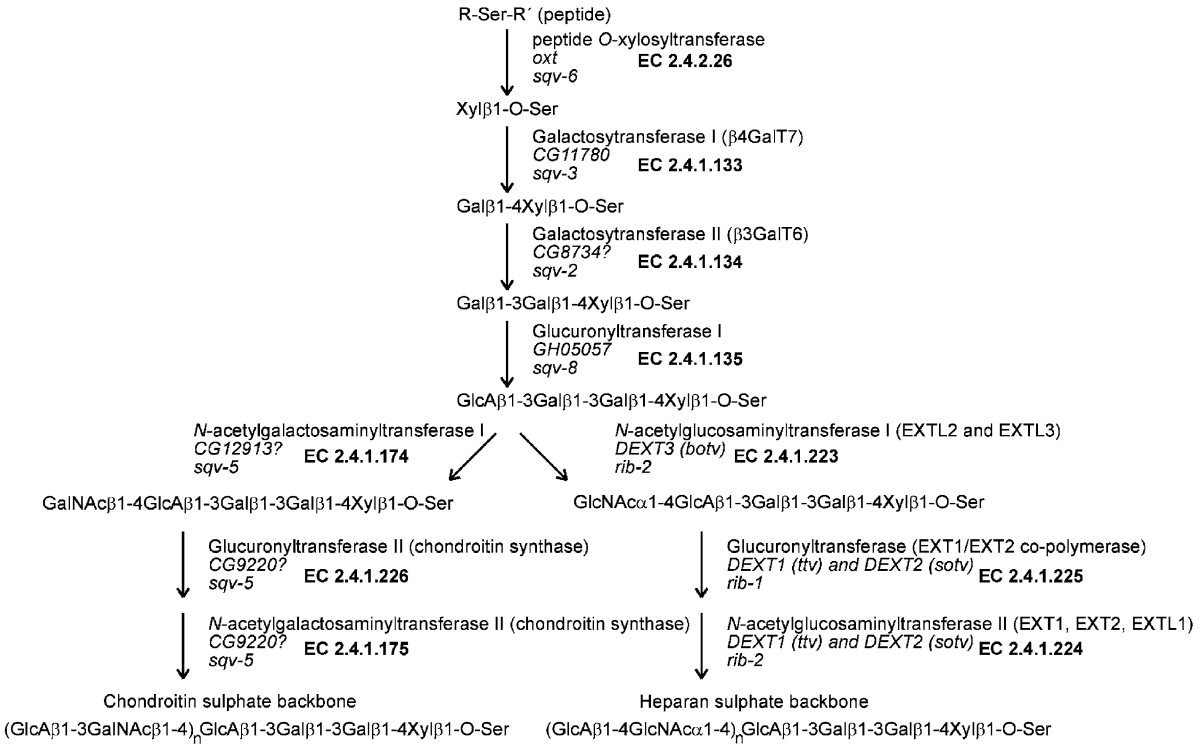

Figure 7

The initial stages of chondroitin and heparan sulfate biosynthesis. Each enzyme is defined by its shorthand name(s) as well as by the abbreviations of the relevant known or proposed corresponding *Drosophila* and *Caenorhabditis* genes

merisation [304]. Defects in all enzymes required for chondroitin synthesis in *Caenorhabditis elegans*, including those involved in formation of the tetrasaccharide core region, are associated with so-called *sqv* (**sq**uashed **v**ulva) phenotypes, indicative of the role of all the glycosyltransferases involved, as well as a transporter and UDP-sugar synthesising enzymes, in morphogenesis [305]. The two genes involved in nematode heparan sulfate biosynthesis are defective in the *rib-1* and *rib-2* mutants [306], whereas the corresponding *Drosophila* EXT-like genes are known as *ttv* (*tout-velu* or all-hairy), *botv* (brother of *ttv*) and *sotv* (sister of *ttv*) [307]. The phenotypes of all three mutant flies involve defects in growth factor signalling indicating that the fly also requires the formation of heparan sulfates for normal development to occur [308].

Once the chondroitin, heparan or keratan backbone has been formed, various modifications take place, particularly *O*-sulfation, *N*-deacetylation/*N*-sulfation and epimerisation to iduronic acid [309,310,311,312], which result in the final sulfated forms of these macromolecules found in nature. RNAi- or morpholino-induced knock-down of heparan sulfotransferases in the fruit fly, worm or zebrafish and a knockout of chondroitin-4-sulfotransferase 1 in the mouse are associated with developmental defects [313,314,315,316]. In humans, defects in the *CHST6* (**c**arbo **h**ydrate **s**ulfo **t**ransferase **6** or corneal GlcNAc-6-sulfotransferase) gene, associated with abnormal keratan sulfate levels, are the apparent cause of macular corneal dystrophy [317], a disease which results in progressive bilateral loss of vision; furthermore, Omani-type spondyloephiphyseal dysplasia, a skeletal disease, is associated with a mutation in the *CHST3* (chondroitin-6-sulfotransferase) gene [318]. Certainly, many growth factors bind to glycosaminoglycan chains and so this accounts for the defects observed in their absence; for instance, heparan sulfate is required for the non-classical secretion of fibroblast growth factor 2 potentially by generating a concentration gradient across the plasma membrane [319].

6 Biosynthesis of Plant Polysaccharides

Akin to the animal proteoglycans, the plant arabinogalactans are considered to be important in plant development [320]; as the name suggests, these glycoconjugates contain arabinose-modified branched galactose polymers attached to protein, which is often attached to the membrane via a GPI anchor. Despite the biological importance, knowledge of the full structures and the relevant enzymology is lacking. This is actually a general phenomenon in terms of our knowledge about plant polysaccharides in general and has been exacerbated by the lack of defined glycosyltransferase acceptor substrates as well as decent quantities of the necessary nucleotide sugars. For instance, only recently has the enzyme required for UDP-arabinofuranose biosynthesis (a mutase) been found [321]. However, there has been much progress in recent years, which has been aided by the sequencing of the *Arabidopsis* genome and by the use of forward and reverse genetics in this plant [322].

In terms of quantity, probably cellulose (Chap. 6.3) is the most important plant polysaccharide and has a key role in maintaining the cell wall. Enzyme complexes, with perhaps 36 subunits, produce this polymer and a number of the relevant *CESA* (cellulose synthase) genes have been identified; defects in some *CESA* genes are associated with some *irx* (**ir**regular **x**ylem) phenotypes [323]. Related proteins, encoded by cellulose synthase-like A (*CslA*) genes, are apparently β-mannan synthases [324]. Mannans are only one of the many hemicellu-

losic polysaccharides which associate with cellulose: xyloglucans and xylans are other examples, for which a number of relevant enzymes have been identified. Xyloglucans contain a poly-β1,4-glucose chain decorated with α1,6-xylose residues, which may be further modified by β1,2-galactose and α1,2-fucose. Examples of all three types of required enzyme have been identified: two xylosyltransferases [325,326], a fucosyltransferase encoded by the *MUR2* gene [327,328] and a galactosyltransferase encoded by the *MUR3* gene [329]. Xylans, on the other hand, contain a poly-β1,4-xylose backbone modified with glucuronic acid and 4-*O*-methylglucuronic acid residues. Relevant *Arabidopsis* mutants, *fra8* (i. e., *fragile fibre 8*), *irx8* and *irx9*, have a 'dwarf plant' phenotype and a defective glucuronoxylan composition compatible with the homology of the corresponding predicted gene products to glycosyltransferases [330,331].

Two other major classes of plant polysaccharides are the homogalacturonans and rhamnogalacturonans of pectin. The *quasimodo1* (*qua1*) mutant also has a 'dwarf' phenotype and shows a reduced homogalacturonan content, although the actual function of the protein encoded by the *QUA1* gene is yet to be proven [332]. Similarly, the exact function of the *ARAD1* (*ARABINAN DEFICIENT 1*) gene has not yet been defined, but it is putatively required for the formation of α1,5-arabinan side chains on rhamnogalacturonan [333]. Recently, an α1,4-galacturonyltransferase (GAUT1) involved in homogalacturonan synthesis [334] and a putative glucuronyltransferase (GUT1), with homology to animal *EXT* heparan synthases, required for the developmentally important borate cross-linking of rhamnogalacturonan-II [335] have been also identified. However, it is obvious that a multitude of genes and enzymes involved in polysaccharide synthesis are still unknown.

7 Structural and Functional Aspects of Glycosyltransferases

As introduced above, glycosyltransferases (GTs) are enzymes which catalyse the transfer of an activated donor sugar, usually a nucleotide-sugar, to an appropriate acceptor molecule that can be another sugar, lipid, protein or small molecule. They are present in both prokaryotes and eukaryotes, and they generally display exquisite specificity for both the glycosyl donor and the acceptor substrates. The vast majority of mammalian GTs are endoplasmic reticulum- and Golgi-resident membrane proteins. Whereas some ER glycosyltransferases possess multiple transmembrane domains, a typical Golgi-resident GT has the topology of a type II membrane protein consisting of a short *N*-terminal cytoplasmic tail followed by a transmembrane domain, a stem region of variable length and a large *C*-terminal catalytic domain that extends into the Golgi lumen. The topology of Golgi GTs may be more complex since some GTs were shown to have additional non-catalytic modules (such as a lectin domain) that could potentially mediate substrate recognition and/or protein-protein interaction. GTs involved in the synthesis of alternating polysaccharides, such as heparin, hyaluronan, are examples of bi-functional enzymes harbouring two separate catalytic domains.

7.1 Classification of Glycosyltransferases

The development of bioinformatics, together with new or improved cloning strategies, led in the last decade to the identification of a wide number of GTs. These enzymes are primarily

classified on the basis of their donor, acceptor and product specificity, according to the recommendations of the International Union of Biochemistry and Molecular Biology (IUBMB). In addition, they are considered as either "inverting" or "retaining" enzymes depending on whether the stereochemistry is changed or conserved during glycosyl transfer. Some of these enzymes have a strict requirement of divalent cations for activity, whereas many others are metal cation-independent or may just be activated by metal cations (such as Mn^{2+}). GTs are also classified into sequence similarity-based families [336] which are kept updated on the Carbohydrate Active enZyme database (CAZy, available at http://afmb.cnrs-mrs.fr/CAZY/). In addition to nucleotide-sugar-dependent GTs, the database also integrates enzymes that utilise dolichol-phospho-sugars, sugar-1-phosphates, and lipid diphospho-sugars as activated donors. At the time of writing (February 2007), the CAZy database comprises over 24,000 known and putative GT sequences that have been divided into 86 GT families (denoted as GTx), the vast majority of these sequences being uncharacterised open reading frames. Although there are families numbered GT1 to GT87, the GT36 family has been reclassified as a glycohydrolase family (GH94) since these are phosphorolytic enzymes, such as a chitobiose phosphorylase, whose 3D structure does not resemble any glycosyltransferase, but rather one of a glycosidase [337].

Large differences in the number and function of GTs are observed among families. Some families are monospecific and comprise only a few sequences whereas other families contain a huge number of sequences from various sources with diverse functions. For these polyspecific families, sequence similarities are mostly restricted to a portion of the catalytic domain. Therefore if a putative GT sequence is related to a large polyspecific family, its precise biochemical function cannot be reliably predicted and one of the major challenges facing glycobiologists, particularly those working on bacterial and plant GTs, is to determine the donor and acceptor specificities of the many hypothetical GT sequences identified through the systematic sequencing of genomes. Eukaryotic genomes encode a wide variety of GTs from many of the sequence-derived families (e. g., 230 human GT sequences that are found in 42 out of 86 GT families). In contrast, GT sequences of archaeal genomes show a different picture since they fall only into two GT families, GT2 and GT4, which represent the two largest inverting and retaining enzyme families, respectively. This sequence-based classification is assumed to integrate both structural and mechanistic features within each family [336]. When applied to glycosylhydrolases, this classification scheme was shown to correlate well with enzyme mechanism (inversion or retention of the anomeric configuration). This may not apply so safely to all GT families, because distant similarities between inverting and retaining CAZy families have been noted, suggesting that these families may share a common ancestor [338,339]. A similar observation has been made for the retaining GT27 and GT78 families which display sequence similarities with the large inverting GT2 family [340,341,342].

7.2 Crystal Structures of Glycosyltransferases

Structure-function studies on GTs have been hampered for many years by the relative paucity of structural data for this important class of enzymes. To date, crystal structures for 39 GTs have been solved and structural information is now available for 25 GT families (*Table 1* and *Table 2*). The past 3 years have seen significant advances in structural glycobiology

with the first three-dimensional structures of sialyltransferases and fucosyltransferases as well as the resolution of several members of the family of UDP-GalNAc:polypeptide α-*N*-acetylgalactosaminyltransferases (ppGalNAcTs) which are involved in the first step of mucin-type *O*-glycosylation. The latter enzyme family is rather unique among glycosyltransferases, containing both catalytic and lectin domains.

In contrast to glycosyl hydrolases, which display a myriad of topologies, GT structures have, thus far, revealed only two folds (and variants thereof), termed GT-A and GT-B [341,343], and which were first observed in the original SpsA and β-glucosyltransferase (BGT) structures [344,345]. The two GT folds now determined consist primarily of $\alpha/\beta/\alpha$ sandwiches, similar or very close to the Rossmann-type fold, a classical structural motif found in many nucleotide-binding proteins. It is striking to note that the GT-A and GT-B folds are also shared by non-GT enzymes, such as nucleotidyltransferases and sugar epimerases [346]. As shown on ❯ *Table 1* and ❯ *Table 2*, 3D structures are available for inverting and retaining GTs originating from eukaryotes and prokaryotes. Most of these proteins have been crystallised in complex with either the donor or/and acceptor substrates (or analogues). Of the 25 GT families that have a three-dimensional structural representative, 13 and 9 families display the canonical GT-A and GT-B folds, respectively. Three of the remaining families can be considered as variants of these two folds (see below). However, it must be emphasised that the two recent structures of peptidoglycan transglycosidases (members of the GT51 family) are not related to either the GT-A or GT-B fold, but they show notable structural similarity to the bacteriophage lambda lysozyme, a glycosidase, both in the overall fold and in the catalytic centre [347,348]; therefore, they are not considered further in this chapter. There is no correlation between the overall fold of a GT and its mechanism of action, since both inverting and retaining enzymes of both fold types are known [341]. A database that gathers structural information concerning GTs is now available (http://www.cermav.cnrs.fr/glyco3D). It contains useful links that permit retrieval of bibliographic information as well as atomic coordinates at the Protein Data Bank, and images are provided to illustrate the details of protein-substrate interactions.

The recent burst of reported GT structures has shed light on their substrate binding and catalytic mechanisms. GTs are thought to use mechanistic strategies that directly parallel those used by the well characterised glycosyl hydrolases. However, while the mechanism of inverting GTs appears to be widely accepted, the mechanism of retaining enzymes remains a topic of considerable debate. These aspects will be discussed later in the chapter.

7.2.1 The GT-A Fold

The GT-A fold is best described as a single $\alpha/\beta/\alpha$ domain that is formed by a central β-sheet flanked by α-helices (❯ *Fig. 8a,b*; see also list in ❯ *Table 1*). The mixed β-sheet typically consists of seven β-strands of topology 3214657 where strand 6 is antiparallel. The central β-sheet is flanked by a smaller one, and the association of both creates the active site. All of the metal ion-dependent GTs for which structures have been determined display this type of fold. Until recently, a general feature of all members of the GT-A superfamily was considered to be the presence of a common motif, the DxD motif, and their requirement for a divalent cation for activity. The DxD motif is a degenerate sequence that is shown in all crystal structures to interact primarily with the phosphate groups of the nucleotide donor through the coordination of a divalent cation, typically Mn^{2+}. However, the recently determined X-ray structure of

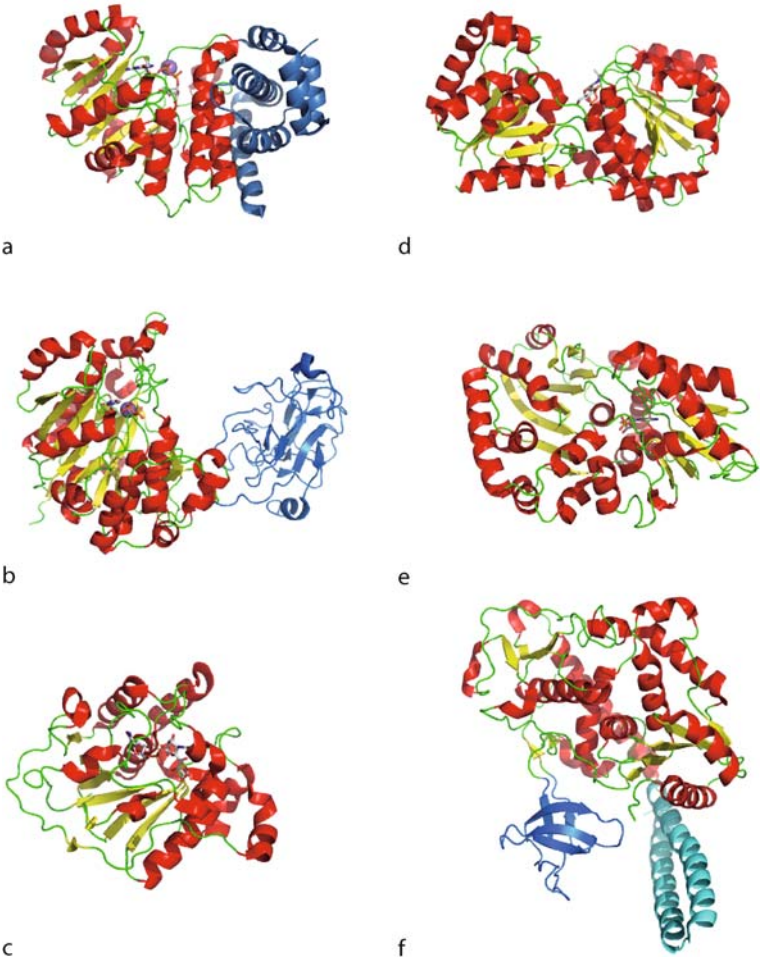

Figure 8

Catalytic domains are coloured yellow and red, and additional domains blue. a Mannosylglycerate synthase (PDB code 2BO8 [342]), b ppGalNAc-transferase 10 (code 2D7I [349]), c sialyltransferase CstII (code 1RO7 [350], d GlcNAc-transferase MurG (code 1NLM [351]), e sialyltransferase PmSTI (code 2EX1 [352], f α6-fucosyltransferase (code 2DE0 [353]). Structures a and b have GT-A folds, d and e are of the GT-B type, whereas c and f are variants of GT-A and GT-B folds, respectively

murine leukocyte type Core 2 β6-*N*-acetylglucosaminyltransferase (C2GnT-L, a key enzyme in the biosynthesis of branched *O*-glycans; see *Sect. 3.1*) shows that this enzyme possesses the canonical GT-A fold but it lacks the characteristic metal ion binding DxD motif [354]. The role played by the metal ion in other metal ion-dependent GT-A structures is served in C2GnT-L by two basic residues located in the *C*-terminus of the catalytic domain. The use of such basic amino acids to counteract the positive charge of the diphosphate moiety is striking-

ly similar to that observed in a number of GT-B fold GTs and this suggests a convergence of catalytic mechanism.

Comparison of the catalytic domains of enzymes of the GT-A superfamily revealed the presence of two regions that are structurally well conserved in both inverting and retaining enzymes [341]. This suggests that common structural elements are necessary for the glycosyl transfer reaction, irrespective of the stereochemistry of the reaction. The first region mostly corresponds to the Rossmann-type nucleotide binding domain, encompassing the first 100–120 residues of the catalytic domain, and that is often terminated by the aforementioned DxD motif. The key amino acids that interact with nucleotide donor are mostly located at equivalent positions. The *C*-terminal part of the catalytic domain is mostly dedicated to the recognition of the acceptor and it generally shows higher variability. However, a common structural motif, that is part of the active site, is observed in the acceptor binding domains of

all GT-A enzymes. It comprises residues that were shown in some crystal structures to interact with both the donor sugar and the sugar acceptor [355,356,357,358].

As mentioned above, the family of UDP-GalNAc:polypeptide α-*N*-acetylgalactosaminyltransferases (ppGalNAcTs, GT27; see *Fig. 8b*) is rather unique among glycosyltransferases, in possessing a C-terminal, ricin-type lectin domain of ~130 residues containing three putative carbohydrate-binding sites. Biochemical analyses suggest that this domain functions in the transfer of GalNAc to glycopeptide but not peptide substrates [372,373]. The recently solved 3D structures of three protein members (ppGalNAc-T1, -T2 and -T10) reveal that the association of ppGalNAcT catalytic and lectin domains can be dynamic and also reveal the molecular bases of substrate recognition [349,365,366]. These studies highlighted the importance of the peptide region linking the catalytic and lectin domains and that is thought to modulate acceptor substrate specificity [349]. This "flexible tether" model proposed by Fritz et al. [366], suggests that lectin domain mobility endows certain ppGalNAcTs with an even greater capacity to adapt to and capture glycosylated substrates, thus ensuring the high density of glycosylation characteristic of mucin domains.

The first structure determined for a sialyltransferase (CstII from *Campylobacter jejuni* of family GT42; see *Fig. 8c*) revealed an unusual variant of the GT-A fold [350]. The protein displays a similar type of fold as the canonical GT-A fold, but with some differences in the connectivity of β-strands (parallel β-sheet of topology 8712456) and it has no DxD motif. Therefore the CstII structure represents a new type of fold. Another prokaryotic sialyltransferase has, though, a GT-B fold (see *Table 2*).

Structural studies on several GT-A enzymes have shown that one or two flexible loops undergo a marked conformational change from an open to a closed conformation upon nucleotide sugar binding, as first observed with GlcNAc-TI [363]. This provides a structural basis for the ordered binding of the donor and acceptor to the enzyme, i. e., the "ordered sequential" binding mechanism (UDP-sugar on first, UDP off last) deduced from earlier kinetic studies on β4Gal-TI and GlcNAc-TI [132,374]. On binding of the metal ion, if required, and the nucleotide sugar, a disordered loop in the free enzyme becomes ordered and moves to act as a lid covering the buried donor substrate. This conformational change creates a pocket that will accommodate the acceptor substrate. After catalysis, the glycosylated product is released first, before the nucleotide. Another significant feature is the observed distorted conformation of the bound nucleotide sugar in the active site that may be important in the catalytic mechanism (for a review, see [375]).

7.2.2 The GT-B Fold

The GT-B fold is characterised by two separate Rossmann-type domains with a connecting linker region and a catalytic site located between the domains. Both domains show an $\alpha/\beta/\alpha$ structure formed by a central parallel β-sheet of general topology 321456 (*Fig. 8d,e*; see also list in *Table 2*). The similarity between the two domains is high enough to propose that they are the result of gene duplication [376]. There is an excellent structural conservation between protein members of the GT-B family, particularly in the *C*-terminal domain which corresponds to the nucleotide binding region. Variations are much more pronounced in the *N*-terminal domains, in the loops and α-helices which point towards the active site, which have evolved to accommodate very different acceptors. The GT-B superfamily is particularly

[a]Mechanism, R: retaining, I: inverting [b]Only the first solved crystal structure is cited for each glycosyltransferase family

remarkable for the diversity of products its members produce, particularly those that classify into GT1 family and which include most of the prokaryotic and plant enzymes that glycosylate secondary metabolites, and a large number of known or putative glucuronosyltransferases that glycosylate potentially toxic lipophilic compounds [377]. Although divalent cations may be required for full activity of GT-B enzymes [377,378], there is no evidence of a bound metal ion associated with catalysis. In the GT-B family, either the positive helix dipole effect of an $\alpha/\beta/\alpha$ structural motif or positively charged side chains of basic residues are found to counteract the negative charge of the diphosphate moiety.

Common themes in GT-B enzymes concern the presence of a conserved peptide motif termed GPGTF ("Glycogen Phosphorylase/Glycosyltransferase" motif) as defined by Wrabl and Grishin [391] located in the nucleotide binding domain and that is involved in binding the glycosyl donors, the involvement of a glutamate residue (that is part of the GPGTF motif) in ribose binding, the presence of a long *C*-terminal α-helix which interacts with the *N*-terminal domain, a conformational change upon sugar donor binding, and the phenomenon that

most of the protein contacts with the acceptor involve residues of the *N*-terminal domain. However, so far, GT-B enzymes do not appear to share any strictly conserved residues and exceptions to the above rules have been recently documented. Glycogen synthases (GT5) lack the glutamate residue that specifically anchors the ribose moiety (GtfA and GtfD that use dTDP also lack the Glu residue) [379,380]. The bacterial sialyltransferase of *Pasteurella multocida* (PmST1, GT80) lacks the typical signature of the GT-B fold of the *C*-terminal α-helix crossing over to the *N*-terminal domain (◉ *Fig. 8e*) [352]. The phage T4 AGT enzyme (GT72) presents an unusual feature since it predominantly binds donor and acceptor substrates via its *C*-terminal domain [389]. Domain movements that would bring the two substrates to correct positions for catalysis are expected for GT-B enzymes. Such conformational changes have been observed upon nucleotide sugar donor binding in BGT (GT63), MurG (GT28), and PMST1 (GT80) [351,352,378]. In contrast, WaaC, a heptosyltransferase of *E. coli* (GT20) does not undergo such domain rotation upon substrate binding, but the substrate analogue (ADP-2F-heptose) and the reaction product (ADP) are found to adopt remarkably distinct conformations inside the active site [386].

Sequence similarities between GT families are extremely low. However, phylogenetic trees based upon sequence alignments derived from the structural superimposition of *C*-terminal domains of 18 GT-B structures (3D representatives of families GT1, GT4, GT5, GT9, GT20, GT28, GT35, GT63, GT72, GT80) intriguingly resulted in a clear separation of inverting and retaining enzymes [383]. The sole "outlier" is the inverting GT80 bacterial sialyltransferase which appears on the "retaining" side of the tree. The GT80 enzyme is also unusual in many other ways in that it uses a nucleoside monophosphate donor and has also been reported to catalyse transglycosylation with retention (in addition to glycosyl transfer with inversion) [352]. Furthermore, the structural overlap of all 18 GT-B enzymes also shows a clear structural basis for the inverting versus retaining enzymes based upon the topology of the loops interacting with the donor sugar itself [383].

The recently determined first two 3D-structures of the fucosyltransferases revealed that these enzymes adopt folds that are variants of the GT-B fold. The bacterial α3-fucosyltransferase of *Helicobacter pylori* [390] belongs to the GT10 family that also comprises the eukaryotic α3- and α3/4-fucosyltransferases. It displays the same 2-domain architecture as other GT-B enzymes but with some differences in the connectivity of β-strands. Since the authors crystallised a truncated and poorly active form of the protein, and also because the overall conformation appeared to be more open than other GT-B enzymes, detailed interactions observed in the crystal structures of the enzyme complexed with GDP and GDP-fucose should be interpreted cautiously. The second fucosyltransferase to have been recently crystallised is the human α6-fucosyltransferase (FUT8) of family GT23, which adds a fucose to the reducing terminal GlcNAc of the core structure of an Asn-linked oligosaccharide [353]. This enzyme displays a quite unusual modular architecture consisting of an *N*-terminal coiled coil region followed by a catalytic domain and a SH3 domain (◉ *Fig. 8f*). SH3 domain-containing proteins are typically localised in the cytosol where they mediate numerous signal transduction pathways via critical protein-protein interactions. The α6-FucT is a type II membrane GT located in the Golgi and thus the function of its SH3 domain, that appears to be unique in GTs, is not yet understood. The catalytic domain is comprised of two sub-structures, an open sheet α/β structure and a Rossmann domain. The three conserved peptide regions that were previously identified in all α2 and α6-fucosyltransferases, as well as in protein-*O*-fucosyltransferases,

are found in the Rossmann domain [392,393]. Although the structure of the *N*-terminal part is not a typical Rossmann fold, the catalytic domain of α6-FucT was found to be similar to the GT-B enzymes, particularly to the ADP-heptose lipopolysaccharide heptosyltransferase of family GT9.

Little information is known about the detailed catalytic mechanism of GT-B enzymes. Sequential ordered as well as random kinetic reactions have been described for enzymes belonging to the GT-B superfamily. For instance, MurG utilises a sequential ordered mechanism in which the nucleotide sugar (UDP-GlcNAc) binds first [351], whereas in the case of BGT, each substrate (UDP-Glc and DNA) can bind randomly [394]. In both cases, large conformational changes that bring the two domains together are observed upon nucleotide sugar binding.

7.3 Molecular Modelling and Fold Recognition Studies

Since only a few topologies have been observed for the GTs that have been crystallised to date, the use of fold recognition methods seems to be a very promising approach. Fold recognition is a theoretical approach which allows alignment of one sequence with one structure by a process referred as "threading" [395]. When performed on selected sequences representing CAZy GT families having no structural representative, such threading analyses predicted that many other GT families should adopt the GT-A or GT-B fold [338,341,346]. The picture that emerged from these studies was the prediction of a GT-A fold and a GT-B fold for 22 and 13 additional families, respectively, and several among them were later confirmed by crystal structures. A fold similar to the one of the bacterial sialyltransferase CstII was predicted with confidence for GT29, the enzyme family which comprises the eukaryotic sialyltransferases [341]. Some families gave weak or moderate scores in fold recognition thus suggesting that novel folds for GTs are likely to be discovered. Fold recognition was also used to identify new GT sequences in the fully sequenced genome of *Mycobacterium tuberculosis* [396]. Probabilistic methods of database searching, such as PSI-BLAST [397] and HMMs [398], have also been used to predict the fold of GTs [339,399].

Molecular modelling has been applied only recently in the field of glycosyltransferases. This approach can be particularly useful to decipher structure-function relationships of this class of enzymes, particularly for a better understanding of the molecular bases governing donor and acceptor specificities, and to identify the key active site residues. Once a sequence has been attributed a fold, it is possible to predict the secondary structure elements, namely α-helices and β-strands, and to align it with sequences of known 3D structure. Ideally, the model must be built using templates that present a maximum of sequence similarities with the candidate protein. However, molecular modelling of GTs presents peculiar difficulties. Sequence similarities between GT families, and even within one family, are extremely low, and this makes sequence alignment particularly difficult. The ratio of loops to secondary structure elements is high in GTs and many crystal structures do not describe the entire catalytic domain, because several loops are flexible and do not present clear electron density. Therefore, the 3D models will have a low confidence index in these regions. Docking of substrates also appears to be a difficult task owing to the flexibility of the nucleotide sugar and the presence of phosphate and divalent cation [400]. Difficulties also come from the fact that large movements of loops and domains are observed in GTs upon substrate binding, and the enzymes can exist in an

"open" or "closed" conformation, therefore complicating the modelling procedure. When the target and the template have sufficient identity, the models are accurate and allow for docking of nucleotide sugar and acceptor. This approach was used to model several GTs belonging to GT6 (a family which comprises the mammalian α3-GalTs and α3-GalNAcTs and which adopts a GT-A fold) [401]. Specificity towards the sugar donor and sugar acceptor was shown to be determined by a few critical residues in the binding site. In addition, a closed active conformation of the modelled enzymes has been proposed that may complement data from the crystal structures of the blood group A and B transferases of family GT6 that have been determined in an open (inactive) conformation [360]. Homology modelling has also been applied to identify key active site residues of plant GTs that adopt a GT-B fold [402,403,404].

The conclusion from this review on the 3D structures of GTs is that a sequence-based classification spreads GTs into a large number of families, but only two general folds, called GT-A and GT-B, have been observed to date. In addition, threading analyses indicate that the majority of as yet uncharacterised GT families could adopt one of these two folds. However, the small variety of folds observed for GTs is compensated by a large structural variability in the acceptor binding domain, thus conferring some functional plasticity which allows fine tuning with respect to the acceptor. Compared to glycosyl hydrolases, our detailed knowledge of catalytic mechanisms of GTs is extremely poor and much work remains.

8 Structural Insights into the Catalytic Mechanism Using Ab Initio Molecular Modelling

Complementary to the crystallographic and kinetic approaches for the examination of glycosyltransferases, ab initio molecular modelling has also increased our understanding of the catalytic mechanism of these enzymes and has opened up the possibility of new approaches in the design of glycosylation inhibitors.

8.1 The Catalytic Mechanism of Glycosyltransferases

The transfer of a glycosyl residue, from an activated donor to an acceptor catalyzed by glycosyltransferases, can be regarded as a nucleophilic displacement of the functional group at the anomeric carbon, e. g. nucleoside diphosphate, of the transferred saccharide residue of a donor by a hydroxyl group of a specific acceptor. The glycosylation reaction can mechanistically proceed with either inversion or retention of stereochemistry at the anomeric carbon of the donor sugar. Glycosyltransferases are, therefore, classified as either retaining or inverting, depending on the stereochemical outcome (see *Fig. 9*).

The catalytic mechanisms of glycosidases and glycosyltransferases were commonly assumed to be rather similar, the main difference being the acceptor molecule to which the glycosyl residue is transferred**:** a water molecule in the case of glycosidases and a free hydroxyl group of a specific saccharide acceptor in the case of glycosyltransferases [405,406,407,408]. With the increase of structural information on glycosyltransferases, some distinct differences between the mechanistic strategies employed by glycosidases and glycosyltransferases are becoming apparent [341,409,410,411,412]. Many aspects of the functions and the catalytic mechanisms of glycosyltransferases, however, are still unresolved. Theoretical studies of enzyme-catalyzed

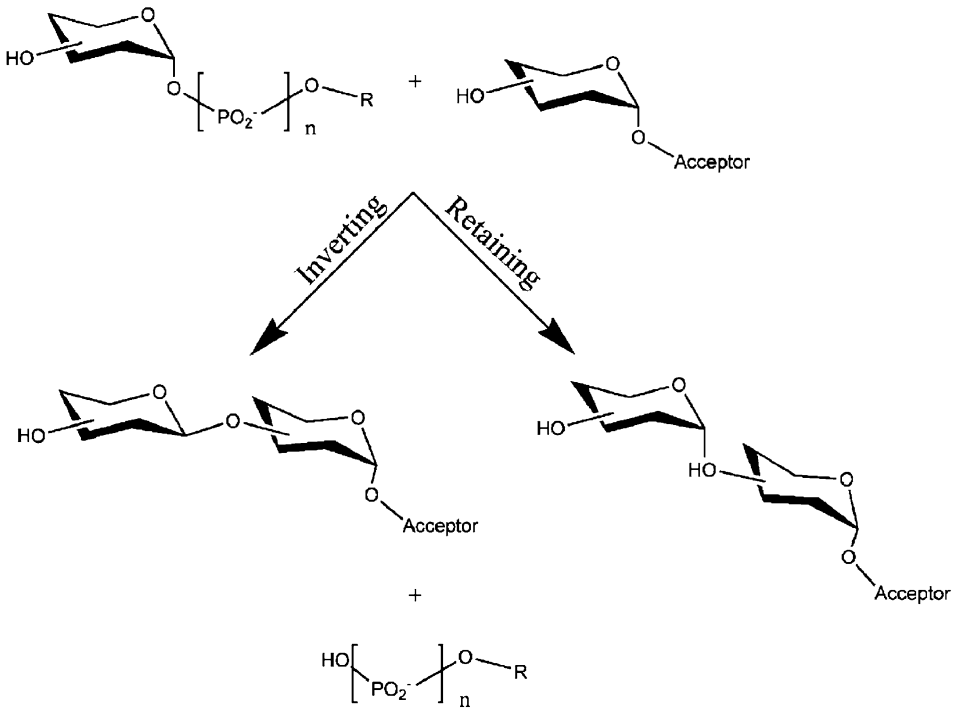

Figure 9
Schematic representation of the overall reaction catalyzed by glycosyltransferases

reactions have recently received a great deal of attention because they can lead to a deeper understanding of enzymatic catalysis. Specifically, hybrid methodologies [413,414] have allowed for the inclusion of the protein environment into the study of the catalytic reaction and represent a promising approach that may offer more detailed insights into the catalytic mechanism of enzymes than is possible by experimental means alone [415,416,417].

8.2 Inverting Glycosyltransferases

The catalytic mechanism of inverting glycosyltransferases has emerged from the extensive theoretical investigations on models of different complexities. The modelling results [418,419] showed that the proton transfer to the glycosidic oxygen is not required for the breaking of the C1–O1 bond, and they imply that, in contrast to glycosidases, glycosyltransferases do not require a second catalytic residue in their active site for the catalytic reaction to proceed. The proposed mechanism, illustrated in *Fig. 10*, suggests a concerted S_N2-type mechanism featuring a nearly simultaneous nucleophilic addition of the oxygen nucleophile from the acceptor to the C1 carbon of the donor sugar, as well as dissociation of the C1–O1 bond of a nucleoside diphosphate accompanied by the proton transfer from nucleophile to the catalytic base.
This type of mechanism is supported by the available crystal structures of inverting glycosyltransferases. In fact, none of the completed structures of glycosyltransferases, either inverting or retaining, has so far revealed the presence of two catalytic amino acids in the active site of

the enzyme. Moreover, the recently solved crystal structure of β1,3-glucuronyltransferase 1 (GlcAT1) in the presence of donor and acceptor substrates [368] provided direct support for the mechanism involving just one catalytic residue.

A recent investigation [420] of the catalytic mechanism of GlcNAc-TI provided additional important information on the structures of the active site models in the Michaelis (ES) and transition state (TS) complexes, respectively. These calculations used a hybrid QM/MM methodology and a model, based on the crystal structure of GlcNAc-TI [363], which contains a whole enzyme and its substrates. The structure of the Michaelis complex model (*Fig. 11*) revealed several features that are relevant for the catalytic reaction. The crucial aspect for the catalytic mechanism is the position of a nucleophile, the C2 hydroxyl group. In the ES, a distance of 2.97 Å between the nucleophile O_{ac} and the anomeric carbon C1 of the donor is such that O_{ac} oxygen is in an appropriate position for the nucleophilic attack. The O_{ac} hydroxyl group also makes the key hydrogen bond with the carboxylate oxygen O_B of the catalytic base [363]. The calculated O_{ac}–O_B and H2–O_B distances of 2.592 Å and 1.677 Å, respectively, indicate a short, strong hydrogen bond (low-barrier hydrogen bond, LBHB) [421]. The LBHB interaction facilitates deprotonation of the nucleophile and thereby increases the nucleophilicity of O_{ac}. The C6 hydroxyl of the transferred sugar makes hydrogen bonds to both the β-phosphate oxygen of the UDP-GlcNAc and to the water molecule HOH14 placed in the active site of the enzyme [363]. The ES structure also shows several hydrogen bonds between the acceptor hydroxyl groups and surrounding enzyme that are supported by kinetic studies on substrate analogues [422]. These experiments showed that either removal or methylation of some hydroxyl groups leads to a loss or a decrease of the enzyme activity.

In the procession from the ES complex to the TS, as expected, the major movements can be observed for the acceptor and for the transferred GlcNAc. The structure of the active site in the TS model is displayed in *Fig. 11*. The TS features nearly simultaneous nucleophilic addition and dissociation steps, as evidenced by the O_{ac}–C1 and C1–O1 bond distances of 1.912 Å and 2.542 Å, respectively. The nucleophile hydrogen atom H2 is located at the oxygen O_B of the catalytic base. The glucopyranose ring adopts the $^4H_3$ conformation in the TS model. The sum of the bond angles surrounding C1 is 354° and shows that C1 is essentially planar. As a result, the anomeric hydrogen H1 is positioned in the plane defined by the C1, C2 and O5 atoms. This arrangement facilitates coincident interactions of C1 with the leaving O1 and the nucleophile O_{acc}. The C1–O5 distance of 1.333 Å points to a significant delocalisation of the O5 lone pairs to C1 and results in the partial double-bond character of the bond between the ring oxygen and the anomeric carbon. This interaction stabilises the partial positive charge on the anomeric carbon C1 within the oxocarbenium ion-like character of the TS. The cleavage of the C1–O1 glycosidic bond is accompanied by the 17° rotation of the β-phosphate oxygen upon going from the ES to the TS complex, while the remaining part of UDP does not show any relevant changes. One can only speculate whether this kind of conformational change is characteristic for inverting glycosyltransferases, since a similar conformational change of the β-phosphate oxygen during a cleavage of the anomeric linkage was observed [423] for β-1,4-galactosyltransferase I.

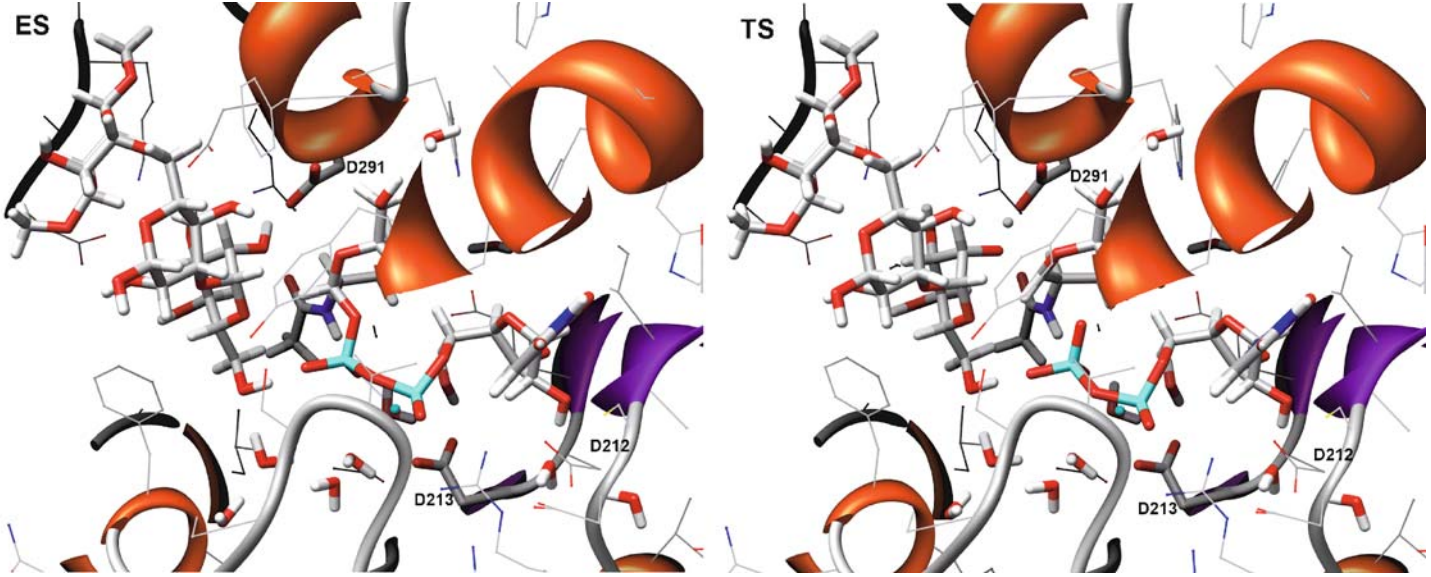

Figure 11

The active site model for the Michaelis complex (ES) and transition-state complex (TS) of GlcNAc-TI, obtained using the QM(DFT)/MM method. Red indicates oxygen, blue-green phosphorus, blue is nitrogen; Mn is a small sphere below the phosphate, close to the loop and D213

The calculated energy barrier for the proposed mechanism ES → TS → PC (*Fig. 12*) is 18.7 kcal mol^{-1} and is consistent with the experimentally observed barriers of 15–25 kcal mol^{-1} (based on published k_{cat} values [424,425]), though this coincidence is likely to be superficial. Further support for the proposed mechanism came from the calculated α-deuterium kinetic isotope effect (KIE). Experimental values of observed α-^{2}H KIE for inverting glycosyltransferases varies in the interval $D_{V/K}$ = 1.050–1.210 [425,426,427,428,429]. The calculated α-^{2}H KIE value of 1.060 is in the range of those experimental determined; however, it is slightly higher than values of measured KIE for the S_N2 mechanism and is considerably lower than KIE values for the reactions corresponding to the S_N1 mechanism. The calculated value may suggest, that in the catalytic reaction, the nucleophilic addition and dissociation of the glycosidic bonds occurs nearly synchronously, as in the S_N2 mechanism, without forming a covalent intermediate with an enzyme. Similar mechanistic features were observed for a dissociative S_N2 mechanism of the purine nucleoside phosphorylase [430], in which the distances of the making and breaking bond are not symmetrical in the transition state, and the length of the breaking bond is longer than the forming bond.

Understanding the structural origin of catalytic efficiency of enzymes is a fundamental goal and challenge in biological science. A comparison of individual energetic contributions from the QM/MM energies revealed that the energetic contribution from the enzyme decreases the overall energetic barrier by 8.8 kcal mol^{-1} and indicates that the GlcNAc-TI environment is favouring the TS complex over the ES complex. Analysis of the calculated structural features indicates several ways in which the GlcNAc-TI environment is involved in the catalytic reaction. In the ES complex, the acceptor is placed in the active site in such a way that the nucleophile oxygen O2 is properly positioned for the nucleophilic attack and for activation by the catalytic base. The O_{ac} atom is at a distance of 3.0 Å from C1 of the donor and 2.6 Å from the catalytic base oxygen. Moreover, the orientation of the nucleophile and the leaving group oxygen atoms represents almost the ideal angle for the nucleophilic attack. In the TS complex, two specific interactions that could be responsible for a specific stabilisation in the TS model were identified, namely, LBHB between the H2 and O_B and strong interactions between the hydrogen atom H6 and β-phosphate oxygen (indicated by a distance of 1.66 Å) that together with the hydrogen from the S322 side chain hydroxyl group stabilise the building of a negative charge on the β-pyrophosphate.

8.3 Retaining Glycosyltransferases

Theoretical investigations [431] of various possible reaction pathway models, describing a double-displacement mechanism for retaining glycosyltransferases, clearly showed that the "classical" mechanism involving two catalytic residues is, from an energy point of view, very doubtful. The calculations showed that the energetically most favourable pathway requires the presence of only one catalytic acid in the active site. This led to a proposed double-displacement mechanism (*Fig. 13*), in which the first step consists of a nucleophilic attack of a catalytic base on the anomeric carbon of the donor and the formation of the covalent glycosyl-enzyme complex with the inverted (β-) configuration at the anomeric carbon C1. In the second step, the hydroxyl group of the acceptor attacks the anomeric carbon of the glycosyl-enzyme complex, with the UDP functioning as a general base to deprotonate the

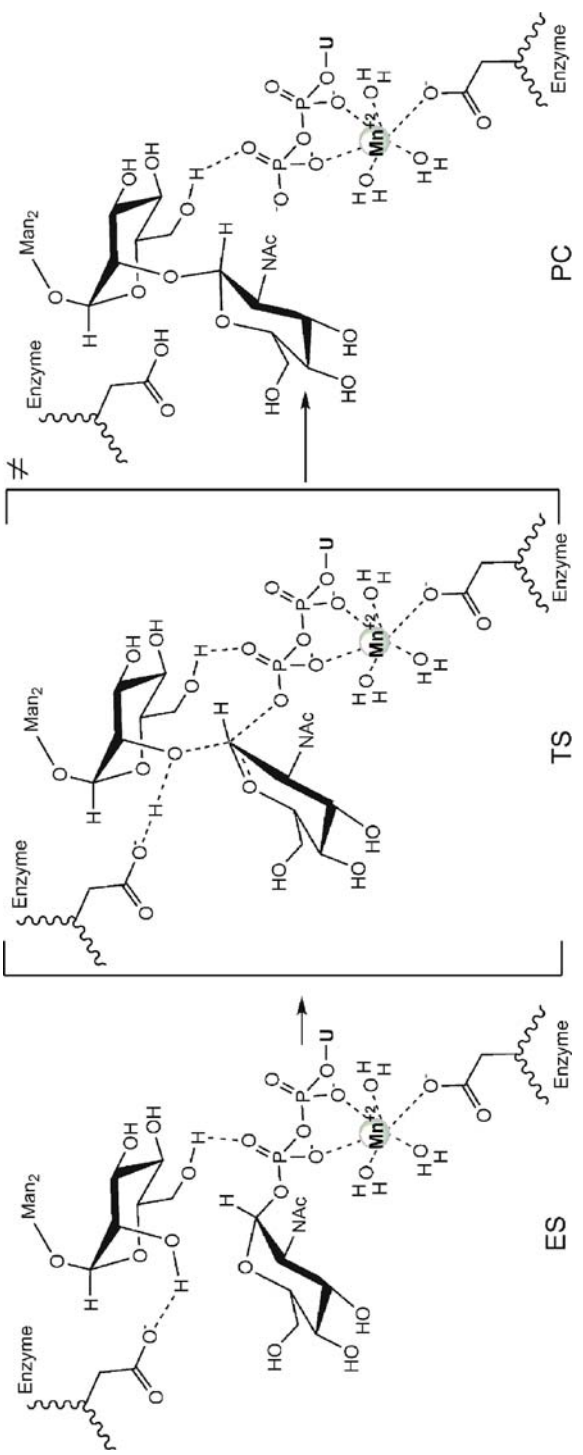

Figure 12

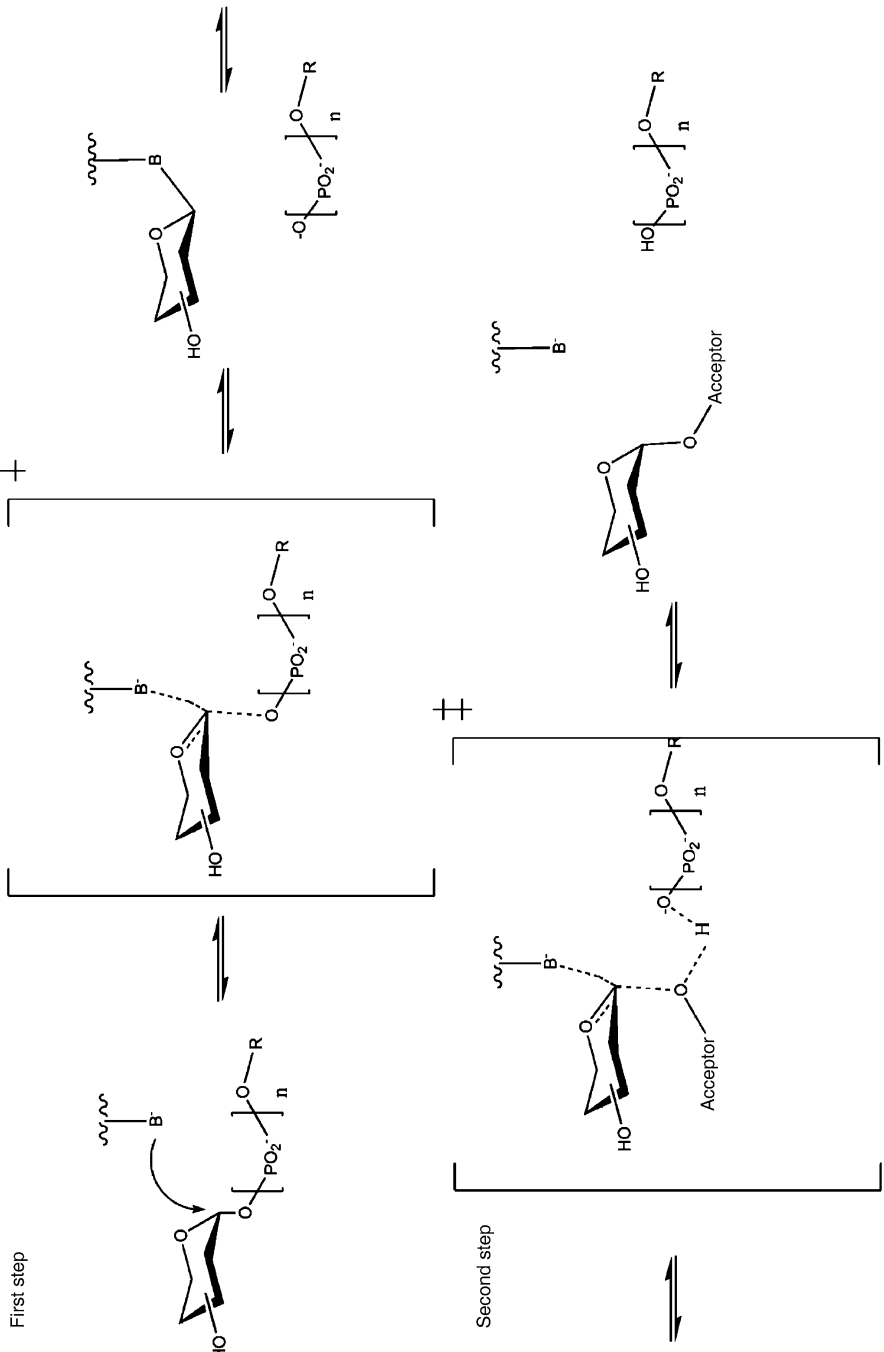

Figure 13
Schematic representation of the proposed double displacement mechanism for retaining glycosyltransferases, inferred from the calculated potential energy surfaces for various mechanisms of retaining glycosyltransferases

hydroxyl group. The second inversion at the anomeric centre occurs during this step, with the resulting glycoside having the α-configuration. The crystal structures of several retaining glycosyltransferases [152,355,359,360,362] support this type of mechanism as they show only one catalytic acid in the active site of the enzyme. However, the conclusive evidence for this mechanism remains to be seen since covalent intermediates have not yet been reported for these enzymes.

Two retaining glycosyltransferases, namely lipopolysaccharyl α-galactosyltransferase C (LgtC) from *Neisseria meningitides* [357] and α1,4-*N*-acetylglucosaminyltransferase EXTL2 [371], represent a very specific case and, therefore, their mechanism was extensively explored both experimentally [357,432,433] and theoretically [434,435,436]. The crystal structures of LgtC and EXTL2 solved in the presence of both the donor and acceptor substrates revealed a catalytic site in which the only functional group appropriately placed for the catalytic reaction was glutamine or arginine in the case of LgtC and EXTL2, respectively. The analysis of thorough investigations [357,432] that focused on whether these and other amino acids can function as possible catalytic nucleophiles was inconclusive. The results for LgtC pointed toward another mechanism that might not require any participation of a catalytic residue, and they led to the suggestion [357] that LgtC glycosyltransferase might instead proceed through a single front-side displacement reaction, also known as a S_{Ni} mechanism.

Molecular modelling examinations [434] of various reaction hypotheses of the galactosyl transfer catalyzed by LgtC using a model based on the crystal structure of LgtC [357] shed some light on this mechanistic puzzle. Calculations predicted that the preferred reaction pathway is a one-step mechanism in which the O_{acc} nucleophile from the acceptor attacks the anomeric carbon of the galactopyranose residue of the donor UDP-Gal from a face of the leaving group with the simultaneous proton transfer to phosphate oxygen. The proposed mechanism, illustrated in *Fig. 14*, proceeds via a front attack similar to the proposed S_{Ni} mechanism [357], but does not directly involve any catalytic acid in the reaction mechanism. Moreover, the calculations clearly showed [434] that for this kind of mechanism the specific orientation of both the donor and acceptor sugar is crucial. From these results, it is apparent that the active site constraints, imposed by the enzyme on the substrates, change the conformation of the donor UDP-Gal and the acceptor to the one that is suitable for the nucleophilic attack from the leaving group side. However, a covalent intermediate recently observed [433] for the Gln198Glu mutant revived discussion of the catalytic mechanism of LgtC, but more experimental evidence is clearly needed to fully understand the catalytic mechanism of retaining glycosyltransferases.

The calculated TS structure of LgtC shows several interesting geometrical features (*Fig. 15*). The most interesting one is that the nucleophilic attack by the acceptor oxygen O_{ac} and the leaving group departure occur on the same face of the transferred galactose [434]. The transition state structure is also characterised by C1–O1 and C1–O_{ac} distances of 2.66 Å and 2.34 Å. The oxygen from the phosphate and the acceptor hydroxyl sandwich the nucleophile proton assisting in the formation of the transition state. This proton is located at the O_{ac}–H and O1–H distances of about 1.09 Å and 1.38 Å, respectively. The distance between the O_{ac} and O1 oxygen is about 2.4 Å and suggests that the LBHB interaction provides, as similarly found for inverting glycosyltransferases, the stabilising energy for the transition state. One can only speculate whether the LBHB interactions represent a general feature employed by glycosyltransferases to facilitate their catalytic action. The ring conformation of the transferred galac-

The calculated models for the transition state complex (TS) of LgtC, obtained using the DFT method

topyranose is a distorted ^4E envelope. It is evident that the geometry of this transition state structure estimated by the ab initio method is unique and differs from the transition state structure models previously determined for inverting or retaining glycosyltransferases.

8.4 Transition State Analysis

Transition states of catalytic reactions are high energy intermediates on reaction paths between reactants and products with lifetimes of $\sim 10^{-13}$ s, and their structure and location in catalytic sites can be only be estimated. In the case of glycosyltransferases, the "entire" transition state consists of both a deformed nucleotide sugar and acceptor oligosaccharide linked in a specific arrangement. Unfortunately, crystal structures of complexes with transition state analogues that could provide some information about the nature of the transition states are not available. Thus, model structures of transition states represent important outcomes of the calculated potential energy surfaces.

Investigations of various models of catalytic mechanism for glycosyltransferases of the GT-A superfamily [418,419,420,431,434] revealed the following general characteristics of the transition state models: a) the ring conformation resembles a half-chair conformation with an oxo-carbenium character at the anomeric carbon; b) the distance of C1–O1 is longer than the normal C–O bond length; c) a new β-glycosidic bond is being created with the bond length larger than the normal bond length; both the forming and breaking bonds are oriented almost perpendicularly with respect to the plane defined by the C2-C1-O5 atoms.

Calculations on glycosyltransferases [418,419,420,431,434] have led to 23 different transition state models. These belong to various reaction pathways having different energetics. However, these TS models provide pertinent information on possible structural variations of transi-

tion states for glycosyltransferases. The structural analysis revealed significant variations in the C1–O_{ac} and C1–O1 bond lengths that can be as large as 1.3 Å and 1.7 Å, respectively. It appeared that calculated TS structures can be clustered using geometrical criteria based on the values of two reaction coordinates [434,435,436]. Indeed, clustering of the TS structures based on the C1–O_{ac} and C1–O1 distances led to three distinct groups that may represent canonical models of transition states. Structural characteristics of these groups are illustrated in ❯ *Fig. 16*. The first group (❯ *Fig. 16a*) is characterised by long C1–O_{ac} bonds within the range of 2.4–2.7 Å and short C1–O1 distances between 1.5 and 2.1 Å. The geometrical parameters of this transition state model are similar to the initial reactants and this canonical form has been termed "early transition state". The second group (❯ *Fig. 16b*) corresponds to the "intermediate transition state" structures where both C1–O_{ac} (2.1–2.4 Å) and C1–O1 (2.5–2.7 Å) distances are elongated compared to their initial values, but the structures did not yet reach the final arrangement observed in the products. The third group (❯ *Fig. 16c*) is characterised by short C1–O_{ac} bonds within the range of 1.4–1.6 Å and long C1–O1 distances between 2.8 Å and 3.2 Å. The geometry of this canonical form is close to that of the final products and therefore has been named "late transition state". The three canonical structures might represent a framework of variations occurring in transition state structures of glycosyltransferases. Of course, the transition state structure of a particular enzyme depends on the structure of the catalytic site which, in turn, imposes constraints on substrates to generate a required transition state structure for a given enzyme. For example, the TS model inferred from QM/MM calculations on GlcNAc-TI corresponds to the intermediate transition state.

8.5 Rational Design of Transition State Analogues

Different strategies have been used in order to identify potent inhibitors of glycosyltransferases [437,438,439,440,441,442,443,444]. In spite of an increasing number of potential inhibitors, only a few of them have exhibited significant activity [443,444]. Though transition state analogues are valued tools for drug discovery as potent and specific inhibitors of enzymes, to date, the ability to generate transition state analogues of glycosyltransferases has lagged behind [442,443,444]. The TS models obtained from molecular modelling may provide blueprints for the design of the transition state analogue inhibitors. A transition state analogue is a stable compound that structurally resembles the three-dimensional structure and charge distribution of the unstable transition state. These analogues have the potential to bind more tightly than the substrates, proportional to the catalytic rate enhancement imposed by the enzyme. With an enzymatic rate enhancement of 10^{10} – 10^{15}, transition state analogues have the potential for near-irreversible binding on the biological scale.

It is clear that, due to the above described characteristics of TS, it would not be possible to design a stable molecule that mimics the TS precisely. However, even crude TS analogues consisting of relevant features are expected to be excellent reversible inhibitors. To achieve this, the TS analogue should contain the main structural features of the TS from both the acceptor and donor. Recently, based on the calculated information, a new scaffold for TS analogues has been designed [445], with an attempt to mimic structural features around the reaction centre. The proposed structural mimic of TS is represented by the (tetrahydro-2-(methylthio)furan-2-yl)methyl phosphate dianion (**1**) shown in ❯ *Fig. 17*.

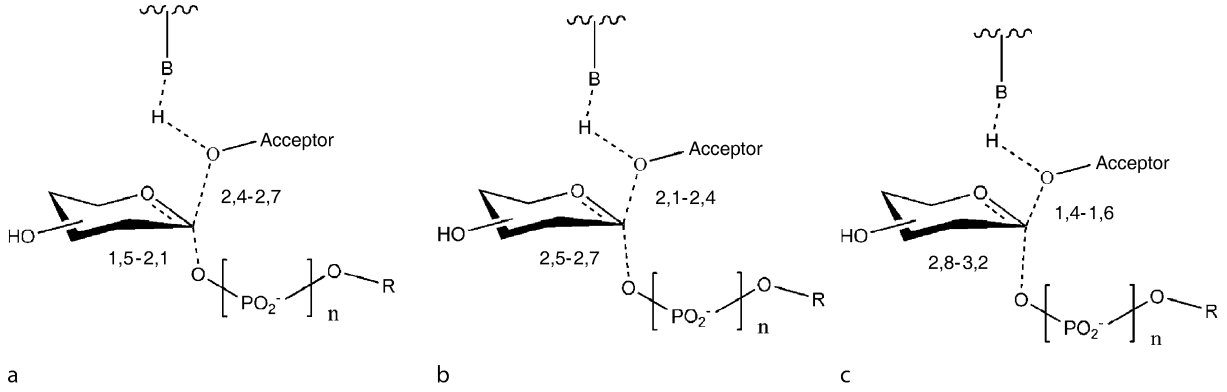

Figure 16
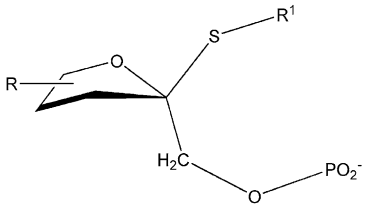
Schematic representation of canonical forms of the transition states for glycosyltransferases. Canonical forms are defined by similarities in their C1–O1 and C1–O_{acc} distances. (a) Early transition state, (b) Intermediate transition state, and (c) Late transition state



R = OH, NHAc, ...etc.
R^1 = Et, Phe, ...etc.

Figure 17
Schematic representation of the proposed TS scaffold for the (tetrahydro-2-(methylthio)furan-2-yl)methyl phosphate dianion (1)

In this scaffold, the enlarged C1–O1 distance presented in TS is accomplished by linking a methyl phosphate group to the C1. In this moiety, the C1–O distance between the anomeric carbon and the phosphate oxygen is 2.4 Å, which is very close to the corresponding distance in the TS; the length of the C1–S5 bond is 1.9 Å, similar to the distance between the anomeric carbon and the attacking oxygen in the TS. The acceptor is mimicked by a thiol linkage, in which the C1–C distance of 2.9 Å corresponds to the prolong C1–O_{ac} distance in the TS. A deformed monosaccharide ring in the TS is represented by a five-membered ring. The structural similarity between the transition state and its analogue is a key factor in determining the binding properties of TS analogues. Generally, low energy conformers of (**1**) closely overlap with the corresponding parts of the TS; the furanose ring oxygen with the pyranose ring oxygen, sulfur with the attacking oxygen, methyl carbon with the acceptor carbon atom, and a phosphate oxygen with the phosphate oxygen of the leaving group of the donor [445]. A superposition also revealed that a phosphate dianion in **1** is properly oriented to interact with a bivalent metal cofactor presented in the active site of retaining glycosyltransferases. While these kinds of electrostatic interactions are very strong, it remains to be seen whether these interactions are sufficient to mimic the UDP part of the donor. Calculations clearly showed that proposed scaffolds for potential transition state analogues exhibit very similar structural features as those predicted for the TS of reactions catalyzed by inverting glycosyltransferases. To further explore binding characteristic of this scaffold, its derivatives were docked into the active site of the TS model of GlcNAc-TI [420]. It appeared that the binding mode of the proposed TS analogues in GlcNAc-TI is very similar to that of the TS [446] as illustrated in *Fig. 18*, which support its utilisation as a TS mimetic.

However, just how potent and specific the inhibitors will be, based on this scaffold, remains to be seen. It is obvious that this scaffold is only a basis for further refinement, which might involve various modifications of substituents on the furanose ring to mimic a transferred monosaccharide, and a substitution of the group linked to the sulfur atom by various larger substituents mimicking the acceptor monosaccharide. In particular, the later variations might be crucial for determining the potency and specificity of design inhibitors, since it is well known that there is a limited number of donor nucleotides and a very large number of possible acceptors that likely define the specificity of glycosyltransferases.

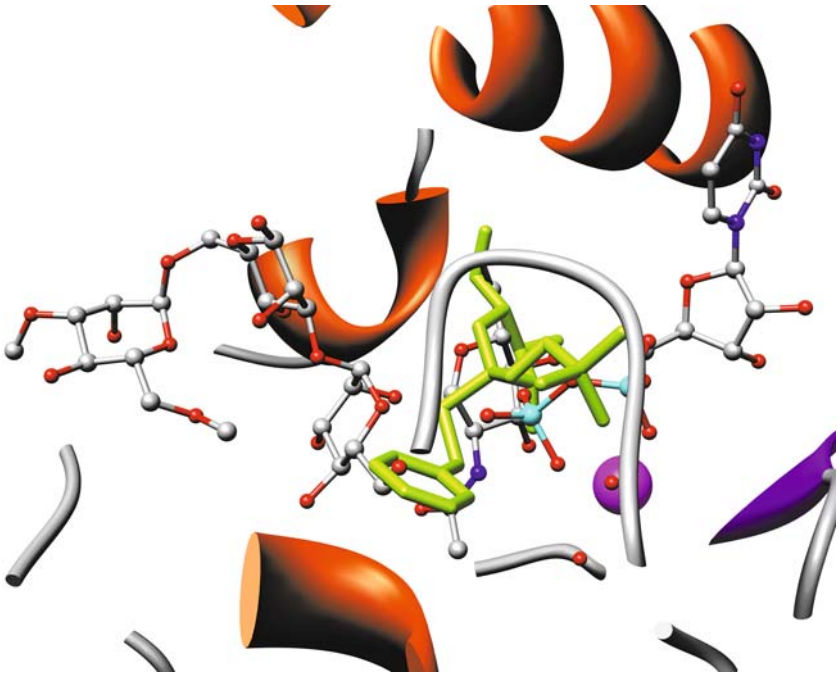


Figure 18
The (tetrahydro-2-(phenylthio)furan-2-yl)methyl phosphate dianion (green) docked into the active site of GnT-I. For comparison, the location of the active site of the TS model is also given

A detailed understanding of glycosyltransferase function provides a basis for their application in the development of new classes of therapeutic agents. It is also clear, however, that more structural, enzymological, and computational work remains to be done to fully understand the catalytic machinery of glycosyltransferases.

9 Concluding Remarks

In our account of the biochemical, biological and enzyme structural aspects of the biosynthesis of oligo- and polysaccharides, we have concentrated on selected aspects of this vast field. It is obvious that the past few years have been very fruitful in the field of structural glycobiology. In particular, the use of recombinant enzymes, genetic ablation techniques and the deployment of mass spectrometric glycan analysis have greatly increased our knowledge about glycosyltransferases and processing glycosidases. Indeed the sheer complexity of glycan biosynthesis has become even clearer. In the future one may expect that further advances will be made through the use of interdisciplinary approaches in determining the function of glycans and the pathways for their biosynthesis; the many questions remaining will occupy glycobiologists and glycochemists in the years ahead.

Acknowledgement

We thank Dr. Harry Schachter (Hospital for Sick Children, Toronto) for his comments on the chapter as a whole and Drs. Inka Brockhausen (Queen's University, Kingston, Ontario), Vlad Panin (Texas A & M University), Terry Butters (University of Oxford) and Terry Smith (University of Dundee) for their advice on latest developments in *O*-glycan, glycosphingolipid and GPI biosynthesis as well as Katharina Paschinger for proof-reading.

Chapter-DOI 10-1007/978-3-540-30429-6_60:

Abstract

An overview of current and potential enzymes used to degrade polysaccharides is presented. Such depolymerases are comprised of glycoside hydrolases, glycosyl transferases, phosphorylases and lyases, and their classification, active sites and action patterns are discussed. Additionally, the mechanisms that these enzymes use to cleave glycosidic linkages is reviewed as are inhibitors of depolymerase activity; reagents which react with amino acid residues, glycoside derivatives, transition state inhibitors and proteinaceous inhibitors. The characterization of various enzymes of microbial, animal or plant origin has led to their widespread use in the production of important oligosaccharides which can be incorporated into food stuffs. Sources of polysaccharides of particular interest in this chapter are those from plants and include inulin, dextran, xylan and pectin, as their hydrolysis products are purported to be functional foods in the context of gastrointestinal health. An alternative use of degraded polysaccharides is in the treatment of disease. The possibility exists to treat bacterial exopolysaccharide with lyases from bacteriophage to produce oligosaccharides exhibiting bioactive sequences. Although this area is currently in its infancy the knowledge is available to investigate further.

Keywords

Action patterns; Adhesion domains; Affinity and mechanism-based inhibitors; Catalytic domains; Classification schemes; Hydrolases; Lyases; Mechanism of action; Phosphorylases; Proteinaceous inhibitors

1 Introduction

Polysaccharides, particularly cellulose and chitin, are the most abundant carbon compounds in the biosphere. They are functionally important as structural and/or protecting materials and are the predominant storage form of carbohydrate in bacteria, protistans, algae, fungi, plants, and animals. They are also important precursors for the enzymatic manufacture of a range of bioactive oligosaccharides with application in nutrition and disease management. In this chapter enzymes involved in polysaccharide depolymerization and biosynthesis will be reviewed with special reference to their specificity, mechanism of action, and structural organization. Applications of such enzymes to the manufacture of bioactive oligosaccharides will also be discussed.

Enzymes with over one hundred different specificities have been recognized to be involved in the reactions of polysaccharide degradation and synthesis. It has not been possible to address each of them. However, particular enzymes or groups of enzymes are discussed to highlight important principles or aspects.

The first section of this chapter deals with enzymes depolymerizing polysaccharides. The reactions they catalyze are essential steps in the provision of assimilable mono- or oligosaccharides from exogenous polysaccharide substrates. The breakdown products are substrates for metabolism and energy production by bacteria, archaeans, single-celled eukaryotes, animals, and fungi. Structural polysaccharides are enzymically degraded in the course of morphogenetic changes, when cells or tissues grow and differentiate, for example, during plant cell wall modification or in the turnover of vertebrate connective tissue and arthropod exoskeletons. Polysaccharide depolymerizing enzymes produced by bacterial, fungal, insect, and nematode pathogens of plants or animals are used to gain access to host tissues. Polysaccharide hydrolases and lyases find many applications in industry, particularly the food industry. These will not all be reviewed here but the potential for manufacture of functional oligosaccharides by enzymatic degradation of polysaccharides will be discussed.

2 Polysaccharide Depolymerizing Enzymes

2.1 Introduction

Glycoside-cleaving enzymes are a diverse group, which more or less selectively, hydrolyze the wide variety of *O*-glycosidic linkages found in glycosides, oligo- and polysaccharides, and glycoconjugates. An account of one group of glycoside hydrolases; those acting on oligogalactosides, is to be found in ❯ Chap. 5.4. This section deals specifically with enzymes depolymerizing interglycosidically, *O*-linked polysaccharides, although, where relevant, information from *O*-glycoside-cleaving enzymes is discussed.

The chemistry of enzymic glycoside cleavage is a focus of attention for carbohydrate chemists and biochemists, and a considerable body of mechanistic information has accumulated, especially with regard to glycoside and polysaccharide hydrolyzing enzymes [1,2,3,4,5,6]. In parallel, there has been an explosion of DNA cloning and direct amino acid sequence determination for glycosidases [7]. In addition, the three-dimensional structures of a growing number of glycoside and polysaccharide-degrading enzymes have been determined.

2.2 Types of Glycoside Depolymerizing Enzymes

Enzyme-catalyzed glycoside cleavages (and syntheses) are considered by Hehre [6,8] to be variants of the same reaction (❯ *Eq. 1*), catalyzed by a single type of enzyme, the glycosylases, comprising glycoside hydrolases, glycosyl transferases, phosphorylases and certain lyases.

$$\text{Glycosyl} - \text{X} + \text{H} - \text{X}' = \text{Glycosyl} - \text{X}' + \text{H} - \text{X} \qquad (1)$$

This description reduces all carbohydrase reactions to an interchange between a glycosyl group and a proton (hydrogen atom) about sites X and X′ in the various potential substrates.

Thus, X may be a saccharide, a 1,2-glycal, a phosphate residue, a nucleoside diphosphate, or a polyprenol diphosphate and X′ the OH of water, an alcohol, and often a saccharide. It is convenient, however, to consider enzymes cleaving polysaccharide chains in one of four classes: hydrolases, glycosyl transferases, lyases, and phosphorylases. These follow the general reactions discussed below.

2.2.1 Hydrolysis

$$\text{Glycosyl} - \text{OR(polysaccharide)} + \text{HOH} = \text{Glycosyl} - \text{OH} + \text{HOR} \tag{2}$$

Some polysaccharide hydrolases also catalyze glycosyl transfer.

2.2.2 Glycosyl Transfer

The glycosyl transferases catalyze redistribution of glycosidic linkages between di-, oligo-, or polysaccharide donor substrates and acceptor oligo- or polysaccharides.

$$\begin{aligned}\text{Glycosyl} - \text{OR}'\text{(di-, oligo- or polysaccharide)} + \text{HOR}''\text{(oligo- or polysaccharide)} \\ = \text{Glycosyl} - \text{OR}'' + \text{HOR}\end{aligned} \tag{3}$$

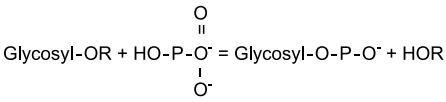
They are considered separately from the polysaccharide hydrolases, but are closely related to them, both mechanistically and structurally. In glycosyl transfer the acceptor water is replaced by a hydroxy group provided by an oligo- or polysaccharide.

2.2.3 Lyase Action (Glycal Formation)

$$\text{Glycosyl} - \text{OR} = 1,2 - \text{Glycal} + \text{HOR} \tag{4}$$

2.2.4 Phosphorolysis

Glycosidic linkages in polysaccharides may also be cleaved by phosphorolysis.
The phosphorolysis reaction is shown in ❯ *Structure 1*.



Structure 1

2.3 Criteria for Classification

2.3.1 Specificity

The Nomenclature Committee of IUB [9] classifies polysaccharide depolymerizing enzymes on the basis of the reaction catalyzed, into *O*-glycoside hydrolases [EC 3.2.1.-], glycosyl transferases [EC 2.4.1.-], lyases [EC 4.2.2.-], and the phosphorylases in [EC 2.4.1.-]. Within each

group, the individual enzymes are sub-classified according to their substrate and product specificity. The Enzyme Nomenclature list is revised continually as new enzymes are discovered and previously included enzymes are better characterized.
Each sub-category of polysaccharide depolymerizing enzymes shows specificity with respect to the configuration of the bond in the glycosidic linkage cleaved, the ring size and configuration of the glycone portion of the substrate, and most often the "aglycone" portion of the substrate. The regioselectivity for the linkage cleaved may in some cases be narrow and in others quite broad. There are also more subtle distinctions between individual enzymes of the same sub-class. Thus differences may occur in the region of the polymeric substrate attacked, i. e., the non-reducing end, the reducing end, or the interior region, the size and state of solubility of the preferred substrate [10], or the structure of the products formed. In addition, and quite fundamentally, the classification in some cases distinguishes different *O*-glycosidases on the basis of the mechanism of cleavage of the glycosidic linkage.

2.3.2 Structure

An additional classification has been introduced that disposes polysaccharide depolymerizing enzymes into glycosidase families based on their amino acid sequence relationships, made possible by direct sequencing or derived from the numerous cloned cDNA or gene sequences for the enzymes [7,11,12,13]. At present, this classification is based on about 5000 known sequences and includes 82 hydrolase, 48 glycosyl transferase families (including phosphorylases) and the ten lyase families. The determination of the three-dimensional structures, at high resolution, of a growing number of these enzymes has permitted amalgamation of some hydrolase and glycosyl transferase families into clans. Members of a clan have common structural features with respect to overall fold motifs, topology of active site residues and catalytic mechanisms, even when the enzymes are without recognized sequence identity [14].

2.4 Active Sites

The catalysis of glycoside cleavage occurs when a region of the polymeric substrate chain is bound at the active site of the enzymes to form an enzyme-substrate complex. The active sites of all types of enzymes involved in polysaccharide depolymerization are formed by catalytic amino acid residues that are directly involved in the covalent bond-breaking or -making processes and by amino acids involved in binding of substrate along an extended binding site. The former category comprises aspartic and glutamic acids in the hydrolases and glycosyl transferases [4,13] and probably arginine in at least some lyases [15]. The typical binding residues can be polar: arginine, histidine, lysine, aspartic and glutamic acids, asparagine, glutamine, serine, threonine or aromatic: tyrosine, phenylalanine, and tryptophan [4,16,17].
The substrate-binding region of the enzyme surface can be envisaged as a series of consecutively arranged binding subsites, complementary to monosaccharide residues in the substrate chain. These are often distributed asymmetrically about the site of glycosidic bond cleavage. In a widely accepted nomenclature [18] describing the monosaccharide-binding subsites in polysaccharide hydrolases, but applying equally well to glycosyl transferases, lyases, and phosphorylases, the subsites are labeled from $-n$ to $+n$ (where n is an integer) and where n

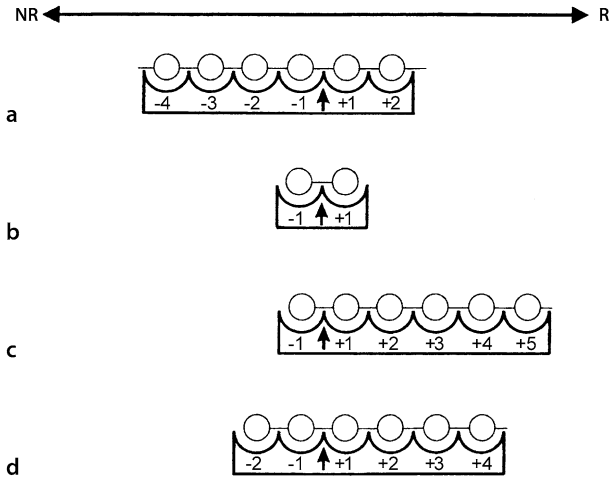


Figure 1
Schematic drawing of monosaccharide binding sites in various glycosyl hydrolases. (a) Subsites of an *endo*-hydrolase, e. g., hen egg white lysozyme, (b) subsites of a disaccharide hydrolase, e. g., ⟨α-glucosidase, (c) subsites of a monosaccharide-releasing *exo*-hydrolase, e. g., glucoamylase, (d) subsites of a disaccharide-releasing *exo*-hydrolase, e. g., β-amylase (after [18])

represents the non-reducing end and $+n$ the reducing end, with cleavage taking place between subsites -1 and $+1$ (*Fig. 1*) [18].

The physical form of the binding subsites can be seen directly from crystallographic analyses of the enzymes in complex with non-reactive substrate analogues or of inactive, mutated enzymes in complex with substrates. This allows the identification of those amino acid residues that are involved in hydrogen bond, or ionic and van der Waals interactions with the bound substrate [19]. This approach was first used for hen egg white lysozyme (reviewed in [20]) and has since been widely applied to other hydrolases, glycosyl transferases, polyuronate lyases, and phosphorylases. Information on stoichiometry and binding thermodynamics, binding kinetics, and conformational changes for substrate analogues can be obtained from solution studies using equilibrium dialysis or gel filtration, surface plasmon resonance and isothermal titration calorimetry, time-resolved fluorescence or transfer nOe NMR spectroscopy, stopped-flow spectrophotometric and temperature jump relaxation methods [21,22,23]. Models of enzyme-substrate complexes can be constructed from the three-dimensional structures using docking procedures involving conformational energy calculations and molecular dynamics. They provide useful insights into the relationship between structure and function [23,24,25,26].

Characterization of the extended substrate-binding site requires information on the number of subsites, the individual subsite binding affinities, bond cleavage frequencies and the location of the catalytic site, which can be determined by analyzing the amount and types of product formed from terminally labeled oligosaccharides [27,28]. The possibility of side reactions such as transglycosylation, and the validity of assumptions that the subsites are independent and that the intrinsic bond cleavage rate is constant, have been addressed in recent applications of the theory [29,30]. In the multiple subsite model it is envisaged that a single substrate and enzyme molecule react at one time, however, it is known that multimolecular substrate reac-

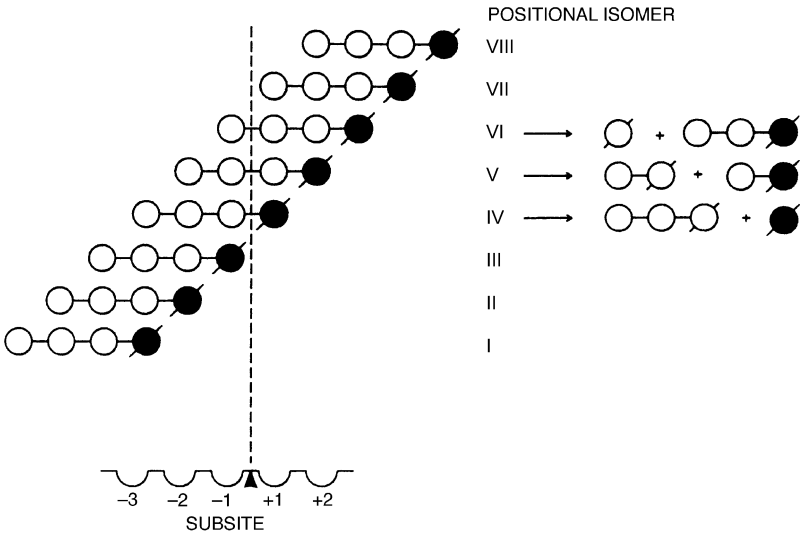

Figure 2
Positional isomers of a tetrasaccharide on a five subsite endo-hydrolase. Of the eight possible positional isomers only IV, V, and VI are productive, i. e., lie over the catalytic site. The cleavage products are shown: subsite on enzyme; position of catalytic site; monosaccharide residue; residue bearing the reducing hemiacetal in substrate; residue bearing the reducing hemiacetal in products (after [28])

tions may occur. These reactions involve, e. g., facilitated binding of one substrate molecule elicited by binding of another. Practical methods are available to assess and minimize these complications [30,31,32].

In the multiple subsite model (*Fig. 2*) [28] an oligosaccharide substrate can interact at the subsites in a number of ways. Thus, a tetrasaccharide may form eight positional isomers with a five subsite enzyme, but only the three in which substrate lies over the catalytic site can be productive. The population of the different complexes is dictated, in principle, by the energetics of interaction of the substrate monomer units with the respective subsites. Each depolymerase has its own subsite map for oligosaccharide substrates, depicting the number of subsites, the location of the catalytic site, and the binding energies contributed by the individual subsites. The latter can be calculated from the bond cleavage frequencies and Michaelis parameters determined for a range of oligosaccharide substrate lengths. A subsite map for two porcine pancreatic α-amylases deduced from kinetic analysis is shown in *Fig. 3* [33].

For this enzyme, kinetic evidence shows several weak oligosaccharide-binding sites in addition to the active site [34], in agreement with the observation that oligosaccharides in the crystal are also bound outside the active site area [35]. Thus, it is important to note that kinetically derived subsite maps may only qualitatively reflect key features of the three-dimensional structure of enzyme-substrate complexes and vice versa. However, the length of the binding site and the position of the catalytic site, as detected from crystallographic or modeled enzyme-ligand complexes generally agree with the subsite map [24,36]. Moreover, conspicuous aromatic stacking onto substrate rings, or H-bonds between charged groups of the enzyme and substrate OH groups tend to reflect high subsite affinity [19].

2.5 Action Patterns

2.5.1 *Endo*-Action

In *endo*-cleavage the enzyme first attacks at an interior glycosidic linkage in the substrate. The *endo*-hydrolases are widely represented among the polysaccharide hydrolases and lyases. The cleavage may represent a single productive encounter with the substrate, so that both polymer fragments are released from the enzyme. This action pattern has been described as *multi-chain* attack (◉ *Fig. 4*) [37].

In other *endo*-cleavages several catalytic events may occur after the first encounter in which one polymer fragment is retained and translocated along the substrate binding site to allow

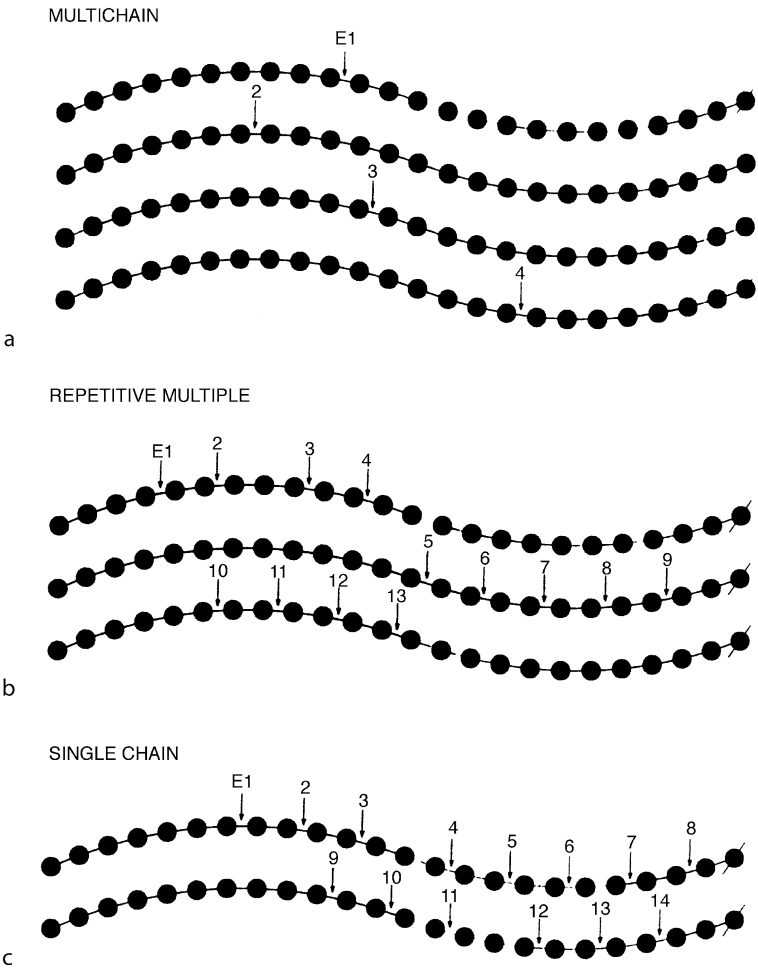

Figure 4
Types of attack patterns for polysaccharide *endo*-hydrolases (after [37])

further cleavages at the catalytic site. This mode of attack is known as *repetitive* or *multiple* attack and the action involves substrate *processivity*. Multiple attack has also been described as *endo-* and *exo*-action (see below). It was first demonstrated for α-amylases [37] but has also been demonstrated for several cellulolytic enzymes [38,39]. In the extreme case, if the enzyme-substrate complex does not dissociate, the bound polysaccharide substrate would degrade to oligosaccharides in a *single chain* attack. However, examples of this mode of attack are not known for polysaccharide degrading enzymes. The degree of multiple attack (DMA) is described by the number of cleavages following the first cleavage of the polymeric substrate. A quantitative analysis of DMA has been developed for α-amylases [37], based on the ratio between the number of oligomeric and polymeric molecules produced from amylose, a linear (1→4)-α-glucan substrate. Average values of DMA vary from 1 through 6 for Taka-amylase A, barley α-amylase, and porcine pancreatic α-amylase [37,40]. The method of Robyt and French [37] provides no information on the chain polarity of the multiple attack, i. e., which cleavage product is retained in the active site. This may be deduced either from the knowledge of the enzyme mechanism or from experiments with end-labeled oligosaccharide substrates. For *endo*-acting enzymes with a retaining mechanism one may assume that, after

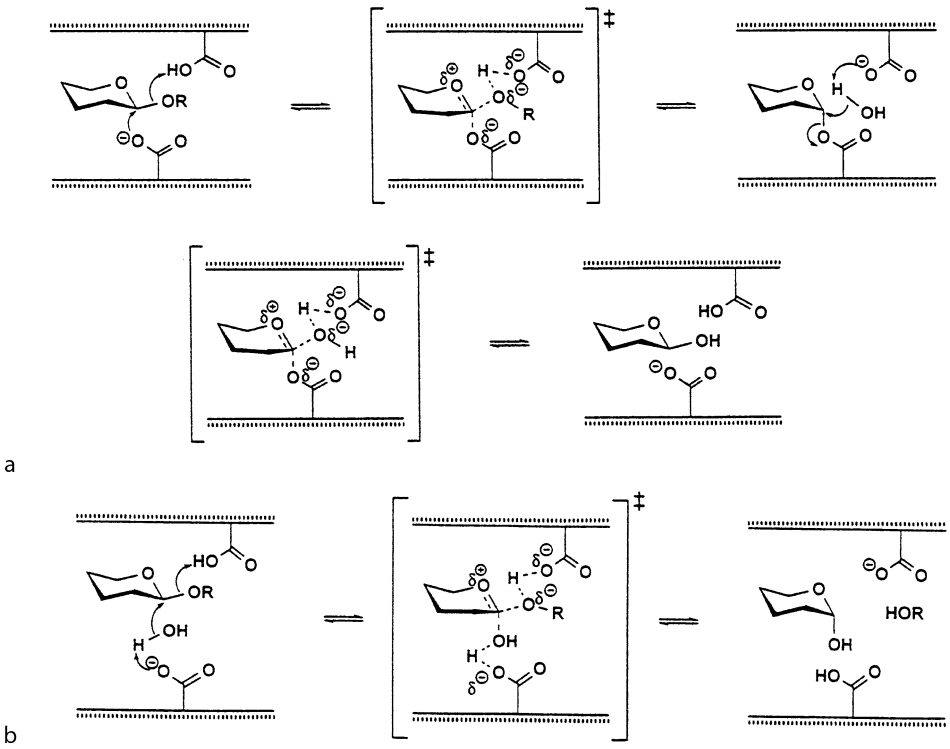

Figure 5
(a) Proposed catalytic mechanism for a retaining β-glycosidase, (b) proposed catalytic mechanism for an inverting β-glycosidase

release of the leaving product, the covalently bound glycosyl intermediate released by attack of water (Fig. 5a) is subsequently translocated in the active site for the next cleavage in the multiple attack reaction. It has been noted that the type of attack may change as the length of the substrate chains decreases during the course of the depolymerization or be dependent on reaction conditions, e. g., pH [41].

2.5.2 *Exo*-Action

Exo-action is well-recognized among the (1→4)-α-, (1→6)-α-, (1→3)-β-, and (1→4)-β-glucan hydrolases, amylolyases, and glycogen and starch phosphorylases. *Exo*-attack generally occurs from the non-reducing end of the substrate chain and is blocked by modification of the terminal residue, e. g., by periodate oxidation in the case of a (1→3)-β-glucan substrate [42,43,44]. *Exo*-cleaving enzymes, depending on the source, may release mono-, di-, or longer oligosaccharides, up to octasaccharides, from the polysaccharide substrate [45,46,47,48,49,50,51,52,53]. The active sites of *exo*-enzymes can also be conveniently described using the now generally accepted nomenclature (see Fig. 1). Thus, the active site of an *exo*-hydrolase, releasing disaccharides, is described as −2, −1, +1, +2, +3, indicating that two glycosyl binding subsites, −2 and −1, accommodate the future product, and that three binding subsites, +1, +2, and +3, interact with glycosyl residues toward the reducing end of the substrate.

Exo-attack may follow the same action patterns as described for *endo*-attack. Thus, β-amylases catalyze the liberation of maltose from the non-reducing end of starch polymer chains in a multiple attack mechanism [54]. Modeling of substrate complexes, for this enzyme, based on its three-dimensional structure, supports the view that the new non-reducing end of the (longer) chain remaining after removal of maltose is translocated to subsite −2 for subsequent attack [55]. The DMA value for the (1→3)-β-exoglucanase from *Sporotrichum pruinosum* QM 806 is 4 [42]. In rare cases, e. g., some cellulases, the *exo*-attack has been described as occurring from the reducing chain end. Thus, the cellulase from *Thermomonospora fusca* E4 [56], which corresponds to the cellobiohydrolase I from *Trichoderma reesei*, displays a preferred release of ^{18}O-labeled cellobiose from the reducing end of ^{18}O-labeled cellopentaose. In contrast, for cellobiohydrolase II the preferred attack between subsites −1 and +1 is at the non-reducing end of cellopentaose [57]. In this connection it should be noted that cellobiohydrolase II (Cel6A) from *Trichoderma reesei*, earlier believed to be an *exo*-enzyme, has been shown to exhibit *endo*-attack through its ability to cleave a bifunctionalized, fluorogenic tetrasaccharide [58]. Thus, it will be important to know whether the *T. fusca* enzyme is a true *exo*-enzyme. It may be envisaged that the attack described as *exo* from the reducing end of the substrate chain may very well be the result of an initial *endo*-action by a retaining enzyme followed by multiple *exo*-attack [38].

2.6 Mechanism of Glycosidic Linkage Cleavage

2.6.1 Hydrolases

The mechanism of enzyme-catalyzed hydrolysis of glycosidic linkages is analogous to acid-catalyzed hydrolysis. Cleavage is between the glycosyl anomeric carbon (C1) and the gly-

cosidic oxygen [59]. The general reaction pathways were first recognized by Koshland [60] who categorized glycoside hydrolases mechanistically on the basis of whether the hydrolysis occurs with retention or inversion of configuration at the newly exposed anomeric center (❯ *Fig. 5*). A distinction can also be made for hydrolases and glycosyl transferases with pyranosyl substrates depending on whether the enzymes cleave equatorial or axial glycosides [2]. Thus, four stereochemical types of glycosidase action, $e \rightarrow e, e \rightarrow a, a \rightarrow a$, and $a \rightarrow e$, can be recognized.

The most probable route for the retaining glycoside hydrolase reaction is through a general acid/base catalysis that involves two crucial carboxylic acid residues at the enzyme's catalytic site. In retaining enzymes the reaction path shown in ❯ *Fig. 5a* involves a double-displacement in which the glycosidic oxygen is protonated by one of the carboxylic acids. The other carboxylic acid acts as a nucleophile, i. e., forms a glycosyl-enzyme and the aglycone departs. A water molecule is then deprotonated and makes a second nucleophilic attack at the anomeric carbon generating a product with the same stereochemistry as the substrate. The dual role of the general acid (acid/base) catalyst in the double displacement reaction involving a covalent glycosyl-enzyme intermediate (❯ *Fig. 5a*) was demonstrated in the *Bacillus circulans* xylanase by the oscillation of its pK value with the individual steps in the reaction pathway [61]. The distance between the two catalytic carboxyls in retaining enzymes is 4.5–5.5 Å (❯ *Fig. 5a*) [62] allowing a close approach of the nucleophile to the anomeric carbon. In the action of retaining enzymes it is proposed that either an oxacarbenium ion-like intermediate or a covalent glycosyl intermediate is involved (❯ *Fig. 5a*). Both states may participate. The covalent intermediate is a carboxylic ester of the catalytic nucleophile in which the glycosyl residue is in an anomeric configuration opposite to that of the substrate. Stable covalent glycosyl intermediates have been isolated by designing substrates with good leaving groups. In inverting enzymes the reaction pathway (❯ *Fig. 5b*) involves a single direct displacement in which the glycosidic oxygen is protonated by one of the pair of carboxylic acids and the aglycone departs concomitantly with the attack by a water molecule activated by the second carboxylic acid residue. In these enzymes the two catalytic acids are separated by 9–9.5 Å (❯ *Fig. 5b*) [62] allowing the water and substrate to bind simultaneously.

There is now substantial direct evidence from crystallographic and mutagenesis studies, and from the use of mechanism-based inhibitors that the two postulated catalytic groups do indeed exist for glycoside hydrolases and glycosyl transferases. The proton donor and catalytic nucleophile are invariably carboxyl groups of aspartyl or glutamyl residues. Further evidence for the proposed reaction schemes has been adduced from kinetic isotope effects [63,64]. The bell-shaped activity-pH profiles for glycoside hydrolases (and glycosyl transferases), with optima generally in the range 4.5–8.0, are consistent with the presence of ionizing groups with pK values below and above the optimum pH. The value of the optimum is determined largely by the nature and environment of the catalytic nucleophile and acid-base catalytic carboxylic acids in the active site [65], but cases with pH optima above and below the normal range have been recorded. Using site-directed mutagenesis, the pK_a values of catalytic residues have been changed with consequential alteration of the pH-activity profile [66,67,68]. However, no correlations were found between altered pH-activity dependence, and the calculated electrostatic fields in *Bacillus licheniformis* α-amylase [67]. Although examples exist of mutated enzymes with altered pH-activity dependence, rational engineering of desired shifts in the pH-activity profiles is considered to have only a limited possibility of being successful.

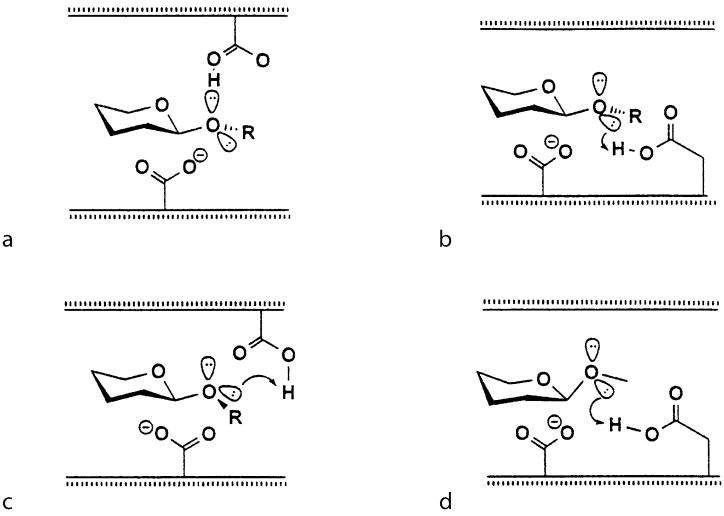

Figure 6

Protonation trajectories. (a) Protonation perpendicular to the plane of the ring, (b) *anti*-protonation, (c) *syn*-protonation, (d) lateral protonation moves the fissile C–O bond into a pseudoaxial position (after [69])

The direction of approach of the proton to the glycosidic oxygen shown in the mechanistic scheme in *Fig. 6a* [69] suggests that its trajectory is from above or below, and perpendicular to the plane of the glycone. It is now clear, however, from studies with inhibitors, analysis of the structures of enzymes in complex with ligands and by modeling, that protonation in many, if not all, glycosidases, does not follow such trajectories [69,70]. In contrast, the direction of protonation is lateral, or side-on, and in the plane of the glycosyl ring (at subsite −1) (*Fig. 6b, c*). Thus, the lateral trajectory of the proton may follow one of two directions with respect to the plane defined by O1, C1, and H1, i. e., it may be *anti* or *syn* to the pyranoside endocyclic O5–C1 bond as shown in *Fig. 6b, c*. The lateral protonation moves the fissile C–O bond into a pseudoaxial position (*Fig. 6d*). Heightman and Vasella [69] state that "It makes sense that the catalytic carboxyl group is located close to the main plane of the pyranoside ring and not above it since the departure of the aglycone in pseudo-axial direction would be restricted if the carboxyl group was located above the plane of the ring" (*Fig. 6a*). Stereoelectronic considerations require that protonation of the glycosidic oxygen atom be accompanied by a lengthening of the fissile C–O bond in a pseudo-axial direction as the incipient oxacarbenium ion develops. This is supported by two high-resolution crystal structures of the cellulases from *Fusarium oxysporum* [71] (Family 7, *syn*-protonation) and *Bacillus agaradherans* (Family 5, *anti*-protonation) [64]. They show that the pyranose ring is distorted to a skew conformation which places the glycosidic bond in a pseudo-axial orientation. A similar observation has been reported for two chitin-degrading enzymes of families 18 and 20 [72]. Similarly, the water molecule which subsequently attacks the glycosyl ester intermediate must have access from the pseudo-axial direction. The recognition of the *anti* or *syn* trajectories of approach of the proton allows families of glycosidases to be further sub-divided [69], emphasizing the relatedness of the members of the sub-divisions in respect to active site structures and mechanisms.

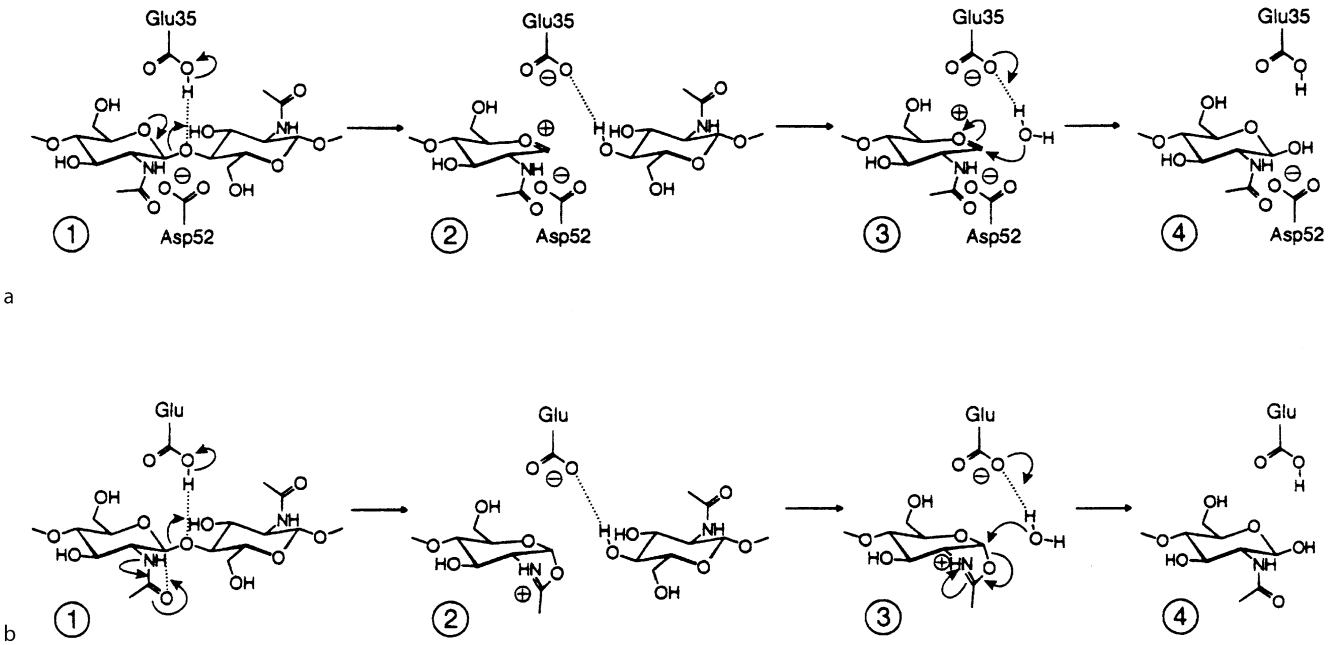

Figure 7

(a) Glycosyl hydrolysis by hen egg white lysozyme following general acid-base catalysis. Glu35 is the acid protonating the glycosidic oxygen and Asp52 is the nucleophile proposed to stabilize the reaction intermediate electrostatically. The two enzyme carboxylates have respective pKa values of 6 and 4. (b) Scheme for retaining chitinases where stabilization is proposed to occur via a covalent oxazolinium ion intermediate. The nucleophile is the *N*-acetyl group of the substrate itself. For stereochemical reasons the scheme is limited to retaining enzymes (from [72])

For a number of retaining polysaccharide hydrolases structural studies have revealed, contrary to expectation, a single obvious candidate for the catalytic acid but no candidate for the catalytic nucleophile near the anomeric carbon. These enzymes include family 18 and 20 chitinases [73], muramidase/transglycosylase [74,75,76], and some lysozymes [77,78]. To explain this it was proposed that in chitinase action the acetamido group of the *N*-acetyl-D-glucosamine monomer in subsite −1 plays the role of the catalytic nucleophile in the attack on the glycosyl intermediate (● *Fig. 7*) [72]. This was supported by X-ray crystallography of the enzyme in complex with allosamidin (see ● *Fig. 17k*), a pseudotetrasaccharide derivative substituted at its reducing end with an oxazoline-like structure.

2.6.2 Lyases

Lyases Acting on Uronic Acid-Containing Polysaccharides These enzymes, classified in [EC 4.2.2.-], are produced by bacteria, bacteriophages, marine gastropods, and a few fungi. Their substrates are all uronic acid-containing polymers with α- or β-(1→4) linkages, such as pectin and pectate (polygalacturonan), alginate, chondroitin, heparin, heparin sulfate, dermatan sulfate, hyaluronan, gellan, the side chain of xanthan and the Vi antigen of enteric bacteria [79]. The lyases so far have been classified into 10 families based on sequence homologies and folding patterns. The bacterial pectate lyases have a pH optimum around 9.5 and require Ca^{2+} for activity. The Ca^{2+} is bound in the active site [80]. The *Erwinia chrysanthemi* pectate lyase C (PelC) has been studied in great detail and generates a trigalacturonide product with a ^{4,5}-unsaturated bond in the galacturonosyl residue at its non-reducing end [81]. The β-elimination reaction (● *Fig. 8*, [82]) in pectolytic cleavage can formally be envisaged as involving three processes: neutralization of the carboxyl group adjacent to the glycosidic linkage cleaved, abstraction of the C5 proton, and transfer of the proton to the glycosidic oxygen. An arginine and an aspartic acid are presumed to play a crucial role in catalysis [15]. The complex of PelC crystallized with a Gal*p*A pentasaccharide shows the substrate fragment bound in a cleft and interacting primarily with positively charged groups: either lysine or

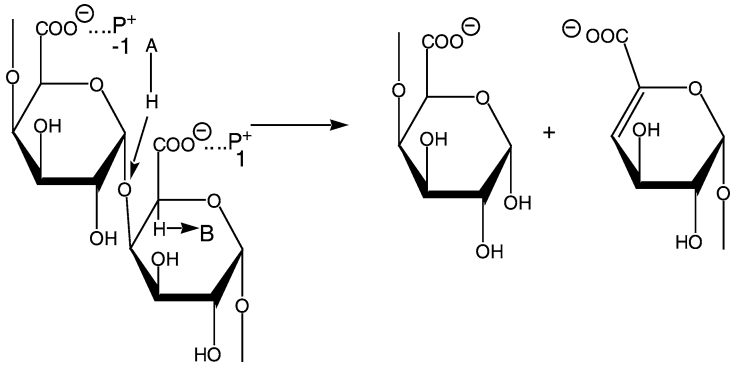

Figure 8
Proposed β-elimination reaction for cleavage of an oligogalacturonide in a pectate lyase (after [82])

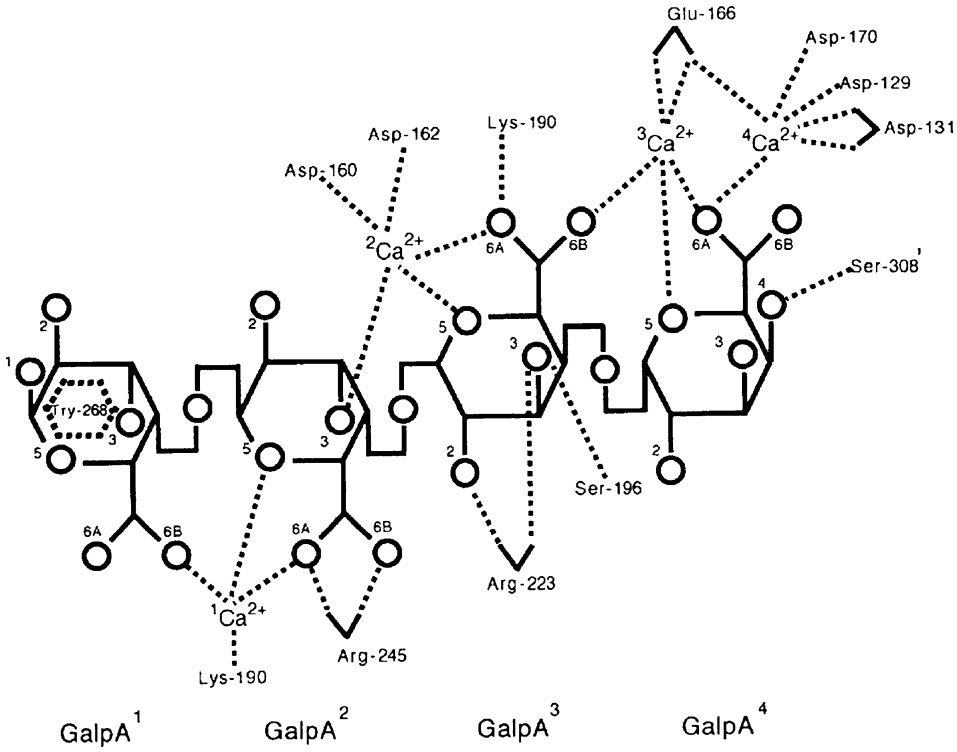

Figure 9

Schematic representation of the Ca^{2+} ion interaction with a tetraGal*p*A in the active site of the mutated (R218K, not shown) pectate lyase (PelC) showing the interactions primarily with positively charged groups: either lysine or arginine residues and four Ca^{2+} ions. GalpA^1 is the reducing saccharide, and GalpA^4 is the non-reducing terminus. The bond cleaved is most likely between Gal*p*A^3 and Gal*p*A^4. Gal*p*A^3 has the most interactions with the enzyme surface. The interactions are shown with *dotted lines*. Oxygen atoms are represented by *circles*, with the corresponding number, and the carbon atoms are assumed at the intersection of the bonds shown as *boldface lines*. Water molecules interacting with tetraGal are not shown (from [83])

arginine on the enzyme and the four Ca^{2+} ions found in the complex. The interaction of PelC with tetraGal*p*A as deduced from the crystal structure is shown in ❯ *Fig. 9* [83].

The protein-oligosaccharide interactions shown in ❯ *Fig. 9* provide a functional explanation for the occurrence of many of the invariant or conserved amino acids in this family of proteins [84]. An arginine residue (Arg218) is proposed to act as a general base in the catalysis. This is suggested by the proximity to the C5 of a Gal*p*A residue, its lower than normal pK_a, 9.5, compared with the calculated pK_a of 12.0–12.5 for all other arginines, and the impairment of activity when the residue is mutated to a lysine [15]. Members of the polysaccharide lyase superfamily (clan) are suggested to have the same reaction mechanism.

Lyases Acting on Neutral Polysaccharides Only one group of enzymes of this type is known, these are the amylolyases or (1→4)-α-glucan (starch) lyases [EC 4.2.2.13] that specifically

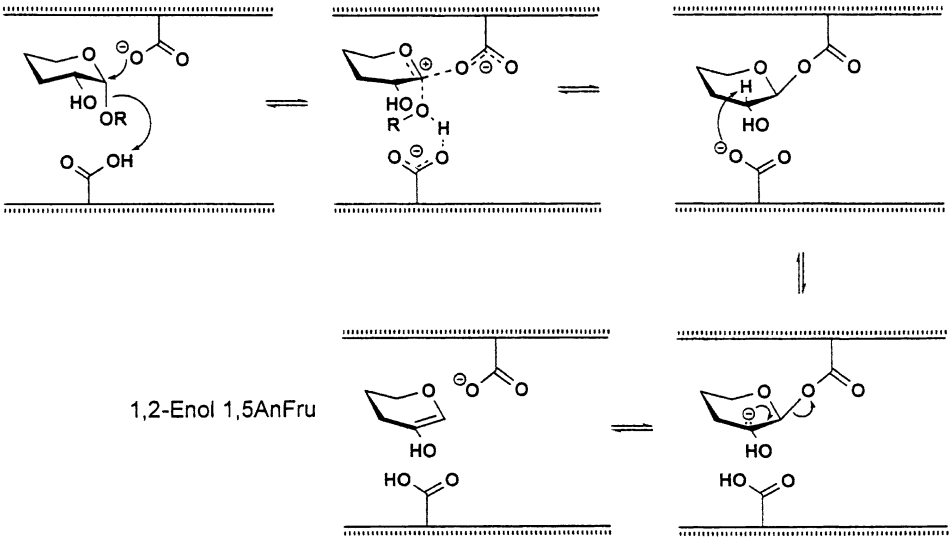

Figure 10
Proposed reaction mechanism of a (1→4)-⟨α-glucan lyase (amylolyase). The non-reducing glucosyl residue of the (1→4)-⟨α-glucan substrate chain is shown, the remainder of the chain is represented by R (after [51]). It has been suggested, however, that the catalytic nucleophile shifts position and becomes protonated by the H-C(2) in an E_{21} or E_{24} elimination (A. Vasella, personal communication)

cleave (1→4)-α-glucosidic linkages in starch or glycogen in an *exo*-action, converting the glucose residues at the non-reducing ends of the substrate to 1,5-AnFru (anhydrofructose), and ultimately liberating the reducing end residue of the substrate as free glucose [51] (● *Fig. 10*). The amylolyases are formally related to the glycosidases that catalyze the formation of 1,2-glycals from 2-deoxy-hexopyranosides detected by the reverse reaction in which a 1,2-glycal is hydrated (termed 'glycal hydrolysis') [85,86]. Amylolyases have been found in the cytosol of some fungi and in the stroma of chloroplasts of red algae, where they may be involved in the depolymerization of algal (Floridean) starch. Sequence alignment of the amylolyases has revealed that they are related to glycoside hydrolase Family 31 that includes α-glucosidases and sucrase-isomaltases. Seven well-conserved segments comprise functional residues including the catalytic groups identified in members of Family 31 [51]. This is the first case of a lyase and a hydrolase belonging to the same family and as such it may illuminate facets of the catalytic reaction mechanisms of both. Apart from sharing substrates with the amylases, the transition state analogue inhibitors, such as, 1-deoxynojirimycin (see ● *Fig. 17b*), and acarbose (see ● *Fig. 17g*), are effective with both types of enzyme. However, other common glycoside hydrolase inhibitors like glucono-1,5-lactone and the cyclodextrins, and the affinity labeling reagents, conduritol-B epoxide (● *Fig. 11a*) and 2′,3′-epoxypropyl-α-D-glucoside, do not inhibit the amylolyases. The mechanism of action [51,87] is likely to resemble that of α-glucosidases to a certain extent (● *Fig. 10*).

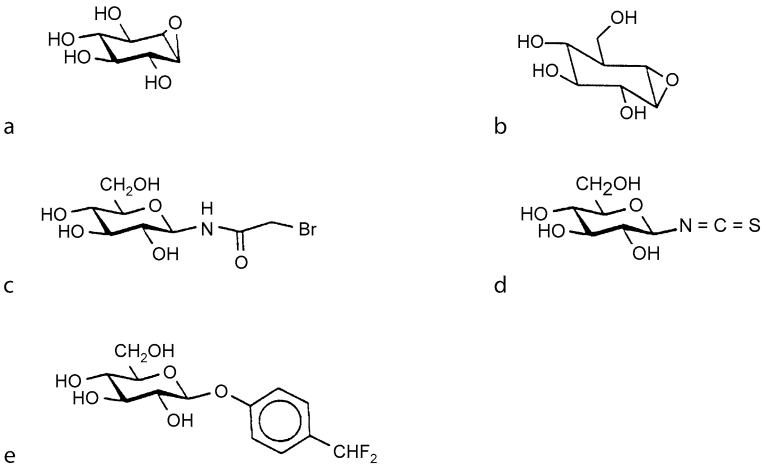

Figure 11

2.6.3 Phosphorolases

Phosphorolysis of glycosidic linkages in α- and β-glucans (*Structure 1*) is an alternative to depolymerization by hydrolysis and is used in mobilizing cellular storage polysaccharides. The glucose-1-phosphate product is a direct intermediate in hexose metabolism. Thus, the phosphorylases are found intracellularly together with their substrates: glycogen in vertebrates, invertebrates, and bacteria; starch polymers in higher plants; and (1→3)-β-glucans (paramylon) in euglenoid protozoa. Bacteria that are able to transport maltodextrins across their cell membranes depolymerize them with a maltodextrin phosphorylase and comparable eukaryotic, bacterial, and archaean phosphorylases for laminaribiose [88], cellobiose, and cellodextrins [89] have been described. The (1→4)-α-glucan phosphorylases from mammalian, plant, and bacterial sources are *exo*-enzymes catalyzing the reversible phosphorolysis of glucosidic linkages at the non-reducing ends of glucosyl chains to produce αGlc-1-phosphate, i. e., with retention of configuration. In the reverse direction, the (1→4)-α-oligoglucoside or glucan acceptor is lengthened by the transfer of the glucosyl moiety from α-glucose 1-phosphate, e. g., to its non-reducing end with the concomitant production of inorganic phosphate. The equilibrium constant for the reaction expressed as the ratio of [Pi]/[Glc-1-P] is 3.6 at pH 6.8. All phosphorylases are dependent for activity on the presence of metal ions, typically Mg^{2+} or Mn^{2+}, and have an absolute requirement for pyridoxal 5′ phosphate as a co-factor [90]. The (1→4)-α-glucan phosphorylases are classified in glycosyl transferase Family 36 and probably have similar kinetic mechanisms.

Phosphorylases from animal, bacterial, and plant sources can be distinguished by their substrate preferences. Animal and bacterial phosphorylases prefer the short outer branches of highly branched α-glucans, such as glycogen. The phosphorylase from *Corynebacterium calluna*, which accumulates a starch-like polysaccharide, is exceptional among bacterial enzymes

in its preference for long chain substrates [91]. *E. coli* possesses, in addition to a genuine glycogen phosphorylase, a maltodextrin phosphorylase [92] which has a high affinity for linear oligosaccharides, and less than 1% activity against glycogen. There are two isoforms of the plant phosphorylase; Pho1, from the cytosol, with a high affinity for amylopectin and glycogen, and Pho2, from plastids, that prefers amylose and maltodextrins. The three-dimensional structures of the mammalian [93,94] and yeast [95,96,97] enzymes reveals the active site in a tunnel with the Glc-1-P situated in the −1 subsite, at its end, far removed from the bulk solvent and adjacent to the essential pyridoxal cofactor [98,99]. The mammalian phosphorylases have not been crystallized in complex with their oligosaccharide substrates. However, the *E. coli* maltodextrin phosphorylase has 98% sequence identity with the mammalian enzyme in the region of the catalytic site and its structure has been determined in complex with bound maltopentaose [100] and the pseudo-oligosaccharide, acarbose (see ❯ *Fig. 17g*) [53,92]. The catalytic site is situated in the center of the large subunit and is accessible through a 20-Å-long channel that forms the oligosaccharide binding site. The non-reducing terminal maltosyl portion of the bound maltopentaose and the acarviosine portion of acarbose occupy subsites +1 and +2 and the reducing terminal maltosyl of acarbose, subsites +3 and +4.

In the *E. coli* maltodextrin phosphorylase, structural analysis of the binary complex with maltopentaose, 4-*S*-α-D-glucopyranosyl-4-maltotetraose (G*S*G4) and the ternary complex with GSG4 and phosphate show the pentasaccharide binding along the catalytic site and occupying subsites −1 to +4 with the phosphate group poised to attack the glycosidic bond and promote phosphorolysis [53]. In all three complexes, the pentasaccharide exhibits an altered conformation across subsites −1 and +1 (❯ *Fig. 12*), from the preferred conformation of (1→4)-α-linked glucosyl polymers. The oligosaccharides can find their way into the catalytic site tunnel only by alteration of the glycosidic torsion angles. Similar observations have been made with porcine pancreatic and barley α-amylase [36,101] and soybean β-amylase [55]. In starch phosphorylase [Pho2(L)] a 78 residue insertion is located beside the mouth of the active-site cleft and presumably sterically hinders the approach of the large highly branched glucan to the active site [102,103].

Muscle glycogen phosphorylase is composed of two identical ∼90 kDa sub-units. The catalytic capability of the enzyme is regulated by phosphorylation/dephosphorylation of a specific serine residue by a glycogen phosphorylase kinase/phosphatase and, non-covalently, by allosteric effectors such as AMP. The enzyme can exist in two states, an unphosphorylated, inactive form and a phosphorylated, active form. The covalent attachment of a phosphate group at serine 14 elicits conformational changes at remote sites mediated through subunit-subunit interactions. These changes lead to opening of a gate, created by a loop that closes the catalytic site in the inactive form, and by rearrangement of certain amino acids, creates a high affinity substrate-binding site. The unphosphorylated form can be activated by binding AMP at a site close to serine 14 which causes conformational changes leading to correct orientation of amino acids involved in subunit-subunit interactions [104,105,106]. By contrast, in the *E. coli* maltodextrin phosphorylase, the relative orientation of the two subunits is quite different and there are significant changes in subunit-subunit interactions. Sequence changes result in loss of the allosteric control sites resulting in the loop, which acts as a gate to control access to the catalytic site in the muscle phosphorylase, being held in the open conformation. In addition to binding (1→4)-α-glucan substrates in the active site, muscle phosphorylase has a non-catalytic, (1→4)-α-glucan-binding site, or 'glycogen storage site,' through which the enzyme may

Figure 12
Proposed catalytic mechanism for a phosphorylase based on the maltose phosphorylase GSG4-P ternary enzyme-substrate complex. (a) The oligosaccharide substrate is bound across the catalytic site in subsites −1 and +1. The phosphate substrate is within hydrogen-bonding distance of the glycosidic oxygen and is stabilized in this position by contacts to Arg569 and Lys574. The phosphate substrate is within hydrogen-bonding distance of the pyridoxal phosphate 5′-phosphate group whose position is stabilized by contacts to water (shown as *asterisks*) and polar amino acid residues. The co-factor 5′-phosphate acts as a general acid to promote attack of inorganic phosphate on the glycosidic oxygen. The oxygen is protonated leading to the cleavage of the C1–O bond and formation of the oxonium-carbonium ion intermediate. (b) The carbonium ion is promoted and stabilized by the inorganic phosphate dianion, the carbonyl oxygen of His377 and the lone pair of electrons on the 3′-OH of the saccharide in subsite +1. The 2′-OH group of the saccharide at subsite −1 is polarized by contact with the inorganic phosphate. (c) The cleaved oligosaccharide is free to diffuse away. Nucleophilic attack by the inorganic phosphate at the C1 position of the carbonium ion leads to the formation of ⟨-glucose 1-phosphate (from [52])

be attached to glycogen particles in vivo [107]. The site is on the enzyme surface some 30 Å from the catalytic site. The affinity for oligosaccharides at this site is higher than for the active site itself [108]. Such a 'storage' site is also present on plant phosphorylases but is lacking in the bacterial enzymes.

Mechanistic studies on phosphorylases suggest a double displacement mechanism is operating. The reaction proceeds through a rapid equilibrium bi-bi kinetic mechanism. There is random addition of the α-glucan and inorganic phosphate substrates, but the binding of one substrate increases the enzyme's affinity for the other substrate. Phosphorylases are able to catalyze the arsenolysis of Glc-1-P and the exchange between Glc-1-P and Pi, but only in the presence of an acceptor [109,110]. The rate-limiting step in the reaction is the interconversion of the ternary phosphorylase-phosphate-glycosyl complex to the ternary phosphorylase-Glc-1-P-glycosyl-complex [111]. By analogy with other retaining enzymes it may be suggested that a glycosyl-enzyme intermediate is involved, but such an intermediate has not been isolated. Positional isotope exchange results with the potato enzyme are consistent with such an intermediate. At present the identity of the presumptive nucleophile is unknown as there is some uncertainty due to the conformational flexibility at the catalytic site, and other mechanisms have been suggested [90]. The role of the essential pyridoxal phosphate bound at Lys 680 by a Schiff base close to the substrate phosphate in glycogen phosphorylase has not been resolved [4,99,112,113,114]. However, studies with the closely related *E. coli* maltodextrin phosphorylase [53] (*Fig. 12*), show that no acidic group participates directly in catalysis, but the 5′-phosphate of the pyridoxal cofactor promotes general acid attack by the inorganic phosphate, resulting in protonation of the glycosidic oxygen of the bond to be cleaved.

Substrate analogue inhibitors of phosphorylase include the ground state analogues, glucose; glucose-1-methylenephosphate and glucose-1,2-cyclic phosphate [107,114,115,116,117]; the dead-end product, heptulose 2-phosphate [99,118] and glucose derivatives with an sp^2 hybridized anomeric center; heptenitol [118,119]; D-gluconohydroximo-1,5-lactone *N*-phenylurethane [120,121]; acarbose [122]; and isofagomine [123,124,125]; nojirimycin tetrazole [113]; glucose spirohydantoins [126,127,128]; alkyl-dihydropyridine-dicarboxylic acid [129] and *N*-acetyl-β-D glucopyranosylamine [130]. 4-Deoxymaltohexaose/pentaose are good competitive inhibitors of phosphorylase with K_m values some 40-fold and 10-fold lower, respectively, than the underivatized oligosaccharides [52]. The increased affinity may relate to a stabilizing effect of the hydroxyl group on the ground state.

2.7 Hydrolase Inhibitors

2.7.1 Reagents Reacting with Amino Acid Residues Required for Activity or Binding

Inhibition or abolition of enzyme activity by group specific reagents that modify amino acid residues with a function in catalysis, or in binding the substrate can provide a preliminary indication of the identity of these important residues. Thus, various carbodiimides and Woodward's reagent K inhibit by reacting with carboxyl groups, other examples include *N*-bromosuccinimide reacting with tryptophans, tetranitromethane reacting with tyrosines, diethyl pyrocarbonate reacting with histidines, a variety of acylating reagents that modify lysines, alkylating reagents that modify thiol groups, and phenylglyoxal that modifies arginines [25,131]. The interpretation of the results needs to be made cautiously since many of the reagents are not absolutely specific and without corroborating evidence it is not possible to assign a catalytic or binding role to the amino acids. Differential labeling with unlabeled reagent in the presence of a substrate or substrate analogue, dissociation of the ligand and reaction with labeled reagent can provide better evidence for the role of specific amino acids in catalytic activity. Thus, acarbose (see *Fig. 17g*), a pseudo-tetrasaccharide substrate analogue and inhibitor of glucoamylase, protected the essential Trp120 from reaction with *N*-bromosuccinimide [132]. Although such reagents can be useful in exploring structure/function relationships, particularly when coupled with sequencing and differential labeling, most often site-directed mutagenesis is preferred in structure/function investigations [16,17]. Formation of hybrid or chimeric enzymes is another powerful tool in structure/function and structure/stability investigations and for protein engineering [133,134,135].

2.7.2 Irreversible Active-Site-Directed Inhibitors

Affinity Labeling These reagents [1,136,137] combine a glycosyl substrate moiety that targets the compound to the catalytic site and a functional group capable of reacting to form a stable, covalent linkage with a group in the active site, sometimes a catalytic amino acid, leading to inactivation of the enzyme. One of the first of this class of inhibitors was the 2,3-epoxypropyl-β-chitobiose used to inactivate lysozyme [138,139,140,141]. These substrate analogues require an acidic group for the protonation of the oxirane ring and a nucleophile for the formation of the covalent bond. The reaction is shown in *Fig. 13*.

Reduction of the glycosyl ester so formed converts the carboxylic acid-bearing residue to the corresponding alcohol and can be used to identify the catalytic amino acid at the site of reaction [139,140]. A panel of these reagents [142] has been used to probe the active sites of a series of β-glucan hydrolases [143] and to 'specifically' label and identify their catalytic nucleophiles [144,145,146,147,148,149,150]. The 2,3-epoxypropyl-α-glucoside reacts with a carboxylic acid in β-amylase [151]. The length of the epoxyalkyl chain influences the effectiveness of the inhibition, which depends on whether the oxirane ring is within reach of the catalytic group [145]. Because the alkyl chains show flexibility, active-site carboxyl groups in the vicinity of the catalytic nucleophile may be labeled, and it is necessary to verify the identity of the labeled group by independent methods such as X-ray crystallography of the enzyme complexed with the inhibitor. This has been achieved for hen egg white lysozyme [152] and

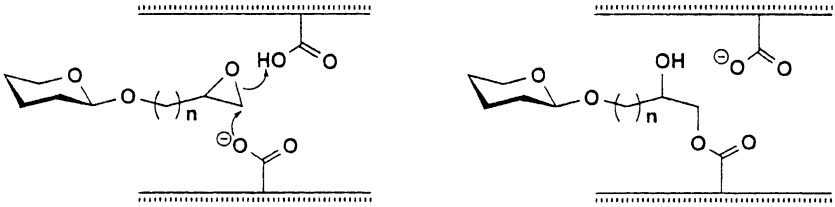

Figure 13
Reaction pathway for epoxyalkyl β-glycoside substrate analogue with a β-glucan hydrolase involving protonation of the oxirane ring by an acid group and the formation of a covalent bond with a nucleophile at the active site

the hybrid *B. macerans/B. amyloliquefaciens* (1→3; 1→4)-*endo*-β-glucanase [150] or with a bona fide mechanism-based inhibitor.

Significant differences in the stereospecificity of the interaction of the epoxyalkyl group between the (1→3; 1→4)-β-glucan hydrolases from *Hordeum vulgare* (Family 17) and *Bacillus subtilis* (Family 6), with indistinguishable substrate specificities, were shown by comparing the series of (*RS*)-epoxalkyl-β-cellobiosides with the pure (3*R*)- and (3*S*)-diastereoisomers [153]. The 3*S*-isomer was most effective for the barley enzyme whereas the 3*R*-isomer was almost without effect. The opposite was true of the *B. subtilis* enzyme. The structure of the *Fusarium oxysporium* (1→4)-β-glucan endohydrolase [154] affinity-labeled with a mixture of *R*- and *S*-forms of epoxybutyl-β-cellobioside shows the butyl moiety lying over the −1 subsite. Both isomers appear to be present, but modeling studies suggest that the electron density is much stronger for the *R*-isomer. Examples of other reagents with functional groups that have been used in affinity labeling of glycoside hydrolases are the oxiranes, conduritol B epoxide (*Fig. 11a*), and the naturally occurring cyclophellitol (*Fig. 11b*) [155], and various glycosyl epimines (aziridines) [156,157], the *N*-bromoacetyl-glycosylamines (*Fig. 11c*) [158], the glucosyl isothiocyanates (*Fig. 11d*) [159], and diazoketones [160]. As is the case with the epoxyalkyl affinity reagents the labeled amino acid residue may not necessarily be the catalytic nucleophile.

Bromoketone *C*-cellobioside and *N*-bromoacetyl-β-D-cellobiosylamine [161] differentially inactivated *Cellulomonas fimi* β-glucanases. The bromoketone derivatives inactivated the (1→4)-β-glucan endohydrolases, CenD and CenA, with stoichiometric labeling of the enzymes, but not the (1→4)-β-glucan exohydrolase Cex, whereas the *N*-bromoacetyl derivatives inactivated CenA and Cex, but not CenD. This is attributed to the different modes of hydrogen bonding of the amide moiety. The amino acid residues labeled were not identified. However, stoichiometric labeling of the putative acid/base, Glu276, in *Saccharomyces cerevisiae* α-glucosidase was obtained using the 1′-bromo-3′-(α-D-mannopyranosyl)-2′-propanone [162]. This Glu is completely conserved in other Family 13 α-glucosidases and α-amylases whose three-dimensional structures have implicated this residue as the acid/base catalyst, i. e., the proton donor. Thus, the bromoketone derivatives are good candidate reagents for labeling the general acid/base catalyst.

Mechanism-Based Inhibitors Another class of active-site-directed inhibitors are glycoside derivatives that require mechanism-based activation in order to react covalently with

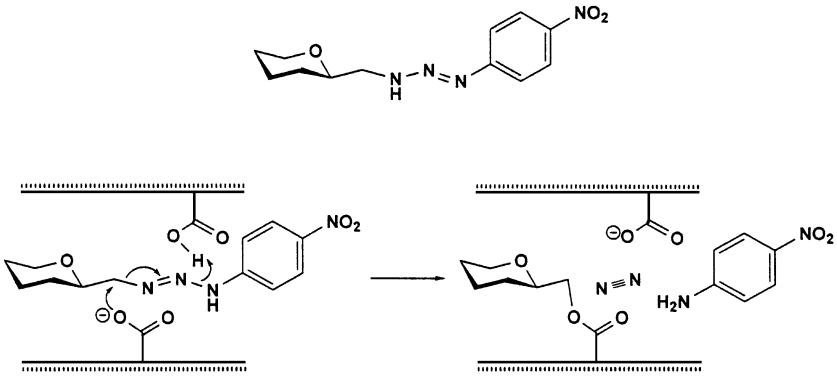

Figure 14
Reaction pathway in glycosyl methyltriazene activation [163]

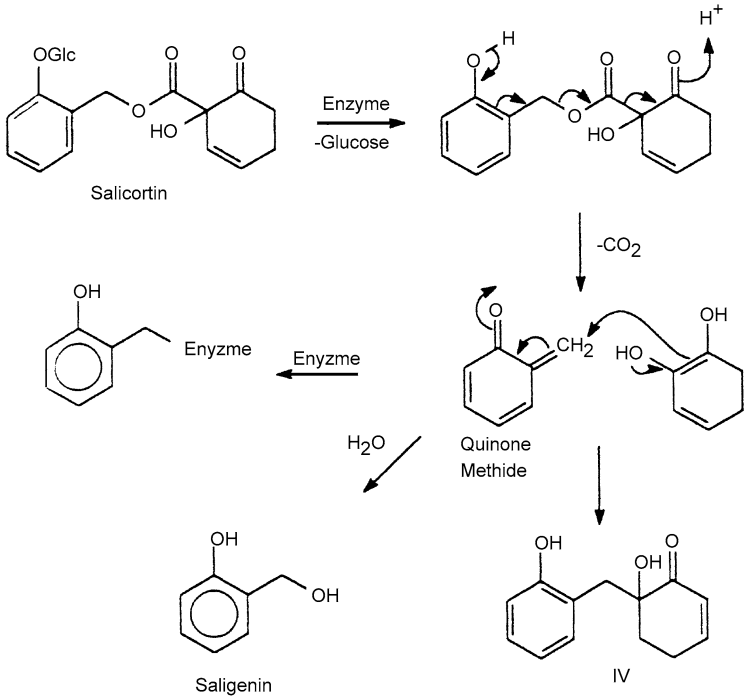

Figure 15
Reaction pathway for salicortin inhibition (after [165])

the enzyme. One class of such nucleophile-specific reagents are the glycosylmethyl-triazenes [163] that require protonation after binding, and decompose to yield a very reactive glycosylmethyl-carbenium ion (*Fig. 14*).

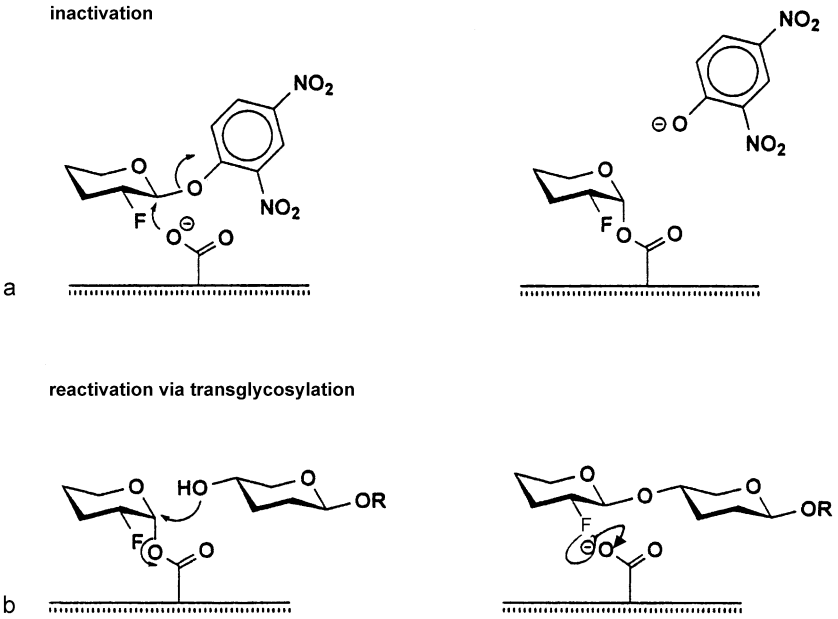

Figure 16
Reaction pathway and mode of activation of a β-glucosidase by 2,4-dinitrophenol 2 deoxy-2-fluoro-D-glycoside (after [137,167])

A second class of mechanism-based inhibitors are those that in the course of their cleavage by the enzyme release an aglycone that rearranges to give a reactive species. Two examples may be cited. Salicortin [164], a natural product, is hydrolyzed by β-glucosidases to produce, by rearrangement, a reactive quinone methide as shown in ❯ *Fig. 15* [165].
The *o*- and *p*-difluoromethylaryl β-glucosides (❯ *Fig. 11e*) [166] are further examples of this class of mechanism-based inhibitors. They are cleaved by β-glucosidases to yield a fluorohydrin that decomposes to hydrogen fluoride and an acyl fluoride that reacts at the active site. A third class of mechanism-based inhibitors are the 2-deoxy-2-fluoro-D-glucosides with good leaving groups, e. g., 2,4-dinitrophenol [167] and the 5-fluoro-D-glucosyl fluoride [168,169]. These reagents form reactive species only after cleavage of the glucosyl moiety and hence are highly specific inhibitors of β-glucosidases and have been used successfully to label a number of $e \rightarrow e$ enzymes. In the reaction (❯ *Fig. 16*) "the covalent intermediate formed is stabilized against hydrolysis, on the one hand, by the inductive destabilization of the positively charged oxacarbenium ion-like transition states by the electronegative fluorine and, on the other, by loss of crucial transition state hydrogen-bonding interactions" [4]. When a good leaving group is incorporated, the first step in the reaction proceeds at a reasonable rate. In some $e \rightarrow e$ enzymes the turnover rate of the intermediate is measurable, but the intermediate is stable enough to allow identification of the nucleophile. The identity of the amino acid residue labeled by affinity- or mechanism-based inhibitors has been determined using sensitive, mass spectrometric methods without the need for radiolabeled reagents [137,170,171].

Many of the affinity- and mechanism-based inhibitors were designed for use with glycoside hydrolases, however, they have potential applications with glycan hydrolases. Their effectiveness may be improved by extending the glycosyl portion to provide tighter binding in the active site. This was demonstrated to be the case in a family of epoxyalkyl β-glucosides and oligoglucosides of various chain lengths [170]. Those with longer oligosaccharide chains were more reactive and the inhibition more specific (see [1,5,137] for a discussion of the operation of these mechanism-based inhibitors).

2.7.3 Transition State Inhibitors

Transition-state analogues represent a class of inhibitors distinct from the active site-directed inhibitors. They are reversibly bound in the active site, and compete with the substrate by mimicking the shape and/or the charge of the transition state. A large number of transition-state inhibitors is available for glycosidases, some of which were developed for therapeutic or other applications, some are effective with polysaccharide depolymerizing enzymes. Transition-state inhibitors are useful tools for elucidating important residues in the enzyme-substrate interaction by protein crystallography. For glycoside hydrolases, an important transition state is believed to be a planar glycosyl-oxacarbenium ion [4,69]. Examples of transition state-analogue inhibitors are aldonolactones such as D-glucono-1,5-lactone (*Fig. 17a*) [1], basic sugar analogues such as the glycosylamines [1], glycosylimidazoles [1], cyclic aminoalditols, such as 1-deoxynojirimycin, (*Fig. 17b*) and isofagomine (*Fig. 17c*) [123,124]; glycotetrazoles, e. g., glucotetrazole (*Fig. 17d*) [69,172,173], pseudosubstrates such as glycals, e. g., D-glucal (*Fig. 17e*) [1], and the aminocyclitols, e. g., valienamine [1], carbacyclic pseudosaccharides incorporating valienamine or an analogue into an oligosaccharide chain, e. g., methylacarviosin (*Fig. 17f*), acarbose (*Fig. 17g*) [35,36,45,101,174,175,176], adiposin (D-*gluco*-dihydroacarbose) (*Fig. 17h*), methyl β-acarviosin (*Fig. 17i*), and methyl β-acarboside (*Fig. 17j*) [177,178,179] and the oxazoline-like pseudotrisaccharide, allosamidine (*Fig. 17k*) [72,74].

From a structural point of view some of these compounds are not perfect transition state analogues, but have closely related structures to, and behave kinetically as, transition state inhibitors [180]. One way to test the validity of a compound as a transition state analogue is by determining the relationship between K_i and k_{cat}/K_m for a series of mutated enzymes such as, e. g., for the acarbose-glucoamylase system [181] where these parameters gave a linear relationship in a double logarithmic plot. The pre-steady state kinetic analysis [177] indicated, however, that the interaction with acarbose elicited a unique conformational change in the enzyme as the final step in its binding mechanism [21]. Thus, thorough analyses of specific inhibitor-enzyme pairs may reveal aspects that are not evident from conventional kinetics. For Family 18 chitinases that follow a substrate-assisted catalytic mechanism involving a neighboring substrate C2′ acetamido group stabilization, molecular mechanical calculations have shown that oxazolines are potential inhibitors [73]. This is supported by the structure of the complex with the natural oxazoline, allosamidin (*Fig. 17k*) [74].

Recently, a series of tetrazoles, including *gluco*tetrazole (◗ *Fig. 17d*), was designed as neutral, stable lactone analogues and correlations were found between k_{cat}/K_m of various glycosidase-substrate pairs [172]. The tetrazole transition-state inhibitors have been used to classify hydrolases according to the *syn* or *anti* in-plane-protonation of the oxygen of the glycosidic bond cleaved [69,173].

2.7.4 Proteinaceous Inhibitors

A variety of polysaccharide hydrolases is inhibited by endogenous or exogenous proteins. These include α-amylases and limit dextrinase [182,183,182,185,186,187,188,189], fungal xylanases [190,191] and polygalacturonases [192]. Most of these inhibitors are from plants [183,185,186,187,192] but some are of microbial origin [182]. Structures of the enzyme-inhibitor complexes are available in some cases, in others only the structure of the free inhibitor is known. Five distinctly different α-amylase-inhibitor complexes have been reported including two for the pancreatic enzyme, one for the barley and two for insect α-amylases. Structural mimicry of the substrate has been observed in the bean (*Phaseolus aureus*) inhibitor-pancreatic α-amylase complex and in the complex of the small amaranth (*Amaranthus hypochondriacus*) inhibitor of the knottin family and the yellow mealworm (*Tenebrio mollitor*) α-amylase [183,187]. For the barley enzyme-inhibitor complex, contacts between the side chains and the carboxylic acid residues at the catalytic site of the enzyme involve a hydrogen bond network mediated through structural water molecules and a fully hydrated calcium ion at the protein-protein interface [186]. The role of the individual amino acid side chains in complex stabilization has been investigated by mutational analysis [135].

2.8 Structural Organization of Glycan Hydrolases

Many microbial polysaccharide hydrolases are secreted in a soluble form into the extracellular environment where their target substrates are found, whereas some bacterial cellulases are components of high molecular mass ($2.0–2.5 \times 10^6$ Da) cellulosome complexes that are anchored to the outer cell surface [193]. The α-amylases found in mammalian saliva and intestinal tract are soluble components of parotid gland and pancreatic secretions, respectively. The aleurone cells of germinating cereal seeds secrete a range of soluble glycanases concerned with mobilization of endosperm cell wall polysaccharides and starch. Some plant cellulases of unknown function are membrane-anchored [194]. In mammalian tissues polysaccharide hydrolases (e. g., lysozyme) may be compartmentalized in membrane-bound organelles (lysosomes), where they are concerned with turnover of cellular constituents and degradation of foreign material. Delivery to, and maintenance of the enzymes in, these various cell, tissue, and extracellular locations, involve specific structural features beyond those participating in substrate-binding and catalysis. Structural analysis of polysaccharide hydrolases (and glycosyl transferases) has shown that most are globular proteins carrying a catalytic domain. Additional non-catalytic domains involved, for example, in substrate binding, association with structural proteins, with membranes or with other catalytic monomers are known. In many instances the presence of a non-catalytic domain has been recognized but the function has not been identified.

2.8.1 Catalytic Domains

The various folding patterns of the polypeptide chain constituting the catalytic domains of glycoside hydrolase families have been reviewed [4]. At the time of writing three-dimensional structures are available for members of over 31 hydrolase families and one unclassified hydrolase and three families of glycosyl transferases and one unclassified (Bernard Henrissat, personal communication).

Topology of Active Sites Most often the active site is confined to one domain but there are examples where the active site is contributed by amino acid residues from two different domains [195,196]. The topology of the active sites of glycan hydrolases may be described in one of three general shapes: a pocket, a cleft or groove, or a tunnel, irrespective of whether the enzyme is inverting or retaining. Examples of the three types are shown in ❯ *Fig. 18*.
In some enzymes of the first group, the pocket may be quite shallow, but in others the pocket is quite deep [45,196,197]. The cleft or groove topology is shown by many polysaccharide hydrolases [46,101,174,176,198,199,201]. The length of the cleft will define the number of glycosyl binding sub-sites and hence the length of the polysaccharide chain that can be accommodated. In cellobiohydrolase II (Cel6A) from *Humicola insolens* [173] and cellulase Cel6A from *Trichoderma reesei* [202] the groove-type topology has been modified to form a tunnel by covering the open cleft with a polypeptide loop [203]. A tunnel-shaped active site would appear to be conducive to multiple attack. It is envisaged that the substrate is threaded through the tunnel, and after a productive binding and cleavage, one product is released and the other remains bound and processes in the active site to give a new productive association allowing repetitive (multiple) attack. How the enzyme-substrate complex is formed is not understood, but may involve opening the 'lid' over the cleft to allow binding. In *T. reesei* Cel 6A, Trp272 at the entrance of the tunnel is critical for the degradation of crystalline cellulose and has been proposed to have a role in threading the glucan chain into the tunnel [204]. In bacterial cyclodextrinase (Family 13) the shape of the active site pocket is altered by homodimer formation in which the *N*-terminal domain of one subunit covers the entrance to the catalytic site of the other, thus causing a change in substrate specificity [205,206].

Substrate Recognition at the Active Site The specificity of glycan hydrolases is determined by the ability of monosaccharide residues in the polysaccharide substrate to be recognized by, and be bound to, contact amino acid residues in the binding site. Generally, the binding of monosaccharide residues is promoted by the presence of planar hydrophobic groups on the enzyme surface, contributed by tyrosine, phenylalanine, or tryptophan side chains, which form a platform on which the hydrophobic face of the glycosyl ring sits. This appears to be a general strategy for protein-monosaccharide ring associations as was first shown for the bacterial arabinose transporting protein [19,207]. However, specificity is determined by substituents on the ring that make hydrogen bonds, either directly or through water molecules and polar interactions, with an array of specific amino acids lining the active site, as illustrated in ❯ *Fig. 19* [208].
There is absolute specificity with respect to the anomeric configuration of the monosaccharide residues in the substrate and the regioselectivity for linkage position is usually absolute for the glycone, but the 'aglycone' binding interactions may be much less stringent. Quite subtle dif-

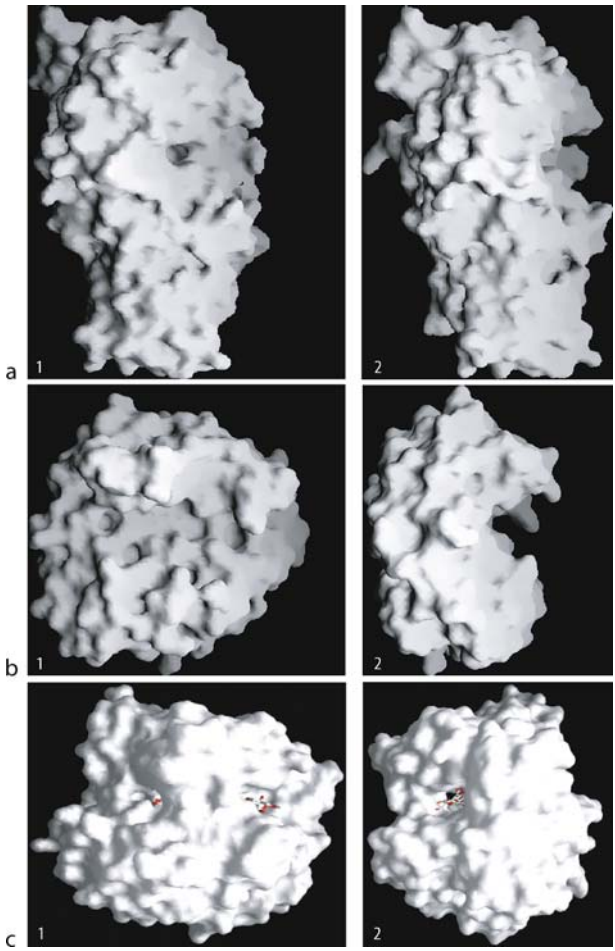

Figure 18

Three types of active sites found in glycan hydrolases. (a) *Hordeum vulgare* β-glucan exo-hydrolase [196]; 1. Viewed from above the catalytic face. 2. Rotated 90° along the long axis. The site appears as a compact hole in the middle of the molecule. (b) *Hordeum vulgare* (1→3;1→4)-β-glucan endo-hydrolase [199]; 1. Viewed from above the catalytic groove, that runs east-west. 2. Rotated 90° perpendicular to the groove axis. (c) *Trichoderma reesei* Cel6A (1→4)-β-glucan cellobiohydrolase (formerly cellobiohydrolase II) [200]; 1. Side-on view of the tunnel containing a substrate analogue. 2. End-on view of the same complex as in 1

ferences in the contact amino acids lead to changes in substrate specificity. This is illustrated by the (1→3)-β- and (1→3;1→4)-β-glucanases from barley, that both belong to Family 17, and have an almost identical folding pattern, with a binding site in the form of a deep cleft (*Fig. 18b*). Both require a laminaribiosyl residue in the −2 and −1 subsites, but the (1→3)-β-glucan hydrolase accepts only a 3-linked glucosyl in the +1 site, whereas the (1→3;1→4)-β-glucan hydrolase accepts only a 4-linked glucosyl residue in this site. Modeling studies suggest that the determinants of substrate specificity are identifiable amino acids in the active

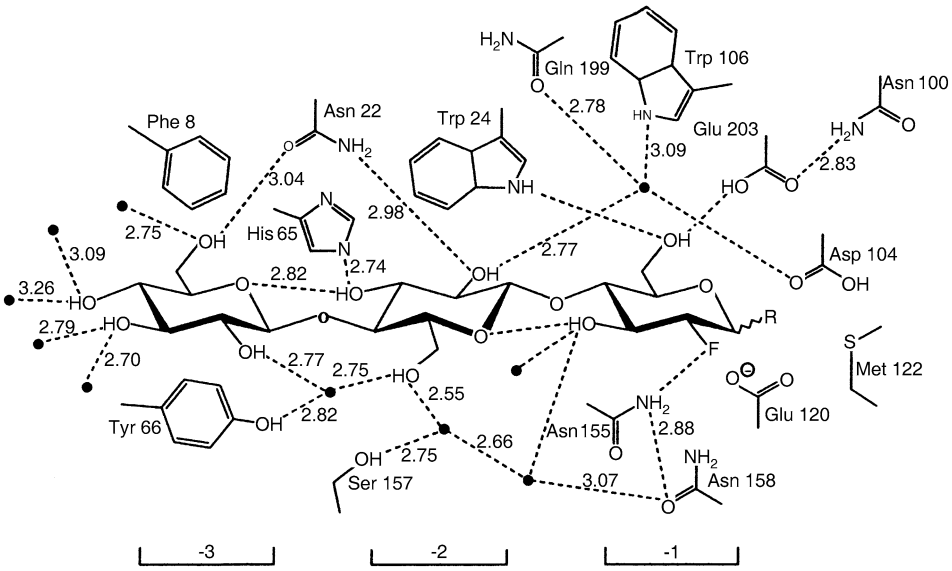

Figure 19
Active site of the *Streptomyces lividans* endoglucanase CelB2 showing the non-bonded interactions between the covalent 2-deoxy-2-fluorocellotriosyl intermediate complex with the nucleophile Glu120 and adjacent amino acids. The F-cellotriosyl portion sits in subsites −3, −2, and −1 (from [208])

site near the conserved catalytic amino acids [199]. The *Rhizopus arrhizus* β-glucan hydrolase has the same glycosyl requirement as the barley and *Bacillus* enzymes but will accept either a 3- or a 4-linked glucosyl residue in the +1 site suggesting a less stringent "aglycone"-binding interaction [209]. The homomorphous (1→4)-β-glucans and (1→4)-β-xylans are sometimes discriminated by cellulases and in other cases they are not [210]. Some chitinases that catalyze the hydrolysis of chitin, a β tGlcNAc homopolymer, also cleave the (1→4)-linkages in murein the homomorphous polysaccharide backbone of the bacterial cell wall peptidoglycan. In murein every other residue is muramic acid, the lactyl ether of GlcNAc, and this is the substrate for animal and bacteriophage lysozymes [211]. Lysozymes, e. g., from hen egg white may also hydrolyze chitin [212]. By an approach involving systematic removal of hydroxy groups [213], on disacccharide substrate it has been possible to determine which OH groups on maltose and isomaltose are needed for binding and hydrolysis by glucoamylase [214,215], but the difficulties of synthesis makes this an impractical strategy for most polysaccharide hydrolyzing enzymes. There are several examples where conformational changes of the protein are seen to accompany substrate binding but it is beyond the scope of the present chapter to include a detailed description of these events. Some well-established cases include: cyclodextrin glycanotransferase where the recognition of the substrate at the active site has been shown to be achieved by concomitant alteration of the conformation of both the substrate and the protein [216]. Structural evidence for a conformational change on substrate binding has been provided for porcine pancreatic α-amylase [36], soybean β-amylase (binding maltose) [197], and the cellobiohydrolase II, Cel6A, from *Humicola insolens* [173] and from *Trichoderma reesei* [217].

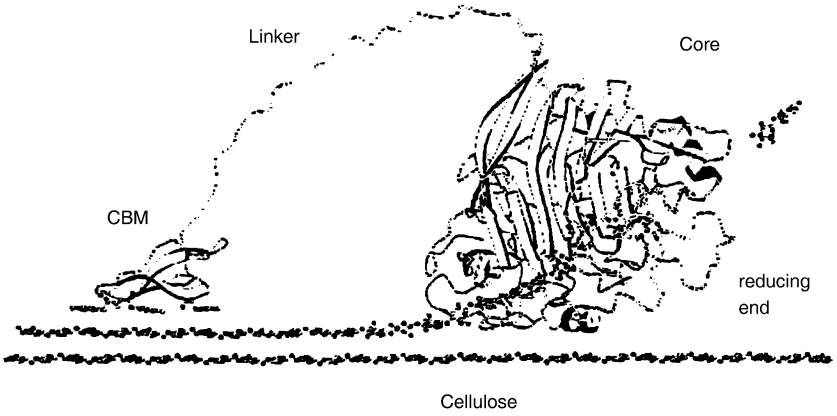

Figure 20
Model of intact cellobiohydrolase 1 (CBH1) from *Trichoderma reesei* bound to a cellulose microfibril surface. The model is based on the crystal structure of CBH1 in complex with cellohexaose, the NMR structure of the cellulose-binding module (CBM) and a modeled linker region. CBH1 is believed by some to act repetitively from the reducing end towards the non-reducing end of the cellulose chain (from [231])

Non-Catalytic, Carbohydrate-Binding Modules Hydrolases acting on large, and sometimes insoluble, substrates [10] such as starch [218,219,220,221], cellulose [222,223,224], xylans [225] and (1→3)-β-glucans [226]. The (1→3)-β-glucan binding modules are conserved in non-catalytic (1→3)-β-glucan-binding proteins from invertebrates [227]. An arabinofuranosidase has been reported with a (1→4)-xylanase-binding module [228] and a xylanase with a cellulose-binding module [229]. A xylanase from a thermophilic bacterium has a binding module for soluble xylans and (1→3;1→4)-β-glucans [230]. The binding module confers thermostability on the enzyme. In cellulases that depolymerize crystalline cellulose, the catalytic domain is connected by a linker peptide to a functionally independent, cellulose-binding module. This module associates very tightly with cellulose microfibril surfaces either in crystalline or non-crystalline areas, depending on the enzyme source, and anchors the associated catalytic domain to the solid substrate thus bringing and maintaining a high local concentration of the enzyme on the cellulose microfibril surface (*Fig. 20* [231]). Removal of the CBM from the catalytic domain results in a significant decrease in the ability to hydrolyze solid substrates.

The smallest CBM, in Family 1, consists of fewer than 40 amino acids and its binding is governed by a planar strip of three tyrosine residues which stack on every second residue of the cellulose chain [232]. The binding is quite tight and not very sensitive to changes in pH but, after replacing two of the tyrosines with histidine by site-directed mutagenesis, binding is still tight but is now pH-sensitive [233], supporting the involvement of the aromatic residues in the binding. A planar binding strip is also a feature of several other CBM families [222]. Some CBMs, in addition to binding the enzyme to the cellulosic surface, appear to disrupt non-covalent interactions between cellulose chains in the crystalline substrate and may potentiate the action of the cellulase [234]. A Family II CBM has been shown to move laterally on the cellulose surface [235] and this may aid in the translocation of the substrate

molecules in the active site in a repetitive action. The CBM of the *Thermomonospora fusca* E4–68 cellulase does not exhibit a planar binding strip topology, but binds to individual chains and is postulated [57] to act in feeding the cellulose substrate into the active site allowing the repetitive (multiple) attack (*Fig. 20*). Non-catalytic, chitin-binding-proteins that adhere to crystalline α-chitin, but not to β-chitin (chitosan), with high affinity, are produced by certain bacteria [236] and the binding involves specific Trp residues. The three-dimensional structure of an isolated starch-binding domain (SBD) from *Aspergillus niger* glucoamylase has been described [221,237,238] and a homologous SBD is seen in the three-dimensional structure of the *Bacillus circulans* CGTase [47]. The SBD is considered to disrupt polysaccharide chain interactions on the starch surface [239] since the release of glucose during solid starch degradation by a proteolyzed form of glucoamylase lacking its SBD is increased by addition of isolated SBD. A mutated SBD from *A. niger* glucoamylase was used to demonstrate that the two binding sites for β-cyclodextrin depend on aromatic residues for function and that they have slightly different binding affinities [238]. Replacement of a CGTase SBD with the one from *A. niger* glucoamylase caused a drastic decrease in activity suggesting that efficient interplay between the binding and catalytic domains is structure-dependent. CGTase has no flexible linker region, as in glucoamylase, but two globular domains connecting the binding and catalytic domains [214,215]. The crystal structure of the SBD of *Bacillus cereus* β-amylase complexed with maltose has been determined [240]. It is homologous to the *A. niger* SBD.
In many cellulose and starch hydrolases with multidomain architecture, highly *O*-glycosylated linker regions connect the catalytic domain and binding and module are considered to provide flexibility in the relative position of the domains on the substrate. The three-dimensional structures of the whole molecules are not known but dynamic light scattering studies of glucoamylase in solution using ligands having a catalytic site ligand, acarbose, connected by spacers of varying length to an SBD ligand, β-cyclodextrin, show that the two domains can come into close contact in solution [241]. Isothermal titration calorimetry indicates that strain is required to accommodate the two target moieties on the two domains in a single molecule of glucoamylase [242].

Adhesion Domains The core of the cellulosome in *Clostridium thermocellum* and *C. cellulolyticum*, is a large (210 kDa in *C. thermocellum*) multidomain, non-enzymic, cellulosome-integrating protein (Cip) (or scaffolding protein, 'scaffoldin'), that binds multiple *endo*-cellulases through high affinity ($K_D = 2.5 \times 10^{-10}$ M) interactions with multiple receptor ('cohesin') domains on the scaffold protein and 'dockerin' domains on the cellulases [243]. The Cip also has a single CBD [222,244]. There is significant synergism in the attack on crystalline cellulose so that the depolymerization of individual cellulose crystals appears to occur completely once attack has been initiated [245].

Other Non-Catalytic Domains. Many polysaccharide depolymerizing enzymes are secreted by bacteria and fungi from their intracellular site of synthesis across the periplasmic space and cell wall into the surroundings. These exported enzymes reach their destination via the general secretory pathway [246] which involves membrane protein complexes such as the bacterial ABC transporters [247] that recognize domains on the secreted proteins. There are several examples of non-catalytic domains on microbial carbohydrases that may play a role in transport from the cells. These include a repeat domain on a chitinase involved

in cell wall/membrane association [248] and cell membrane-associated pullulanase [249]. Fibronectin type III-like repeats found in several microbial carbohydrases may play a role in secretion [250].

Structure-Stability Relationships The thermostability and pH stability of polysaccharide hydrolases and glycosyl transferases vary according to the source. Generally, the enzymes originating from animal, plant, and mesophilic organisms are irreversibly inactivated above about 50 °C. Thermophilic bacteria and archaeans are a source of thermostable polysaccharide hydrolases with stabilities up to 80 °C and exceptionally up to 100 °C; and some of these enzymes are also halotolerant [251,252]. Polysaccharide hydrolases are normally stable in the pH range 4–8 but again there are acidophilic and alkalophilic organisms whose enzymes are stable at lower or higher pH values, respectively. The range of catalytic rate constants and half-lives of the extremophiles makes them candidates for application in industrial processes. Although metal ions do not participate directly in the catalysis by polysaccharide hydrolases, some e. g. a-amylases require Ca^{2+} and Na^{+} for activity [253,254]. One or more Ca^{2+} ions bind to and stabilize certain folding elements that are necessary for maintaining the active conformation of the enzyme. The requirement is usually detected by abstraction of the metal ion with a chelator such as EDTA or EGTA [255].

3 Application of Polysaccharide Depolymerases to Manufacture Bioactive Oligosaccharides

3.1 Manufacture of Nutritional Oligosaccharides

Recent years have seen an increase in interest in oligosaccharides that can play a role in optimizing health (See Chap. 5.3). These include the prebiotic oligosaccharides [256,257] and also oligosaccharides designed to inhibit adhesion of bacteria and toxins to human cells [258,259,260,261]. Whilst synthetic chemistry can manufacture almost any carbohydrate structure, large scale manufacture will probably not be based on traditional chemistry techniques. Most manufacturing technologies for bulk carbohydrates rely on enzymes, mostly polysaccharide depolymerases [262]. Polysaccharides represent a huge resource of chemical structures that can be liberated by enzymes.

A rapidly developing class of functional carbohydrates are the prebiotics (Chap. 5.3). Currently these selectively stimulate health-positive bacteria in the colon [256]. There are, however, possibilities to enhance their functionality. One such functional enhancement would be persistence of the prebiotic fermentation to the distal colon [263]. One way to approach this is to produce oligosaccharide mixtures with controlled molecular weight distributions.

3.1.1 Hydrolysis of Inulin

Inulin is a recognized prebiotic carbohydrate in its own right but is also used as a source of fructo-oligosaccharides by hydrolysis. Inulin, a fructan polymer is widely distributed in plants [264] and chicory (*Cichorium intybus*) is extensively used as a source of inulin for commercial purposes [265]. The roots of chicory contain 15 to 20% inulin and 5 to 10%

oligofructose, low amounts of glucose, fructose and sucrose have also been reported [266]. Inulin derived from chicory has a degree of polymerization of 2 to 60 with an average DP of 12, whereas the oligofructose component has a DP between 2 (F2) to 5 (GF4). A polydisperse carbohydrate, inulin exists as a linear β-(2→1) linked D-fructofuranose terminating in a glucose residue at the reducing end. The demand for fructan type compounds such as inulin and oligofructose is increasing due to the reported physiological benefits conferred on the host when these products are consumed. Such benefits include; modulation of the colonic microflora as inulin has purported prebiotic effects in vivo [256,267], enhances mineral absorption [268,269], modulates either the digestion and/or absorption or the metabolism of lipids [270] and exerts a positive influence on the body's defense mechanisms [265]. Although inulin occurs naturally in many fruits and vegetables, its quantity may be too low to beneficially influence the host, additionally cooking of these foods may influence the amount of inulin subsequently available, thus an attractive approach is the large scale manufacture of inulinoligosaccharides (IOS), a term which can be used interchangeably with fructooligosaccharides (FOS). It must be mentioned that FOS can be produced by one of two methods; (1) the hydrolysis of inulin by endoinulinases and (2) by enzymatic synthesis using sucrose as the substrate and a β-fructosidase possessing transfructosylation activity.

Using inulin as a substrate can yield two very different products depending on the enzyme used. An exo-inulinase (EC 3.2.1.26 β-D-fructofuranoside) is primarily used for the complete hydrolysis of inulin to fructose to produce an ultra high fructose syrup, whereas an endo-inulinase (EC 3.2.1.7 2→1-β-fructan-fructanohydrolase) attacks the internal linkages of inulin to produce oligosaccharides of varying DP. While extensive research is available on the production of fructose syrups there is less literature available on the manufacture of IOS, however this trend is changing due to the realization of the health benefits associated with IOS. Yazawa and Tamura [271] produced IOS through the acid treatment of inulin, although not an enzymatic process, IOS of different DP was produced. Results from a subsequent in vitro study suggested these oligomers of DP4 to 25 were selectively metabolized by *Bifidobacterium infantis*, a beneficial bacteria associated with host well being. Yeast, filamentous fungi and bacteria are all sources of inulinases their properties and applications have been reviewed elsewhere [272,273,274] and it is the action of the endo-inulinases which are of particular interest here. Such enzymes have been isolated from *Aspergillus*, *Pseudomonas* and *Xanthanomonas* sp.

Free enzyme versus immobilized enzyme can influence the yield of IOS, additionally an immobilized system would be favorable economically as the biocatalyst can be reused, enables continuous production and the end product is free of contamination. Kim et al. [275] intended to make a comparison between the reaction kinetics of free and immobilized endo-inulinases in a batch reactor however significant differences were observed in the reaction behavior and product composition due to the form of enzyme used and the initial concentration of substrate. Yun et al. [276] investigated the effect of inulin concentration on the production of IOS by free and immobilized endo-inulinase from *Pseudomonas* sp. Their findings corroborate those of Kim et al. [275] whereby different products are formed depending on the form of enzyme; a soluble enzyme yielded inulobiose and DP3 products, whereby the immobilized form predominantly produced inulobiose. As the concentration of inulin increased the yield of IOS did not increase in the soluble system and in the immobilized the yield remained the same. Although the enzyme was derived from *Pseudomonas* the immobilized form required a differ-

ent optimal pH to the soluble, pH 3.5 as opposed to pH 6, the lower pH resulted in a faster rate of hydrolysis of inulin, in addition a higher quantity of enzyme was used as the effectiveness factor is significantly decreased following immobilization. The yields of IOS produced by the free and immobilized endo-inulinase were 72 and 83%, respectively.

Form of enzyme and concentration of substrate influence the yield and type of IOS produced, however another study by Yun et al. [277] used whole cells of *Escherichia coli* HB101 whereby the gene for an endo-inulinase from *Pseudomonas* sp was expressed. In a batch reactor the production of IOS using the recombinant enzyme was compared to that of the native and there were differences in the DP distribution of the products formed although the yield of IOS was comparable. The native form produced less inulobiose and more DP4 and >DP4 products compared to the recombinant. Additionally Yun et al. [277] studied the effect of different reactor conditions; batch processing versus continuous using immobilized recombinant cells but no differences in product composition were observed.

Nakamura et al. [278] used immobilized endo-inulinase from *Aspergillus niger* in a continuous process to produce IOS. This particular enzyme was isolated from an endo-inulinase hyperproducing mutant 817 from the wild type strain *A. niger* 12 [279] which had previously been used in the production of fructose syrups by complete hydrolysis of inulin. Although the extracellular inulinase was partially purified, exo-inulinase activity remained, albeit at lower levels to the endo type. Various I/S ratios (I = endo-inulinase activity, S = exo-inulinase activity) were investigated (I/S = 4.5, I/S = 25 and I/S = 50) and the higher I/S ratio of 50 at the maximal flow rate of 6.0 ml min^{-1} produced a mixture of oligomers with a DP of 3–5.

Purified and partially purified endo-inulinases from *Aspergillus ficuum* for production of IOS were studied by Zhengyu et al. [280]. The yield of IOS was markedly different depending on the biocatalyst purity, the partially pure endo-inulinase produced an IOS yield of 50%, whereas the purified form produced an IOS yield of 70% in the same operating conditions. The product composition was also different; inulobiose – triose and tetraose where the predominant products of the partially purified form and the DP distribution for the purified enzyme ranged form DP2 to DP8 with relatively high levels of DP3 and DP4. The optimal substrate for the purified endo-inulinase was also determined. Pure inulin, Jerusalem artichoke powder and Jerusalem artichoke juice were used and the latter substrate produced an IOS yield of 80% during a 72-h reaction with a wide DP range (2–8), however no DP 6 was produced. A mixed enzyme system using endo-inulinases from *Xanthanomonos* and *Pseudomonas* sp is an interesting approach in the production of IOS [281].

3.1.2 Partial Hydrolysis of Dextran

Isomalto-oligosaccharides are commercial prebiotics in Japan [257] (Chap. 5.3). These are (1→6)-α-gluco-oligosaccharides with a degree of polymerization of two to five. The low DP means that the commercial product is partially metabolized by humans. Larger oligodextrans would be expected to have lower digestibility and increased colonic persistence. A promising manufacturing route to controlled molecular weight oligodextrans has been proposed using enzyme membrane reactors [282]. Such reactor systems use ultrafiltration membranes to retain enzymes in the system and to control the molecular weight of the product oligosaccharides (*Fig. 21*).

Table 1
Carbohydrate composition (%) of commercially available IMO product [285]

DP*	Components	IMO+
DP1	Glucose	3.8
DP2	Maltose	4.5
	Isomaltose	22.8
	Others**	13.1
DP3	Maltotriose	0.9
	Panose	11.6
	Isomaltotriose	16.7
DP4	Isomaltotetraose and others	17.7
DP5	Isomaltopentaose and others	7.2
≥DP6	Isomaltohexaose and others	1.7

+Isomalt 900® from Showa Sangyo Co. Ltd, Tokyo, Japan. *Denotes degree of polymerization. **Nigerose and kojibiose

In conventional production of IMO, starch is first hydrolyzed to maltooligosaccharides by α-amylase (EC 3.2.1.1) and pullulanase (EC 3.2.1.41). Then, α-glucosidase (EC 3.2.1.20) is added to convert the $\alpha 1 \rightarrow 4$ linked maltooligosaccharide into $\alpha 1 \rightarrow 6$ linked isomaltooligosaccharides. Finally, glucose is removed, giving a maximum IMO concentration of around 40%. About 40% glucose remains in the mixture [283,284]. ❯ *Table 1* [285] lists the composition of a commercial IMO product.

Oligodextran is a collective term used to indicate carbohydrate mixtures derived from dextran. It consists of an IMO part and a dextran part (< 70 kDa) [282], because of the resulting higher DP, oligodextrans are less digestible than IMO [286]. Commercially, they are either produced by acid hydrolysis of the native dextran from *Leuconostoc mesenteroides*, or by direct in vitro synthesis catalyzed by dextransucrase (EC 2.4.1.5) [287,288,289]. The dextran produced by *L. mesenteroides* NRRL B512F consists of 95% $\alpha 1 \rightarrow 6$ bonds, constituting the backbone of the molecule, and 5% side chains attached to the backbone through $\alpha 1 \rightarrow 3$ bonds [289]. Dextranases (1,6-α-D-glucanhydrolases EC 3.2.1.11) belong to the general class of hydrolytic enzymes and their name is derived from their catalytic function of hydrolyzing dextrans. These enzymes are used for the production of isomaltose or higher IMO's.

Dextranases from different sources exhibit diverse action patterns, but fundamentally they specifically hydrolyze the $\alpha(1 \rightarrow 6)$ glucosidic linkages of dextrans to produce primary isomlatose and some D-glucose as final products [290]. They are further divided into two classes, namely endodextranases and exodextranases. Endodextranases catalyze the rapid and random hydrolysis of the dextan $\alpha(1 \rightarrow 6)$ glucosidic linkages, irrespective of the position of these linkages in the dextran molecule (some selectivity exists), whereas endodextranases attack the $\alpha(1 \rightarrow 6)$ glucosidic bonds endwise liberating glucose [291]. The selectivity and limitation of the hydrolytic action of dextranases is attributed to their inability in hydrolyzing the branch linkages of dextrans ($\alpha(1 \rightarrow 3)$ bonds) [292]. In the case of endodextranases presence of excess branch linkages to a dextran molecule constitutes the polysaccharide highly resistant to degradation since the enzyme binding necessary for the hydrolytic action is inhibited [293]. The number of binding subsites of the endodextranases vary between 5–12 and a similar number of continuously $\alpha(1 \rightarrow 6)$ linked glucose residues, without any branch linkages in between are necessary for the attachment to take place [290]. Moreover the $\alpha(1 \rightarrow 6)$ glucosidic linkages in the vicinity of the branch linkages possess a greater degree of resistance towards hydrolysis compared to more distant ones [294]. Endodextranases have been isolated from extracellular fluids or cell extracts of fungi (e. g. *Penicillium funiculosum*, *P. lilacinum*, *Aspergillus carneous* and some of their mutants) and bacterial sources (*Lactobacillus bifidus*, *Cytophaga*, *Pseudomonas)* [292,293,295,296,297,298]. The most commonly used sources of endodextranases are from the Penicillium species in particular *P. funiculosum*, *P. lilacinum*, and *P. notatum* since they exert high enzyme yields and are easily purified [293,295,297].

Endodextranase type enzymes due to their rapid and random hydrolysis of dextrans are of interest for oligosaccharide production. Their inability to hydrolyze the branch linkages of dextrans determines the degree of hydrolysis and consequently gives rise to a variety of products depending on the frequency and the length of these branch points [292]. Bourne et al. [295,299] reported that *P. lilacinum* and *P. funiculosum* dextranses act upon a virtually unbranched dextran and the final products are glucose isomaltose and isomaltotriose with isomaltose being the main product and with the *P. funiculosum* enzyme producing slightly more glucose. Branched dextran hydrolysis results in a greater variety of products, which in the case of *L. mesenteroides* dextran are in the range between tri- to octasaccharide, linear or containing a branch linkage [294,299]. These products of the first hydrolysis can act as substrate for further hydrolysis but as the molecular weight decreases the rate of hydrolysis decreases [294]. In more recent studies [300] it was reported (for dextranse degradation of dextran hydro-gels) that the action of the enzyme could be divided into two steps. In the first step long unsubstituted chains (18 or

more) of glucose residues are hydrolyzed and in the second the hydrolysis products become the substrate for further breakdown. In studies concerning the rate of hydrolysis it was reported that the hydrolysis increases at relatively low substrate concentrations due to decreased viscosity and reduced product inhibition. High enzyme concentrations decreased the hydrolysis efficiency due to increased transglycosylation reactions, and presence of other low molecular weight sugars in the digests did not affect the enzyme activity or the total yield of hydrolysis products [301].

Mountzouris et al. [302] investigated the types of oligodextrans that would be generated via controlled enzymatic depolymerization of dextran using an endodextranase (Dextranase 50 L from *Penicillium lilacinum*). The reaction was carried out in an ultrafiltration stirred-cell membrane reactor fitted with a 10,000 MWCO membrane. It was found that the DE (dextrose equivalent) increased with increasing enzyme concentration and decreasing substrate concentration. At high enzyme concentrations, product DE values ranged from 18–38 and the oligosaccharide content of the products ranged from 27–82% (w/w). The oligosaccharides consisted mainly of isomaltose and isomaltotriose. At medium and low enzyme concentrations, the oligosaccharide yield was lower (30–40%) and the DE values of the oligosaccharides produced were also lower (in the range of 18–22). Anaerobic batch culture fermenters showed that dextran and oligodextrans supported growth of bifidobacteria with high levels of persistence for 48 h [303].

In a later study, Mountzouris et al. [282] investigated the continuous production of oligodextrans in a continuous stirred tank (CSTR) membrane reactor system. Substrate (industrial grade dextran from *Leuconostoc mesenteroides* B 512F) and enzyme were the same as those used previously. Oligodextran yields ranged between 84.4 and 98.7%. DE values ranged from 22–41 and the oligosaccharide content ranged from 55.9 to 93.4% (w/w), which was higher than in the batch membrane reactor. Three types of oligosaccharides with respect to their polysaccharide content were produced: a. < 15%, b. 15–30% and c. > 30% and < 44 %. The oligosaccharide content was found to be affected, not only by substrate and enzyme concentrations, but also by the residence time, higher residence time resulting in products with higher oligosaccharide content. The oligosaccharide content was fairly constant at 21.7–24.8% in all products, DP 4, 7, and 8 being the predominant ones. Isomaltotriose ranged from 21.6 to 35.2% (w/w). The novel oligodextrans generated in this work are expected to have lower digestibility than the already commercially available IMO and to give different physicochemical properties. Tanriseven and Dogan [304] produced IMO by using *L. mesenteroides* B 512 FM dextransucrase immobilized in alginate fibers. The product profile was the following: fructose (20.4%), glucose (21.2%), leucrose (3.8%), DP2 (4.7%), DP3 (5.1%), DP4 (6.6%), DP5 (6.4%), DP6 (5.7%), DP7 (4.4%), DP8 (2.2%), DP9 (2.6%), DP10 and bigger (16.9%). The authors concluded that the use of alginate fibers rather than beads leads to better performance and repetitive use.

3.1.3 Hydrolysis of Xylan to Produce Xylo-Oligosaccharides

XOS are manufactured by enzymatic hydrolysis of xylan from corn cobs, oat spelt xylan or wheat arabinoxylan [257]. Xylan, a principle type of hemicellulose exists as a linear polymer of β-D-xylopyranosyl units linked by 1→4 glycosidic bonds. Depending on the origin, different substituents such as arabinfuranosyl, 4-*O*-methylglucuronosyl and acetyl groups are present. Typical raw materials for XOS production include hardwoods, corn cobs, straws,

bagasses, hulls, malt cakes and bran [305]. Three different approaches exist for production of XOS: 1. enzyme treatment of lignicellulosic material (LCM), 2. chemical fractionation of LCM, with subsequent enzymatic hydrolysis and 3. hydrolytic degradation of xylan by steam, water or dilute acid solutions [305].

In the enzymatic production of XOS, low enzymatic activities are preferable in order to avoid degradation down to monosaccharides, di-, tri- and tetrasaccharides being the required products [305]. The enzyme used for XOS production is an endo-1-4-β-xylanase (1,4-β-D-xylan

Table 2
Summary of xylanase characteristics

Enzyme source	MW	Opt. pH	Opt. T (°C)	Best yield conditions	Products	Yield XOS
P. chyrosporium, G. trabeum, H. sheweinitzii, T. viride	Nd	4.5–5.0	40	Substrate: 1 g of hylglucuronoxylan	Aldotetraouronic acid from *T. viride**	75.7–91.3%
Trichoderma longibrachiatum	37.7 kDa	5.0–6.0	45	Oat spelt	Xylobiose, xylotetraose and higher DP XOSs	Nd
Robillarda sp.	23,400 Da	4.5–5.5	55		Xylobiose	
Irpex lacteus				Xyloglycans and aryl-xylooligosaccharides	1,4-β Glycosidic linkages, or 1,3 and 1,4 β xylosidic linkages	
T. viride				23 g reduced hardwood xylan at 40 °C for 24 h	4-*O*-Methyl-α-D-glucopyranosyl-(1-2)-D-xylotriose and 4-*O*-methyl-α-D-glucopyranosyl-(1-2)-D-xylotetraose	Neutral and acidic products were 13.0 g and 2.1 g, respectively
A. oryzae	Nd	Nd	Nd	Xylan (3 g)	Xylotriose, xylobiose, and xylose	1 g/L each
T. reesei	Nd	Nd	Nd	Unbleached birch kraft pulp, with endoxylanase 40 °C for 24 h at pH 5.5, with β-xylosidase at 40 °C for 24 h at pH 5.5 and then α-glucuronidase for 48 h at 40 °C	Acidic : (4ΔUA)-β-D-xylotetraose, (4ΔUA)-β-D-xylopentaose, (4-*O*-methyl-α-D-glucurono)-β-D-xylotetraose and (4-*O*-methyl-α-D-glucurono)-β-D-xylopentaose Neutral: were D- xylose, β-1,4-D-xylobiose and β-1,4-D-xylotriose	Nd

xylanohydrolase EC 3.2.1.8). This endo- acting enzyme cleaves the glycosidic bonds in the xylan backbone subsequently reducing the degree of polymerization of the substrate. Factors influencing the extent of hydrolysis include chain length, the degree of branching and presence of substituents. Additionally, purity of the enzyme is critical to reduce or prevent complete hydrolysis to xylose by contaminating β-xylosidases. *T. reesei*, *T. harzianum*, *T. viride* and *T. koningii* are known to produce xylanases [306]. *Table 2* lists other reported sources and extensive reviews on xylanases are available [307,308]. Fungal endo xylanases have an activity between 40–80 °C and between pH4–6.5. Extracellular enzymes from *Thermobifida fusca* were successfully used to produce XOS from various lignocellulolytic agricultural waste, however physical pretreatment of the substrate was a prerequisite to expose the xylosidic linkages to enable enzymatic hydrolysis [309]. Although various treatments are used (alkaline extraction, acidic treatment and cooking), for the production of XOS the acidic approach is undesirable as high quantities of xylose may be produced. An endo xylanase from *Aspergillus versicolor* has also been reported for production of XOS using xylan as substrate, interestingly no xylobiose or xylose were detected [310]. Techniques used to characterize the XOS include capillary zone electrophoresis and MALDI-TOF-MS [311].

3.1.4 Partial Hydrolysis of Pectins

Pectins are classified as dietary fiber and are reported to exert a beneficial effect on the gastrointestinal tract of the host (Chap. 5.3), thus the oligosaccharides derived from these may have similar or additional functionalities. Also, the oligosaccharides would be of a lower molecular weight, possibly more soluble than the native pectin as well as less viscous making them more amenable to be incorporated into foodstuffs. The approach of controlled partial hydrolysis applied to dextrans above has also been used to manufacture pectic oligosaccharides [312]. Enzyme membrane reactors were established to hydrolyze high methoxy citrus pectin (60–68% methylation) and low methoxy apple pectin (8% methylation) to low molecular weight oligosaccharides. A commercial endo-polygalacturonase (EC 3.2.1.15) from *Aspergillus pulverulentus* (Pectinas DL "Amano") chosen after screening several available preparations for the absence of pectin methylesterase (EC 3.1.1.11). Conversion to product was dependent on the degree of methylation where higher product conversions were achieved when the apple pectin was used as substrate compared to the citrus pectin. Yamaguchi et al. [313] studied the partial hydrolysis of citrus pectin (75% degree of esterification) using a crude enzyme mix from *Kluyveromyces fragilis*. Although a low molecular weight pectin was formed, the extent of hydrolysis was not comparable to that achieved by Olano-Martin et al. [312] as the molecular weight was 66,000 Daltons compared to the 3500 Dalton product from the continuous hydrolysis of a 60–60% methylated citrus pectin. It has been suggested that the pectins with a high degree of esterification are less susceptible to hydrolysis by endo-polygalacturonases than the pectin esterases, however other parameters such as temperature, enzyme concentration, origin and purity of enzyme, substrate concentration, pH, time and reactor will no doubt also influence the hydrolysis. The functionalities of the products produced by Yamaguchi et al. [313] and Olano-Martin et al. [312] have been investigated in vitro and although results are promising further in vitro studies would be required to substantiate a health claim before clinical trials are performed. The product oligosaccharides were found to have prebiotic potential using in vitro model fermentation systems [314]

and were characterized for their ability to inhibit the adhesion of *E. coli* verocytotoxins to human cells [315]. Lipid accumulation by the liver of rats was repressed, however serum cholesterol was not suggesting the molecular weight of the oligosaccharides could influence this.

3.1.5 Degradation of Bacterial Exopolysaccharide (EPS)

Bacterial EPS are a diverse group of polysaccharides comprised of a wide range of monosaccharide residues such as glucose, galactose and mannose. Historically most attention has been given to the EPS of Gram negative bacteria, particularly those of the various serotypes of *Klebsiella* spp. and *E. coli*, where the EPS carries the K antigenic specificity. Many of these EPS sequences carry potentially bioactive oligosaccharide sequences cryptically encoded in their primary structures. Many recognized receptor-active sequences can be found in these EPS molecules (*Table 3*). Economic methods of hydrolysis and isolation of these sequences would facilitate large scale production of receptor active oligosaccharides for subsequent development into more potent therapeutic derivatives [259,260].

Bacterial EPS tend to be rather refractory to most polysaccharide hydrolases [79]. A promising approach to preparation of oligosaccharides, however, is the use of bacteriophage. Many bacteriophage produce capsular depolymerase enzymes to degrade the EPS capsule and gain access to the bacterial cell surface. These enzymes are capable of reducing the EPS of their host organism to the repeating oligosaccharide unit. Many of these enzymes have been characterized [79,316] and they frequently display a very high degree of specificity for one particular linkage in the EPS sequence. They can either be hydrolases or lyases [79] although deacetylases (carboxylic ester or amide hydrolases) can also be found [317]. These cleave the acetyl substituents from the EPS.

No pure depolymerase enzymes are available commercially, and they have to be isolated from the bacteriophage particles [318]. Bacteriophage may be found in the natural habitat of their host bacteria, for example bacteriophages of the *Enterobacteriaceae* can be isolated from human or animal feces or in sewage [317,319]. It is in the base plate of the bacteriophage where the depolymerase is thought to be located [317]. However, it has also been discovered that in many of the systems studied the enzyme also exists as a soluble protein, found in the cell lysates following viral maturation. Yurewicz [320] has investigated the catalytic and molecular properties of enzyme from each source, finding that both are similar.

The exopolysaccharide can be broken down rapidly or slowly by endo- or exo- acting enzymes respectively. The majority of enzymes investigated to date are endoglycanases and endo- acting polysaccharide lyases [79]. Exceptions to this are the findings by Mishra et al. [321] who identified a polysaccharide which required both endo- and exo- acting enzymes to be degraded. Although phage enzymes are highly specific, it has been observed that some enzymes can act on more than one polysaccharide. Depolymerases from *E. coli* systems have been found to be active against *Aerobacter cloacae* polysaccharide and vice versa [322].

Various parameters need to be considered before performing EPS hydrolysis, namely substrate specificity, temperature, reaction medium, duration, and pH. Carboxyl reduction of EPS [323,324] prior to hydrolysis renders the bacteriophage enzyme inactive against the EPS, even though the polymer structure remains intact. A preliminary indication of the presence of depolymerase activity can be seen by the presence of a translucent halo surrounding the phage

Table 3
List of oligosaccharide repeating units resulting from bacteriophage hydrolysis (modified from Sutherland, 1999). Highlighted linkages represent anti-adhesive sequences

Oligosaccharide	Source
Glc[1]β1→4GlcAβ1→2Rhaα1→3Rhaα1→2Rhaα1→3Gal	Klebsiella K36 EPS

[1]Pyruvylated, [2]acetylated and formylated

plaques on confluent agar cultures of the host organism. In some studies the phage induced enzymes were recovered from cell lysates [323,324] for hydrolysis of the EPS and in others, crude preparations of phage were used [325,326,327]. Different temperatures have been used for EPS hydrolysis, 35 °C [328], 37 °C [323,325,326,329], and 40 °C [318]. The duration of the reaction has also varied. Dutton et al. [326] investigates hydrolysis at 24, 67, and 72 h.
Oligosaccharides prepared using this manufacturing technology can be used in in vitro assays to determine their anti-adhesive properties and might be suitable for anti-adhesion therapy as

they are likely to be non-immunogenic, are of low molecular weight and are soluble [258]. It is hoped that these compounds would be specific for the pathogen to be eliminated, unlike antibiotics which are not as specific, however extensive trials in vitro and in vivo would be required to confirm this.

Abstract

This chapter will give you an overview of recent approaches for drug development, focusing on the function and roles of carbohydrates. ❯ *Section 2* will outline the biochemical functions of polysaccharide (neutral polysaccharide, chitin and chitosan, glycosaminoglycan, and synthetic polysaccharides) and glycopolymers and the perspectives of their medicinal/medical use. ❯ *Section 3* will outline recent biopharmaceutical research and development, utilizing

In: *Glycoscience*. Fraser-Reid B, Tatsuta K, Thiem J (eds)
Chapter-DOI 10-1007/978-3-540-30429-6_61:

the functions of carbohydrates. *Section 4* will outline drug discovery and development of new medicines targeting carbohydrates. In addition, recent advances in carbohydrate synthesis technology, needed for development of new medicines, will also be described.

Keywords

Glycodrug; Carbohydrate; Polysaccharides; Glycoprotein; Biopharmaceutical; Therapeutic antibody; Lysosomal disease; Lectin; Vaccine

Abbreviations

ADCC antibody-dependent cellular cytotoxicity
CHO chinese hamster ovary
DDS drug delivery systems
EPO erythropoietin
FGF fibroblast growth factors

1 Introduction

Technology for carbohydrate synthesis and analysis has been advanced remarkably in recent years. Studies have been actively performed for the purpose of elucidating the properties and importance of carbohydrate which is one of the three major macromolecules existing in the biological body (DNA, protein, and carbohydrate) for the purpose of creating new medicines through such studies. It is known that the carbohydrate not only serves as a source of energy for organisms but also is involved in intercellular signal transduction and immune system through forming complex carbohydrates (carbohydrate bound to protein or lipid). Furthermore, carbohydrate is known to be closely involved in sicknesses such as infection and cancer. For these reasons, research on drug development targeting carbohydrates has been actively performed. In addition, research on development of drug delivery systems (DDS) through attaching carbohydrate to various medicines has been carried out, making use of the unique tissue transfer and host protein-protective function of carbohydrate in vivo. This chapter will outline recent approaches for drug development, focusing on the function and roles of carbohydrates.

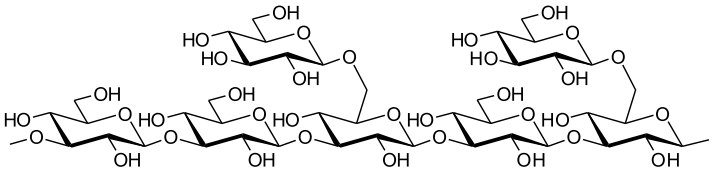
2 Polysaccharide-Based Glycodrugs

2.1 Introduction

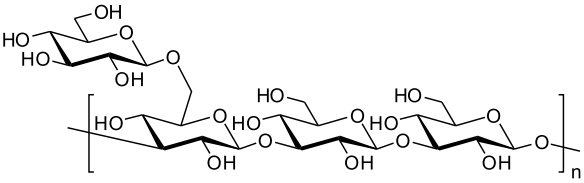
Polysaccharides commonly found in nature (starch, cellulose, mannan, xylan, laminaran, gum, etc.) are playing an important role not only in the food industry but also for use as materials. However, recent research tends to focus on applying these polysaccharides as substances with diverse biochemical functions or medicines. This section will outline the biochemical functions of polysaccharides and synthetic carbohydrate-bound polymers and the perspectives of their medicinal/medical use.

2.2 Neutral Polysaccharides

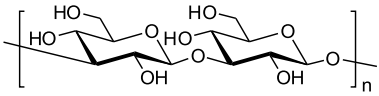
The most famous example of non-specific polysaccharide immunoadjuvants is lentinan isolated from *Lentinus edodes*. Since 1985, lentinan has been used as an antitumor agent. Lentinan is a (1→3)-β-glucopyranan bearing (1→6)-β-glucopyranoside branches (*Scheme 1*). This neutral polysaccharide suppresses the proliferation of sarcoma 180 tumors implanted subcutaneously in mice. Its antitumor activity was due to a host-mediated reaction with participation of thymus or thymus-dependent cells [1]. The lymphokines induced by this polysaccharide enhance the activity of lymphocytes (e. g., macrophages, helper T cells, and/or natural killer cells) in a dramatic manner [2,3,4,5]. Lentinan-like (1→3)-β-glucopyranan (schizophyllan) contained in the insoluble fraction of *Schizophyllum commune* has the structure shown in *Scheme 2* and is known to possess antitumor activity [6].



Scheme 1



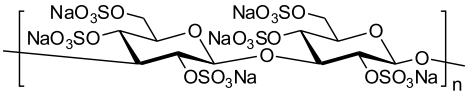
Scheme 2



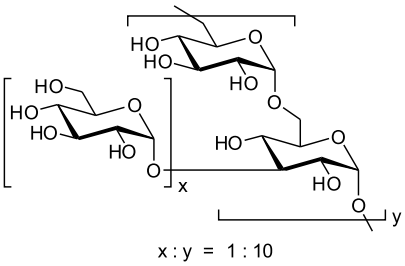
Scheme 3

Curdlan, which is a linear (1→3)-β-D-glucan (*Scheme 3*), also suppresses the proliferation of subcutaneously implanted sarcoma 180 markedly [7]. Curdlan sulfate with a high degree of substitution (*Scheme 4*) is reported to exert strong anti-human immunodeficiency virus (anti-HIV) activity [8,9].

Dextran (*Scheme 5*) solutions have been used as a plasma volume expander since 1947 owing to their non-immunogenic and well-tolerated nature as plasma substitutes [10]. Furthermore, since dextran suppresses erythrocyte aggregation and reduces blood viscosity, it has



Scheme 4

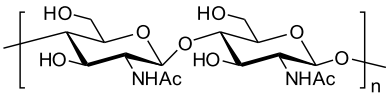


Scheme 5

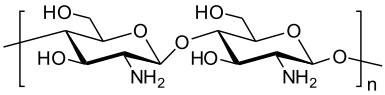
been reported to be useful for improving blood flow [11,12]. Dextran sulfates work as heparin-like anticoagulation agents and it has been reported that dextran sulfates strongly inhibited the replication of human immunodeficiency virus 1 (HIV-1) in vitro [13,14].

2.3 Chitin and Chitosan

Chitin is a cellulose-like (1→4)-β-D-glycan bearing an acetamide functional group at the C2 position of pyranose (*Scheme 6*), and is widely distributed in nature. Although chitin has been reported as a potentially biocompatible molecular material, it has a disadvantage of poor solubility in common organic solvents due to its extremely rigid crystalline structure [15]. Chitosan, derived from chitin by complete *N*-deacetylation under suitable alkaline conditions, has much improved solubility and has been used as a versatile intermediate to prepare a variety of functional derivatives (*Scheme 7*) [16]. Partially *N*-deacetylated chitin and some chitooligosaccharides exhibited significant immunoadjuvant activity in mice [17,18,19]. This finding accelerated the applications of chitin-related compounds in the biomedical and pharmaceutical fields. Immunological investigations on chitin and chitosan provide valuable information pertaining to activation of peritoneal macrophages, suppression of tumor growth and host protection against bacterial infection [20]. Minami et al. reported that when chitin or chitosan was used as a biological filling agent after surgical removal of tumor cells, it allowed rapid formation of granular tissue and remarkable improvement of surgical applications with no side effects [21,22,23].



Scheme 6

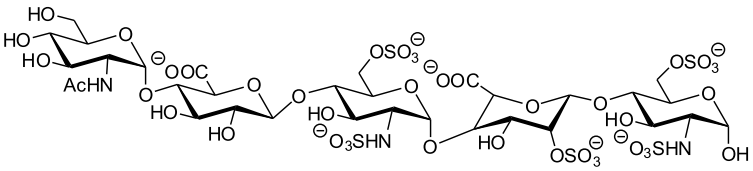


Scheme 7

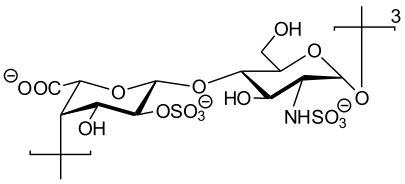
2.4 Glycosaminoglycans

Heparan sulfate proteoglycans, wich contain heparin, are ubiquitously distributed on the cell surface and in extracellular matrix. Interactions between heparan sulfate and various protein ligands are mediated by the specific oligosaccharide structures of polysaccharides (*Scheme 8*, *Scheme 9* and *Scheme 10*). The pentasaccharide sequence of heparin, bound to antithrombin III (AT-III), is a well-known example (*Scheme 8*). This sequence is indispensable for this kind of compound to serve as an anticoagulant clinically used for the prevention and treatment of thromboembolic disease [24]. Basic and acidic fibroblast growth factors (bFGF and aFGF) are known to bind to a dual receptor system composed of heparan sulfate proteoglycans and tyrosine kinase receptors on the cell surface. The binding structure of heparin sulfates with bFGF or aFGF are shown in *Scheme 9* and *Scheme 10*, respectively. Because basic and acidic FGF are additionally involved in the growth of tissue and blood vessels in fetuses, children and adults, and in the ectopic vascularization seen in patients with cancer or diabetic retinopathy, close attention has been paid to heparan sulfate that interacts with FGF. Development of drugs which can control these interactions is expected to cultivate a new dimension of treatment for these diseases [25].

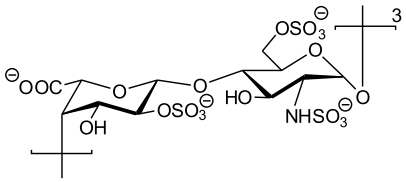
Hyaluronic acid is a non-sulfated and free glycosaminoglycan chain composed of D-glucuronic acid (GlcA) and *N*-acetyl-D-glucosamine (GlcNAc) (*Scheme 11*). Like collagen, fibronectin and heparan sulfate proteoglycan, hyaluronic acid is one of the most important macromolecules found in extracellular matrix. A highly viscous solution containing hyaluronic acid is suited for shock absorbing functions in cartilage. Recently, a high molecular mass



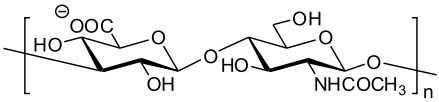
Scheme 8



Scheme 9



Scheme 10

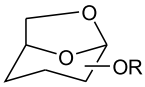


Scheme 11

hyaluronic acid named "Artz" (600,000–1,200,000) was developed as a drug effective for osteoarthritis of the knee and frozen shoulder syndrome. Artz has been shown to protect the articular cartilage, to inhibit unusual emigration of cartilage matrix and to alleviate the severe pain in arthrotic diseases.

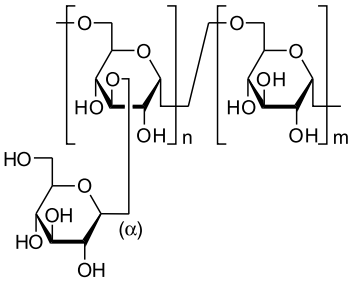
2.5 Synthetic Polysaccharides and Glycopolymers

Chemical synthesis is a promising strategy for creating bioactive polysaccharides and their analogues by utilizing polysaccharides found in nature because chemical synthesis is a powerful method not only for the construction of natural polysaccharides but also for the design of non-natural polysaccharide analogues having tailored biological functions. Polysaccharides and their derivatives can be synthesized if monosaccharides or their derivatives or their promoters are subjected directly to polycondensation reactions in the presence of appropriate condensation reagents. However, this type of synthesis seems to require much labor and time for regioselective protection and deprotection. Ring-opening polymerization of sugar orthoesters or anhydrosugar derivatives represents one of the best methods for the construction of stereoregular polysaccharides with high molecular masses. For example, branched type (1→6)-α-D-glucopyranan with remarkable hypoglycemic activity was synthesized by polymerization of 1,6-anhydrosugar derivative (*Scheme 12*) and subsequent chemoenzymatic manipulations (*Scheme 13*) [26,27]. The versatility of 1,6-anhydrosugar derivatives was demonstrated by the synthesis of a variety of stereoregular and bioactive polysaccharides with high molecular masses. In recent years, a new type of polymerizable glycoside has been often utilized for synthesis of glycopolymers with carbohydrate branches [28]. Glycopolymer obtained from acrylamide glycosides has excellent solubility in water and has been used as ligands of glycosylated proteins such as lectins and glycosyltransferases [29]. Glycopolymers containing sialic acid or sialo-oligosaccharide have been synthesized and used as potent inhibitors of influenza virus infection. Cross-linked glycopolymers and polystyrene-based glycopolymers are suitable for research on cell adhesion, cell culture and designing polymer films and fibers used as virus filters utilizing their specific carbohydrate-protein interaction. Among



R = protective group

Scheme 12



Scheme 13

numerous neoglycoconjugates, glycopolymers are the simplest in design, the most facile of the diverse types and the easiest to synthesize for use in biomedical research and practical utilization.

3 Development of Next-Generation Biopharmaceuticals by Glycoengineering

3.1 Introduction

Many of the proteins found in the biological body have complex carbohydrates. Modification with carbohydrates is increasingly acknowledged as one of the most important "post-translational modifications" determining the fate of the protein, as is the case with phosphorylation. Although the functions of carbohydrates bound to proteins in vivo have not yet been fully clarified, carbohydrates are not a mere decoration but are known to contribute greatly to stabilization of protein structure, improvement in water solubility, and elevation of the degree of diversity and selectivity of bioreactions. In recent years, biopharmaceutical research and development, utilizing the functions of carbohydrates, has been actively carried out. Examples of practical application of the findings from such research are presented briefly in this section.

3.2 Functionalization of Protein-Based Biopharmaceuticals by Glycoengineering

Various bioactive proteins produced by genetic engineering (e. g., recombinant cytokines, hormones, and so on) have already been clinically used. However, these bioactive proteins involve

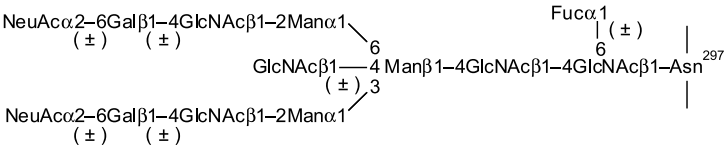
various problems. How to resolve the problems of instability in the biological body and short half-life in blood are important open issues. Carbohydrate modification has recently been attracting close attention as one means of resolving these issues [30].

The most noteworthy example of success in recent years is erythropoietin (EPO), a glycoprotein which stimulates erythrocyte formation. This protein has three *N*-linked carbohydrates and one *O*-linked carbohydrate on its surface. These carbohydrates are indispensable for the stable structure of EPO and expression of its activity in vivo [31]. It has been shown that when the number of *N*-linked carbohydrates was increased from 3 to 5 by recombinant gene technology with CHO cells, derivatives with three times prolonged half-life in blood were obtained [30,32]. The five *N*-linked carbohydrates cover the surface of the protein, making the EPO less likely to bind to receptors but to be retained in blood for longer periods of time, resulting in long-lasting efficacy. The sialic acid at the terminal decreases the clearance of this EPO in the liver and kidney, possibly leading to prolonged half-life in blood.

Attempts at changing the fate of compounds in vivo by means of carbohydrate modification are not confined to EPO. For example, it has been reported that new functional characteristics (e. g., prolonged half-life in blood, improved solubility in water, etc.) can be achieved by attaching carbohydrates to particular positions of compounds, e. g., thrombopoietin with only *O*-linked carbohydrate [32] and insulin without any carbohydrates [33,34]. Thus, carbohydrate modification is being acknowledged as a useful technique for modifying the functions of proteins.

3.3 Functionalization of Antibody-Based Biopharmaceuticals by Glycoengineering

Following recent advances in antibody engineering, it is now possible to synthesize humanized antibodies [35]. Because of clinical applicability, antibody-based medicines are one of the biopharmaceutical categories that have attracted close attention in recent years [36]. IgG has been most frequently used for the prevention and treatment of various diseases. The CH2 region of IgG has *N*-linked carbohydrates (usually complex type double stranded chains) in diverse manners (*Scheme 14*). It has recently been revealed that differences in the carbohydrate structure affect the effecter activity of antibodies such as antibody-dependent cellular cytotoxicity (ADCC) and their half-life in blood, inviting close attention from the viewpoint of improving the responses to antibody-based medicines [37,38,39].



Scheme 14

A noteworthy recent finding is that the ADCC activity of antibodies was elevated more than 100-fold by elimination of fucose from the *N*-linked carbohydrates in the CH2 region [38,39]. This is probably because elimination of fucose elevates the binding affinity of FcγRIIIa

expressed on NK cells serving as a trigger for expression of ADCC activity [40]. Another known approach to improve ADCC activity is modification of the amino acid sequence of the Fc region of antibody [41]. However, when applying this technique, the problem with antigenicity needs to be resolved. Fucose-free antibodies are expected to be highly safe since their structure resembles the one seen in the biological body [42].

There are many unresolved questions over the relationship of carbohydrate structure to antibody activity, kinetics and specificity. However, it is evident that the carbohydrate structure greatly affects the antibody functions. Attempts at improving the functions of antibodies by means of carbohydrate modification are now viewed as valuable from the standpoint of their potential for commercialization [43,44].

3.4 Drug Delivery Systems of Enzyme-Based Biopharmaceuticals Utilizing Carbohydrate Functions

The term "lysosomal disease" is used to indicate a group of genetic diseases involving reduced enzyme activity due to mutation of genes encoding lysosomal enzyme and its related factors and accumulation of the undegraded substrate which should normally be degraded by lysosomal enzyme [45,46]. Enzyme replacement therapy has been introduced clinically for the treatment of this disease [47,48,49]. With this therapy, uptake of lysosomal enzyme by cells is promoted by the binding of the specific carbohydrate (attached to the enzyme) to the carbohydrate receptor on the target cell surface and by the mechanism for transport of the enzyme into lysosomes.

For example, alglucerase (extracted from placenta) and imiglucerase (recombinant type) have been used for the treatment of Gaucher's disease [50,51]. These drugs are glucocerebrosidase which has carbohydrates involving mannose at the termini and targets macrophages [52]. In addition, agalsidase β was developed as an agent for the treatment of Fabry's disease, targeting lysosome [53,54]. Agalsidase β is recombinant α-galactosidase A produced in CHO cells. Its highly sialylated carbohydrates suppress uptake of the drug by the liver, and its uptake into lysosome is enabled in a reliable manner by keeping the mannose-6-phosphoric acid level for the efficient transport of the drug into the target lysosome [55].

As illustrated above, utilization of the targeting function of carbohydrates has enabled efficient enzyme replacement therapy and its clinical application. Efforts are currently being made to develop new technology to ensure adequate amounts of enzymes and to enable the application of this kind of drug to the treatment of lysosome disease complicated by disorders of the central nervous system.

3.5 Recent Advances in Glycoprotein Synthesis

Production systems based on animal cells are usually used for the production of glycoprotein-based biopharmaceuticals. Following advances in genetic recombinant technology, it is now possible to control the site and number of carbohydrate insertion in a highly sophisticated manner, and new-generations of glycoprotein-based biopharmaceuticals with novel functions are being developed one after another. However, production systems based on animal cells involve disadvantages such as difficulty in quality control and relatively high production costs.

These systems have the shortcoming of yielding glycoproteins in which carbohydrates not seen in humans are partially present. Furthermore, these carbohydrates are not homogeneous. To resolve these problems, attempts have been made to develop new glycoprotein production techniques making use of some other cell expression systems [56].

Among the research topics in this field, the most advanced pertains to development of a recombinant protein production system with yeast serving as the host [57]. The carbohydrates of the glycoprotein, produced with yeast serving as the host, are usually the high mannose type which cannot be utilized as medicines because of antigenicity. However, by modifying the yeast genetically to yield a recombinant yeast capable of expressing the enzyme needed for synthesis of human type carbohydrates, it is becoming possible to produce human type glycoprotein and also to introduce sialic acid to the *N*-glycan terminal [58].

Regarding research on topics other than those related to yeast expression systems, Betenbaugh and Lee et al., and Jarvis et al. reported synthesis of proteins with modified human type carbohydrates using insect cells [59,60,61,62]. Abei et al. and Shultz et al. reported innovative techniques allowing synthesis of glycoproteins with *Escherichia coli* serving as the host [63,64,65]. Further advances are expected in these fields of research.

Research involving chemical or enzymatic glycosylation has also been carried out actively [66,67]. For example, reports have been published concerning methods of site-specific glycosylation of proteins, using microbial transglutaminase [33,34,68]. Attempts have also been made to expand the line-up of recombinant glycosyltransferases which can be massively produced, including some examples of success in developing practical protein glycosylation techniques making use of GalNAc transferase or sialic acid transferase or selective PEGylation techniques [69,70,71].

Increasing attention has recently been paid to the chemical synthesis and semisynthesis of glycoproteins making use of the native chemical ligation [72,73] and the expressed protein ligation [81]. In this approach, glycopeptide fragments are first synthesized or biosynthesized as building blocks, then fragment peptides are conjugated by chemoselective reactions to make full-size glycoproteins [74,75,80,82]. One of the limitations of this method is that an *N*-terminal cysteine residue is required for the peptide conjugation, which restricts the target protein sequence. To overcome this limitation, some cysteine-free ligation techniques also have been developed [78,79]. These chemical-based approaches which make it possible to generate homogeneous glycoproteins would be a powerful tool in the research of biological functions of glycoproteins and their applications.

4 Drug Discovery Strategies Focusing on Disease-Related Carbohydrates

4.1 Introduction

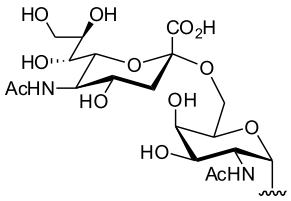
Carbohydrates play important roles in recognition of substances on the cell surface and in transduction of signals. Carbohydrates are involved closely in various diseases such as infection and cancer. For these reasons, increasing efforts have been made to conduct research for drug development, focusing on carbohydrates in the biological body. This section will outline development of new medicines targeting carbohydrates. In addition, recent advances in

carbohydrate synthesis technology, needed for development of new medicines, will also be presented.

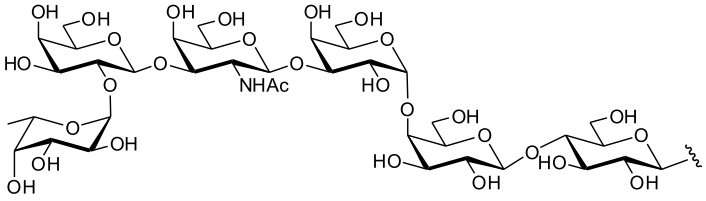
4.2 Drug Discovery Targeting Disease-Related Changes in Carbohydrates

Regarding carbohydrates in the biological body, it is known that the expression level of specific carbohydrates changes in association with the onset of various diseases. It is often unknown whether the change in carbohydrate structure and the onset of disease are both underlying factors or the change in carbohydrate structure induces the symptoms of the disease. However, if the causal relationship between such changes in carbohydrate structure and onset of diseases is clarified and if the condition of individual sick patients is assessed on the basis of changes in carbohydrate for subsequent specific therapy targeting particular carbohydrates, it will be possible to treat these diseases efficiently.

Following carcinogenesis, remarkable changes are noted in the carbohydrates of the superficial layers of cells [83]. Analysis of changes in cell surface carbohydrate during the course of progression and metastasis of tumors will be useful in the diagnosis and treatment of tumors. For example, it has been reported that sialyl Tn antigen (*Scheme 15*), composed of incomplete *O*-linked carbohydrates, showed high expression in various tumors [84]. Following such a finding, efforts have been made to develop a vaccine for cancer targeting the sialyl Tn antigen [85]. Among others, intensive efforts are now made to develop synthetic vaccines composed of sialyl Tn carbohydrates bound to carrier protein KLH for use in the management of metastatic breast cancer and metastatic uterine cancer [86,87]. In addition, various carbohydrate antigens such as glycolipids highly expressed in melanoma cells and globo-H (*Scheme 16*) (a protruding epitope seen in prostate cancer) have been discovered [88,89,90,91], and efforts to develop vaccines based on these antigens have been made.



Scheme 15



Scheme 16

Regarding the metastasizing potentials of tumor cells, close attention is now paid to GlcNAc transferase V (GnT-V) which acts on the branching structure of *N*-linked carbohydrates and form a characteristic carbohydrate structure (β-1,6-GlcNAc chain) [92,93]. GnT-V is highly expressed on cancer with high metastatic potentials. It has been reported that metastasis of cancer was suppressed in GnT-V knockout mice [94]. These findings suggest that GnT-V is associated with the malignancy level of various cancers. If GnT-V can be controlled, suppression of cancer metastasis may be possible. For example, it has been shown at the cellular level that the metastatic potential of cancer was reduced by increasing the expression of GnT-III which competes with GnT-V during carbohydrate synthesis [95,96,97]. Thus, GnT-V seems to serve as a key factor suppressing the metastasis of cancer. It has become a noteworthy target during efforts for drug development.

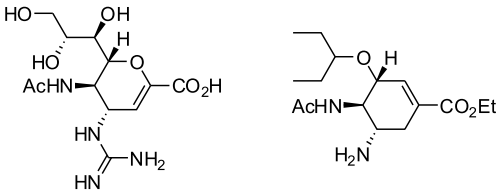
Other than changes in carbohydrates associated with cancers, various carbohydrate changes specific to some particular diseases have been reported, including changes in IgG carbohydrates associated with rheumatoid arthritis [98], abnormal α-dystroglycan carbohydrates associated with muscular dystrophy [99,100,101], and insufficiency of *O*-linked carbohydrates of the hinge region associated with IgG nephropathy [102,103]. Active research has been performed to investigate the causal relationship of these changes to sickness and to develop valid means of treatment. Following recent advances in carbohydrate structure analysis technology, it is now considered important to develop a database of changes in carbohydrates associated with each disease.

4.3 Drug Discovery Targeting Carbohydrate-Lectin Interactions

Numerous reports have been published concerning the attempts of developing drugs targeting interactions between carbohydrates and lectin in vivo. For example, active research has been performed on ligands of selectin (playing an important role in the onset of inflammation) to carbohydrates [104,105,106,107]. It has also been reported that interactions between carbohydrates and lectin are important when viruses and bacteria invade host cells [108]. This section will outline efforts of drug development targeting carbohydrate-lectin interactions, citing research on anti-influenza drugs as an example.

The influenza virus is one of the most extensively studied viruses at present. The influenza virus recognizes sialic acid on the host cell surface, followed by infection and transmission [109]. Two spike-formed proteins (hemagglutinin and neuraminidase) are found on the surface of the influenza virus [110,111]. Hemagglutinin binds to the host cells through recognizing the ligand containing sialic acid on the surface of infected cells, while neuraminidase eliminates sialic acid from the cell surface to avoid inhibition of the transmission of newly formed virus particles.

Because hemagglutinin has a high affinity for the infected cells by the binding of its multivalent binding site to multiple sialic acid molecules, it is not easy to develop low-molecular-weight hemagglutinin inhibitors which can inhibit interactions between hemagglutinin and receptors. To develop inhibitors with high inhibitory activity, research has been carried out to develop clusters of sialic acid derivatives that serve as ligand molecules. For example, reports have been published concerning research on efficiency inhibition of hemagglutinin functions using macromolecules with scaffolds made of synthetic polymers, cyclodextrin, dendrimers,



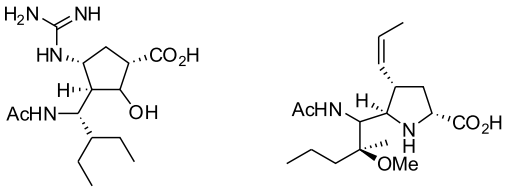
Zanamivir Oseltamivir

Scheme 17

peptides, etc. [112,113,114,115,116]. However, there are many open issues which need to be resolved before developing oral-dose preparations of large ligand molecules.

Neuraminidase inhibitors are a more attractive target of drug development. This is because it is possible to design an inhibitor with a high affinity for neuraminidase by mimicking the transition state seen during fragmentation of sialic acid with neuraminidase [117]. As examples of such neuraminidase inhibitors, zanamivir (a lung administration type drug derived from sialic acid) and oseltamivir (an oral-dose prodrug derived from shikimic acid) have been developed (*Scheme 17*) [118,119], and they have been introduced clinically as remarkable new medicines effective against both type A and B influenza virus. However, species of influenza virus resistant to each of these drugs have appeared. It is still an important issue to develop new anti-influenza drugs [120].

Compounds derived from a cyclopentane or pyrrolidine skeleton have recently been attracting close attention as next-generation neuraminidase inhibitors [121,122,123,124,125], and active efforts have been made for screening of such compounds (*Scheme 18*). Attempts have also been made to prevent virus infection by removing the tracheal sialic acid receptors (the starting point of viral infection) through direct inhalation of sialidase [126].

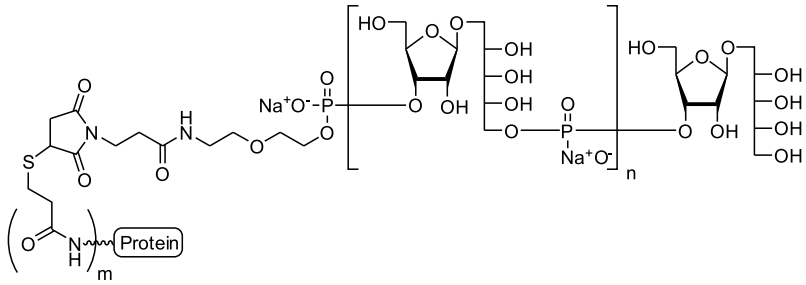


Scheme 18

4.4 Drug Discovery Targeting Carbohydrates of Pathogens

Microorganisms responsible for infection (various bacteria, viruses, protozoan, etc.) often have carbohydrates different from those seen in humans. For this reason, it will be possible to prevent the onset of associated diseases by using drugs targeted at these particular carbohydrates [127]. This section will outline these drugs.

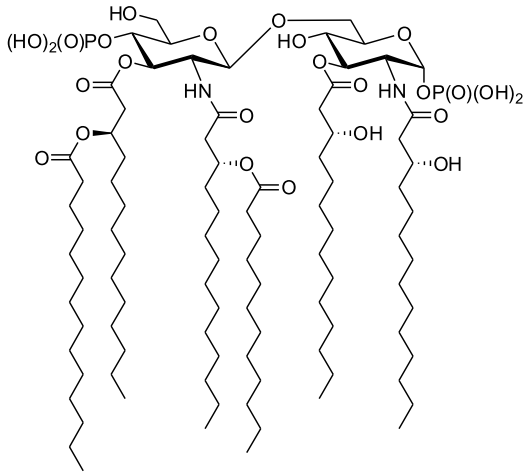
Capsular polysaccharide of bacteria is one of the significant targets for development of vaccines [128]. For example, *Haemophilus influenza* type B (Hib) vaccine, made of a polysaccharide-protein conjugate, is now used worldwide as a highly effective therapy [129]. Verez-



Scheme 19

Bencomo et al. demonstrated that a chemically synthesized Hib vaccine had an activity comparable to that of existing vaccines prepared from Hib polysaccharides and that vaccines based on synthetic complex carbohydrates would be useful (*Scheme 19*) [130]. Their report now serves as a base for establishing similar approaches to the control of other human pathogens.

Pathogenic Gram-negative bacteria have complex glycolipids called lipo-oligosaccharide and lipo-polysaccharide on the tunica external of the cells. These glycolipids also serve as the target for developing vaccines for use in the prevention of infection, similar to those stated above [131]. Meanwhile, lipo-polysaccharides, released as a result of collapse of bacteria can trigger serious inflammation. The skeleton needed for induction of such inflammation is called "Lipid A" (*Scheme 20*), which can induce fever and acute inflammatory reactions (so-called "septic shock") even at a very small amount [132]. In recent years, Lipid A analogues which may be used as antagonists have been explored, toward the goal of developing new drugs for the treatment of sepsis [133,134,135].



E. Coli Lipid A

Scheme 20

Other than the above-mentioned drugs, vaccines targeted at the glycoprotein on the surface of *Staphylococcus aureus* (a Gram-positive bacterium) are now under development [136]. Research on development of drugs targeted at the specific carbohydrates of protozoan parasites [137,138], and viruses such as HIV is also under way [139,140].

4.5 Recent Advances in Carbohydrate Synthesis for Glycodrug Discovery

Carbohydrates assume very complex structures in humans. To understand their diverse functions and apply them as medicines, it is essential to synthesize and evaluate various carbohydrates and complex carbohydrates in a compressive and high throughput manner. In practice, improvement of the synthetic throughput of diverse samples is contributing greatly to advancing genomics and proteomics. Methods of synthesis for establishment of the library of diverse carbohydrate compounds are also being developed.

For example, one-pot synthesis of carbohydrates is a valid means of immediately obtaining various carbohydrates [141]. Among others, the technique of programmable one-pot synthesis developed by Wong et al. allows efficient synthesis by means of quantitative evaluation and programmed control of the reactivity of each building block utilized for glycosylation [142]. The technique of solid-phase synthesis is a method of chemical synthesis with excellent throughputs [143]. Seeberger et al. succeeded in developing an automated synthesis of carbohydrates by utilizing solid-phase synthetic technique [144,145].

Remarkable advances have also been made in the techniques for synthesis making use of enzymes. Enzymatic methods have exerted their high efficacy when various glycoconjugates are synthesized [141]. For example, Thorson et al. developed glycorandomization, a technique by which a library of glycosylated compounds is established through enzymatic reactions from free monosaccharide libraries, using engineered enzymes [146,147]. They have carried out studies, applying this technique to various natural compounds. Nishimura et al. are developing carbohydrate synthesis engineering with glycosyltransferase, using unique substrates bound to water-soluble polymers. Their method is applicable to high throughput synthesis of not only carbohydrates but also glycoconjugates, such as glycolipids and glycopeptides [148,149,150]. The libraries associated with the carbohydrates, prepared in these ways, have been integrated into carbohydrate micro-arrays [151,152], which are now being utilized for screening of new specific carbohydrate antigens and for drug development research towards the goal of vaccine development.

Chapter-DOI 10-1007/978-3-540-30429-6_62:

Abstract

The importance of monosaccharides in chemical biology is now well appreciated and as a result much attention has been placed on the development of new biomedical applications for both monosaccharides and their derivatives. Within this chapter an overview of the biochemistry and medical applications of monosaccharides is presented to introduce the reader to their key applications and highlight opportunities for future developments. Thus, a systematic review of the key monosaccharides that feature within chemical biology and biomedical applications is presented (e. g. pentoses, hexoses, heptoses, aminosaccharides, deoxysaccharides, alditols, uronic and aldulosonic acids, phosphorylated and sulfated monosaccharides) with an emphasis being placed on understanding, predicting, and influencing the interactions of the monosaccharides with biological systems.

Keywords

Monosaccharide complexes; Enzymes; Transporters; Receptors; Metabolic engineering; Monosaccharide mimetics; Diagnosis of malignant diseases; Cancer therapy

Abbreviations

ADP adenosine diphosphate
ATP adenosine triphosphate
cAMP cyclic adenosine monophosphate
cDNA complementary DNA
COG cluster of orthologous groups
Da Dalton
GLUT glucose transporter
K_d apparent dissociation constant
K_m Michaelis constant
NAD nicotinamide adenosine dinucleotide
NADP nicotinamide adenosine dinucleotide phosphate
UCP uncoupling protein
V_{max} maximal velocity of the enzymic reaction

1 Introduction

The aim of this chapter is to discuss the chemical biology and biomedical applications of monosaccharides that occur as important metabolic intermediates, as essential components of various body fluids, and as important biological recognition markers. In these capacities monosaccharides enter into numerous interactions with specific membrane transporters, intracellular enzymes, and carbohydrate receptors, which in turn defines their chemical biology and suggests avenues for important biomedical developments. In particular, the use of monosaccharides in diagnostics and therapies will be discussed herein with emphasis being clearly placed on newly emerging and recently established applications. In general the monosaccha-

rides discussed contain at least five carbon atoms. Although a detailed discussion of monosaccharide chemistry will not be provided herein it should be appreciated that carbohydrates are rich in functional groups and in particular that ring-closed monosaccharides can be considered to contain three principal chemical facets: the reactive hemiacetal hydroxy group, the outer chain of hydrophilic hydroxy side groups, and the inner hydrophobic hydrocarbon core. Additional functionality can be incorporated by introduction of other substituents onto the carbohydrate backbone, for example polar, charged groups such as carboxylic acids, phosphates, or sulfates are often incorporated within biologically significant monosaccharides. A recent review by Kremer and Gallo-Rodriguez that has highlighted the properties and synthesis of naturally occurring monosaccharides is recommended for additional background reading [1]. The roles of carbohydrates as therapeutics and their use in the design of drugs have also been reviewed [2].

2 Ketoses and Aldoses

2.1 Pentoses

The structures of pentoses which occur in nature and enter into interactions 2 with the sensor, transport, enzymatic, and receptor systems are presented in *Fig. 1*.

While both D- and L-arabinose as well as D-xylose occur in Nature mostly as pyranoses in a C1 chair configuration, D-ribose and D-lyxose are found in the furanose forms.

Pentoses are of prime importance for contemporary organisms as structural components of nucleic acids. The existence of the primordial RNA world, in which RNA is suggested to act as a catalyst as well as an informational macromolecule, assumes a large prebiotic source of ribose. Alternatively, the possible existence of pre-RNA molecules with backbones different from ribose phosphate has been considered [3].

Pentoses are important metabolites for microorganisms, many of which can use them as a sole source of carbon and energy. In order to metabolize pentoses efficiently, microorganisms possess specific periplasmic sensory/binding systems for these sugars, which cooperate

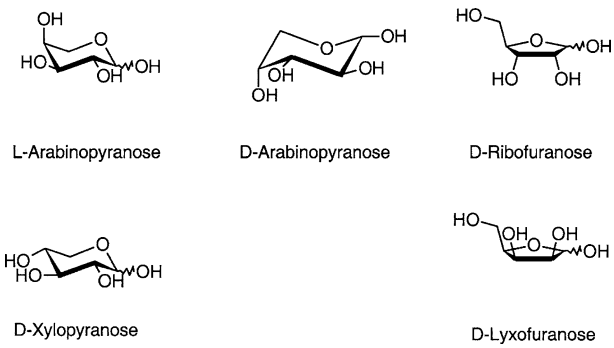

Figure 1
Structures of pentoses in which these monosaccharides interact with the biomolecules of living matter

with pentose/H^+ membrane symporters. Intracellularly, pentoses are converted enzymatically into their phosphate derivatives, and then introduced into the common pool of intracellular metabolites through a series of enzymatic conversions leading to sugars that may eventually enter the pentose phosphate and Entner–Doudoroff pathways. Thus, L-arabinose is converted into L-ribulose by L-arabinose isomerase, and then to L-ribulose 5-phosphate and D-xylulose 5-phosphate by the concerted action of ribulokinase and ribulose 5-phosphate-4-epimerase in order to enter into the intermediary metabolism through reactions of the pentose phosphate cycle. D-Ribose is similarly converted to D-ribose 5-phosphate by ribokinase, which is then isomerized into D-ribulose 5-phosphate by ribose phosphate isomerase, and finally to D-xylulose 5-phosphate by ribulose 5-phosphate-3-epimerase in order to link to the above pathways. The reaction scheme for D-xylose is simple: inside the cell it is converted to D-xylulose by xylose isomerase, and phosphorylated to D-xylulose 5-phosphate by xylulokinase to join once again the above pathway. Microbial metabolism of certain pentoses is more complex; for instance, L-xylulose is intracellularly reduced to xylitol by L-xylulose reductase and then reoxidized to D-xylulose by D-xylulose oxidase. Alternatively, this sugar may also be first phosphorylated by L-xylulokinase to L-xylulose 5-phosphate, which is subsequently epimerized into L-ribulose 5-phosphate by ribulose 5-phosphate-3-epimerase.

In plants and some other eukaryotes, pentoses are components of cell wall polysaccharides such as xylans and arabinogalactans. More interestingly, all "green" forms of life, i. e., those that perform photosynthesis, contain ribulose 1,5-bisphosphate carboxylase/oxygenase (often abbreviated as Rubisco) as the central enzyme involved in carbon dioxide fixation. Consequently, this enzyme has become of interest in numerous genetic engineering projects aimed at the improvement of photosynthesis in agriculturally important plants [4].

In vertebrates, pentoses are poorly metabolized in vivo, and often even decrease the efficiency of utilization when used in combination with other monosaccharides, such as glucose [5,6]. Small amounts of pentoses can apparently be introduced into the metabolism through the activity of intestinal microflora. Thus, interesting isolates of *Clostridium methylpentosum* that ferment only methylpentoses (L-rhamnose and L-fucose) and pentoses (L-lyxose, D-arabinose) have been obtained from the human intestine [7]. However, these reactivities represent quantitatively a negligible capacity when compared to the turnover of other sugars in the intestine. An explanation for this small ability of the vertebrates to utilize pentoses may be found not only in the lack of the specific enzymes of pentose metabolism, but also in the inhibitory effects that pentoses exert upon intestinal sucrase and other hexoses-metabolizing enzymes [8]. The same findings also seem to apply under in vitro conditions, where it has been shown that isolated organs such as the working heart metabolize certain pentoses extremely slowly, and this leads to rapid glycogen depletion and decreases in oxygen consumption [9]. In transformed cells, pentose phosphate pathways are considered to be important in the biochemistry of the tumor proliferation processes because of their role in supplying tumor cells with NADP for intracellular anabolic reactions [10]. Interestingly, the metabolism of pentoses is interlinked with that of glycuronic acids, and ascorbic acid (vitamin C) biosynthesis. Ascorbic acid is readily oxidized into dehydroascorbic acid, and this is dehydrated and decarboxylated into L-xylose. This carbohydrate is subsequently turned into L-xylulose, xylitol, and D-xylulose, which can enter the pentose phosphate cycle after phosphorylation.

2.1.1 Genetics of Pentose Enzymes and Transporters

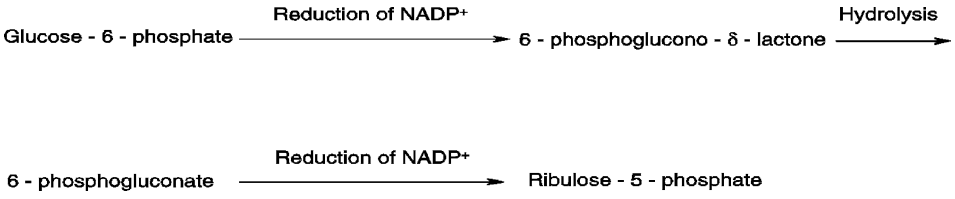
The genetics of certain enzymatic systems responsible for the metabolism of pentoses have been well studied, and the corresponding genes cloned, sequenced, and their position within the genome confirmed during the recent whole genome sequencing initiatives in several microorganisms. Moreover, the clustering of these genes and their protein products into clusters of orthologous groups (COG) of proteins has been performed by the National Center for Biotechnological Information of the NIH for 21 complete genomes representing 17 major phylogenetic lineages. The availability of the complete DNA sequence for several microbial genomes and of the COG assignments has become extremely useful for considerations on the evolutionary perspectives of the most important pentose-specific binding proteins, membrane transporters, and enzymes in prokaryotes and some eukaryotes. A detailed review on the current state of genome sequencing with regard to monosaccharides and glycomics has been published [11].

The metabolism of D-ribose is relatively simple because of its easy link to reactions of the pentose phosphate cycle. D-Ribose is phosphorylated by ribulokinase, an enzyme that is again widely distributed among various organisms except those that are parasites depending on the metabolism of their host: a total of 40 proteins are listed in COG0524.

A wide range of organisms must synthesize pentoses from common hexoses, for which they utilize the pentose phosphate pathway that occurs widely among many prokaryotes and eukaryotes. In an oxidative reaction, glucose 6-phosphate is converted into ribulose 5-phosphate according to (*Eq. 1*).

The pentose phosphate pathway also catalyzes the interconversion of three-, four-, five-, six-, and seven-carbon sugars in a series of non-oxidative reactions. All these reactions occur in the cytosol, and in plants part of the pentose phosphate pathway also participates in the formation of hexoses from CO_2 in photosynthesis. Thus, D-ribulose 5-phosphate can be directly converted into D-ribose 5-phosphate by phosphopentose isomerase, or to D-xylulose 5-phosphate by phosphopentose epimerase. D-Xylulose 5-phosphate can then be combined with D-ribose 5-phosphate to give rise to sedoheptulose 7-phosphate and glyceraldehyde-3-phosphate. This reaction is a transfer of a two-carbon unit catalyzed by transketolase. Both products of this reaction can be further converted into erythrose 4-phosphate and fructose 6-phosphate. The four-carbon sugar phosphate erythrose 4-phosphate can then enter into another transketolase-catalyzed reaction with the D-xylulose 5-phosphate to form glyceraldehyde 3-phosphate and fructose 6-phosphate, both of which can finally enter glycolysis.

Some eukaryotes are unable to assimilate pentoses efficiently. For instance, the yeast *Saccharomyces cerevisiae* cannot metabolize D-xylose, although four strains were found to utilize



Equation 1

small amounts of xylose aerobically in the presence of a mixture of other facilitating substrates [12]. When [^{14}C]-xylose was utilized in the presence of ribose under anaerobic conditions, the radioactive label was detected mainly in xylitol, but no label in ethanol was found. Under aerobic conditions the radioactive label was distributed between xylitol (91.3%), CO_2 (2.6%), and biomass (1.7%); no other metabolic products were detected [12].

In those organisms that perform photosynthesis, further phosphorylation of D-ribulose 5-phosphate into D-ribulose 1,5-diphosphate by phosphoribulokinase represents an important prerequisite in CO_2 fixation. As has already been mentioned, the key and extensively studied enzyme involved in this reaction is D-ribulose 1,5-bisphosphate carboxylase/oxygenase. The subfamily divergence in this multigene family has been studied in certain plants of Triticeae and other families [13]. The occurrence of this enzyme in anoxic Archaea is very interesting, since it had to evolve in the absence of molecular oxygen [14].

In vertebrates, pentoses and their derivatives are known to cause hepatic ATP catabolism by trapping the inorganic phosphate in the form of glycerol 3-phosphate as a consequence of an increase in the NADH/NAD$^+$ ratio. In isolated rat hepatocytes, 5 mM D-xylulose decreased ATP by 80% and the intracellular phosphate by 70% within 5 min [15]. D-Xylulose increased the concentration of D-xylulose 5-phosphate approximately 25-fold in 5 min. However, the main cause of the depletion of ATP and inorganic phosphate in these cells was the dramatic increase (approximately 50-fold) in the concentration of seduheptulose 7-phosphate in 10 min. The D-ribose 5-phosphate concentration increased approximately 15-fold [15]. Xylulose 5-phosphate was found to be an important regulator of several metabolic pathways in rats, including the hepatic expression of glucose 6-phosphatase and phosphoenol pyruvate carboxykinase [16], regulation of L-type pyruvate kinase through the glucose response element [17], and inhibition of glucose utilization in liver by fatty acids [18].

2.1.2 Structural Investigations of Pentose Enzymes, Transporters and Receptors

Molecular details beyond those found by classical enzymology are rapidly becoming available from structural studies, and these should allow a better understanding of the nature of binding and catalytic activities of the various enzymes, membrane transporters, and receptor proteins. Along these lines of research, periplasmic carbohydrate-binding proteins have been studied in particular detail. The periplasmic arabinose-binding protein (*araF* gene product) of *Escherichia coli* has been extensively characterized by X-ray crystallography and directed mutagenesis by Quiocho's group. The structure of this protein complexed with L-arabinose molecule (in the $^4C_1$ pyranose chair conformation) has been solved by high-resolution protein crystallography [19]. The sugar molecule is buried in the cleft between the two lobes of this bilobate protein. All sugar hydroxy groups are hydrogen-bonded to side-chain residues: beta-OH to Lys_{10} and Asp_{90}, 2-OH to Lys_{10}, 3-OH to Glu_{14} and Asn_{205}, and 4-OH to Asn_{232}. Interestingly, Lys_{10}, Glu_{14}, and Asp_{90} are associated with one domain of the protein, while Asn_{205} and Asn_{232} are in the second lobe (*Fig. 2*).

Structural changes in the protein accompany binding, as indicated by the inaccessibility of the bound L-arabinose to the aqueous environment [19]. Interestingly, unlike many other carbohydrate binding proteins that display a strict anomeric selectivity, α-L-arabinose can be equally well accommodated in the carbohydrate-binding site of this protein. In this case, however, only

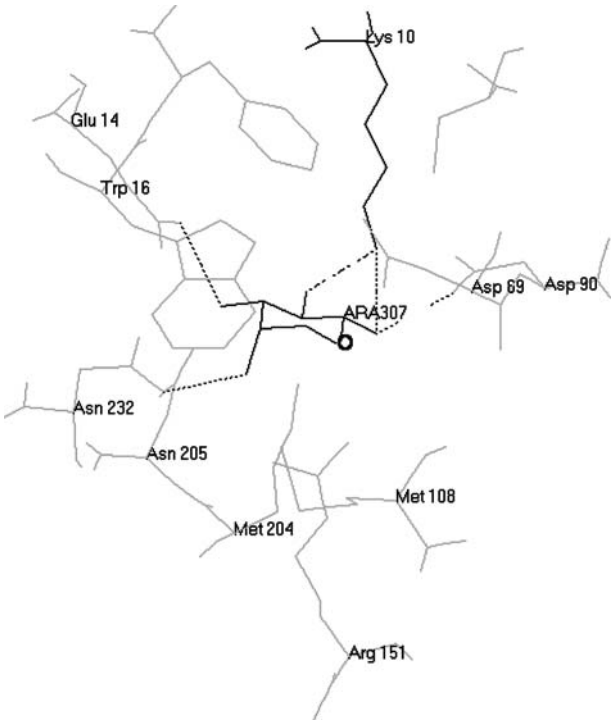


Figure 2
Arabinose binding protein in complex with β-L-arabinose (ARA)

a single hydrogen bond between the anomeric hydroxyl group and the aspartic acid D90 of the protein may be formed (*Fig. 3*).

L-Arabinose isomerase has been purified from *Escherichia coli*. The enzyme catalyzes the isomerization of L-arabinose to L-ribulose by a proton transfer mechanism in contrast to xylose isomerase which uses a hydride transfer mechanism to perform a similar isomerization [20]. This enzyme has high substrate specificity for L-arabinose, and its catalytic activity is dependent on manganese(II). It has been shown, however, that the enzyme could catalyze the exchange of the proton attached to C2 of arabinose with the solvent even in the absence of metal ion [20].

The periplasmic binding proteins for D-ribose and L-glucose/L-galactose of Gram-negative bacteria compete for a common inner membrane receptor in bacterial chemotaxis, and are the essential primary receptors for their respective membrane transport systems. The comparison of the high resolution structures of the periplasmic receptors for ribose (from *E. coli*) and glucose or galactose (from both *E. coli* and *Salmonella typhimurium*) highlights the features of these proteins important in their dual functions. Many structural features including some hydrophobic core interactions, a buried aspartate residue, and several unusual turns are conserved between the two proteins. The ribose receptor adopts the most closed structure, while the *Salmonella* glucose-galactose receptor has the most open structure [21]. The X-ray struc-

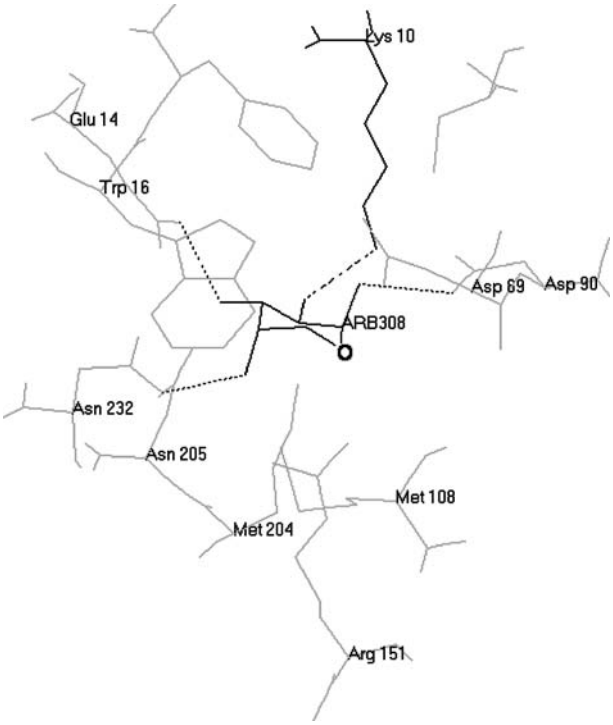

Figure 3
Arabinose binding protein with α-L-arabinose (ARB)

ture of the periplasmic ribose-binding protein from *E. coli* was solved at 3 Å resolution by the method of multiple isomorphous replacement. The protein consists of two highly similar structural domains, each of which is composed of a core of parallel β-sheets flanked on both sides by α-helices. The two domains are related to each other by an almost perfect two-fold axis of rotation, with the C termini of the β-strands of each sheet pointing toward the center of the molecule. Three short stretches of amino acid chain link these two domains, and presumably act as a hinge to allow relative movement of the domains in functionally important conformational changes. The ligand β-D-ribose is bound between the domains in its pyranose form, held by interactions with side-chains of the interior loops. The binding site is precisely tailored, with a combination of hydrogen bonding, hydrophobic and steric effects giving rise to tight binding (0.1 µM for ribose) and high specificity. Four out of seven binding-site residues are charged (2 each of aspartate and arginine) and contribute two hydrogen bonds each. The remaining hydrogen bonds are contributed by asparagine and glutamine residues. Three phenylalanine residues supply the hydrophobic component, packing against both faces of the sugar molecule [21].

The kinetic intermediates in the folding of ribose-binding protein have been examined by fluorescence spectroscopy in protein possessing of the engineered tyrosine residues [22]. The conformational changes of the ribose-binding protein upon the binding of sugar were inves-

tigated using small-angle X-ray scattering experiments. The monomeric form of the protein decreased in radius of gyration upon ligand binding. While the closed form of the protein is stabilized by the protein-sugar interaction, the open conformation is stable due to close contacts between the two domains [22].

2.1.3 Biomedicine

The use of pentoses and other monosaccharides in biomedicine should be based on utilizing the chemical biology of individual compounds and their derivatives as described in the preceding section. Although this is certainly true in a good number of examples, many other instances of the practical use of pentoses are still largely based on empirical observations.

Some important biomedical implications of pentoses are based on the "non-specific" reactivity of the reducing hemiacetal group with proteins and other macromolecular components of living systems. The identification of pentosidine (imidazo[4,5-*b*]pyridinium) molecules synthesized through cross-linking of lysines and arginines in aged proteins by some pentoses (arabinose, lyxose, ribose, xylose) raised new questions concerning the role of pentoses in the ageing process [23]. Pentoses have been shown to participate in the formation of the advanced glycation end-products in collagen [24] and in rat liver histone octamers [25].

Biotypes of *Burkholderia pseudomallei*, a free-living organism causing the potentially lethal tropical infection melioidosis endemic in many parts of eastern Asia and northern Australia, can be distinguished based on their ability to assimilate L-arabinose. Whereas some soil isolated specimens can utilize this substrate, all clinical isolates tested so far could not. In addition to a cultivation test, the arabinose-negative clinical isolates can be diagnosed using a monoclonal antibody reacting with a high-molecular mass component expressed specifically only in L-arabinose minus strains [26]. A marked increase in the urinary secretion of arabinose and analogues of Kreb's cycle metabolites was observed in two brothers with autistic features (autism is a psychological disorder characterized by daydreaming hallucinations and disregard of external reality) [27].

Synthetic arabinose derivatives have recently shown promise as antimycobacterial, antiviral, and antithrombotic agents. Thus, a series of hydrolytically stable aza analogues of arabinofuranose was prepared, and evaluated as agents against *Mycobacterium tuberculosis* and *Mycobacterium avis.* The compounds were designed to mimic the putative arabinose donor (1-β-D-arabinofuranosyl decaprenol-1-phosphate) involved in the biogenesis of the essential cell wall polysaccharide, arabinogalactan (● *Fig. 4*). One of the synthesized compounds showed significant antimycobacterial activity in infected macrophage models [28].

1-β-D-Arabinofuranosylthymine and its 2,2′-anhydro derivative are potent anti-herpes simplex drugs. The three-dimensional crystal structure of 2,2′-anhydro-1-β-D-arabinofuranosylthymine revealed a rigid structure with the arabinose ring in the unusual O1′-*endo*-pucker conformation [29]. 4-Cyanophenyl- and 4-nitrophenyl-1,5-dithio-L- and -D-arabinopyranoside derivatives showed oral antithrombic effects in rats higher than beciparcil used as the reference compound ● *Fig. 5* [30].

Oligonucleotides containing 2′-deoxy-2′-fluoro-D-arabinose or -D-ribose form stable, triple-helical complexes stabilized by the intermolecular 2′-OH phosphate contacts and sugar puckering: these derivatives have promoted interest in relation to compounds synthesized for DNA targeting in vivo ● *Fig. 6* [31].

D-Lyxose, an epimer of D-arabinose rarely found in Nature, has been identified as an important component of the glycolipid adhesion receptors for mycobacteriophages, and the derivatives of this monosaccharide are currently used to evaluate the precise structural requirements for the attachment of the mycobacteriophage to the cell wall of its host [32]. Derivatives of α-nucleotides of D- and L-lyxofuranosylbenzimidazoles and ribofuranosylbenzimidazoles have been evaluated as antiviral agents *Fig. 7* [33].

In relation to the participation of ribose in ribonucleotides, experiments with oral or intravenous administration of this monosaccharide to patients with myoadenylate deaminase

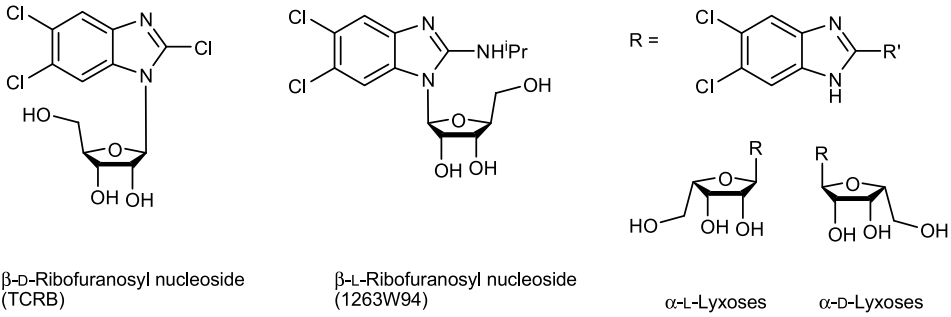

Figure 7
Antiviral agents

deficiency were performed: it appeared that the sugar may serve both as an energy source and as the stimulant of de novo synthesis of purine nucleotides [34]. Oral administration of 10 mmol/kg/day of D-ribose to patients with an inherited deficit of adenylosuccinase displaying severe psychomotor retardation and epilepsy resulted in improved behavior and a progressive reduction of seizure frequency [35].

D-Ribose has been added to the solutions used for the preservation of heart transplants since it maintains high levels of ATP and other high energy phosphates in these organs [36]. Infusion of ribose facilitates the redistribution of ^{201}Tl used in the diagnosis of coronary artery disease [37]. This effect is especially dramatic during the early imaging as compared with the late, 24 h imaging [37].

A xylose breath test has found usage for the diagnosis of small bowel bacterial overgrowth. These are performed with ^{13}C or ^{14}C techniques, and have been found to predict reliably small-bowel bacterial overgrowth in susceptible children [38,39].

Essential pentosuria is a metabolic condition characterized by deficiency in the major isoform of L-xylulose reductases in human tissues; homozygote individuals have only a residual activity of the enzyme [40], and thus excrete large concentrations of L-xylulose into urine. A minimum estimate of the frequency of the pentosuria allele in an Ashkenazi-Jewish population is 0.0127 [41]. This metabolic disease is absolutely harmless, especially because the specific and selective analytical techniques in use in modern diabetology should prevent a false positive diagnosis in essential pentosuria patients.

2.2 Hexoses

The predominant structures in which hexoses exert their biological activities are highlighted in *Fig. 8*. Hexoses most often found in biological systems, such as D-glucose, D-galactose, and D-mannose, are mostly observed in their cyclic pyranosyl forms (chair conformations).

Hexoses are monosaccharides of central importance in Nature since they are often the sole or the most important single source of easily available energy and feature as sources of carbon building blocks in a wide range of metabolic pathways. The origin of elementary hexoses during the chemical evolution has been proposed to occur according to a five-stage scenario [42].

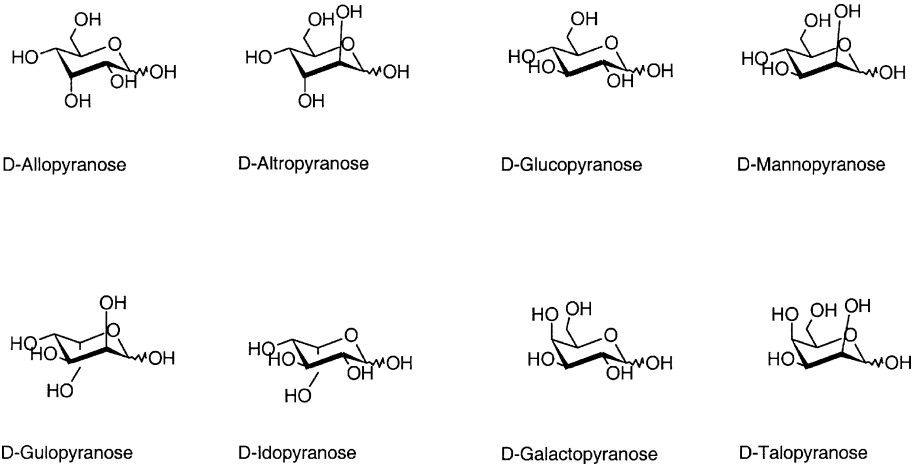

Figure 8
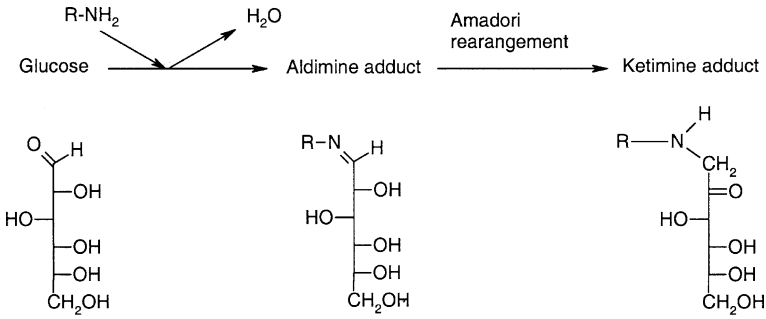
Structures of hexoses in which these monosaccharides interact with the biomolecules of living matter

The utilization of galactose as a key recognition molecule (based on its distinctive axial C4 hydroxy group [43], and its outermost location in glycoconjugates) may have evolved rather late, concomitantly with the evolution of multicellular organisms [44]. A possible scenario on the origin of saccharides and an investigation of saccharide structures, classic glycochemical reactions and biosynthetic features of monosaccharides, has been recently reviewed. In this hypothesis, fructose, glucose and mannose are the saccharides having been generated before the birth of life, whereas the others are characterized as "late-comer" saccharides as a result of the development of metabolism [45].

Glucose is clearly the most important single hexose and the most abundant of all monosaccharides and indeed the most abundant organic molecule on the planet. This unique feature of D-glucose is probably related to its chemical reactivity with proteins, which is thought to be the lowest of all the hexoses. Hence, it shows a minimal tendency to form glycation products with the reactive amino acid side-chains of proteins. On the other hand, glucose derivatives are formed under non-physiologically high concentrations of glucose by a mechanism involving the formation of Schiff-base adducts composed primarily of the ε-amino groups of lysyl residues in proteins and glucose, followed by Amadori rearrangement leading to more stable ketimine adducts shown in (*Eq. 2*).

Recently, the rapid preparation of carbohydrates has been facilitated by a synthetic route based on aldol coupling of three aldehydes used for the de novo production of polyol differentiated hexoses in only two chemical steps. The dimerization of alpha-oxyaldehydes, catalyzed by L-proline, is followed by a tandem Mukaiyama aldol addition-cyclization step catalyzed by a Lewis acid. Differentially protected glucose, allose, and mannose stereoisomers can each be selected, in high yield [46]. Microwave irradiation is becoming an increasingly popular method of carbohydrate synthesis and has been the subject of a recent review [47].

Hexoses play a central role in the carbohydrate metabolism in a large number of organisms. *Scheme 1* provides a basic summary allowing one to understand the central position of hexoses, and D-glucose in particular, in the intermediary metabolism.



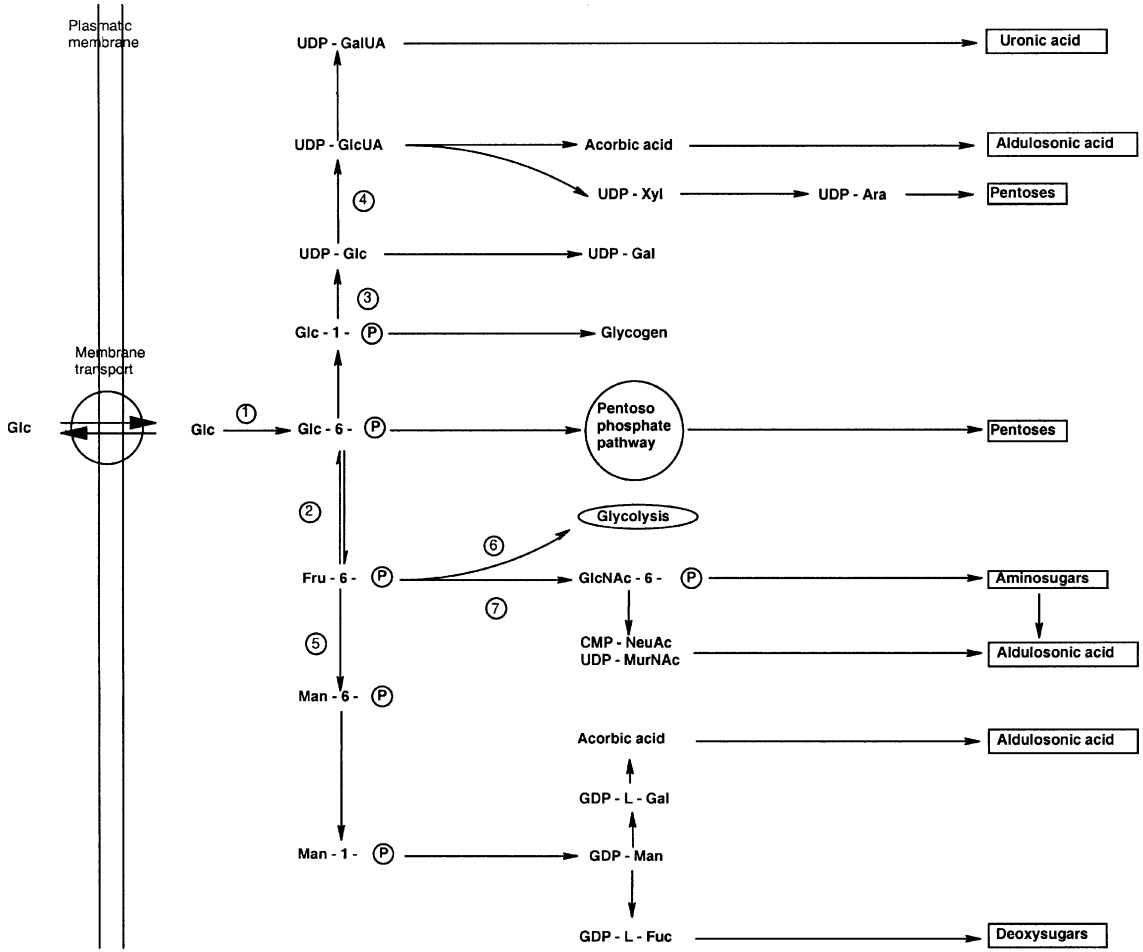
Equation 2

In many higher eukaryotes, including humans, glucose represents an important source of readily available energy for many cells, notable for cells of the nervous system. The concentration of glucose in the blood and other body fluids is thus under a tight control of hormonal and nervous regulatory circuits. The blood glucose level in a healthy person after an overnight fast is around 4.4 mmol L^{-1}, and during the day usually ranges from 4.4 to 6.6 mmol L^{-1}. The blood glucose level is controlled primarily by the liver, which can take up or release large amounts of glucose in response to hormonal signals and the level of glucose itself. Glucose is the sole fuel for the brain, except during prolonged starvation when it is replaced by ketone substances. In the resting state, the brain accounts for up to 60% of the utilization of glucose by the whole body. Non-invasive ^{13}C-NMR measurements have shown that, due to the existence of the well known blood-brain barrier, the concentration of glucose in the brain is about 1 mmol L^{-1} when the plasma level is 4.7 mmol L^{-1}. However, when the plasma level of glucose drops down below 2.2 mmol L^{-1} during hypoglycemia, the glucose concentration in the brain can approach the K_m of hexokinase (approximately 0.05 mmol L^{-1}) leading to a significant slow down in the rate of glycolysis.

Unlike the liver, muscles cannot produce glucose due to the lack of glucose 6-phosphatase. Therefore, they retain glucose from the blood supply as fuel. Since the rate of glycolysis in the actively contracting muscle far exceeds that of the citric acid cycle, part of the pyruvate is converted into lactate and alanine; these compounds are then rebuilt into glucose in liver. Since the adipose tissue is not able to phosphorylate endogenous glycerol because of the lack of a specific kinase, it needs glucose for the synthesis of triacylglycerols.

As opposed to D-hexoses, the role of L-hexoses in the metabolism of vertebrates has been the subject of much dispute. It became obvious from recent studies that only some L-sugars such as L-fructose or L-gulose can make an appreciable contribution to the metabolism, while some others such as L-glucose cannot [48]. Similarly to the situation with pentoses, microorganisms residing in the large intestine are thought to be mainly responsible for the uptake and utilization of these carbohydrates.

Intracellular hexose-specific receptors have been tightly linked with the processes of refolding and intracellular targeting of glycoproteins. Proteins are glycosylated cotranslationally immediately after their passage into the cisternae of the endoplasmic reticulum by *en bloc* transfer of the entire oligosaccharide precursor containing two moles of *N*-acetyl-D-glucosamine,



Scheme 1
Central role of hexoses in the intermediary metabolism of the monosaccharides. Individual reactions are catalyzed by the following enzymes: 1, glucokinase; 2, glucose 6-phosphate isomerase; 3, UTP:glucose 1-phosphate uridyltransferase; 4, UDP-glucose dehydrogenase; 5, mannose 6-phosphate isomerase; 6, phospofructokinase; 7, glutamine:fructose 6-phosphate amidotransferase

nine moles of mannose, and three moles of glucose. Two of these three terminally positioned glucoses are cleaved off soon after glycosylation, but the third glucose is used by the endoplasmic reticulum chaperones calreticulin (soluble) and calnexin (membrane-bound) to bind the partially folded glycoprotein, and assist in its correct folding [49,50]. Completely folded glycoproteins are then fully deglucosylated, and leave the endoplasmic reticulum. Folded glycoproteins seem to interact with the two chaperones to different extents, depending on the nature of the particular (glyco)protein [51].

The role of hexoses in eukaryotic organisms goes beyond their metabolic and structural functions, because they are seminal in the biological recognition phenomena as well. Hexose-specific receptors are crucial for the adherence of microbes to eukaryotic cells, uptake of aged serum glycoproteins, antigen phagocytosis, presentation to the cells of the immune system, and complement activation by bacteria. Mannose is the hexose that often features prominently in these reactions of the innate immune systems, since it is abundantly expressed at the surface of microbes, but only rarely occurs in structures of any of the various eukaryotic glycoconjugates. Antibodies against certain hexoses such as galactose are the most abundant natural auto-antibodies, and thus represent major concerns in transplantation immunology, especially in relation to the use of xenotransplants.

2.2.1 Structural Investigations of Hexose Enzymes, Receptors and Transporters

The structure of the D-allose binding protein from *Escherichia coli* (AlsB) bound to D-allose has been solved at 1.8 Å resolution using the molecular replacement method. As in other members of this family, especially the ribose-binding protein, with which the allose-binding protein shares 35% sequence identity, the structure consists of two similar domains joined by a three-stranded hinge region [52]. The protein exists in solution in a dynamic equilibrium of closed and open conformations which is an important part of its function. In the closed, ligand-bound form, D-allose is buried at the domain interface. Only the β-anomer of allopyranose is seen in the crystal structure, although the α-anomer can potentially bind with a similar affinity. Extensive hydrogen bonding as well as hydrophobic interactions are found to be important for the specific binding; altogether 10 residues from both the domains form 14 hydrogen bonds with the sugar. In addition, three aromatic rings, one from each domain with faces parallel to the plane of the sugar ring and a third perpendicular to this plane make up hydrophobic stacking surfaces for the ring hydrogen atoms. These results indicate that the aromatic rings forming the sugar binding cleft can sterically block the binding of any hexose epimer except D-allose, 6-deoxy-D-allose, or 3-deoxy-D-glucose; the latter two are expected to bind with reduced affinity due to the loss of some hydrogen bonds. However, the pyranose form of the pentose D-ribose can also fit into the allose-binding protein cleft, allowing this protein to function as a low affinity transporter for D-ribose as well [52].

The D-glucose/D-galactose-binding protein of 33 kDa found in the periplasm of bacterial cells serves as the primary high-affinity receptor for active transport, and as the receptor mediating chemotaxis towards both sugar epimers. The protein from *Escherichia coli* bindsD-glucose with $K_d = 2 \times 10^{-7}$ M, and binding of D-glucose is about two-fold tighter than binding of D-galactose. The crystal structures of both complexes refined to 2.0 Å resolution provide an understanding of the chemistry of the recognition of both monosaccharides in atomic detail [53,54]. In the two complex structures, the sugar ring is positioned identically in the

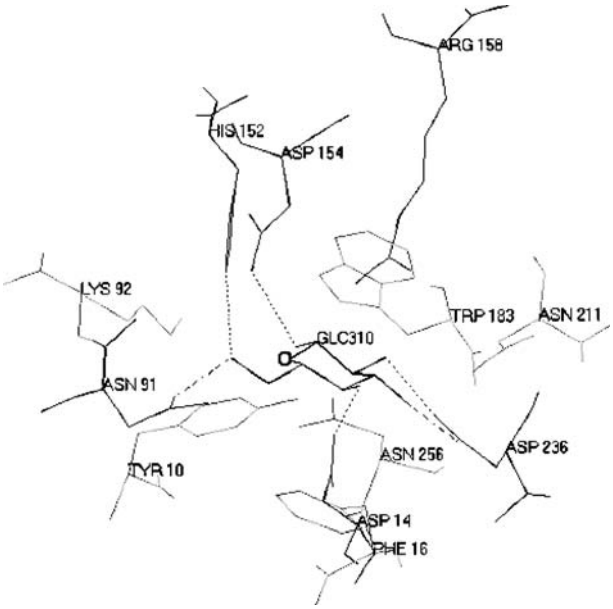


Figure 9
D-Galactose/D-glucose binding protein complexed with β-D-glucose (Glc)

binding site, and each hydroxy group common to both monosaccharides is involved in very similar cooperative hydrogen-bonding interaction with protein residues and ordered water molecules. Only the β-anomer of both monosaccharides is bound, and aspartic acid D154 is primarily responsible for accepting a hydrogen bond from the anomeric hydroxy group (*Fig. 9*).

Recognition of both sugar epimers is accomplished primarily by hydrogen bonding of D14 through an OD1 interaction with the equatorial OH-4 of D-glucose, or through the OD2 interaction with the axial OH-4 of D-galactose (see *Fig. 6*). Bacterial periplasmic binding proteins for L-arabinose, D-ribose, and D-glucose/D-galactose show noticeable similarities at the level of their three-dimensional structures, despite the lack of the obvious similarities in their primary structures [55]. All three binding proteins, which may have diverged from a common ancestor, serve as the primary receptors for bacterial high-affinity sugar transport systems. Many of the conserved residues reside in the binding site located in the cleft between the two lobes of these proteins. Moreover, D-ribose-binding protein and D-glucose/D-galactose-binding proteins also serve as receptors for chemotaxis. An exposed site located in one domain and including G_{74} is responsible for interaction with the trg transmembrane signal transducer thus triggering chemotaxis through the two respective monosaccharide-binding proteins. This site, together with the one proven to exist in the other domain of the protein, could be used by the signal transducer with which both binding proteins interact in such a way that it allows discrimination between the substrate-loaded "closed cleft" structure and the unligated "open cleft" conformation structures [55].

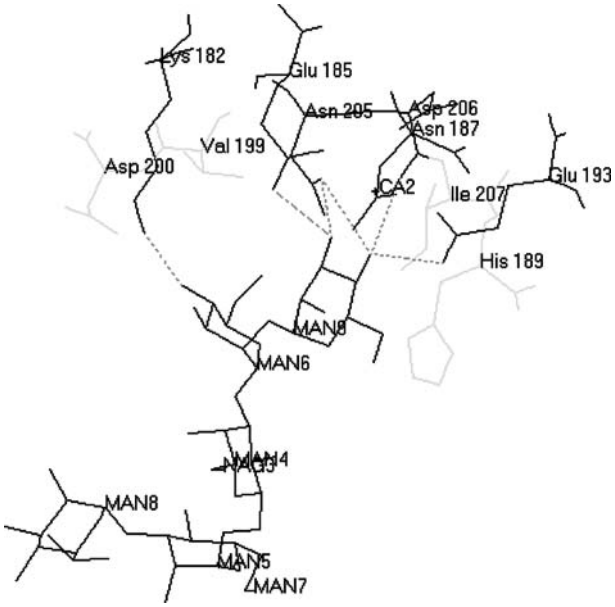

Figure 10
Mannose-binding protein A (lectin domain) complexed with Ca^{2+}(CA) and glucopeptide (MAN: mannose, NAG: *N*-acetylgalactosamine)

The crystal structure of human hexokinase in complex with the ATP analogue AMP-PNP has been solved at 2.25 Å resolution. One molecule of the ATP analogue is bound to each *N*-terminal domain of the dimeric enzyme in a surface cleft showing specific interaction with the nucleotides and a localized positive electrostatic effect. The molecular symmetry brings the two ATP analogue molecules to the center of two extended surface regions [56].

A group of *C*-type lectin receptors specific for D-mannose and related monosaccharides is important in the reactions of innate immunity based on the recognition of mannose-rich bacterial cell wall polysaccharides generally not occurring at the surface of eukaryotic cells. They involve both soluble mannose-binding proteins produced in the liver and secreted into serum as important acute-phase inflammation proteins, and the cell-bound macrophage mannose receptor that is an important pattern recognition receptor involved in host defense [57,58]. The rat mannose-binding protein became a prototype molecule for the structure of the protein fold of the entire *C*-type lectin superfamily [59]. The crystal structure of a C-type mannose-binding protein complexed with an oligomannose asparaginyl-oligosaccharide revealed that Ca^{2+} forms coordination bonds with the carbohydrate ligand. The carbohydrate specificity was determined by a network of coordination and hydrogen bonds that stabilizes the ternary complex of protein, Ca^{2+}, and sugar. The primary determinant of the monosaccharide specificity of this protein is the presence of hydroxy groups in positions equivalent to the 3- and 4-OH groups in D-mannose (*Fig. 10*).

This arrangement allows the recognition of some other hexoses (D-glucose), hexosamines (*N*-acetyl-D-glucosamine), and deoxyhexoses (L-fucose), while preventing some other mono-

saccharides from binding (e. g., D-galactose or *N*-acetyl-D-galactosamine both having axial 4-OH groups) [60]. Moreover, the structure of a mannose-binding carbohydrate-recognition domain in complex with a saccharide ligand suggests that two glutamic acid-asparagine pairs are essential determinants of ligand binding by this domain [60]. In *C*-type lectins that bind galactose with higher affinity than mannose one of these pairs is replaced by glutamine-aspartic acid. On the basis of this knowledge it was possible to engineer galactose-binding activity into a C-type mannose-binding protein by a simple switch in a position of a single amide group [61].

The natural forms of mannose-binding proteins are highly oligomeric molecules composed of trimers forming higher order complexes. The structure of the trimeric unit of the mannose-binding protein has been solved by protein crystallography to 1.8 Å resolution. The carbohydrate-binding sites in this trimeric protein are too far apart for a single trimer to bind multivalently with a typical mammalian high-mannose oligosaccharide. Thus, this protein can recognize pathogens selectively by binding avidly only to the widely spaced, repetitive sugar arrays on the pathogenic cell surface [62]. Molecular determinants of oligomer formation and complement fixation by these proteins have been investigated for proteins overexpressed in eukaryotic (Chinese hamster ovary) cells. Recombinant eukaryotic protein was posttranslationally modified in the same way as the native protein. Analysis of the isolated oligomers of mannose-binding protein revealed that the larger oligomers are more efficient in the activation of complement [63].

Macrophage mannose receptors are unique in their possession of eight linearly arrayed carbohydrate-recognition domains as a part of a single polypeptide. Although additional binding contributions coming from domains 5 and 7 may occur in complex saccharide ligand recognition, carbohydrate domain 4 of this receptor can alone account for the specificity of the entire receptor towards various monosaccharides [64]. For this reason, the greatest attention in binding and modeling studies has been paid to this particular protein segment of the entire receptor [65]. Recently, additional molecules belonging to the macrophage mannose receptor family have been cloned, sequenced and functionally characterized; of these, the dendritic cell receptor decalectin bearing a linear array of ten modules related to C-type lectin carbohydrate-recognition domains is worth mentioning [66].

The D-galactose-binding protein essential for transport and chemotaxis in *Escherichia coli* has been analyzed structurally by X-ray diffraction from the 3 Å resolution electron-density map obtained from multiple isomorphous replacement phases. Despite the lack of significant sequence homology, the overall course of the polypeptide backbone of the D-galactose-binding protein is remarkably similar to that of the L-arabinose-binding protein, the first of this family of proteins to be solved. Both structures are elongated (axial ratios 2:1) and composed of two globular domains. For both proteins, the arrangements of the elements of the secondary structure in both domains are identical: both lobes contain a core of β-plated sheet with a pair of helices on either side of the plane of the sheet. The four major hydrophobic clusters that stabilize the structure of the L-arabinose-binding protein are also present in the D-galactose-binding protein [67].

Extracellular or cell surface membrane receptors for D-galactose are widespread among higher eukaryotes. Isothermal titration calorimetry of the *C*-type lectin receptors from the tunicate *Polyandrocarpa misakiensis* revealed the presence of a single calcium atom per monomer with a dissociation constant of 2.6 µM, and confirmed the monosaccharide speci-

ficity of this receptor [68]. The X-ray crystal structure of the lectin complexed with D-galactose was solved at 2.2 Å resolution. Analytical ultracentrifugation revealed that the receptor behaved as a dimer in solution, and this was reflected by the presence of two subunits in the asymmetric unit with the dimeric interface formed by antiparallel pairing of the two *N*-terminal β-strands and hydrophobic interactions. The receptor adopts a typical *C*-type lectin fold with the main differences in structure from other *C*-type lectins being seen in the diverse loop region, and in the second α-helix, which is involved in the formation of the dimeric interface. D-Galactose is bound through coordination of the 3- and 4-hydroxy oxygen atoms with a bound calcium atom. Additional hydrogen bonds are formed directly between serine, aspartate, and glutamate side-chains of the protein and the sugar 3- and 4-hydroxy groups. Comparison of D-galactose binding by this receptor with D-mannose binding by the rat mannose-binding protein reveals how monosaccharide specificity is achieved in this receptor. A tryptophan side chain close to the monosaccharide-binding site, and the distribution of hydrogen-bond acceptors and donors around the 3- and 4-hydroxy groups of the sugar are essential determinants of the specificity. These elements are, however, arranged in a very different way than those in an engineered galactose-specific mutant of the mannose-binding protein, which is the only other D-galactose-specific receptor studied by rigorous structural procedures [61,68].

The uptake of monosaccharides across the plasma membrane of most mammalian cells is mediated by a family of facilitative transporters known as GLUTs. There are six known GLUT isoforms (GLUT1–GLUT7, GLUT6 is a pseudogene with no protein product) that are expressed in a tissue-specific manner [69]. Of the different GLUT transporters, GLUT5 is thought to function specifically as a fructose transporter with little ability to mediate the uptake of glucose. The intestine is a major site of GLUT5 expression consistent with the idea that this carrier plays a major role in the absorption of dietary fructose. Expression of this transporter has been studied in colorectal carcinoma cell line Caco-2, and found to be controlled by the carbohydrate content in the culture medium, and by the metabolic status of the cells [70]. More recently, it has been shown that the expression is co-regulated by thyroid hormone and D-glucose [70]. GLUT5 is also expressed in a number of other human tissues including skeletal muscle, adipose tissue, brain, and sperm, however, the precise physiological role in these tissues remains somewhat less well defined. It has been found lately that D-fructose transport facilitated by GLUT5 in skeletal muscle is saturable, is not inhibited by cytochalasin B, and is not acutely regulated by exercise. In contrast, the uptake of glucose is suppressed by cytochalasin B and regulated by exercise [71].

The domains responsible for D-fructose specificity of GLUT5 were investigated by creating chimeras of GLUT5 with the selective glucose transporter GLUT3, which were expressed in *Xenopus* oocytes. From the detailed analysis of these chimeras, it appeared that the amino terminal through the third transmembrane domain together with the polypeptide portion between the fifth and the eleventh transmembrane stretches seemed to be necessary for fructose uptake [72].

The crystal structure of the entire 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, a key bifunctional regulator of both glycolysis and gluconeogenesis, has been solved at 2.0 Å resolution. The entire enzyme is a homodimer of 55 kDa subunits arranged in a head-to-head fashion, with each monomer consisting of an independent kinase and phosphatase domain. The location of γ-*S*-ATP and inorganic phosphate in the kinase and phosphatase domains,

respectively, allowed one to locate and describe the active sites of both domains. While the similarity of the phosphatase domain to a family of proteins containing the cofactor-independent phosphoglycerate mutases and acid phosphatases has already been mentioned, the kinase domain is clearly related to the superfamily of mononucleotide binding proteins, particularly with adenylate cyclase and the nucleotide-binding portion of the G proteins [73].

2.2.2 Regulation of Hexose Metabolism in Multicellular Eukaryotic Organisms

Glucose is the primary fuel for many eukaryotic cells. In higher, multicellular eukaryotes, the glucose levels in cells and body fluids are under a tight hormonal control assuring the homeostasis of the inner environment. During normal daily living, two peptide hormones – insulin and glucagon – regulate blood glucose levels in these organisms. Insulin acts on many cells in the body to produce both immediate and long-term effects. Within seconds insulin binds to its cell surface receptor, induces receptor autophosphorylation, and activation of the receptor protein tyrosine kinase. In subsequent minutes a 10–20 fold increase in the rate of glucose transport into many tissues (notably muscle cells and adipocytes of the fat tissues) occurs primarily due to an increase in the number of plasma membrane glucose transporters. This dramatic increase in the capacity of intracellular glucose uptake is not dependent on gene induction or new protein synthesis, but proceeds through an interesting mechanism involving rapid externalization on the cell surface of an abundant GLUT4 glucose transporter (an isoform found only in muscle cells and adipocytes) from intracellular endosome-like vesicles. Such an externalization results in an up to ten-fold increase in the number of cell surface transporters, which, together with some activation of these transporters accounts for the above-mentioned profound effects in glucose internalization. Continued exposure to higher concentrations (approximately 10^{-8} M) of insulin will eventually result in increased expression of liver enzymes that synthesize glycogen, and of adipocyte enzymes that synthesize triacylglycerols. Insulin also functions as a growth factor for many cells, but its growth-promoting actions may be the result of its binding to the insulin-like growth factor 1 receptor, rather then to the insulin receptor itself, especially since the latter receptor is significantly downregulated by prolonged exposure to insulin action.

The concentration of glucose in the blood of higher eukaryotes including humans has been thought to represent an important signal that regulates food intake and energy homeostasis. In the well-known Mayers's glucostatic hypothesis it has been postulated that small declines in glucose concentrations or utilization trigger meal initiation [74]. Both the liver and the brain have been hypothesized to monitor and respond to changes of immediately available energy, and control food intake [75,76]. Although elevated glucose concentrations have been shown to trigger insulin biosynthesis at the level of transcription and translation, the molecular mechanisms underlying the immediate transcriptional control have only recently been revealed. Evidence has been obtained that physiologically stimulated insulin secretion from the pancreatic β-cells promote insulin biosynthesis by enhancing insulin gene transcription in an autocrine manner [77]. As the most recent investigations point to the central role of the hexosamine biosynthetic pathway as a cellular "sensor" of energy and glucose availability. Nevertheless, current investigations support the hypothesis that glucose inhibits glutaminolysis in pancreatic β-cells in a concentration-dependent manner. In the basal interprandial state, glutaminolysis is partially turned on in β-cells because of glutamate dehydrogenase activation [78].

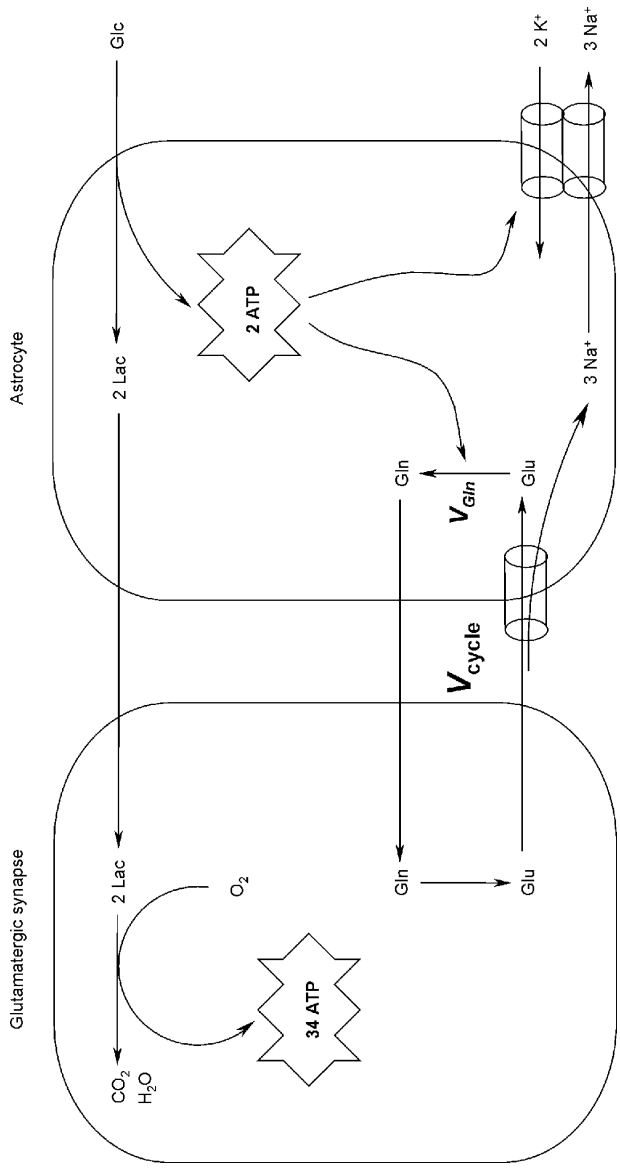
The brain has evolved as the central organ responsible for glucose sensing and glucose metabolism regulation. It receives neural inputs from glucosensors in the periphery but also contains neurons that directly sense changes in the blood glucose levels by using glucose as a signal to alter their transmission activities. Both obesity and diabetes are associated with several alterations in brain glucose sensing [79]. This role of glucose in the metabolism and coordinated activity of neurons has been clarified to considerable extent only recently [80]. As schematically depicted in ❯ *Scheme 2*, both the release of high concentrations of glutamate, and high energy production are required for glutamatergic neuronal synapses in order to mediate efficient activation of specific brain areas, processes that can be directly visualized by positron emission tomography or functional magnetic resonance imaging. Specialized glial cells in the brain, astrocytes, are assisting neurons in performing these tasks by accumulating glucose through their end-feet that cover virtually all capillary walls in the brain, and are enriched in glucose transporters. Inside the astrocyte, glucose is metabolized through glycolysis giving rise to both 2 mols of ATP necessary to drive the glutamate/glutamine cycle as well as transmembrane Na^+/K^+-ATPase (see ❯ *Scheme 2*).

Two moles of lactate are transported to neurons, and metabolized oxidatively to supply ATP for the energy demands of the latter cell [80]. Continuous (4 days) intracerebroventricular leptin infusion enhances insulin-stimulated glucose metabolism and favors the expression of the uncoupling proteins UCP1, UCP2 and UCP3 [81].

In other tissues, numerous hepatic and adipocytic genes are transcriptionally controlled by glucose and insulin. This is the case, for example, for the pyruvate kinase L gene in the liver and of the spot 14 gene in adipocytes [82]. At the hepatic level, the role of insulin is mainly to stimulate the synthesis of glucokinase, needed for phosphorylation of D-glucose to D-glucose 6-phosphate. However, an efficient regulation of the pyruvate kinase L gene by glucose also requires the synthesis of the glucose transporter GLUT2: in its absence the transcription of the gene is independent of the concentration of glucose in the medium. The role of GLUT2 seems to be in the depletion of the gluconeogenic cells in D-glucose 6-phosphate when cultivated without glucose.D-Glucose 6-phosphate seems to act through one of its pentose phosphate pathway metabolites, most probably through D-xylulose 5-phosphate controlling the activity of the cellular protein kinase/protein phosphatase cascades [82].

Ethanol impairs monosaccharide uptake and affects the synthesis, intracellular transport, subcellular distribution and secretion of these glycoproteins, suggesting alterations in glycosylation. Ethanol has been shown to increase the uptake of monosaccharides and the protein levels of GLUT1 but decreased those of mannosidase II. It alters the carbohydrate moiety of proteins and increases cell surface glycoproteins containing terminal mannose [83].

Membrane translocation of the glucose transporters in eukaryotic cells requires a complicated membrane architecture involving many accessory proteins as parts of the intracellular transport machinery. Thus, insulin-stimulated glucose transport inside the cells and translocation of the GLUT4 transporter require regulated interactions between the v-SNARE adaptor, the VAMP2 protein, and syntaxin 4. A novel syntaxin 4-binding protein, Synip, has also been isolated. Insulin induces dissociation of the Synip:syntaxin 4 complex due to an apparent decrease in the binding affinity of Synip for syntaxin 4. In contrast, the carboxy-terminal domain of Synip does not dissociate from syntaxin 4 in response to insulin stimulation, but inhibits glucose transport and GLUT4 translocation [84].



Scheme 2
Stoichiometry of glutamate (Glu)-mediated synaptic transmission and glucose usage. V_{cycle} is the reaction of the tricarboxylic acid cycle, V_{Gln} is the rate of the neurotransmitter cycle converting glutamate to glutamine (Gln)

Glucose deprivation has been shown to cause activation of Lyn kinase, c-Jun *N*-terminal kinase 1 and to increase the expression of basic fibroblast growth factor and c-Myc in adriamycin-resistant human breast cancer cells. Thus, glucose oxidation may be linked to cellular oxidative stress as evidenced from increase in the steady state of oxidized glutathione and intracellular peroxides [85]. A unique glucose-dependent apoptotic pathway is induced by the cellular oncogen c-Myc in transformed fibroblasts [86].

Noninsulin-dependent diabetes mellitus (NIDDM) is an increasingly common disease, and involves an increase in the capacity of the intestine to absorb monosaccharides. This has been linked to a combination of intestinal structural change with a specific increase in the expression of the monosaccharide transporters SGLT1, GLUT5, and GLUT2 [87].

Some hexoses are not common components of the metabolic pathways, but can have potential pharmacological effects. A notable example here is the all-*cis*-hexose D-allose that causes a striking down-regulation of hexose transport [88], most probably through the action of D-allose phosphate as the active down-regulator [89]. The fact that treatment of cells with tunicamycin, a well documented inhibitor of complex *N*-linked glycan biosynthesis, tightens this blockage of hexose transport has been correlated to impairment of glycosylation of specific glucose transporters [90]. More recent data indicate that D-allose-mediated depression of hexose transport in mammalian cells is mediated through the modulation of the intrinsic activity of the glucose transporter GLUT4 [91].

The ability of all eight D-aldohexoses to stimulate insulin release and biosynthesis was compared with their ability to serve as a metabolic substrate for the isolated islets of Langerhans. Insulin release and synthesis were stimulated by glucose or mannose, but not by allose, altrose, gulose, idose, galactose, or talose. Lactate formation was increased above values found in the absence of added substrate by 20 mmol/L glucose or mannose, but not by allose, altrose, gulose, galactose, or talose. These results support the substrate-site hypothesis for the recognition of sugars as the stimulus of insulin release and synthesis [92].

2.2.3 Generation of New Hexose-Utilizing Organisms by Metabolic Engineering

It has been shown that the diversion of lactose carbon through the tagatose pathway reduces the intracellular fructose 1,6-bisphosphate and growth rate in 20 strains of *Streptococcus bovis*. In these strains, glucose and the glucose moiety of lactose were metabolized by the Embden–Meyerhoff–Parnas pathway, but the galactose moiety of lactose was catabolized by the tagatose pathway through a scheme that bypasses D-fructose 1,6-bisphosphate [93]. Expression of the *pmi* gene from *Escherichia coli* encoding phosphomannose isomerase in *Zymomonas mobilis* leads to utilization of mannose as a novel growth substrate [94].

2.2.4 Biomedicine

Hexoses have found many biomedical applications, based mostly on their specific biological functions, but also on the unspecific (mostly protective) effects they have on tissues and organs. Considering the latter effects, hexoses have been found to exert a profound influence on the vitrification properties of ethylene glycol-based solutions used in cryobiology for the preservation of oocytes and other cells [95]. Glucose, mannose, and fructose have been shown to preserve physiological activities of various tissues, and have thus become important components

of the tissue and organ preserving solutions [96]. Solutions of both D-hexoses and L-hexoses, with the exception of D-idose, have been shown to protect cells significantly against thermal damage, increasing their survival factor up to one hundred times [97]. By direct determination of some hexoses such as D-talose, D-idose, and L-galactose it has been found that the polyhydroxy compounds must accumulate intracellularly for cellular heat protection. Many effects of hexoses on the cells of the vertebrate immune system have been recorded over the last period, but many of these effects were shown to be non-specific on later examination. As an example, monosaccharides were found to inhibit antigen-specific T-cell activation, but this inhibition was later interpreted as a chemical reactivity of these compounds dependent on the presence of an aldehyde function in their molecule [98].

The chemical reactivity of glucose leading to the glycation of abundant blood proteins such as albumin or hemoglobin is of eminent medical importance, and the determination of the fraction of glycated albumin or glycated hemoglobin has become a routine and reliable tool for the assessment of the long-term management of the diabetes patients [99]. Increased levels of the hemoglobin A1c serve as the definitive indicators of a long-term decompensation in these patients, and can even be used for postmortem diagnosis in cases of unsuspected diabetes mellitus leading to otherwise unexplained deaths [100]. Moreover, the advanced glycation end-products resulting from the reaction of hexoses with tissue proteins represent an important factor in diabetic complications [101] and Alzheimer's disease [102]. Aminoguanidine, a hydrazine-like molecule, has been studied extensively both in vitro and in vivo as an inhibitor of the formation of advanced glycation end-products [101]. More recently, a new class of inhibitors has been evaluated based on aryl or heterocyclic carboxamidophenoxy-isobutyric acids and related molecules [103].

The use of a series of small carbohydrates to stabilize proteins/peptides that misfold in Alzheimer's amyloid-beta peptides (Abeta) has been reported. The carbohydrates vary only in their distribution of potential H-bonding partners thus promoting various structural changes in Abeta. The utilization of a combinatorial strategy may represent a novel drug design strategy [104]. Two of the biochemical features of Alzheimer's disease that contribute to neurodegeneration are intracellular oxidative stress and elevated levels of trace metal irons including Fe^{III}, Cu^{II} and Zn^{II} [105]. Recently, a glucose prodrug which contains metal ion chelating ligands has been reported for use as a potential new therapy ❯ *Fig. 11*. The compound contains a functionalized bidentate hydroxypyridinone moiety and is designed to cross the blood brain barrier. The glucose-prodrug strategy solves the potential problem of premature metal binding by using carbohydrates as both the masking and directing substituent [106].

Figure 11
Metal chelating compounds

Metabolic flux through the hexosamine biosynthetic pathway (HBP) is increased in the presence of high glucose and potentially stimulates the expression of genes associated with the development of diabetic nephropathy. A number of synthetic processes are coupled to the HBP, including enzymatic intracellular *O*-glycosylation, the addition of single *O*-linked *N*-acetylglucosamine monosaccharides to serine or threonine residues. In glomerular mesangial cells, HG- stimulated plasminogen activator inhibitor-1 (PAI-1) gene expression requires the HBP and the transcription factor, Sp1. It has been shown that among the pathways served by the HBP, *O*-GlcNAcylation, is obligatory for HG- induced PAI-1 gene expression and Sp1 transcriptional activation in mesangial cells [107].

The identification of leptin as an important hormonal factor involved in glucose utilization, diabetes, and the regulation of body weight lead to the current evaluation of this protein as a drug for the treatment of diabetes and obesity. In this respect, it has been found that leptin can inhibit glucose-induced insulin secretion from pancreatic islets [108], enhance insulin-stimulated glucose metabolism and expression of white adipose tissue uncoupling protein UCP2 and muscle uncoupling protein UCP3 [109], and contributes to the reduction of whole body adiposity by enhancing energy consumption in brown adipose tissue and muscle, and by attenuating the energy storage in the white adipose tissue [110].

Specifically designed boronic acids containing fluorescent sensors have been prepared, by a simple one-step synthetic procedure, in the progression toward non-invasive and continuous glucose monitoring. The sensors contain a boronic acid moiety as an effective glucose chelating group with the 6-methoxyquinolinium nucleus as a fluorescent indicator and are readily water soluble ❯ *Fig. 12* [111].

Similarly, 2-acrylamidophenylboronate has been synthesized and its ability to bind with glucose investigated both in solution and when integrated into a holographic sensor [112]. A glucose sensor comprising a reflection hologram incorporated into a thin, acrylamide hydrogel film bearing the *cis*-diol binding ligand, 3-actylamidophenylboronic acid, has been described. The potential for using this holographic sensor to detect real-time changes in bacterial cell metabolism was demonstrated by monitoring the germination and subsequent vegetative growth of Bacillus subtilis spores [113]. The boronic acid group has also been linked to an azo dye showing a color change from orange to purple in the presence of sugar at neutral pH [114].

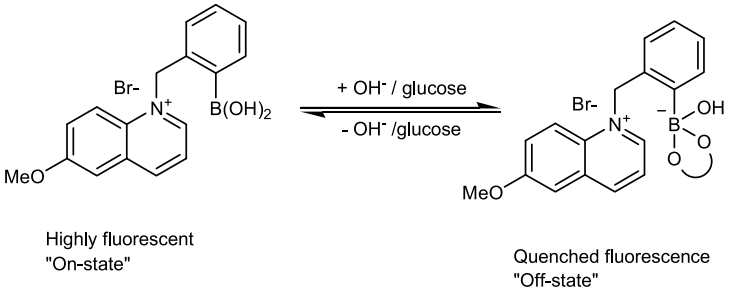

Figure 12
Glucose chelating boronic acid compounds used as sensors

Most cancer cells exhibit increased glycolysis and use this metabolic pathway for generation of ATP as a main source of their energy supply. This event is known as the Warburg effect and is considered as one of the most fundamental metabolic alterations during malignant transformation. Developing new therapies to inhibit glycolysis will provide a new class of anticancer agent that is likely to have broad therapeutic applications. These strategies have been recently reviewed [115].

Oral or intravenous administration of glucose has been evaluated as a potential possibility for sensitization before thermoradiotherapy. It has been concluded that intravenous and intravenous plus oral glucose administration are equally effective in inducing tumor acute acidification [116].

Recently, complexes of vanadyl(IV) with four monosaccharides were tested in two osteoblast-like cell lines (MC3T3E1 and UMR106). Many complexes caused stimulation of UMR106 proliferation (120% basal) in the range of 2.5 to 25 µmol/L. In the nontransformed osteoblasts, some vanadyl-saccharide complexes stimulated the mitogenesis (115% basal) in the same range of concentration. The glucose and sucrose complexes were the most efficient inhibitory agents (65 and 88% of inhibition vs. basal, respectively) for tumoral cells at 100 µmol/L. The galactose and turanose complexes exerted a similar effect in the nontransformed osteoblasts [117]. These vanadium derivatives are potential antitumor drugs.

A library of glycoconjugate benzenesulfonamides that contain carbohydrate-triazole units has been evaluated for their ability to inhibit three human transmembrane carbonic anhydrase isozymes hCA IX, hCA XII and hCA XIV which have potential as drug targets ❯ *Fig. 13* [118].

The glucose transporter GLUT1 has been identified as a highly sensitive marker of malignancy in body cavity effusions [119] suggesting that GLUT1 immunostaining may become useful in diagnostic cytopathology. Similarly, the expression of GLUT1 in colorectal carcinoma is a marker of poor prognosis [120]. Malignantly transformed cells transport glucose more efficiently than normal cells, both due to the increased expression of glucose transporters, and due to the expression of higher affinity transporters, such as GLUT2. Impaired regulation of GLUT2 seems to be the molecular cause of the hereditary maturity-onset diabetes of the young type I [121,122]. GLUT1 is expressed in complex hyperplasia with atypia and in adenocarcinoma. It has been recently shown that GLUT-1 immunostaining is useful in distinguishing benign hyperplasia from hyperplasia strongly associated with malignancy and that GLUT-1-

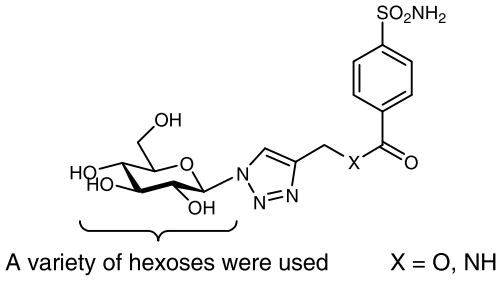

Figure 13
Benzenesulfonamide carbohydrates

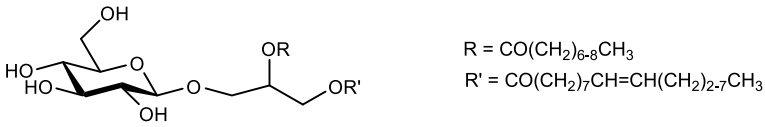

Figure 14
Antimicrobial diglyceride carbohydrates

mediated glucose transport may allow hypoxic tumor cells distant from stromal blood vessels to survive through glycolysis. This would suggest that the expression of GLUT-1 transporter may be closely related to the malignant transformation of epithelial endometrial tumors by supporting their increased need for glucose metabolism. GLUT-1 is preferentially expressed in atypical endometrial hyperplasia and endometrial adenocarcinoma [123].

The NO-mediated iron mobilization from cells has been linked to the presence of glucose. Due to its high affinity for iron, nitrogen monoxide (NO) affects cellular iron metabolism. It has been demonstrated that NO generators increase Fe-59 efflux from cells pre-labeled with Fe-59-transferrin by adding D-glucose to the reincubation medium this mechanism was potentiated. It has been shown that the metabolizable D-glucose and D-mannose stimulated NO-mediated Fe-59 mobilization. Other sugars, not easily metabolized by fibroblasts, had no effect [124]. This may have important implications for intracellular signaling by NO and also the NO-mediated cytotoxicity of activated macrophage that is partly due to iron release from tumor target cells.

The antimicrobial activity of a number of monoglucosyl diglycerides has been evaluated against gram-positive and gram-negative bacteria and fungi. It was shown that the 1,2-disubstition of the glyceride and the presence of an octanoyl side chain were essential structural features for activity ➤ *Fig. 14* [125].

Novel monosaccharide derivatives of D-allose have been evaluated as potent inhibitors of cellular proliferation in thymidine incorporation assays. These compounds show promise for the development of selective inhibitors of the growth of tumor cells as opposed to their normal counterparts [126]. It has also been shown that D-allose has a significant inhibitory effect on cancer cell proliferation in a dose-dependent manner, although the exact mechanism remains unclear [127]. This suggests that D-allose may be an effective adjuvant therapeutic agent against cancer in the future and may represent a new class of compounds with possible therapeutic potential. More specifically, D-allose has been shown to have a significant inhibitory effect on ovarian cancer cell proliferation in a dose-dependent manner, causing moderate G2/M arrest in the cell cycle, up-regulation of Cdk inhibitors p21 and p27 levels, and the induction of apoptosis in OVCAR-3 cells [128].

D-Mannose is an interesting hexose from the biomedical point of view, since the dietary inclusion of somewhat high doses of this monosaccharide was shown to provide a specific protection against various microorganisms in a wide variety of biological models. Thus, such treatment has been shown to be associated with the reduction in the numbers of *Salmonella enteretidis* in the caecal contact of chicken challenged by the food [129]. Similarly, mannose and its derivatives are able to prevent infection of macrophages and lymphocytes by HIV-1 [130], and adherence of type 1-piliated *Escherichia coli* to carbohydrate structures of vaginal mucosa that play a major role in the pathogenesis of ascending urinary tract infec-

tions in women [131]. Obviously, to make these treatments more useful for the above-mentioned applications, the proper clustering of D-mannose residues will be an important prerequisite.

The effect of several hexoses on wound healing has been investigated in cylindrical hollow sponge implants used as an inductive matrix for the growth of granulation tissues. While the infusion of the implant with D-mannose solutions inhibited the inflammation reaction in wound healing, D-galactose infusions enhanced wound healing [121].D-Galactose is an important hexose used clinically for the evaluation of hepatic functions in liver cirrhosis [122]. Clinical studies have been initiated aiming at the use of the D-galactose-specific liver receptors. It has been shown that treatment with galactose can prevent hepatic metastases in colorectal carcinoma patients [132], and that galactosylated cationic liposomes may be used as vehicles for gene transfer into the liver because of the interaction with the above asialoglycoprotein receptor [133].

D-Fructose has found numerous applications in biomedicine as an important component of tissue infusion and preservation solutions. It has been reported that fructose is the monosaccharide that best maintains the ATP and 2,3-diphosphoglycerate levels in red blood cells during the fourth to sixth week of whole blood storage [134]. Similarly, D-fructose protects rat hepatocytes against injury during the process of isolation and microencapsulation [135], and protects cells against oxidative injury by iron chelation [136]. Malabsorption of D-fructose is important in medical diagnosis since it has been shown to be associated with early signs of mental depression, although further studies will be needed to clarify the nature of this association [137]. Expression of the fructose transporter GLUT5 as an early diagnostic marker of human breast cancer opens opportunities for the development of novel strategies for the early diagnosis and treatment of this form of cancer [138].

The extensive expression of GLUT2 aswell as GLUT5 (glucose/fructose and fructose transporters, respectively) in malignant human tissues indicates that fructose may be a good energy substrate in tumor cells. This suggests that fructose uptake could be used for positron emission tomography imaging and, may possibly represent a novel target for the development of therapeutic agents in different human cancers [139]. Positron therapy with F-18-2-deoxy-2-fluoro-D-glucose (F-18-FDG) in a breast cancer animal model has been used to affect tumor growth rate and survival (positherapy) [140,141,142]. The molecular and cellular regulation of glucose transporter proteins in cancer has been recently reviewed [143] and [144].

Hydroxylated derivatives of topiramate, a novel antiepileptic drug based on D-fructose, are being evaluated in ongoing investigations [145,146].

D-Tagatose is a hexose of a great promise for biomedicine. This monosaccharide has been evaluated as an antioxidant and cytoprotective agent against chemically induced cell injury [147]. It has also become a center of attention for nutritionists and diabetologists as a new candidate sweetener that is as sweet as sucrose yet provides zero available energy [148]. Its application as a sweetener would certainly be supported by very low genotoxicity when tested in many assays including the Ames *Salmonella typhimurium* reverse mutation assay, the *Escherichia coli*/mammalian microsome assays, and chromosomal aberration assays in Chinese hamster ovary cells [149], and its low general influence on several clinically followed biochemical parameters [150].

Tagatose is currently being developed for the potential treatment of obesity and type two diabetes and is also under investigation for the potential treatment of anemia, hemophilia and

medical problems related to infertility, birth weight and excessive maternal food intake. Phase I and II clinical trials have been completed [151].
In Escherichia coli, L-arabinose isomerase (ECAI) catalyzes the isomerization of L-arabinose to L-ribulose. This enzyme is also of commercial interest as it catalyzes the conversion of D-galactose to D-tagatose in vitro. The crystal structure of ECAI was solved and refined at 2.6 angstrom resolution [152].

2.3 Heptoses

Despite the fact that many heptoses are by far less prominent in Nature than hexoses these monosaccharides are found both as metabolic intermediates, and as structural carbohydrates of bacterial cell walls.D-Sedoheptulose 7-phosphate is an important intermediate of the pentose cycle, and D-sedoheptulose 1,7-bisphosphate is present in plants as an intermediate of the dark phase of photosynthetic reactions. L-Glycero-D-*manno*-heptose was isolated from the oligosaccharides obtained by partial acid hydrolysis of the lipopolysaccharide from *Escherichia coli* K-12 strain W3100 [153] and *Haemophilus influenzae* [154]. Both L-glycero-D-*manno*-heptose and D-glycero-D-*manno*-heptose were isolated from the lipopolysaccharide of *Vibrio parahaemolyticus* [155].
Despite their quite recent history of investigation, two key enzymes of heptose metabolism have been purified and characterized biochemically, which open opportunities for structural studies [156].

2.3.1 Biomedicine

D-Mannoheptulose is currently used as a tool for competitive inhibition of D-glucose phosphorylation, metabolism, and functional effects in pancreatic islet β-cells, and other tissues [157]. An important diagnostic marker linking the early diabetes to obesity is the loss of D-mannoheptulose inhibition of glucose-induced insulin secretion in obese individuals, indicating the loss of sensitivity to competitive inhibition at the level of glucokinase [158]. On the other hand, the glucokinase activity in tumor cells is characterized by a high K_m for D-glucose, lack of feedback inhibition by D-glucose 6-phosphate, and potent inhibition by the specific glucokinase inhibitor, D-mannoheptulose. Moreover, mannoheptulose can cause efficient inhibition of glucose uptake by tumor cells, and inhibits growth of tumor cells in culture [159]. Rates of growth of human tumors in experimental animals are also dramatically reduced by as much as 65–80% during the administration of a dose of 1.7 mg of D-mannoheptulose per g body weight per day for 5 days. Thus, a naturally occurring D-mannoheptulose, which can be purified from avocados and is assumed to be of low toxicity, may become a potent natural anticarcinogen [159].

3 Aminosaccharides

Figure 15 presents the structures of the three most important and abundant hexosamines found in nature: *N*-acetyl-D-glucosamine, *N*-acetyl-D-galactosamine, and *N*-acetyl-D-mannosamine.

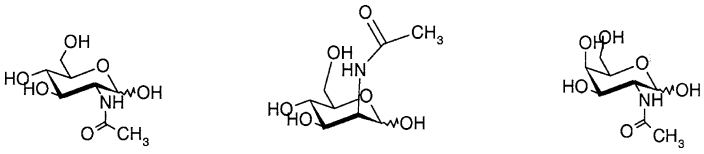

Figure 15
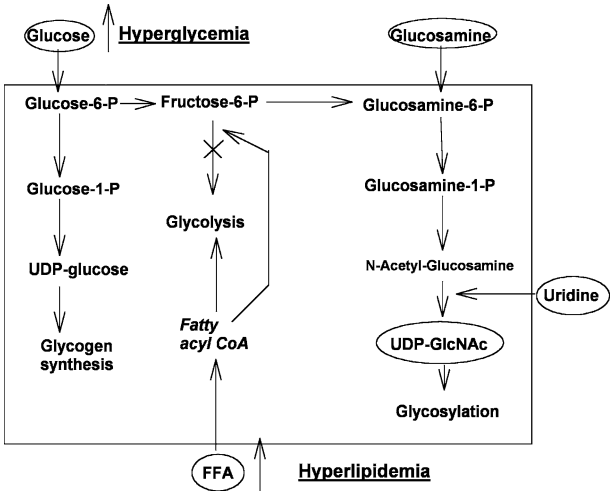
Structures of some aminohexoses in which these monosaccharides interact with the biomolecules of living matter

Aminosaccharides represent a specific class of sugars in that they bear both hydrophilic and ionizable, basic functionalities. However, in most naturally occurring aminosaccharides the amino group is acylated (most often acetylated), and this additional modification provides the *N*-acetylaminosaccharides with an extra group that is often critical in their biological interactions, despite its only moderately hydrophobic character (a similar aspect is also seen for the deoxysaccharides). In their acetylated form, aminosaccharides are among the most abundant constituents of cell wall polysaccharides, with chitin, a polysaccharide containing mostly linear β-1→4 linked *N*-acetyl-D-glucosamine chains, being the second most widely synthesized polysaccharide in nature. From this point of view, the biosynthesis of hexosamines catalyzed by glutamine: fructose 6-phosphate amidotransferase as the rate-limiting enzyme proceeds actively in a very wide range of organisms. In several vertebrates hexosamine biosynthesis has been identified as the critical cellular "sensor" of energy availability mediating the effects of glucose on the expression of several gene products [160]. Recently, evidence has been provided for rapid activation of the *obese* (*ob*) gene producing the "leaning" protein leptin in skeletal muscle by glucosamine [161]. Increased tissue concentrations of the end-product of the hexosamine biosynthesis pathways, UDP-*N*-acetyl-D-glucosamine (see *Scheme 3*), result in rapid and marked increases in leptin messenger RNA and protein levels.
Plasma leptin levels and leptin mRNA and protein levels in adipose tissues also increase. Most importantly, data indicate that leptin synthesis is also stimulated by either hyperglycemia or hyperlipidemia, which also increases tissue levels of UDP-*N*-acetyl-D-glucosamine in conscious rodents. These findings unveil an important biochemical link between the increased availability of certain nutrients and leptin expression [161].
The widespread availability of the acetylated hexosamines at the microbial surfaces [162], [163] certainly makes these monosaccharides favorite targets for both the innate and the adoptive immune system responses. The corresponding carbohydrate receptors are found among the animal lectins, anticarbohydrate antibodies as well as enzymes of the carbohydrate metabolism. While some of these recognition systems are related to the receptors already described in preceding sections due to their broad carbohydrate reactivities, a few systems seem to be unique for the recognition of the acetylated hexosamines. Notable among these proteins is the rat NKR-P1A antigen that has been characterized as an important activation receptor of rat natural killer cells, a specialized subset of lymphocytes involved in antitumor and antiviral defense [164,165]. The recombinant soluble form of this receptor binds specifically to both *N*-acetyl-D-glucosamine and *N*-acetyl-D-galactosamine linked to protein or chemically synthesized linkers [166,167]. Although some complex oligosaccharide sequences



Scheme 3

Sites of entry of glucose, glucosamine and uridine into the hexosamine biosynthesis pathway and the role of free fatty acids (FFA). Glucose is phosphorylated to produce glucose 6-phosphate, which is used mainly in glycogen synthesis and glycolysis pathways. The hexosamine pathway receives approximately 1 to 3% of the incoming glucose through the conversion of fructose 6-phosphate into glucosamine 6-phosphate by the rate-limiting enzyme glutamine:fructose 6-phosphate amidotransferase. Alternatively, glucosamine can enter the cell directly, and is phosphorylated to produce glucosamine 6-phosphate. Further metabolites are formed by the subsequent acylation and uridylation of the glucosamine 6-phosphate. Increased FFA availability generates increased levels of fatty-acyl-CoA, leading to inhibition (crossed reaction arrow) of glycolysis. An increased accumulation of fructose 6-phosphate leads to the increase in the concentration of the corresponding substrate. Modified according to ref. [161]

can possibly represent physiological ligands for this protein [168], and despite the evidence that linear oligomers of *N*-acetyl-D-glucosamine can be good ligands for this receptor [169], the carbohydrate-binding modules of this receptor have, even in their monomeric form, measurable reactivities towards simple *N*-acetyl-D-hexosamines, with *N*-acetyl-D-mannosamine being the best ligand in some oligosaccharide sequences [170].

3.1 Biomedicine

The central role of hexosamine biosynthesis intermediates as the sensors of the general metabolic status led to attempts to use the corresponding monosaccharides for feeding modulation in experimental animals.D-Glucosamine, *N*-acetyl-D-glucosamine, and 2,5-anhydro-D-mannitol were infused into the third cerebroventricle of the rat to compare their effects on food intake. D-Glucosamine at 24 μmol L^{-1} accelerated eating, and concomitantly increased plasma glucose, free fatty acids, and glycerol without affecting plasma insulin concentrations while *N*-acetyl-D-glucosamine induced feeding, but only upon oral administration [171].
The measurements of serum fructosamine may provide an alternative diagnostic tool to the more established monitoring methods, and become a clinically useful procedure for monitoring diabetes mellitus in veterinary medicine [172].

N-Acetyl-D-glucosamine has been evaluated as a clinically useful osmotic solute in peritoneal dialysis solutions [173]. This usage of the sugar would be well in accord with its good biological compatibility and beneficial influence on wound healing [174].

Synthetically engineered polyvalent dendrimer glucosamine conjugates have been used to prevent scar tissue formation. Water-soluble conjugates of D(+)-glucosamine and D(+)-glucosamine 6-sulfate have been shown to block fibroblast growth factor-2 mediated endothelial cell proliferation and neoangiogenesis in human Matrigel and placental angiogenesis assays [175].

Glucosamine represents one of the most commonly used drugs to treat osteoarthritis although the mechanism of its antiarthritic activity is still poorly understood. It has been shown that both glucosamine and *N*-acetylglucosamine inhibit IL-1 beta- and TNF-a-induced NO production in normal human articular chondrocytes. A novel mechanism for the inhibition of inflammatory processes has been suggested. The suppression of IL-1 beta -induced NO production is associated with inhibition of inducible NO synthase mRNA and protein expression. In addition, *N*-acetylglucosamine also suppresses the production of IL-1 beta -induced cyclooxygenase-2 and IL-6 [176].

In Alzheimer's disease, the major pathological features are diffuse and senile plaques that are primarily composed of the amyloid-beta (A beta) peptide. It has been proposed that proteoglycans and glycosaminoglycans (GAG) facilitate amyloid fibril formation and help stabilize the plaque aggregates, hence the use of therapeutics based on A beta -GAG interactions. The development of potential compounds based on the model of A beta -chondroitin sulfate binding can lead to effective inhibitors of the GAG-induced amyloid formation. It has been shown, that the sulfated D-GalNAc-4S, D-GalNAc-6S, and D-GalNAc-4S,6S, but not D-GalNAc, D-GlcNAc, or Delta UA-GalNAc, induce the fibrillar features of A beta -GAG interactions and compete with the intact chondroitin sulfate and heparin GAGs for A beta binding, as illustrated by competitive inhibition ELISAs [177].

Some unusual aminosaccharides can have antibacterial and antibiotic effects: this is the case of 3-amino-3-deoxy-D-glucose isolated from deep-sea bacteria (a *Bacillus* strain) collected at a depth of 4310 m [178]. More importantly, cellular receptors responsible for the adherence of microbes to eukaryotic cells are often lectin-type adhesins [179], and aminosaccharide treatment can result in the protection against microbial infections [180].

Finally, a notable antitumor effect of free or clustered aminosaccharides should be mentioned. Some aminosaccharides such as D-galactosamine have direct cytotoxic effects on certain experimental tumors [181], while D-mannosamine is selectively toxic for human malignant T-lymphoid cell lines [182]. It has been shown that aminosugars, especially D-mannosamine, produce hydrogen peroxide to cause DNA damage, which mediates apoptosis resulting in tumor growth inhibition [183].

4 Deoxysaccharides

By removing the hydrophilic hydroxy group from the structure of the respective monosaccharides in deoxy sugars, the hydrophobic character of certain areas in the molecule is increased. This fact may be considered to be rather minor, but in reality can often have a dramatic effect on the way how these molecules behave in solution, and most importantly, how they are rec-

ognized by their specific recognition proteins. In most instances, increasing the hydrophobic character increases the possibility for a deoxysaccharide to interact with various receptors or transporters more specifically. This is the reason why so many important antibiotics, drugs, and ligand mimetics fall into this class of monosaccharides. The above-mentioned effect seems to be most evident when the hydroxy group has been removed from the exocyclic C6 substituent. Classical example of this specific effect are provided by the 6-deoxymonosaccharides such as L-fucose (6-deoxy-L-galactose). In complex oligosaccharide sequences this monosaccharide is often localized in the terminal position, such as in blood group oligosaccharide sequences. This fact together with their relatively higher hydrophobic character, allows them to play such a dominant role in many important intercellular adhesive reactions [184], activation of cellular immunity, and in the immune antibody response [185].

Microorganisms can synthesize a wide range of deoxysaccharides and deoxyaminosaccharides that are not commonly contained in eukaryotic organisms, many of which occur as sugar components of important antibiotics. The nomenclature used for these aminosaccharides is still mostly trivial, and the biosynthetic pathways for some of these compounds are now being explored. *N*-Acetylviosamine is a component of bacterial lipopolysaccharide sequences, and the gene coding for an enzyme involved in dTDP-*N*-acetylviosamine (viaminose is 4-amino-4,6-dideoxy-D-glucose) synthesis has been identified in the gene cluster involved in the O7-specific lipopolysaccharide biosynthesis [186]. Similarly, the identification of the perosamine (perosamine is 4-amino-4,6-dideoxy-D-mannose) synthase gene of *Brucella melitensis* 16M may eventually allow us to understand the biosynthesis of the smooth lipopolysaccharides thought to be important virulence factors of these organisms [187].

The process of guanosine 5′-diphosphate-L-fucose biosynthesis is conserved throughout evolution from prokaryotes to man. In animals, GDP-L-fucose is the substrate for fucosyltransferases that participate in the biosynthesis and remodeling of the glycoconjugates including ABH blood group and Lewis-system antigens. The de novo pathway of GDP-L-fucose biosynthesis starts from GDP-D-mannose and proceeds through GDP-D-mannose 4,6 dehydratase and GDP-4-keto-6-deoxy-D-mannose epimerase/reductase. The genetic syndrome named severe leukocyte adhesion deficiency type II is known to result from a deficiency in this de novo pathway, resulting in the severe hypofucosylation of all glycoconjugates bearing fucose in various linkages. The crystal structures of the apo- and holoepimerase have been solved at 2.1 and 2.2 Å resolution, respectively. Each subunit of the homodimeric enzyme having a 34 kDa subunit is composed of two domains. The *N*-terminal domain binds $NADP^+$, and the *C*-terminal domain of 100 residues has α/β topology. The nicotinamide of the nucleotide and the connected ribose ring are located close to residues Ser_{107}, Tyr_{136}, and Lys_{140}. The enzyme is reminiscent of the fold observed in UDP-galactose epimerase [188].

4.1 Biomedicine

Deoxysaccharides express a range of extremely interesting biological activities that include antibiotic, antitumor, and antimalaria activities, as well as profound effects on cell–cell adhesion and cellular activation. Thus, 3-fluoro-3-deoxy-D-galactose displays high affinity for aldose reductase allowing the use of this compound as an excellent probe for investigations related to aldose reductase activity involved in cataract formation (see also the following

section) [189,190]. 2-Deoxy-D-ribose induces programmed cell death (apoptosis) in HL-60 leukemic cells [191], and has radiosensitizing effects on cancer cells [192,193]. Similarly, the apoptotic effects of the steroidal alkaloid solamargine have been shown to be dependent on the L-rhamnose moiety found in this compound [194]. 2-Deoxy-D-glucose enhances the cytotoxicity of topoisomerase inhibitors in human tumor cell lines [195].
1-Deoxy-D-xylulose 5-phosphate reductoisomerase inhibitors are potent antimalarial drugs [196]. The identical compound causes activation of T cells bearing Vγ9/Vδ2 receptors [197]. A peptide derivative of L-fucopyranose enhanced the activity of natural killer lymphocytes more than interleukin-2 [198]. The measurements of the serum levels of fucose are a important tumor diagnosis marker [199]. Interesting sugar mimetics have been recently constructed as E-selectin inhibitors in order to substitute an expensive oligosaccharide ligand, sialyl Lewis^x; in these derivatives, a five-membered fucose ring occurs which can still bind to calcium in the carbohydrate-recognition domain of E-selectin [200].

5 Alditols

Alditols are often observed as the end-products of monosaccharide metabolism that are stored in various cellular and tissue compartments with low redox potentials. However, there are also examples of alditols as important metabolic intermediates allowing the interconversion of rare forms of certain monosaccharides. In enteric bacteria such as *Escherichia coli* the hexitol galactitol is taken up through enzyme II of the phosphoenol pyruvate-dependent phosphotransferase system and accumulated inside the cell as galactitol 1-phosphate. The genes involved in galactitol metabolism have been cloned on a 7.8 kb DNA fragment [201].
The formation of alditols in eye lenses is one of the major complications in diabetic patients. Interestingly, the detailed molecular pattern of the lens alditols allows us to differentiate between the diabetic lens having increased concentrations of sorbitol 3-phosphate and fructose 3-phosphate, and the galactosemic lens, where the major products are galactitol 2-phosphate and galactitol 3-phosphate [202]. 2,5-Anhydro-D-mannitol is an analogue of fructose that has become popular in cellular metabolic studies using perfused rat liver [203].

5.1 Biomedicine

Alditols have been finding an increasing number of biomedical applications. Xylitol is a sweetener with important technological properties, an anticariogenic compound with low caloric value and negative dissolution heat. It has been used successfully in food formulations and in the pharmaceutical industry [204]. Xylitol has been shown to reduce plaque acid, and its anti-caries efficiency in combination with sodium fluoride has been confirmed by numerous clinical studies [205]. Xylitol is the only commercially used sugar substitute proven to have an antimicrobial effect on pneumococci [206]. Moreover, xylitol has been shown to display anti-adhesive effect on otopathogenic bacteria [207]. Determination of D-arabinitol/L-arabinitol ratios in urine may serve as an important diagnostic marker of invasive candidiasis [208]. Stable butyrate derivatives of D,L-xylitol have been shown to represent important cellular activation factors that can induce maturation and apoptosis in human acute myeloid leukemia cells [209].

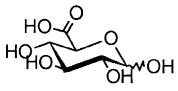
6 Uronic and Aldulosonic Acids

This group of monosaccharides includes structurally somewhat heterogeneous groups of compounds bearing the carboxylic group in their molecule (see ❯ *Fig. 16* for structures of some common compounds). The chemical effects of this group are primarily in conferring charge, and thus further increasing both the solubility of these derivatives, and their ability to interact with enzymes, receptors, and transporters through an ionic interaction. Ascorbic acid (vitamin C) is often arbitrarily included into this group of compounds that otherwise contain mostly glucuronate, galacturonate, mannuronate, sialic acids, *N*-acetylmuramic acid, 3-deoxy-D-*manno*-2-octulosonic acid, and other monosaccharides. However, one should keep in mind that ascorbic acid is ***not*** a monosaccharide bearing a carboxyl function, being chemically L-*threo*-hexulosono-1,4-lactone-2,3-enediol (see structures in ❯ *Fig. 16*).

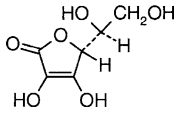
It has been suggested that the evolvement of sialic acids in microorganisms and higher animals may have stimulated evolution and rendered organisms less vulnerable to environmental attacks from viruses [210].

Glucuronic acid and sialic acid are normally present in conjugated forms. After degradation of these components in lysosomes, the free monosaccharides are released by a specific membrane transport system. The lysosomal sialic acid transporter from rat liver has been purified to apparent homogeneity in a reconstitutively active form. The transporter recognized structurally different types of acidic monosaccharides such as sialic acid, glucuronic acid, and iduronic acid. The transport was proton gradient dependent, and saturable with a K_m of approximately 0.4 mM [211].

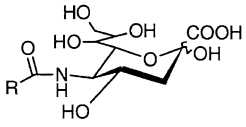
It has been suggested that de-*N*-acetyled sialic acid occurs on native gangliosides of certain tumors and cell lines. Although claims for their natural existence were based upon monoclonal antibodies and pulse-chase experiments, there have been no reports of their chemical detection until the report by Varki providing the first chemical proof for naturally occurring de-*N*-acetyl-



D-glucuronic acid



L-ascorbic acid



R = CH_3 N-acetyl-neuraminic acid

R = CH_2OH N-glycolyl-neuraminic acid

Figure 16
Structures of some charged monosaccharides in which these compounds interact with the biomolecules of living matter

gangliosides [212]. Synthetic de-*N*-acetyl-gangliosides have been shown to possess potent biological properties in vitro.

The interesting chemistry of sialic acid has been discussed in several reviews [213,214,215]. Sialic acid is an important component of complex oligosaccharides, when it is placed in the terminal position, and often masks the penultimate saccharide sequences. In this position, it interacts with numerous receptors including the influenza virus neuraminidase, and receptors mediating intercellular interactions such as the selectins (members of the *C*-type animal lectin family) and siglecs (or sialoadhesins, members of the immunoglobulin superfamily). The structure of influenza B neuraminidase in complex with sialic acid has been solved by X-ray crystallography at 2.2 Å resolution (*Fig. 17*) [216].

The good structural knowledge of this complex led to the development of structural mimetics of the sialic acid ligands with the advent of the development of inhibitors of viral binding and infection. One such approach has been to prepare derivatives of sialic acid with extended *N*-acyl groups, such as *N*-propanoyl, *N*-butanoyl, and *N*-pentanoyl; an elongation of *N*-acyl group resulted in inhibition of influenza A virus binding and infection [217]. The structure, function and evolution of viral sialate-*O*-acetylesterases has been recently reviewed with specific focus on the hemagglutinin-esterases of nidoviruses [218]. These enzymes help the virus achieve cell selectivity via protein-carbohydrate interactions of specific Sia subtypes.

The use of monosaccharide-based arrays to detect bacterial toxins, viruses and bacteria has been reported [219]. Arrays of *N*-acetyl galactosamine and *N*-acetylneuraminic acid derivatives were immobilized and were probed with fluorescently labeled bacterial cells and protein

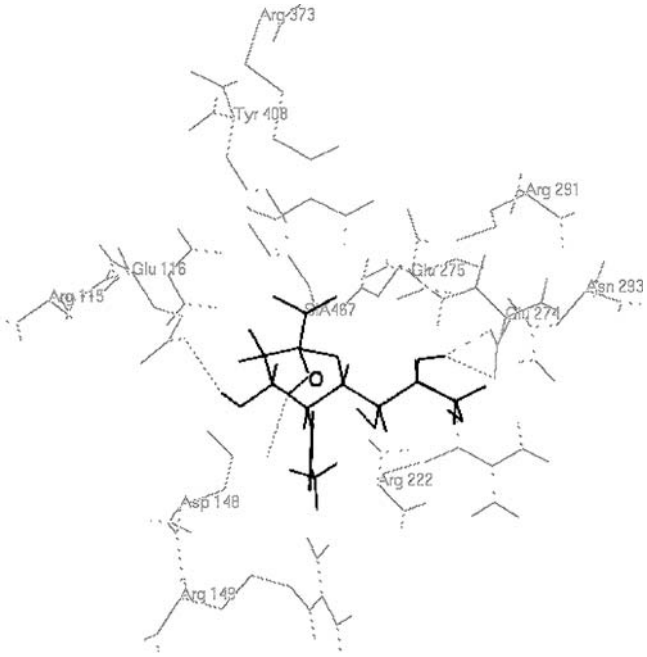


Figure 17
Influenza B neuraminidase and its complex with sialic acid (SIA)

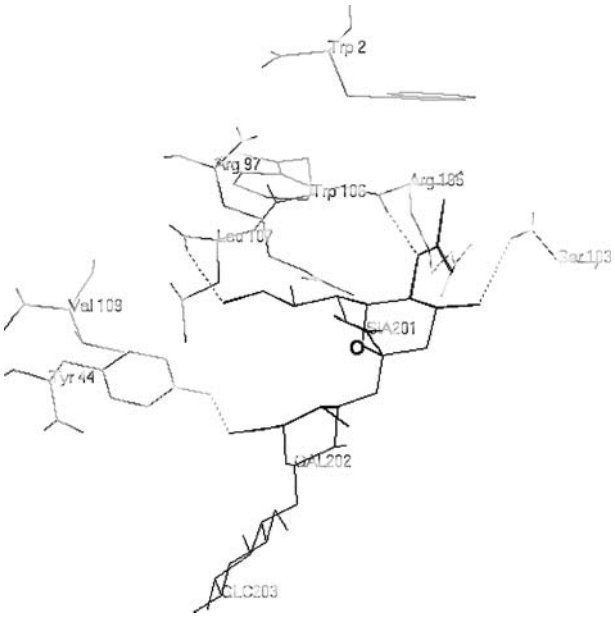

Figure 18
The structure of the *N*-terminal domain of sialoadhesin in complex with 3′siallylactose (SIA: sialic acid, GAL: galactose, GLC: glucose)

toxins. Salmonella typhimurium, Listeria monocytogenes, Escherichia coli and staphylococcal enterotoxin B (SEB) did not bind to either of the monosaccharides however, cholera toxin and tetanus toxin bound to GaINAc and Neu5Ac. This shows that the binding of the toxins to the carbohydrates is density dependent and semi-selective.

The involvement of sialic acid in the interaction of leukocyte adhesion receptors of the selectins with their ligands has been a subject of numerous reviews. It is obvious from these studies that sialic acid is involved in this interaction because of the charge of its carboxylic group that can be substituted with sulfate [220]. More recently, selectin/mannose-binding protein chimeras have been constructed to understand the mechanism involved in the binding of sialylated $Lexis^x$ oligosaccharide by this receptor [221].

The crystal structure of the *N*-terminal domain of sialoadhesin in complex with sialyllactose as ligand has been solved at 1.85 Å resolution [222]. The structure of the immunoglobulin domain contained in this receptor conforms to the V-set immunoglobulin-like fold but contains several distinctive features. The carboxylate of sialic acid forms a salt bridge with a side chain of Arg_{97} (◉ *Fig. 18*).

Hydrophobic interactions are made between the acetamido methyl group and the side chain of Trp_2, C9 of the glycerol side chain and the side chain of Trp_{106}, and C6 of galactose and the side chain of Leu_{107}. Hydrogen bonds are made between sialic acid and the main chain atoms of Ser_{103}, Leu_{107}, and Arg_{105}.

Although plant-derived ascorbate remains the major source of vitamin C in the human diet, its biosynthetic pathway is still unknown. However, recently it has been found that both

D-mannose and L-galactose are efficient precursors for ascorbate synthesis, that proceeds through a pathway involving GDP-D-mannose, GDP-L-galactose, L-galactose, and L-galactono-1,4-lactone [223].

6.1 Biomedicine

Monitoring of the levels of total sialic acid and lipid-associated sialic acid in serum is an important diagnostic tool for the detection of precancerous lesions [224]. Transition-state analogues derived from sialic acid are potent inhibitors of sialidases from various influenza virus strains, and these have been evaluated clinically as influenza remedies [225]. A detailed review of our current knowledge regarding the occurrence, specificity and function of sialic acid-specific lectins, particularly those that occur in viruses, bacteria and non-vertebrate eukaryotes has been recently published [226].

Several diseases are caused by defective sialic acid metabolism. Sialic acids cleaved off from degraded sialoglyco-conjugates are exported from lysosomes by a membrane transporter, named sialin, which is defective in two allelic inherited diseases: infantile sialic acid storage disease (ISSD) and Salla disease [227]. The function of sialin is basically known. Sialin's biosynthesis and intracellular trafficking as well as functional consequences of disease mutations have been characterized as well as the expression, localization, and targeting of the wild-type sialin [228]. A functional assay of human sialin has been developed and used to determine how pathogenic mutations affect transport [229].

"Sialic acid engineering" refers to the strategy whereby cell surface carbohydrates are modified by the bio-synthetic incorporation of metabolic intermediates, such as non-natural *N*-acetylmannosamine (ManNAc) analogues, into cellular glycoconjugates. Acetylated ManNAc analogues for use in sialic acid engineering applications have been developed and have been shown to be metabolized up to 900-fold more efficiently than their natural counterparts [230].

The protective effects of ascorbate as both a general antioxidant and a specific cofactor in the biosynthesis of collagen and other tissue proteins has been widely discussed in both the scientific and lay community, but its protective effects against the formation of cataract [231] and apoptosis of T cells [232] are probably worth mentioning. The estimated average requirement of ascorbate for the human diet is approximately 100 mg per day, and is usually adequately met by consumption of fruits and vegetables [233].

7 Phosphorylated and Sulfated Monosaccharides

Phosphorylated monosaccharides are common metabolic intermediates of all classes of monosaccharides, and as such they have already been mentioned in the preceding sections. Here, mostly the role of these compounds related to the cellular recognition events, and cell-cell adhesion events will be discussed. Two important receptors specific for D-mannose 6-phosphate are responsible for the proper delivery of the lysosomal enzymes into their target compartment. It appears from functional studies that there is certain redundancy in the biological function of these receptors; but knock-out mouse studies indicate that the lack of the large (205 kDa) cation-independent mannose 6-phosphate receptor appears to perturb lysosome function to a greater degree than the lack of the smaller (46 kDa) cation-dependent receptor [234]. The molecular basis for lysozyme recognition has been recently revealed

from X-ray analysis of the extracytoplasmic domain of the cation dependent receptor in complex with mannose 6-phosphate at 1.8 Å resolution [235]. The monomeric fold contained a nine-stranded, flattened β-barrel which bears a striking resemblance to avidin.
The second class of proteins that seem to bind mannose 6-phosphate and sulfated oligosaccharides derived from heparin are the seminal plasma spermadhesins, a group of small, structurally well defined proteins with possible biological function in sperm capacitation and sperm-egg interaction [236,237].
The sulfated monosaccharides have been gaining prominence recently as they seem to play a well documented role as the critical components of the oligosaccharide ligands for the selectins. The structural and biochemical progress in this area is very fast with both the contribution from chemical synthesis and enzymology of the specific sulfotransferases [238].

7.1 Biomedicine

Phosphorylated and sulfated monosaccharides promise a great potential from the point of view of their biomedical applications. Administration of certain phosphorylated monosaccharides such as fructose 1,6-bisphosphate during early reperfusion significantly improves the function of the post-ischemic heart [239]. The mannose 6-phosphate/insulin-like growth factor 2 receptor has been identified as the putative breast tumor suppressor factor, and it seems to be involved in multiple aspects of tumor pathophysiology including the deregulated growth, apoptosis, angiogenesis, and invasion [240]. The structure, distribution and function in the central nervous system of mannose 6-phosphate/insulin-like growth factor 2 has been reviewed [241].
The use of heparin-related sulfated oligosaccharides attached to long-circulating liposomes has been reported for cancer immunomodulation by the carbohydrate ligands for the lymphocyte receptor NKR-P1 [242].

8 Other Monosaccharides

Additional monosaccharide derivatives have been involved in biological studies that do not fall into the previously listed chemical categories. Of these, the acetylated monosaccharide derivatives have attracted the highest consideration. In particular, the insulinotropic action of L-glucose pentaacetate has been evaluated in animal and clinical studies [243]. Similarly, the tetraacetate derivative of 2-deoxy-D-glucose has been evaluated because of its cytotoxic effects upon lymphocytes, fibroblasts, and melanoma cells [244]. 2-Deoxy-D-glucose tetraacetate has been shown to display cytostatic and cytotoxic activity in various lines of tumoral cells. It was found to inhibit cell growth and confer chemosensitivity to cisplatin in two lines of human melanoma cells, poorly responsive to cisplatin [245].

9 Conclusions and Future Perspectives

In recent years much progress has been made in elucidating the roles of monosaccharides in chemical biology and biomedicine. The impact of monosaccharides within biological and medicinal applications has been further extended by using synthetic chemistry to prepare

novel derivatives. Of central importance is the incorporation of monosaccharides, as well as larger saccharides, within microarray technologies, to facilitate the identification of new carbohydrate-binding proteins as well as new ligands for already known carbohydrate-binding proteins. It is envisaged that both naturally occurring and synthetic carbohydrates will be required for the manufacture of microarrays that are sufficiently comprehensive and representative of entire glycomes. New leads to biological pathways that involve carbohydrate-protein interactions and new therapeutic targets are amongst the biomedically important outcomes that are anticipated from such applications [246,247]. Carbohydrate arrays fabricated on gold films have already been used to study carbohydrate-protein interactions with surface plasmon resonance (SPR) imaging. The binding of the carbohydrate-binding proteins concanavalin A (ConA) and jacalin to arrays composed of the monosaccharides mannose and galactose was monitored and adsorption coefficients were obtained [248]. Moreover, the interactions of single-walled carbon nanotubes with monosaccharides have been studied [249] and the ability of self-assembled receptors to stereoselectively recognize a saccharide has been described [250]. Another area of recent interest has been the use of monosaccharides in the design and synthesis of novel glycopeptides, nonpeptidal peptidomimetics for peptides, and abiotic proteins and this has necessitated the de novo synthesis of carbohydrate amino acids and carbohydrate scaffolds and carboproteins. This area has been recently reviewed [251,252]. Monosaccharides have also been used within combinatorial chemistry strategies, as scaffolds for the production of solid phase supported libraries. Such approaches have exploited the presence of multiple hydroxyl functionalities within the sugar scaffold, by derivatization of each hydroxyl group in turn to incorporate a range of different pharmacophores. This has even allowed entry to a variety of bicyclic and polycyclic polyfunctionalized structures of interest [253,254].

To conclude, considering our still rather immature understanding of many cellular receptors for the monosaccharides, it can be predicted that the collaboration between carbohydrate chemists and biologists in this fascinating field of research will continue to thrive in the coming years offering the potential for many new and significant biomedical advances.

Abstract

Over the past three decades the field of glycobiology has expanded beyond a basic understanding of the structure and biosynthesis of glycoprotein, proteoglycans, and glycolipids toward a more detailed picture of how these molecules afford communication through binding to mammalian lectins. Although the number of different mammalian lectin domains appears to be finite and even much smaller than early estimates predicated based on the diversity of glycan structures, nature appears capable of using these in numerous combinations to fine tune specificity. The following provides an overview of the major classes of mammalian lectins and discusses their glycan binding specificity. The review provides a snapshot of the field of glycobiology that continues to grow providing an increasing number of examples of biological processes that rely upon glycan-lectin binding.

Keywords

Lectin; Mannose binding protein; Selectin; Asialoglycoprotein receptor; Macrophage mannose receptor; Mannose-6-phosphate receptor; Galectin; Pentraxin; Siglec; Oligomerization

Abbreviations

CTLDs	C-type lectin-like domains
CRD	C-type carbohydrate recognition domains
MBP-A	mannose-binding protein-A
MBP	mannose-binding protein
MDCC	MBP-dependent cell-mediated cytotoxicity
TNF-α	tumor necrosis factor-α
IL-1	interleukin-1
LAD-II	leukocyte adhesion deficiency type II
EGF	epidermal growth factor-like
CR	consensus repeat
HUVECs	human umbilical cord vein endothelial cells
ASGPR	asialoglycoprotein receptor
HL	hepatic lectin
RTG-r	rat testis Gal receptor
CHL	chicken hepatic lectin
AHL	alligator hepatic lectin
MMR	macrophage mannose receptor
LH	lutropin
DC-SIGN	dentritic cell specific ICAM-3 grabbing non-integrin
ICAM-3	integrin cell adhesion molecule 3
M6P	Man-6-phosphate
IGF-II/CI-MPR	insulin-like growth factor II/cation-independent M6P receptor
CLC	Charcot–Leydon crystal protein
HL	Hodgkin's lymphoma
CRP	C reactive protein

SAP	serum amyloid protein
PE	phosphoethanolamine
PC	phosphocholine
Ig	immunoglobulin
SIGLECS	sialic acid binding **i**mmuno**g**lobulin-like lectins
MAG	myelin-associated glycoprotein

1 Introduction

Lectins are proteins which bind to carbohydrate and must be neither of immune origin (e. g. not antibodies) nor catalytic (e. g. not enzymes) [1]. Carbohydrate recognition systems have been described as a functional triad of lectin, carrier (protein, peptide, or lipid), and carbohydrate [2]. Glycorecognition systems are important in the mediation of inflammation and immune response, protein trafficking, developmental regulation, cell adhesion and migration, cancer, nerve communication, cytotoxicity, fertilization, and the regulation of serum half-life of proteins and hormones, among other proposed or documented functions [2,3]. A number of unrelated microorganisms utilize lectin-carrier-carbohydrate interactions to infect hosts and prolong their survival [3]. Lectins are often found in the seeds of legume plants where they exhibit a wide variety of carbohydrate specificities, often for saccharides which are not native to the legume where they are found [4,5]. Legume lectins are nearly always oligomeric and are useful reagents for the agglutination of cells and precipitation of multivalent carbohydrates. Although there is little known regarding the native functions of legume lectins, they have proved themselves valuable as *in vitro* tools for immunology and glycobiology [4].

While many of the subtleties of glycorecognition have not been fully elucidated, two admittedly unique examples of the functional roles for carbohydrates may serve to convince the reader of their general importance in biology. First, ABO and Lewis blood groups are carbohydrate antigens present on *N*- and *O*-linked oligosaccharides and glycolipids. The fate of the recipient of a human blood transfusion who has not been adequately crossmatched for blood typing highlights the biological importance of carbohydrate recognition [6]. Secondly, ricin is a 60 kDa heterodimeric protein composed of catalytic (A subunit) and Gal-specific lectin (B subunit) domains and has been described as the most toxic substance known to man [5]. Cell adhesion is mediated by sugar binding to the B subunit, followed by endocytosis of the A and B subunits during non-specific homeostatic receptor recycling. In the reducing environment of the cell, the subunits dissociate and the A subunit is freed to catalyze depurination of the 28S ribosomal RNA subunit [5].

In the following, we present the structure and function of carbohydrate-lectin interactions with particular emphasis on the five known families of animal lectins [7,8]. These groups of structurally (and often functionally) distinct lectins can be divided into *C*-type (calcium-requiring) lectins, P-type (Man-6-phosphate binding) lectins, *S*-type (galectins) lectins, pentraxins, and I-type (immunoglobulin-like) lectins. Within these groups of lectins a wide (e. g. within *C*-type lectins) or a very narrow range of carbohydrate specificities (e. g. within galectins) have been observed. A number of recent X-ray crystal structures of lectins bound to ligand (see discussion below) have served to further our understanding of how binding specificity is achieved.

The number of identical or different subunits which oligomerize to constitute a biologically relevant receptor is considered in detail. Additionally, we present the sometimes well-documented but often speculative biological roles for the members of these lectin families.

2 C-Type Lectins

2.1 C-Type Lectin Subgroups

Of the 65 human proteins identified as containing *C*-type lectin-like domains (CTLDs), approximately half function as lectins. The *C*-type carbohydrate recognition domains (CRD) can be classified broadly into two groups, based on the relative orientation of the 3- and 4-hydroxyl groups of monosaccharides which interact with the primary ligand-binding site, with preferred ligands possessing equatorial geometry at these positions [9]. Approximately two-thirds of lectins are Man-type; containing CRD with affinity for mannose and *N*-acetylglucosamine, the others are referred to as Gal-type, and bind galactose and *N*-acetylgalactosamine [10]. The CRDs are characterized by a common overall fold and sequence homology, including 14 invariant and 23 conserved residues along their 115 to 130 amino acid length [11]. While the CRDs of *C*-type lectins are conserved, the overall topology and organization of the non-CRD regions of these lectins are diverse as reviewed elsewhere [11,12,13,14]. *C*-type lectins in group I are monomeric proteoglycans with domains flanking the *C*-terminal CRD (*Fig. 1*). Group II (type II receptors, indicating that they are integral membrane proteins with an intracellular *N*-terminus and an extracellular *C*-terminus), III (soluble, e. g. not membrane-associated proteins, collectins), and V (type II lymphocyte antigens) *C*-type lectins have trimeric structures (see discussion below) by virtue of the association of non-lectin *N*-terminal regions [15]. Group III collectins can form higher-ordered structures, such as pulmonary surfactant protein which forms 12-mer cruciform structures, as evidenced by electron microscopy, where the *N*-terminal regions of four trimers associate into a macromolecular cross [16]. It is unclear whether functional group IV selectin receptors (see discussion below) oligomerize.

Group VI consists of receptors with multiple lectin domains in a single polypeptide and is composed of the macrophage mannose, phospholipase A_2, DEC 205, and S4GGnM receptors [18]. Consistent with the observation that group VI lectins serve to endocytose ligands, they are referred to as the endocytic *C*-type lectins, although it may be noted that a number of group II *C*-type lectins, such as asialoglycoprotein receptors, are also endocytic. Group VII *C*-type lectins are the simplest structures consisting of a CRD without flanking domains [11]. Thirteen human proteins containing CTLDs have been identified by genomic screens and have been classified into seven additional groups [10].

2.2 Mannose Binding Protein

The conserved sequences and available X-ray crystal structures of *C*-type lectin CRDs correlate with a common structural motif identified in rat serum mannose-binding protein-A (MBP-A) as represented in *Fig. 2* [19,20]. There are two α-helices, 6 β-strands, and 2 disulfide bonds common to this motif. Divalent cation binding sites are located in the loop regions.

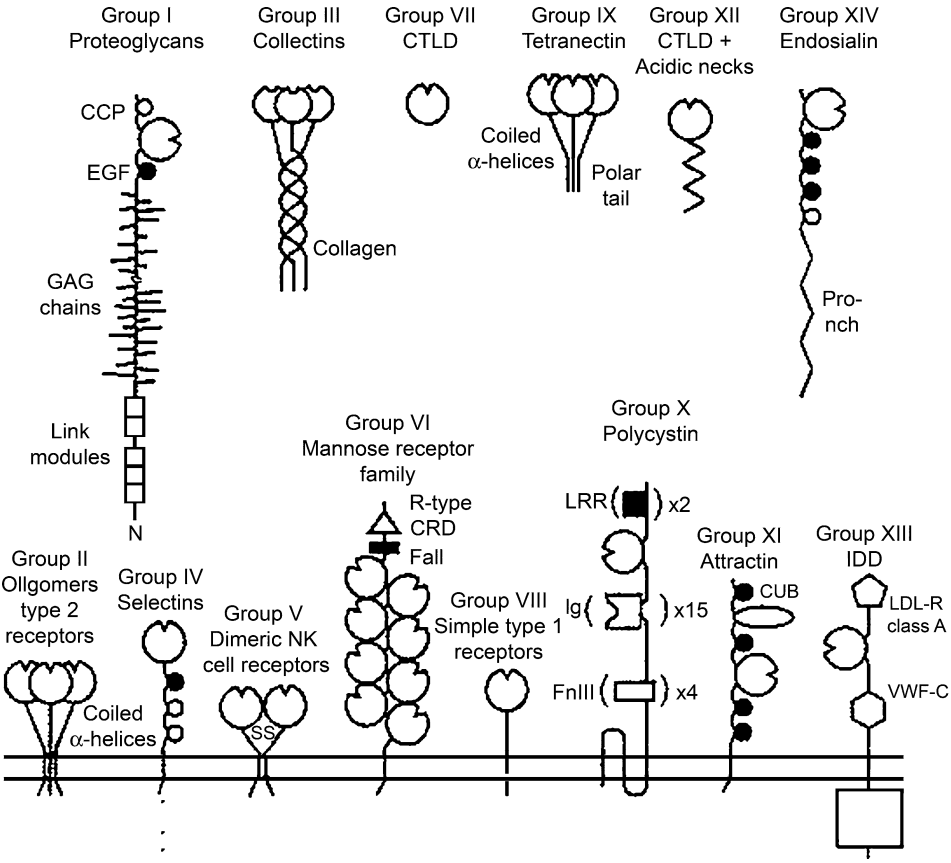

Figure 1

Domain organization of proteins containing CTLDs. CCP, complement control protein; CUB, complement components Clr/Cls, Uegf and bone morphogenetic protein-I; EGF, epidermal growth factor; Fn, fibronectin; LDL-R, low-density lipoprotein receptor; LLR, leucine-rich repeat; SS, disulfide bond; VWF-C, von Willebrand factor. Groups I, III, VII, IX, XII, and XIV are found in solution, while groups II, IV–VI, VII, X–XI, and XIII are membrane-associated. (Reproduced with permission from [17])

Calcium one is considered to be involved in maintaining lectin structure while calcium two coordinates directly with carbohydrate, and calcium three is believed to be an artifact of crystallization [20].

Chemical cross-linking experiments have determined, and X-ray crystallography has confirmed, that the oligomeric arrangement of MBP-A is a homotrimer with three axes of symmetry held together by the *N*-terminal regions interacting in a triple coiled-coil of α-helices [15]. The binding sites are 53 Å apart, significantly farther apart than that determined for the rat hepatic lectin (see discussion below). This indicates that a trimer of MBPs is unlikely to show cooperativity between subunits to interact with high avidity to a single high-mannose oligosaccharide, while foreign carbohydrate polymers such as yeast mannan would be expected to bind

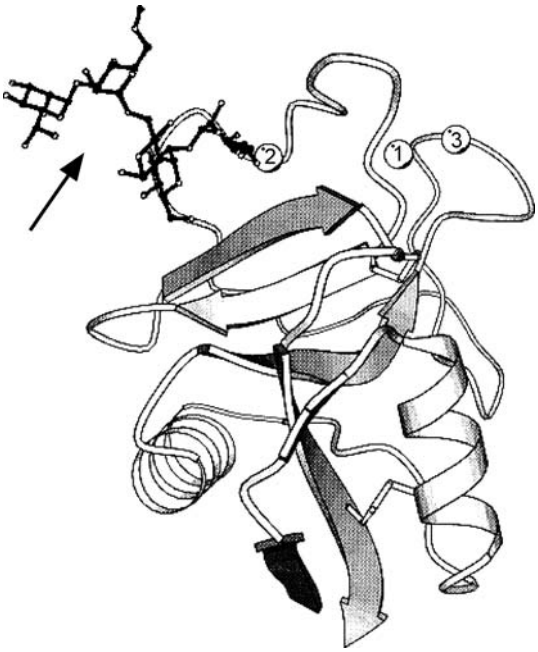

Figure 2

more tightly by interacting with all three subunits of a MBP-trimer [15]. The three-dimensional X-ray crystal structure of MBP-C [21] demonstrates a topology nearly identical to that of MBP-A.

The mode of specific recognition of different sugars by highly homologous *C*-type lectin CRDs have been advanced by Drickamer and colleagues. It may be noted that while MBPs recognize Man, other hexoses with vicinal, equatorial hydroxyls at positions 3 and 4 have been shown to specifically bind these lectins, suggesting that MBPs may bind to a variety of saccharides [22]. Ligand discrimination between GlcNAc, Gal/GalNAc, Man, and Fuc residues have been delineated to the orientation of similar binding site residues which interact with or exclude individual hexoses based on equatorial and/or axial substituents [23]. Subtle mutations of the binding site residues of MBP-A have been shown to alter its binding specificity from Man to mimic the binding properties of asialoglycoprotein receptors, that bind to Gal [24,25], GalNAc [26,27], and GlcNAc [28]. MBP has also been altered to possess E-selectin-like specificity for the Fuc-containing sialyl $Lewis^x$ tetrasaccharide [29,30,31].

MBPs have been proposed to act as a primitive complement-dependent arm of the immune system [32]. A functional role has been shown in the clearance of yeast [33], complement fixation of bacteria [34], and the blocking of viral infectivity (human immunodeficiency and influenza viruses) [35,36]. Two serine proteases (MASP-1 and MASP-2) have been shown to be associated with the MBP receptor and are required for complement activation by MBP [37]. A recent

study suggests that there is an additional complement-independent pathway mediating MBP cytotoxicity [38]. MBP-dependent cell-mediated cytotoxicity (MDCC) has demonstrated anti-cancer activity in mice injected with human colorectal carcinoma cells [38]. Patients with a deficiency in the MBP gene demonstrate a life-long increased susceptibility to infection [39]. This is evident for cystic fibrosis patients in which MBL-deficiency influence the severity of chronic infection by *Pseudomonas aeruginosa* and *Burkholderia cepacia* [40]. An affinity purified form of MBL has been developed and used in a phase 1 clinical to treat patients with opsinization defect [41].

2.3 Selectins

The selectins are a family of lectins that mediate the movement of leukocytes from the bloodstream into sites of inflammation. This multistep cascade proceeds by initial attachment leading to the rolling of leukocytes along endothelial vasculature via selectin-carbohydrate interactions. Subsequent firm adhesion requires chemoattractant activation of leukocyte β_2 integrins which mediate arrest through interaction with endothelial receptors. Leukocytes then extravasate between endothelial cells in the direction of chemoattractants as indicated in *Fig. 3* [42].

There are three selectin molecules: E (endothelial), P (platelet), and L (leukocyte), (reviewed in [43]) named for their cellular localization. P-selectin is released to the cell surface from storage vesicles in endothelial cells and platelets minutes after stimulation by a number of activators, such as thrombin or histamine [42]. E-selectin expression on the endothelial cell surface

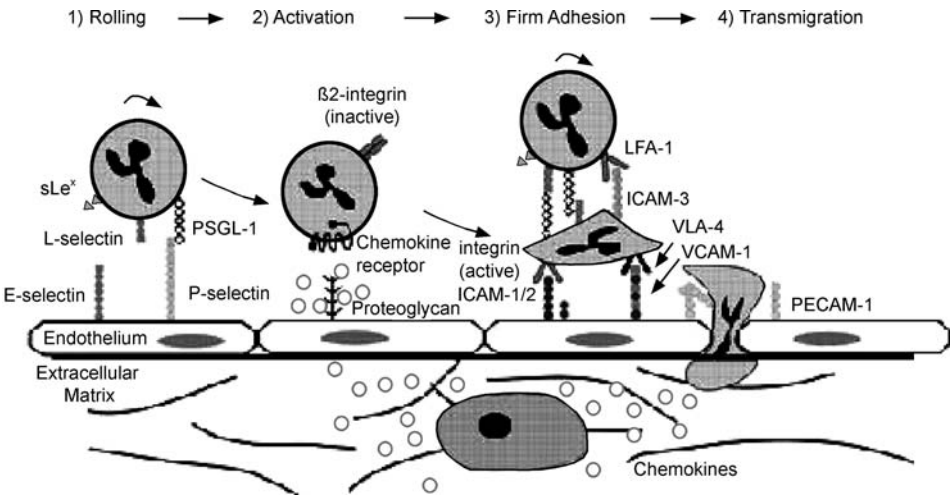

Figure 3

Leukocyte rolling and adhesion. The migration of leukocytes to sites of inflammation begins with attachment (1a.) followed by rolling (1b.), activation (2), cessation of movement and flattening against the vessel wall (3), and trans-endothelial migration (4). Steps 1a–2 are mediated by selectins, 1b–4 by chemoattractants, and 3–4 by β_2 integrins. (Adapted with permission from [42])

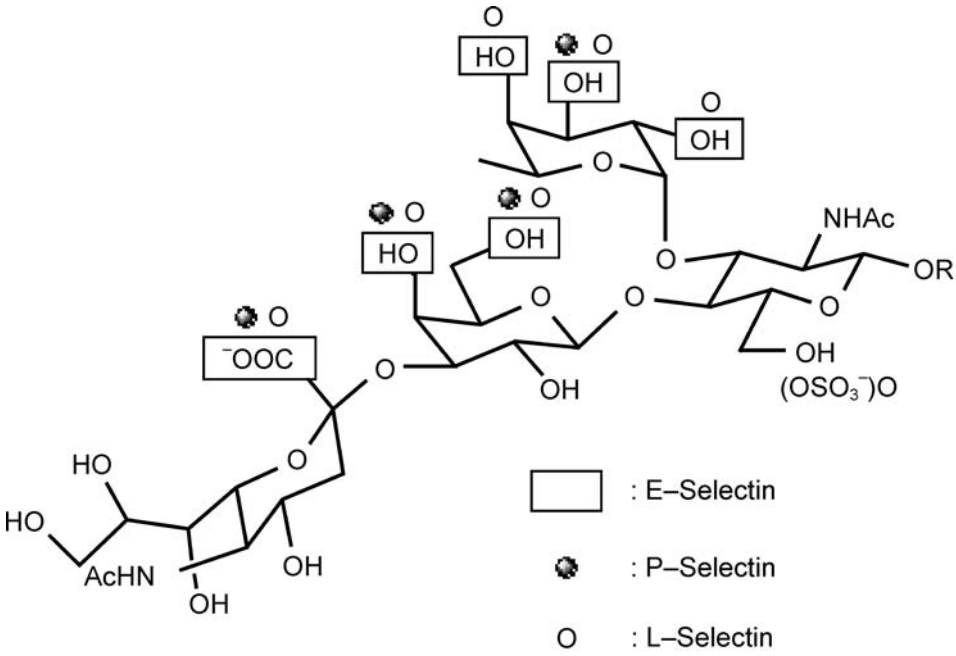

Figure 4
Selectins bind to different functional groups of the sialyl Lewis^x tetrasaccharide. Functional groups considered to be important for binding to each of the selectins are indicated. (Reprinted with permission from [49])

requires de novo mRNA transcription, peaking 3–6 hours after stimulation with activators such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), or bacterial lipopolysaccharide [44]. These cytokines also upregulate the transcription of P-selectin, resulting in increased expression 2–4 hours following stimulation [42].

All three selectins bind sialyl Lewis^x (SLe^x, NeuAcα2-3Galβ1-4[Fucα1-3]GlcNAc) which is proposed to be the minimal carbohydrate ligand for all three selectins, although sialyl Lewis^a (NeuAcα2-3Galβ1-3[Fucα1-4]GlcNAc), 3′SO_4-Le^a and 3′SO_4-Le^x bind with affinities similar to SLe^x [45,46,47,48].

Pharmacophore studies utilizing ligands with addition or deletion of hydroxyl groups and modifications to sialic acids have produced a foundation for understanding the nature of the interactions between SLe^x and each selectin as shown in *Fig. 4* [49]. Selectins do not tolerate the deletion of Fuc hydroxyls, while the only moiety of NeuAc necessary for binding is the *C*-1 carboxylate. Gal C-4 and C-6 hydroxyls are important for binding, while the remainder of Galβ1-4GlcNAc is considered to function primarily as a scaffold on which Fuc and NeuAc (or sulfate) are positioned for receptor binding [49].

A variety of pathological consequences are the result of malfunctions related to the selectins. Patients with a rare disease known as leukocyte adhesion deficiency type II (LAD-II, whereas LAD-I is a defect in the common β_2 integrin subunit) lack the appropriate de novo fucosylation pathway to biosynthesize SLe^x, and consequently suffer from repeated severe bacterial

infections in their early youth [50,51]. Selectin "knockout" mice have been genetically engineered and demonstrate abnormal leukocyte rolling, as well as an increased susceptibility to infection [52]. It has also been proposed that the selectins mediate tumor metastases via tumor cell expression of SLe^x [48].

The SLe^x epitope is expressed on inflammation-induced acute phase proteins which serve as endogenous competitors for selectins and mediate a dampening of the immune response, returning inflammation to homeostasis [53]. Inhibitors of the selectins have been proposed to be useful therapies for treating inflammatory disorders including respiratory distress [54], hypersensitivity responses [55], and surgically induced myocardial ischemic reperfusion injury [56]. Animal studies have shown that the inhibition of selectin-carbohydrate interactions can alleviate these inflammatory responses.

E-, P-, and L-selectin each consist of an *N*-terminal *C*-type lectin carbohydrate recognition domain (CRD), an epidermal growth factor-like (EGF) subunit, a number of short consensus repeat (CR) units, a membrane spanning region, and a *C*-terminal cytoplasmic tail. There is approximately 72% homology for analogous selectin CRDs across species, and ~ 52% homology between different selectins within a species [43]. Notably, the selectins are unique among *C*-type lectins as they have only one calcium binding site [57]. While the 3-dimensional structure of E-selectin CRD and EGF domains without ligand bound has been elucidated by X-ray crystallography [57], there is not yet an unambiguous understanding of the binding interactions between selectins and their ligands. The interactions of a mutant MBP with its binding specificity subtly altered to mimic E-selectin (as described above) have been elucidated by X-ray crystallography as shown in ❯ *Fig. 5* [58].

As expected, this structure shows that calcium complexes directly to Fuc hydroxyls rather than serving a purely structural role. Gal C-4 and C-6 hydroxyls are hydrogen bonded to lectin side chains, while the acetyl and backbone groups of GlcNAc participate in hydrophobic bonding. Interestingly, this structure fails to demonstrate interactions between the lectin and the C-1 carboxylate of NeuAc [58]. Lys 213 [57,59] (in MBP numbering), or alternatively Arg 97 [60] have been independently identified as likely electrostatic binding partners with the negatively charged carboxylate. The NMR structure of SLe^x bound to E-selectin suggests a binding pocket where Lys 111 is positioned to hydrogen bond the C-7 hydroxyl of NeuAc, and Lys 113 is an electrostatic binding partner for the C-1 carboxylic acid of NeuAc [61]. E-selectin mutants Lys113Ala (residue 213 in MBP numbering) and Arg97Ala demonstrate a complete loss of affinity for SLe^x [57,59]. Conservative mutation of these residues (e. g. Lys113Arg [60] and Arg97Lys [57]) failed to restore SLe^x binding activity, while mutant Lys113Glu bound as well as wild-type [60].

Although NeuAc (or an appropriately spaced negatively charged carboxylate isostere) is required for binding to the selectins [62], the model of an electrostatic interaction between the C-1 carboxylate and binding site lysine(s) has not been confirmed. A short sequence of lysine and arginine residues shown to be conserved in six bacterial sialic acid binding lectins [*H. pylori* hpaA, *E. coli* fimbral adhesion (SfaS), *E. coli* K99 fibrillar adhesion protein (K99), *E. coli* colonization factor antigen I (CFA/1), *V. cholerae* heat-labile toxin B subunit (CT-B), and heat-labile *E. coli* enterotoxin (LTI-B)] was proposed to comprise a sialic acid binding consensus sequence, and the positive charge of these residues in the binding pocket prompted the theory that they were electrostatic binding partners for the C-1 carboxylate of sialic acids [63]. The "basic consensus sequence" residues of the K99 and SfaS lectins were

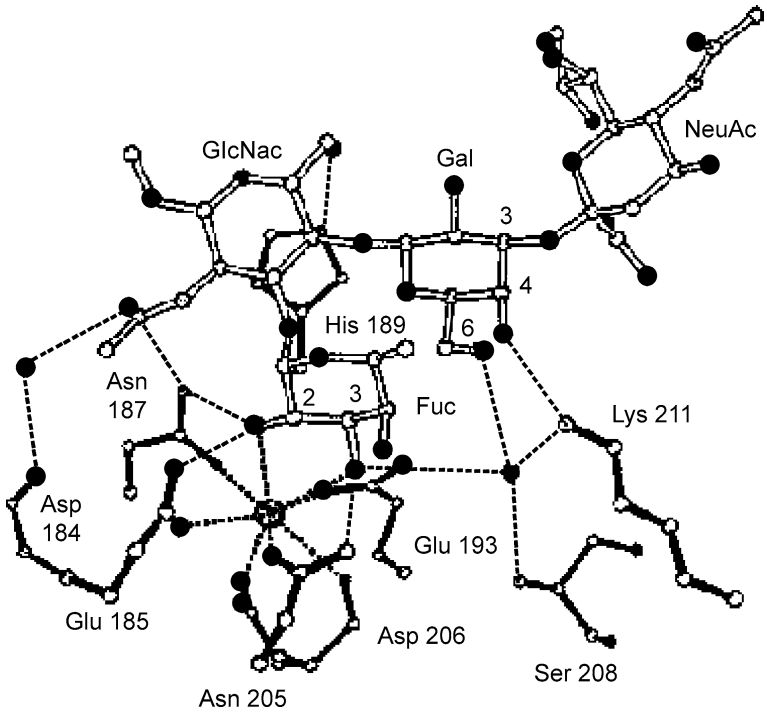

Figure 5
X-ray crystal structure of the binding site of a mutant mannose binding protein with specificity for sialyl Lewis X with ligand bound. See text for details. (Reprinted with permission from [30])

mutated to neutral residues, and resulted in a loss of binding [64,65]. It has been shown that selective chemical modification of lysine and arginine residues of CT-B blocks binding to sialic acids [66]. It was not until the X-ray crystal structures of the CT-B and LTI-B bound to ligands ganglioside G_{M1} and lactose [67,68] were published that this theory was questioned. The conserved lysine and arginine residues are not part of the binding site, and their roles are structural rather than important for binding.

There is evidence that biologically relevant selectin receptors are multimeric. Gel permeation chromatography of P-selectin isolated from human platelets showed an apparent molecular weight of 2000 kDa which was shifted to an apparent molecular weight of 470 kDa (the apparent molecular weight of P-selectin by SDS-PAGE is 120 kDa) when eluted with detergent [69]. Analytical ultracentrifugation of P-selectin has indicated that it forms higher ordered species from dimers to hexamers [70]. Likewise, E-selectin demonstrates the formation of high molecular weight species by size-exclusion chromatography [71].

Another line of evidence for multimeric organization of selectins comes from increased binding of multivalent ligands. Selectin-ligand interactions are noted to be weak (K_D = mM) consistent with the interactions of many lectins with monovalent ligands [72]. Bivalent SLe^x ligands show a five-fold increase over monovalent ligands in blocking neutrophil binding to immo-

bilized E-selectin [73,74]. Bovine serum albumin (BSA) bearing 7, 11, or 16 SLe^x moieties displayed a 20, 900, or 1000-fold increase in avidity, respectively, in an assay measuring leukocyte binding to immobilized E-selectin [75]. Monovalent, divalent, and tetravalent SLe^x moieties on linear and branched carbohydrate scaffolds inhibited L-selectin dependent adhesion of lymphocytes with potencies increasing in order of valency to an IC_{50} of 1 nM for tetravalent structures [76,77]. Liposomes bearing SLe^x have shown enhanced inhibition of human umbilical cord vein endothelial cells (HUVECs) binding to immobilized E-selectin by seven orders of magnitude compared to monovalent ligand [78]. One explanation for the increased potency of multivalent ligands is that a cluster of appropriately spaced ligands is in a unique position to interact with the multiple binding sites of a cluster of lectins (the "multivalency effect" as discussed below). Another recently offered explanation suggests that the apparent avidity of lectin-carbohydrate interactions depends upon whether the lectin or the carbohydrate is immobilized [79]. When the carbohydrate is immobilized, the lectin binding as measured by surface plasmon resonance is five orders of magnitude greater than when the lectin is immobilized. It has been proposed that the "multivalency effect" of lectin-carbohydrate interactions often attributed to lectin oligomerization can sometimes be attributed to an artifact of a slower k_{off} for ligands which are either larger than monosaccharides or bear multiple ligands [79].

Although SLe^x, SLe^a or their sulfated derivatives are widely considered to be "the ligands" for the selectins, appropriate sialylation/sulfation and fucosylation for biologically relevant binding to selectins could potentially occur on any number of *N*- or *O*-linked oligosaccharides, carbohydrate polymers, or glycolipids. A number of candidate selectin ligands have been identified (reviewed in [43,80,81]). The best characterized ligand for P-selectin is dimeric PSGL-1, presenting SLe^x–type determinants on the non-reducing end of *O*-linked oligosaccharides [82,83,84]. Three candidate ligands for L-selectin have been isolated. They are GlyCAM-1, CD34, and MAdCAM-1 presenting SLe^x on the non-reducing end of *O*-linked oligosaccharides [85,86]. Ligands for E-selectin have been advanced as either glycolipids [87,88] or the glycoprotein ESL-1, the latter presenting relevant carbohydrate determinants on *N*-linked oligosaccharides [89,90,91]. Dissociation constants for the binding of selectins to multivalent ligands and potential ligand-carriers are typically in the range of nM [70,92,93,94], while binding to monovalent sialylated or sulfated Lewis antigens are in the range of mM [95].

2.4 Asialoglycoprotein Receptors

The nomenclature of "asialoglycoprotein receptor" was first used to describe the apparent function of a mammalian liver cell surface lectin. This lectin was shown to bind and endocytose glycoproteins by virtue of the non-reducing terminal Gal residues present on oligosaccharides exposed by non-specific or enzymatic removal of sialic acid residues, and was consistent with the rapid clearance of serum glycoproteins following desialylation [96]. It has become apparent that a number of endocytic receptors rapidly purge appropriately glycosylated proteins of differing carbohydrate specificities from serum [97].

The canonical asialoglycoprotein receptor (ASGPR) is the hepatic lectin (HL) common to mammals, first reported in the rat in 1974 by Ashwell and co-workers [98] {reviewed in [99,100,101]}. Rat HL is a complex of two homologous *C*-type lectins (46 kDa HL-1 and

50 kDa HL-2/3) specific for Gal and GalNAc [102]. The "multivalency effect" encompasses the idea that the binding of appropriately spaced single ligands on a common backbone may achieve an avidity equal to the sum of individual affinities limited only by the loss of translational and rotational entropy intrinsic to the spatial limitations of the backbone. In perhaps the clearest demonstration of this effect, it has been determined that the binding of rat HL is inhibited by monovalent Gal (IC_{50} 1 mM), biantennary non-reducing *N*-linked oligosaccharide terminating in Gal (IC_{50} 1 μM), triantennary Gal-terminating oligosaccharide (IC_{50} 10 nM for one isoform, the others being less potent), and tetraantennary Gal-terminating oligosaccharide (IC_{50} 1 nM). This indicated that a trimeric lectin binds to a trimeric oligosaccharide with high affinity [103,104]. It has been estimated that the distance between binding sites is from 17–43 Å [105]. Ligand photo-affinity labeling of the subunits of the rat HL has defined the geometry of subunits as a trimeric receptor composed of one HL-2/3 subunit and two HL-1 subunits [106]. Capitalizing on the high avidity binding of triantennary Gal/GalNAc-terminating oligosaccharides for endocytic HL, agents have been prepared as potential carriers of therapeutic DNA for receptor-mediated gene delivery to parenchymal hepatocytes [107,108,109]. Although a biological role has been established for HL, transgenic mice which lack the minor subunit of HL (HL-2 "knockout mice") demonstrate only a mildly abnormal phenotype, and while they fail to clear appropriately glycosylated glycoproteins, there is no serum accumulation of these glycoproteins [110,111].

A 32–34 kDa Gal/GalNAc specific *C*-type lectin (M-ASGP-BP) has also been detected in mammalian macrophages [112]. It is 59% identical to RHL-1 and 45% identical to RHL-2/3 at the amino acid level, with a shorter cytoplasmic tail and an insert between the membrane spanning region and CRD. Enhanced avidity of clustered saccharide ligands suggests that in contrast to HL recognition of a distinct triantennary oligosaccharide, oligomeric M-ASGP-BP binds to triantennary oligosaccharides with potencies equal to a random cluster of Gal residues [113]. Additionally, while HL prefers ligands terminating in GalNAc, M-ASGP-BP is selective for Gal [113].

Fuc/GlcNAc specific receptors have been identified in mammalian tissues. An endocytic *C*-type lectin recognizing Fucα1-3Galβ1-4GlcNAc found in Kupffer cells (macrophages specific to the liver), is present as two subunits of 77 and 88 kDa [114,115,116,117,118]. A 180 kDa Fuc/GlcNAc specific lectin has also been localized to Kupffer cells and rat alveolar macrophages [119,120].

A Gal/GalNAc specific *C*-type lectin which is antigenically similar to RHL-2/3 has been detected in mammalian testes. The rat testis Gal receptor (RTG-r) is expressed throughout testicular development, and in spermatids and sperm it is restricted to the plasma membrane overlaying the dorsal portion of the head. Rather than functioning in the clearance of serum glycoproteins, this lectin has been proposed to be important in spermatogenesis and events leading to sperm-egg recognition [121].

The avian homolog of the mammalian liver asialoglycoprotein receptor has been reported. Isolated as a 26 kDa glycoprotein, the chicken hepatic lectin (CHL) exhibits divalent cation-dependent lectin activity requiring a pH greater than 6.5 [122]. It has been shown to mediate endocytosis of glycoproteins bearing non-reducing terminal GlcNAc residues [123]. Avian glycoproteins possess Gal-terminating oligosaccharides, which could be trimmed to bear GlcNAc residues for clearance by CHL [124,125]. Chemical cross-linking of CHL has demonstrated oligomeric species ranging from monomer to hexamer [126]. However, radiation inac-

tivation and sedimentation equilibrium analysis has shown a distribution of oligomeric species, suggesting that while diffuse higher ordered species may be present, the functional state of the receptor is likely a trimer [127].

The major liver lectin of the alligator has been isolated and characterized as a calcium-dependent D-Man/L-Fuc specific lectin, designated as the alligator hepatic lectin (AHL). AHL is present as two bands of equal intensity at 21 and 23 kDa by SDS-PAGE. Binding to ligand is inhibited below pH 6.5, consistent with dissociation in acidic endosomal compartments [128]. Chemical cross-linking of AHL showed dimeric, trimeric, and diffuse higher ordered species of lectin, with the formation of oligomers being favored in the presence of multimeric ligand. This result was consistent with size-exclusion chromatography which indicated species present as monomers, dimers, and trimers. Unfortunately, this lectin has yet to be sequenced or cloned making its designation as a *C*-type lectin unclear. It has been speculated that a hierarchy of hepatic lectins in different organisms from mammals (recognizing Gal/GalNAc) to birds (recognizing GlcNAc) to reptiles (recognizing Man) may coincide with the terminal monosaccharides present on complex-type *N*-glycans in these classes of vertebrates, and function in their clearance from serum [128].

2.5 Endocytic C-Type Lectins

The macrophage mannose receptor (MMR) is a type I membrane-spanning protein with an intracellular *C*-terminus and an extracellular *N*-terminus possessing eight extracellular *C*-type lectin domains (CRD 1–8). CRD 4 is the only lectin domain that requires divalent cation to bind Man when expressed alone [129]. Only CRDs 4 and 5 resist digestion by a protease specific for a sequence that is inaccessible when bound to calcium [130], indicating that the remaining CRDs are not functional. However, the expression of truncated polypeptides has shown that CRDs 4–8 are required for binding to mannosylated glycoproteins, mannan, invertase, and Man-BSA neoglycoprotein, as well as to demonstrate ligand endocytosis equivalent to wild-type MMR [130]. Site-directed mutagenesis has established that the second ("structural") calcium binding site in MMR is located in a position unique to this *C*-type lectin [131]. Similar to other Man-specific lectins, this receptor also binds weakly to hexoses with equatorial vicinal C-3 and C-4 hydroxyls such as Fuc and Glc/NAc. The biologically relevant ligands for MMR were originally described (see main discussion) as polyvalent mannosylated ligands such as microbial carbohydrate polymers which could interact with the clustered CRDs of a single polypeptide. thus MMR would appear to function in host defense, clearing foreign molecules by endocytosis [131]. The orientation of Man bound to MMR as determined by NMR [132] is notably different from that of MBP and may reflect subtle differences in the binding specificity for these lectins.

The 180 kDa S4GGnM receptor is structurally similar *C*-type lectin located in liver Kupffer cells and hepatocytes and is specific for 4-sulfo-GalNAcβ1-4GlcNAcβ1-2Manα-bearing glycopeptides such as lutropin (LH) and thyrotropin. this highly regulated carbohydrate determinant is responsible for the rapid clearance of these hormones from the serum following their release from the pituitary gland [133]. This receptor and the pituitary synthesis of its unique carbohydrate ligand are conserved in vertebrates ranging from fish to mammals [134].

Since MMR and S4GGnM-R possess significant sequence homology, and similar topology and antigenicity, the cross-reactivity of their binding specificity has been examined. Surprisingly, both MMR and S4GGnM-R contain eight *C*-type lectin CRDs specific form Man as well as a single *N*-terminal cysteine-rich region specific for S4GGnM [135]. Since both lectins have dual specificity for both ligands and are highly related, the above described limited roles for each lectin have called into question [135]. It has been suggested that a more appropriate nomenclature for these lectins would be the liver and lung Man/S4GGnM-R. A potential explanation for the biological differences between these lectins utilizes the receptor oligomerization theory. Perhaps a cluster of *N*-terminal S4GGnM-recognizing regions of a dimeric/multimeric liver Man/S4GGnM-R could bind ligands such as lutropin tightly, while a monomeric lung Man/S4GGnM-R could not [135].

DC-SIGN and DC-SIGNR are homologous *C*-type lectins belonging to subgroup II. The DC-SIGN gene is located on the human chromosome 19p13 in close proximity to the DC-SIGNR (dendritic cell-specific ICAM-3 grabbing non-integrin-related) gene. These type II transmembrane receptors mediate cell-cell interactions within the immune system by binding to intracellular adhesion molecule-3 independent of the conventional ICAM-3 ligand, lymphocyte function-associated antigen-1 [9].

DC-SIGN (CD209) binds high mannose oligosaccharides, such as the $Man_9GlcNAc_2$ oligosaccharide found on the gp120 envelope glycoprotein of HIV-1, and in this way facilitates viral infection in *trans* of CD4+ T-cells [136]. DC-SIGN also functions as a receptor for *Mycobacterium tuberculosis* [137], hepatitis C virus [138], Ebola virus [139], and human cytomegalovirus [140].

3 P-Type Lectins

3.1 Architecture of P-Type Lectins

The two lectins that bind specifically to Man-6-phosphate (M6P) and compose the family of P-type lectins are the 43–46 kDa cation-dependent M6P receptor (CD-MPR) and the 275–300 kDa insulin-like growth factor II/cation-independent M6P receptor (IGF-II/CI-MPR). The structure and function of these receptors have been reviewed in detail elsewhere [141,142,143,144]. The IGF-II/CI-MPR is composed of a short *N*-terminal region, followed by a large extracellular domain of 15 repeating subunits, followed by a single transmembrane domain, and a *C*-terminal cytoplasmic tail. The CD-MPR is composed of a short *N*-terminal region, followed by a single extracellular domain homologous to each of the 15 repeating domains of the IGF-II/CI-MPR, followed by a single transmembrane domain, and a *C*-terminal cytoplasmic tail [141]. A schematic representation of the two M6PR lectins is shown in ❯ *Fig. 6* [143].

The binding sites for M6P have been localized to the extracellular domain of CD-MPR and to extracellular repeats 3 and 9 of IGF-II/CI-MPR [145]. Site-directed mutagenesis has implicated Arg 435 (in repeat 3) and Arg 1334 (in repeat 9) in bovine IGF-II/CI-MPR as important for binding [146]. Scanning Ala mutants of bovine CD-MPR in Gln 66, His 105, Arg 111, Glu 133, Arg 135, and Tyr 143 among others, demonstrated a loss in binding affinity and predicted that these residues may be important for binding [147]. The 3-dimensional structure of the

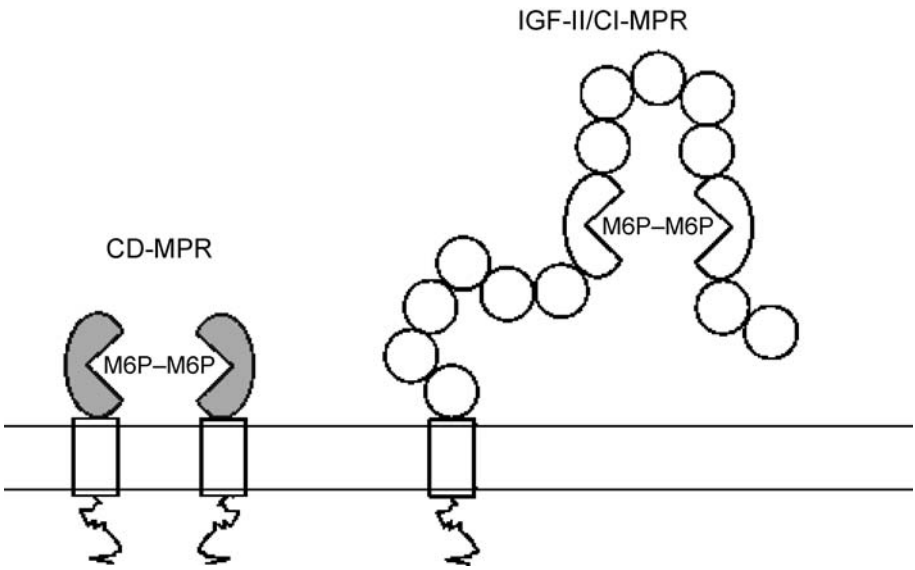

Figure 6
Model for receptor interactions with bivalent mannose-6-phosphate ligands. Dimeric CD-MPR subunits each bind one molecule of M6P, while monomeric IGF-II/CI-MPR has two lectin domains, each binding one molecule of M6P. (Adapted with permission from [143])

extracellular region of bovine CD-MPR complexed with M6P has recently been determined by X-ray crystallography [148]. The composition of this domain includes nine β-strands and one α-helix with three disulfide bonds oriented such that strands 5–9 and 1–4 form perpendicular β-sheets in a β-barrel arrangement as shown in *Fig. 7*. All six cysteines participate in inter-sheet stabilization by three disulfide bonds [148].

Amino acids involved in binding M6P are shown in *Fig. 8*. The phosphate moiety is coordinated by His 105, Asn 104, Asp 103 and divalent cation. Each hydroxyl of Man is hydrogen-bonded to binding site residues, while no interactions between the hydrophobic carbohydrate backbone and aromatic side chains are observed [148]. The multiple contacts between lectin and M6P, in contrast to that observed for many lectins which mediate cell surface interactions, are reflected in μM binding constants, reminiscent of bacterial arabinose-binding protein which functions as a sugar transport protein [149].

In contrast to CD-MPR, IGF-II/CI-MPR lacks residues corresponding to Glu 101 and Arg 111 which coordinate divalent cation, and may help explain why this lectin does not require metals for high-affinity binding [148]. In contrast to the *C*-type lectins which show no binding in the presence of EDTA, the absence of divalent cation only moderately raises the binding constant of CD-MPR to ligands such as pentamannose phosphate from 2×10^{-6} M to 2.5×10^{-5} M [150].

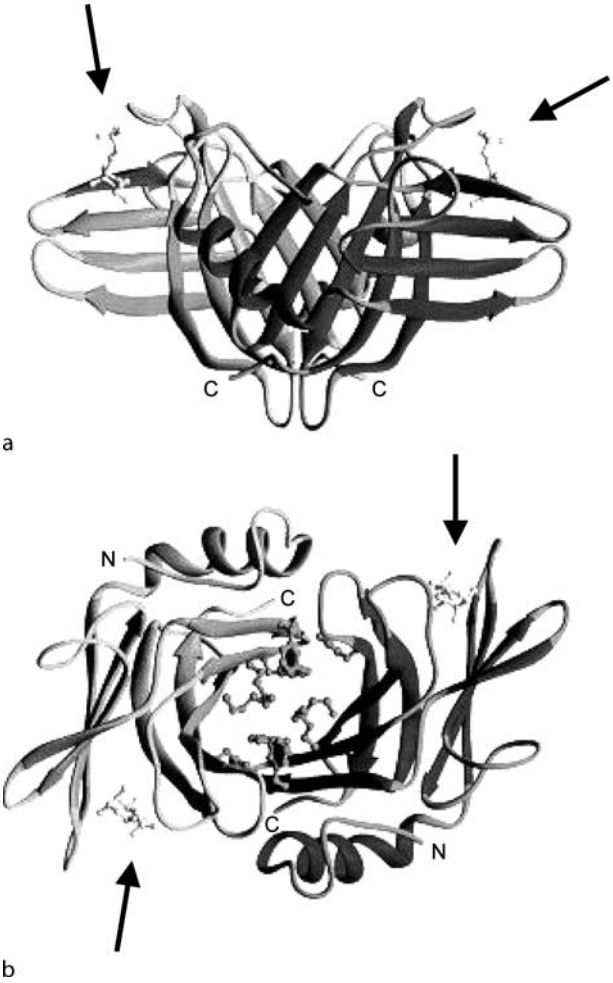

Figure 7

3.2 Oligomerization of P-Type Lectins

Equilibrium binding experiments with monomeric M6P and diphosphorylated high-mannose oligosaccharides have established that CD-MPR has one binding site per monomer which can be occupied by a single monovalent or a single divalent ligand in solution [150], while similar studies on the IGF-II/CI-MPR revealed two binding sites per monomer which can be occupied by two monovalent or a single divalent ligand in solution [151]. The relative avidities as measured by equilibrium dialysis of CD-MPR for M6P or a diphosphorylated high-mannose oligosaccharide were 8×10^{-6} M and 2×10^{-7} M, respectively [150], as compared

to 7×10^6 M and 2×10^{-9} M, respectively, for IGF-II/CI-MPR [151]. On the basis of this data, it has been proposed that a dimeric MPR binds with high affinity to glycoproteins decorated with diphosphorylated oligosaccharides, while no such dimerization may be required for ligand interactions with IGF-II/CI-MPR [141]. The two binding sites of IGF-II/CI-MPR are not functionally equivalent, as evidenced by the failure of mutants of critical Arg residues in either domain 3 or 9 to show compensation for each other [152].

The CD-MPR crystallizes as a dimer with relevant binding sites spaced 40 Å apart [148]. The distance between antennae for *N*-linked oligosaccharides is generally considered to be 20 Å [72], although X-ray crystallography has shown the non-reducing ends of a biantennary oligosaccharides as far as 24–27 Å apart [153], which indicates that a diphosphorylated high-mannose oligosaccharide is unlikely to interact with both binding sites of a dimeric receptor. The authors propose that a tetrameric receptor may be capable of mediating this interaction, although this theory is at odds with above mentioned data noting a binding ratio of one diphosphorylated oligosaccharide to two CD-MPR [148].

Both M6P receptors have been noted to form oligomers. Cross-linking of soluble CD-MPR and IGF-II/CI-MPR have demonstrated that receptor oligomerization depends upon pH, receptor concentration, and the presence or absence of ligand [154,155,156]. The on-off rates of association are relatively fast, indicating that oligomerization is a process in dynamic equilibrium.

Dimeric and tetrameric forms of CD-MPR are favored by a pH optimum of 6.3–6.4, dropping sharply above and below, and by the presence of ligand [156]. There is evidence that upon binding glycoproteins bearing multiple M6P moieties, monovalent IGF-II/CI-MPR dimerizes [157]. An attractive theory which explains the formation of oligomeric M6PRs has been advanced. High-affinity binding of M6PRs may be due to self-association in the golgi near neutral pH at high receptor concentration. Upon vesicular transport to endosomes, the dilution of receptor and lowering of pH induces self-dissociation, causing release of ligand, providing a mechanism for receptor recycling between golgi and endosome [141]. However, the experimental conditions of isolated receptors and membrane preparations under which this hypothesis has been tested may or may not reflect the actual cellular environment. Recently, cross-linking of CD-MPR in intact cells has been performed with membrane-permeable reagents. In this in situ system, CD-MPR remained dimeric upon raising endosomal pH, metabolic blockage of M6P ligand, or localization to the cell surface [158]. These findings suggest that tuning of receptor affinity for ligand is unlikely to be regulated by oligomerization. Additionally, the authors suggest that an alternative mechanism of regulating receptor affinity may be due to conformational changes in the lectin or ligand [158].

3.3 Biological Roles of P-Type Lectins

In few cases have the biological roles of lectins been more firmly established than for CD-MPR and IGF-II/CI-MPR. In the trans-golgi both receptors bind to proteins which have been decorated with M6P, such as acid hydrolases. The receptor *C*-terminal cytoplasmic targeting amino acid sequence serves as a recognition signal for transport to the endosomal compartment, where dissociation of lectin and M6P-protein takes place [141,142,143]. Lysosomal storage diseases (reviewed in [159]) are characterized by the failure to deliver acid hydrolases (or the delivery of ineffective acid hydrolysases) to the endosome, *en route* to the lysosomal compartment. This causes the accumulation of undegraded macromolecules in these compartments. Although the vast majority of lysosomal storage diseases are traced to biological defects other than M6P receptors, these two lectins are the only known proteins which serve to guide endosomal trafficking. CD-MPR and IGF-II/CI-MPR have overlapping but not identical roles. There is evidence that while IGF-II/CI-MPR is capable of endocytosis of ligands from the cell surface, CD-MPR is not. IGF-II/CI-MPR but not CD-MPR serves to turnover IGF by endocytosis [160,161]. Ligands for the M6P receptors are overlapping but not redundant, such that a high affinity ligand for CD-MPR is not necessarily a high affinity ligand for IGF-II/CI-MPR [162].

A strain of genetically engineered homo- and heterozygous “knockout” mice lacking CD-MPR has been shown to be indistinguishable from normal mice, including levels and activities of lysosomal enzymes [163]. In contrast, the IGF-II/CI-MPR knockout mutation is lethal [164]. However, IGF-II/CI-MPR null mice can be “rescued” to viable but abnormal phenotypes by genomic alteration to provide a background lacking in either IGF or IGF1r (IGF-receptor) [165]. The implication is that death is a consequence of overstimulation by IGF, while a milder phenotype is likely mediated by the CI-MPR function in IGF-II/CI-MPR knockout mice [165].

The IGF-II /CI-MPR has also been found in the circulation as a result of proteolytic release from the cell surface. The soluble receptor has been postulated to sequester IGF-II, thereby controlling the proliferative effects of this mitogen [166]. Consequently, the ability of the IGF-II/CI-MPR to target lysosomal enzymes, to bind TGF-b, and to bind IGF-II has implicated it in a role in tumor suppression. The discovery that there are a variety of mutations in the IGF-II/CI-MPR in human cancers have provided further evidence of this association [167,168,169,170].

4 *S*-Type Lectins

4.1 Architecture of the Galectins

The *S*-type (referring to conserved cysteine residues) lectin family has been designated the galectins [171], reflecting their common specificity for Gal presented as Galβ1-4Glc/NAc or Galβ1-3Glc/NAc. Thus far, there are fourteen numbered galectins (galectins 1–10, and 12–14) and five galectin like proteins (GRIFIN, HSPC159, PP13, PPL13, and OvGal11). Galectins do not contain a signal peptide and are secreted by non-classical mechanisms. They are not integral membrane proteins and binding does not require metals [172]. A diagrammatic representation of the known mammalian galectins is shown in *Fig. 9*. With the possible exceptions of galectins 3, 5, and 10, all known mammalian galectins are either dimeric or contain two CRDs in a single compact structure.

The structure and function of galectins have been reviewed in detail elsewhere [171,172,173,174,175,176]. Three-dimensional structures for galectins 1–3, 7, and 10 have been determined

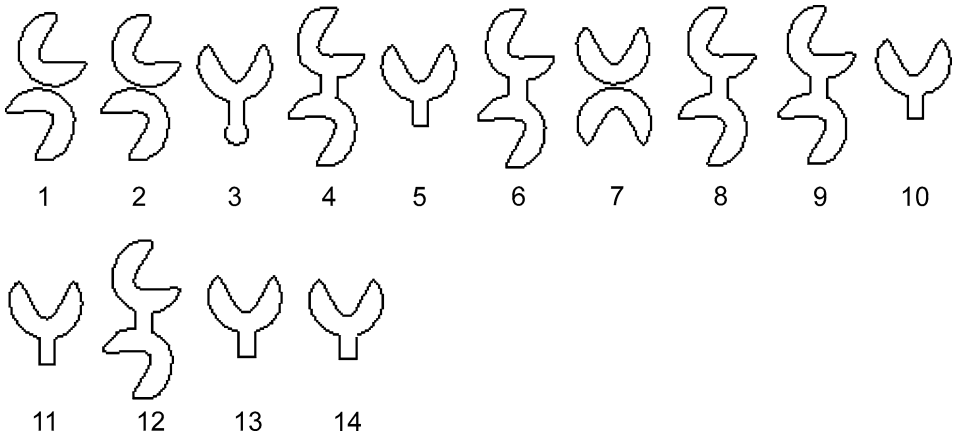

Figure 9
Representation of the structures of galectins 1–14. Galectins 1, 2, and 7 are shown as dimers, while monomeric galectins 4, 6, 8, 9, and 12 each contain two lectin domains. Galectins 3, 5, 10, 11, 13, and 14 are depicted as monomers each with a single lectin domain. (Adapted with permission from [175])

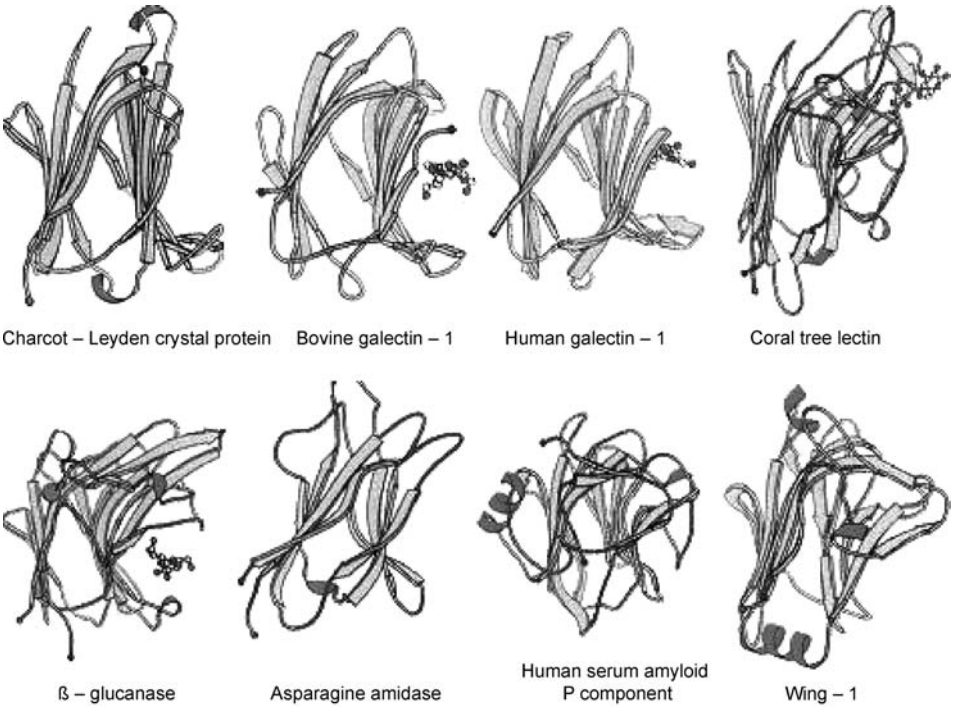

Figure 10

by X-ray crystallography [177,178,179,180,181]. A common motif determined for galectins consists of 5 conserved β-strands forming the first β-sheet, opposed by 6 β-strands forming a second β-sheet oriented in a β-sandwich which has become known as the "jelly-roll" motif [182], named for its resemblance to a pastry. This motif is common to all known legume lectins (reviewed in [4,5]), being first identified in concanavalin A, and likely is the result of convergent evolution from different ancestors since there is little primary amino acid or nucleotide homology between legume lectins and galectins. *Figure 10* depicts the lectin domain of three galectins, and shows that the motif is common to many lectins and otherwise unrelated proteins [181].

4.2 Oligomerization of Galectins

The dimeric nature of galectins 1 and 2 was first demonstrated by size-exclusion chromatography and crosslinking experiments [183]. Their 3-dimensional structures have more recently been characterized as dimers of individual 14 kDa CRDs, demonstrating two-fold axes of symmetry [153,177,178]. The CRDs of a single dimer are oriented away from each other such that binding sites cannot each interact with antennae of a single biantennary oligosaccha-

ride [153], but can serve as a cross-linker for β-galactosides. Non-covalent dimeric association is observed in galectins 1, 2, 5, 7, 10, 13, and 14 [184]. Galectins 4, 6, 8, and 9 and 12 contain two CRDs in a single compact protein, oriented apart as seen in galectins 1 and 2 [185, 186,187].

The crystal structure of galectins 1, 2, 3, 7, and 10 have been solved providing a detailed understanding of their dimeric nature [153,178,179,180]. Residues corresponding to the *N*-terminal region of galectins 1 and 2 which have been implicated as important for dimerization are absent in galectin 3 [179]. However, it has been shown that full-length galectin 3 forms oligomers which can be trapped by chemical cross-linking, while galectin 3 expressed as only the *C*-terminal lectin domain is primarily monomeric [188]. Additionally, full-length galectin 3 demonstrates hemagglutination activity while the *C*-terminal fragment is devoid of this activity [188]. Galectin 3 also shows positive cooperativity in binding to laminin, giving rise to speculation that both subunits of this possibly dimeric lectin can simultaneously bind Gal on the antennae of a biantennary *N*-glycans [189]. It is unclear if galectin 5 is functionally a monomer or an oligomer. While it does not show the presence of higher ordered species by size exclusion chromatography, its ability to hemagglutinate erythrocytes suggests that its functional state is oligomeric [184].

Charcot–Leydon crystal protein (CLC) has been designated galectin 10 based on its 15–30% sequence identity and structural similarity to other galectins [181]. Additionally, seven of twelve residues conserved in galectin carbohydrate binding sites are present [181]. CLC autocrystallizes in a hexameric bipyramidal arrangement [190]. CLC weakly binds to GlcNAc or LacNAc and its lectin activity has only been shown by binding to these monosaccharides immobilized on affinity columns [185]. CLC demonstrates enzymatic activity as a lysolecithin acylhydrolase and is a major constituent of total protein in eosinophils and basophils [191].

The amino acids considered to be required for ligand binding by galectins are shown for the representative galectin 2 in complex with lactose in ❯ *Fig. 11* [178]. The hydrogen bonding interactions are dominated by the C-4 hydroxyl group of Gal which binds to the side chains of His 45, Asn 47, and Arg 49, and the C-3 hydroxyl group of Glc which is in contact with Arg 49, Asn 58, Glu 68, and Arg 70. Also seen are hydrogen bonds from Asn 58 and Glu 68 to the C-6 hydroxyl of Gal. The multiple hydrogen bonds to the C-4 hydroxyl and the C-6 hydroxyl suggests that ligand discrimination is accomplished through recognition of the axial C-4 hydroxyl. Hydrophobic interactions of the indole side chain of Trp 65 with the pyranose ring of Gal suggest a reason why the binding site cannot accommodate a monosaccharide with an equatorial C-4 hydroxyl [178]. X-ray crystal structures of galectins bound to lactose, LacNAc or biantennary *N*-acetyllactosamine terminating oligosaccharide show a conserved hydrogen bonding network consistent with that determined for galectin 2 [164,181] (❯ *Table 1*).

While the terminal Gal residue is in intimate contact with the lectin binding pocket, the Glc/GlcNAc residue is oriented away from this region, presumably making a smaller contribution to binding specificity and affinity [177]. The lactose/LacNAc binding sites of galectins are located within a wide protein cleft, suggesting that the internal sugar residues of carbohydrate polymers, such as polylactosaminoglycans, can be accommodated by galectins [180]. No thiol residues participate in ligand binding and the cysteines can be either oxidized or reduced without affecting binding [177]. Additionally, the complex of galectin 1 with biantennary oligosaccharide shows the ability of galectins to crosslink molecules bearing greater than one ligand in solution [153].

4.3 Proposed Biological Roles of Galectins

Galectins are conserved in a number of unrelated organisms such as marine sponges, nematodes, frogs, birds, and mammals, suggesting that β-galactoside binding lectins may be biologically important [175,185,187,192]. The tissue-specific localization of several galectins is the strongest evidence for their functions. While it is clear from the examples given below that a number of galectins are involved in growth regulation, cell adhesion, cell migration, cancer, and immune responses, it is not clear that any of these processes are meditated by galectins in non-redundant pathways. Genetically engineered "knockout" mice lacking galectins 1 and 3 show no phenotypic abnormalities, indicating that these galectins under normal conditions are not necessary for survival [193]. However, in thioglycolate-induced peritonitis, galectin 3 null mice demonstrate reduced recruitment of leukocytes to sites of inflammation [194].
Galectin 1 is proposed to mediate cell adhesion, regulate cellular proliferation, and mediate cellular apoptosis [192]. Galectin 3 has been implicated in cell adhesion, regulation of inflammation, pre-mRNA splicing, as well as protecting against induced apoptosis [192]. Cell-cell and/or cell-extracellular matrix cross-linking functions have been proposed for galectins 4 and 6 [185]. The selective expression of galectin 5 in erythrocytes suggests roles in maturation and/or cell adhesion of erythrocytes [185]. Likewise, galectin 7 is a constitutive marker for

all keratinocyte subtypes but its specific function is unclear at this time [195]. Galectin 9 may mediate clonal deletion of thymocytes, as evidenced by its role in lactose-dependent apoptosis of these cells in vitro [196]. An isoform of galectin 9 shows chemoattractant activity which is selective for eosinophils [197].

Several galectins have altered expression in tumor cells relative to normal cells. The high expression of galectin 1 correlates with thyroid tumors whereas high and low expression of galectin 3 has been proposed as a marker for a number of other malignancies [192]. The absence of galectin 7 in squamous carcinoma cell lines may serve a diagnostic role [195]. Likewise, the overexpression of galectin 8 may serve as a marker for prostate cancer [187]. The expression of galectin 9 is increased in Hodgkin's lymphoma (HL) patients where 50% of clinical populations possess antibodies against galectin 9 [185].

5 Pentraxins

The non-covalent association of identical subunits of C reactive protein (CRP) and serum amyloid protein (SAP) into flat pentameric disc-like arrangements identifies the pentraxin family of lectins [198]. These calcium-dependent plasma-soluble lectins containing a conserved octapeptide "signature sequence" of HXCXS/TWXS are categorized into the classical short pentraxins CRP and SAP (reviewed in [199,200]), and the more recently described long pentraxins (reviewed in [201]). The *C*-terminal region of long pentraxins bears significant homology to short pentraxins [202].

5.1 Short Pentraxins

The short pentraxins were first described in the 1930s [203] and are the major components of a host of cytokine-induced liver proteins which mediate clearance of pathogens, known as acute phase proteins [200]. CRP shows 67–76% and SAP demonstrates 63–70% identical amino acids for the same protein in different species, while CRP and SAP share 42–54% identity in the same species [200]. Short pentraxins are conserved in vertebrates and are also present in unrelated organisms such as the horseshoe crab [202]. A number of biological functions have been proposed for CRP and SAP including complement activation, binding to sites of injury, activation of leukocytes, and association with amyloid fibrils [200].
The 3-dimensional structure of SAP as determined by X-ray crystallography is considered to be representative of pentraxin structures [204,205]. The overall topography is consistent with earlier studies observing a decameric stacking of pentamers of disc-like identical monomer subunits (*Fig. 12*). However, CRP oligomerizes into pentameric, but not decameric multimers [202]. Pentraxin monomers display a jelly-roll motif, similar to galectins and legume lectins, with two anti-parallel β-sheets of seven and eight β-strands respectively, around a hydrophobic interior where one strand is flanked on either end by α-helices [204,205]. Notably, pentraxins and legume lectin domains show approximately 11% sequence identity [201]. SAP contains two bound calcium ions, one of which occupies a coordination site

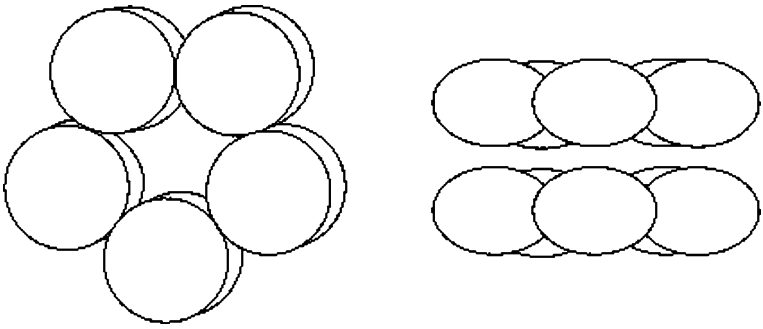

Figure 12
Representation of the decameric arrangement of pentraxin serum amyloid P component subunits. (a) "top" view, (b) "side" view

between β-strands and serves to orient binding site amino acid residues [204,205]. Although the highest affinity ligands for SAP are phosphoethanolamine (PE) and phosphocholine (PC), the lectin selectively binds to terminal β-galactosides and also binds to polyanions such as heparin [206,207]. The complex of SAP with 4,6-*O*-(1-carboxyethylidene)-β-D-Gal showed only one hydrogen bond to Gal while the majority of binding interactions were specific to the aglycone, explaining the failure of monosaccharides to show specific binding. An adjacent and overlapping but not identical site has been identified as responsible for binding to PE and PC [204,205].

CRP binds terminal β-galactosides at a pH optimum of 5–6 and lectin binding assays require that both lectin and ligand be immobilized. Thus it has been suggested that serum CRP does not function as a lectin under normal physiological conditions and binds carbohydrate only under conditions where tissues are inflamed or hypoxic [208].

5.2 Long Pentraxins

Although more than seven highly homologous long pentraxins have been biologically characterized, in few cases they have been shown to bind carbohydrate. For example, lectin activity was satisfied for 46 kDa rat Narp (**n**euronal **a**ctivity-**r**egulated **p**entraxin) by binding to agar in the absence of EDTA [209]. Alternatively, the multimeric organization of pentraxins has been well documented. The formation of higher molecular weight oligomers of apexin [210,211], PTX3 [212], and horseshoe crab limulin [213,214,215] has been shown to require non-reducing conditions, which converge to monomeric species in the presence of DTT.

Horseshoe crab limulin binds to mammalian sialic acids and bacterial KDO [213] and is a sialic acid-specific hemagglutinin as well as cytolytic to erythrocytes in vitro [214]. In contrast to other pentraxins, limulin subunits have been proposed to associate as twelve 45 kDa AB complexes in doubly stacked hexameric disc-like oligomers [202,214].

6 I-Type Lectins

6.1 The Immunoglobulin Fold

Proteins belonging to the immunoglobulin (Ig) superfamily possess domains homologous to the constant (C) and variable (V) regions of antibodies. C regions of antibodies are composed of 5–10 amino acid long anti-parallel β-strands with strands ABDE and GFC (*Fig. 13*) organized into sandwiches of two opposing β-sheets around a hydrophobic interior stabilized by disulfide bonds between strands B and F. V regions bear similar topology to C regions yet contain two additional β-strands making GFCC′C″ β-sheets [216] as depicted in *Fig. 13*. This structural topology was originally described for antibodies [217], and subsequent structural determinations have shown that a large and diverse superfamily of proteins, some of which are lectins, contain domains with homology to the immunoglobulins [216].

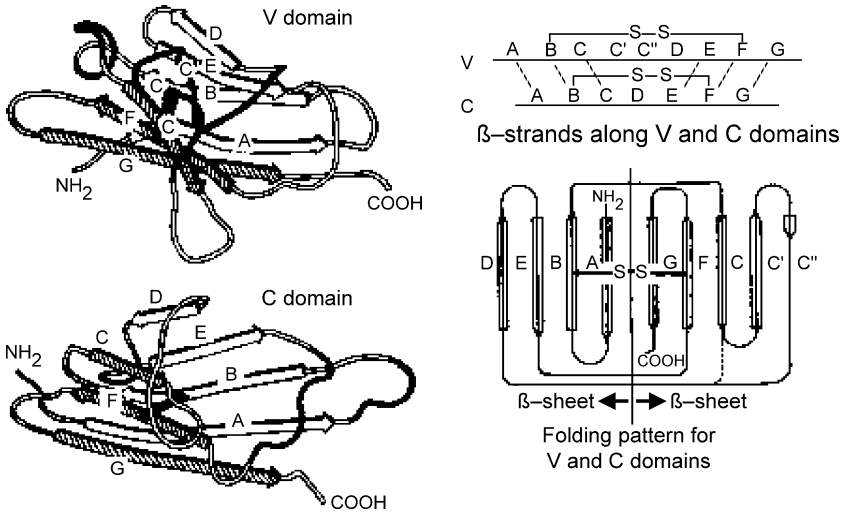

Figure 13
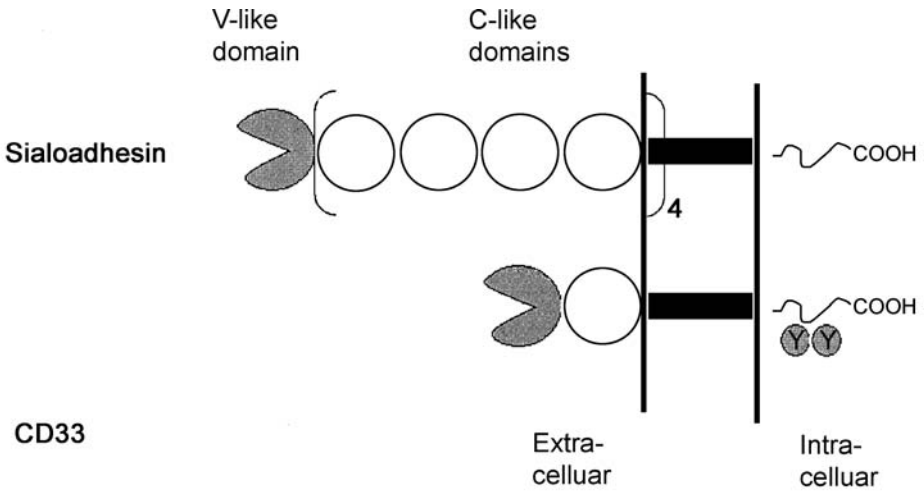
The immunoglobulin fold shown for an antibody. β-strands associate into β-sheets which compose the V and C regions. See text for details. (Reproduced with permission from [216])

6.2 The Architecture of Siglecs

A subset of lectins belonging to the I-type (Immunoglobulin-like) family formerly known as sialo adhesions [218] has been designated the siglecs (**s**ialic acid binding **i**mmuno**g**lobulin-like **lec**tins) [219]. The single *N*-terminal domain of the siglecs is homologous to the V region of antibodies and is followed by a varied number of repeat domains homologous to the C region of antibodies (*Fig. 14*). V-like and C2-like domains are followed by a transmembrane segment, and a *C*-terminal cytoplasmic tail which typically contains tyrosine motifs. The currently known members of the siglec family are sialoadhesion (Sn, hSiglec-1), CD22 (hSiglec-2), CD33 (hSiglec-3), myelin-associated glycoprotein (MAG, hSiglec-4), and hSiglec-5–hSiglec-11. Homologies between siglecs are realized in their *N*-terminal V-like carbohydrate-binding domains and in their cytoplasmic tyrosine motifs, and variation is seen in the tissue and cell types they are expressed in [220]. The I-type lectins which do not bind sialic acid and have C2 or V1-like domains include integrins ICAM-1 (CD54), PECAM-1 (CD31), and N-CAM comprised of repeats of C2-like domains, while P_o glycoprotein contains a single V-like domain [7].

Antibody sequence homology predictions and the X-ray crystal structure of hSiglec-1 in complex with NeuAcα2-3Galβ1-4Glc [221] have shown that although the V-like *N*-terminal domain adheres to the canonical Ig fold, four major structural differences between antibodies and siglecs exist. The siglecs have an intersheet disulfide bond between strands B and E, rather than between B and F in immunoglobulins. Likewise, the G strand is split into two smaller strands, the B-C loop is larger and extended, and there is a lack of β structure in the C$''$ region of siglecs [221].



Human siglecs	Number of Ig domains	Number of cytoplasmic tyrosine motifs	Sialic-acid-binding specificity	Expression
Sialoadhesin/hSiglec-1	17	0	2,3>2,6>2,8	Mac
CD22/hSiglec-2	7	6	2,6	B
CD33/hSiglec-3	2	2	2,6>2,3	My-pro, Mon
MAG/hSiglec-4	5	1	2,3>>2,6	Oligo, Schwann
hSiglec-5	4	2	2,3=2,6>2,8	Mon, N, B
hSiglec-6	3	2	STn	B, Plac
hSiglec-7	3	2	2,8>>2,6>2,3	Mon, NK
hSiglec-8	3	2	2,3>2,6	Eos, Baso, Mast
hSiglec-9	3	2	2,3=2,6	Mon, N, NK, B
hSiglec-10	5	3	2,3=2,6	Mon, NK
hSiglec-11	5	2	2,8	Mac

Figure 14
Representation of siglec domains. *N*-terminal lectin domains are shown with a binding pocket, extracellular domains are depicted as *circles*, transmembrane units as *black rectangles*, *C*-terminal cytoplasmic tails by *lines*, and tyrosine-based motifs as Y. 2,3, 2,6 and 2,8 refer to the α2,3- α2,6- and α2,8-glycosidic linkages of sialic acid to galactose (2,3 and 2,6) or sialic acid itself (2,8). B, Bcells; Baso, basophils; Eos, eosiniphils; Mac, macrophages; Mast, mast cells; Mon, monocytes; My-pro, myeloid progenitors; N, neutrophils; NK, natural killer cells; Oligo, oligodendrocytes; Plac, placentral trophoblasts; Schwann, Schwann cells

The region of antibodies responsible for binding antigen is on the ends of the β-sandwich, at the hypervariable regions [216]. However, the carbohydrate binding sites of hSiglec-1 and CD22 were predicted by site-directed mutagenesis to be along the face of the β-sandwich, with key residues along strands G, F, C, and C′ implicated as important for binding [222,223]. The 3-dimensional structure of hSiglec-1 has confirmed these predictions, and demonstrated the role of a basic arginine residue as an electrostatic partner for the C-1 carboxylate of

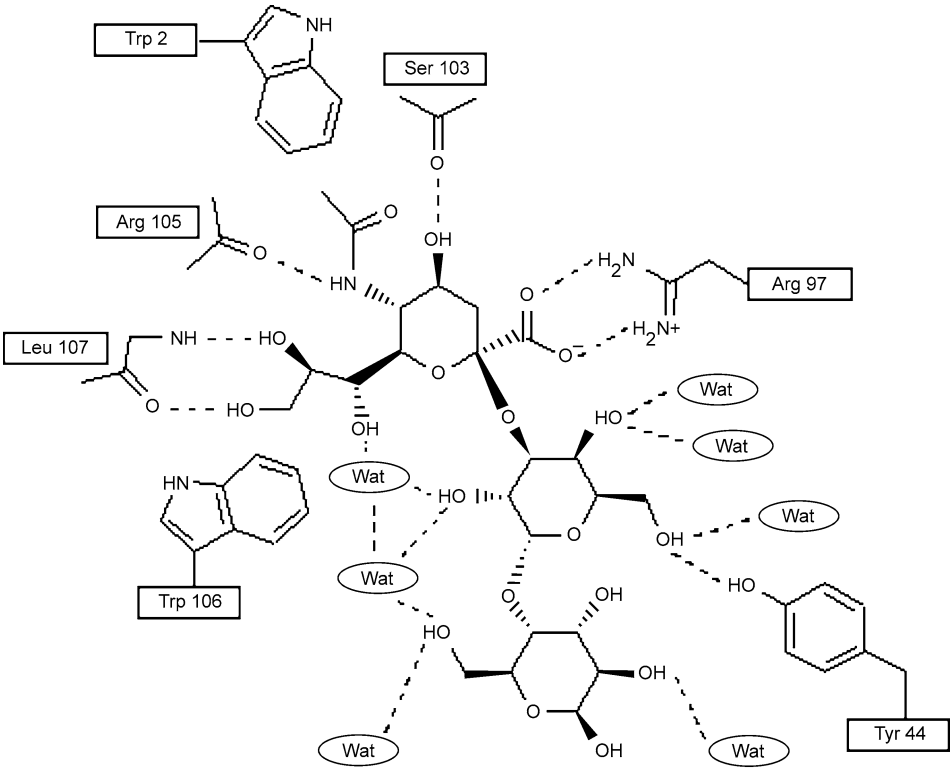


Figure 15
X-ray crystal structure of the binding site of sialoadhesion with NeuAcα2-3Galβ1-4Glc bound. *Dashed lines* indicate hydrogen bonds. (Reproduced with permission from [221])

NeuAc [221]. The complex of sialoadhesin with NeuAcα2-3Galβ1-4Glc (*Fig. 15*) shows seven hydrogen bonds and two hydrophobic interactions with sialic acid, while Gal and Glc make fewer contacts [221], consistent with the proposal that lactose is a scaffold upon which ligand discrimination centers on NeuAc.

6.3 Specificities of Siglecs

The ligands for all 11 known siglecs are sialylated carbohydrates. Although the most common sialic acid is NeuAc, it may be noted that there are over 40 biologically occuring sialic acids [224]. The most prevalent modifications to NeuAc are glycolyl acylation on the 5 position (a modification common in mammals but absent in humans [225]) and acetylation on the glycerol side chain [226]. The ligand specificities of siglecs were first determined by evaluating the binding of siglec-Fc chimeras to erythrocytes which had been desialylated, and then resialylated with sialyltransferases to prepare NeuAcα2-3Galβ1-3GalNAc (3O), NeuAcα2-3Galβ1-4GlcNAc (3N), or NeuAcα2-6Galβ1-4GlcNAc (6N) structures. CD22 bound only to

RBCs expressing 6N, MAG bound only to 3O, while CD33 and Sn bound to either 3O or 3N [218]. Subsequent studies showed that while CD22 binds only to α2-6 sialylated structures and siglec-5 binds to either α2-6 or α2-3 sialylated structures, all other siglecs bind only to α2-3 sialylated structures [227]. Chemical modification of the C-1 carboxylate, *N*-acetyl group, and glycerol side chain of NeuAc blocks the binding of MAG, Sn, and SMP to relevant glycolipids, while MAG but not Sn requires the C-7 and C-4 hydroxyls [228,229]. Modifications to the *N*-acyl group of NeuAc showed distinct binding specificities between siglecs, which has been proposed to function as a tuning mechanism for ligand discrimination [230].

Figure 16 shows truncated sialic structures highlighting the relevant interactions between sialic acid and siglec in comparison to other sialic acid specific lectins [8,231]. It is apparent that sialic acids are recognized by siglecs as the non-reducing terminal moiety of saccharides. The minimal structure required by human MAG was shown to be NeuAcα2-3Galβ1-4Glc [228], while Sn requires NeuAcα2-3Galβ1-4GlcNAc, human CD22 requires NeuAc(Gc)α2-6Galβ1-4Glc(NAc), and mouse CD22 requires NeuGcα2-6Galβ1-4Glc(NAc) [229]. The preference of murine CD22 for a C-5 *N*-glycolyl substituent is not mirrored by mouse MAG which prefers C-5 *N*-acetyl substituents [228,229].

6.4 Regulation of Siglec Binding

The sialylated structures which mediate siglec binding are relatively common epitopes, occurring on *N*- and *O*-linked oligosaccharides and glycolipids disseminated throughout the body. This observation leads to speculation that siglecs might bind non-specifically to any appropriately glycosylated structure. However, the binding of Fc-Siglec chimeras has been shown to be limited to certain tissue types [218] (*Fig. 17*). One explanation for this apparent discrepancy invokes the compartmentalization argument, noting that siglecs are restricted to certain cell lineages and physiological locations. An alternative explanation is that siglecs are masked or blocked until activated for binding. In order to demonstrate sialic acid-dependent binding for recombinant CD22, CD33, MAG, and SMP expressed in COS or CHO cells, it is necessary to enzymatically remove sialic acids from the surface of these cells [232,233,234,235]. The nomenclature adopted by the field has been to describe *cis* ligands as those expressed on the cell expressing siglecs, in contrast to *trans* ligands on the target cell [235]. Glycosylation on a single asparagine residue of CD22 and CD33 is required for the proper lectin folding, evident by failure to bind ligand, and lack of recognition by monoclonal antibodies when these lectins are either deglycosylated by treatment with *N*-glycosidase F or when this asparagine is mutated to no longer support glycosylation [233,234]. However, when the *N*-linked oligosaccharides at this site are sialylated, sialic acid recognition by the lectins is abrogated [234]. This indicates that either sialylated structures adjacent to siglecs, or the siglecs themselves block binding to exogenous sialylated ligands. This phenomenon is not observed for sialoadhesion, which can be rationalized by its 17 Ig-like domains extending the lectin domain from the cell surface, presumably out of reach of endogenous sialylated structures, or that Sn does not contain this *N*-glycosylation site [235,236]. However, this phenomenon is also absent for siglec-5, whose extracellular domains are a length intermediate between CD22 and CD33, and contain this *N*-glycosylation site [237]. It has been proposed that “masking” serves as a downregulatory mechanism where cell surface siglecs are blocked from binding cellular or secreted ligands

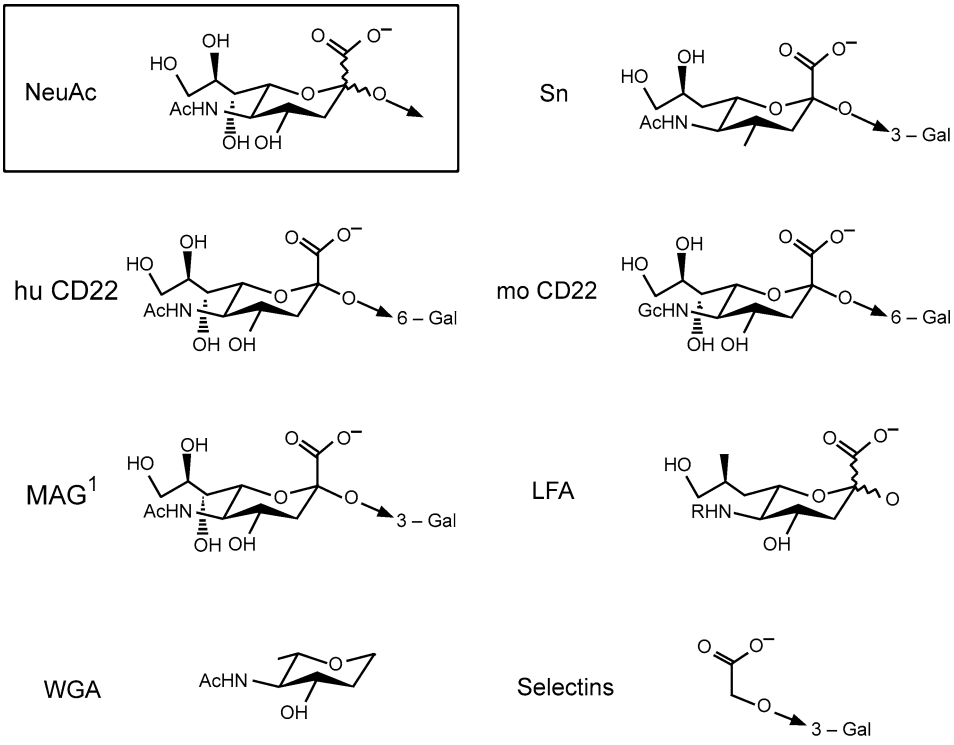

Figure 16
Truncated structures of sialic acids show the moieties required for binding to various sialic acid-specific lectins. LFA is *Limax flavus* agglutinin [231] and WGA is wheat germ agglutinin [5]. The binding importance of sialic acid C-4 and C-7 hydroxyls for MAG has not yet been determined. R indicates that LFA tolerates a variety of equatorial bulky substituents on the C-5 *N*-acyl group of sialic acids

until the cell upon which they are expressed is activated by desialylation [234]. This has been reproduced in biologically relevant B cells in the case of CD22 [234]. Desialylation could be accomplished by downregulation of sialyltransferases, or the action of neuraminidases.

6.5 Biological Roles of the Six Known Siglecs

Much is known about siglec structure and ligand-binding specificity, and in many cases tissue and ligand distribution have been elucidated (*Fig. 17*). However, it has been more difficult to determine the biological role of siglecs. Since Sn is only expressed in mature macrophages, and binds preferentially to cells of myeloblast lineage, it has been proposed to function in the regulation of myeloid cell interactions [218]. This is supported by the observation that the highest level of Sn expression under non-inflammatory conditions is in secondary lymphoid tissues and bone marrow macrophages where it is found at contact sites between macrophages and developing granulocytes [236].

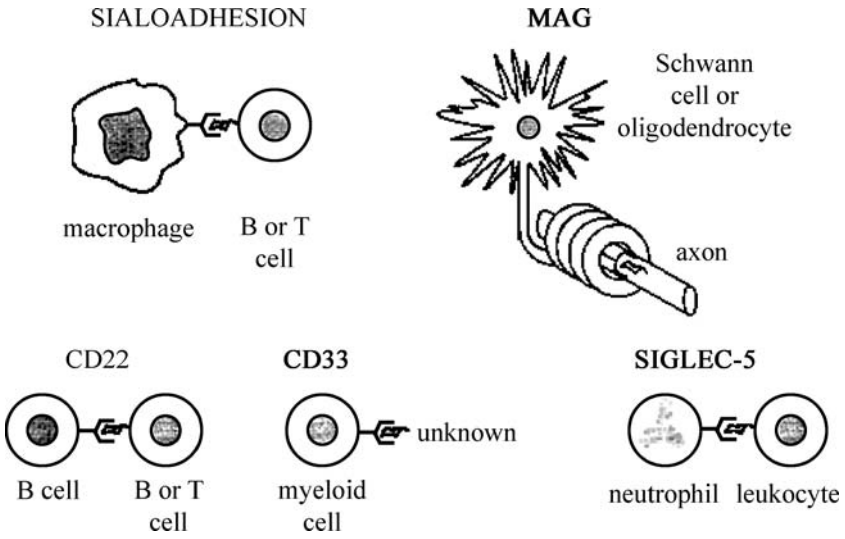

Figure 17
The tissue locations of siglecs and the tissues to which they have been shown to bind. Cells expressing siglecs are indicated by prongs. Cells expressing ligands are indicated by pyranose rings. The tissue CD33 binds have not yet been determined. Abbreviations: MAG (myelin-associated glycoprotein). (Adapted with permission from [218])

CD22 was first recognized as a useful marker for the stages of B cell development. Following the identification of CD22 as an Ig-superfamily member it was determined that cross-linking of CD22 with anti-CD22 IgG-conjugated beads induced an enhanced B cell immune response [238]. The cytoplasmic tail of CD22 contains a V/IXYXXL sequence which has been shown in other proteins to interact with an effector of the B cell antigen receptor SHP-1. CD22 has been proposed to interact with and dephosphorylate SHP-1, explaining its down-regulatory function in B cell antigen response [238]. The hyperimmune response of CD22 knockout mice is not as severe as that seen in SHP-1 knockout mice [239], suggesting a redundancy in this pathway. In addition to helping set the threshold for B cell receptor response, CD22 has also been proposed to have a role in B cell elimination, since it is a stage-specific marker [238]. In addition to the *C*-terminal cytoplasmic domain, the *N*-terminal lectin domain of CD22 could participate in regulation of antigen receptor signaling, since concomitant with the activation of B cells is the upregulation of βGal α2-6 sialyltransferase, which would cause self-association or association with molecules other than those in contact with the B cell receptor, drawing CD22 away from its function as a negative modulator [238]. This could also be accomplished through CD22 interactions with other α2-6 sialylated cells when they are in intimate contact with B-cells.

CD33 was first identified as a 67 kD differentiation marker for subsets of myeloid cells. It has also been useful as a marker for myeloid versus lymphoid leukemias. CD33 expression in cells of hematopoietic origin has led to the proposal that it participates in myeloid cell differentiation and mediates cellular interactions [240].

MAG is a 100 kD glycoprotein which has 8–9 potential *N*-linked glycosylation sites and is typically 30% carbohydrate by weight [241]. The location of MAG in myelinating oligodendroglia and myelin-forming Schwann cells and its intimate contact with axons has led to the proposal that it participates in the myelination of neurons [218]. MAG knockout mice have been shown to myelinate normally [242], or alternatively with subtly altered periaxonal architecture [243], indicating that degenerate pathways may operate in myelination or that the role of MAG in myelination is minimal. MAG has also been proposed to inhibit axon regeneration, as evidenced by in vitro and in vivo experiments. Cytoplasmic phosphorylation sites have been identified in MAG and a possible role has been elucidated in signal transduction pathways [241].

Siglec-5 has been proposed to participate in acute inflammatory responses, since it is localized to neutrophils and it does not require cell-surface desialylation to unmask its sialic acid binding. hSiglec-5-4L, a an hSiglec-5 isoform has been identified, and a soluble Fc chimaeric protein containing the hSiglec-5-4L extracellular domain binds glycophorin A in a sialic acid-dependent manner [244].

Other putative functions of Siglecs include binding sialic acid on the same cell surface, interacting with soluble sialylated glycoprotein ligands, or inhibiting cell-cell interactions involving Siglecs [10].

7 Conclusions

Great strides have been made with respect to the ligand binding specificities and molecular structures of the five families of mammalian lectins. A rational pattern of ligand discrimination emerges based upon the three-dimensional orientation of binding site amino acid residues, specific ligand tissue distribution, and lectin regulation to exhibit or lack binding activity under different cellular conditions. Lectins bind monosaccharides and monovalent ligands with low affinity while binding multimeric ligands and ligand-carrier complexes with high-avidity. Lectin oligomeric state and carbohydrate-binding domain orientation in multimeric association serves to discriminate between ligands (e. g. MBP is most likely to bind with high-avidity to foreign carbohydrate polymers while RHL is most likely to bind to triantennary Gal-terminating *N*-glycans on endogenous glycoproteins, both by virtue of the quaternary topology of their oligomeric subunits). Since the spacing of carbohydrate residues on oligosaccharides is important for biologically relevant lectin-carbohydrate interactions, the utilization of unnatural carbohydrate structures linked to synthetic polymer scaffolds as ligands for lectins may require careful consideration of spatial constraints.

Progress is being made to determine the biological functions of animal lectins. There is evidence for a myriad of roles for lectin-carbohydrate interactions, suggesting that lectins and sugars mediate their effects through non-redundant pathways. Lectin “knockout” experiments have demonstrated phenotypic abnormalities which can be traced to important biological roles. Since glycosylation is a highly regulated biological process conserved throughout evolution, it is obvious that these often subtle interactions serve to optimize and complement the function of organisms to provide an evolutionary advantage.

Chapter-DOI 10-1007/978-3-540-30429-6_64:

Abstract

The binding of proteins to individual glycoconjugates is often weak. In physiological settings, carbohydrate–protein interactions often benefit from multivalency—multiple copies of the carbohydrate epitope engage with multiple copies of a carbohydrate–binding protein. This mode of molecular recognition is especially important in cell adhesion because the individual interactions need to be kinetically labile yet highly specific. This review discusses why protein–carbohydrate interactions are especially well-suited for multivalent binding, the binding modes and energetic forces that underlie multivalent protein–carbohydrate complexes, and the utility of multivalent carbohydrate derivatives for exploring multivalent binding and inhibiting physiologically and medically important protein–carbohydrate interactions.

Keywords

Carbohydrates; Polyvalency; Molecular recognition; Lectins; Cell adhesion

Abbreviations

ASGR	asialoglycoprotein receptor
ATRP	atom-transfer radical polymerization
bFGF	basic fibroblast growth factor
BSA	bovine serum albumin
ConA	concanavalin A
ELLA	enzyme-linked lectin inhibition assay
EcorL	*Erythrina corallodendrum*
FRET	Förster resonance energy transfer
LOL I	*Lathyrus ochrus* lectin I
LT	labile enterotoxin
LFA	*Limax flavus*
MBPs	mannose-binding proteins
PAMAM	polyamidoamine
ROMP	ring-opening metathesis polymerization
SLT	Shiga-like toxins
SPR	surface plasmon resonance

1 Introduction

Protein–carbohydrate recognition events mediate numerous physiological processes including fertilization, pathogen-cell adhesion, and the inflammatory response [1,2,3,4,5]. Given the

specificity of these biological recognition events, it is surprising that monovalent protein–carbohydrate interactions are so weak. A general perception is that high affinity complexation is required for physiological recognition processes ($K_D \sim 10^{-9}$ M), yet monovalent protein–carbohydrate interactions typically occur with low affinity ($K_D \sim 10^{-3}$ M). Despite the physiological importance of such low affinity interactions, most studies of biologically relevant molecular recognition events focus on high affinity interactions. Here, we will focus on low affinity but multivalent protein–carbohydrate interactions. Multivalency (multiple binding epitopes interact with multiple receptors) is a key mode of recognition that operates in essential physiological recognition processes. Multivalent binding is prevalent in protein–carbohydrate interactions.

1.1 Characteristics of Protein–Carbohydrate Interactions

To understand the importance and functional roles of multivalent interactions, background in the interactions involved in monovalent protein–carbohydrate binding is valuable. X-ray crystallographic studies have served to illuminate the molecular interactions that govern carbohydrate binding by proteins [6,7,8,9,10]. Extracellular carbohydrate binding sites are generally shallow and solvent-exposed. Thus, the proteins make only a handful of direct contacts to the ligand. A brief summary of the types of interactions seen in carbohydrate–protein complexes will be presented as a prelude to an in-depth discussion of multivalent binding.

1.1.1 Hydrogen Bonds

With the high density of hydroxy groups displayed by carbohydrates, hydrogen bonding is expected to play an important role in their recognition. Although the energetic contributions of hydrogen bonds to protein–carbohydrate binding have been debated, it is clear that the directionality of hydrogen bonds is critical to the specificity of carbohydrate recognition [11]. One example of hydrogen bond-mediated specificity control is found in the complex of galectin-1, a mammalian lectin that specifically binds lactose derivatives, with *N*-acetyllactosamine [12]. The protein uses arginine, asparagine, and histidine residues to form direct hydrogen bonds with the axial 4-position hydroxyl group of the galactose residue (❯ *Fig. 1*). Thus, the protein exploits several contacts to a single hydroxyl group to differentiate between galactose and related carbohydrates (e. g., glucose or mannose) that have an equatorial hydroxyl group at the 4-position. Carbohydrate functional groups that are not critical for discriminating between related carbohydrate epitopes are often solvent-exposed [6].

The recognition of carbohydrates by lectins is also faciliated by the high density of potential hydrogen-bonding partners in the former. Vicinal hydroxyl groups in both the equatorial–axial and equatorial–equatorial configurations are spaced about 2.8 Å apart, such that bidentate interactions with two atoms of the same amino acid residue are favorable. In several complexes determined by X-ray crystallography, galactose 3- and 4-hydroxyl groups are observed to hydrogen bond to a single aspartic acid side chain carboxylate group (❯ *Fig. 2*). In addition to direct interactions between amino acid residues and saccharide hydroxyl groups, indirect, water-mediated hydrogen bonds are common (❯ *Sect. 1.1.5*) [13,14].

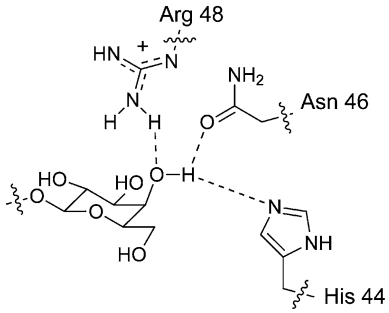

Figure 1

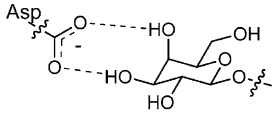

Figure 2
Bidentate hydrogen-bonding interaction with an aspartate sidechain and the 3 and 4 position hydroxyl groups of galactose

1.1.2 Hydrophobic Effects

Although carbohydrates have many polar functional groups, many mono- and oligosaccharides are amphiphilic. Thus, they present significant nonpolar surface area that can interact with complementary hydrophobic amino acid residues. The directionality of hydrogen bonds formed in the binding site serves to orient the carbohydrate so that the complementary surfaces are aligned [15]. Indeed, aromatic amino acid side chains are observed to interact with bound sugars in numerous structures determined by X-ray crystallographic analysis. For example, the α-face of β-galactose presents a continuous nonpolar surface from carbons three through six, and the α-face is observed to pack against aromatic side chains in lectin–galactose complexes (*Fig. 3*).

As noted by Weis and Drickamer the aliphatic protons of the sugar ring bear a small partial positive charge, which could lead to weak, favorable interactions with the π-cloud of aromatic residues in an analogous fashion to edge-face stacking of aromatic residues in protein structures [6,16,17]. In accord with the hydrophobicity of lectin binding sites, carbohydrates bearing aromatic aglycones are often bound with significantly greater affinity than the corresponding glycosides lacking such hydrophobic substituents [18]. Indeed, a screen for inhibitors of the dendritic cell lectin DC-SIGN resulted in the identification of aromatic small molecules that do not resemble its carbohydrate ligands [19].

An additional role for aromatic groups in carbohydrate binding may be to stabilize the *exo*-anomeric effect [20]. The *exo*-cyclic O1 lone pair of a pyranose (e. g., glucose) can donate electron density into the C1–O5 σ^* orbital while decreasing electron density in the C1–O5

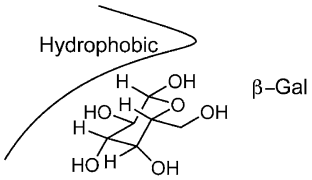

Figure 3
The α-face of galactose is nonpolar

bond (see *Fig. 7*); this preference for the gauche glycosidic conformation, is referred to as the *exo*-anomeric effect [20,21]. As indicated by the resonance structure, the partial positive character on C1 would be stabilized by cation-π interactions with aromatic amino acids in the binding site [20]. It is an intriguing possibility that this stabilization is the source of the prevalence of aromatic amino acid side chains in the carbohydrate-binding sites of lectins.

1.1.3 The Role of Calcium Ions

Calcium ions are required for activity of many families of carbohydrate-binding proteins. The most common function for calcium ions in lectins is structural; the calcium ion can serve to orient important protein functional groups for ligand coordination. For example, in legume lectins it is common for conserved amino acid residues (e. g., asparagine and aspartic acid) to simultaneously coordinate a calcium ion and participate in hydrogen-bonding interactions with the bound saccharide [22,23]. The mammalian *C*-type lectins employ direct contacts between calcium and hydroxyl groups of the bound saccharide. In the structure of rat serum mannose binding protein, a C-type lectin, the binding site calcium ion is coordinated by the equatorial hydroxy groups at C3 and C4 of mannose [24] (*Fig. 4*). Ligand exchange for calcium(II) complexes is rapid [25], suggesting saccharide binding events that occur with direct ligand–calcium coordination could benefit from fast association rates.

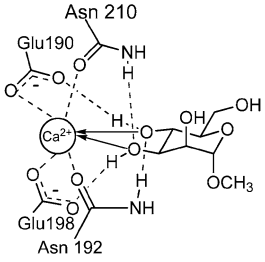

Figure 4
Mannose forms direct contents to a protein coordinated calcium ion in complex with MBP-C

1.1.4 Coulombic Interactions

Many carbohydrate-binding proteins discriminate between potential ligands through Coulombic interactions. Certain biologically important saccharides, such as sialyl Lewis^x, other

sialic acid derivatives, and heparin, contain anionic groups that are recognized by their respective receptors. Crystallographic studies of a heparin-derived saccharide bound to basic fibroblast growth factor (bFGF) suggest that several anionic sulfate substituents of the heparin fragment make ion pairing or direct hydrogen-bonding contacts with protein side chains [26,27,28,29,30]. The anionic substituents of heparin are also partially solvent exposed, interacting both with bFGF residues and solvent. Another illustrative example of the contributions that Coulombic interactions can make to the association of carbohydrates and proteins is found in the structure of sialyl Lewis^x bound to P-selectin [22]. A salt bridge is formed between the C1 carboxylate of sialic acid and a protein arginine, enabling binding and recognition. Structure–function studies performed in other systems also highlight the importance of anionic carbohydrate substituents in binding their protein targets. One system, involving L-selectin-mediated recruitment of leukocytes to sites of tissue damage, will be discussed in detail in *Sect. 2*.

1.1.5 The Role of Water

The ability of water to act as both a hydrogen bond donor and acceptor makes it ideal for interacting with the dense display of hydroxyl groups furnished by carbohydrates. Moreover, numerous X-ray crystallographic studies demonstrate that water plays an important role in the recognition of carbohydrates. Indeed, 20 water molecules are involved in the binding of *Lathyrus ochrus* lectin I (LOL I) to the linear trisaccharide Man(α1-3)Man(β1-4)GlcNAc [31]. Comparison of complexes containing different sugars bound to the same lectin often shows the same water-mediated hydrogen bonds between protein and carbohydrate [6].

Though valuable, crystallographic studies do not reveal the energetic contributions of water-mediated hydrogen bonds to protein–carbohydrate complexes. The energetic impetus for complex formation has been debated, and Lemieux has argued that the driving force for carbohydrate complexation is the reorganization of water molecules upon binding [14]. In this model, solvation of the amphiphilic carbohydrate and the protein binding pocket perturbs the low energy organization of the bulk water structure. Release of some of these higher energy water molecules to the bulk upon binding accounts for the favorable enthalpy of binding [32,33]. This rationalization was stimulated by extensive calorimetric studies of the thermodynamics of saccharide epitope binding by lectins which revealed enthalpic- entropic compensation as the hydrophobicity of the carbohydrate ligands was varied. The data suggest that hydrophobic patches on the carbohydrate surface raise the energy of water at the surface and release of this disordered water to bulk is enthalpically favorable but results in a decrease in entropy. The disruption of the more ordered water structure about polar hydroxyl groups on ligand binding is enthalpically unfavorable but entropically favorable. According to this model it is the reorganization of water molecules which provides the driving force for protein–carbohydrate complexation. A detailed understanding of the role of solvation in protein-saccharide interactions remains elusive. Studies on carbohydrate ligands binding to the lectin concanavalin A (ConA) have added additional insight [34], although the complex results of a further concanavalin A study led to the suggestion that the specific details of the binding site dictated energetic outcomes, and that empirical rules regarding water displacement were not predictive [35].

1.1.6 Conformational Flexibility

Oligosaccharides possess varying degrees of conformational flexibility. The conformational flexibility of the constituent monosaccharides is typically low, with the common pyranose residues residing primarily in a single conformation. Pyranoses with more than one axial substituent, such as iduronic acid, tend to be more flexible due to steric congestion present in all conformers. The conformational flexibility of iduronic acid has been suggested to be important for the recognition of heparin by heparin-binding proteins (*Fig. 5*) [36]. For most oligosaccharides, however, the source of conformational flexibility is associated with rotation about the glycosidic linkages [37,38].

Linear oligosaccharides often exhibit the characteristics of multiple conformers. The conformational flexibility of oligosaccharides suggests that there is a loss in conformational entropy upon binding; therefore, conformationally constrained analogs may be bound with higher affinity. It is difficult to dissect the loss of conformational entropy on ligand binding from other thermodynamic parameters; however, the conformational restriction of inter-saccharide bond rotamers upon binding has been estimated to carry a conformational entropy penalty as large as 1–2 kcal/mol [39].

Despite predictions that restricting flexibility will be beneficial, it has proved difficult to generate high affinity inhibitors by restricting conformational entropy. Indeed, the installation of conformational constraints can have complex effects on oligosaccharide binding. The challenges are highlighted in a study in which the thermodynamics of conformationally constrained trisaccharides binding to a well-characterized, monoclonal antibody Se155-4, were determined calorimetrically. X-ray crystallographic analysis of the parent trisaccharide bound to the antibody suggested that tethers could be used to constrain glycosidic bond rotamers without disrupting protein–carbohydrate contacts (*Fig. 6*). Nevertheless, the oligomethylene ether-tethered compounds **4–6** (*Fig. 6*) show weaker overall binding relative to the parent trisaccharide **1** with an unanticipated loss in entropy and a favorable change in enthalpy. The aryl dithioether tethered trisaccharide, **7**, functions as designed, exhibiting tighter antibody binding due to a favorable entropy term. The magnitude of the affinity increase, however, is diminished by an unfavorable change in the enthalpy of binding relative to the parent ligand. The conformations of the acetal-tethered trisaccharides **2**, **3** (*Fig. 6*) are significantly distorted from the native trisaccharide and are not recognized by the antibody. The conformations of the remaining four constrained trisaccharides appear to be similar to that of the parent structure by both NMR experiments and molecular dynamics simulations. Thus, the origins of the ther-

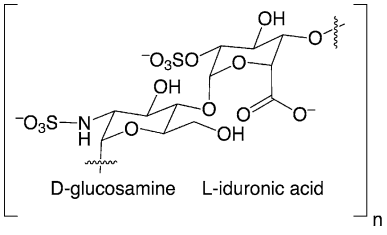

Figure 5
Structure of a disaccharide unit found in heparin and heparan sulfate proteoglycans

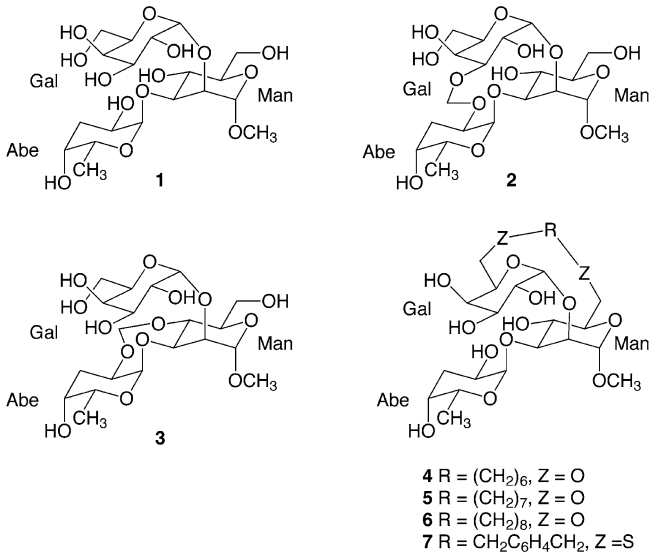

Figure 6
Conformationally constrained trisaccharide derivatives synthesized and studied by Bundle and coworkers

modynamic differences in binding were attributed to the structures of the tethers. These results can be explained by Lemieux's model: Higher energy water structure about the hydrophobic oligomethylene linker in compounds **4–6** could contribute to the favorable enthalpy of binding as these higher energy molecules are released to the bulk water. This study suggests that only small affinity enhancements are to be gained by the preorganization of glycosidic bond rotamers in the design of carbohydrate-based inhibitors [40,41].

Conformational controls are naturally present in oligosaccharides. For example, the *exo*-anomeric effect appears to preorganize oligosaccharides. The *exo*-anomeric effect describes the observed conformational preference of the exocyclic C1–O (glycosidic) bond for a rotamer in which a lone pair of electrons (*Fig. 7*) of the exocyclic oxygen is antiperiplanar to the polar, endocyclic C1–O bond [21,42]. The extent to which the *exo*-anomeric effect is operative and serves to rigidify glycosidic linkages in aqueous solvent has been debated.

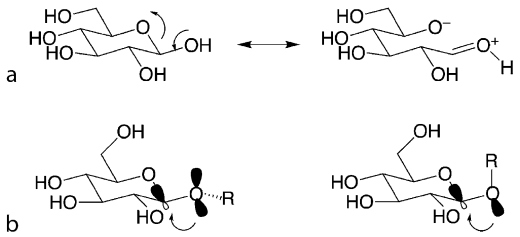

Figure 7
The *exo*-anomeric effect favors conformations in which the O1 oxygen is oriented such that its lone pair is an antiperiplanar orientation to the C1–O bond

However, molecular modeling studies in which the force field parameters are adjusted for the *exo*- anomeric effect tend to yield conformational preferences consistent with those observed in solution. Further, two recent structures of protein–carbohydrate complexes reveal that the bound carbohydrate ligands adopt conformations consistent with the *exo*-anomeric effect—remarkably a lack of electron density between C1 and O5 could be observed [20,43]. Thus, likely due to a combination of steric and electronic factors, many branched oligosaccharides appear to occupy a single low energy conformation in solution. Still, the potential energy wells are predicted to be relatively shallow and broad, suggesting that these oligosaccharides may alter their conformations without significant energetic cost [38,39,44].

1.2 Mechanisms of Multivalent Ligand Binding

Multivalent ligands can engage membrane-bound receptors through multiple different binding modes (*Fig. 8*). Indeed, many naturally occuring lectins and their ligands are multivalent. For example, membrane-bound glycoproteins can serve as scaffolds that present multiple oligosaccharide determinants. Additionally, saccharide-binding receptors often form oligomeric quaternary structures. Thus, an understanding of the various mechanisms that mediate monovalent protein–carbohydrate interactions is necessary but not sufficient. The understanding of complex physiological systems is complicated by the multiplicity of individual ligand-receptor interactions [45,46,47,48,49,50,51], which afford energetic contributions by different mechanisms. There are several distinct mechanisms that contribute to the increases in binding affinity commonly attributed to "multivalency" or "cluster" effects. Briefly, the variables that can be added to the intrinsic affinity of the relevant monovalent protein–saccharide interaction are the sum of individual interactions, the distance and orientation of recognition elements, and the contributions of the scaffold on which these recognition elements are displayed. The sum of these factors can result in an increased *functional affinity* of the multivalent ligand for its cognate receptor. The term *functional affinity* is useful as it describes a measurable quantity, the apparent association constant, for multivalent ligands. An understanding of the contributions that individual mechanisms can make to protein–carbohydrate recognition is required to effectively design multivalent ligands.

1.2.1 Entropy

Consideration of entropic effects is vital to an understanding of multivalent interactions. For multivalent ligands, loss of translational entropy is complete with the binding of the first recognition element; subsequent binding interactions can proceed without paying an additional translational entropy penalty [52,53]. This favorable entropic contribution inherent to multipoint binding is counteracted by the conformational energy cost upon binding of the multidentate ligand. The conformational entropy term is affected by structural features of the multivalent ligand such as the conformational rigidity of the scaffold on which the binding determinants are displayed and the favored orientation of each recognition subunit [48,54,55,56]. It should be noted that the translational entropy penalty for binding membrane bound receptors is not as great as that incurred for a receptor–ligand interaction in solution, because membrane bound molecules diffuse in two dimensions rather than three.

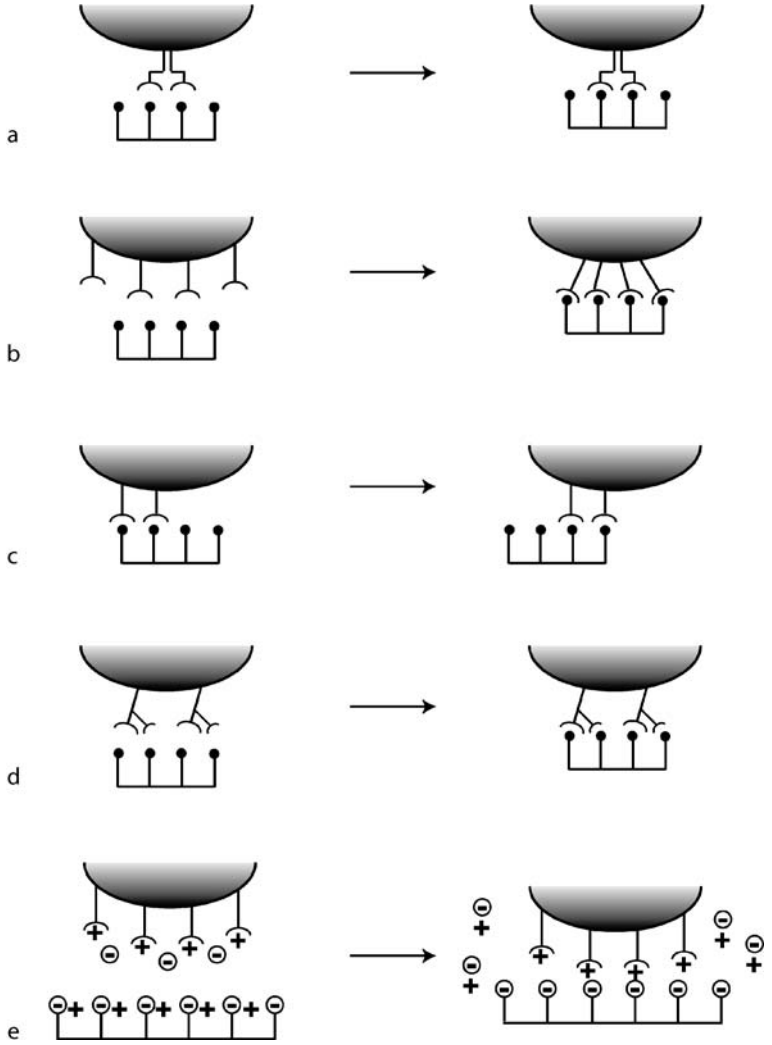

Figure 8

(c) Increased local ligand concentration (slow off-rates due to statistical effects). (d) Subsite binding (occupation of secondary binding sites on a single receptor). (e) The polyelectrolyte effect

1.2.2 The Chelate Effect

The simultaneous interaction of multiple saccharide epitopes of polyvalent ligands with oligomeric receptors can lead to interactions of high functional affinity when the orientation of the saccharide recognition elements corresponds to that of the receptor (*Fig. 8*). The mechanism of affinity increase is often described as the chelate effect [52,53]. This idea is

consistent with models developed for antibody–antigen interactions [57]. Historically, the chelate effect describes the observation that electrophilic metal centers are often coordinated with higher affinity by divalent, covalently linked, electron-donating groups. Thus, the chelate effect describes multiple interactions which, after formation of the first contact, are effectively intramolecular [53]. The observed free energy of binding will be related to the sum of the free energies of binding for each individual receptor–ligand interaction such that the free energy of interaction (ΔG_{obs}) for an oligomeric receptor $R_1 - R_2 \cdots - R_n$ with an oligomeric ligand, $L_1 - L_2 \cdots - L_n$ can be estimated by the equation:

$$\Delta G_{obs} = \Delta G(R_1 - L_1) + \Delta G(R_2 - L_2) + \cdots + \Delta G(R_n - L_n)$$

This model predicts that the formation of additional contacts should give exponential affinity increases, but fails to take into account an entropy cost related to the conformational flexibility of the tethers linking the binding epitopes [52]. Loss of conformational entropy can diminish the functional affinity enhancement derived from chelation. In a system in which the saccharide epitopes are favorably oriented, high functional affinities for multivalent receptor–ligand interactions can be achieved for relatively small complexes with only a few individual protein–carbohydrate interactions. The potential of chelate effect-mediated affinity enhancement has been demonstrated by the binding of a non-natural trimer of the glycopeptide antibiotic vancomycin to a trimer of its dipeptide ligand D-Ala-D-Ala; this complex has an affinity similar to that of the avidin–biotin interaction [58]. The design of this artificial multivalent interaction was facilitated by the fact that both binding epitopes are relatively small molecules and the spacing between recognition elements could be controlled.

1.2.3 Receptor Clustering

The chelate effect is distinct from multivalent binding modes that require receptor clustering [59]. Since the cell membrane is fluid, receptors are free to diffuse in two dimensions; this mobility can lead to clustering of receptors. In such a system, the unliganded state of the saccharide-binding protein may not have the same distribution on the cell surface as the bound species. This clustering occurs with an entropy cost, but it does not require that the multidentate saccharide display match precisely the display of receptors on the cell surface.

1.2.4 Concentration Effects

A dense array of receptors and/or ligands can lead to an increase in observed affinity through mechanisms other than the chelate effect. For example, a high effective concentration of recognition epitopes and/or receptors can result in high functional affinity. This concept can be demonstrated by modeling the binding event as a two-step process. The first event is the formation of a transitory encounter complex that can either proceed to form the final, stable ligand receptor complex or dissociate in an unproductive event. In the case of a multivalent ligand, the probability that the encounter complex will arrive at a productive receptor–ligand interaction is higher due to an increased local concentration of ligand. The structural requirements for multidentate saccharide derivatives to bind to oligomeric lectins with increased affinity due to concentration effects are not as stringent as those for classical chelate effect-mediated affinity enhancement [60].

1.2.5 Extended and Secondary Binding Sites

Lectins can bind multidentate or large saccharides with enhanced affinity due to interactions of the ligand with recognition elements outside the primary saccharide binding site [61]. Ligand substituents can interact with a second thermodynamically independent binding site or through extension of the primary binding site. In the first case, distinct secondary binding sites may offer interactions of a different character to those present in the primary interactions. In the second case, groups that are not recognized by the lectin can independently form van der Waals or water-mediated contacts to the protein. The distinction between the carbohydrate binding site and recognition elements outside it is not always clearly defined because binding sites are shallow [6,9]. However, structural studies of certain carbohydrate binding proteins have revealed distinct, secondary saccharide binding sites [61,62]. Although the physiological relevance of such sites remains obscure, multivalent ligands with the ability to occupy both sites simultaneously will be more effective inhibitors. The secondary binding sites may endow lectins not only with higher binding affinities for selected oligosaccharides, but with the ability to discriminate between multivalent ligands by binding site or saccharide orientation.

1.2.6 Polyelectrolyte Effect

As previously discussed for monovalent binding, some naturally occurring, multivalent saccharide derivatives possess multiple anionic groups. Although specific anionic groups are important in certain systems, the charge density associated with such ligands can influence their binding behavior. As in the case of protein–DNA association, the polyelectrolyte effect plays an important role [63]; the entropically favorable release of counterions into solution as the protein binds provides a driving force for association of the two macromolecules. Physiological mucin-like ligands, which display multiple copies of sulfated saccharide epitopes, may rely on similar effects for their interaction with the selectins. The polyelectrolyte effect is distinct from the specific Coulombic interactions discussed in *Sect. 1.1.4*; however, ligands that display the multiple charged groups required for specific interaction with a receptor will also likely benefit from this effect.

1.2.7 Evolutionary Considerations

Monosaccharides are bound with high affinity by some proteins [10]. In contrast, extracellular proteins typically bind monovalent carbohydrate epitopes with low affinity; they exhibit marked preferences for binding to multidentate saccharide ligands. What advantages are conferred by multivalent binding?

Because cell–cell recognition events mediated by protein–carbohydrate interactions occur on the cell surface, it is necessary to consider the effect of an array of ligand receptor interactions. Multivalent interactions allow mechanisms other than the intrinsic affinity of a recognition epitope for a receptor to control recognition events. If a tight interaction is observed between a monomeric receptor–ligand pair, multiple copies of this interaction will also bind tightly, leading to a lack of specificity. Multivalency can facilitate discrimination between structurally similar recognition epitopes when monovalent binding events are of low affinity [54,64,65]. Consider a monovalent ligand that is bound by a given receptor with some affinity: A small change in the ligand structure might diminish the affinity of the interaction

by one order of magnitude. In contrast, multivalent arrays of the two ligands can be much more selective: A trivalent receptor could, in principle, exhibit a 10^3 difference in functional affinity for trivalent displays of the two ligands. Thus, multivalent binding can be highly selective [51,64,65,66].

Multivalent systems allow for high functional affinity but exhibit unique kinetics. For example, they exhibit greater reversibility of binding in the presence of competing ligands [58]. In contrast, for monovalent binding events, the dissociation is determined solely by the rate constant for dissociation and is not affected by the addition of competing ligands. Their kinetic lability confers additional flexibility on processes mediated by multivalency. For example binding events composed of multiple weak interactions are expected to be more resistant to shear stress than a single tight interaction [67]; this feature is likely to be significant for some cell–cell recognition processes.

Finally, in multivalent systems, changes in the spacing or orientation of recognition elements could alter the nature of an interaction, without changes in the recognition elements themselves [54,55]. Indeed, the epitope density of a multivalent display has been shown to affect receptor cluster stoichiometry and rate of formation [54], and the architecture of the multivalent scaffold has been shown to determine whether a multivalent display acts as an inhibitor or effector [55]. Thus, different types of glycoconjugates might bind the same lectin yet elicit very different physiological responses.

2 Inhibitors of Multivalent Interactions

We discuss various ligands and their functions as well as provide some interpretation of the mechanisms underlying their function. A variety of different scaffolds has been used to present multiple copies of recognition epitopes. The structure of the scaffold can have a marked effect on its mode of multivalent binding [55], so the features of a ligand can be chosen for a specific purpose (e. g., clustering the target receptor or occupying a subsite). We have grouped these into the following classes: low molecular weight ligands, dendrimers, large spherical displays, and linear polymeric scaffolds. This review is not intended to be comprehensive, rather, specific examples have been chosen to represent a larger body of work.

2.1 Low-Molecular-Weight Ligands

Small templates that present 2–10 saccharide epitopes can exhibit enhanced affinity for target proteins. The small size of such multivalent ligands allows for characterization of the spatial relationships between relevant epitopes. Studies on recognition events with ligands of this type have provided interesting results. However, templates of this type present recognition epitopes in a manner that differs significantly from common, natural systems in valency and geometry. It can be useful to think of these small molecules as mimicking single, multiantennary saccharide epitopes (◉ *Fig. 9a*), but not the larger displays furnished by glycoproteins (◉ *Fig. 9b*). Thus, to mimic glycoporteins, different types of multivalent ligands are required. Intriguingly, there are have been exciting examples in which relatively small molecules can participate in multivalent binding.

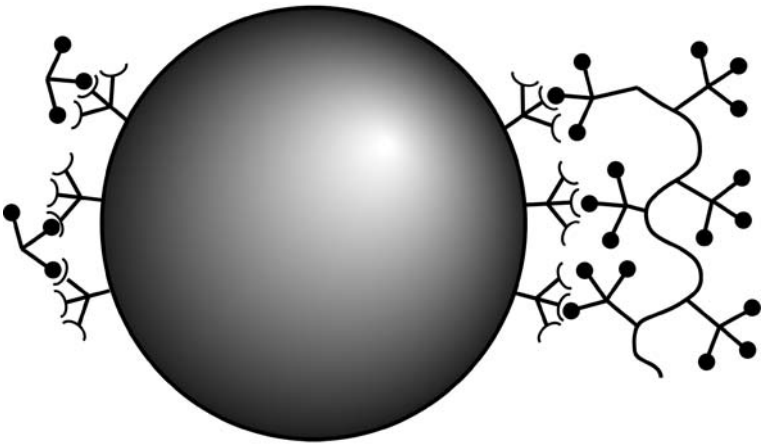

Figure 9
Two distinct types of multivalent binding used by natural systems. (a) Multiantennary saccharide derivatives bind multivalently. (b) Glycoproteins display several epitopes and can span large distances

2.1.1 Ligands for the Hepatic Lectin

Studies on saccharide recognition by the asialoglycoprotein receptor (ASGR), also known as the hepatic lectin, have yielded insight into the features of multivalent ligands that give rise to enhanced functional affinities. Although the physiological significance of this receptor is not completely clear, the ASGR is an endocytotic receptor found on hepatocytes and is believed to be responsible for the recycling of desialylated proteins that carry triantennary oligosaccharide chains [68,69]. In groundbreaking investigations, Lee and coworkers evaluated the ability of synthetic, peptide-based multivalent carbohydrate displays to bind to the asialoglycoprotein receptor, using templates based on aspartic acid, glutamic acid and aminotris(hydroxymethyl)methane (*Fig. 10*) [65,70].

Variations in the spacing of recognition epitopes, through the use of different linker groups as well as the valency of the template, were studied by monitoring inhibition of a radiolabelled ligand for ASGR, asialoorosomucoid, binding to either isolated receptors or hepatocytes. The synthetic clusters displaying three *N*-acetylgalactosamine residues, in which 6-aminohexylgalactosides were linked to glutamic acid residues through amide bonds, YEE(ah-GalNAc)$_3$, compound **12** (*Fig. 11*), exhibited the best inhibitory potency for rat hepatic lectin. Structurally related divalent derivatives were less potent and the monovalent derivatives showed the poorest activity. Trivalent saccharide displays based on the aminotris(hydroxymethyl)methane template were less effective than those derived from the glutamate or aspartate scaffolds (*Fig. 10*). The galactose bearing template **9** (sug=β-galactose) was only two-fold more potent than a monovalent galactose derivative when binding to solubilized lectin was assayed and approximately 70-fold more active when binding to hepatocytes was evaluated. These modest increases suggest that the saccharide residues on the aminotris(hydroxymethyl)methane are too closely spaced (9 Å maximum) to span more

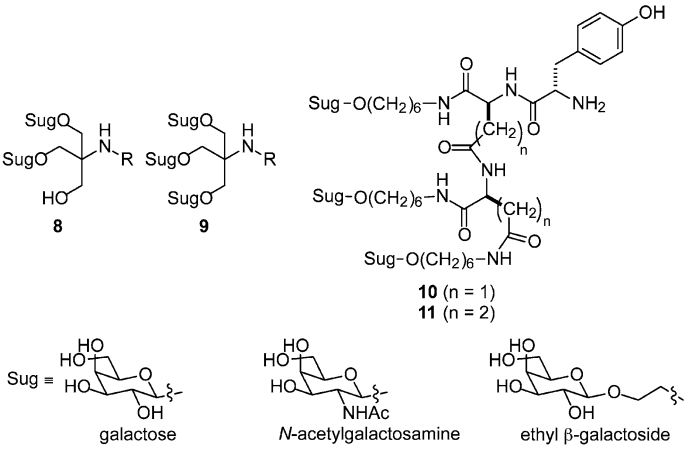

Figure 10
Lee's cluster galactoside inhibitors of the hepatic lectin

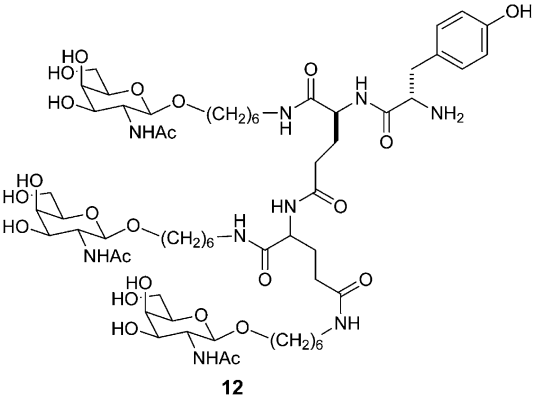

Figure 11
Compound 12, displaying three GalNAc residues, was found to bind tightly to the asialoglycoprotein receptor (ASGR)

than one ASGR carbohydrate binding site. This result is consistent with investigations with triantennary saccharides that suggest that the optimum spacing between galactose residues is 15–30 Å [71,72].

The binding properties of isolated ASGR and the cell surface receptor are different, highlighting the interdependence of receptor organization in the membrane and ligand display. The trivalent aspartic and glutamic acid-based inhibitors **10** and **11** (*Fig. 10*) were significantly more active (1000–10,000-fold) against hepatocytes than were the corresponding monovalent analogs, yet smaller differences (approximately 100-fold) were observed with purified lectin. There are two potential reasons for this difference: the lectin may be organized differently on the cell surface than in the isolated form, or the ligands may bind to more than one lectin on the

cell surface. Because receptor-mediated endocytosis is believed to involve aggregation of cell surface receptors, the triantennary galactose derivatives may trigger endocytosis by oligomerizing the cytoplasmic domains of ASGR subunits. Thus, the role of multivalency, in this case, may be to facilitate receptor-mediated endocytosis [73]. Though how these multivalent ligands function is not known, it is clear from these studies that the presentation of one or two additional carbohydrate epitopes on an appropriate template can have a dramatic effect on the functional affinity of small molecule ligands for membrane-bound lectins.

2.1.2 Ligands for the Mannose Binding Proteins

The substantial binding enhancement observed with small multivalent ligands in the case of the ASGR stimulated efforts to apply similar templates to other lectins. The mannose-binding proteins (MBPs) play a significant role in the innate immune system of human infants [74]. However, the mannose derivative of ligand **11** (*Fig. 10*) showed no appreciable affinity enhancement for rat MBP-A, a homotrimeric protein with a mannose binding site on each subunit. This observation is consistent with the X-ray structural data which show the crystallized trimeric rat MBP-A fragment to have carbohydrate binding sites separated by 53 Å, larger than the maximum distance between ligands displayed on the tripeptide template [75]. The ligands, in this case, cannot exploit inter-oligomer binding, as the target protein is not membrane-bound. For intra-oligomer binding, a template with the required spacing would have to overcome a considerable entropy penalty to simultaneously place recognition epitopes in binding sites separated by such large distances. The ASGR recognizes branching within an oligosaccharide epitope, but the MBPs appear to recognize widely spaced mannosylated epitopes on a glycoprotein or cell surface.

Thus, low molecular weight templates appear to be suitable for only a subset of systems. Finding the right template for binding epitope display is difficult. An additional challenge is that the syntheses of such defined multivalent displays can be rather complex. Some general strategies that address these issues are emerging. Some elegant illustrations of applying modular design principles to generate potent multivalent ligands for the AB_5 are described in the next section.

2.1.3 Ligands for AB_5 Toxins

The AB_5 family of bacterial toxins, which includes cholera, pertussis, Shiga, and Shiga-like toxins (SLT), consists of a single A subunit and a pentagonal arrangement of 5 B subunits [76]. These toxins invade cells through the multivalent interaction of the B subunits with carbohydrate residues of gangliosides. The functional toxin receptor on mammalian cells for SLTs is the trisaccharide of the glycolipid Gb_3 [77]. A dimeric Gb_3 derivative was generated and found to occupy both the primary and secondary binding sites of SLT [78]. The affinity of this dimeric ligand for SLT is 40-fold greater than the monomer [79]. To generate an even more potent ligand, a pentamer was designed, in which the dimeric Gb_3 derivative was appended to a glucose core. The resulting compound, dubbed STARFISH, displays five copies of the trisaccharide dimer (*Fig. 12*). Remarkably, STARFISH is an inhibitor that is > 1,000,000-fold more potent in inhibiting SLT-mediated cell death over the monovalent trisaccharide [79].

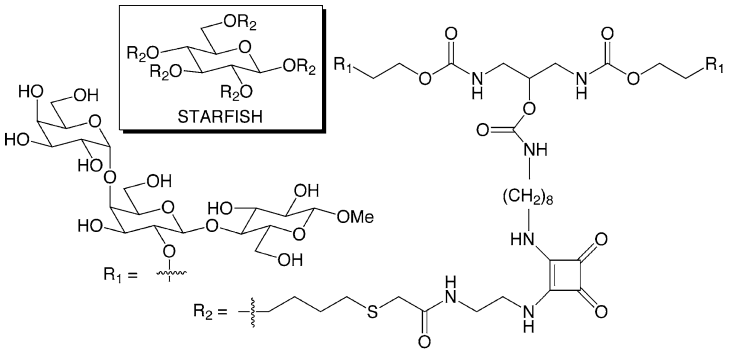

Figure 12
Potent decameric ligands for the AB_5 toxin Shiga-like toxin

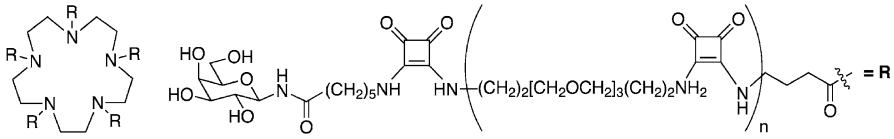

Figure 13
Modular pentavalent ligands for the AB_5 toxin enterotoxin

Although the pentavalent compound was designed to interact one to one with the pentameric SLT, structural studies showed one STARFISH inhibitor binding to two SLT pentamers. These studies again highlight the ability of multivalent ligands to mediate protein assembly [50,55,80,81]. Though rational design was not completely successful at predicting the ultimate mode of action, the resulting multivalent display exhibited tremendous efficacy.

A different study focused on the heat-labile enterotoxin (LT) [82]. A series of pentavalent saccharide derivatives were generated using a modular synthetic approach. These compounds were designed to examine the effect of linker length and overall ligand dimensions on LT binding (*Fig. 13*). The best pentavalent inhibitor is 100,000-fold more active than the monovalent ligand. Importantly, the activity of the compound depends upon the effective linker length—the most effective inhibitor displays sugars separated by distances similar to those of the binding sites within the LT pentamer. The results suggest that the inhibitor saccharides bind simultaneously to all five of the B subunits of the toxin. Further work on similar systems by Fan and coworkers generated additional inhibitors and observed 1:1 binding in the structure of the complex [83,84].

Pieters and coworkers [85] designed cholera toxin inhibitors based on three factors: (1) usage of the authentic receptor oligosaccharide as the monovalent ligand, (2) use of multivalent dendritic scaffolds, and (3) the used of elongated spacer arms of optimized length. This strategy enabled the synthesis of multivalent dendrimers with 47,500-fold tighter binding than monovalent ligand. In a similar system, recent work by Kiick and coworkers [86] demonstrated, using galactose-bearing glycopolypeptides, that correct saccharide spacing, as analyzed from crystallographic structures, was a primary determinant for controlling binding to cholera toxin.

2.1.4 Bivalent Inhibitors of the Selectins

E-Selectin, a lectin involved in mediating the inflammatory response [87,88,89,90,91], has also been targeted with low molecular weight, multidentate ligands [92,93]. Unlike ASGR or influenza virus hemagglutinin, E-selectin is not known to have an oligomeric quaternary structure. Nevertheless, the protein is anchored in the membrane and therefore could participate in multivalent receptor-ligand interactions. To probe this possibility, Wong, Paulson and coworkers explored the dimerization of sialyl Lewis^x (sLe^x) recognition epitopes in the study of multivalent ligand recognition by E-selectin [94]. They prepared dimeric sLe^x derivatives linked by different spacer groups (● *Fig. 14*) and evaluated their activities.

Some of the bivalent ligands were more active than the corresponding monomeric sLe^x derivative **15**. The most potent ligand, **18**, was 5-fold more potent. Bivalent ligands linked by 1,4-butanediol, **13**, or 1,5-pentanediol, **14**, exhibited no increased potency over the pentasaccharide standard. These results emphasize the importance of entropy concerns in the binding of multivalent ligands. Related compounds, for example those with increased hydrophobicity, generated by Miyauchi and coworkers are more effective inhibitors (● *Fig. 15*) [95].

By appending sLe^x epitopes to an aromatic template and functionalizing the amino group of sLe^x with a large, hydrophobic residue **21** (● *Fig. 15*), a compound more effective (8-fold) than the aforementioned dimers was generated. The small increases in functional affinities obtained with these bivalent compounds suggest that they may make favorable contacts outside of the

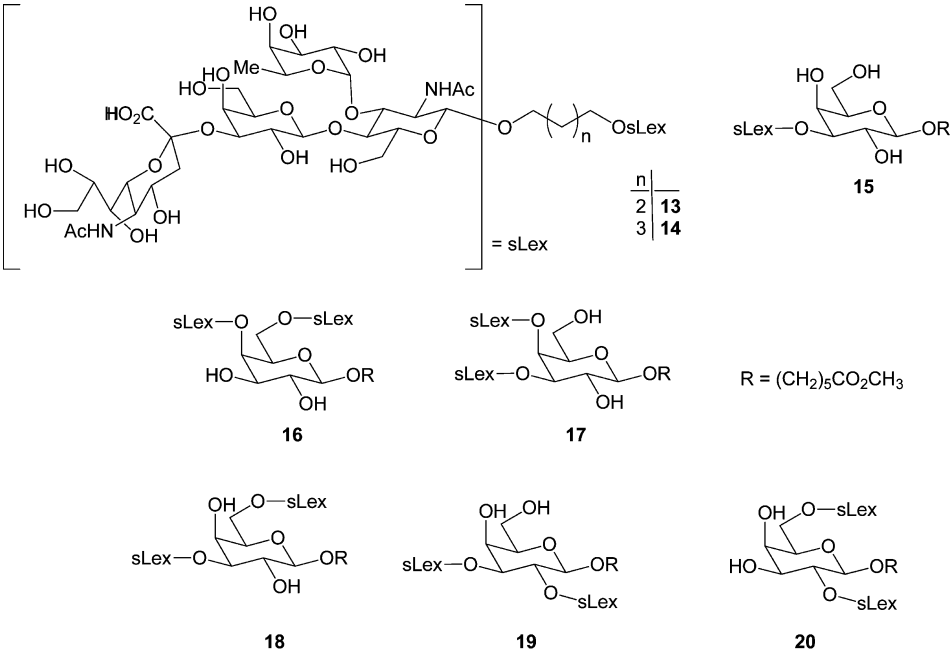

Figure 14
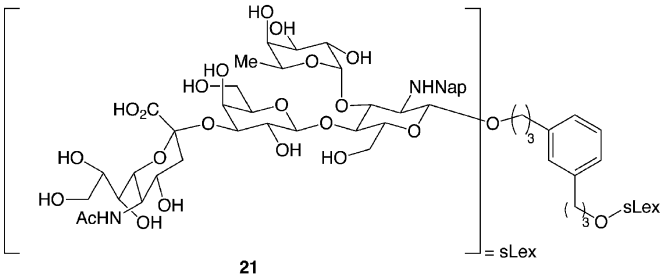
Dimeric sLe^x derivatives with varying linkers



21

Figure 15
Hydrophobic sLe^x dimer with rigid linker generated by Miyauchi and coworkers

binding site rather than simultaneously interacting with two different proteins. These results are consistent with studies suggesting that the physiological ligands are more complex than sLe^x [88,96].

2.1.5 Low-Molecular-Weight Multivalent Displays Can Cluster Proteins

Low molecular weight multivalent displays of ligands can have increased activities relative to monovalent ligands, even when it is clear that the multivalent ligands are too small to span the multiple binding sites of their target lectin [97]. This phenomenon was investigated with using a low molecular weight macrocycle displaying three mannose residues to test binding to the mannose-binding lectin concanavalin A [80]. A trivalent macrocycle (*Fig. 16*) was more potent than a monovalent mannose derivative and, contrasting previous reports of lectin-ligand precipitation [98], was found to function by favorably clustering lectins in solution. Surface plasmon resonance (SPR) was used to demonstrate increased interaction with a liganded surface and Förster resonance energy transfer (FRET) to show clustering in solution. Together, these results demonstrate that low molecular weight ligands, despite their small size, can favorably interact with multiple binding partners.

2.2 Dendrimers as Inhibitors of Protein–Carbohydrate Interactions

Recent developments in the synthesis of dendrimers have stimulated interest in the use of these novel macromolecules. Although many applications have been proposed for dendritic molecules, perhaps one of the most promising is as scaffolds for the study of molecular recognition events [99,100,101,102,103,104]. Dendrimers are oligomeric molecules; however they offer some of the advantages of both polymers and small molecules. Thus, they are capable of displaying a large number of functional groups, yet are monodisperse. The iterative fashion in which dendrimers are synthesized, combined with their relatively small size, results in defined structures which can be characterized readily by using conventional analytical techniques, such as mass spectrometry. It is also possible to rapidly generate a series of dendrimers based on a common, backbone to systematically characterize small differences in recognition of the displayed ligands. The dense display of functional groups by dendrimers has prompted their derivatization with diverse, biologically relevant molecules. The potential of dendrimers

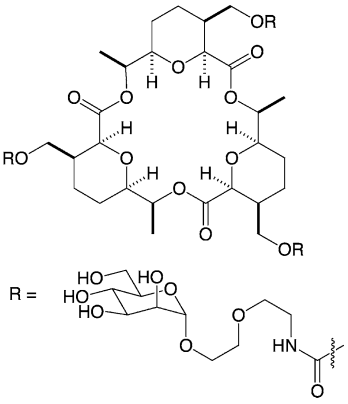


Figure 16
A trivalent mannose derivative that promotes lectin clustering

to act as scaffolds for the multivalent presentation of ligands has sparked the interest of several research groups studying protein–carbohydrate interactions [47,105,106,107,108].

2.2.1 Dendrimers Targeted at Influenza Virus Hemagglutinin

Roy and coworkers have designed inhibitors of influenza virus hemagglutinin based on several different dendrimer backbones [109,110]. Using solid phase syntheses, they generated sialic acid-displaying dendrimers based on a poly-L-lysine core structure (*Fig. 17*) as ligands for influenza virus hemagglutinin. These dendrimers, which bear 2, 4, 8, or 16 pendant sialic

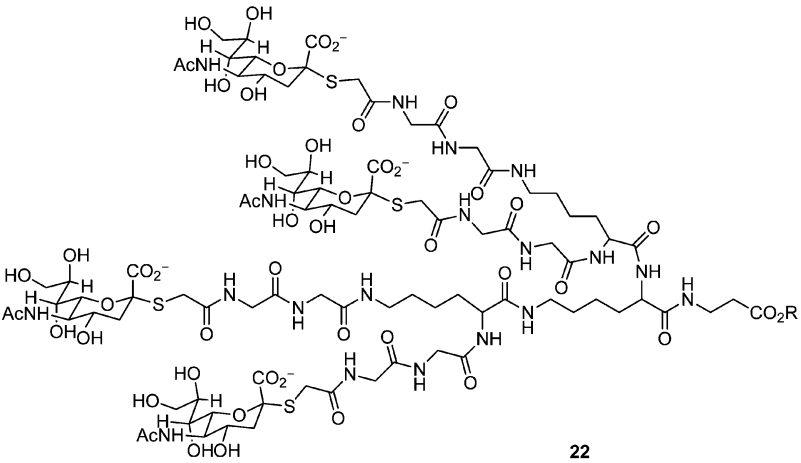

Figure 17
Sialosides displayed on a poly-L-lysine core structure

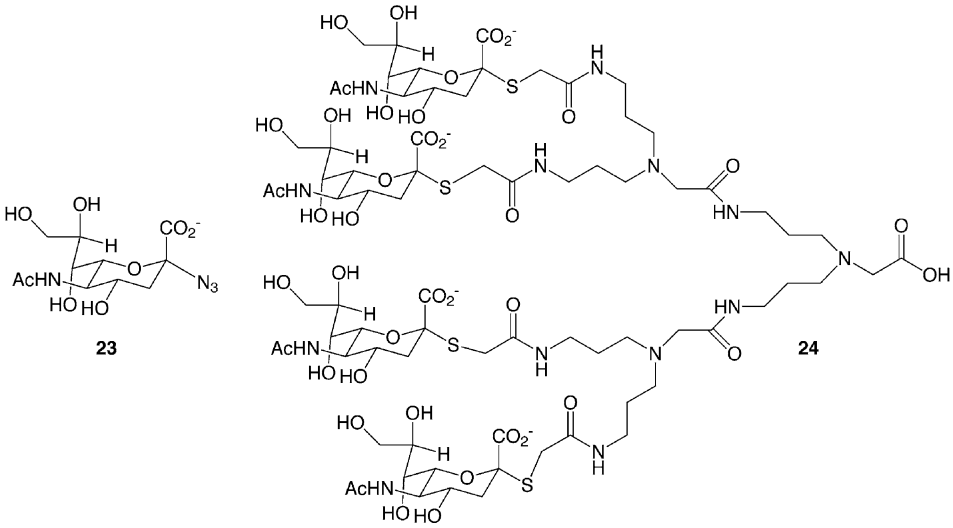

Figure 18
Representative divergent dendrimer, bearing four sialosides

acid residues inhibit viral hemagglutinin-mediated agglutination of erythrocytes at dendrimer concentrations of 625, 312, 156, and 19 μM, respectively. Still, the enhancements in inhibitory potency on a saccharide residue basis (compared to a monosialoside) range from 2-fold to 10-fold. Thus, the dendrimers display only modest enhancements in potency.

Using a competitive enzyme-linked lectin inhibition assay (ELLA), Roy and coworkers compared the activities of structurally related dendrimer displays. These displays varied in the point of branching on the dendritic scaffold. The test assessed the ability of each dendrimer to inhibit the binding of a dimeric lectin from *Limax flavus* (LFA) to the highly sialylated A_1-acid glycoprotein, (10–12.5% sialic acid by weight). Several α-thiosialoside derived from 2 different dendrimer scaffolds (*Fig. 18* and *Fig. 19*) were prepared and evaluated using the aforementioned assay. The divergent dendrimers were prepared in valencies of 2, 4, 8, and 16 (*Fig. 18*) and the radially substituted dendrimers in valencies of 4, 8, and 12 (*Fig. 19*). The dendrimer displaying four thiosialosides was found to be the most efficient inhibitor from either series, with an IC_{50} value of 12 nM. The potency of the dendrimers on a per sialoside basis was 127-fold greater than that of the standard, NeuAcαN_3, **23**. Though this > 100-fold enhancement is significant, not all the dendrimers were more potent. Those of the divergent series displaying 8 and 16 thiosialosides were less efficient on a per sialoside basis than the standard. Interestingly, insoluble complexes were formed when the dendrimers were incubated with LFA, presumably due to crosslinking of the lectin by the inhibitors.

Although some structural features can influence the activity of the dendrimers [111], Roy's studies identified few major differences between dendrimers of different structure. If the dendrimers were acting via the chelate effect, changes in the distance between epitopes would be expected to perturb their functional affinity significantly. As stated above, however, the dendrimers crosslink their target proteins. Because small variations in their structure are unlikely

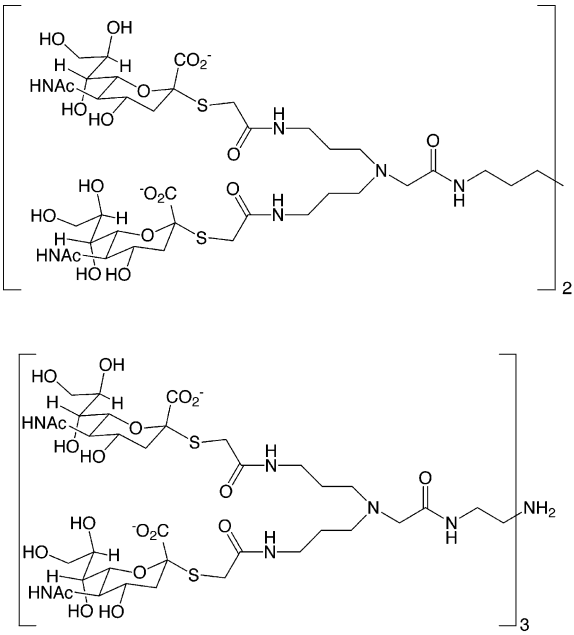

Figure 19
Roy's radially distributed sialoside-bearing dendrimers of valency 4 and 6

to have large effects on their ability to mediate lectin clustering, all of the dendrimers have similar potencies.

In a study comparing dendrimers to other architectures for multivalent display [including low molecular weight displays, globular proteins, and ring-opening metathesis polymerization (ROMP)-derived polymers], dendrimers were found to cluster a different soluble lectin (concanvalin A) [55]. These results suggest that a major mode by which dendrimers function is to cluster lectins. The benefits and drawbacks of clustering by PAMAM dendrimers and other scaffolds have been discussed [50].

2.3 Spherical Displays

2.3.1 Liposomes

Liposomes provide spherical displays with intriguing potential for the polyvalent presentation of carbohydrates (*Fig. 20*). Liposomes, assemblies in which a lipid bilayer surrounds an aqueous core, are particularly interesting due to their potential use as drug delivery agents. The therapeutic applications of lipid vesicles have been studied; it is thought that incorporation of specific recognition elements in the lipid bilayer could allow tissue-targeted drug delivery [112,113].

Studies by the Whitesides group highlighted the ability of saccharide-bearing liposomes to function as efficient inhibitors of protein–carbohydrate recognition events [114]. The lipo-

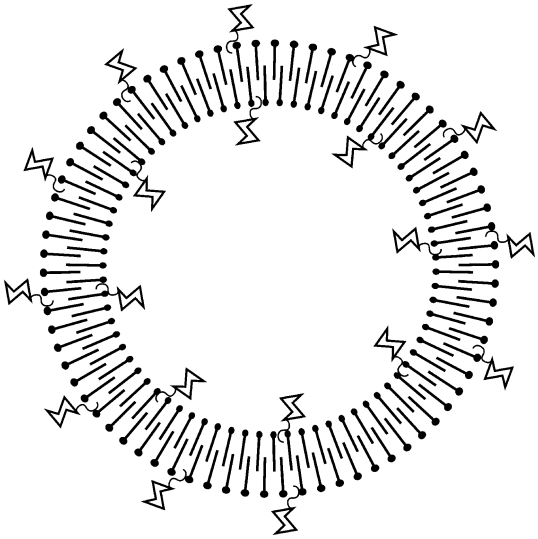

Figure 20
A schematic representation of carbohydrate-bearing liposomes

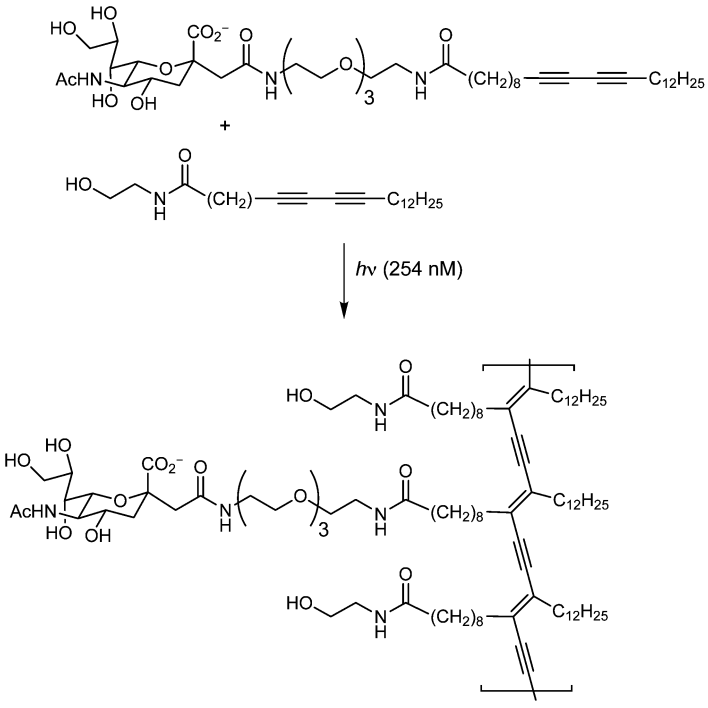

Figure 21
Covalent crosslinking of sialic acid-displaying liposomes

somes are much more potent than those of the low molecular weight multidentate ligands. Within the liposome assemblies, which are held together by noncovalent interactions, the saccharide-substituted lipids can reorganize to bind optimally to the target protein. Covalently crosslinked liposomes also can function as highly effective multivalent displays [115]. Presumably they present ligands at a range of distances and geometries, some of which are complementary to the distribution of the protein receptors on the virus surface. The potencies of the best liposomal inhibitors suggest that these displays may be able to mimic glycoproteins rather than just saccharide epitopes.

In studies by Spevak et al. [115], lipids carrying sialic acid residues attached through *C*-glycosidic linkages were synthesized and crosslinked with varying amounts of unsubstituted lipid to give covalently crosslinked liposomes displaying different concentrations of sialic acid residues (*Fig. 21*) [115]. As in the case of sialic acid-substituted acrylamide polymers (*Sect. 2.4.1*), inhibitory potency was found to increase with the amount of sialic acid displayed on the liposome surface up to a certain concentration; no inhibition of hemagglutination was observed for liposomes carrying 30% or 60% of the sialic acid derivative. This finding emphasizes the importance of the display of charged ligands for multivalent binding and shows that higher density presentations do not necessarily exhibit higher potency. On a saccharide residue basis, liposomes can be highly effective, with minimum inhibitory concentrations of sialic acid of approximately 20 nM. Liposomes present a polyvalent surface array that is quite large; consequently, some of the enhanced inhibitory potency may derive from steric stabilization (*Sect. 2.4.1*).

Liposomal inhibitors of the selectins have been generated that are highly potent inhibitors of these proteins. Liposomes that present multiple copies of the tetrasaccharide sLe^x exhibit affinity enhancements for E-selectin of approximately 500-fold relative to the monomeric sLe^x derivatives [116]. Spevak et al. have incorporated sLe^x derivatives in covalently crosslinked liposomes (*Fig. 22*) [117]. These highly anionic liposomes, prepared with lipid **25**, containing 5% of sLe^x derivatized lipid, inhibit at nanomolar concentrations, the interaction of P-selectin with sLe^x. In contrast, the glycoliposomes prepared with the neutral matrix lipid, **26**, showed no inhibitory activity. Maltose and lactose functionalized lipids, used as controls, were inactive as monomers. However, cross-linked liposomes displaying lactose or maltose prepared with anionic lipid, **25**, were only 10-fold less active than the sLe^x display. These results are consistent with the preference, and apparent broad specificity, of P-selectin for binding highly anionic ligands [118,119,120,121,122,123]. Moreover, they highlight the difficulties of using liposomes as specific inhibitors.

In another example of liposome usage, a multivalent display of a C-3-modified sialoside on liposomes has been shown to inhibit influenza virus replication [124]. Hemagglutinin and sialidase are both involved in both glycoproteins, are involved in attachment and detachment of viral particles on the host cell through recognition of sialyl residues. In this case, the C-3-modified sialoside liposome seems to be such a successful inhibitor of viral replication because it successfully targets two different enzymes that act on multivalent carbohydrate displays.

2.3.2 Resin Bound Ligands

Another venue for saccharide display is on solid support. Resins that have been employed include polystyrene beads, polystyrene modified with polyethylene glycol (TentaGel), and

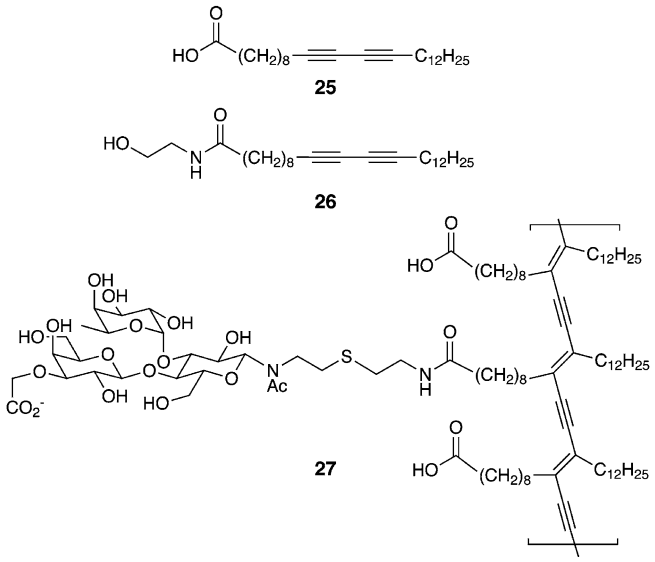

Figure 22
Covalently crosslinked inhibitors of P-selectin

Synsorb. Because several of these supports are also used in solid-phase synthesis, an advantage of using carbohydrate-displaying beads as model systems for polyvalent recognition events is that libraries of saccharides can be assembled. Therefore, structure–function relationships can be determined rapidly.

Kahne and coworkers exploited the opportunity to probe multivalent recognition using libraries of carbohydrate derivatives on TentaGel beads [125,126]. They synthesized an encoded library designed to contain approximately 1300 disaccharide derivatives, including a derivative of the known ligand, Galβ(1-3)GalNAc. The functionalized beads were then assayed by treatment with biotinylated lectin from *Bauhinia purpurea*, incubation with streptavidin- conjugated alkaline phosphatase, and washing and staining of the beads gave a colorimetric readout of the amount of bound lectin. Decoding of the library indicated that compounds other than the known ligand bind to the lectin with high affinity when displayed on TentaGel. To evaluate the potency of the new compounds on a monovalent basis, compounds **28**, **30**, and **31** were synthesized and assayed for their ability to inhibit lectin binding to TentaGel beads derivatized with Galβ1,3GalNAc (◉ *Fig. 23*).

Surprisingly, the binding affinities of the corresponding soluble, monovalent compounds and those displayed on the insoluble resin did not correlate. Compound **28** was the best monovalent inhibitor, while the polyvalent derivative **29** was stained only at high lectin concentrations. Kahne and coworkers suggest the intriguing possibility that biological displays may have unique properties that do not reflect those of the parent monovalent ligand. Although this hypothesis is consistent with the results, other interpretations of the data are possible. For example, it can be difficult to evaluate the efficiency of solid-phase syntheses; thus, the beads could present varying densities of ligand to the lectin. Other studies reveal that differences in the amount of ligand displayed can have dramatic effects on functional affinities [127].

Figure 23
Disaccharide derivatives identified from a library of compounds, which Kahne and coworkers synthesized on TentaGel beads

Moreover, the resin-bound ligands may interact not only with the targeted binding site on the protein, but also with a secondary binding site. For the library used, several of the functional groups incorporated into the synthesis of the saccharide-like epitopes are not found in naturally occurring saccharides. The disaccharide derivatives studied bear aromatic groups at the anomeric position, as well as hydrophobic acyl groups at the two position, which considerably distort the hydrophobicity of these molecules with respect to the known carbohydrate ligands. Some lectins have aromatic binding sites which are distinct from the saccharide binding regions [18]. Therefore, a secondary site could have a very different character, complicating the interpretation of structure–activity relationships. Furthermore, the resin displaying the ligands may alter the solvation sphere of the ligands, thereby changing the energetics of ligand receptor binding events. Elucidation of the origin of the observed alteration in specificity and its relevance to biological recognition await further experiments.

In addition to resin-bound carbohydrate derivatives, surface-bound carbohydrates or glycoconjugates are also proving valuable in the form of carbohydrate microarrays. Array technology, adapted from cDNA microarray printing techniques, allows the coating of various surfaces with carbohydrate moieties. Thus, the specificity of a lectin for different oligosaccharides or glycoconjugates can be determined in a single of experiment. Indeed, glycan arrays have begun to illuminate the specificities of carbohydrate binding partners with previously unattainable rapidity. This topic has been the subject of several reviews [128,129,130,131,132,133], which provide additional details. Because the surface presentation of the oligosacharide epitopes is multivalent, the glycoconjugate displays can exhibit increased avidity (and perhaps specificity) for the target receptor [134,135]. Moreover, properties of multivalency (such as influence of density, orientation, or pattern) can be studied.

2.4 Linear Polymeric Scaffolds

With the exception of trivalent ligands designed for the ASGR receptor and those that block the AB_5 toxins, efforts to design small multidentate ligands typically result in relatively modest increases in functional affinities. This may be because most small ligand clusters mimic naturally occurring, multi-antennary oligosaccharides, yet the physiological recognition events

occur over large surface areas. In physiological settings, saccharide epitopes can be separated by large distances. For example, multiple copies of carbohydrate ligands can be displayed on glycoprotein backbones. Additionally, multiple copies of a glycoprotein can be presented on the cell surface. Similarly, many copies of any given glycolipid are distributed throughout a membrane. To study the importance of multivalency in a given system, macromolecular displays can be used as scaffolds for the presentation of carbohydrate epitopes. For example, proteins have been used as vehicles for displaying multiple carbohydrate epitopes [136]. The display of carbohydrate ligands on inert carrier proteins such as bovine serum albumin (BSA) can afford useful reagents for the study of multivalent protein–carbohydrate binding in a given system. Still, proteins have fixed dimensions and therefore can span a limited distances. In contrast, polymers can span large distances, and their features, sizes and valencies can be altered systematically. Thus, they serve as excellent probes of multivalent binding events.

2.4.1 Acrylamide Polymers

An efficient method for the synthesis of carbohydrate bearing polymers is the radical polymerization of acrylic acid derivatives [137]. The mild conditions of the radical polymerization and the convenient preparation of the polymerization substrates, make acrylamide polymers suitable for the study of multivalent binding [47,138,139,140,141,142,143]. Several research groups have synthesized acrylamide-based polymers and demonstrated their efficacy in inhibition of influenza virus binding to erythrocytes [144,145,146,147,148]. The demonstration that sialic acid-displaying acrylamide polymers are effective inhibitors of hemagglutinin-mediated viral adhesion has stimulated considerable effort to optimize the application of this strategy.
Polymers incorporating varying mole fractions of sialic acid on a polyacrylamide or polyacrylate backbone have been synthesized by two general strategies (*Fig. 24*). Free radical copolymerization of a sialic acid-bearing acrylamide with acrylamide itself or with acrylamide derivatives affords the target materials. Alternatively, an amine-bearing sialic acid derivative

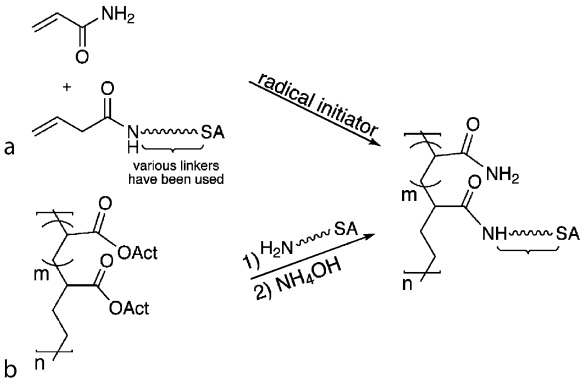

Figure 24
Two strategies for the production of polyacrylamides bearing sugar residues. (a) Copolymerization of acrylamide and a sugar-bearing monomer. (b) Coupling to activated esters on a preformed polymeric backbone. SA = α-*N*-acetyl-neuraminic acid (sialic acid), Act = activating group

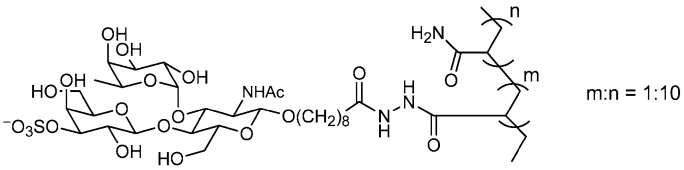
can be coupled to activated esters on a preformed acrylamide backbone [147,148]. Varying monomer reaction rates probably complicate copolymerization by the former strategy, while the latter strategy is expected to result in a random distribution of ligands. A key benefit of the latter strategy is that structure–function relationships in which the ligand structure is varied can be more readily addressed. The polymers prepared by the radical polymerization strategy are large, composed of approximately 2000 monomer units.

Sialic acid-bearing acrylamide polymers prepared by both methods were tested in two in vitro assays of multivalent binding affinity and were found to function as effective multivalent ligands [145,149]. In both cases, the polymers showed large enhancements of inhibitory potency relative to monovalent sialic acid derivatives: Enhancements of 10^3–10^4 were attained for the polymeric sialosides. The inhibitory potency was found to depend significantly on the density of the sialic acid groups displayed on the polymer backbone, with optimal activity at relatively low ratios of sialoside to acrylamide. The optimal proportion varies somewhat and is likely dependent on the sialic acid derivative employed, the method of synthesis, and the assay system used to evaluate the polymers; but sialic acid densities of 10% and 20% have been reported to give the most effective inhibition. These studies contributed to establishing the applicability of synthetic polymeric materials for the study of multivalent molecular recognition events.

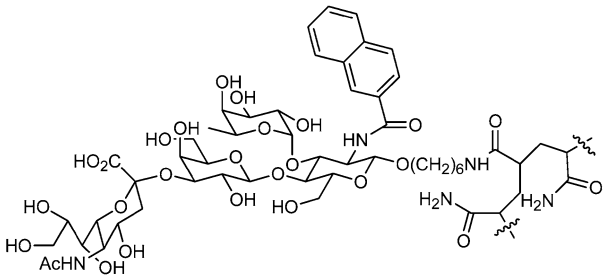
These promising results encouraged efforts to optimize the activity of acrylamide-based displays by modifying polymer structure. The modifications include varying the backbone charge, changing the length of the linker to the sialoside, and copolymerization with monomers bearing aromatic groups. Interestingly, polymers derivatized with *C*-glycosidic analogs of sialic acid exhibited inhibitory potencies equal to their *O*-linked counterparts in a hemagglutination inhibition assay; these results are relevant to the development of carbohydrate-containing therapeutic agents because *C*-glycosides are resistant to in vivo degradation. A highly active of this class is a copolymer resulting from three-components, which bears 20% [145] of a sialic acid *C*-glycoside and 10% benzylamine on a polyacrylamide backbone [149]. The incorporation of benzylamine was inspired by the observation that the most effective monomeric sialosides reported bear hydrophobic, aromatic substituents. Thus, there is a consistency between features that control monovalent binding and those that contribute to multivalent recognition.

Acrylamide polymers derivatized with sLe^x or sLe^x mimetics have been synthesized to target the selectins (◉ *Fig. 25*) [144,150]. Inhibition of glycoprotein binding to immobilized E-selectin by polymers displaying sLe^x derivatives is enhanced approximately 10–100-fold over the potency of monomeric ligands [144]. The effective enhancement of ligands **32** and **33** over their respective monomers is small compared to the increased potencies observed for polymers targeted at influenza virus hemagglutinin. The differences may result from the assays employed. For example, immobilized E-selectin may not mimic the cell surface display of this protein. Alternatively, the differences may result from the organization of the protein receptors. Specifically, viral hemagglutinin exists as a trimer in the membrane, but E-selectin appears to be a monomer.

Syntheses of sialic acid-bearing acrylamide based polymers have established general procedures for generating saccharide-displaying polymers. These methods can be readily applied to multivalent molecular recognition events in other systems. Carbohydrate-substituted polyacrylamides have been shown to be good substrates for glycosidases and glycosyl transferases [151,152], and these enzymes can be used to generate multivalent derivatives of complex carbohydrates to be prepared. Advances in the synthesis of complex oligosaccharide-deriva-



32



33

Figure 25
Acrylamide copolymers, bearing derivatives of sLe^x

tized acrylamide polymers should facilitate future studies of multivalent binding in different receptor systems [153,154].

A disadvantage of traditional acrylamide polymerization reactions is the heterogeneity of the products that result. A radical polymerization method that produces polymers of similar structure but that are much more homogeneous is atom-transfer radical polymerization (ATRP) [155,156]. ATRP has been used to synthesize carbohydrate-substituted polymers with low polydispersities [157,158,159,160,161]. Materials that display sugar residues such as glucofuranose [160], glucopyranose [161], and *N*-acetyl-D-glucosamines [159].

Multivalent Binding and Steric Effects Several research groups have found that polymeric materials are more efficient at inhibiting hemagglutinin-mediated viral adhesion. However, the molecular basis for the observed increase in inhibitory potency is not known. Indeed, antibodies targeted to viral receptors unrelated to hemagglutinin were blocked from binding to their targets, indicating that sites other than the sialic acid receptor were involved [162]. The increased inhibitory efficiency could be attributed to the sum of the effects detailed in ❯ *Sect. 1.2*. Alternatively, the large size of these high molecular weight polymers and their accompanying solvation spheres could, once bound to the erythrocyte surface, sterically obstruct the approach of virus to the cell surface.

To dissect the contributions of classical multivalent effects from the steric mechanism, Whitesides and coworkers demonstrated that when monomeric sialic acid derivatives were added along with the acrylamide polymer, more efficient (on a molar sialic acid basis) inhibition of agglutination was observed [149,162,163]. Addition of the monomeric inhibitors is proposed to have two effects. First, displacement of a polymer-displayed ligand by monomer would lower the affinity of the polymer for the surface of the virus. Second, the size of the polymer not bound to the surface is necessarily increased, and thereby increases the ability of the polymer

to inhibit the approach to the erythrocyte surface. This mechanism is termed "*steric stabilization*". Thus, for the most efficient inhibition, complete binding of polymer-displayed sialic acid epitopes is not necessary or desirable. This steric stabilization mechanism results from a combination of specific (ligand–receptor) interactions and nonspecific steric effects. On the basis of this mechanism, a novel strategy for the inhibition of adhesion events was proposed: Receptors which are not directly involved in adhesion may be used to bind a large polymer to the cell surface which then may occlude, nonspecifically, the approach and adhesion of cells. This mechanism highlights the complexity of the systems involved in multivalency and the difficulty in ascribing affinity enhancements to specific molecular mechanisms without detailed analysis of binding data.

2.4.2 Polyamino Acid Backbones

Several groups have employed polyamino acid backbones as templates for the display of multiple carbohydrate residues [164,165]. For example, potent E-selectin antagonists have been generated from polylysine [166,167] These materials are highly effective inhibitors of leukocyte rolling. Multivalent polylysine displays have also been used to inhibit Shiga-like toxin binding [168].

Highly potent inhibitors of influenza virus have been generated using a polyglutamic acid backbone. Specifically, Kanie, Wong and coworkers modified polyglutamate with lysoganglioside GM_3 (*Fig. 26*) [169]. The polyglutamic acid backbone was chosen for its low toxicity, low immunogenicity and biodegradability. It was anticipated that presenting the saccharide epitope in conjunction with the sphingosine group would afford potent inhibitors of influenza virus-mediated hemagglutination that could function by more than one mechanism. Specifically, the lipid groups could interact with hydrophobic amino acid side-chains of hemagglutinin or insert into the viral membrane. To facilitate binding studies, the polymer was tagged with a fluorescent reporter. They found that the resulting compounds could inhibit the target process at picomolar concentrations.

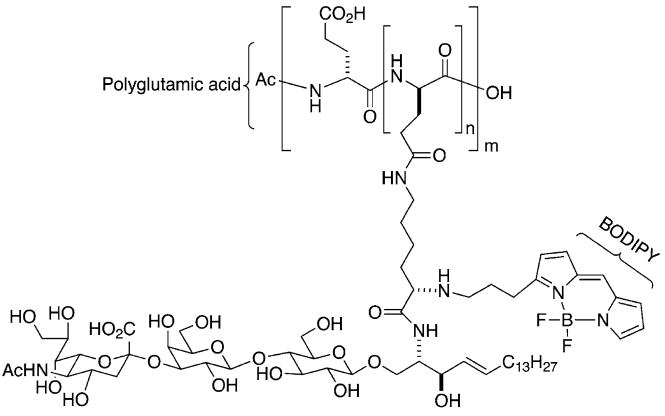


Figure 26
Lysoganglioside GM3-polyglutamic acid conjugate

2.4.3 Polymers Generated by Ring-Opening Metathesis

As described above, acrylamide polymerization reactions are commonly used to generate multivalent carbohydrate derivatives. Still, these reactions produce highly polydisperse mixtures [154], which complicates the interpretation of binding data. The disadvantages posed by standard acrylamide polymerizations have spurred the application of alternative polymerization strategies that can be used to generate more homogenous materials. One such polymerization is the ring-opening metathesis polymerization.

Ruthenium-catalyzed ROMP tolerates highly functionalized, water-soluble monomers. ROMP initiators, such as molybdenum alkylidenes, are effective for oligomerization of protected saccharides [170]. Moreover, ROMP performed under aqueous conditions can be used to produce polymers bearing unprotected carbohydrate substituents [171,172]. Indeed, the ruthenium carbenes are so tolerant that they can oligomerize monomers bearing sulfate groups [121,173]. In addition, initiation can be fast relative to polymer chain propagation, and termination events are generally rare; therefore, this strategy can be used to produce polymers of low polydispersity and defined length [59,174,175,176].

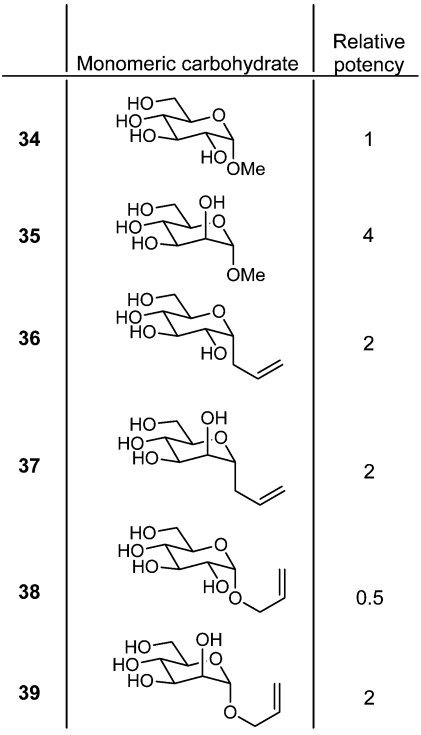

Figure 27
Different monovalent carbohydrate derivatives show similar low affinity for ConA. Relative potency = IC_{50} compound / IC_{50} α-Me-glucoside

Like the dendrimers described in the previous section, polymers generated by ROMP can vary dramatically in size and valency – their size can correspond to the small decavalent ligands discussed in *Sect. 2.1* as well as the large linear acrylamide polymers described in *Sect. 2.3.1* Accordingly, ROMP can give rise to multidentate ligands with saccharide residues that can occupy widely spaced binding sites (e. g., 10–300 Å). The favorable characteristics of ROMP for the synthesis of polymers bearing biologically functional ligands has been exploited [5,56,59,176,177], Mortell et al. first showed that saccharide epitopes appended from the polymer backbone could interact specifically with carbohydrate binding proteins, and that such materials are effective multidentate ligands [171]. In addition they demonstrated the discriminatory potential of multivalent displays of different binding epitopes for their protein targets [64]. The ligand specificity was revealed by assaying mannose- and glucose-derived polymers for the ability to inhibit agglutination of red blood cells by the mannose- and glucose-binding plant lectin, concanavalin A. Carbohydrate-bearing polymers were found to inhibit agglutination at concentrations of up to 50,000-fold lower than monomeric ligands on a saccharide residue basis (*Fig. 27*).

To test the specificity of ligand interaction, the activities of a monovalent glucoside and mannoside with those of their multivalent counterparts were compared (*Fig. 27* and *Fig. 28*).

Figure 29
Synthesis of defined-length, mannose-bearing neoglycopolymers using Grubbs' ruthenium initiator

ConA binds the monovalent *C*-mannoside, **37**, with a slightly (0.2 kcal mol^{-1}) [178] more favorable free energy than the corresponding *C*-glucoside, **36**. Given this small difference, it is not surprising that ConA cannot discriminate between the monovalent mannose and glucose ligands in a hemagglutination assay. In contrast, inhibitory potency of the mannose-substituted **41** versus the glucose-substituted polymer **40** was 100-fold greater [64]. Thus, the discrimination between the polymers was remarkable.

This enhancement of specificity through multipoint contacts may contribute to the exquisite specificity of cell–cell recognition events in nature. Although the observed enhancements in affinity and specificity, with which these neoglycopolymers bind to ConA, are consistent with the chelate effect, polymers of varying length were required for further elucidation of the mechanism by which the binding of these neoglycopolymers to ConA is enhanced.

A key advantage of the ROMP strategy is that defined metallocarbene initiators can be used to generate materials of different lengths, simply by varying the ratio of initiator to monomer. The Grubbs ruthenium catalyst gives initiation rates with reactive, strained, cyclic olefins that are significantly greater (approximately eight-fold) than the rate of propagation [174,179]. These relative rates allow for low product dispersity, if the polymerization is living. Thus, the average polymer length can be controlled by the reaction stoichiometry (monomer: initiator ratio). Accordingly, a defined ruthenium-carbene was chosen for the synthesis of a series of oligomers differing in valency (*Fig. 29*) [180]. By varying the reaction conditions, mannose-displaying oligomers ranging in average length from 10 to 150 monomer units were synthesized. In addition a series was generated in which the backbone was reduced to eliminate alkene isomers and to evaluate the role of backbone flexibility on activity. The resulting two sets of oligomers were then tested in the ConA-mediated hemagglutination assay described above.

The inhibitory potency of the mannose displaying polymers increases dramatically with polymer length, with materials of 50 residues displaying activity approximately 2000-fold higher activity than α-methyl mannoside on a saccharide residue basis [180]. Inspection of the ConA tetramer structure reveals that the saccharide binding sites within the homotetramer are approximately 65 Å apart. The neoglycopolymers produced in this study are a mixture of alkene backbone isomers. Molecular modeling of the most compact, limiting case, containing all *cis* backbone alkene isomers would require approximately 35 residues to span two binding sites within the ConA tetramer. Polymers composed of all *trans*-backbone alkenes would bridge two sites with approximately 17 monomer units. Moreover, it should be anticipated

that polymer potency would increase dramatically up to average length 50, as this length is adequate for all neoglycopolymer backbone alkene isomers to place saccharides in two binding sites simultaneously. The dependence of inhibitory potential on the average length of the polymers is consistent with these materials operating via the chelate effect. Polymers that can place saccharide residues in two binding sites on the lectin simultaneously apparently have the highest activity [180,181].

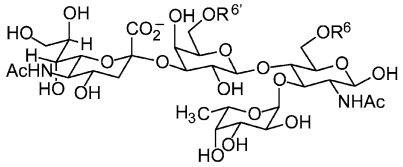
Although the chelate effect can account for much of the observed affinity enhancements, it cannot completely explain the dependence of affinity on polymer length. If the chelate effect was the only mechanism for increasing functional affinities, polymers composed of more residues than required to span the binding sites should display decreased activities, on a saccharide residue basis, relative to the shorter polymers, but they do not. The increased potency of longer polymers and those too short to bridge distinct saccharide binding sites, can be attributed to statistical effects, which lead to slower off-rates. That is, the high local concentration of mannose derivatives favors rebinding of individual epitopes and disfavors dissociation of the polymer.

The role of statistical effects can be investigated using multivalent ligands to explore a protein–carbohydrate interaction that cannot benefit from the chelate effect. The lectin of *Erythrina corallodendrum*, (EcorL) is a dimer with saccharide binding sites oriented in opposite directions; therefore, a multidentate ligand is expected to occupy only one saccharide binding site. Lactose-substituted polymers were synthesized and tested for inhibition of EcorL-mediated hemagglutination [60]. The lactose-bearing neoglycopolymers exhibited only a 5-fold increase in inhibitory potency on a saccharide residue basis. This increase in inhibitory potency is similar in magnitude to those observed with small molecules and dendrimers.

It is also conceivable that steric stabilization plays a role in the inhibition of hemagglutination by the longer polymers although it should be noted that the polymers generated via ROMP are considerably smaller than the acrylamide- based polymers that benefit from the steric mechanism. Moreover, the assays for the ROMP-derived ligands do not involve direct binding to a surface-immobilized receptor. It is also possible that the ability of ligands to cluster multiple copies of ConA is a key factor in their potency.

Selectins appear to be another example in which multivalency provides high functional affinity and specificity, yet these proteins are not oligomeric. The selectins (E-, P-, and L-selectin), a family of three saccharide binding proteins that mediate the recruitment of leukocytes from the bloodstream to sites of tissue damage, have been the subject of intense study since their discovery [88,96,182,183,184,185,186]. The three proteins all bind sLe^x weakly as a monomer; however, it appears that the endogenous ligands are more complex and bind with higher affinity. Thus, it seems likely that it is the features of the glycoproteins, including the multivalent presentation of saccharide epitopes may be important for binding [187,188,189,190].

L-Selectin is one family member that may participate in multivalent interactions. Interestingly, endogenous L-selectin ligands, such as GlyCAM-1 [191,192], are mucins:. They are higly *O*-glycosylated, extended polypeptides from which multiple saccharide recognition elements extend [193,194]. GlyCAM-1 has been shown to primarily present the saccharide capping groups 6-sulfo-sialyl Lewis^x (6-sulfo sLe^x) and 6′-sulfo-sialyl Lewis^x (6′-sulfo sLe^x). The identification of these tetrasaccharide capping groups, coupled with the requirement for GlyCAM-1 sulfation for L-selectin binding, led to the hypothesis that the specificity of GlyCAM-1 binding to L-selectin might be controlled by multivalent recognition of the displayed, sulfated saccharides [173,195,196,197,198,199].



44 sLe^x $R^6 = R^{6'} = H$

Figure 30
sLe^x derivatives and the sulfated Le^x derivatives generated by Kiessling and coworkers for the study of inhibition of leukocyte rolling

To study the importance of sulfation in the context of multivalent presentation, Sanders et al. sought to mimic the critical features of the physiological L-selectin ligand using the ROMP-generated neoglycopolymers [173]. The neoglycopolymers, like mucins, display multiple saccharide epitopes on an extended backbone. Monovalent compounds in which the sialic acid residue of sLe^x has been replaced by a sulfate were synthesized along with their multivalent counterparts (*Fig. 30*) [67,200,201]. Examination of the monovalent compounds in an ELISA using immobilized GlyCAM-1 as the L-selectin ligand, the trisaccharide 3′,6′-disulfo Le^x, **47** showed inhibitory potential similar to sLe^x, but 3′,6-disulfo Le^x, **48**, exhibited higher potency. This finding indicates that 6-sulfo sLe^x is an important recognition epitope, which binds to L-selectin with higher affinity than sLe^x [197,198,202].

Investigation of the inhibitory behavior of the sulfated neoglycopolymers, **49** and **50**, revealed that the multivalent arrays display similar activity in a static assay; both are approximately 80-fold (per saccharide residue) more effective at inhibiting L-selectin binding to heparin than is monovalent sLe^x. The ability of both polymeric ligands to block binding is consistent with numerous reports in which a variety of highly sulfated, multivalent ligands show comparable inhibition of L-selectin binding in static assays [203]. In contrast, under the more physiologically relevant conditions of shear flow [204], there is a dramatic difference in the inhibitory behavior of the two related ligands [173,199,205]. Neoglycopolymer **49** shows no ability to diminish L-selectin mediated cell rolling, while the 6-sulfated material, **50**, shows potent inhibitory capacity. One hypothesis the authors suggest is that compound **50** is poised to form multivalent interactions with cell surface L-selectin. Intriguingly, compound **50** is the most

potent inhibitor of L-selectin known. These studies reveal that both the recognition epitope and its multivalent display are important for specific recognition.

The challenges of synthesizing highly sulfated polymers led to the development of an alternative route to multivalent ligands through ROMP. Because *N*-hydroxysuccinimide esters are compatible with metathesis, ROMP-derived polymers can be generated that bear these activated esters, and nucleophilic functional groups bearing carbohydrate ligands can readily be appended [206]. Additionally, unique functional groups can be installed through selective end-capping of polymers generated by ROMP [207]. Fluorescent reporter groups have installed, and these can be used to test for multivalent binding [208,209]. These techniques have enabled ROMP-derived polymers to aggregate Jurkat T cell leukemia cells by noncovalently crosslinking [81], inhibit L-selectin [207] [208], induce protein oligomerization [156], and bind to B cells by engaging the lectin CD22 [210].

The development of new polymer chemistry will continue to provide access to diverse and novel multivalent ligands. These can be used to ask new types of mechanistic quesitons and to generate highly effective ligands for carbohydrate-binding proteins. As the importance of protein – carbohydrate interactions continues to grow, access to ligands that can be used to illuminate and control these processes will become even more valuable.

3 Applications

Researchers are beginning to exploit empirical evidence that synthetic, multivalent, saccharide-bearing materials can interact effectively with carbohydrate-binding receptors. While the study of multivalent protein–carbohydrate interactions is an emerging field, there is great potential for intervention in therapeutically relevant biological processes ranging from cell–cell recognition in inflammation to the attachment of pathogens such as influenza virus to regulating the immune system. Thus, synthetic materials with the ability to modulate these interactions are of considerable interest.

The applications of synthetic, multivalent carbohydrate derivatives range from their use as inhibitors to biosensors [211] to cell type-specific targeting agents [81,212,213]. Further investigations into the fundamental issues of protein–carbohydrate recognition will provide additional tools and insights for the modulation of physiological processes.

4 Conclusions

Complex networks of variables influence the interactions of proteins with carbohydrates on cell surfaces. The affinity and specificity of cell–cell recognition processes mediated by protein–carbohydrate interactions depends not only on the inherent specificity of one receptor for a specific saccharide epitope, but factors which are not operative in monovalent interactions. These factors include the location of the protein in vivo (on the cell surface or in circulation), the oligomerization state of the protein, its display of saccharide binding sites, the display of saccharide recognition epitopes, and the conformational preferences of the scaffold for ligand display. Given this range of variables, the factors that contribute to favorable multivalent protein–carbohydrate interactions are difficult to dissect. Moreover, cryptic alterations in the environment surrounding recognition elements may have dramatic effects on recogni-

tion [214,215]. Even with these challenges, considerable progress has been made towards illuminating the molecular mechanisms and physiological implications of multivalent processes. These advances are critical because an understanding of multivalent recognition events can be applied to the design of synthetic molecules that can modulate these processes. Progress in synthetic chemistry is providing powerful tools for the study of these fundamental, biological recognition events. This interplay, in which developments in chemical synthesis are used to advance our knowledge of biological systems, provides chemistry and biology with new challenges and opportunities.

12.5 Biomedicine of Enkephalin-Derived Glycopeptide Analgesics

Robin Polt
University of Arizona, Tucson, AZ 85721-0041, USA
polt@u.arizona.edu

Abstract

The incorporation of glycosides into peptide neurotransmitters imparts drug-like character to the neurotransmitter "message" via "membrane hopping". The importance of the glycopeptide-membrane interaction is emphasized, and the *biousian* theory is briefly explained. Application of this approach to enkephalins, the endogenous opioid peptides, leads to potent analgesic compounds capable of systemic delivery. The clinical applications of these compounds are advocated by the author.

Keywords

Glycoproteins; Blood-brain barrier; Hormones; *O*-Linked glycopeptides; Opiates; Transport

Abbreviations

ACTH	adrenocorticotropic hormone
BBB	blood-brain barrier
CHO	Chinese hamster ovary
CNS	central nervous system
CFS	cerebrospinal fluid
DAMGO	Tyr-*D*Ala-Gly-*N*-Me-Phe-glycinol
DPDPE	cyclo-*S*-*S*-[Tyr-D-Pen-Gly-Phe-D-Pen] or D-Pen-D-enkephalin
GPCR	G protein-coupled receptor
GMP	good manufacturing practice

SAR structure-activity relationship

1 Endogenous Opioid Peptides

Enkephalins are the endogenous peptide ligands for the opioid receptors that were discovered in the 1970s [1]. The opioid receptors are members of the G protein-coupled receptor (GPCR) family, a class of membrane-bound receptors that exhibit a conserved topology and represent 80% of all known receptors [2]. Analysis of the deduced amino acid sequences of the many GPCRs that have been cloned indicates that they have a seven transmembrane motif with three external and three internal loops. The domains with the greatest similarity are the transmembrane regions and the intracellular loops, and the most divergent are the extracellular loops and the amino- and carboxyl-terminals. This well-populated class of receptors that includes numerous neurotransmitter and hormonal receptors represents a very attractive target for drug design. In neuronal cells, activation of opioid receptors is coupled, via pertussis-toxin-sensitive G proteins, to various effectors including adenylate cyclase and K^+ and Ca^{2+} channels [3].
The endogenous ligands of these opiate receptors have been identified as a family of more than 20 opioid peptides that originate from the three precursor proteins: pro-opiomelanorcortin (POMC), the common protein precursor for β-endorphin, ACTH, and additional MSH-containing peptides; pro-enkephalin A, the precursor for met- and leu-enkephalin and several larger enkephalin-containing peptides (e. g. peptides E and F) and pro-enkephalin B (prodynorphin), another precursor for leu-enkephalin and for larger opioid peptides (e. g. the dynorphins and neo-endorphins). The opioid peptides are generated from their respective precursors by selective proteolysis, mainly at basic and paired basic residues. Collectively, these peptides are referred to as "endorphins", and all possess the Tyr-Gly-Gly-Phe opioid "message". The activation of the opioid receptors produces analgesia as well as many other effects. Endogenous opioid peptides typically have short half-lives in vivo due to rapid enzymatic biodegradation, and poor bioavailability in tissues and organs. The challenge facing chemists and pharmacologists is to improve metabolic stability and extend their bioavailability while maintaining potency and selectivity [4,5].
The isolation of various endogenous opioid peptides and their classification into families from common precursor proteins has led to attempts to pair particular opioid peptides with opioid receptor sub-types, μ (mu, MOP or MOR), δ (delta, DOP or DOR), or κ (kappa, KOP or KOR). All of the endogenous peptide ligands are agonists at the opioid receptors. The pro-enkephalin-related peptides all show a preference for the δ receptor. All dynorphins and neo-endorphins show κ agonism, but dynorphin A_{1-8} retains a preference for the δ receptor, whereas dynorphin A_{1-13} is potent at both μ and κ receptors. The pro-opiomelanocortin family gives rise to only one opioid peptide, β-endorphin, which is a very potent agonist at both μ and δ receptors with a slight preference for δ. None of the peptide ligands are particularly selective for any opioid receptor sub-type. The precise biological significance of this ligand-receptor "overlap" is unknown [6].

Table 1
Representative endogenous opioids

POMC (porcine)	
β-Endorphin:	**Tyr-Gly-Gly-Phe-Met**-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-~Phe-Lys-Asn-Ala-Ile-Val-Lys-Asn-Ala-His-Lys-Lys-Gly-Gln

Currently, almost all clinically available opioid drugs target the μ receptor for relief of moderate to severe pain, reflecting a common mechanism of action similar to morphine. Morphine shows preference for μ-opioid receptors, but also binds to δ and κ receptors with low affinity. These "narcotics" remain the most widely used drugs for severe pain, and also produce a suite of side effects, including pruritus (itching), miosis (contraction of the pupils), sedation, constipation, and respiratory depression. All currently available μ-agonists display tolerance in vivo and have a potential to produce both physical and psychological addiction, and statistical data reveal that opiate drug abuse and addiction is increasing [7].

Results from Bilsky [8], Chang [9], Negus [10], Dykstra [11], and others show that compounds with mixed μ and δ opioid receptor agonist activity ($\mu + \delta$ approach) may have utility in achieving a similar, or even a greater degree of analgesia and fewer adverse effects than μ-selective agonists such as fentanyl or morphine. Activation of δ-opioid receptors was initially thought to have *no* side effects, but this does not seem likely. Using other criteria, it has been shown that mixed μ-agonist and δ-antagonist activity (μ–δ approach) produces analgesia

with lowered tolerance [12,13]. Clearly, opioids with altered agonist profiles should be studied as a treatment for various types of pain, including severe pain, chronic pain, and neuropathic pain. The use of glycosylated "*address segments*" to promote "*membrane hopping*" and penetration of the blood-brain barrier (BBB) should allow such studies to proceed without more invasive means to deliver peptide "*messages*" to the CNS [14,15].

Initially, we were intrigued by reports that morphine-6-glucuronide (M6G) (❯ *Fig. 1*) apparently penetrated the BBB and produced potent analgesia [16], despite the fact that the resulting zwitterionic metabolite could not possibly be diffusing through the lipophilic BBB [17]. This fact, coupled with a report that an enkephalin galactoside analogue was much more potent than the corresponding glucoside [18], (❯ *Fig. 2*) led us to hypothesize (*incorrectly*) that the glucose transport system GLUT-1 might be involved [19]. Early work in the Davis lab [20] and more recent work by others [21] confirmed that GLUT-1 was *not* involved in the transport of glycopeptides across the BBB [24]. Several research groups began to explore the attachment of carbohydrate groups to opioid peptides in order to influence receptor binding (μ vs. δ), improve serum stability, and enhance peptide delivery to the brain or spinal column.

2 Design Principles for Glycosylated Enkephalins with Improved Bioavailability

Enkephalin analogues bearing glycosyl residues were first synthesized and evaluated pharmacologically by Rodriguez [18], Schiller [27], and Horvat [26] (❯ *Fig. 2*). The hydroxyproline glycoside linkage in the Rodriguez compound is found in nature and may be properly referred to as a *glycopeptide*. The acyl glycoside on the right, and other glycosidic linkages *not* found in nature are more properly referred to as *neo-glycopeptide structures*. Many glycosylated enkephalin analogues have now been prepared and tested in vitro and in vivo. It is safe to generalize that the glycoside or carbohydrate moiety should not be located near the *N*-terminus to avoid interference with binding to the opioid receptors. Likewise, it may be safe to say that selectivity for the opioid subtype ($\mu/\delta/\kappa$) is largely, but not exclusively determined by the amino acid sequence. For earlier reviews of many synthetic glycopeptide derivatives of enkephalin, and some other glycopeptides, along with more complete discussions of opioid SAR, see Polt [25] and Horvat [26]. Many glycosylated enkephalins show greatly enhanced binding activity to μ- and/or δ-receptors and remarkable central analgesic activity when administered peripherally. The potential of glycoconjugates to modify potency, receptor selectivity, and bioavailability has now been clearly and abundantly demonstrated. What remains to be demonstrated are the clinical benefits of glycosylated enkephalin derivatives.

Our own work in this area began with glycosylated DPDPE analogues depicted in ❯ *Table 2*. The synthesis of these cyclic disulfides was not always straightforward, and the –S–S– bond proved to be somewhat labile. While most peptide chemists were focusing on improving $\mu/\delta/\kappa$ selectivity for the generation of better pharmacological *tools*, we chose to focus our efforts on the development of better *drugs*, by selecting for enhanced potency, bioavailability, and penetration of the BBB [4,5,28].

Table 2
Disulfide-linked glycopeptides related to DPDPE

	Glyco-DCDCE	Glyco-DPDPE	Glyco-DPLCE
δ-binding	46.4 ($\pm$ 53) nM	85 nM	<1 nM
μ-binding	45.4 ($\pm$ 26) nM	48000 nM	>400 nM

Building on the extensive opioid SAR of the enkephalins, it was relatively straightforward to choose opioid peptide agonists with the desired μ/δ selectivity, and convert them into glycopeptides with similar selectivity. We tried to avoid, or at least ignore κ-agonists, since this receptor has been associated with dysphoria. Enkephalins possess highly amphipathic conformations that promote strong interactions with membranes [29,30,31], and it is likely that most if not all peptide neurotransmitters share this feature. Thus, when a peptide neurotransmitter is released from a pre-synaptic vesicle, it needs to travel only several hundred angstroms at most (the distance between the pre- and post-synaptic membranes), where it can adsorb strongly to the post-synaptic neuronal membrane. A rapid *2-dimensional* "search" for the receptor in turn facilitates rapid binding of the neurotransmitter to a membrane-bound receptor. Surface-assisted "reduction-of-dimensionality" calculations were examined by Max Delbrück in which he quantitatively demonstrated the viability of this theory [32]. The probability of a membrane-bound neuropeptide finding its corresponding receptor approaches 100%, assuming the absence of convection and that the membrane is fluid (*Fig. 3*). This model has also been endorsed by Robert Schwyzer, who invokes the membrane as a "catalyst" or "matrix" for receptor-ligand interactions [33].

In a recent study [34], we chose to minimize the confounding effects of $\mu/\delta/\kappa$-selectivity by choosing DAMGO (D-**A**lanine-*N*-**M**ethylphenylalanine-**G**lycin**o**l-Enkephalin), a highly μ-selective ligand, for our "message segment". The attachment of a glycoside (or other water-soluble moieties) near the *C*-terminus of the peptide led to increased stability of the aqueous state without perturbation of the membrane-bound conformation of the peptide message [35]. Thus, instead of simply binding to a biologic membrane, the glycopeptide can "*hop off*" the membrane, free to travel some distance before it encounters another membrane that will permit the glycopeptide to "*hop on*" again. By balancing the free energy of the two states (e. g. membrane-bound state versus aqueous state, *Fig. 4*), the glycopeptide will spend the optimal amount of time in the aqueous phase in order to impart drug-like characteristics to the largely membrane-bound peptide neurotransmitter. This can be accomplished by the addition

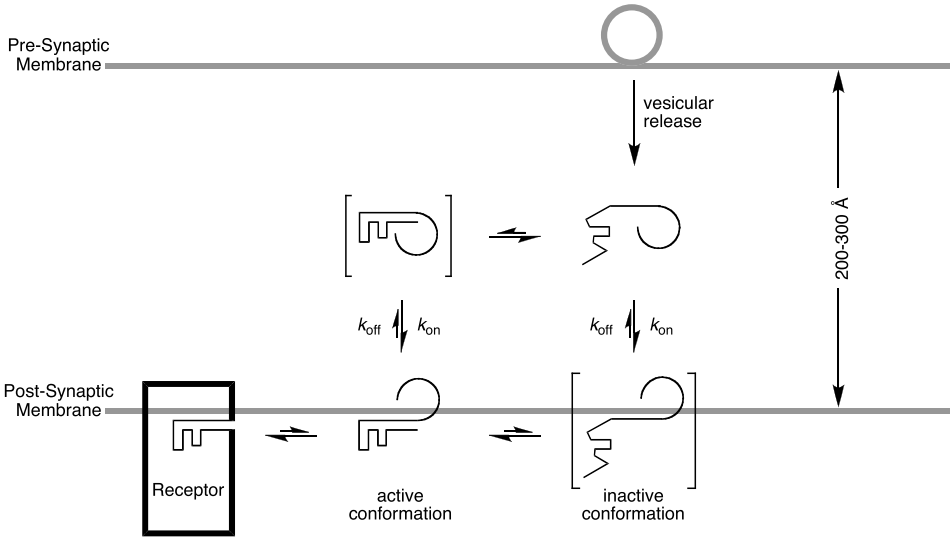

Figure 3
The membrane plays a dominant role in "the search" for the receptor and subsequent binding [33]

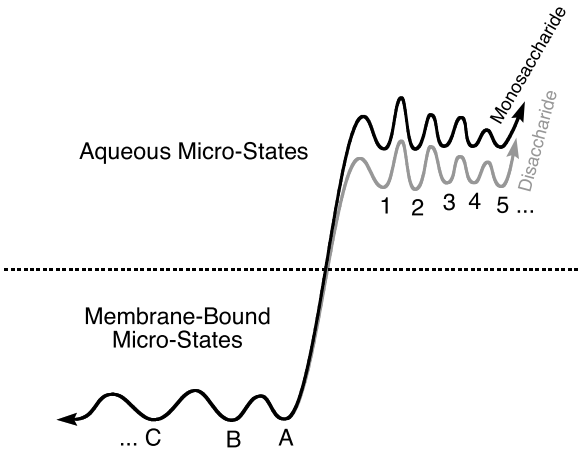

Figure 4
Membrane bound conformations (microstates) vs. aqueous conformations

of larger saccharides with increased hydrodynamic volumes (e. g. disaccharide vs. monosaccharide) [36].

If the glycopeptide spends too much time in the aqueous compartment, then the interaction with its receptors will be reduced. Thus, the glycopeptide needs to spend sufficient time in the membrane to bind to the receptor and undergo endocytosis (vide infra). We have attempted to quantify this process, or at least to rationalize it, by calculating the solvent-accessible sur-

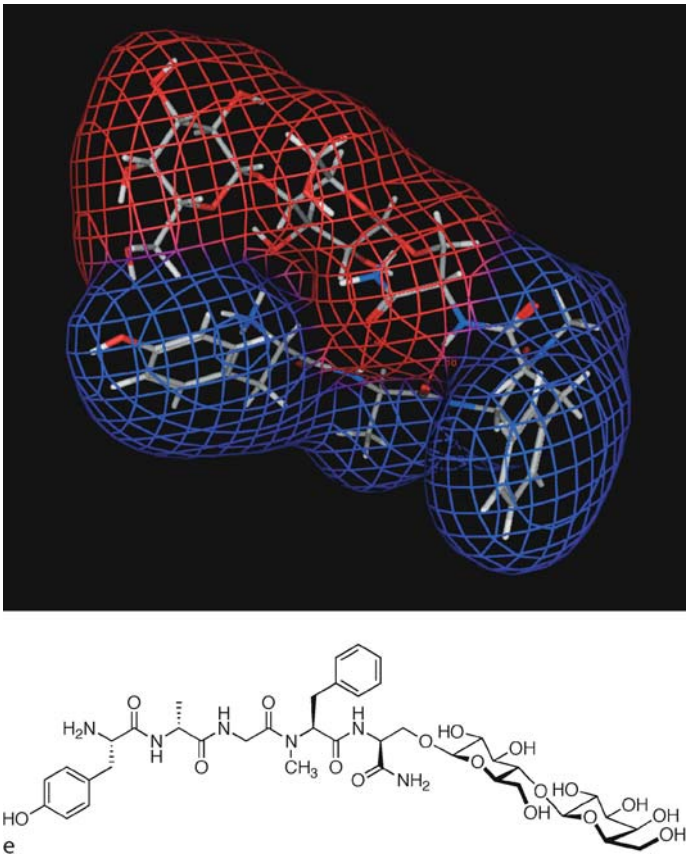

Figure 5
Glycosylated DAMGO derivatives

face area (Connolly surface, *Fig. 5*), and dividing that area into a hydrophilic surface and a lipophilic surface [34].

The amphipathic nature of the DAMGO derivatives was visualized (*Fig. 5*) using the molecular mechanics package of MOE® (Chemical Computing Group, Montreal, Canada) and by labelling the surface blue to indicate the lipophilic portion of the surface (A_{lipid}) and red to indicate the hydrophilic portion of the surface (A_{water}). The ratio of the two types of surface areas was used to create an expression of the amphipathicity in the form of an equilibrium constant using the formula $\mathbf{A} = e^{Awater/Alipid}$. The precise amphipathicity of each molecule is fluxional as each molecule is flexible, existing as an ensemble of conformations (A, B, C… or 1,2,3,4,5… c.f. *Fig. 4*), even when bound to a membrane or micelle [35,37].

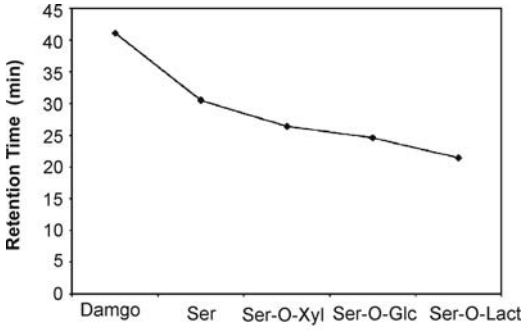
The DAMGO derivatives (*Fig. 5*), including DAMGO itself were administered to mice using intravenous (i.v.) injection, as well as after intracerebroventricular (i.c.v.) injection, and the in vivo responses measured using the 55 °C tail-flick assay by our collaborators in the Bilsky lab at the University of New England. Full dose-response curves were obtained, and the

antinociceptive potency of each drug was recorded as the amount of drug required to obtain 50% activity, or the A_{50} value. Interestingly, when the i.v. potency was plotted versus several measures of amphipathicity, similar U-shaped or V-shaped curves were obtained (*Fig. 6*). The binding affinities of each compound for the $\mu/\delta/\kappa$-opiate receptors were measured by our collaborators in the Bidlack lab at the University of Rochester Medical Center. Binding was measured using radioimmunoassay methods with human opiate receptors expressed in CHO cells. All of the DAMGO derivatives were extremely potent and selective for the μ-receptor. The antinociception and binding values are summarized in *Table 3*, along with values for morphine and ACR-150 (vide infra).

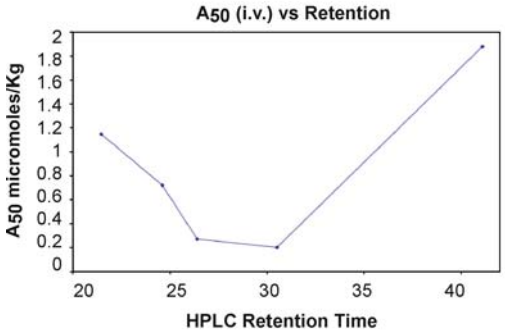
Several of these μ-selective DAMGO derivatives are sufficiently bioavailable and potent enough to be clinically useful, but still show side effect profiles that are similar to morphine or fentanyl. Use of the opioid agonist bearing an *O*-serinyl β-lactoside ACR-150 (*Table 3*) based on the Roques sequence Tyr-D-Thr-Gly-Phe-Leu-Ser (DTLES) [38] is expected to show reduced side effects, and has been subjected to more intense study. Fractional-kilogram amounts of GMP-grade ACR-150 have been produced by two independent contractors, and bioanalytical methods have been developed in order to monitor serum levels of the glycopeptide. This *lactoside* glycopeptide not only shows increased penetration of the BBB and potent antinociception in mice, but also shows diminished side effects normally associated with μ-agonists [4] (*Fig. 7*). Studies of the corresponding *glucoside* have been published [39].

By now it is clear that glycosylation of an enkephalin-derived peptide increases penetration of the peptide across the rat BBB in situ and increases systemic bioavailability of the compound in vivo. A significant feature of these studies is the use of reliable methods for the synthesis of multi-gram quantities of ACR-150 [40,41], which has allowed for further study in vivo. This has allowed us to observe the increased potency of the opioid glycopeptide following i.v. or s.c. (subcutaneous) administration, and assessment of the side-effect profile of ACR-150 following systemic administration. By administering the compound systemically, the glycopeptide presumably accesses opioid receptors in both the brain and spinal cord, an important consideration in the development of physical dependence in mice [42]. The results indicate that ACR-150 produced less physical dependence in mice than equivalent doses of morphine using an acute model (4 day), and additional studies are needed to assess the development of physical dependence using chronic models. Unlike μ-agonists that show strong locomotor effects in mice, locomotor stimulation by ACR-150 is absent. It is hoped that the pre-clinical studies done with this glycopeptide will result in the commercial application of glycosylated enkephalins for the treatment of pain, and that these studies can be published in the open literature very soon.

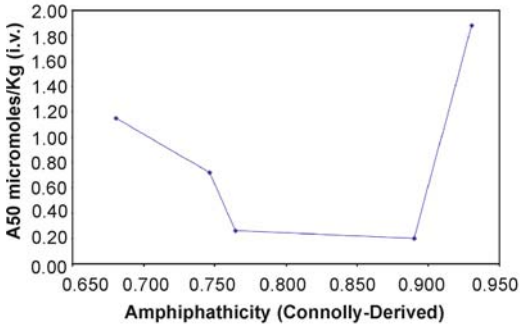
It is too far early to assess the actual *clinical* relevance of ACR-150 (*Fig. 7*) and related glycopeptides, but it is not too early to state with some assurance that this compound or a similar glycopeptide should be subjected to the necessary pre-clinical studies with the intention of testing glycopeptide-based analgesia in human subjects. Other glycosylated opioid peptides would seem to have similar promise, most notably those prepared in the laboratories of Rocchi [43,44], and Negri [45]; dermorphins and related glycopeptoids; the laboratory of Tomatis who has been working with deltorphins in addition to dermorphins [46]; Schiller [47]; Horvat [48]; and Toth, who has been working with glycolipoyl enkephalin analogues [49] (*Fig. 8*). All of these compounds bear some promise for the future, but ACR-150 has been manufactured in fractional-kilogram amounts under the conditions of good manufacturing



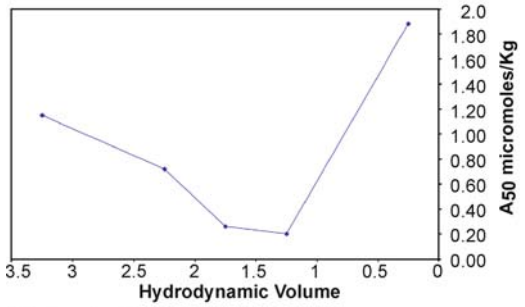
a RP-HPLC Retention Time vs Glycosylation



b Antinociception vs RP-HPLC Retention Time



c Antinociception vs Amphiphathicity



d Antinociception vs Hydrodynamic Volume

Figure 6

Centrally mediated antinociception in mice shows a U-shaped or V-shaped curve when correlated with three different measures of amphipathicity. All three analyses produce a U- or V-shape, as predicted by the biousian hypothesis [15]. Amphipathicity values A, were calculated using the formula $A = e^{Awater/Alipid}$. (a) RP-HPLC retention time vs. glycosylation. Retention times on a C_{18} column decrease monotonically as the degree of glycosylation is increased. (b) Antinociception vs. RP-HPLC retention time. Antinociception, or A_{50} values, as measured by 55 °C mouse tail-flick assay after i.v. administration of each glycopeptide [34] is recorded on the Y-axis as a function of HPLC retention times. (c) Antinociception vs. amphipathicity (A values). A_{50} values as a function of amphipathicity. Connolly-derived amphipathicity values are plotted along the X-axes, and A_{50} values derived from mouse intravenous tail-flick data are plotted on the Y-axis. (d) Antinociception vs. hydrodynamic volume. A_{50} values as a function of hydrodynamic values (glucose units) for the hydrophilic address segment

Table 3

Peak antinociception (A_{50} values) determined following i.c.v. and i.v. administration and receptor binding (K_i values) of the μ-selective DAMGO derivatives. Values for the balanced μ/δ-agonist ACR-150 (YtGFLS*, where S* is the β-lactoside of L-serine amide) are also listed, along with values for morphine sulfate included for comparison. A_{50} values were determined after intracerebral ventricular (i.c.v.) administration or intravenous (i.v.) administration using the mouse 55 °C tail-flick assay. Binding was determined in Chinese hamster ovary (CHO) cell membranes, expressing either the human μ, δ, or κ opioid receptor. Each radiolabelled reference drug (indicated above) was incubated with 12 concentrations of the glycopeptide. Nonspecific binding was measured by the inclusion of 10 mM naloxone. Binding data are the mean K_i values from three experiments performed in triplicate [34].

Opioid drug	A_{50} i.c.v. (pmol/mouse)	A_{50} i.v. (μmol/kg)	[^{3}H]DAMGO (μ)

DAMGO-Ser-Lact	1600	350	1:2400:530

process (GMP), a fact which has greatly facilitated consideration of this class of glycosylated enkephalins as pharmaceutical entities.

The two circled compounds bear further comment. Terasaki's peptide, TAPA [50], is known to penetrate the BBB *without* the benefit of glycosylation. Presumably, this is because the

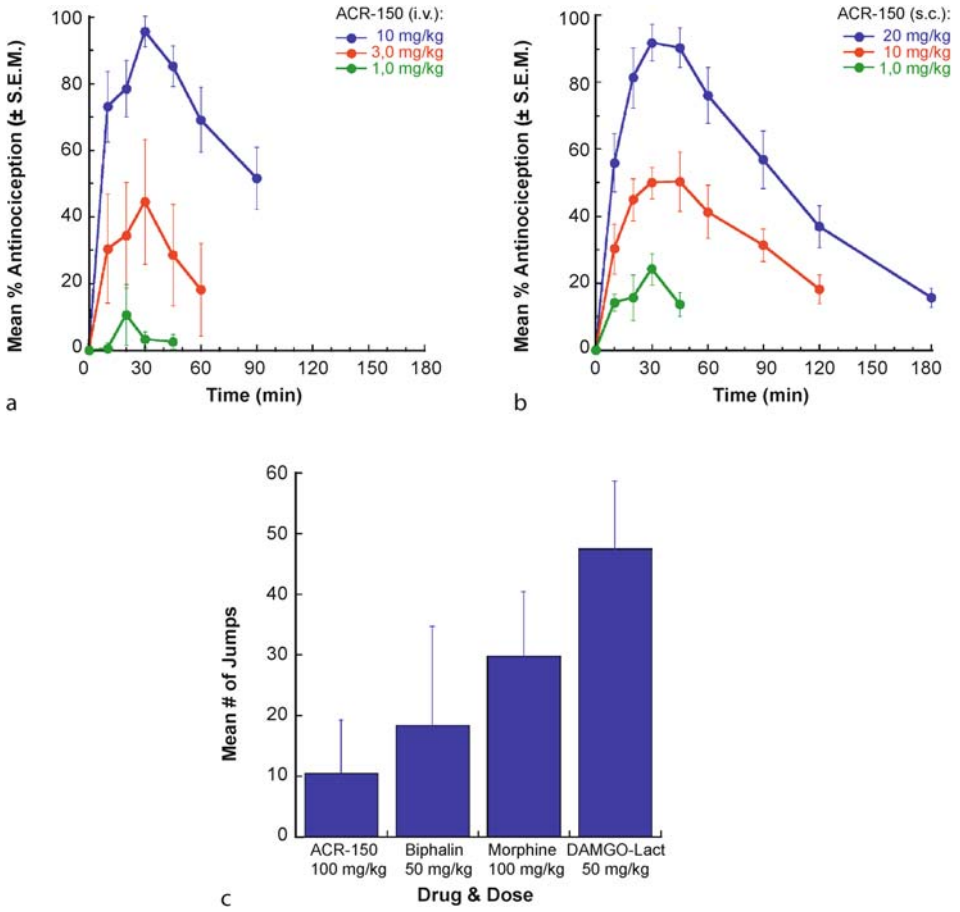

Figure 7
Effects of ACR-150 in mice. a Potency i.v. b Potency s.c. c Addiction potential of ACR-150, compared with biphalin, morphine, and the DAMGO-lactoside, in order of increasing μ-selectivity

charged group is highly solvated and the peptide can "hop" along the membrane in the same way that is postulated for the glycopeptides [34]. It is possible that Rocchi's Lys^7 compounds may also benefit from the additional charge in the molecule.

3 Putative Mechanism for Blood-Brain Barrier Penetration

The BBB of the brain has two major components. An endothelial layer lies between the arterial blood in the brain capillaries and the interstitial fluid of the brain. In humans, the surface area of the endothelial layer in the brain is approximately 21 square meters [51]. An epithelial layer lies between venous blood and the cerebrospinal fluid (CSF) in the choroid plexus, and has a surface area of only 0.021 square meters in humans [52]. At the spinal cord, the BBB

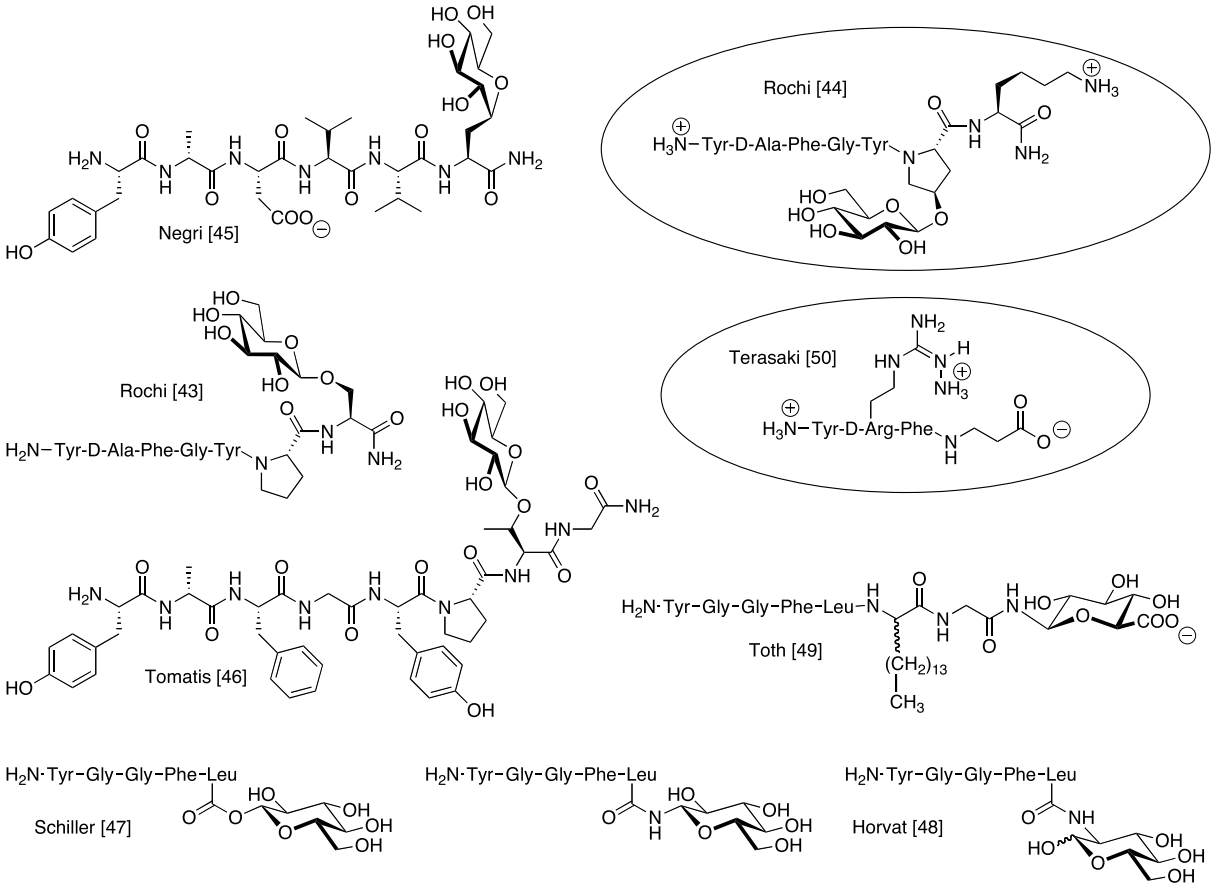

Figure 8
Other peptide-based opioids

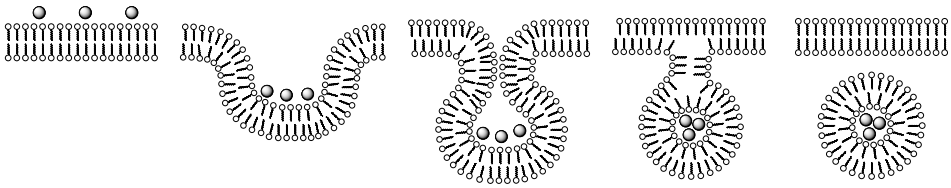

Figure 9
Endocytosis of glycopeptide drugs

only consists of the endothelial barrier. Thus, CSF is created in the choroid plexus and flows around the brain and down to the spinal column. Complete turnover of CSF takes about 5 h in humans. The BBB presents a physical obstacle, and also a metabolic one as well, possessing both oxidative enzymes and peptidases, including enkephalinase. Thus, peptides are normally rapidly degraded before they reach the CSF. This enzymatic gauntlet may be as important as the lipophilic barrier in excluding peptide pharmaceuticals from the CNS. It should also be noted that entry to the CSF does not guarantee that a drug will enter the brain, as many peptides are rapidly exported back to the bloodstream. For a complete discussion of the BBB, or more properly, the neurovascular unit, see the review by Hawkins and Davis [53].

We postulate that BBB penetration of the glycopeptides is initiated by an endocytotic event, (*Fig. 9*) and can probably best be described as adsorptive transcytosis [4,5,15]. The peptide E-2078, an analog of Dynorphin1-8, was shown to cross the BBB via adsorptive mediated endocytosis and transcytosis [54]. Current studies in our lab and our collaborators' labs are designed to more fully elucidate the mechanism of BBB transport of our drug candidates. Studies with much larger dynorphin or endorphin analogues with amphipathic helix address regions indicate that much larger glycopeptides (>2000 M.W.) can penetrate the BBB, as well [55].

4 Drugs for the Brain from the Brain

Outlook. Pain is ubiquitous in medical practice, and analgesics are essential tools for any clinician. While there has been much research into new applications and new formulations of long-standing opioid drugs, it is surprising that very few new drug entities have come into the marketplace for the treatment of pain in decades. The past three decades of research with enkephalin peptide analogues have generated many potent and selective opiate ligands, which have proved invaluable for research in the mechanisms of pain transmission. Use of these ligands as *pharmaceuticals* and not only as biochemical tools has been advanced by an understanding of the factors that govern their stability in serum and in the brain, and how they can penetrate the BBB. Our prediction is that as the greater pharmacological community becomes aware of the hard-won advances in this field, and begins to gain an appreciation of the potential benefits offered by peptide-based analgesics, that the problems associated with the use of peptide and glycopeptide pharmaceuticals will be rapidly solved, and that glycopeptides will find widespread clinical application, particularly in the CNS.

Key to the solution of these problems is the realization of the role of the cell-surface membrane in altering the conformation of even short glycopeptides. It seems certain that a better

understanding of the interaction of glycopeptide amphipaths with membranes could lead to a new pharmacology based on endogenous neuropeptides that have already evolved to agonize or antagonize particular receptors (nature's inherent design). Over 250 endogenous peptides have already been identified that bind to some 50 different receptors in the CNS. What is suggested here are the first necessary steps toward understanding the interaction of glycopeptides with membranes, which is key to both receptor binding and BBB transport. Thus, drugs *for* the brain can be derived *from* the brain.

Acknowledgement

We would like to thank the National Science Foundation, the Office of Naval Research, and the National Institutes of Health (NINDS) for support of our work with glycopeptides. We would also like to thank numerous collaborators in both industry and academia, but especially Edward J. Bilsky, Richard D. Egleton, Peg Davis, Frank Porreca, Henry I. Yamamura, Jean M. Bidlack, S. Steven Negus, and Victor J. Hruby for their invaluable assistance.

Abstract

Carbohydrates are found in nature in manyfold conjugated ways and in addition, they are conjugated to numerous carrier molecules by synthetic means. This chapter outlines the structures and most important biological and organic aspects of glycosylated natural products which serve as antimicrobial drugs as well as antitumor therapeutics. In addition, modern concepts of synthetic glycosciences leading to unusual glycoconjugates are surveyed in the last two sections, covering glycoconjugates derived from sugar amino acids as well as functional glycoconjugates, such as multivalent derivatives or those equipped with a functional tether.

SAA sugar amino acid

1 Introduction

Molecules, in which carbohydrates are covalently bound to proteins or lipids, have been termed glycoconjugates. They are a fascinating group of molecules for chemists and biochemists because of the enormous number and variability of the structures in which they occur as well as the wide array of their biological functions. Consequently, it has been difficult to classify these molecules in a comprehensive way, the more so since new carbohydrate-containing compounds with new linkage types are still being found. For example, to the rich world of *O*- and *N*-linked glycoproteins other types of carbohydrate-peptide junctions have to be added such as an α-*C*-glycosidic linkage of D-mannose bound to the C2 of a tryptophan (Trp) amino acid residue (*Fig. 1*) [1,2], which has been discovered on human ribonuclease (RNase) 2. NMR studies have shown that the mannose moiety in native RNase 2 adopts different orientations around its *C*-linkage compared to the denatured protein. Thus the three-dimensional structure of the protein apparently induces a specific orientation of the mannose residue.

In RNase 2 the main structural roles of the *C*-linked mannose seem to be to stabilize the *N*-terminal loop of the protein and to keep Trp7 in a specific orientation, compared to the non-*C*-glycosylated form [3]. Site-directed mutagenesis has revealed that the sequence Trp-x-x-Trp is required for the *C*-mannosylation of the first tryptophan [4]. This *C*-glycosidic linkage has been proved to occur also in a number of other mammalian proteins, such as interleukin-12, complements, properdin, thrombospondin, erythropoietin receptor, mucins, and a bovine lens protein [5,6,7,8,9,10,11]. It has been demonstrated that the *C*-mannosylation is an enzyme-catalyzed event [12].

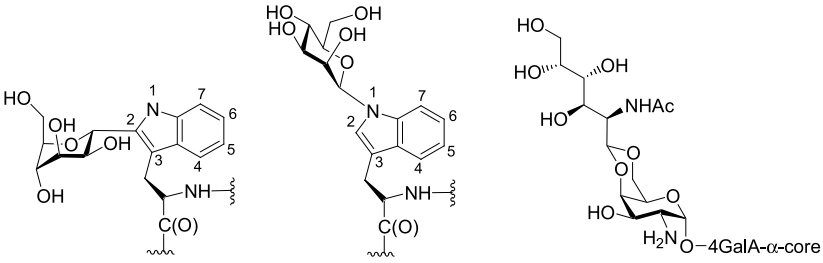

Figure 1
Unusual glycoconjugates

Recently an *N*-mannosylated tryptophan residue has been described for *Aedes aegypti* chorion peroxidase (CPO) [13] which plays a crucial role in chorion hardening by catalyzing chorion protein cross-linking through dityrosine formation. This enzyme is extremely resistant to denaturing conditions, which seems intimately related to its posttranslational modifications, including glycosylation. Other than in RNAse 2 mannose is linked to the N1 atom of the indole ring of Trp residue (*Fig. 1*). Three of the seven available Trp residues in mature CPO are partially or completely mannosylated.

Also in the field of glycolipids unusual types of glycosidic linkage have been discovered [14], such as an open-chain acetal-linked *N*-acetylgalactosamine in the core part of the lipopolysaccharides from *Proteus* microorganisms (*Fig. 1*).

A growing number of special glycoconjugate structures with unusual functions are known such as the antifreeze glycoproteins [15] found in antarctic and arctic fish families. These compounds have the ability to depress the freezing point of the organism such that it can survive the subzero temperatures encountered in its environment. Their antifreeze activity is lowering the freezing temperature in organs around 500 times more than predicted from solution colligative properties. Antifreeze glycoproteins (AFGPs) can be isolated as a heterogenous mixture of compounds from different marine fish, which makes a good characterization difficult. They have a simple, repeating unit glycoprotein structure, which can be expressed as Ala-[Ala-(Galβ1→3GalNAcα1)Thr-Ala]-Ala. AFGP 1 is the largest fraction (33.7 kDa) and AFGP 8 (2.6 kDa, *Fig. 2*) is the lowest molecular weight fraction. Molecular cloning does not allow us to produce the glycosylated antifreeze proteins, while their chemical synthesis has been successfully carried out [16].

The physical properties of AFGPs are very attractive for the cryopreservation of cells, tissues, and organs. Recently, a functional *C*-linked analogue of native AFGP 8 has been synthesized and tested in vitro [17]. These studies have revealed that AFGP 8 is cytotoxic to human embryonic liver and human embryonic kidney cells at concentrations higher than 2 and 0.63 mg/mL, respectively, whereas in contrast, the synthetic *C*-linked AFGP analogue displayed no in vitro cytotoxicity even at high concentrations (*Fig. 2*).

A large amount of natural products, however, contain carbohydrate moieties attached to other molecules than proteins and lipids in a variety of ways [18]. All of these compounds have in common that they are composed of an aglycon and one or more appended saccharide units. They are classified according to the nature of their aglycon moiety or are divided into categories depending on their biological activity. As such glycosylated natural products very often

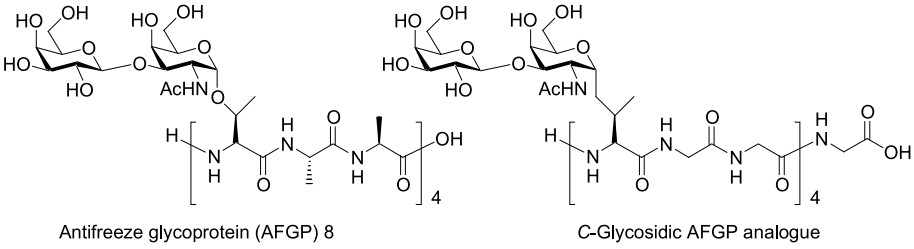

Figure 2
Glycoconjugates with antifreezing properties

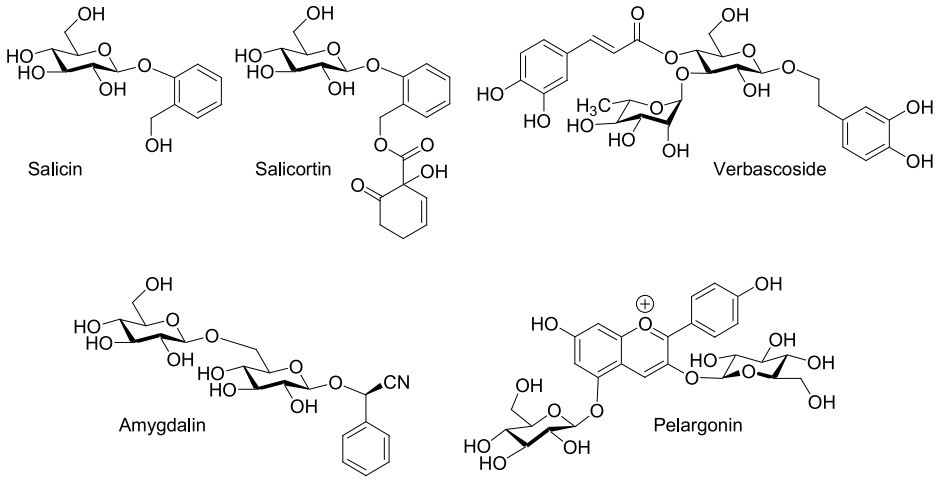

Figure 3
'Historical' glycoconjugates

exhibit activities against a variety of microbes and human tumors, they have attracted significant attention in medicine and pharmaceutical industry [19]. Some of them are of low molecular weight having structures and activities which have been identified much earlier than when the importance of cell membrane glycoproteins and glycolipids was elucidated. Salicin for example (*Fig. 3*), is the β-glucoside of salicylic alcohol and has been found in the middle of the 19th century to be responsible for the pain relieving effects of the bark of the willow- and the poplar-tree. These properties have been known since the times of Hippocrates and include antipyretic, analgesic, antiphlogistic, and antirheumatic activities. Salicortin A (*Fig. 3*) is a derivative of salicin, which also occurs as an ingredient of willow-tree bark and protects these plants against insects. Phenylethyl glycosides represent another example of relatively simple molecules, in which a 2-phenylethyl β-D-glucopyranoside is functionalized with an aromatic acid, e. g. cinnamic acid, caffeic acid, or ferulic acid [20]. They are an interesting group of natural products which are widely distributed in the plant kingdom. Verbascoside (*Fig. 3*) is a typical representative, belonging to the largest class of phenylethyl glycosides, those with a rhamnose residue attached to the 3-position of the central glucose unit. It has been established that verbascoside is a potent inhibitor of protein kinase C and of aldose reductase. Furthermore, it possesses antibacterial, antiviral, and antitumor activity, as well as cytotoxic and immunomodulatory properties. A total synthesis of verbascoside has been reported [21].

A large variety of relatively simple glycosylated cyanohydrins are known as cyanogenics, that is, they liberate hydrogen cyanide. The poisonous properties of some HCN-liberating plants were known already in ancient Egypt and liberated HCN was first detected and reported in 1802 by the pharmacist Bohm in Berlin. Amygdalin (*Fig. 3*) is a famous example of this class of cyanogenic glycosides, which was first synthesized in 1924 [22].

Anthocyanidin glycosides, on the other hand are interesting color pigments in plants. All glycosylated anthocyanidins are called anthocyanins and named according to the exact substitution pattern of the flavylium aglycon. Pelargonin (*Fig. 3*) has an orange color in acidic

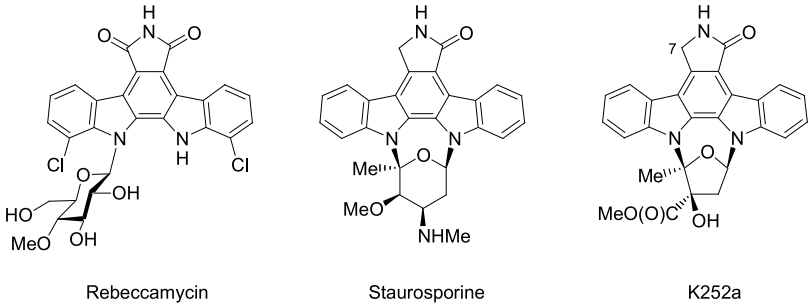

Figure 4
Secondary metabolites based on carbohydrates

solution. Color stabilization and variation of anthocyanins seems to originate from the hydrophobic interaction of the aromatic moieties in aqueous solution as well as from slight pH changes [23].

The majority of bioactive glycoconjugates have been found to be biosynthesized by bacteria and other microorganisms. Over the last 50 years, many molecules which appear to be dispensable for the primary metabolic activities of microorganisms such as growth, have been isolated and their structures have been elucidated; they have been called "secondary metabolites". Secondary metabolites from microorganisms are of substantial interest for the field of drug discovery and for pharmaceutical enterprises. Compared to plant derived metabolites, bioactive compounds from microorganisms are accessible in unlimited quantities by in vitro-bioprocessing technologies. Rebeccamycin for instance (*Fig. 4*) [24,25,26,27] was isolated from *Nocardia aerocolonigenes*, a member of the ascomycetales family. It consists of a symmetrical indolocarbazole chromophore which is glycosylated with a 4-*O*-methyl-glucoside and shows strong antitumor activity. It is structurally related to staurosporine (*Fig. 4*), an indole alkaloid produced by *Streptomyces staurosporeus*, which is effective as an antimycotic and inhibits blood coagulation. Furthermore, staurosporin is a potent, however unspecific inhibitor of protein kinases. Protein kinases are vital to the signal transduction pathways which carry external signals to the nucleus of the cell. The disruption of cellular signal transduction via protein kinase malfunction has been related to the onset of several disease states, including rheumatoid arthritis, systemic lupus, erythematosis, diabetes melitus, Alzheimer's disease and cancer. Highly specific inhibitors of protein kinases are sought as valuable tools to study the cellular roles of individual protein kinases and also seem to be of value for chemotherapeutic intervention.

Searching for more specific inhibitors of protein kinases, numerous derivatives of staurosporine have been isolated as well as synthesized. Among those, a furanosylated congener, K252a (*Fig. 4*), has been isolated and found to inhibit protein kinase C with an IC_{50} value of 32 nanomolar. The synthesis of C(7)-methyl derivatives of K252a has been reported [28].

Synthetic means have often been successfully used to improve specificities and activities of naturally occurring drugs which are taken as lead structures. Also molecular hybrids [29], combining structural elements of different classes of natural products have offered advantages, such as synthetic 2-phenylchinolin-carbohydrate hybrids, which were shown to cleave DNA on photoinduction [30].

Many other glycoconjugates have much more complex structures than the molecules mentioned so far in this chapter. They have been classified according to the chemical nature of their aglycon moieties and a collection of these compounds will be discussed in the following sections. The elucidation of their structures, biosynthesis and biological properties has been equally fascinating and difficult. Moreover, the interest in the discovery of even new classes of glycosylated natural products and their synthesis [31,32] has become increasingly important in view of the increasing antibiotic resistances of bacteria [33]. While the era of antibiotics, which has been started in the 1930s with the introduction of penicillin and the sulfonamides, suggested a pharmacological victory over formerly lethal bacterial infections, this vision is fading away nowadays. Since the first clinical use of antibiotics in the Second World War, a variety of novel antibacterial drugs from microorganisms have been introduced and basically against all of them bacteria have developed resistances. This experience has not stopped researchers from seeking new antimicrobial drugs [34] and indeed some of the most recently investigated compounds form the last line of defense against the most dangerous multi-resistant bacterial strains. In addition to their antimicrobial activities these compounds are highly attractive because of their potent activity against a variety of human tumors.

The bacterial antibiotics, herein discussed, contain a rich spectrum of deoxysugars [35] and aminosugars, often having branched chains. These exhibit a great range of activities; target binding and specificity functions have been ascribed to the deoxysugar components of numerous bacterial antibiotics such as in the case of aureolic acids, anthracyclines, or enediynes. The deoxysugar components of these compounds add a great deal to structure-activity relationships.

Presumably, bacterial infections cannot be treated by solely an armada of drugs and even further new, active natural products. A better understanding of their biology and of biosynthesis of the involved molecules, including the biosynthesis of the deoxysugar portions [36], and gaining more knowledge about control of biosynthesis, the related gene clusters and related biochemical effects, will eventually lead to alternatives in antimicrobial treatment. Microbiological modifications of microorganisms have led to modified secondary metabolites with an altered spectrum of activities. This has been especially successful with a group of Gram-positive bacteria belonging to the family actinomycetales, particularly the streptomycetes, which are especially prolific producers of secondary metabolites, many of which show antibiotic activity. Various strategies of "antibiotic pharmacobiotechnology", including mutagenesis, biotransformation, mutational biosynthesis and precursor feeding have been applied to actinomycetes to alter the spectrum of metabolites formed with the aim to produce compounds with high potency or a broad activity spectrum. Among these efforts, the selective mutagenesis of the producer of the avermectins, represents one of the successful examples [37].

Thus, methods of microbial chemistry have complemented sophisticated organic chemistry and led to a variety of half-synthetic products against which no resistances have been developed as yet. Also numerous mimetics of active carbohydrate structures and glycoconjugates have been synthesized, among which antiadhesive multivalent glycoconjugates and functionalized glycoconjugates form promising groups of molecules in drug research. Therefore, approaches in which carbohydrates have been modified and tested as molecular tools as vaccines or to inhibit microbial adhesion to their host cells, for example, will be mentioned in the last section.

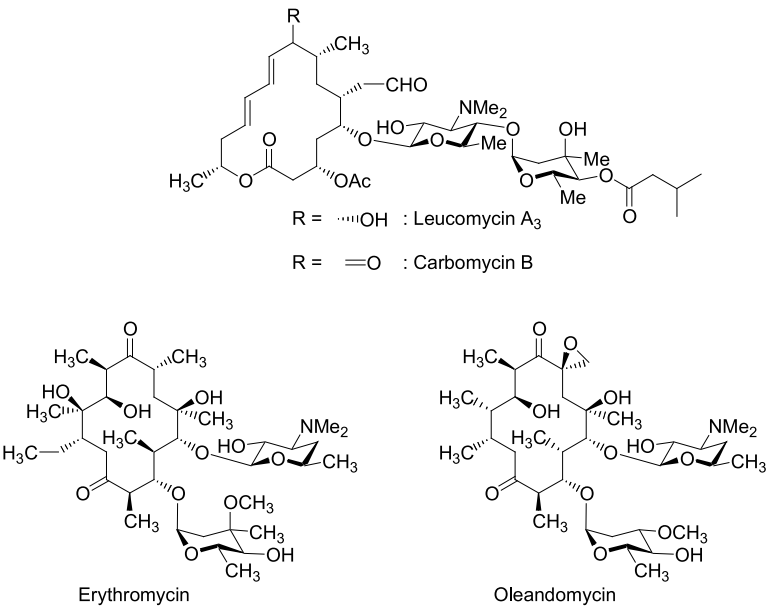
2 Structures, Occurrence and Properties of Antitumor and Antimicrobial Glycoconjugates

2.1 Macrolide Antibiotics

Macrolide antibiotics are glycosides with a macrocyclic lactone aglycon, which is formed in the polyketide biosynthetic pathway [38,39]. The lactone ring is 12-, 14-, 16-, or 18-membered. The polyoxo-macrolides such as the classical antibiotic erythromycin are produced by *streptomyces* microorganisms and form a clinically important group of polyketide antibiotics. Erythromycin (● *Fig. 5*) is the major component out of a mixture of macrolide antibiotics which is formed by *Saccharopolyspora erythraea*. It contains two deoxysugars attached to the aglycon, L-cladinose and D-desosamine.

More than 500 different representatives of the macrolide antibiotics are known, most of which are biologically active against Gram-positive bacteria, displaying a relatively low toxicity. Clinically used are erythromycin, oleandomycin, carbomycin and leucomycin (● *Fig. 5*). They act as inhibitors of the bacterial protein biosynthesis by binding to the 50S-ribosomal subunit. The synthesis of the two clinically important 16-membered ring macrolide antibiotics leucomycin A3 and carbomycin B could be started from D-glucose, which was chosen because it contained three of the required stereocenters [40].

Macrolide antibiotics contain a wide spectrum of deoxysugars which are biosynthesized on different pathways [41]. For chlorothricin (● *Fig. 6*) for example, the stereochemical course



● Figure 5
Glycosylated macrolide antibiotics

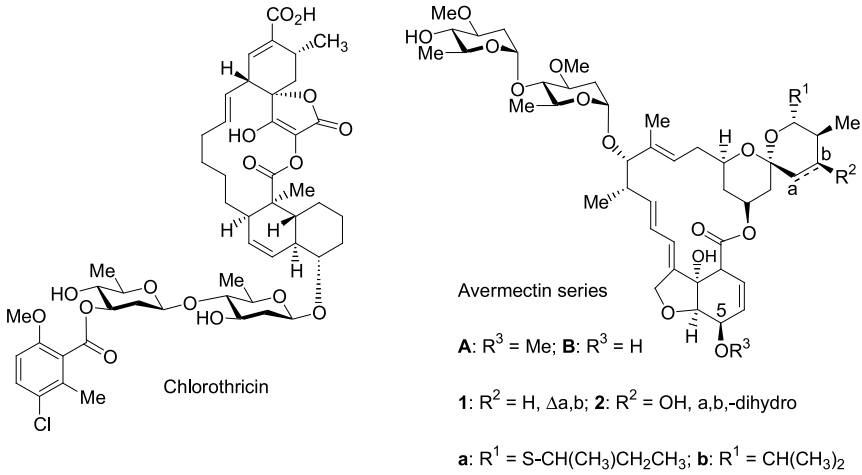


Figure 6
Macrolide glycoconjugates with polycyclic aglycon

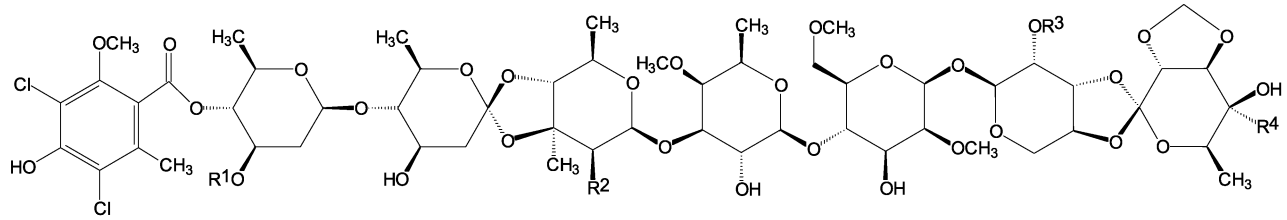
of the replacement of the 2-hydroxy group by hydrogen in the biosynthesis of the 2,6-dideoxy-sugar moieties (β-D-olivose) was shown to proceed with inversion of configuration at C-2 by feeding deuterated glucose to chlorothricin-producing *Streptomyces antibioticus* Tü99 [42]. The chemical synthesis of macrolide antibiotics has been reviewed [43].

The avermectins [44,45] represent a special class of macrolide antibiotics, comprising a complex of 16-membered pentacyclic lactones containing two L-oleandrose units attached to the aglycon. The avermectins are produced and isolated from *Streptomyces avermitilis* and exhibit broad insecticidal, ascaricidal, and antithelmintic activity even at very low concentrations without showing any antibacterial or antifungal activity. They interact in a unique manner with the GABA (γ-aminobutyric acid)-regulated chloride channels. The complex is composed of eight related components (*Fig. 6*), four major (**A1a**, **A2a**, **B1a** and **B2a**) and four minor ones (**A1b**, **A2b**, **B1b** and **B2b**).

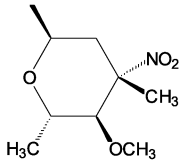
It has been shown for avermectin B that the hydroxyl group at C-5 and a disaccharide moiety are essential for antiparasitic, mitocidal and selective insecticidal activities. Chemical modification of the macrolide-type avermectins resulted in ivermectin which was commercialized to be used in agriculture and animal health care as well as in human medicine.

2.2 Orthosomycins

The orthosomycin antibiotics [46] are structurally characterized by one or more interglycosidic spiro-ortholactone linkages, replacing the traditional acetal junctions [47]. The natural occurrence of orthoesters is rare, but within recent years several examples of antibiotics possessing this common structural feature have been described. The orthosomycins include flambamycin, the everninomicins-B, -C, -D and –2, hygromycin, the destomycins-A, -B and -C and the antibiotics SS-56-C and A-396-I (*Fig. 7*). The orthosomycins have been divided into two



sug =



Flambaymycin: $R^1 = H, R^2 = OH, R^3 = COCH(CH_3)_2, R^4 = COCH_3$

Everninomicin B: $R^1 = sug, R^2 = OH, R^3 = CH_3, R^4 = CH(OCH_3)CH_3$

Everninomicin C: $R^1 = sug, R^2 = H, R^3 = CH_3, R^4 = CH(OCH_3)CH_3$

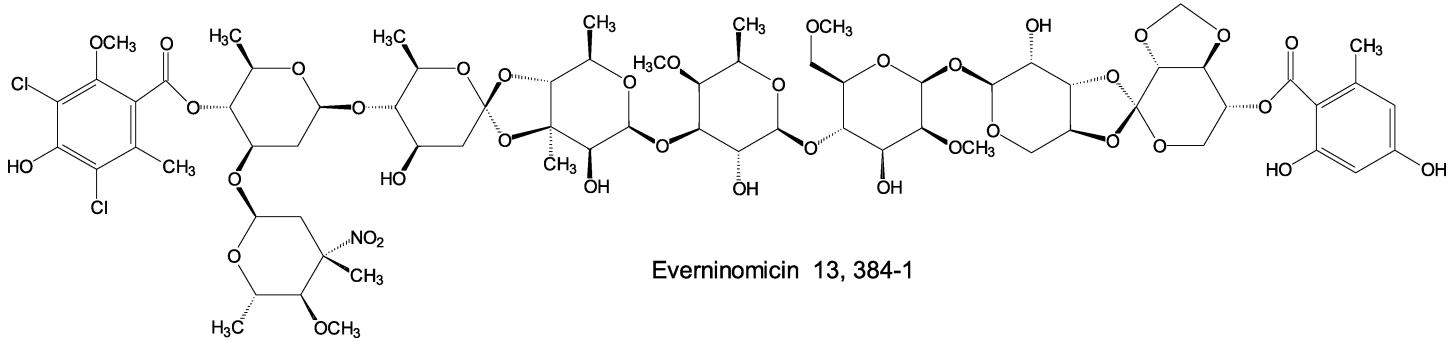
Everninomicin D: $R^1 = sug, R^2 = H, R^3 = CH_3, R^4 = (S)\text{-}CH(OCH_3)CH_3$

Everninomicin 2: $R^1 = H, R^2 = H, R^3 = CH_3, R^4 = (S)\text{-}CH(OCH_3)CH_3$

Avilamycin A: $R^1 = H, R^2 = H, R^3 = COCH(CH_3)_2, R^4 = COCH_3$

Avilamycin C: $R^1 = H, R^2 = H, R^3 = COCH(CH_3)_2, R^4 = (S)\text{-}CH(OCH_3)CH_3$

Curamycin A: $R^1 = H, R^2 = H, R^3 = COCH_3, R^4 = COCH_3$



Everninomicin 13, 384-1

Figure 7
Structures of the orthosomycins

distinct series on the basis of additional structural features, namely those which are esters of dichloroisoeverninic acid, for example flambamycin and the everninomicins and those which contain an aminocyclitol residue, for example hygromycin B and the destomycins. Orthosomycin antibiotics have been isolated for example from several streptomyces species.

The avilamycin antibiotic complex is comprised of 16 components, synthesized from *Streptomyces viridochromogenes*. Avilamycins as many other orthosomycins are active against Gram-positive bacteria, however advantageously show no toxicity or mutagenicity, as it was found for a number of other orthosomycins. The antibacterial effect was shown to operate via protein synthesis perturbation. By blocking of the binding site of aminoacyl-tRNA, a ribosomal attachment is inhibited. This results in an interruption of the translation step and thus a defect in peptide processing.

Everninomicin 13,384–1 (◉ *Fig. 7*) has recently become an important synthetic target as it has been shown to be effective against methicillin-resistant staphylococci as well as against vancomycin-resistant streptococci and enterococci and therefore, represents a promising new drug [48,49,50]. It was first isolated from *Micromonospora carbonacea var. africana*, found in Kenya and carries a novel oligosaccharide structure with two sensitive orthoester moieties. The oligosaccharide chain is terminated at both ends by two highly substituted aromatic esters; furthermore, it contains a 1,1′-interglycosidic linkage, a nitrosugar (evernitrose), 13 ring systems and 35 stereocenters.

2.3 Saccharomicin Antibiotics

Rapid emergence of bacterial resistance to antimicrobial agents has been recognized as an epidemic of global proportions. Particularly in hospital-acquired infections, many pathogenic bacteria are multiply resistant to several classes of antibiotics, effectively narrowing therapeutic options. For multiply resistant *Staphylococcus aureus*, vancomycin currently represents the last line of defense, whereas for certain resistant strains of *Mycobacterium tuberculosis* and vancomycin-resistant enterococci, no viable alternatives exist. Consequently there is renewed emphasis on the discovery of novel antibiotics. Lately, from an antibiotic complex designated LL-C19004, produced by the rare actinomycete *Saccharothrix espanaensis*, two novel heptadecaglycoside antibiotics have been isolated and named saccharomicin A and B (◉ *Fig. 8*) [51].

Saccharomicins represent a rather new class of antibiotics in which the absolute stereochemistry of the sugar residues still awaits clarification. This family is unrelated to all other known families of antibiotics and they show activity both in vivo and in vitro against multiply resistant strains of *Staphylococcus aureus* as well as vancomycin-resistant enterococci. The aglycon *N*-(*m*, *p*-dihydroxycinnamoyl)taurine was the first reported example of an amide bond linkage between cinnamic acid and taurine. In addition, the oligosaccharide portion of the molecules also exhibits unique features. Two of the four 4-*epi*-vancosamine residues are protonated, and considering the sulfate groups, the molecule apparently exists as a quadruple zwitterion. The antimicrobial activity of the saccharomicins may be attributed to their zwitterionic property that presumably folds the molecule into two loops. The macrocyclic backbone conformation may interact with bacterial cell walls and thus cause damage.

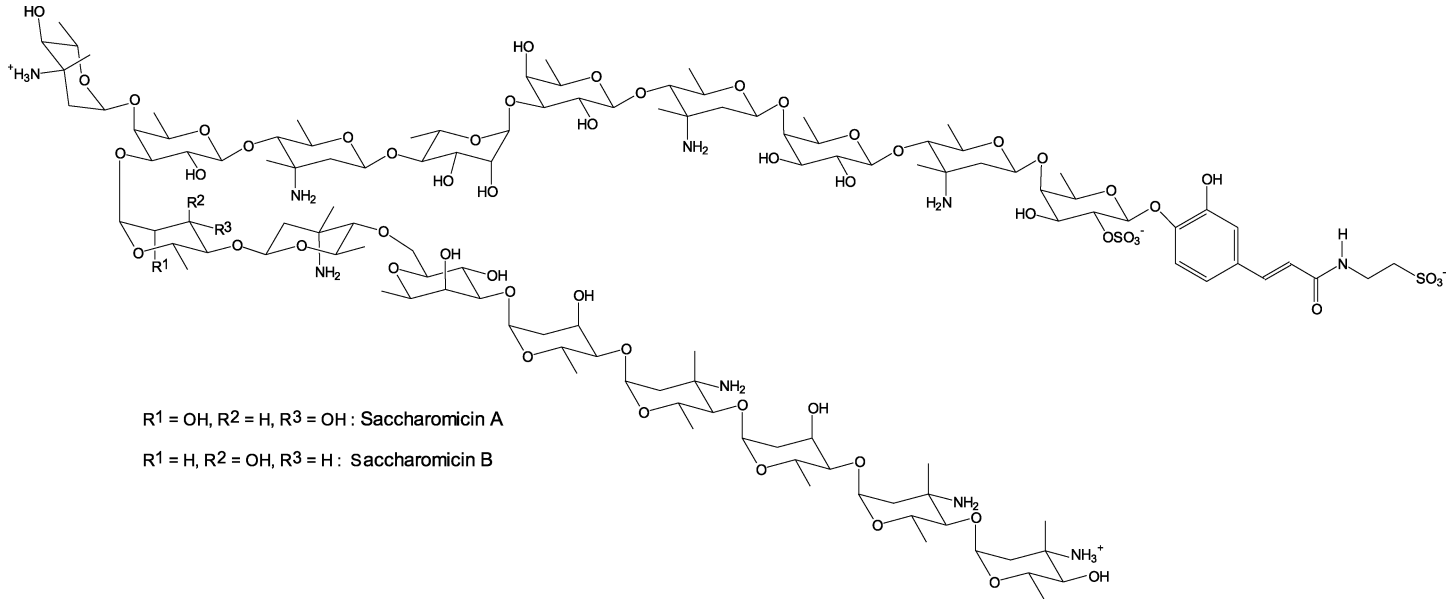


Figure 8
Structures of the saccharomicin antibiotics

2.4 Toxins of Marine Origin

Marine sources have only begun to be utilized for natural product search in the last 50–60 years [52]. Many of the compounds isolated form marine origins have been shown to be extremely effective toxins, like the famous tetrodotoxin. Diarrhetic shellfish poisoning is associated with eating bivalves such as mussels, scallops, or clams which have accumulated dinoflagellate toxins. The causative organisms have been identified as several dinoflagellates in the genus *Dinophysis*. Appearance of the dinoflagellates leads to toxification of the shellfish. The toxins responsible for most human diarrhetic shellfish poisoning, connected with symptoms such as diarrhea, nausea, vomiting and abdominal pain are okadaic acid and pectenotoxin 1 (❯ *Fig. 9*).

Okadaic acid was first isolated from the sponges *Halichondria okadai* and *Halichondria melanodocia* and was shown to be ultimately produced by dinoflagellates such as *Prorocentrum lima*. Okadaic acid contributes substantially to the analysis of phosphorylation and

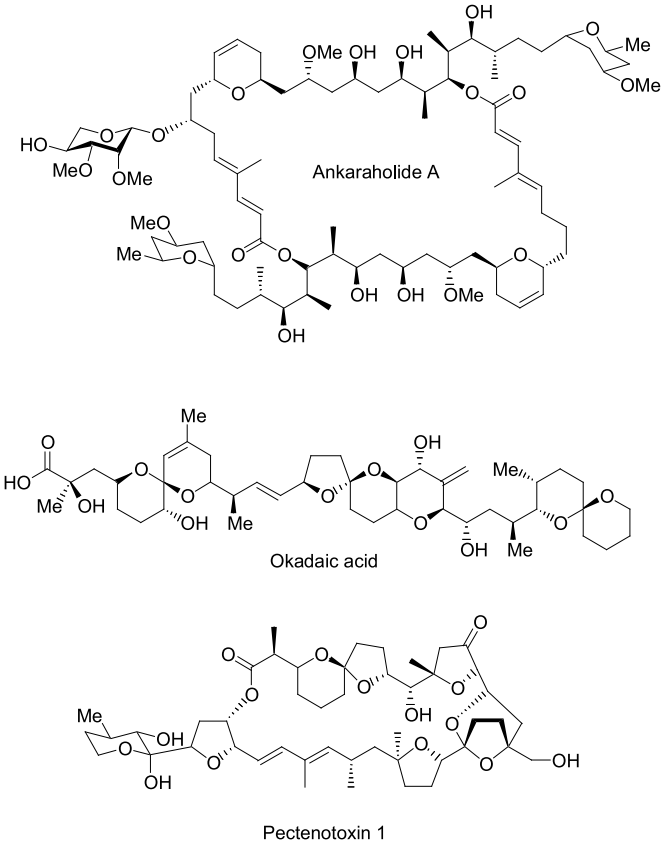

Figure 9
Carbohydrate-conjugated marine toxins

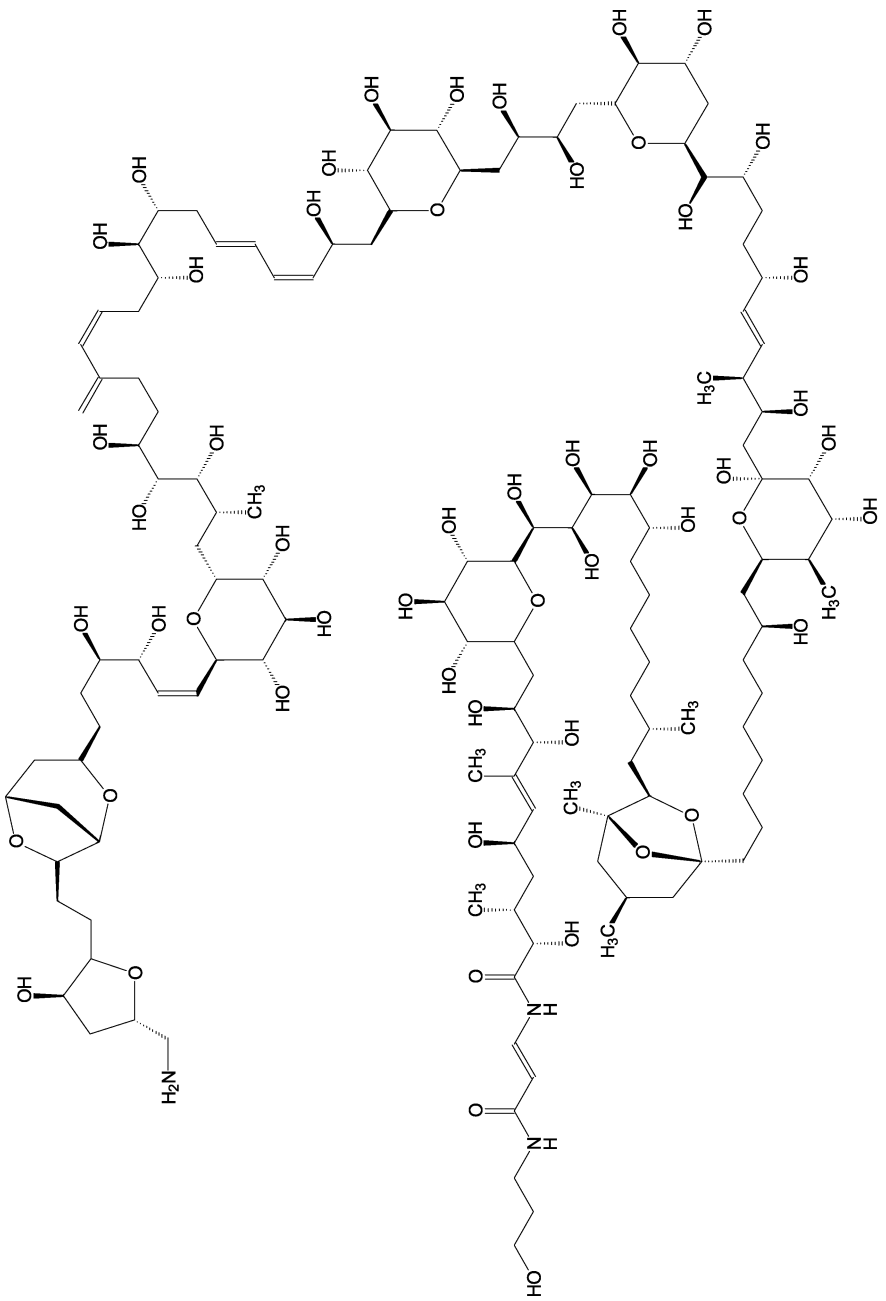

Figure 10
Structure of the famous marine toxin palytoxin

dephosphorylation processes in eukaryotic cell metabolism leading to the understanding of tumor growth processes with kinases as cell proliferation stimulators (tumor promotors) and phosphatases as cell proliferation inhibitors (tumor suppressors) [53].

Palytoxin (Fig. 10) is one of the most poisonous non-peptidic substances known, being even 25 times more toxic than tetrodotoxin. It was first discovered as the toxic principle of the Hawaiian legendary "limu-make-O-Hana (deadly seaweed of Hana)", which is actually the soft coral *Palythoa toxica*. Palytoxin has been isolated from soft corals of the genus *Palythoa* representing one of the largest marine-derived natural products yet isolated. In the meantime, palytoxin and its analogs have also been found in a wide variety of other organisms, in a seaweed *Chondria armata*, in crabs belonging to the genera *Demania* and *Lophozozymus*, in a triggerfish *Melichtys vidua* and in a file-fish *Alutera scripta*.

Palytoxin [54] has 64 stereocenters and 7 carbon-carbon double bonds that could exhibit geometrical isomerism; thus palytoxin could theoretically exist as 2^{71} different stereoisomeric forms, nevertheless, it is produced in nature as a single stereoisomer. Palytoxin acts by forming pores in the cell membrane by which membrane permeability for Na^+ and K^+ ions—at higher palytoxin concentrations also for ATP—is elevated. This results in induction of contraction of smooth muscle in every contracting organ.

Search for new biologically active secondary metabolites from marine cyanobacteria has led to the isolation of swinholide A from Fijian cyanobacterium [55]. This compound was formerly isolated from marine sponges. The bioassay-guided investigation of another cyanobacterium from Madagascar resulted in the identification of two other glycosylated swinholide derivatives, ankaraholide A and B, which differ only in one methyl group (Fig. 11). As cyanobacteria are symbiotic microorganisms of sponges, these bacteria might be the true producers of the swinholide metabolites.

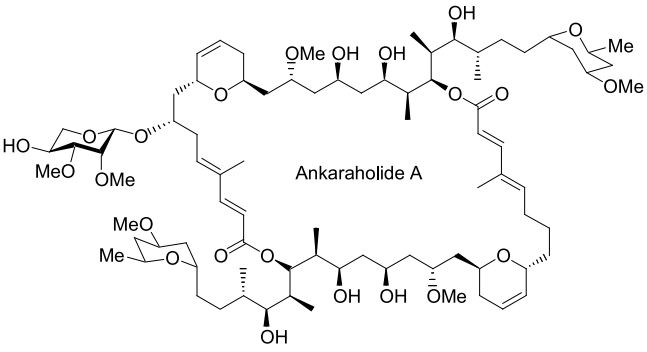

Figure 11
Structure of the glycosylated swinholide derivative ankaraholide

2.5 Spiroketal Glycosides and Cardiac Glycosides

Spiroketal glycosides are widely distributed in nature [56] displaying a broad spectrum of biological activities. Typical examples are the papulacandines, tricyclic spiroketal glycosides

which are produced by *Papularia sphaerosperma* (● *Fig. 12*). They have been found to have antibiotic activity and to inhibit β-glucan biosynthesis in yeast [57]. For papulacandin D [58] antifungal activity was reported.

Some members of a group of natural products, called the saponins also contain spiroglycosidic moieties, such as digitonin (● *Fig. 13*). The saponins resemble a family of amphiphilic glycosides forming colloidal detergent-type solutions in water. According to the chemical nature of their aglycon (sapogenine), they are grouped into steroid saponins and triterpene saponins. There are only very few saponins which originate from animals, such as from asteroids which produce the so-called holuthuroids and asterosaponins, respectively, which are toxic steroidal saponins an used for self-defense. They possess a wide variety of pharmacological activities, they are cytotoxic, haemolytic, and microbicidal. Cyclic saponins such as sepositosid A (● *Fig. 13*) are typical for the asteroid species *Echinaster*.

Osladin (● *Fig. 14*), a steroidal trisaccharide saponin, is the sweet principle of a fern, *Polypodium vulgare*, being more than 500 times sweeter than sucrose. These compounds are of interest as society shows a continuous and growing demand for highly sweet non-caloric and non-cariogenic sucrose substitutes, otherwise having the pleasant properties of sucrose. Some naturally occurring terpene glycosides, such as the sesquiterpenoid glycosides from *Sapindus rarak*, are especially interesting in this regard [59]. Structure-sweetness relationships among the natural terpenoid glycoside sweeteners have been a matter of investigation [60].

A steroid moiety is also typical for cardiac glycosides [61], for which the synonyms digitalis and cardiac steroids are often used. Cardiac glycosides act on the heart by direct as well as indirect mechanisms to enhance the force and velocity of contraction. In addition, they slow down the rate of atrioventricular conduction. Higher doses cause toxic and sometimes lethal effects. Plants and preparations containing cardiac glycosides have been used as poisons and drugs in herbal medicine since ancient times. The cardiac glycosides are characterized by a lactone ring at the 17β-position of the steroid aglycon and a sugar moiety at its 3β-position. They are found in a variety of plants distributed over a broad geographic area, and in some animals as well. Many natural products of the cardiac glycoside type have also been isolated from marine sources [62]. The best known source of cardiac glycosides is *Digitalis purpurea* (purple foxglove) found in Europe and Asia. The prototype of digitalis glycosides is digitoxin, a steroidal aglycon called digitoxigenin equipped with a trisaccharide of three D-digitoxose moieties (● *Fig. 14*).

2.6 Aureolic Acids

Aureolic acids are a group of tetrahydroanthracene oligosaccharide antibiotics, the name of which is related to their characteristic golden appearance. Members of the aureolic acid group include chromomycin A_3, olivomycin A and mithramycin, as the most prominent examples (● *Fig. 15*).

The aglycon of chromomycin A_3 is identical to that of mithramycin, but differs from that of olivomycin A by a methyl group. Conversely, the sugar components for chromomycin A_3 and olivomycin A are nearly identical, while those in mithramycin are different. Research has established that these drugs exhibit their activity by intercalating into host DNA and thus inhibiting normal cellular functions. Aureolic acids require a divalent metal ion, preferably

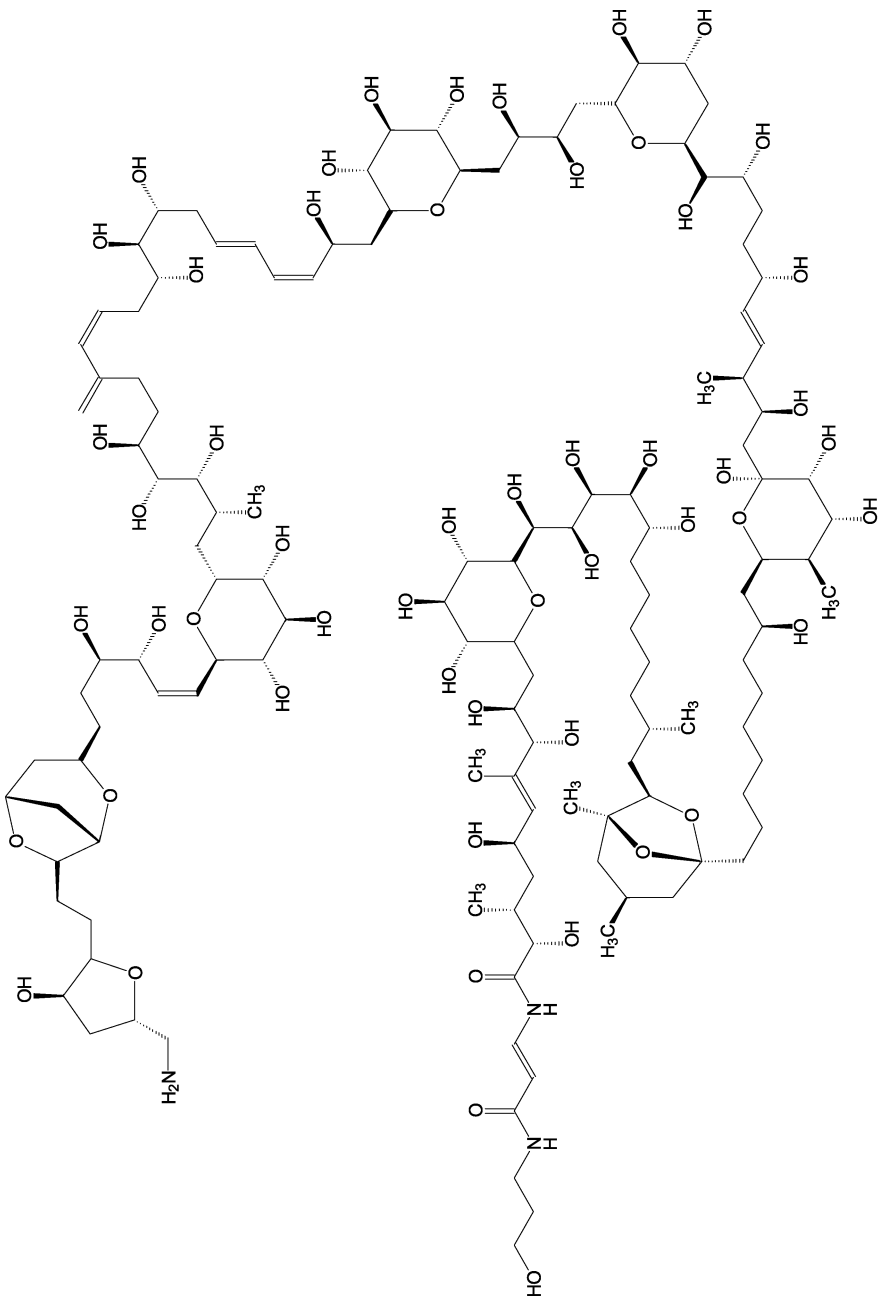

Figure 12
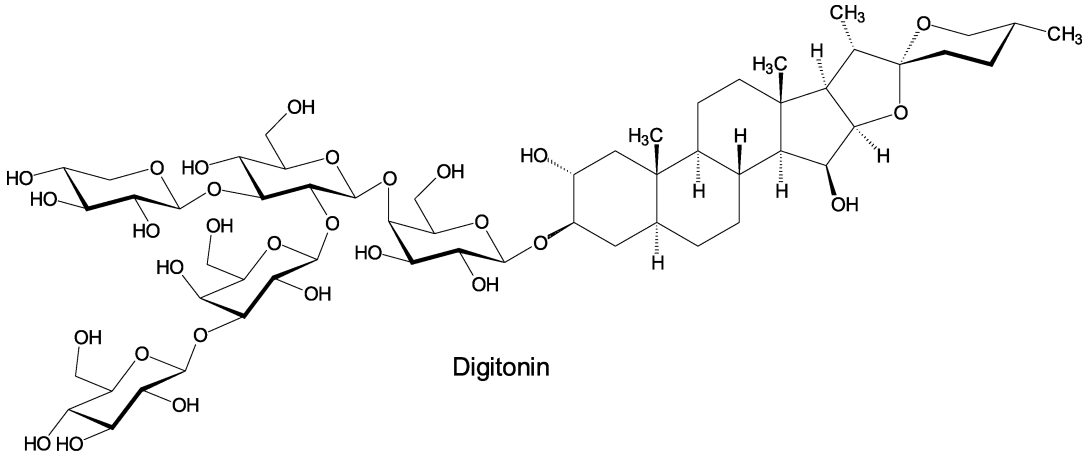
Structure of glycosidic spiroketals



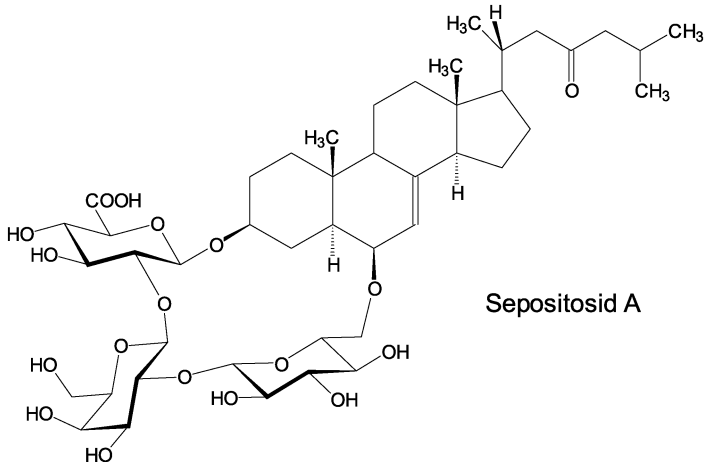


Figure 13
Glycosylated steroid derivatives

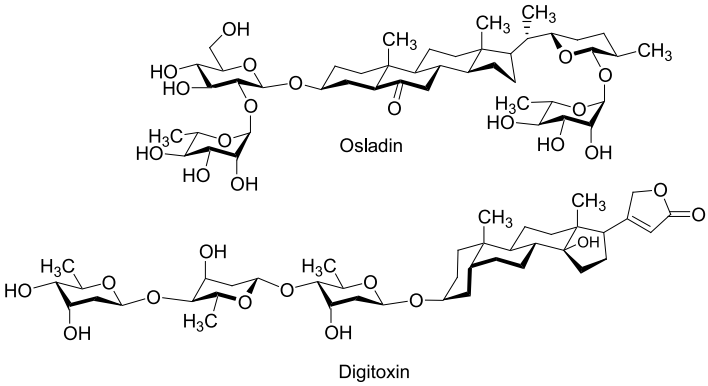

Figure 14
Cardiac glycosides depicted with their conformational characteristics

a Mg^{2+} ion [63] and a guanine-containing target for activity [64]. They form symmetrical dimer cation complexes and bind in the minor groove of DNA thus inhibiting RNA synthesis. Comparing the effects of aureolic acids with different sugar portions supports the idea that the carbohydrate moiety plays a role in determining the sequence specificity of the drug. The structures of the 2:1 complexes of chromomycin A_3 [65] and mithramycin [66] with DNA have been resolved by NMR spectroscopy. In these experiments, the hydrogen-bonding interactions of the deoxysugars with both strands of the DNA double helix were unveiled. The trisaccharide moieties in these aureolic acids were found to align with the minor groove, and they are also involved in the stabilization of the 2:1 drug-metal complex before DNA binding occurs. Removal of the trisaccharide inactivates the drug.

2.7 Anthracycline Antibiotics and Angucyclines

Anthracycline antibiotics are effective antitumor agents and are widely prescribed in chemotherapeutic treatments for a number of human tumors, with doxorubicin (adriamycin) and daunorubicin (daunomycin) being the most popular members (*Fig. 16*) [67]. These compounds contain a tetracyclic chromophore to which one or more deoxysugars are attached with or without amino groups. Anthracyclines may also contain deoxyuloses as in aclacinomycin A and even the aglycon structure can be further complicated as seen in arugomycin (*Fig. 16*). Removal of these sugars results in at least a partial loss of biological activity.
Several X-ray crystal structures and solution NMR structures have shown that the tetracyclic chromophore of these drugs intercalates DNA and alters the local topology [68]. In addition the glycosidic moiety binds in the minor groove – in case of arugomycin also to the major groove [69]. Another mode of activity for anthracyclines is direct inhibition of topoisomerase II [70]. In the case of anthracycline antibiotics, it appears that the oligosaccharide chains do not play a significant role in the DNA sequence selectivity as can be seen with calicheamicins. Intercalation of the chromophore into DNA seems to be the dominant interaction which both determines preferred binding sequences and directs the binding of the saccha-

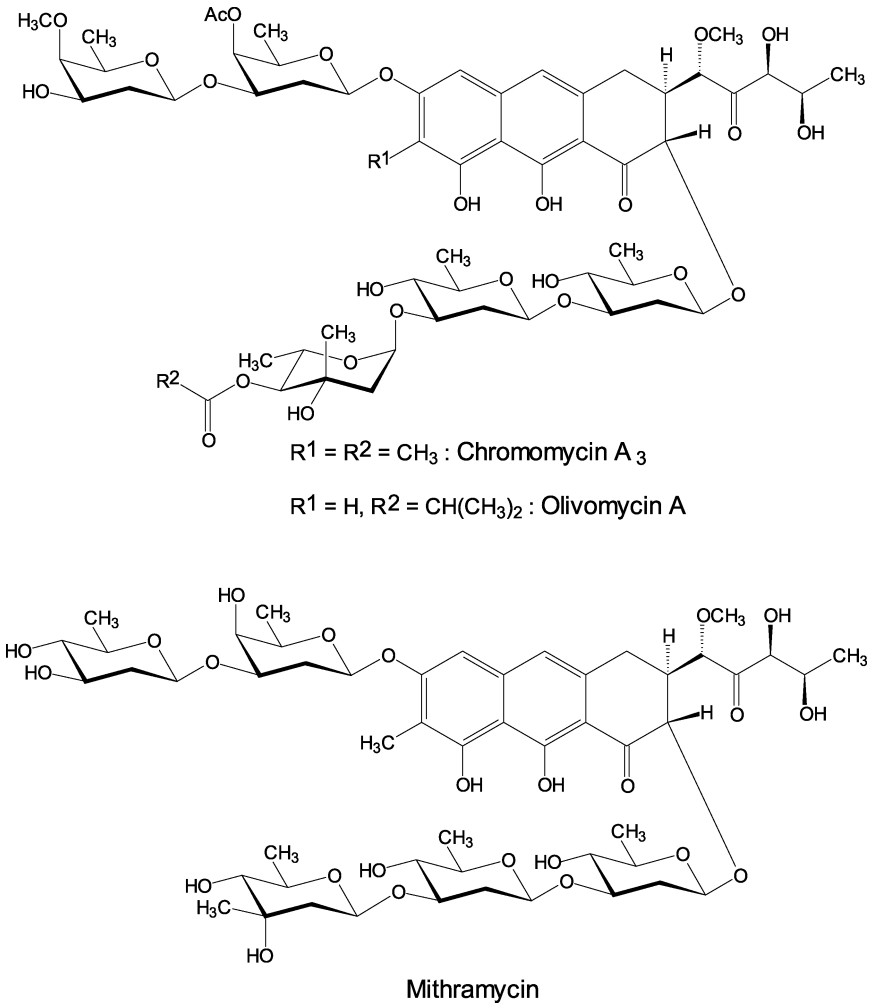

Figure 15
Structures of aureolic acids

rides into the minor groove. Nevertheless, the saccharide side chains have been shown to dramatically enhance the binding affinity of the drugs for DNA. Additionally, in aclacinomycin A the trisaccharide binding forced the DNA to kink toward the major groove with opening of the minor groove [71].

An emerging new class of antibiotics are the quinoide angucyclines [72] which in contrast to the related linearly condensed anthracyclines, do not only show anticancer activity but also a multitude of other interesting biological activities such as antibacterial or antiviral properties and enzyme inhibition. The angucyclinones have been classified based on the degree of oxygenation and *C*-glycoside formation [73]. Representative examples are aquayamycin

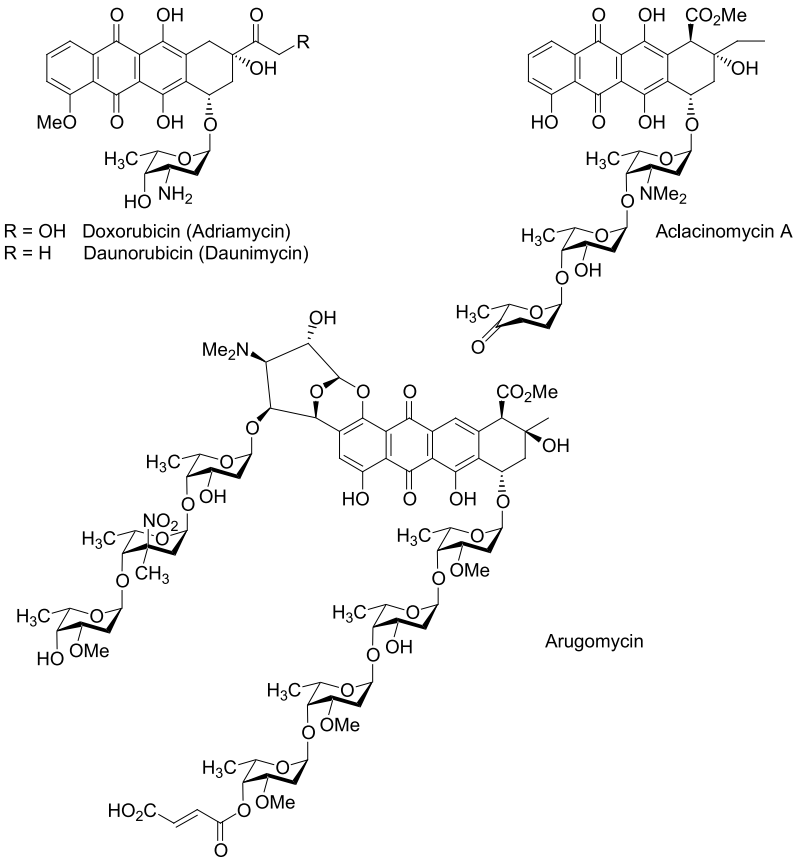

Figure 16
Structures of anthracycline antibiotics

in which an olivose is *C*-glycosidically linked and the saquayamycins, such as saquayamycin A (*Fig. 17*).

Many investigations have been dedicated toward the elucidation of the biosynthetic pathways leading to the deoxysugars found in anthracyclines and angucyclines such as in case of the angucycline antibiotic landomycin A (*Fig. 18*), produced by the actinomycete strain *Streptomyces cyanogenus* [74]. Landomycin A has a unique structure consisting of a decaketide aglycon and a hexadeoxysaccharide chain.

2.8 Enediyne Antibiotics

The enediyne antibiotics [75,76] have arrived on the scene in the 1980s with calicheamicin γ_1^I isolated from *Micromonospora echinospora calichensis*. They have a novel molecular structure which makes the enediyne antibiotics natural prodrugs; that is, the enediyne antibiotics

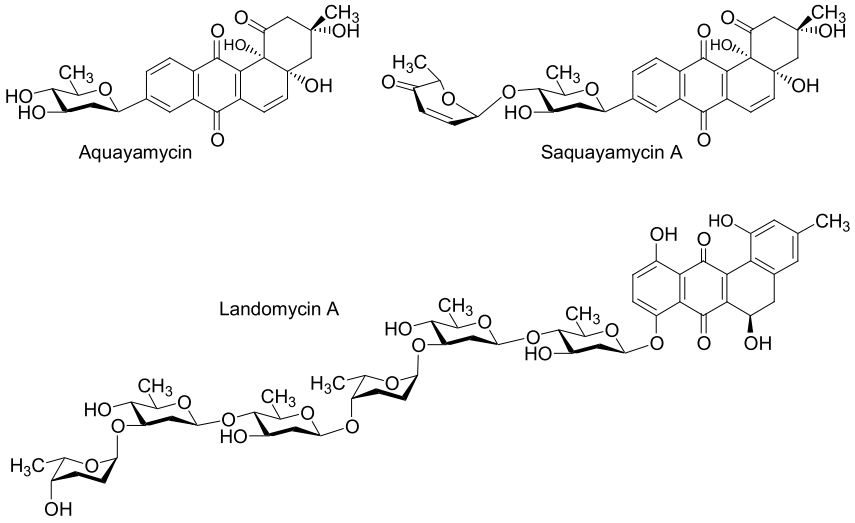

Figure 17
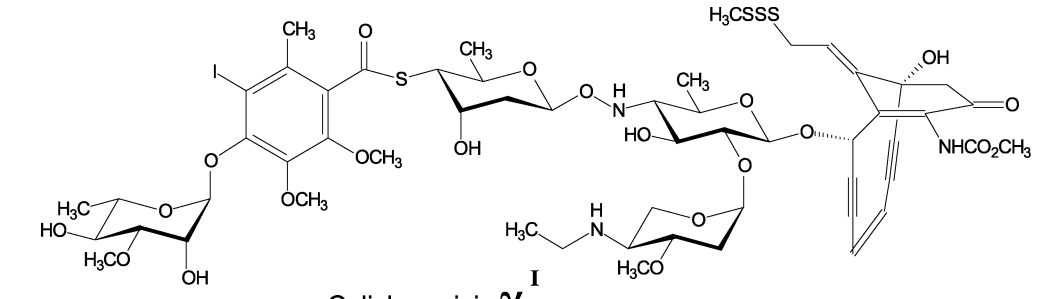
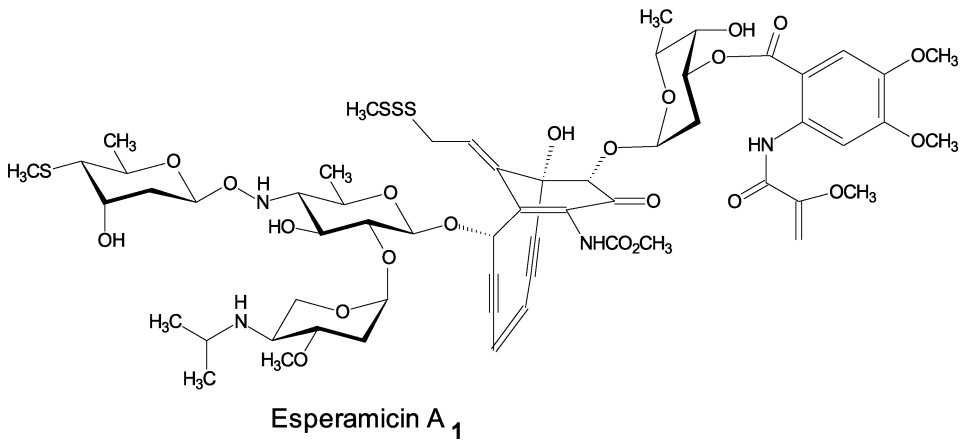
Structures of quinoide angucyclines

have to undergo an activation step before they can unfold their biological activity. In brief, this process includes strong binding to duplex DNA, double-strand cleavage of the genetic material by formation of a benzenoid diradical, and as a consequence potent antitumor and antibiotic activity. The antitumor activity of calicheamicin γ_1^I is over 1000 times higher than that of adriamycin, which is widely used in chemotherapy, when tested in murine tumor models [77]. The structure of calicheamicin γ_1^I (*Fig. 18*) is comprised of an unusual carbohydrate domain, a hexasubstituted benzene ring and a cyclic enediyne chromophore carrying a trisulfide moiety that acts as a triggering device for the cascade of events which leads, via a Bergman cycloaromatization [78], to the diradical species and DNA rupture. First the (Z)-1,5-diyn-3-ene unit is sequence-specifically [79,80] delivered to the minor groove of the DNA helix, whereupon reduction of the chromophore leads to cycloaromatization of the enediyne and 1,4-benzenoid diradical formation. The diradical is positioned to abstract hydrogen atoms from the sugar phosphate backbone of the nearby DNA, thus causing single- or double-strand scission of the helix and forming the molecular basis for the cytotoxic activity of these drugs. The oligosaccharide domain of calicheamicin γ_1^I is endowed with high affinity for certain DNA sequences, and acts as the delivery system of the molecule to its biological target. Thus, the sugar portions of the enediyne antibiotics are vital to the biological activity; although the aglycon can bind to DNA, it does so with far less affinity and no sequence selectivity [81]. Additionally, the calicheamicinone aglycon is not efficient at double-strand scission. On the other hand, the carbohydrate portion without the aglycon is able to bind DNA with nearly the same interactions as those of the carbohydrates in the whole drug [82] and it can block transcription. These observations are in contrast to the anthracycline antibiotics, whose sequence selectivity is determined primarily by the aglycon and whose carbohydrate moieties are unable to bind DNA in the absence of the aglycon.





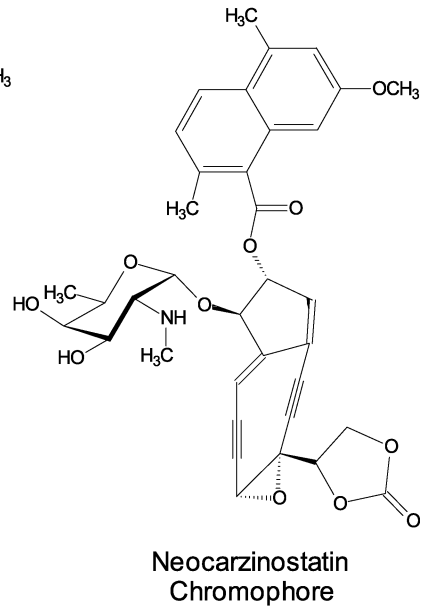


Figure 18
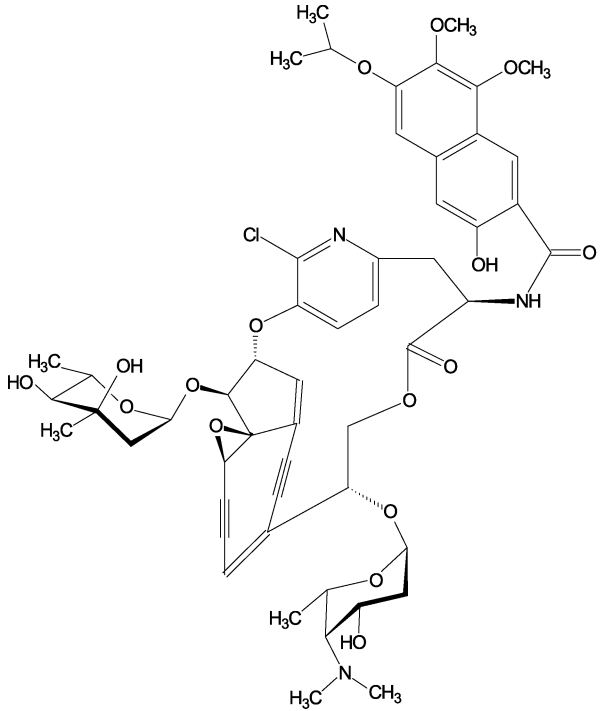
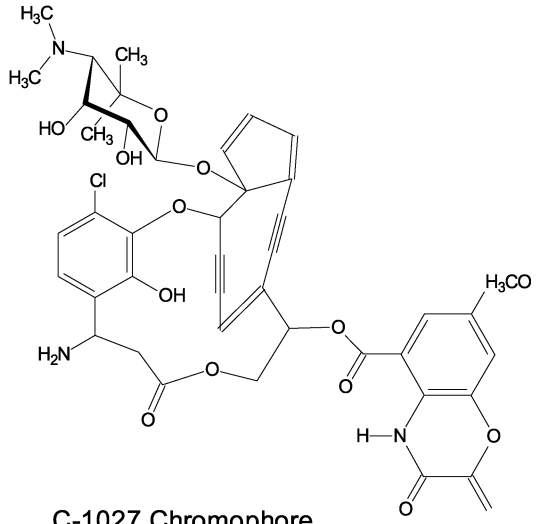
Structures of important enediyne antibiotics



Kedarcidin Chromophore



C-1027 Chromophore

Figure 19
Enediyne antibiotics with unusual chromophore

The family of enediynes includes the calicheamicins, esperamycins, dynemicin A, which is not glycosylated, the C-1027 chromophore and kedarcidin (◗ *Fig. 18* and ◗ *Fig. 19*). The neocarzinostatin chromophore, which does not contain an (Z)-enediyne, is also included in this family of compounds because of a similar mode of action.

The calicheamicins have been isolated from *Micromonospora echinospora calichensis*. They are highly active against Gram-positive as well as Gram-negative bacteria and especially effective against tumors. The esperamycins are a subclass of the naturally occurring enediynes, being effective against a broad spectrum of bacteria and effective as cytostatics.

Neocarzinostatin (NCS) is a naturally occurring 1:1-complex of a protein moiety and the NCS-chromophore, which can be isolated from *Streptomyces carzinostaticus* [83]. The chromophore portion is responsible for the biological activity, whereas the protein part is important for stabilization and transportation of the drug, which shows strong cytostatic and antibacterial activity, based on its ability to cleave DNA.

How would neocarzinostatin-containing species protect themselves against its DNA-disrupting properties? The answer lies in the protein part of neocarzinostatin, which is responsible for selecting thiol groups with which to react. It was shown that the neocarzinostatin apoprotein is responsible for shielding the labile chromophore from attack by the most abundant eukaryote cellular thiol groups before the drug reaches the target DNA. For example, while 2-mercaptoethanol can inactivate the protein-bound chromophore, glutathione is rejected by the protein. This selective inactivation may be the basis of the self-protective functionality of the microorganisms that produce neocarzinostatin.

Highly complex synthetic schemes have been devised for a number of members of the enediyne class of potent anticancer agents. However, despite their potency, the enediynes' reactivity and toxicity have limited their usefulness as drugs. Therefore, attempts have been made to prepare semi-synthetic enediyne derivatives to reduce toxic side effects of the enediyne antibiotics [84] and to simplify their synthesis including the preparation of enediyne mimetics [85], as for example to increase the reactivity of enediynes by metal-ion coordination. Furthermore, hybrid molecules have been prepared. As in the anthracycline daunorubicin the non-glycosylated aglyone is inactive and also does not show DNA intercalation, molecular hybrids of calicheamicin γ_1^I and the anthracycline aglycon have been synthesized for which the name "chalichearubinine" was coined, in order to combine DNA sequence specificity of calicheamicin γ_1^I with the activity spectrum of daunorubicin [86].

Relatively little has been known about how these bacterial natural products are synthesized in nature. Recently, it has been shown that the enediyne cores of both C-1027 and calicheamicin are synthesized via a common polyketide pathway, suggesting that all enediynes are biosynthesized in the same manner [87]. The stretch of the *Streptomyces globisporus* genome necessary for biosynthesis of the nine-membered enediyne C-1027 was cloned and characterized and it was found that disruption of the single polyketide synthase (PKS) gene in this region stops C-1027 production. By disrupting a hydroxylase gene in the C-1027 cluster, a novel C-1027 analog with improved chemical stability could be created and thus new drug candidates may arise by genetic manipulation of the biosynthetic pathways.

2.9 Aminoglycoside Antibiotics

This group of antibiotics consists entirely of moieties derived from carbohydrate metabolism, i. e., the molecules can be rather characterized as "pseudooligosaccharides" than as "glycoconjugates". Aminoglycoside antibiotics have long been used as very efficient drugs against Gram-positive and Gram-negative bacteria as well as mycobacterial infections. Streptomycin was the first oligosaccharide analog with pharmaceutical relevance, discovered in 1944 [88]. Streptomycin and its relatives were found in culture filtrates of several streptomyces strains. Since the discovery of streptomycin, a great number of aminoglycoside antibiotics have been isolated worldwide from the cultures of actinomycetes and bacteria such as *Streptomyces*, *Nocardia*, *Micromonospora*, and *Bacillus*. Early works of the structure elucidation were reviewed [89].

The terms "aminoglycoside" as well as "aminocyclitol antibiotic" which are used for this class of natural products refer to the structural aspect. Most of the aminoglycoside antibiotics contain aminosugars and an aminocyclitol or a cyclitol moiety. The middle furanose part in streptomycin is called streptose and was the first branched-chain sugar obtained from microorganisms. The other rings in streptomycin are a *N*-methyl-L-glucosamine moiety and an aminocyclitol called streptidine (❯ *Fig. 20*).

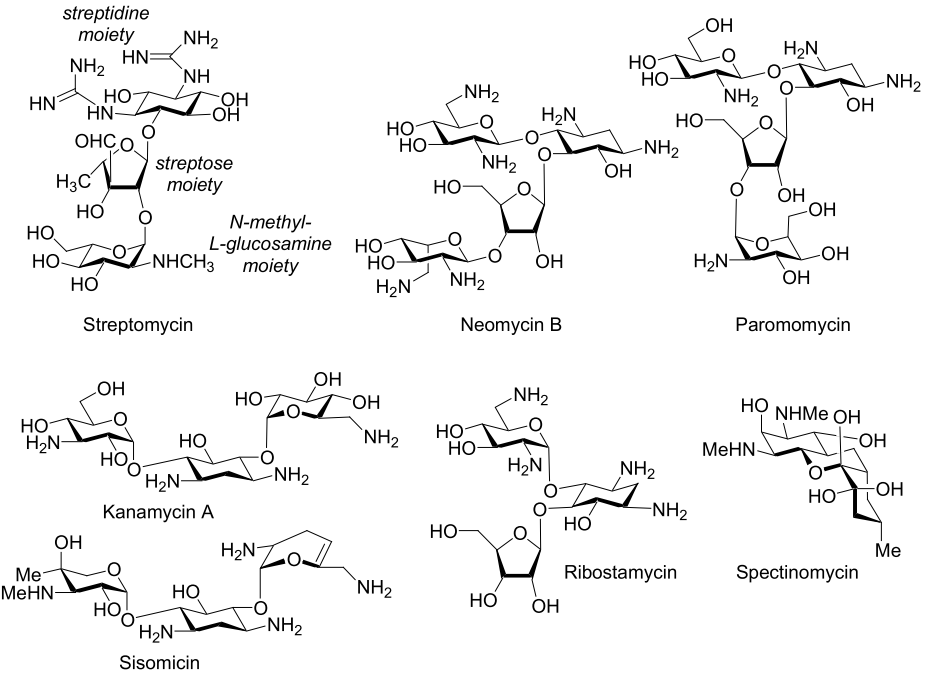


Figure 20
Structures of important aminoglycosides

The structural diversity of aminoglycosides is large. They consist of two to five monomers and contain almost a one-to-one ratio between amino and hydroxy groups. The antibiotics of the neomycin group have a 4,5-disubstituted 2-deoxy-streptamine. Neomycins B and C were isolated from the culture broth of *Streptomyces fradiae* and contain four rings [90]. They are closely related to paromomycin which has been an important aminoglycoside for biological studies owing to its excellent affinity for the A site region of rRNA of bacterial ribosomes [91]. The kanamycins possess a 4,6-disubstituted 2-deoxystreptamine; they are produced by *Streptomyces kanamyceticus*, and have been clinically used against a variety of bacteria, especially against streptomycin-resistant tuberculosis. Sisomicin was isolated from the culture broth of *Micromonospora inyoensis*; it contains an unsaturated aminosugar at the 4-position of 2-deoxystreptamine [92]. *Micromonospora inyoensis* produced a dimeric compound, named 66–40C as a minor component of sisomicin [93]. This compound suggested that the 6′-position of sisomicin is biosynthetically aminated via an aldehyde intermediate. Sisomicin has been used as a chemotherapeutic agent.

The spectinomycins (❯ *Fig. 20*) have a fused three-ring system which consists of a 4,5-disubstituted actinamine and an ulose. Spectinomycin is produced by *Streptomyces spectabilis* and *Streptomyces flavopersius*. It has been clinically used for treatment of the gonorrhea infection. A related structure has been discovered with spenolimycin which was isolated from the culture filtrate of *Streptomyces gilvospiralis*. Efforts have been directed toward semisynthetic aminoglycoside antibiotics to treat multi-drug resistant bacteria [94].

Aminoglycoside antibiotics interact with a great variety of RNA molecules [95] including sequences that are important for retroviral replication. The potential of RNA as a new drug target has recently come up, with the recognition that RNA molecules can adopt complex three-dimensional structures that, as with proteins, enable the design of specific ligands. Another reason for the present interest comes from the fact that many pathogenic agents, such as retroviruses, encode their genetic information in RNA strands. Thus, any biological function involving RNA is a potential target.

The interactions between aminoglycosides and RNA are influenced by the number and basicity of amino groups present [96] and thus the strength of this interaction is dominated by electrostatics, with the positively charged aminoglycosides displacing metal ions. As the metal ions which are associated with the highly charged RNA molecules participate in RNA three-dimensional folding and provide active centers in catalytic RNA molecules, aminoglycosides can promote conformational changes, prevent folding of the RNA into an active tertiary architecture or displace catalytically active ions [97]. To better understand the function of aminoglycosides at a molecular level, their interactions with RNA are considered a good model system [98]. The elucidation of the molecular details of this interaction would eventually facilitate the development of new antibiotics.

Unfortunately, as with many other antibiotics, the efficiency of aminoglycosides has been compromised by the emergence of resistant bacterial strains [99]. Bacteria produce enzymes such as phosphotransferases and acetyltransferases to inactivate aminoglycosides by enzymatic modification of specific hydroxyl groups or amino groups of the aminoglycosides. *Escherichia coli*, for example, can inactivate streptomycin by using an enzyme which transfers AMP from ATP onto the 3″-OH of the antibiotic to produce 3″-O-adenylylstreptomycin (❯ *Fig. 21*) [100]. Chemically modified aminoglycosides have been used to investigate their interactions with nucleic acids. A neomycin-acridine conjugate (❯ *Fig. 22*), for example, has been used to

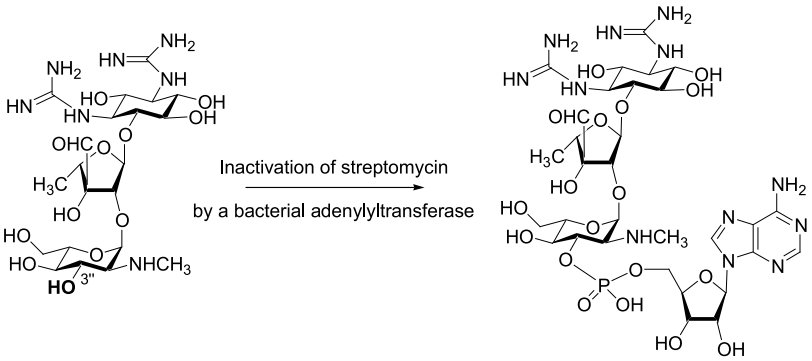

Figure 21
Enzymatic inactivation of streptomycin

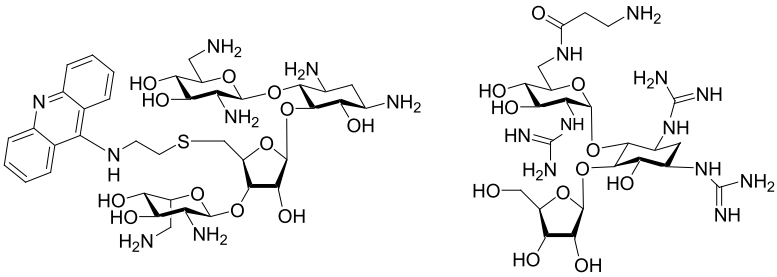

Figure 22
Functional aminoglycoside conjugates

show preference of neomycin binding to A-form nucleic acids [101]. A β-alanyl-modified ribostamycin derivative (*Fig. 22*) has been synthesized to allow its immobilization and to facilitate functional assays [102]. Additional guanidinium moieties improve RNA binding.

2.10 Moenomycins

The moenomycin antibiotics possess sophisticated glycolipid-type structures, as shown for moenomycin A (*Fig. 23*), which are difficult to synthesize [103]. The first total synthesis of moenomycin A has only recently been accomplished [104].

An explanation for the antibiotic activity of this class of bioactive molecules has been suggested [105,106]. It is believed that moenomycins interact in the transglycosylation step of the biosynthesis of the bacterial cell wall peptidoglycan. Two groups of antibiotics are known to interfere in this step, the glycopeptide antibiotics such as vancomycin, preventing the approach of the transglycosylase to its substrate by binding to mucopeptide precursor molecules, and the moenomycin antibiotics, which function by an entirely different mechanism: Moenomycins

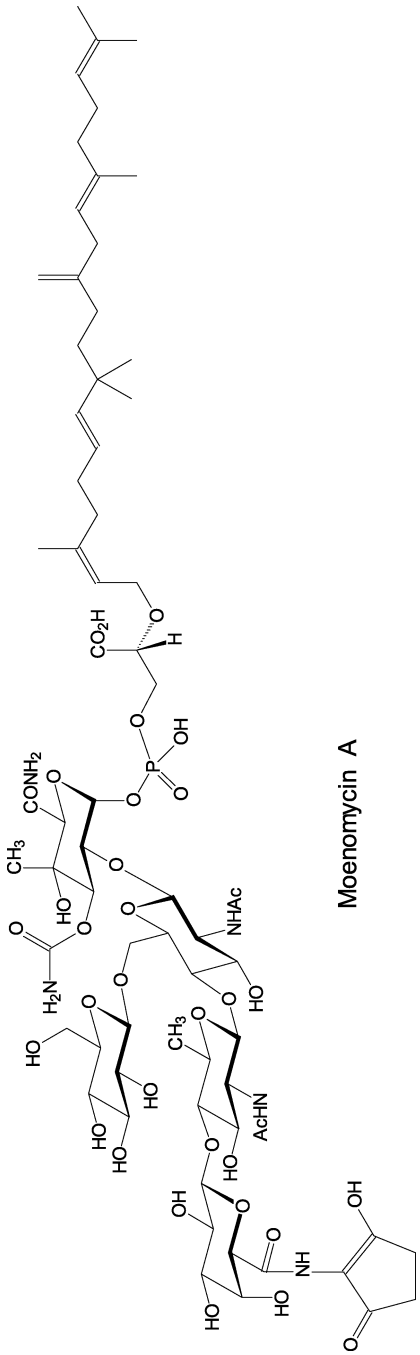

Figure 23
Structure of moenomycin

prevent transglycosylation of the peptide chain by reversibly binding to the necessary enzyme transglycosylase [107,108], thus acting as enzyme inhibitors.

Transglycosylases are specific oligosaccharyltransferases which transfer a precursor-oligosaccharide onto a peptide chain [109,110,111]. They use lipid-bound sugar pyrophosphates as their substrates. The lipid unit in bacteria is a C_{55} isoprenoid (bacterioprenol) whereas in the eukaryotic dolichol cycle long-chain polyprenol alcohols (dolichols) of varying chain lengths (C_{40}–C_{120}) are used. Bacterial transglycosylation is believed to proceed in such a way that the growing peptidoglycan chain linked to bacterioprenol via a pyrophosphate bridge acts as the glycosyl donor whereas a disaccharide intermediate, so-called lipid II, acts as glycosyl acceptor.

In *E. coli* the transglycosylation reaction is catalyzed by the high-molecular weight penicillin-binding proteins. These are bifunctional enzymes which catalyze the transglycosylation reaction as well as the transpeptidation reaction, in which the sugar strands are cross-linked via short peptide chains [112]. As peptidoglycan glycosyltransferases, which catalyze the polymerization step of cell-wall biosynthesis are highly conserved across all bacteria, they form an important drug target for antibiotic-resistant bacteria. An X-ray structure of the bifunctional cell-wall cross-linking enzyme, including its transpeptidase and glycosyltransferase domains has recently be determined [113].

The moenomycins are believed to compete for the binding sites of the enzyme with its natural substrates. Its oligosaccharide moiety is recognized by transglycosylase in a highly specific interaction. A second prerequisite for the transglycosylase-inhibiting activity of moenomycin has been shown to be intercalation of the antibiotic into the cell membrane mediated by its lipid moiety [114]. However, the lipophilic isoprenoid chain of moenomycin also accounts for its poor pharmacokinetic properties, preventing its clinical use in humans. As removal of this unit completely abolishes biological activity, current research is dedicated to the question, whether this portion of the molecule can be replaced by a shorter lipid [115].

2.11 Glycopeptide Antibiotics – the Vancomycin Group

The increasing problem of bacterial resistances against the classical antibiotics has led to a growing importance of the glycopeptide antibiotics as new potent drugs. Molecules of this group have a peptide backbone of 7 amino acids in common with over 100 examples being structurally elucidated. Glycopeptide antibiotics [116,117,118] are effective against a broad spectrum of Gram-positive and Gram-negative bacteria. The most well-known representative is vancomycin (❯ *Fig. 24*) which is used to treat infections caused by the penicillin-resistant *Staphylococcus aureus*, which has also developed resistances against methicillin and almost all other common antibiotics such as the cephalosporins, tetracyclins, aminoglycosides, erythromycin and the sulfonamides.

Vancomycin was discovered in the 1950s in a soil sample collected in the jungle of Borneo and isolated by Eli Lilly from culture broth of the actinomycete *Streptomyces orientalis*, which was later named *Nocardia orientalis* and finally *Amycolatopsis orientalis*. It was first used in clinics in 1959, and today also teicoplanin (❯ *Fig. 25*) is being used clinically. The other glycopeptides of the vancomycin group such as ristocetin A (❯ *Fig. 26*) have too many toxic side effects to be used as a therapeutic. Vancomycin and teicoplanin are among the last antibiotics

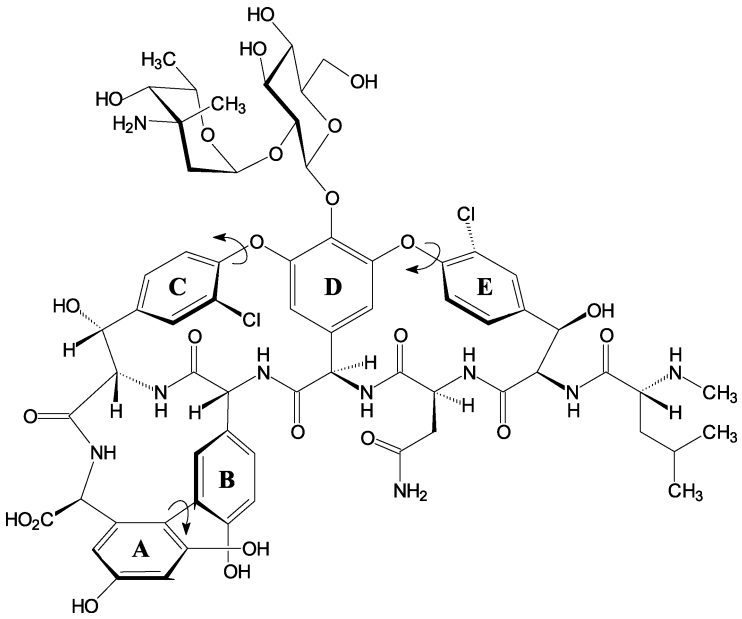

Figure 24
Structure of vancomycin. Vancomycin has three elements of atropisomerism as indicated by *three arrows*

forming a line of defense against resistant bacteria, however, also vancomycin-resistant strains have already developed [119,120].

Glycopeptide antibiotics are normally produced as a mixture of compounds by a single bacterial strain. They are structurally varied especially with regard to their glycosylation. Until today, ristocetin A is the only glycopeptide antibiotic which has been found to have a tetrasaccharide moiety bound to the fourth amino acid residue of the peptide backbone. Teicoplanin has a glucosamine moiety at this position which is *N*-acylated with a C_{11}-side chain. This side chain is responsible for the advantageous pharmacological features of this compound. The sugar moieties in glycopeptide antibiotics improve the solubility of the respective compounds thus facilitating transport of the drugs to their targets.

Most of the monosaccharide moieties found in glycopeptide antibiotics fall into two groups, hexoses and 6-deoxy-hexoses on one hand and aminotrideoxyhexoses on the other(◘ *Fig. 27*). A number of rare sugars such as 4-oxovancosamine and ureidovancosamine are also found.

Most of the difficult syntheses leading to these monosaccharide have recently been reviewed [121]. Vancosamine, which can be regarded as the *C*-3-methyl analog of daunosamine, is one of the most widely distributed monosaccharide constituents in glycopeptide antibiotics [122]. De novo syntheses of vancosamine derivatives have recently been reported [123,124].

The structure of vancosamine was elucidated in 1982 [125] and its total synthesis was finally accomplished in 1999. By 1998 two groups, had reported independent total syntheses of the vancomycin aglycon [126,127,128,129,130] and by early 1999 the first total synthesis [131,132,133,134,135] of vancomycin itself appeared in the literature followed by another

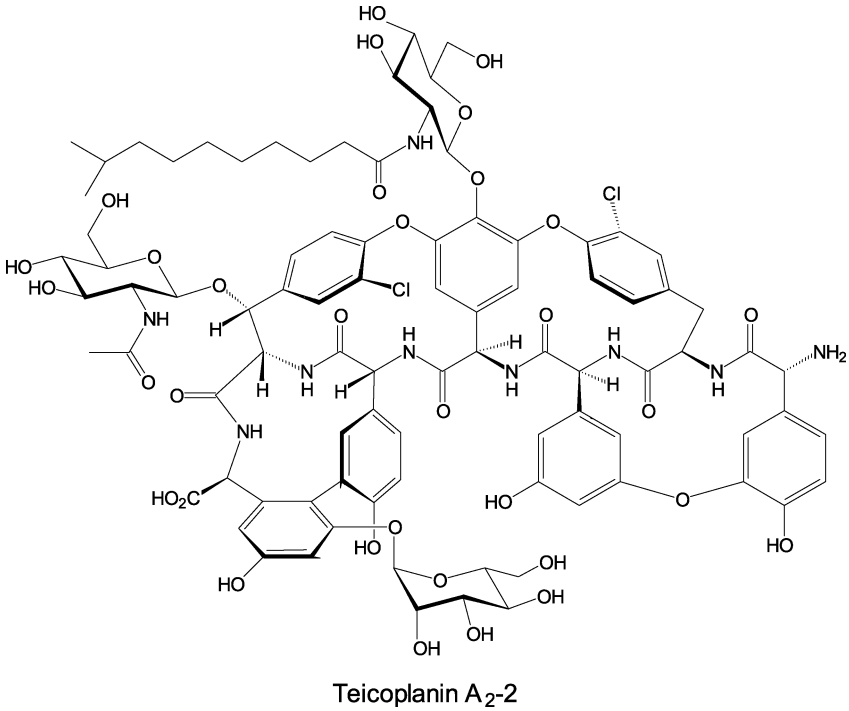

Figure 25
Structure of teicoplanin

report of the aglycon synthesis [136]. Besides the difficult carbohydrate chemistry, for the total synthesis of vancomycin a total of 18 stereocenters had to be correctly assembled. Furthermore three elements of atropisomerism in the aglycon had to be established, given by the biarylic system AB as well as the ether-linked biaryl moieties C-O-D and D-O-E (*Fig. 24*).

The vancomycin antibiotics act by an intriguing mechanism [137,138]. They interfere with the transglycosylation step of the bacterial peptidoglycan biosynthesis. Vancomycin binds to mucopeptide precursor molecules of the bacterial cell wall, terminating in Lys-D-Ala-D-Ala [139] and thereby preventing the approach of the transglycosylase.

Bacterial cell wall biosynthesis proceeds in two steps at the exterior of the cell. First disaccharide moieties with peptides attached are transported from the cytoplasm to the outside of the cell, where they are linked together catalyzed by transglycosylase. Subsequently the resulting long glycopeptide chains are, catalyzed by a transpeptidase, cross-linked through their peptide moieties to improve their mechanical stability. The enzyme recognizes the sequence D-Ala-D-Ala at the end of a peptide chain, cleaves the terminal alanin residue and then links the remainder to the peptide chain of an adjacent glycopeptide. How does vancomycin interact in this process?

The antibiotic forms a number of hydrogen bonds to the mucopeptide precursor molecule with which it interacts. This alignment is strengthened by hydrophobic interactions between

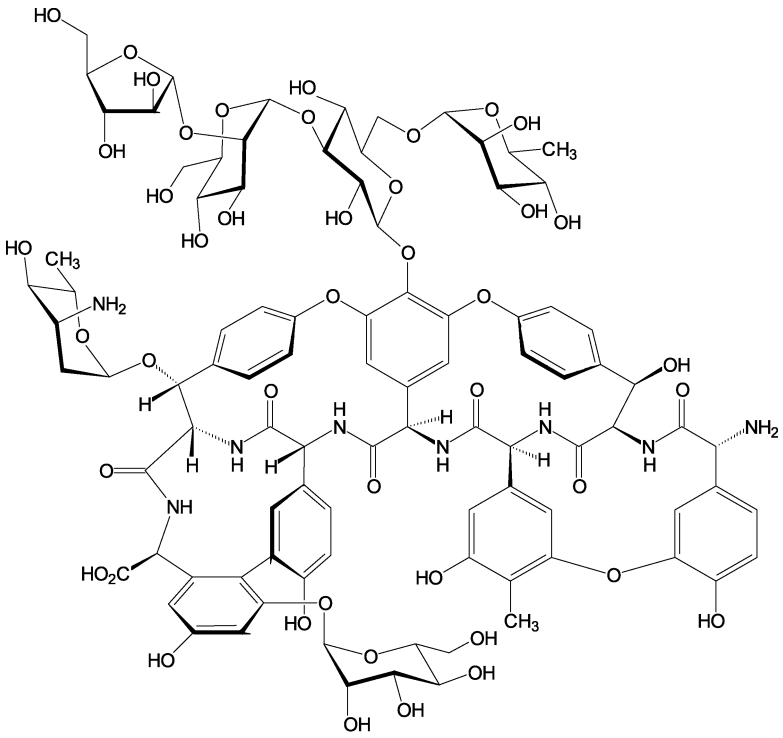

Figure 26
Structure of ristocetin

the alanyl methyl groups of the ligand and the antibiotic's hydrocarbon moieties (*Fig. 28*, hydrogen bonds are indicated by dashed lines).

As shown with a synthetic cell wall analog, effective binding is critically dependent on firm complexation of the carboxylate at the *C*-terminus of the mucopeptide. This interaction adds the largest contribution to the exothermic term of the interaction (20–30 kJ mol^{-1}). To guarantee this, binding of the carboxylate group in a pocket of three NH-groups of the antibiotic has to be stronger than its association in water. This is most likely accomplished by forcing these three CO-NH-dipoles into an especially close neighborhood, for which the necessary energy has been paid during the biosynthesis of the drug. This allows a better solvatization of the carboxylate than water would be able to provide it.

The two amide-amide-hydrogen bonds, also indicated in *Fig. 28*, add almost no direct contribution to improve ligand binding. Indirectly, however, they play an important role as they help to orient the ligand in such a way that the hydrophobic interactions with the alanyl-methyl groups can optimize binding, finally increasing binding energy by a factor of 10^3. Moreover, they restrict the flexibility of the ligand in the binding pocket of the antibiotic, thereby improving binding of the terminal carboxylate.

Figure 27
Unusual monosaccharide components found in glycopeptide antibiotics

This concert of interactions may reflect a general principle, according to which weak interactions can lead to strong molecular recognition. Thus, a total of weak interactions provided by closely positioned functional groups can provide a significant increase in binding energy by restricting the flexibility of a receptor-bound ligand. This implies that the cooperativity of the binding process is not determined by entropy such as in case of the classical chelate effect,

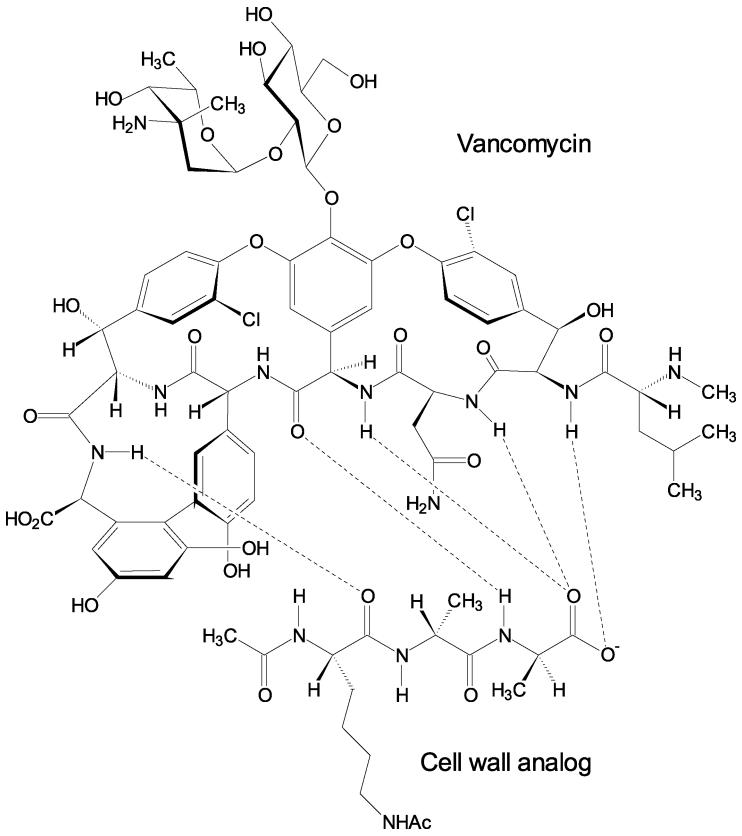

Figure 28
Strong binding of vancomycin to a cell wall analog results from a concert of weak interactions

where many interactions to the same molecule lead to anchoring the ligand to the receptor, but rather by an enthalpic effect, cooperatively increasing the strength of one particular interaction. This is an intriguing observation, which might be of general importance when molecular recognition processes are determined by weak interactions.

2.12 Sugar Amino Acids

Conjugation of carbohydrates with amino acids has become an important field of modern glycosciences. This type of compounds has been named 'sugar amino acids', abbreviated SAAs, and has found many interesting applications in drug design [140]. However, also among the naturally occurring compounds many SAAs are found. One prominent family of sugar amino acids consists of neuraminic acid derivatives which are *N*- or *O*-acylated. The main substituents on nitrogen are acetyl and glycosyl. Derivatives of glucosaminuronic acid are detected in the cancomycin family of antibiotics, similar to vancomycin [141] and natural SAAs

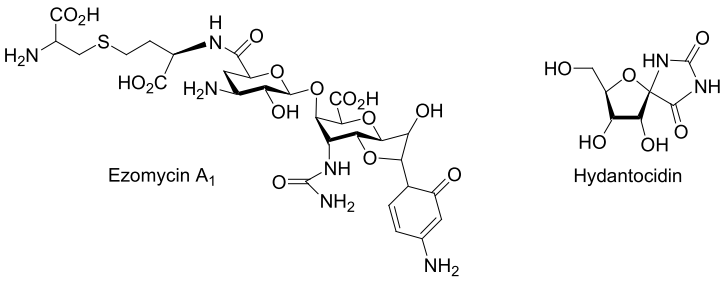

Figure 29
Naturally occuring glyco amino acids

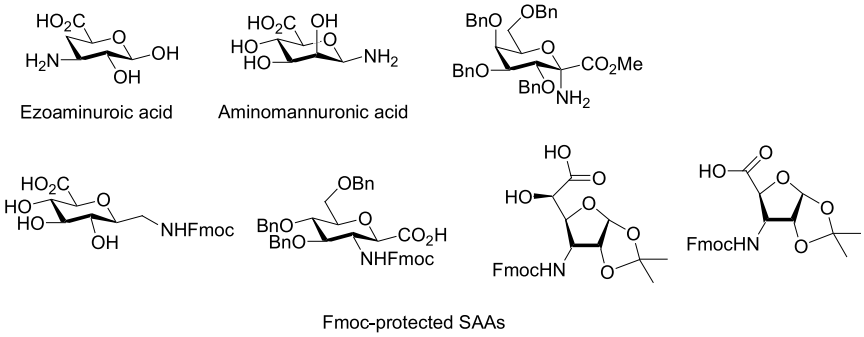

Figure 30
Synthetic glyco amino acids

can also be found in nucleoside antibiotics [142]. Two examples of SAA-containing natural products are depicted in *Fig. 29*: Ezomycin A_1 containing two different 3-amino-3-deoxy uronic acids [143] and the furanoid SAA (+)-hydantocidin, which represents a spiro hydantoin derivative and exhibits herbicidal activity [144].

SAAs are valuable building blocks in drug design and drug research, allowing for the preparation of modified analogs of biologically active peptides or glycoconjugates as well as oligomerization and cyclization to conformationally restricted and designed glycopeptides. Sugar amino acids have been made of furanoid or pyranoid α- β-, γ- or δ-amino acids. Some examples can be seen in *Fig. 30*.

Synthesis of individual SAAs and their incorporation into peptidic or saccharidic structures has been successful in medicinal chemistry [145]. A number of carbohydrate-based structures have been designed as mimetics of the potent peptidic antagonist of integrins, the RGD-motif. Integrins are proteins which are located at the cell surface of a number of different cell types. They play an important role in cell-matrix interactions as well as in tumorgenesis. This invoked a pharmaceutical interest in antagonists of integrins to block angiogenesis. The recognition sequence of integrins such as $\alpha_V\beta_3$ has been shown to be the RGD(Arg-Gly-Asp)-motif (*Fig. 31*). Sugar amino acids were used as turn mimetics [146] in the RGD sequence

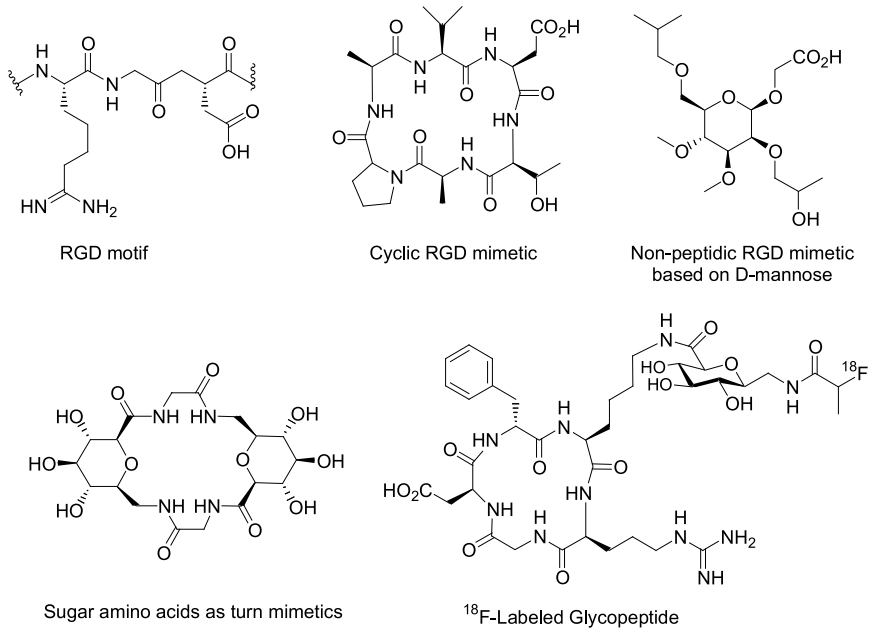

Figure 31
Use of glyco amino acids in biological chemistry

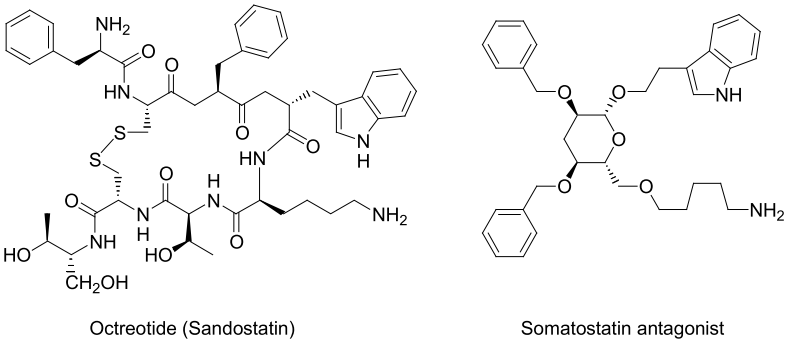

Figure 32
Carbohydrate scaffolds can serve to mimic more complex biologically active compounds

to improve the pharmacokinetic properties of these compounds and to introduce radio-nuclides such as ^{18}F for tumor imaging (*Fig. 31*) [147]. Carbohydrate derivatives such as of D-mannose have also been used to mimic peptidic RGD mimetics (*Fig. 31*).

Furthermore, as carbohydrates provide a source of multifunctional molecules with well-defined stereochemistry, they have been used as scaffolds to present pharmacophoric groups in a distinct arrangement. The first so-called carbohydrate privileged structure has been a somatostatin agonist which contained a deoxyglucose nucleus [148] (*Fig. 32*). Somato-

statin (also known as growth hormone inhibiting hormone (GHIH) or somatotropin release-inhibiting hormone (SRIF) is a peptide hormone that regulates the endocrine system and affects neurotransmission and cell proliferation via interaction with G-protein-coupled somatostatin receptors and inhibition of the release of numerous secondary hormones. Somatostatin analogs are of great interest in medical therapy such as for treatment of acromegaly. Octreotide (sandostatin) is a cyclic α-octapeptide which serves as analogue of the tetradecapeptide somatostatin.

2.13 Functional Glycoconjugates

As glycoconjugates on cell surfaces are involved in numerous processes of cellular biology such as inflammation, cell-cell interactions, cell recognition, immunological response, metastasis and fertilization, they form interesting targets for medicinal chemistry and pharmaceutical research as well as industry. Moreover, the glycocalyx of a cell has been found to be specific for a particular species, cell type and even its developmental or health status. To gain insight into the biological processes in which glycocalyx carbohydrates are involved, synthetic glycoconjugates have been utilized to probe protein-carbohydrate, carbohydrate-carbohydrate and carbohydrate-nucleic acid interactions [149].

Many different approaches to functionalized glycoconjugates have been investigated and published. Multivalent glycoconjugates [150,151,152,153] have been synthesized in the form of glycodendrimers [154] for example, with respect to the multivalency effects [155] which are of importance in glycobiology [156]. In addition, multivalent assemblies and arrays of carbohydrates have been realized, such as in the case of glyco-decorated self assembled monolayers (SAMs) [157,158], as gold glyconanoparticles [159] or as carbohydrate microarrays in so-called glyco-chips [160]. Moreover, carbohydrates have been attached to functional probes such as fluorescent markers, biotin or magnetic beads [161]. *Figure 33* shows an example of a glucose-based cluster mannoside which has been conjugated to fluoresceine [162] together with an carbohydrate-functionalized fluorescent, poly(*p*-phenylene ethylene) (PPE) which can be used for the detection of *Escherichia coli* [163]. A fluorescence resonance energy transfer (FRET) experiment allows to detect *E. coli* binding to the mannose-decorated polymer.

As bacteria as well as many other microbes bind to carbohydrates which are displayed on the surface of their host and target cells to allow firm adhesion to the cell surface, inhibition of this carbohydrate-dependent adhesion process has been the goal of a concept named anti-adhesion therapy [164]. For the approach to treating microbial infection target-designed multivalent glycomimetics have been investigated in vitro [165,166,167,168,169,170,171].

In addition, carbohydrate conjugates can be utilized to develop carbohydrate-based vaccines for treatment of diseases in which carbohydrate toxins or antigens, respectively, are involved. Thus, fully synthetic glycoconjugates might be developed into vaccines for malaria, and other parasites such as different bacteria, tuberculosis, tropical diseases, leishmaniasis and the *Influenzae* virus.

The last two decades have witnessed the production and clinical testing of polysaccharide–protein conjugates specific for at least four different bacteria which normally cause considerable mortality and morbidity, especially in young children. In some cases, immunizing children from 4 months of age, with a booster early in the second year, has resulted in remarkably high success rates in protecting them from disease. For one pathogen, *Haemophilus*

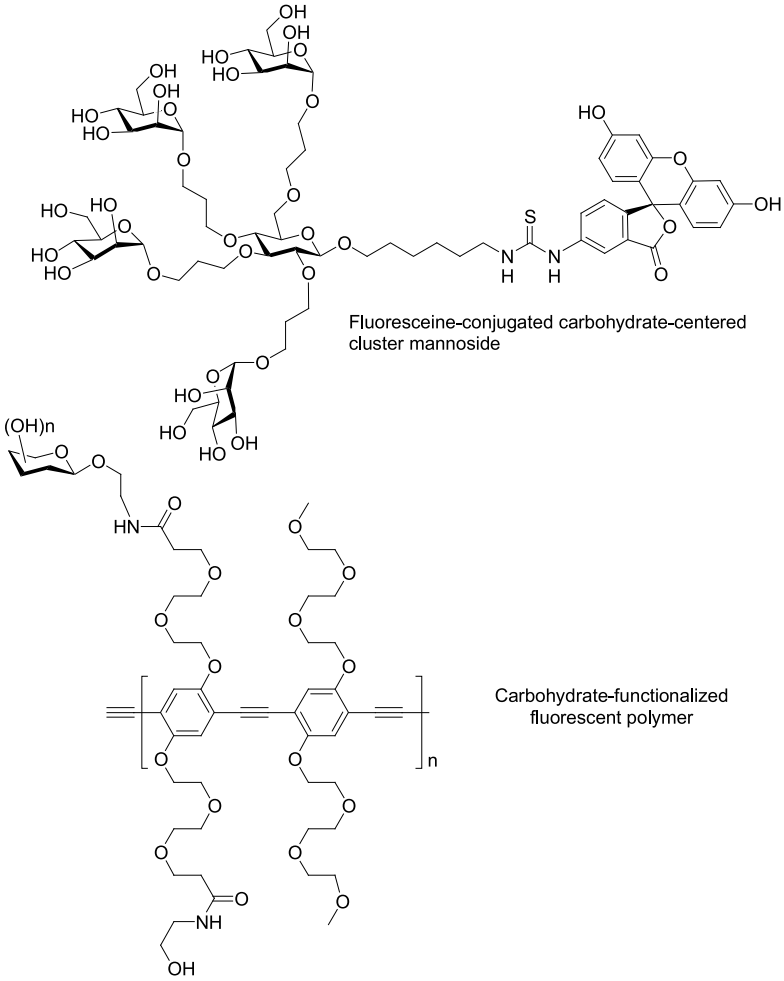

Figure 33
Fluorescent glycoconjugates

influenza type B, the success rate has been sufficiently high (> 95%). The results of immunization with conjugate vaccines to *Streptococcus pneumoniae*, *Neisseria meningiditis*, and *Salmonella typhi* are also very encouraging [172].

Some examples of research under development include a synthetic conjugated polysaccharide vaccine against *Haemophilus influenzae* type B, which has been described in 2004 (*Fig. 34*). The vaccine prototype was obtained by conjugation to human serum albumin (HSA) [173].

Furthermore, very recently a malaria vaccine has been suggested [174] which is based on the total synthesis of the malaria toxin responsible for the morbidity and mortality associated with malaria. The malaria parasite expresses a large amount of glycosylphosphatidylinositol

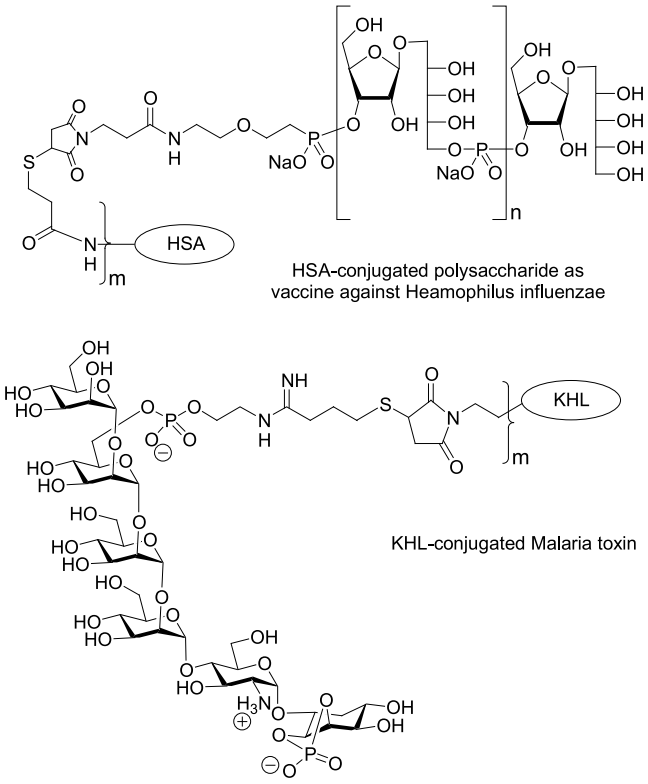

Figure 34
Protein-conjugated carbohydrates as vaccine candidates

(GPI) on the cell surface and there is evidence that the inflammatory cascade is triggered by this malaria toxin. A malaria vaccine could serve as an alternative to current malaria treatment which suffers from growing drug resistance. Fully synthetic material toxin has been conjugated to the carrier protein KHL (*Fig. 34*) and this conjugate proved highly immunogenic in mice and was able to prevent infection.

Chapter-DOI 10-1007/978-3-540-30429-6_67:

Abstract

A large number of biologically active compounds are glycosides. Sometimes the glycosidic residue is crucial for their activity, in other cases glycosylation only improves pharmacokinetic parameters. Recent developments in molecular glycobiology brought better understanding of aglycon vs. glycoside activities, and made possible the development of new, more active or more effective glycodrugs based on these findings – a very illustrative recent example is vancomycin. The new enzymatic methodology "glycorandomization" enabled preparation of glycoside libraries and opened up paths to the preparation of optimized or entirely novel glycoside antibiotics. This chapter deals with an array of glycosidic compounds currently used in medicine but also covers the biological activity of some glycosidic metabolites of known drugs. The chapter discusses glycosides of vitamins, polyphenolic glycosides (flavonoids), alkaloid glycosides, glycosides of antibiotics, glycopeptides, cardiac glycosides, steroid and terpenoid glycosides etc. The physiological role of the glycosyl moiety and structure-activity relations (SAR) in the glycosidic moiety (-ies) are also discussed.

Keywords

Natural products; Glycosides; Structure-activity relations; Glycorandomization; Flavonoid glycosides; Vitamin glycosides; Antibiotics; Alkaloid glycosides; Steroid glycosides; DNA interactions

Abbreviations

ATP adenosine triphosphate

NK natural killer
RA retinoic acid
RAG retinoic acid glucuronide
RNA ribonucleic acid

1 Introduction

Many biologically active compounds are glycosides. Glycosides comprise several important classes of compounds such as antibiotics, hormones, sweeteners, alkaloids, flavonoids, etc. Sometimes the glycosidic residue is crucial for their activity; in other cases it only improves pharmacokinetic parameters. Owing to recent developments in molecular glycobiology a greater understanding has been gained of aglycon vs. glycoside activity and – based on these findings – it has become possible to develop new, more active or more effective glycodrugs.

Nevertheless, it is nearly impossible to define a general pattern of biological activities for the glycosides compared to the respective aglycons. Some well-selected examples can illustrate general trends and show the effects and potential applications of the compounds carrying the glycosidic moiety in relation to the respective aglycons.

It is generally accepted that glycosides are more water-soluble than the respective aglycons. Attaching the glycosidic moiety to a molecule increases its hydrophilicity. This effect influences pharmacokinetic properties of the respective compounds, e. g., circulation, elimination and concentration in the body fluids.

Modified hydrophilicity, however, influences mainly the membrane transport. Some compounds enter the cells just because of their "solubility" in the membrane components. Glycosylation can, in some cases, restrict or inhibit cell uptake of the particular compounds. Glycosylation can strongly influence transport through such important barriers as the hemato-encephalitic barrier and block the entrance of many compounds into brain tissue. Contrary to this, some glucosides can be transported actively into the brain tissue using the glucose-transport system. Another important barrier, in which glycosylation plays a crucial role is the placental barrier. Here entry of many glucuronides to fetal tissue is blocked, thus preventing intoxication by metabolites of xenobiotics. On the other hand, some glycosidic moieties can interact with receptors or lectins on the cell surfaces followed by their active uptake. A good example is the high affinity of β-galactosides to hepatocytes due to galectin-C occurring in high concentration on their surface.

Carbohydrates and glycosides recently emerged as a novel class of nucleic acid-binding compounds. Detailed study of the factors affecting the site-selectivity of some recently discovered antitumor antibiotics has shed new light on the role that oligosaccharides may play in nucleic acid recognition.

An important aspect for prediction of the respective glycoconjugate activities is also their susceptibility towards glycosidic cleavage at various sites of application. In the stomach and in the intestine most of the glycosides are hydrolyzed, either by the action of the acidic environment (stomach) or by the action of glycosidases (small intestine). There are, however, glycosides that are not hydrolyzed easily – e. g. α-galactosides – and such compounds are either unable to pass the hemato-intestinal barrier or they penetrate unhydrolyzed. Nonresorbed glycoconjugates can be cleaved later in the colon or metabolized by the action of the intestinal microflora. Glycosidases are present also in other body fluids, e. g. blood serum contains lysozyme that cleaves effectively β-*N*-acetylhexosaminides.

There exist, however, glycosides with specific individual biological activity that cannot be simply derived from the respective activity of the aglycon. The final activity is then given by the overall molecular structure.

Comparison of biological activities of aglycon and its respective glycoside can indicate some structure-effect correlations and also demonstrate the advantage (or uselessness) of introducing glycosyl moieties into pharmacologically interesting molecules.

Exploitation of the SAR data of the glycosides (most often glycosidic antibiotics) enabled synthetic modification and optimization of their glycon part. Recently, however, the new brilliant methodology "glycorandomization", based on the enzymatic modifications of glycosides, enabled the preparation of glycoside libraries. This method employing natural and mutant glycosyltransferases with wobbling specificities opened up new paths to the preparation of optimized or entirely novel glycoside antibiotics.

This chapter deals with "small molecules" – glycosides – aiming at the description of the function of the glycon part in the biological activities of the respective compounds. New, recently developed methods, leading to the bio-functional optimization of this moiety are also described.

2 Polyphenol Glycosides

Most of the polyphenols are produced by plants. Phenolic OH groups are generally good targets for biological glycosylations and many phenolic compounds occur virtually only in their glycosylated forms.

Glycosides of polyphenolic compounds, e. g. those of flavonoids, constitute a large group and novel findings increase their number extremely quickly. The list of flavone and flavonol glycosides known up to 1986 contains about 900 entries [1]. In the survey of Harborne and Williams [2] covering discoveries in anthocyanins and other flavonoids from January 1995 to December 1997 over 160 new glycosides of flavonoids are reported.

Many of them served as important components of traditional medicines. It is very interesting from the point-of-view of structure-effect correlations that minute alterations in their structures, e. g. positional changes of OH groups, bring about dramatic changes in their biological effects. Naturally, in the view of such minor changes, glycosylation of these compounds

sometimes completely changes their activity. For instance, quercetin (3,3′,4′,5,7-pentahydroxyflavon, 16) is now considered to be an extremely dangerous toxic and mutagenic compound (even though it was used previously as a colorant). However, its various glycosides [e. g., quercitrin ([17]), hyperin, spiraeosid, rutin (see also ❯ *Sect. 6.1.4* in this chapter)] occur frequently in plant material sometimes used as food, and many are considered to be beneficial to human health.

2.1 Anthocyanins

Anthocyanins are the most important group of water-soluble plant pigments visible to human eyes. Glycosylation of anthocyanins has many effects – physico-chemical effects such as antioxidant stabilization and also color stabilization or "deepening" caused by "sandwich stacking" controlled by the glycosyl substitution. This effect is well-known in "heavenly blue anthocyanidin" (HBA, **1**) (❯ *Scheme 1*) from *Ipomoea tricolor* (Convolvulaceae). HBA carries complex glycosyl-ester moieties attached to C-3 of peonidin (aglycon) containing ester-bound residues of caffeyl acid (❯ *Fig. 1*).

The whole structure then folds into a sandwich structure, in which aromatic residues of caffeic acid interact with the aromatic system of the aglycon peonidin [3]. This stacking results in the bathochromic shift of the complex. Moreover, this and similar glycosyl-acyl conjugates of the anthocyanidines stabilize these pigments at various pH within the plant vacuoles in the range of 4–6 against hydration and tautomerization resulting in profound changes of electron spectral properties (loss of color). Stability of color is often crucial for the biology of the plants, e. g. pollination by insects.

Anthocyanidins may also be important factors – with other flavonoids – in the resistance of plants to insect attack. Thus, the complete cyanidin 3-β-glucoside (**2**)(❯ *Scheme 2*) and not only the aglycon itself was shown to protect cotton leaves against the feeding of tobacco budworm [1].

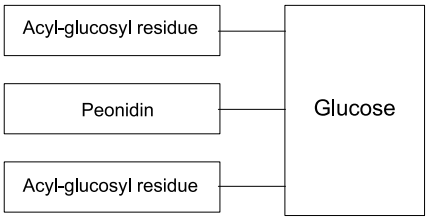

Figure 1
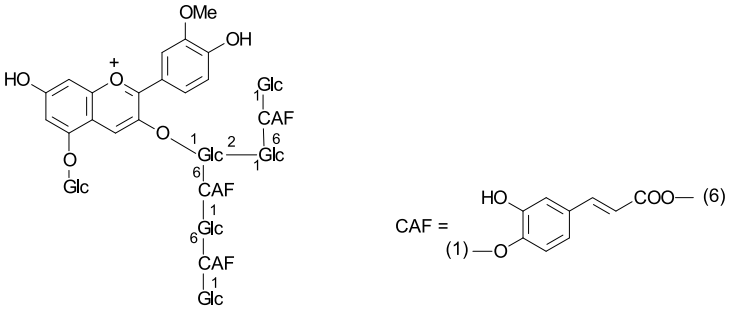
Model of the sandwich stacking

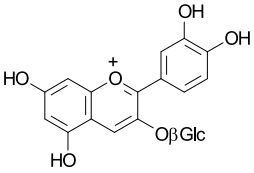
2.2 Flavonoid and Isoflavonoid Glycosides

The raison d'être for the proliferation of flavone and flavonol glycosides in nature continues to intrigue plant scientists. The ability of UV-B radiation to damage DNA, RNA and proteins as



1 (HBA) peonidin acyl-glycoside

Scheme 1



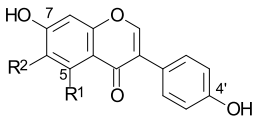
2

Scheme 2

well as to impair processes like photosynthesis is well known. Constituents of leaf epidermis such as polyphenols and their glucosides provide a means of absorbing the damaging radiation. An example of this has been demonstrated in the case of the needles of *Pinus silvestris* (pine tree). Two main compounds, isoquercitrin 3′,6′-di-*p*-coumarate and kaempferol 3-β-glucoside, have been found to be induced in seedlings under simulated global radiation. The concentration of the acylated kaempferol 3-β-glucoside reached 2.4 µmol/g fresh wt. [4].

In the case of plant pollens, it has long been recognized that flavonol glycosides are widely present and apparently contribute to the yellow color in the pollen. It is interesting that the two glycosides most frequently encountered are the 3-sophorosides of kaempferol and quercetin, and, furthermore, if these are not present, closely related 2′-*O*-glycosides of a flavonol 3-β-glucoside are normally encountered. Further examples are two methylated herbacetin 3-sophorosides reported in *Ranunculus*, *Raphanus* and *Klea* pollens [1,5]. The function of flavonoid glycosides in pollen is still uncertain in most plants, but in the case of *Petunia hybrida*, there is rather good evidence that it has a critical role in subsequent pollen tube growth, once the pollination has occurred. Structure-activity relationships have been explored in the case of *Petunia*, and a kaempferol diglycoside does appear to be the most active constituent [6].

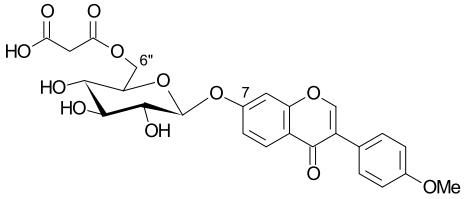
Glycosides and malonyl glycosides of isoflavones, and some other flavonoids often serve as their storage and transport forms. The most-studied systems for isoflavonoid glycoside metabolism are white lupine (*Lupinus albus*) root and cell cultures containing a range of mono- and diglucosides of genistein (**4**), 2′-hydroxygenistein and their 6- or 3′-prenyl derivatives [7], and soybean seeds and seedlings, and chickpea cell suspension cultures.



3 R^1 = H, R^2 = H

4 R^1 = OH, R^2 = H

5 R^1 = H, R^2 = OMe



6

Scheme 3

Features of the accumulation and metabolism of these compounds differ somewhat in the different species. In soybean seed hypocotyls, the 7-*O*-*β*-glucosides, 7-*O*-*β*-glucoside-6″-*O*-malonates, and 7-*O*-*β*-glucoside-6″-*O*-acetates of the isoflavones daidzenin (**3**), genistenin (**4**), and glycitein (**5**) occur (*Scheme 3*). All of them have been shown to increase during seed development in the pod to maximum levels between 45 and 60 days after flowering [8]. Three days after germination, the metabolism of the young leaf shifts from isoflavonoid to flavonoid accumulation [9], although low levels of isoflavone glycosides remain [10].

A similar pattern of isoflavonoids and their glycosides is observed in alfalfa where formonetin 7-*O*-*β*-glucoside-6″-*O*-malonate (**6**) accumulates in roots along with other isoflavonoid constituents [11].

Infection of soybean with pathogenic fungus *Phytophthora sojae* leads to dramatic changes in isoflavone glycoside profiles and distribution. In the leaves, the nonglycosylated pterocarpan glyceolin accumulates to high levels only in the hypersensitive lesion formed in a resistant interaction, whereas the glucosides and malonyl glucosides of **3**, **4** and **5** accumulate in a broad area around the lesion [10]. In cotyledons the already constitutive pools of isoflavone glycosides are rapidly mobilized and, in the case of **3** the aglycon can be used for phytoalexin synthesis [12].

Some flavonoid glycosides are prepared synthetically or by biotransformations, usually for pharmaceutical purposes. Silybin (**7**) is a flavonolignan that is extracted from seeds of milk thistle (*Silybum marianum*) and it is used extensively as a potent hepatoprotectant and an antidote in mushroom poisoning. The major drawback of this compound is its low water solubility (about 0.43 g/L). Therefore, its glycosylation was accomplished by biological [13] and chemical methods [14].

Biotransformation using plant cell cultures afforded silybin 7-*β*-glucoside (**8**) [13] and chemical glycosylations gave silybin glycosides at C-23 (*β*-glucoside, *β*-galactoside, *β*-maltoside and *β*-lactoside **9**–**12**). The solubility of silybin glycosides was improved considerably compared to the aglycon (**9**, 13.0; **10**, 1.7; **11**, 3.8 and **12**, 5.6 g/L)(*Scheme 4*). Biological tests

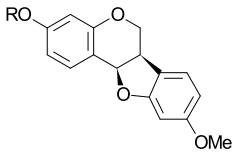
β-Lactosyl (β-Lac) β-Maltosyl (β-Malt)

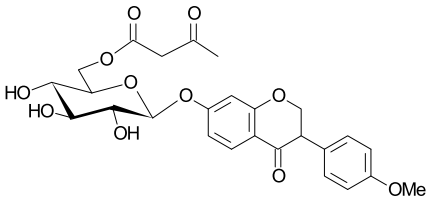
Scheme 4

showed that the above silybin glycosides have considerably higher antioxidative activity, the β-glucoside being the best that is ca. 10-times better than aglycon itself. Silybin monoglycosides show also better hepatoprotective activity than the aglycon. Similar effects were observed also in the tests with membrane lipoperoxidation of the mitochondrial membranes, in which silybin glycosides, mainly β-glucoside and β-galactoside, were found to be ca. 50–70% better antilipoperoxidants. The cytotoxicity at higher concentrations of silybin towards hepatocytes at conc. over 0.1 mM can be lowered by its glycosylation – in this case especially the β-maltoside and β-lactoside display substantially lower toxicity at high concentrations. Silybin β-galactoside was found to have better hepatoprotective activities in vivo presumably due to β-galactosyl residue causing higher affinity towards hepatocytes.

Flavonoids occurring virtually in all plant-derived food have a strong effect on the mammalian biology, mainly on immunity, inflammation and cancer [15]. A well described case of an immunomodulative effect for flavonoid glycoside is plantagoside (5,7,3′,4′,5′-pentahydroxyflavanone 3′-β-*O*-glucoside) that inhibits proliferative response of Balb/c spleen cells to the T-cell mitogen concanavalin A. On the contrary it has no effect on the mitogenic activity of lipopolysaccharides or phytohaemaglutinin thus demonstrating that the later two mitogens probably utilize activation pathways that are insensitive to this particular glyco-flavonoid. The fact that plantagoside is an α-mannosidase inhibitor [16] is of interest as well. Glycosides of isoflavonoids also have important functions in the communication between leguminous plants and nitrogen-fixing bacteria. Some of them are able to trigger *Nod* genes responsible for for-



13 (-)-medicarpin R = H
14 R = βGlc



15

16 quercetin R = H
17 quercitrin R = βGlc

Scheme 6

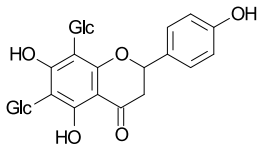
mation of lipochitooligosaccharide signal molecules, which in turn induce root hair curling and the cortical cell division that characterize the early development of the nodule.

Root exudates from alfalfa inoculated with *Rhizobium melioti* contain the pterocarpan medicarpin (**13**) and its β-glucoside (**14**), as well as formonetin 7-*O*-β-glucoside-6″-*O*-malonate (**15**) (Scheme 5). Levels of **14** are increased when plants are grown under low nitrogen conditions [17]. Formonetin and its 7-*O*-glucoside do not possess *Nod* gene-inducing activity for the alfalfa symbiont. Surprisingly, however, **15** can induce *Rhizobium nod* genes via interactions with both the NodD1 and NodD1-recognition proteins [18]. The Nod factors synthesized as a result of *Nod* gene activation are active on alfalfa roots at concentrations of around 10^{-9} M.

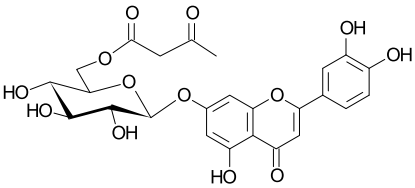
Flavonoids and their glycosides mediate also communication between plants and insects, serving like "pollination factors". This effect is caused mainly by the final color of the anthocyanin complex and is not related to the extent of glycosylation. Flavonoid glycosides also serve as feeding stimulants, e. g. isoquercitrin (quercetin 3-*O*-β-glucoside, **17**)(Scheme 6) that serves as a "biting factor" in feeding of *Bombyx mori* (silkworm) on the *Morus alba* leaves [19].

There are further examples of feeding stimulants from the group of flavonoid glycosides such as, e. g. kaempferol 3-*O*-β-xyloside and some others.

These compounds can be also effective antifeedants and here the glycosylation pattern is of crucial importance. Rutin [91] is a feeding stimulant to the tobacco hornworm, *Manduca sexta*,



18



19

Scheme 7

and quercetin 3-rhamnoside (less one glucose in comparison to rutin) acts as an antifeedant to the same species [20].

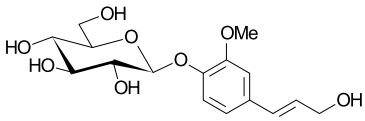
The larvae of most butterfly and moth species are monophagous or oligophagous, i. e. they feed from only one or a few (usually closely related) host plants. Caterpillars are much less mobile than winged adults and are unlikely to find the right food if the eggs, from which they hatch, have been laid on the wrong plant species. Thus, the oviposition choice of an adult female is crucial to larval survival. Most butterflies use visual and/or olfactory cues for the oviposition. The female will lay eggs only when she detects specific oviposition stimulants on the plant. As oviposition stimulants usually a complex cocktail is involved and flavonoid glycosides are an important part of this cocktail.

The first flavonoid glycoside that was found to induce ovipositional response in a butterfly was vicenin-2 (apigenin 6,8-di-*C*-glucoside, **18**) in the *Citrus*-feeding swallowtail *Papilio xuthus* [21]. Later more flavonoid glycosides were identified to be oviposition stimulants (naringenin 7-*O*-β-rutinoside, hesperetin 7-*O*-β-rutinoside and rutin) [22]. Another documented oviposition inducing flavonoid glycoside is 7-(6″-malonyl-β-D-glucopyranosyl)-luteolin (**19**) present in carrot (*Daucus carota*) that attracts *Papilio polyxenes* (Black swallowtail). The malonyl group in the flavonoid glycoside seems to be crucial, since the unmalonylated luteolin 7-glucoside and the corresponding glucuronide (also present in the carrot leaves) has little or no effect [23] (*Scheme 7*).

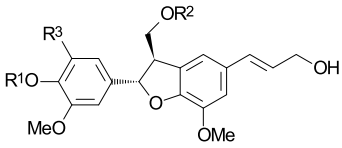
Flavonoid glycosides after intake by the insects are also sequestrated without hydrolysis and can be found in the insect tissues.

2.3 Lignins and Lignans

Coniferin (**20**) is one of the most abundant lignan glycosides occurring mostly in coniferous trees and some other plants. It is the dominant transport and storage form of coniferyl alcohol, which in turn constitutes the main building block of lignins.



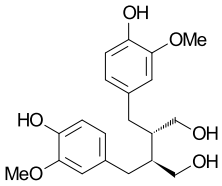
20



21 R^1 = βGlc R^2 = R^3 = H

22 R^1 = H R^2 = βGlc R^3 = H

23 R^1 = H R^2 = βGlc R^3 = OMe



24

Scheme 8

β-Glucosides of dehydroconiferyl alcohols (**21**–**23**) (*Scheme 8*) and the respective 2,3-epimers are growth factors isolated from transformed *Vinca rosea* tumor cells [24]. These compounds are not fragments of cell walls, but are produced directly from coniferyl alcohol [25]. Nonglycosylated derivatives do not have the cytokinine activity.

One of the most abundant lignans, for example in flaxseed, is di-β-glucoside of (+)-secoisolariciresinol (**24**) (both phenolic OH glycosylated). This compound is in vivo deglycosylated by intestinal microflora and by further demethylation and oxidation converted into enterolactone. These compounds called "mammalian lactones" enter the enterohepatic circulation, and there exists good evidence that their presence lovers incidence of the hormone-related cnacers [26]. They also lower the incidence of colon tumors. The above-mentioned diglycoside of **24** was also shown to act as an effective radical scavenger [27].

One of the most prominent lignans in terms of pharmacological application, in which glycosylation plays a crucial role, is podophylotoxin (**25**). This compound is the main active principle of podophyllin, a resin obtained from rhizomes of *Podophyllum peltatum*. Early pharmacological results with *Podophylum* lignans were disappointing. In spite of its antitumor promise direct administration of **25** was compromised by severe gastrointestinal toxicity. However, derivatized glycosides showed very promising activity in vitro and in vivo [28] and two of

27 R^2 =

Scheme 9

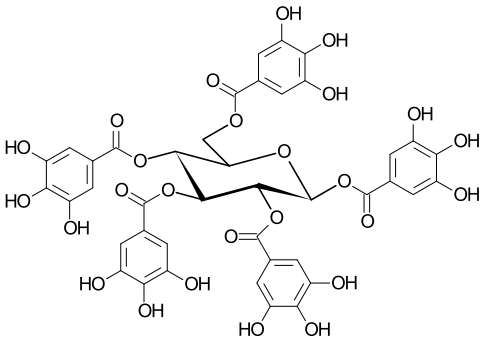
them, the ethylidene derivative etoposide (**26**) and the 4,6-alkylidene derivative of thiophencarbaldehyde, teniposide (**27**), were developed as anticancer drugs. In contrast to a classical spindle poison **25**, which causes arrest of the cells in the metaphase, attaching sugar moieties prevented tubulin interaction and thus microtubular assembly was not inhibited [29,30]. Etoposide (**26**) has proven to be useful in the treatment of patients with small-cell lung cancer, Kaposi's sarcoma, lymphoma and leukemia while teniposide (**27**) is mainly used to treat acute lymphatic leukemia, neuroblastoma and brain tumors in children (*Scheme 9*).

2.4 Gallotannins

Gallotannins (e. g., 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranose, **28** (*Scheme 10*)) are abundant compounds of glycosidic character in plant material. As plant preparations these compounds had been used from ancient times as traditional medicine in wound healing, as an astringent and as an antidote in many intoxications (precipitation of the noxa) and the compounds also act as an effective antioxidant. These effects, however, cannot be attributed to the glycosidic moiety in the center of the molecule but mostly to the polyphenolic nature of the galloyl residues.

3 Glycosidic Antibiotics

Antibiotics form a large group of compounds of a vast structural diversity that are able to suppress or inhibit growth of one type of cells (microbial, fungal, tumor, genetically altered, etc.) and do not or to a lesser extent affect the growth of host cells. This definition is only very broad as it cannot embrace all the subtle effects of the various types of antibiotics.



28

Scheme 10

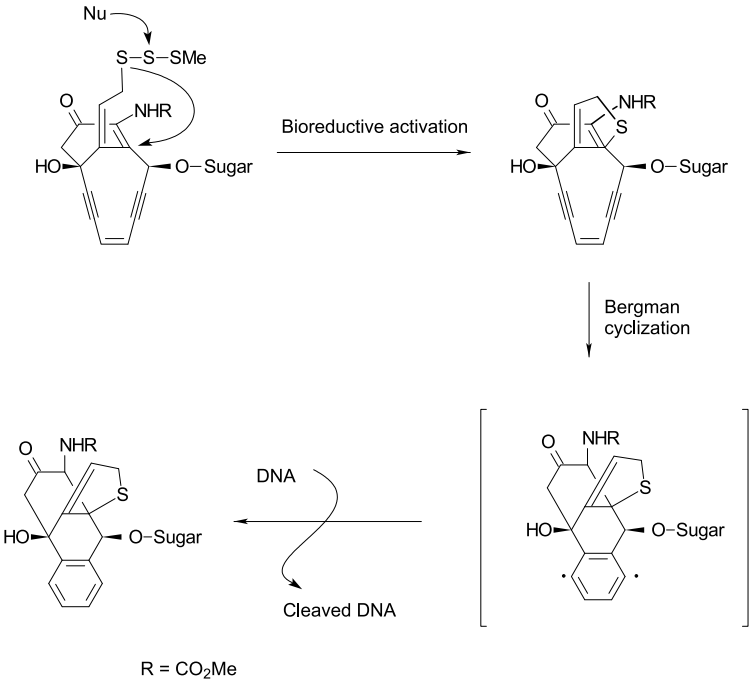
As in virtually all other groups of biologically active compounds, also in the group of antibiotics sugars play a very important role [31]. Occurrence of quite uncommon deoxy- and aminosugars is another typical feature of a large group of glycosidic antibiotics.
In this section we would like to focus on recent findings or typical cases.

3.1 Enediyne Antibiotics

The enediyne antibiotics [32] are extremely potent antitumor agents with a unique bicyclo[7.3.1]enediyne substructure. This group includes mainly calicheamycins [33], esperamycins [34], and dynemycins. Neocarzinostatin [35] and others (e. g., maduropeptin and kedarcidin) are also classified as belonging to this family. At room temperature in the presence of DNA, the core system of an enedyine antibiotic undergoes an interesting reaction yielding diradicals on sp^2 carbon that causes DNA strand breakage (*Scheme 11*). During studies of the structures of calicheamycin γ^1 and esperamycin A_1, it became apparent that enedyines could be triggered to aromatize via cleavage of the trisulfide with formation of a diradical intermediate as the biologically active species.

3.1.1 Calicheamycin

Calicheamycin γ^1 (**29**) was isolated from the cultivation broth of *Micromonospora echinospora* enriched with iodide. Compound **29** binds to the minor groove of DNA showing a high degree of base pair sequence-specificity, and a high degree of double strand to single strand cleavage of DNA. This occurs mostly at the sites 5′-TCCT/AGGA and 5′-TCTC/GAGA. The double stranded scissions suggest that **29** binds in the minor groove with the diradical positioned in such a way as to allow hydrogen abstraction from each strand [36]. The degree of specificity has been attributed to the carbohydrate moiety of the molecule, with the oligosaccharidic moiety aligned towards the 3′-end of the DNA. Studies have shown that the aglycon of **29** binds to DNA with lower affinity and in a nonsequence-specific manner [37]. Carbohydrates of calicheamycin γ^1 are lipophilic, which makes them favorable to interact with DNA.

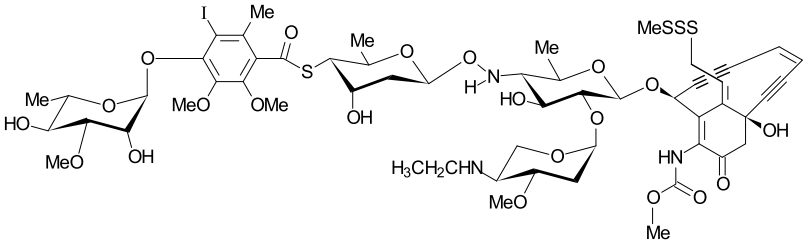


Scheme 11

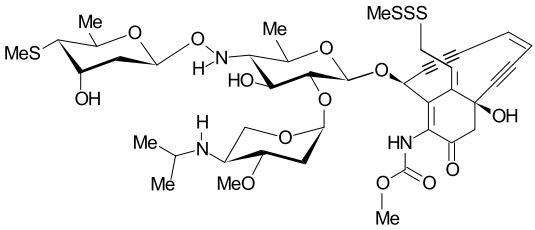
There is evidence that the iodine atom of the aromatic ring interacts with the C-2 amino groups of one or both guanines in TCCT:AGGA duplex DNA [38]. The binding energy of the oligosaccharide domain of **29** to the above DNA sequence within the duplex DNA is 31.6 kJ/mol. The sulfur atom of the third glycosidic moiety forms a hydrogen bond with an exposed amino proton from 3′-guanine in a drug-DNA complex [39]. This sugar was shown to be positioned edgewise in the minor groove allowing the aromatic ring to be placed between the minor groove with its iodine and methyl group positioned deep inside the minor groove.

Esperamycin C (**30**) can be considered to be an analogue of calicheamycine void of the rhamnosyl moiety and the aromatic part. Compound **30** causes double strand DNA cleavage but with considerably lower sequence selectivity. The aromatic and rhamnose moieties of **29** seem to determine the sequence specificity and the monodirectional mode of binding but they have little or no effect on orientating the aglycon within the DNA. NMR studies and molecular modeling demonstrated that also other sugar moieties in **29** specifically interact with DNA, e. g. the second carbohydrate moiety within the sugar-phosphate of DNA. The hydroxylamine glycosidic linkage causes two linked sugars to adopt an unusual eclipsed conformation giving the oligosaccharides the correct shape and rigidity to allow selective binding in the minor groove of DNA [38] (*Scheme 12*).

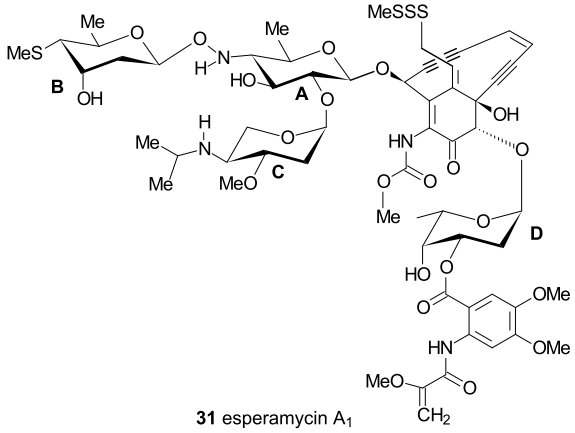
The monomer and the "head-to-head" dimer of the oligosaccharide segment of **29** have been shown to inhibit DNA transcription factors [39]. The dimeric glycoside was a more effective inhibitor than the corresponding respective monomer. The inhibitory effect has been attribut-



29 calicheamycin γ^1



30 esperamycin C



31 esperamycin A_1

Scheme 12

ed to the conformational changes in DNA caused by interactions with the sugar and this in turn interferes with the transcription factor DNA recognition. The base sequence selectivity of the calicheamycin carbohydrate to DNA may open up new possibilities for the chemical control of genetic information. It can, however, be stated that obviously deoxy- and substituted saccharides should be employed to enhance hydrophobic interactions.

3.1.2 Esperamycin

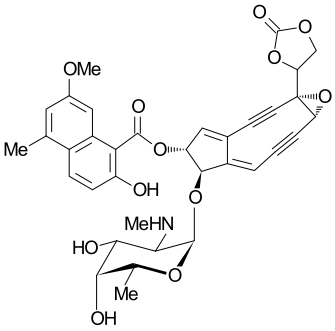
Esperamycins (esperamycin C **30**, esperamycin A_1 **31** and others), isolated from *Actinomadura verrucosospora*, display very strong antitumor activity due to DNA cleavage effected by the aglycon [40]. Esperamycin A_1 causes mostly single strand DNA cleavage and is far less sequence-specific than **29** having a similar aglycon.
Structure analysis of the esperamycin A_1–d(CGGATCCG) duplex showed that the drug bound in the minor groove with the methoxyanthranilate moiety intercalates at the (G2-G3):(6′-C7′) segment [41]. It was demonstrated that the isolated deoxyfucose anthranilate group did not interact with DNA, however, this moiety was shown to contribute 4–8 kJ/mol to the binding energy of **31**.
Esperamycin C causes double strand lesions involving deoxyribose hydrogen abstraction from the 4′- and 5′-positions, whereas esperamycin A_1 causes lesions from the 1′- and 5′-positions. This change to the 1′-position for esperamycin A_1 is believed to be due to deoxyfucose anthranilate, which intercalates in the DNA. The A-B sugars of the A-B-C trisaccharide are positioned deep into the minor groove. The OH groups of the trisaccharide A-B-C are positioned close to potential hydrogen bond acceptors, and favorable van der Waals interactions thus help to stabilize the complex [42].

3.1.3 Neocarzinostatin

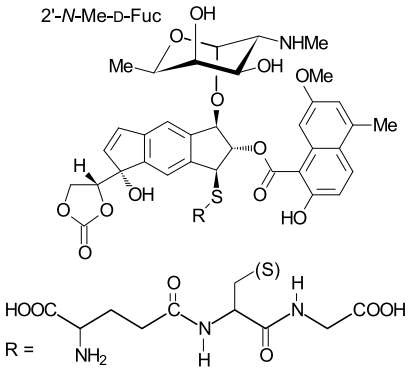
Neocarzinostatin, isolated from *Streptomyces carzinostaticus*, consists of a mixture of chromophore (**32**) and a protein [43]. This compound having potent antitumor and antibacterial activities induces single strand and double strand scissions in a ration 5:1, respectively, with a preference for T and A residues. The sequence specificity differs from other enedyines partly because of the different glycosylation pattern of the molecule.
The 2′-*N*-methyl-D-fucosamine, naphthoate and tetrahydroindacene of the postactivated-neocarzinostatin (rearranged complex with oligopeptide, **33**) (*Scheme 13*) were shown to have the correct structure to bind to specific sequences of DNA such as AGC sites. Specific sites are suggested for chemical modification that may alter selectivity of binding/cleavage, one of these sites being the N-2 of the 2′-*N*-methyl-D-fucosamine [44].

3.2 Anthracyclines

Anthracyclines represent a relatively large group of natural, semisynthetic and synthetic compounds [45]. Some compounds of this type are used in cancer treatment, several promising candidates are in clinical testing. Anthracyclines have also good antibacterial activity, however, due to their toxicity they are not used clinically in the treatment of infectious diseases. At present daunomycin (**34**) is used for the treatment of leukemia and adriamycin (**35**) is used for treatment of some solid tumors. These two compounds were studied in great detail. Modifications on both the aglycon and saccharidic parts have been performed. Changes of the saccharidic moiety were achieved by substitution of existing groups, e. g. *N*-alkylation, *N*-acylation, *O*-alkylation, formation of tetrahydropyranyl derivatives etc.



32 neocarzinostatin



33 post-activated neocarzinostatin

Scheme 13

3.2.1 Daunomycin

The anticancer activity of daunomycin (**34**) (*Scheme 14*) is attributed to the intercalation of the drug with DNA. This pattern of effect is common to all anthracyclines [46]. Two daunomycin molecules intercalate at each of the two C:G sites at either site of the duplex d(CGTACG). This binding results in an increase in base pair-separation from 3.4 to 6.8 Å as the molecule associates, which in turn leads to an unwinding of the helix and the formation of a noncovalent complex with the DNA. This results in the inhibition of DNA replication and RNA transcription [47].

Rings B-D of the aglycon are intercalated with the DNA, leaving ring A and the aminosugar as anchoring units. The cationic aminosugar and the hydroxy group of ring A fill the minor groove, which displaces water and ions from the groove. The aminosugar does not show hydrogen bonds to adjacent bases. The amino and hydroxy groups of the sugar face out of the minor groove, and it has been suggested that they may interact with polymerases, which could prevent or retard the action of these enzymes.

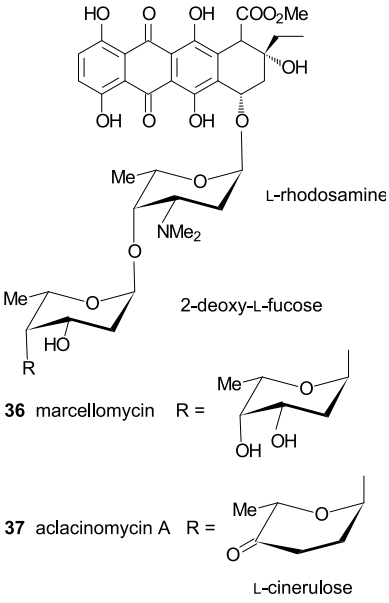
35 adriamycin R = $COCH_2OH$



Scheme 14

It was observed that anthracyclines containing several glycosyl moieties have, in general, less side effects. For example, marcellomycin (**36**) and aclacinomycin A (**37**) show lower cardiotoxicity than daunomycin.

This is also the reason for the many attempts to introduce one or more additional carbohydrate moieties. Reaction of daunomycinone with diols providing its 7-*O*-hydroxyalkyl derivatives enabled attachment of the sugars in a different manner leading to derivatives with lower toxicity [48].

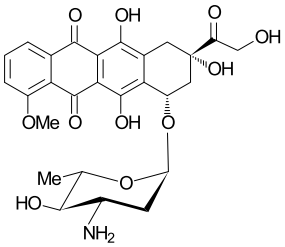
Nogalamycine, which contains two sugars (one attached to the D-ring and the second attached at C-7 of the A-ring), binds to DNA in a slightly different manner [31].

3.2.2 Glycosyl Derivatives of Anthracyclines

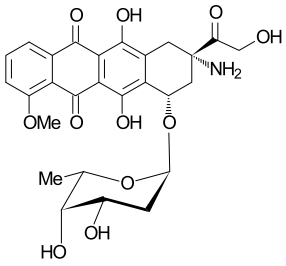
In natural anthracyclines the sugars are linked by α-glycosidic linkages, the corresponding β-glycosides were found to be inactive [49]. L-arabino analogues of daunomycin and doxorubicin, 4′-epidaunomycin and 4′-epidoxorubicin (**38**), were shown to have similar activity to the natural anthracyclines, the latter (**38**) also has a lower cardiotoxicity and is now used clinically [50] (*Scheme 15*).

Neutral synthetic sugar derivatives, for example SM-5887 (**39**), display good antitumor activity with reduction in local tissue toxicity and cardiotoxicity compared to, for example, adriamycin (**35**) [51].

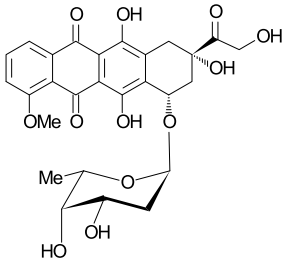
Drug resistance in the anthracycline cancerostatics has been addressed by the study of the influence of the amino group of daunosamine. It seems that this group is recognized by the P-gp multidrug transporter (P-glycoprotein is an ATP-dependent transmembrane drug exporter). Comparative studies of doxorubicin and hydroxyrubicin (**40**) in drug-resistant tumor cells demonstrated that **40** partially or completely circumvents P-gp-mediated drug resistance due to its decreased transport by P-gp compared with doxorubicin [52].



38

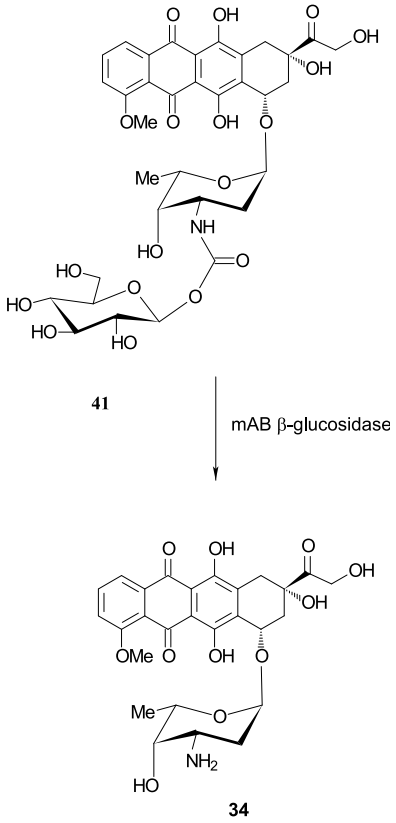


39



40

Scheme 15



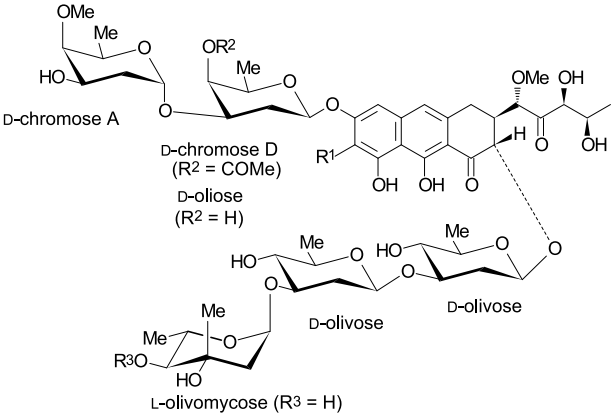
Scheme 16

There have been also attempts to prepare targeted drugs based on anthracyclines employing the recognition of some specific sugars by receptors on the tumor cells. Thus, a β-glucoside derivative of adriamycin (**41**) was used in an antibody-directed enzyme-prodrug therapy (*Scheme 16*) [53].

3.2.3 Aureolic Acids

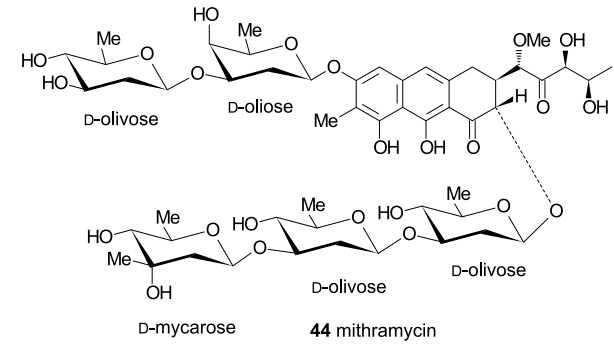
Members of the aureolic acid group include chromomycin A_3 (**42**), olivomycin A (**43**) and mithramycin (plicamycin) (**44**). The aglycon of chromomycin A_3 is identical to that of mithramycin, but differs from that of olivomycin A by a methyl group. Conversely, the sugar components for chromomycin A_3 and olivomycin are nearly identical, while those in mithramycin are different (*Scheme 17*).

These drugs require a divalent metal ion, preferably an Mg^{2+} ion and a guanine-containing target for activity. They were identified to be inhibitors of DNA-dependent RNA polymerase. It was found that **42** lacking some of the sugar moieties was less active [54] and the aglycon does not bind to DNA at all [55].



42 chromomycin A_3 R^1 = Me, R^2 = R^3 = COMe

43 olivomycin A R^1 = H, R^2 = COMe, R^3 = $COCHMe_2$



44 mithramycin

Scheme 17

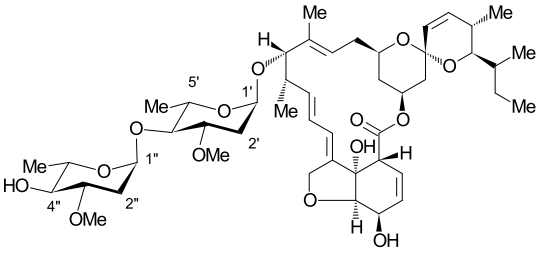
The mode of action of these antibiotics is different from other anthracyclines despite their aglycon similarity. Aureolic acids do not intercalate into DNA but they bind to CG rich regions. NMR studies demonstrated that **42** forms a symmetrical dimer with self complementary d(TTGGCCAA) with the hydrophobic edge of the chromophore located next to the GC:CC site [56]. The sugars in the olivose-olivose-olivomycose trisaccharide extend towards the 3′-direction of the octanucleotide in the minor groove. The chromose disaccharide and the hydrophilic side chain are directed to the phosphate backbone. The trisaccharide part olivose-olivose-olivomycose is essential for stabilization of the drug-Mg^{2+} complex that binds effectively to DNA, removal of chromose A has no effect on the complex formation [57].

The action of mithramycin (**44**) is virtually the same, however, it is less specific for the respective DNA sequence, which can be explained by the additional hydrogen-binding potential of D-mycarose [58].

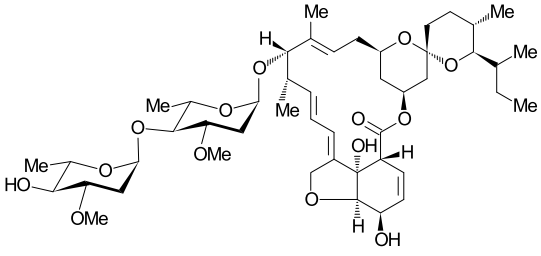
3.3 Avermectins

This class of macrolide antibiotic has mostly antiparasitic activity. Avermectin B_{1a} (**45**) and ivermectin (**46**) (Scheme 18) are used mostly in veterinary medicine, however, some semisynthetic derivatives are also used for treatment of onchocerciasis in humans [59]. The action of avermectin is believed to stimulate specific chloride ion transport systems increasing the membrane permeability to Cl^- ions via GABA (γ-butyrate) receptors and non-GABA receptors [60].

The aglycon of avermectin has poor antiparasitic activity. Positions 4′ and 4″ of the oleandrose moieties were modified partly because of feasibility. The synthesis of the 4″-amino-4″-deoxyoleandrose derivative of avermectin B_1 and ivermectin was based on the observation that most macrolide antibiotics contained a basic amino group [61]. One of the derivatives, 4″-*epi*-acetamido-4″-deoxyavermectin B_1, is currently under development as a novel avermectin endectoside [61]. Besides, also 2″-α-fluoro (*ax.*) and 2″-β-fluoro (*eq.*) derivatives of avermectins were prepared to strengthen the glycosidic bond. These derivatives have interesting activities in some bioassays compared to the parental compounds [62].



45 avermectin B_{1a}



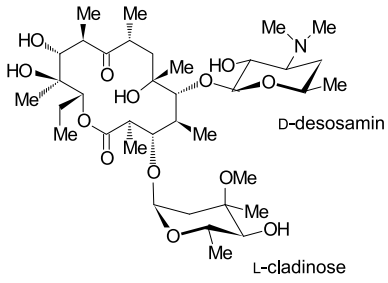
46 ivermectin

Scheme 18

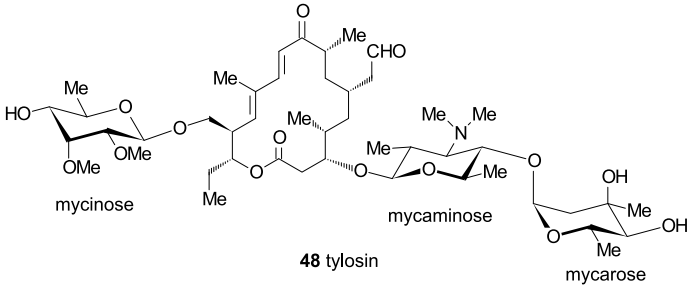
3.4 Macrolide Antibiotics

Macrolide antibiotics containing a large lactone ring (hence the title macrolide) consisting of 14 atoms are biosynthetically related to avermectins being also polyketides. The first member of this group erythromycin A (**47**) was isolated in 1952 [63] and it soon became an important antibiotic widely used in clinical medicine against Gram-positive bacteria. It constitutes the main treatment for many pulmonary infections such as Legionnaire's disease. Other families of macrolides are known containing 12- or 16-membered macrolide rings. A representative of the latter family is tylosin (**48**) (*Scheme 19*), a commercially important antibacterial agent used in veterinary medicine. The 12-membered ring macrolides have not been used clinically. Most of the macrolides contain deoxy- and aminosugars. Although it was established [64,65] that the sugar moieties are absolutely essential for the microbial activity of these compounds it is difficult to judge their role in the activity as the exact mode of action is unclear.

The mode of action of macrolide antibiotics involves the inhibition of protein synthesis of specific binding to the 50S ribosomal subunit but without a specific target at the 23S ribosomal subunit and various proteins [66]. Nevertheless, the exact interaction of the macrolide and the ribosome unit is still not fully understood. In principle, the macrolide antibiotic should inhibit also mammalian mitochondrial protein synthesis but they are unable to penetrate the mitochondrial membrane.



47 erythromycin A



48 tylosin

Scheme 19

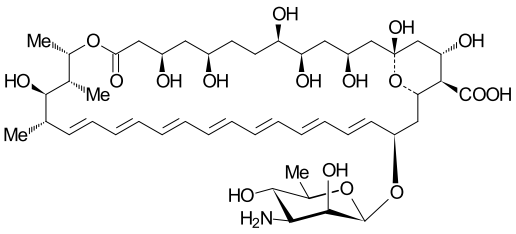
Sugar moieties have been linked with many pharmacological properties displayed by the macrolide antibiotics [67]. Basicity of the nitrogen in aminosugars improves the active transport of the compounds into the cell, however, its protonation/deprotonation does not affect the uptake. It was shown [68] that the more basic macrolides are the more effective ones. Esterification of the glycosidic position 2′ improves pharmacological and pharmacokinetic properties of the resulting drug lowering unwanted gastrointestinal side effects [69].

3.5 Polyenes

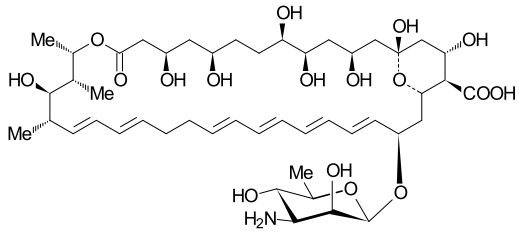
Polyene macrolides consist of a macrocyclic lactone, a polyene chromophore, and a polyhydroxylated chain which often bears glycosidic residues. These antibiotics, e. g., amphotericin B (**49**) and nystatin A_1 (**50**) (› *Scheme 20*), are used as potent antifungal antibiotics although they cause side effects such as nephrotoxicity, hemolytic anemia and electrolyte abnormalities [70].

These compounds interact with ergosterol contained in cell membranes of lower eukaryotes (fungi, yeasts) forming pores in their membranes. These channels cause a shunt in the membrane potential and leach the cellular ions [71].

Structure-activity studies on amphotericin B (**49**) have shown the importance of the basic nitrogen of D-mycosamine for the activity [72]. The polyene is orientated with the polar head at the



49 amphotericin B



50 nystatin A_1

Scheme 20

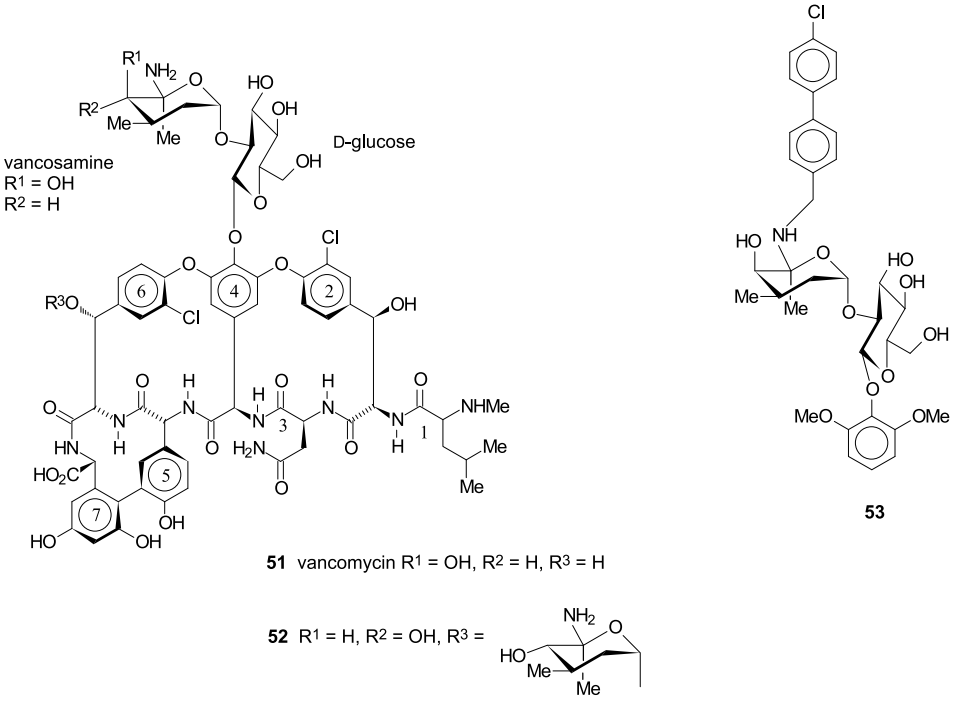
membrane–water interface and it has been suggested that the basic amino group of the sugar and the carbonyl group form a "cage-like" hydrogen-bonded structure with sterol containing a 3-β-hydroxy group and water.
N-Glycosylation of D-mycosamine in the polyenes leads to antibiotics with reduced toxicity and similar activity to the parent compound but increased water solubility and, therefore, better bioavailability [73].

3.6 Glycopeptides

This group of antibiotics is made up of complex polypeptide aglycones, which are abundantly glycosylated with mono-, di- and tetrasaccharides [74]. To date about 100 members of this group are known, such as vancomycin, teicoplanin, bleomycin, ristocetin etc. Some of them are very important, as they are often *ultimum refugium* – the last possible treatment for multiply resistant bacterial infections. Recent discoveries demonstrated that glycosidic residues play crucial roles in their activity and this opens up a large area for developing new glycosidic antibiotics, as shown in the case of vancomycin.
The story of the involvement of glycosyl moieties in vancomycin activity is probably one of the most illustrative and also very topical as glycosyl derivatives of vancomycin quite recently proved to be very effective against multiply resistant (even vancomycin-resistant) bacteria.

3.6.1 Vancomycin

Vancomycin (**51**) (❯ *Scheme 21*) [75] is a glycopeptide antibiotic that is widely used in the treatment of Gram-positive bacterial infections. It was discovered in a soil sample from the jungles of Borneo during a research program carried out by the pharmaceutical company Eli Lilly in the mid-1950s. At present its importance has increased considerably as it is one of the few antibiotics effective against nosokomial infections, e. g., multiply resistant bacteria – a typical example is methiciline-resistant *Staphylococcus aureus* (MRSA), and together with gentamycin it is an antibiotic of last resort.
Vancomycin consists of a core heptapeptide with attached saccharide moieties, one of which is the deoxyaminosugar vancosamine. Vancomycin exhibits its antibacterial activity by binding bacterial cell wall mucopeptide precursors terminating in the sequence L-Lys-D-Ala-D-Ala [76], thereby impeding further processing of these intermediates into peptidoglycans. Five hydrogen bonds account for this binding specificity, and the disruption of one of these hydrogen bonds by the replacement of the terminal alanine with lactate (D-Ala-D-Lac) in the mucopeptide precursor is the molecular basis for the resistance to **51**.
Because of the ultimate importance of vancomycin in the treatment of often fatal infections caused by multiply resistant bacteria, extensive efforts have been directed toward the discovery of vancomycin derivatives with activity against the drug-resistant bacteria [77]. As a result of these efforts, several derivatives such as **52** (LY264826) have been found to be up to 500 times more effective than vancomycin itself. The most notable difference is the presence of another aminosugar (R^3) attached to the amino acid 6. This extra sugar possibly facilitates the dimerization of the antibiotic and/or anchors the antibiotic to the cell membrane, both of which have been shown to be important for vancomycin activity [75]. It was also demonstrated that the conformations of vancomycin and its aglycon differ in their alignment of the amide protons



Scheme 21

that participate in the hydrogen-binding network with cell-wall precursors [78]. Alkylation of the 3-amino group on the disaccharide at amino acid residue 4 further enhances the activity, probably by serving as a hydrophobic anchor to the cell membrane [79].

Another target for modification of vancomycin is the vancosamine moiety. Recently, it was found that *N*-alkylation with *n*-decyl or 4-chlorobiphenylyl groups results in an antibiotic acting by a different mechanism than vancomycin itself [80] and, therefore, exhibits activity against vancomycin-resistant microorganisms. Sugar-altered vancomycin interferes with the polymerization of a glycopeptide monomer and disrupts its ability to form cell-wall material in the first place. Thus, altered vancomycin may disrupt cell-wall formation at multiple targets of the glycopeptide monomer, straight-chain polymer, and cross-link reinforcement.

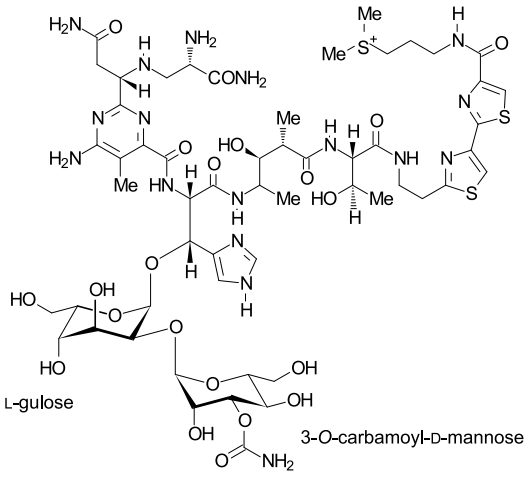
In fact, the altered disaccharide derivative itself (**53**) has strong antibacterial activity, even if not attached to the rest of the large vancomycin molecule [80]. This compound, however, acts by a different mechanism than vancomycin. It inhibits the transglycosylation step that precedes the transpeptidase step blocked by vancomycin itself. This finding explains a complex mechanism of action of the derivative **52**.

These findings offer possibilities to use sugar chemistry to make glycopeptide antibiotics such as vancomycin more potent against bacteria, for example, if vancosamine was replaced by daunosamine (3-desmethyl-vancosamine). Although this derivative differs from **51** only in one methyl group at the terminal sugar, it shows some notable differences in activity [81]. A general methodology for selective glycosylation of the vancomycin aglycon has been developed

by Kahne's group [82]. It is quite likely that a wide-ranging investigation of different sugars will lead to more significant improvements across a range of bacterial strains. This case and analogous approaches are discussed in detail in ❯ *Sect. 8* of this chapter.

3.6.2 Bleomycin

Bleomycin A_2 (**54**) (❯ *Scheme 22*) has antimicrobial activity against both Gram-positive and Gram-negative bacteria but it is clinically often used as an antitumor agent. The mode of action of bleomycin is DNA strand scission occurring in the presence of Fe^{2+} and molecular oxygen [74]. It was demonstrated that the sugars do not contribute to the binding affinity or the DNA cleavage selectivity, although the presence of the sugar enhances the DNA cleavage efficiency by 2–5 times [78]. The sugar moieties are suggested to contribute to the binding of O_2 and activation and protection of the reactive iron-oxo or perferryl intermediate to activated bleomycin [83].

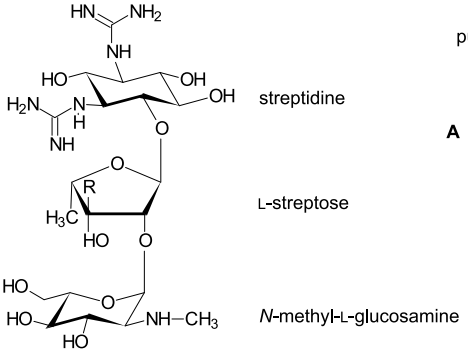


54 bleomycin A_2

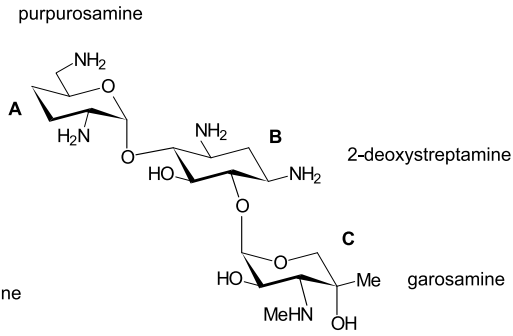
Scheme 22

3.7 Aminocyclitol Antibiotics

The term "aminoglycoside" refers to the structural aspects. Most of the aminoglycoside antibiotics contain aminosugar(s) and an aminocyclitol or a cyclitol moiety; therefore, this group is also called "aminocyclitol antibiotics." A review on structural aspects, synthesis and chemical modifications of these compounds was published by Ikeda and Umezawa in 1999 [210].
Streptomycin (**55**), dihydrostreptomycin (**56**) and gentamycin (**57**) (❯ *Scheme 23*) are typical representatives of a large group of the aminocyclitol antibiotics. They interact with ribosomal RNA causing a decrease in translational accuracy and inhibit translocation of the ribosome [84]. These antibiotics bind to a conserved sequence of rRNA that is near the site of codon-anticodon recognition in the aminoacyl-tRNA site of the 30S subunit.



55 streptomycin R = CHO
56 dihydrostreptomycin R = CH_2OH



57 gentamycin A

Scheme 23

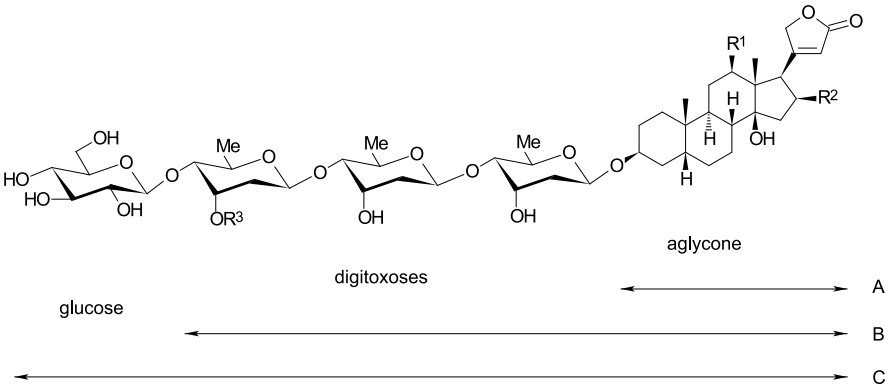
A comparison of various aminoglycosidic antibiotics suggests chemical groups that are essential for their function [85]. Both amino groups of the B ring (see e. g. in **57**), which are positively charged at physiological pH, contribute to RNA binding as hydrogen donors.
Recent investigation of the binding mechanism of gentamycin C1A (**57**) has shown that it binds in the major groove of the RNA. Rings A and B of gentamycin direct specific RNA-drug interactions. Ring C of gentamycin, which distinguishes this subclass of aminoglycosides, also directs specific RNA interactions with conserved base pairs [86].
Resistance to this type of antibiotic is usually mediated by acetylation, adenylation and phosphorylation mostly in rings A and B causing thus lowered or abolished antibiotic affinity to the RNA [87].

4 Steroid and Terpenoid Glycosides

This group involves a considerable number of physiologically active compounds whose activity is largely dependent on the complete structure, including the glycosidic moiety. A number of these compounds have detergent properties, e. g., saponins, and such physicochemical properties are partly responsible for their toxicity, e. g. the hemolytic activity of some saponins is caused by the damage of the erythrocyte membrane.

4.1 Cardiac Glycosides

Cardiac glycosides consist of a five-ring cardenolide aglycon, called a genin, with a number of attached monosaccharides, which often include deoxysugars. These steroidal compounds are usually isolated from plant material (digitoxin, strophantidine), but they have been dis-



Structure part	Description	R^1	R^2	R^3
Part A (aglycon)	Digitoxigenin	H	H	–
	Gitoxigenin	H	H	–
	Digoxigenin	OH	H	–
Part B (trioside)	Digitoxin	H	H	H
	Gitoxin	H	OH	H
	Digoxin	OH	H	H
Part C (tetraoside)	Purpurea glycoside A	H	H	H
	Purpurea glycoside B	H	OH	H
		OH	H	H
Acetylated tetraosides	Lanatosid A	H	H	CH_3CO
	Lanatosid B	H	OH	CH_3CO
	Lanatosid C	OH	H	CH_3CO

Figure 2

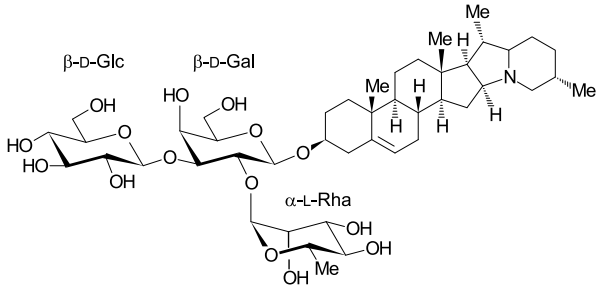
covered in higher mammals as adrenal cortical hormones (ouabain) [88]. Possibly using the same binding site as the natural hormone, cardiac glycosides inhibit Na^+/K^+-ATPases [89,90], resulting in an ionotropic activity that has proven to be useful in the treatment of various heart conditions, e. g., atrial tachyarrythmias, and it is used to produce a positive ionotropic effect in congestive heart failure [91]. This activity is enhanced several-fold due to the presence of the sugars in these compounds [92,93]. The sugar moiety is thought to be important in uptake, distribution and binding stability [94]. Cleavage of the sugar moieties forms the genin (*Fig. 2*) which retains a diminished affinity while the sugar moiety alone has no activity [94,95]. Altering the structure of the sugar(s) has a dramatic influence on the activity of the cardiac glycoside. Cardiac glycosides having $\beta(1\rightarrow4)$ sugar linkages have stronger activities than those with $\beta(1\rightarrow6)$ and $\beta(1\rightarrow2)$ linkages [96,97], α-linkages further diminish the activity [98]. Sugars having 4′-OH axial groups (e. g., galactose) diminish the binding, 3′-OH axial and 2′-OH equatorial groups appear to contribute to the binding [99]. Also, the addition of a 6′-OH group slightly diminishes the activity [99].

Therefore, existing natural digitoxose/glucose containing cardenolides seem to be optimal despite extensive structure-effect studies targeted to its optimization.

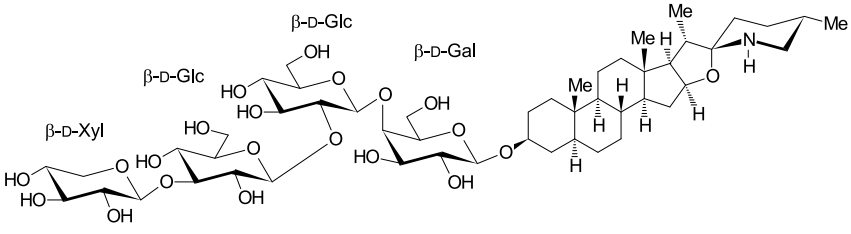
Some studies have revealed that the saccharides lengthen the half-life of the activity by preventing the host from modifying the genin and neutralizing its inhibitory activity [100]. The sugar proximate to the genin has the strangest effect on binding and activity of the drug [101]. Even though the structure of the cardiac glycoside binding site has been extensively studied [102], its detailed nature remains unknown, namely the aminoacid residues which interact with the sugar moiety. Nevertheless, a three-step model has been proposed to account for the interaction between a cardiac glycoside and its receptor. The binding event can proceed via reversible binding of the steroid core with the receptor, followed by a conformational change that exposes a sugar-binding motif, which then binds to the saccharides and hinders dissociation [103].

4.2 Saponins

Originally, the name "saponin" implied a group of soap-like natural surfactants that form long-lasting bubbles on shaking an aqueous solution. An aglycone of saponins is designated as sapogenin or sapogenol (triterpene sapogenins and steroidal sapogenins). Saponins having one sugar moiety are called monodesmosides, and those having two sugar moieties at different positions are called bisdesmosides. Saponins often occur in higher plants, which are frequently used for human and animal consumption, therefore, their physiological activities are of utmost



58 α-solanine



59 α-tomatine

Scheme 24

importance [104]. They can be found in larger amounts in, e. g., soybeans, peas, beans, oats, potatoes, tomatoes, tea, liquorice, ginseng, and in forage as, e. g., alfalfa, lupine, sunflowers, guar etc. Some of the saponins contain nitrogen and these are sometimes included in the alkaloids, e. g., solasodine, α-solanine (**58**) or α-tomatine (**59**) (› *Scheme 24*) and they are rather toxic acting mostly as acetylcholine esterase inhibitors. Hydrolysis (cleavage of glycoside) of, e. g., α-solanin results in overall loss of its toxicity.

Recently, a series of 20 steroidal glycosides from *Solanum* (e. g., glycosides of diosgenin, solasodine, solasonine, etc.) was examined for their anticarcinogenic activities and the following conclusions were drawn: As regarding the sugar linkage, the glycosides possessing a terminal α-L-rhamnosyl moiety (β-chacotriose) are the most effective; as for the aglycon, the glycosides carrying a spirostanol aglycon showed the strongest activity, and even the aglycon without the sugar had strong activity [105]. Generally, saponins due to their large structural diversity have many biological effects. As a raison d'être of saponins in plants its defensive role against microbial pathogens and some predators is often reported. Many saponins were also tested for their antibiotic and anticancer activities, however, no detailed data for the function of their glycosidic moieties were given, therefore, it is beyond of the scope of this review.

4.2.1 Ginsengosides

Ginseng saponins, e. g., dammarane-type saponins are extracted from the root of *Panax ginseng*. They have been used in various formulations in oriental countries for more than 5000 years especially as a tonic [106]. Ginsengosides are highly glycosylated and their activity often differs depending on the number of glycosyl units attached. They can be interconverted by trimming by glycosidases and this is a way by which some more scarce ginsengosides are produced [107].

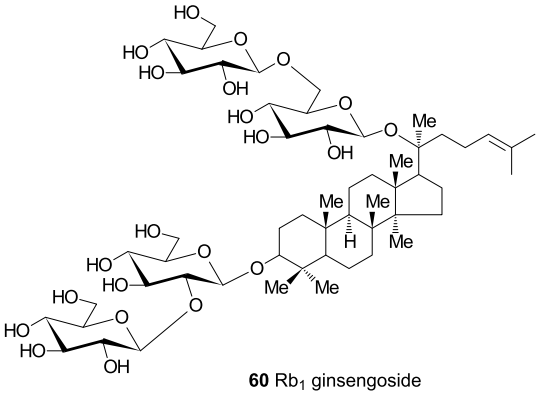
Ginsengoside Rb_1 (**60**) is a representative of the saponins derived from 20(*S*)-protopanaxadiol. It exhibits central nervous system-depressant and antipsychotic activity, protection against stress ulcer, increase of gastrointestinal motility and weak anti-inflammatory action. Rg_1 (**61**) – the major saponin of 20(*S*)-protopanaxatriol – shows weak CNS-stimulant action, antifatigue activity and blood pressure activity [108,109] (› *Scheme 25*).

Some other saponins have been reported to have potentiation activity on the nerve growth factor [110], stimulation of the pituitary-adrenocortical system [111], etc.

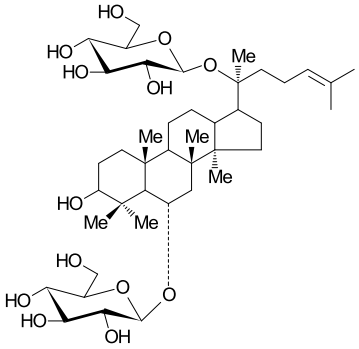
4.3 "Sweet Glycosides"

4.3.1 Osladin

Osladin (**62**) is a steroidal glycoside that is about 500-times sweeter than sucrose. It was isolated by the Czech chemists Jizba and Herout in 1967 [112] from the rhizomes of European fern *Polypodium vulgare* known for its very sweet taste. Its structure has been recently revised [113] by total synthesis. During the synthesis it was shown that minute changes in the structure result in total loss of the sweet taste. Thus, this is a typical glycoside whose overall structure – including the glycosidic part – is crucial for the respective activity.



60 Rb_1 ginsengoside



61 Rg_1 ginsengoside

Scheme 25

4.3.2 Steviol Glycosides

Leaves of *Stevia rebaudiana* (Compositae) are a source of several sweet glycosides of steviol (**63**) [114]. The major glycoside, stevioside (**64**), is used in oriental countries as a food sweetener and the second major glycoside named rebaudioside (**65**), which is sweeter and more delicious than stevioside, is utilized in beverages.

Stevioside (**64**) and rubusoside (**66**) taste somehow bitter, and show aftertaste. To improve the sweetness and the taste, modifications of sugar moieties of both the glycosides were performed by enzymatic glycosylations and/or enzymatic trimming. Cyclomaltodextrin-glucanotransferase (CGTase) efficiently catalyzes transfer of the α-glucosyl moiety (one or more) from starch onto the 4-OH of a glucosyl moiety. Stevioside was treated with this system and it resulted in a complex mixture of mono-, di-, tri-, and polyglucosylated derivatives on both existing glucose moieties of the original compound. Significant improvements of the quality of

taste were observed for most of the glucosylated products, especially for S1a and S2a, which were mono- and di- glucosylated at the 13-sophorosyl moiety of stevioside [115]. A remarkable enhancement of the intensity of sweetness was also observed for both these products, while glucosylation at the 19-*O*-glucosyl moiety (ester bound) resulted in a decrease of the intensity of sweetness (◉ *Table 1*).

Rubusoside was also transglucosylated by the same enzyme system and a large number of products were obtained. Strong enhancement of the sweetness intensity was observed for the products, which were di- or tri-glucosylated at the 13-*O*-glucosyl moiety. Tetraglucosylation at the 13-*O*-glucosyl moiety as well as glucosylation at the 19-*O*-glucosyl moiety led to a decrease in sweetness [116]. Therefore, after transglucosylation the products are "trimmed" enzymatically using β-amylase which releases maltose from the nonreducing end of the α-glucoside. By this treatment maltotriose- and higher α1-4-glucosyl chains were trimmed into monoglucosides and maltosides, which resulted in further improvement of sweetness. The commercial product of transglucosylated stevioside always undergoes this treatment [117].

Replacement of the 19-*O*-glucosyl group by a β-galactosyl group led to worsening of the taste [118]. Significant improvement of the taste quality was achieved by enzymatic transfructosylation at the 19-*O*-Glc moiety of both stevioside and rubusoside [119]. The β-fructofuranosyl moiety is, however, unstable and prone to hydrolysis.

This case is a practical demonstration of the advantage of a glycosidic moiety modification for optimization of physiological properties of the compound(s).

4.3.3 Glycosides of Glycyrrhetic Acid

The major sweet principle of licorice root (*Glycyrrhiza glabra*), glycyrrhizin (**67**) (◉ *Scheme 28*) (content ~ 4%), has been used as a sweetener and flavor enhancer in foods, tobacco products and also in medicine as an anti-inflammatory agent.

A structure-sweetness relationship study has shown that the monoglucuronide of glycyrrhetic acid is about 5-times sweeter than **67** and ca. 1000-times sweeter than sucrose [120]. Replacement of the second glucuronic acid by, e. g., xylose or glucose resulted also in an improvement of the taste and enhancement of sweetness [120].

The monoglucuronide of **67** is now commercially produced using a β-glucuronidase from yeast *Cryptococcus magnus* MG-27 that cleaves selectively only one GlcA moiety [121]. This compound has also better pharmacological properties such as, e. g., an inhibitory effect against skin carcinogenesis and pulmonary tumorigenesis (in mice) [122].

4.4 Glycosides as Aroma Precursors

Glycosides serve often as aroma precursors. It is known that many plants after crushing develop strong aroma. Many of these cases can be attributed to the hydrolysis of glycosides as released aglycons are more volatile than the respective glycosides.

Saliva contains α-glucosidase (ptyalin) and, therefore, experiments with α-glucosides of some aromatic alcohols were performed to enable slow liberation of the fragrances while chewing the food or a chewing gum. However, these approaches have not been very successful up to now.

Table 1

Sweetness quality and intensity of various glucosyl derivatives of stevioside

Compound	19-*O*-glycosyl (R1)	13-*O*-glycosyl (R2)	RS	QT
Stevioside (**64**)	-Glc	-Glc-Glc	160	0
Rebaudioside (**65**)	-Glc	-Glc-Glc Glc	210	+2
Rubusoside (**66**)	-Glc	-Glc	134	-2
S1a	-Glc	-Glc-Glc-α-Glc	180	+4
S2a	-Glc	-Glc-Glc-α-Glc-α-Glc	205	+4
S3a	-Glc	-Glc-Glc-α-Glc-α-Glc-α-Glc	117	+3
S1b	-Glc-α-Glc	-Glc-Glc	133	+2
S2b	-Glc-α-Glc	-Glc-Glc-α-Glc	136	+1
S3b	-Glc-α-Glc	-Glc-Glc-α-Glc-α-Glc	146	0
S2c	-Glc-α-Glc-α-Glc	-Glc-Glc	136	0
S3c	-Glc-α-Glc-α-Glc	-Glc-Glc-α-Glc	150	+1
S3d	-Glc-α-Glc-α-Glc-α-Glc	-Glc-Glc	121	+3

RS – relative sweetness to sucrose; QT – quality of taste, stevioside: 0, + better, - worse

Scheme 29

Another possibility is to use glycosides of some fragrances to be liberated from tobacco products (by pyrolysis). Since the respective glycosides are not volatile this would limit loss of aroma during storage.

4.4.1 Terpenoid Glycosides from Ginger

A typical example for glycosidic aroma precursors are the terpenoid glycosides discovered recently in fresh young ginger [123].

Linalool and geraniol contribute the most to the fresh ginger aroma. From fresh ginger β-glucopyranosides of 5-hydroxyborneol, 1,8-epoxy-*p*-menthan-3-ol (**68**), 2-heptanol, geraniol (**69**), nerol, citronellol (**70**), (*R*)-linalool (**71**), and some others were isolated. Enzymatic hydrolysis of these compounds with acetone powder prepared from ginger (cold acetone protein precipitate that usually contains intact enzymes from the respective tissue) liberated from the above glycosides the respective fragrance aglycons. This demonstrates that some fragrance components are stored in their glycosidic form and they are released during processing of the ginger.

5 Alkaloid Glycosides

Although alkaloids are mostly produced by plants where glycosylation occurs quite often there are only a few examples of natural alkaloid glycosides, and their biological activities have not been studied to a large extent. There are, however, many examples of alkaloid glycosides prepared artificially for a specific (pharmacological) reason.

5.1 Glycosides of Ergot Alkaloids

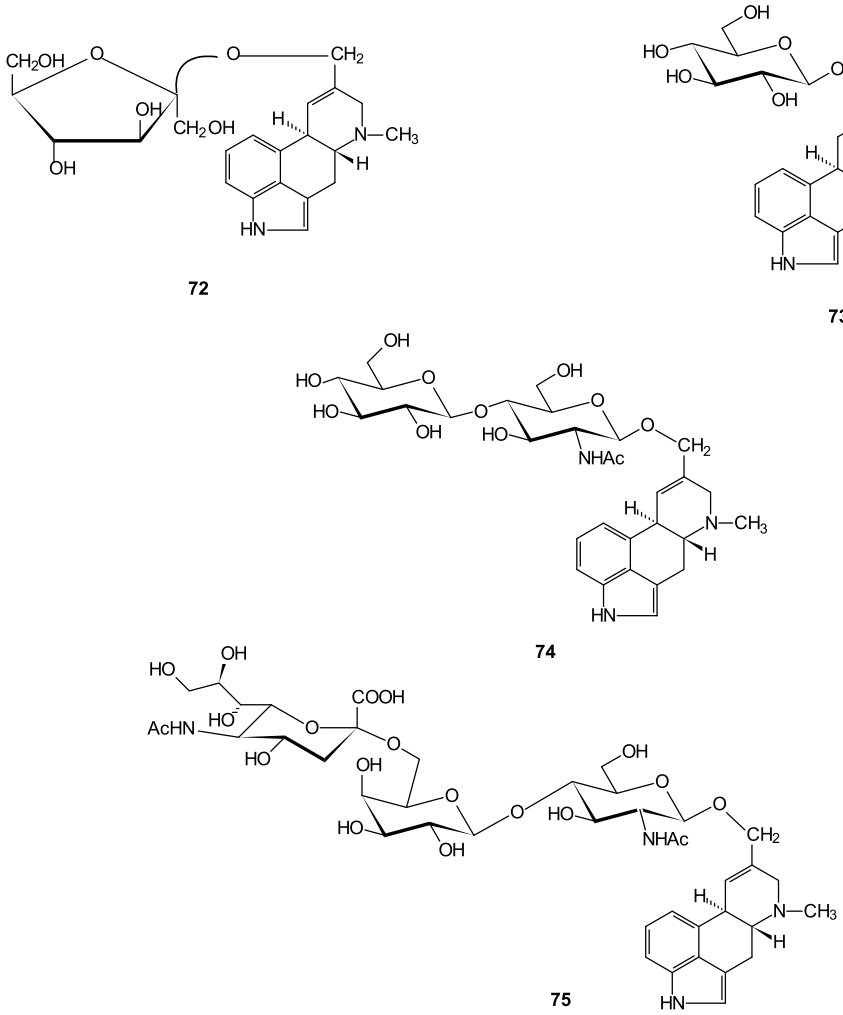
Ergot alkaloids that are produced by the parasitic fungus *Claviceps purpurea* (Ergot) [124] cover a large field of therapeutic uses as drugs of high potency in the treatment of uterine atonia, postpartum bleeding, migraine, orthostatic circulatory disturbances, senile cerebral insufficiency, hypertension, hyperprolactinemia, acromegaly, and parkinsonism [125]. Recently, new therapeutic uses have emerged, such as, for example, against schizophrenia, applications based on newly discovered antibacterial and cytostatic effects, immunomodulatory and hypolipemic activity [126,127,128,129]. Glycosides of EA were isolated as naturally occurring products, and recently a number were prepared by chemical and enzymatic methods. Their promising physiological effects stimulate future research in this field. The first natural EA glycoside, elymoclavine-*O*-β-D-fructofuranoside (**72**) (*Scheme 30*), was isolated from a saprophytic culture of *Claviceps* sp. strain SD-58 by Floss et al. [130]. This glycoside was formed from elymoclavine produced by the microorganism by the action of enzyme invertase present in the fungal mycelium.

Recently, a large series of glycosides of ergot alkaloids was prepared using both chemical and enzymatic methods [131,132,133,134]. Preliminary results obtained indicate that some of these derivatives could have very interesting activities compared to their aglycons.

Some glycosides of 9,10-dihydrolysergol and elymoclavine were tested for their inhibitory activity to prolactin secretion [135,136]. Only 9,10-dihydrolysegol-*O*-β-D-glucopyranoside (**73**) exhibited significantly ($p < 0.001$) higher inhibitory activity.

More systematic studies were performed on the immunomodulatory activity of these new alkaloid glycosides. A large panel of the glycosides, e. g., of elymoclavine and 9,10-dihydrolysergol was tested for their stimulatory activity on cytotoxic lymphocytes. These lymphocytes form the effector arm of cell-mediated immune responses to infection and tumors.

The effect of the alkaloid glycosides was tested on natural killer (NK) cell mediated cytotoxicity of the human resting and activated peripheral blood mononuclear cells (PBMC) against MOLT4 T lymphoma cells (resistant to lysis by fresh PBMC cells and sensitive to activated cells) [128,134,137]. All compounds were tested in a concentration range from 10^{-6} to 10^{-15} M. The maximum immunomodulatory effect was obtained at 10^{-10} M. These effects are mediated by cell surface receptors. After addition of free saccharides to the effector-target cell mixture, the cytotoxic activity of resting fresh lymphocytes has been enhanced in all cases. The most potent stimulation was observed by addition of glucose. The glycosylation of elymoclavine does not influence its cytotoxic activity, however in the case of DH-lysergol its cytotoxic-potentiating activity strongly increased especially in the case of the β-glucoside

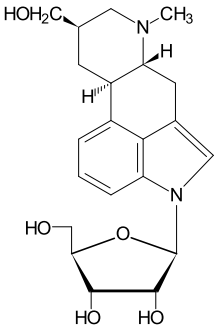


Scheme 30

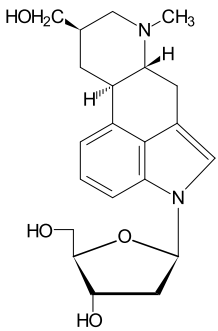
(**73**) and the β-lactoside (**74**). The lytic capacity of activated killer cells was not influenced by any preparation tested.

The effects of elymoclavine and DH-lysergol glycosides were tested also with the cytotoxicity of resting PBMC cells against the NK-sensitive cell tumor line K562 and against the NK-resistant RAJI tumor cell line [128,134,137]. Stimulation of NK cells against the sensitive K 562 was best with the DH-lysergol itself, its glycosylation lowered the stimulatory effects. Galactosylation of elymoclavine potentiated stimulation activity compared to the aglycon.

Interesting results were obtained in stimulation of NK cells against the resistant tumor cell line RAJI. The attachment of β-Glc and mainly Neu5Acα(2→6)Galβ(1→4)GlcNAcβ-*O*-



76



77

Scheme 31

glycosidic moieties to elymoclavine (**75**) had a strong stimulatory effect [134,137]. β-Galactosylation of DH-lysergol also potentiated its effects.

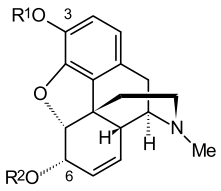
These and some other glycosides were further tested for their immunomodulatory activity on mouse splenocyte models (Balb/c and athymic nude Nu/Nu mice). Here mostly elymoclavine β-galactoside and lactoside had the highest activity [128].

A large panel of ergot alkaloid glycosides and their aglycons was tested for antiviral activities including anti-HIV activity against the replication of HIV-1(III_B) and HIV-2(ROD) in acutely infected MT-4 cells, for their activity in persistently infected HUT-78/III_B cells and for broad spectrum antiviral activity in E_6SM cells cultures against *Herpes simplex* virus-1 (KOS), *Herpes simplex* virus-2 (G), *Vaccinia* virus, *Vesicular stomatitis* virus, *Herpes simplex* virus-1 TK^- B2006 and *Herpes simplex* virus-1 TK^- VMW1837, in HeLa cell cultures against *Vesicular stomatitis* virus, *Coxsackie* virus B4 and *Respiratory syncytial* virus and in Vero cell cultures against *Parainfluenza*-3 virus, *Reovirus*, *Sindbis* virus, *Coxsackie* virus B4 and *Punta Toro* virus [134,138,139]. It was found, however, that virtually all alkaloids and their glycosides tested have cytotoxic concentration below the threshold of their antiviral activity. In some alkaloids, e. g., dihydrolysergol, their cytotoxity was considerably lowered by *N*-ribosylation (**76**) and deoxyribosylation (**77**) (*Scheme 31*). Testing of cytostatic activity of mainly *N*-glycosides of ergot alkaloid (ribosides and deoxyribosides) will be necessary.

Some selected β-galactosides of ergot alkaloids and respective aglycons (elymoclavine and chanoclavine) were tested for their capability to influence basal and forskoline stimulated adenylate-cyclase in ciliary protrusion (*recessus cilliaris*) of the rabbit eye. No significant effects were found. However, both ergot alkaloidgalactosides strongly diminished intraocular pressure in rabbits and their effect was considerably higher than in the respective aglycons [134]. This suggests their potential anti-glaucoma activity.

5.2 Morphine Glucuronides

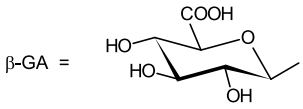
Morphine (**78**) is an important analgesic with a long history of usage. This drug has, however, unwanted side effects. Recently it was found that one glycosidic metabolite – morphine-β-6-



78 (morphine) $R^1 = H$, $R^2 = H$

79 $R^1 = H$, $R^2 = \beta$-GA

80 $R^1 = \beta$-GA, $R^2 = H$



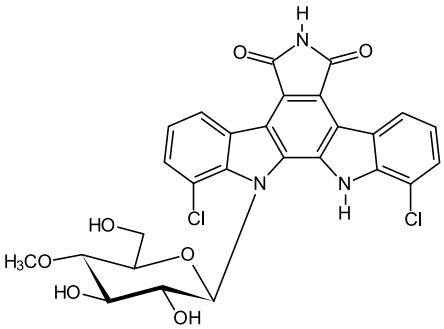
Scheme 32

glucuronide (**79**) – has quite interesting biological effects that are rather different from those of the parental drug.

Morphine has two nucleophilic sites that may be glucuronylated, a 3-hydroxy group on an aromatic ring and an alcoholic 6-hydroxy group.

Conjugation of the 3-hydroxy group occurs in many mammalian species, while glucuronylation at the 6 position appears to be unique to man [140]. This metabolite accumulates in blood of humans with chronic dosing to values greater than morphine [141]. Although the analgesic potency of **79** has been acknowledged for more than two decades, the potential clinical use of this glycoside has only recently been recognized [142]. Morphine β-6-glucuronide (**79**), but not the morphine β-3-glucuronide (**80**) (*Scheme 32*), binds to μ_1 and μ_2 receptors with affinities similar to morphine in mouse brain [140,141]. On the basis of the pharmacodynamic action the 6-glucuronide (**79**) is more than three-times more active than an equimolar subcutaneous dose of morphine in mice [140]. Recent clinical studies in cancer patients given **79** indicated that useful analgesic effects are achieved with an absence of nausea and vomiting [143] that is often caused by morphine itself. Interestingly, **79** present in plasma is distributed into the cerebral spinal fluid, but only one tenth compared to morphine [142]. The potency of morphine β-6-glucuronide is in part explained by an unexpectedly high lipophilicity of the folded form of the molecule. Studies [143] using force-field and quantum mechanical calculations indicate that the glucuronide conjugates of morphine can exist in conformational equilibrium between the extended and folded form of the molecule. The extended conformer, which predominates in aqueous media, is highly hydrophilic because it efficiently exposes polar groups of the molecule to the surrounding aqueous milieu. On the other hand, the folded conformers mask part of these polar groups and are much more lipophilic. The folded forms likely predominate in media of low polarity such as biological membranes [143].

Contrary to its 6-isomer (**79**) morphine-β-3-glucuronide is not an analgesic but it is a potent μ-opioid receptor antagonist. The 3-glucuronide also resembles morphine in that it cau-



81 rebeccamycin

Scheme 33

ses allodynia, a condition in which an ordinarily innocuous stimulus is perceived as painful [144].

5.3 Rebeccamycin

Rebeccamycin **81** (*Scheme 33*) is an interesting alkaloid-type antibiotic that is produced by *Streptomycetes* [145]. Rebeccamycin inhibits the growth of human lung adenocarcinoma cells and produces single strand breaks in the DNA of these cells. A related antibiotic without chlorine, staurosporin, produced by *Streptomyces staurosporeus*, was reported to have antifungal and hypotensive activity [143]. In both structures the 4-*O*-methyl-β-glucopyranosyl moiety forms an *N*-glycosidic bond. A certain analogy with the nucleosides can be traced which may be responsible for its antineoplastic activity.

6 Glycosides of Vitamins

Both hydrophilic and lipophilic glycosides of vitamins often occur in nature and some of them were prepared by chemical and biochemical methods. Recently, an outbreak of papers [146,147,148,149,150,151] was observed dealing with their chemistry and biology, and a comprehensive review on the biological significance of various vitamin glycosides was published [152].

Glycosylated vitamins have an advantage over the respective aglycons in their better solubility in water (especially the lipophilic ones), stability against UV-light, heat and oxidation, reduction in bitter taste and odor (e. g., thiamin), and resistance to enzymatic actions. Some of the vitamin glycoconjugates have altered or improved pharmacokinetic properties. For the synthesis and biosynthesis of vitamin glycosides the presence of a free OH group is mandatory.

We will discuss the vitamin glycosides at length not only because of the quite active research in this area but also for the reason that many vitamin glycosides occur in natural sources as vitamers or they are formed as important and physiologically active metabolites in organism.

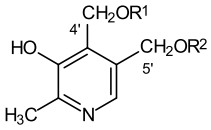
6.1 Water-Soluble Vitamins

6.1.1 Pyridoxine

Extensive research on biological activities has been performed on 5′-*O*-(*β*-D-glucopyranosyl)-pyridoxine **83** (*Scheme 34*), because it is a major form of pyridoxine (**82**, vitamin B_6) in plant-derived foods. Experiments in vivo and in vitro have indicated the lowering of uptake of vitamin B_6 caused by its *β*-glucoside **83** [153,154,155,156]. The presence of pyridoxine *β*-glucoside reduces the bioavailability of pyridoxine usually from plant material by 75–80% [157]. This compound (**83**) is cleaved partly only in the small intestine, but not in the liver [148]. A highly selective pyridoxine-*β*-D-glucosidase was found in the jejunal pig mucosa [149].
Less work was, however, devoted to *α*-glucosides, *β*-glucosides, and *β*-fructosides of pyridoxine, which occur less commonly in nature as a result of transglycosylations.
Recently, it was demonstrated that pyridoxine *α*-glucosides (**84**, **85**) serve nutritionally as well as pyridoxine in terms of transport across everted intestinal sacs, metabolic conversion to active form by liver or kidney homogenate, and the appearance of B_6-derivatives (pyridoxine, pyridoxal, and pyridoxal phosphate) in the blood of B_6-deficient rats after oral administration, while **83** serves very poorly as a B_6 nutrient [157]. Moreover, it has been reported that the 5′-*O*-(*α*-D-glucopyranosyl)-pyridoxine (**84**) does not inhibit the uptake of pyridoxine and is readily converted to pyridoxine in freshly isolated liver cells, while **83** competitively inhibits the uptake of pyridoxine into liver cells [158]. It was found that the 5′-glucoside (**84**) is cleaved in the liver about 5–6-times faster than its regioisomer 4′-*O*-(*α*-D-glucopyranosyl)-pyridoxine (**85**). These facts support the excellent nutritional efficiency of pyridoxine-*α*-glucosides, especially the 5′-isomer. Pyridoxine *α*-glucoside (**84**) has been observed to be much more stable against UV light irradiation and heating than pyridoxine itself [159].
The case of pyridoxine glycosides clearly demonstrates that type of glycosylation strongly modulates the biological activity. In addition, the type of glycosidic linkage (*α*- vs. *β*-) and the site of attachment at quasi-identical carbons also has a strong influence on the final biological activity of the drug.

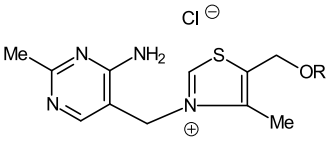
6.1.2 Thiamin

Thiamin (**86**, vitamin B_1) (*Scheme 35*) occurs in nature free and in phosphorylated form. Its glycosides have not been identified in natural material. The artificial glycosylation of



82 (pyridoxine) $R^1 = R^2 = H$
83 $R^1 = H$, $R^2 = \beta$-Glc*p*
84 $R^1 = H$, $R^2 = \alpha$-Glc*p*
85 $R^1 = \alpha$-Glc*p*, $R^2 = H$

Scheme 34



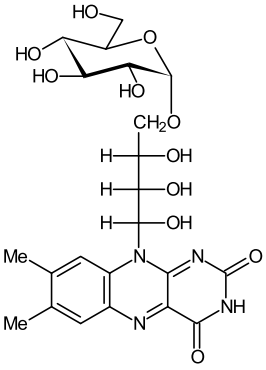
86 (thiamin) R = H
87 R = β-Gal*p*
88 R = α-Glc*p*
89 R^1 = β-Glc*p*NAc

Scheme 35

thiamin was motivated mostly by needs to remove unpleasant taste and odor of the compound and to increase its stability against UV light. *O*-*β*-Galactoside (**87**) [160], *O*-*α*-glucoside (**88**) [161], and *0*-*β*-*N*-acetylglucosaminide (**89**) [162] of thiamin were prepared by enzymatic synthesis using glycosidases. Biological activities were tested only with the *α*-glucoside. This compound, similarly to other glycosides does not have the specific thiamin odor and strong tongue-pricking taste, in contrast it is mildly sweet. *O*-*α*-Glucosylthiamine has 73% activity of a molar equivalent of thiamin hydrochloride, when its use by thiamin-deficient male rats on semisynthetic diet was examined in terms of its effect on the growth curve, food intake, liver weight, and hepatic thiamin content [161]. Pig liver *α*-glucosidase completely hydrolyzed **88** to glucose and thiamin thus some of the thiamin glycosides can be useful as food additives or in medicine.

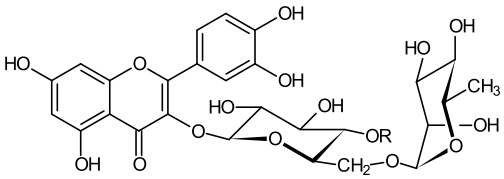
6.1.3 Riboflavin

Riboflavin (vitamin B_2) occurs in nature also in the form of the glycoside, e. g., as riboflavin 5′-*α*-D-glucoside in the liver (**90**) (*Scheme 36*). It is formed from free riboflavin by liver *α*-transglucosylase employing maltose as a donor for an *α*-glucosyl unit [163]. This glycoside is nearly bio-equivalent to riboflavin [164]; it enters the isolated hepatocytes more slowly than free riboflavin and it is hydrolyzed to the free vitamin upon entry.



90

Scheme 36



91 (rutin) R = H
92 R = α-Glcp

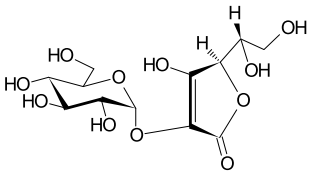
Scheme 37

6.1.4 Rutin

Rutin (**91**, vitamin P) (*Scheme 37*) is one of the most widespread quercetin glycosides (quercetin-3-*O*-rutinoside). Formally, it should be classified as a flavonoid but because of its activities (essential as a capillary protectant) it is included in the vitamin group. Rutin is a glycoside itself, composed of quercetin and the disaccharide rutinose [6-*O*-(α-L-rhamnopyranosyl)-D-glucose]. Its water solubility is rather low (ca. 0.1 g/l) and, therefore, by enzymatic glycosylation 4^{G}-α-D-glucopyranosyl-rutin (**92**) was prepared [165]. Its solubility was considerably increased (30000-times higher than rutin). Its improved biological activity has been predicted based on the finding that this glucoside is hydrolyzed by pig liver α-glucosidase [165].

6.1.5 Ascorbic Acid

Ascorbic acid (vitamin C) is involved in many biological processes, such as collagen synthesis, antioxidation, intestinal absorption of iron, and metabolism of some aminoacids. Search for and preparation of its glycosides was motivated mostly by the need for more stable compounds (resistant to oxidation) having the same or better bioavailability. The first glycoside of ascorbic acid was prepared by Yamamoto [166] and its structure was presumed to be 6-*O*-α-glucopyranosyl-L-ascorbic acid, and it was postulated that this glycoconjugate is formed in vivo by α-glucosidases. Its sensitivity to oxidation was the same as ascorbic acid and its biological activity was inferior to it. Later, another glycoside, 2-*O*-α-glucopyranosyl-L-ascorbic acid (**93**) (*Scheme 38*), was synthesized by an enzymatic regioselective transglucosylation [167]. This glycoside was found to show similar bioavailability as the aglycon in vivo [168] and in vitro [169]. This compound was, however, considerably more stable towards oxidative stress and UV irradiation. In fact, the glycoside **93** itself has no reducing power because of the substitution at the 2-OH group that is involved in redox reactions of ascorbic acid. Oral administration of **93** (guinea pigs) resulted in a remarkable increase of ascorbate in various tissues as well as in plasma [170]. Ascorbic acid was released from **93** at the mucosal side, and it was actively taken up across the intestinal membrane into the serosal side, whereas **93** itself permeated but poorly. Hydrolysis of **93** was mediated by maltase that could be inhibited by castanospermine. Ascorbate was transported by an active uptake system.
Ascorbate, because of its in vivo inhibitory action on melanin synthesis is also used as a skin-whitening agent in cosmetics (e. g., in Japan) [171]. Glycoside **93** was tested in vitro and in



93

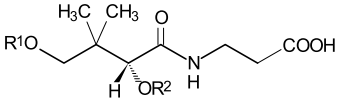
Scheme 38

vivo in humans and compared with ascorbate and ascorbic acid 2-phosphate that is conventionally used for these purposes. It was found that after percutaneous application of **93** the level of ascorbate sustained for a longer period than in the case of phosphate. Also the melanin synthesis (in B18 melanoma cells) was better inhibited by **93** than by ascorbic acid 2-phosphate. From these in vivo and in vitro results it was concluded that by using **93** the level of ascorbate sustains for a longer period. The compound has also UV protective activity against UV-induced damage of human skin keratocytes and fibroblasts.

6.1.6 Pantothenate

Pantothenic acid (**94**) (*Scheme 39*) (denoted as vitamin B_3 or B_5 – sometimes confused with nicotinamide) is widely distributed in animals, plants, and microorganisms as a component of CoA and thus plays an important role in many metabolic pathways. 4′-*O*-(*β*-glucopyranosyl)-D(*R*)-pantothenic acid (**95**) was isolated from tomato juice [172,173] as a growth factor of malo-lactic fermentation bacteria, responsible for the fermentative formation of malic and lactic acids in various food processes, such as for example, wine making. The structure of compound **95** was confirmed by the synthesis and also other glycosides, e. g., 2′-*O*-*β*-glucopyranoside (**96**) and respective glycosides from L and DL forms of **94** were prepared [173]. From comparative studies it follows that the 4′-glucoside was about 50-times more effective than the respective 2′-glucoside or the aglycon (all in D form), the L-form being ineffective. It was suggested that the activity of (**95**) was due to a specific membrane transport of malo-lactic fermentative bacteria. This case also demonstrates the significance of regioisomers of glycosides for their physiological activities.

Following these studies, D-pantothenic acid *β*-glucopyranoside (**95**) was prepared by action of various *β*-glucosidases [174]. Also *α*-glucoside of pantotheic acid was isolated, however, the



94 (D-pantothenic acid) $R^1 = H,\ R^2 = H$
95 $R^1 = \beta\text{-Glc}p,\ R^2 = H$
96 $R^1 = H,\ R^2 = \beta\text{-Glc}p$

Scheme 39

site of the glucosyl attachment was not exactly determined (proposed 4′- position) [175]. Studies of pantothenate metabolism in dogs have demonstrated in vivo glucosylation [176]. Following administration of an oral dose of pantothenate (3 mg/kg), about 60% of pantothenate was excreted in the form of its glucoside **95**.

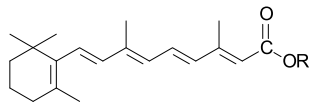
6.1.7 Nicotinamide

Glycosides of this vitamin (sometimes denoted as vitamin B_3) were not described, however, there exists an evidence that bound niacin from wheat bran (termed niacytin) has a single nicotinic acid moiety at least partially linked to an aromatic amine with glucose, xylose, and arabinose in a 6:3:1 molar ratio per molecule, with approximately three cinnamic acid esters [152,177,178]. It seems that these glycosidic complexes limit the bioavailability of the nicotinamide and for its liberation they must be treated, e. g., by soaking corn in a lime solution, traditionally performed in Central America during production of tortillas [179].

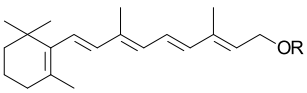
6.2 Lipophilic Vitamins

6.2.1 Retinol

Vitamin A has long been recognized as an essential nutrient in mammals for growth, vision, reproduction, cell differentiation, and the integrity of the immune system [180]. Different metabolic forms of vitamin A show different activities: 11-*cis* retinal is the major ligand for the opsins in vision, 9-*cis* and all-*trans* retinoic acid (**97**, RA) (*Scheme 40*) are active in cell differentiation and in embryogenesis, and retinol and its esters primarily serve as transport and storage forms of the vitamin [180]. In addition to fulfilling their physiological functions, vitamin A and its derivatives and analogs show therapeutic utility in several types of cancer and skin disorders [180]. After the important observation that retinoic acid reduced the onset and number of chemically induced papillomas in mice [181], many analogs, now termed retinoids,



97 (all-*trans*-retinoic acid) R = H
100 (retinoyl β-glucuronide) R = β-glucuronyl



98 (all-*trans*-retinol) R = H
99 (retinol β-glucuronide) R = β-glucuronyl

Scheme 40

were synthesized and tested for their efficacy [182]. The major problem that arose in using retinoids therapeutically was their toxicity [180].

Besides synthetic derivatives useful in therapy there exists a natural derivative of retinol (**98**), and retinoic acid(s) e. g., all-*trans*-retinyl β-glucuronide (**99**) [183] and all-*trans*-retinoyl β-glucuronide (**100**) [184]. These vitamin A glycosides were first identified as billiary metabolites of vitamin A, and they are now prepared also chemically for their favorable biological effects [185,186].

After administration of all-*trans*-, 13-*cis*- or 9-*cis*-retinoic acid, the respective retinoyl glucuronides (RAG) have been identified as the major metabolite in most mammal models including the human system. Like RA, RAG is biologically active in promoting the growth of vitamin A-deficient rats [187] and in the induction of differentiation of, e. g., HL-60 cells [188], but unlike RA, RAG is less cytotoxic and teratogenic. Like RA, RAG is also effective in the topical treatment of human acne [189], but unlike RA, it does not produce any side effects associated with RA therapy [189].

All-*trans*-RAG was investigated (in mice) for its teratogenicity because of its lower placental transfer compared to free RA [190]. Surprisingly, it was found to be a more potent teratogen than RA itself because intravenous or subcutaneous application of RAG was followed by its fast hydrolysis causing high levels of RA. Pharmacokinetic studies nevertheless confirmed lower transplacental transfer of RAG compared to RA [190].

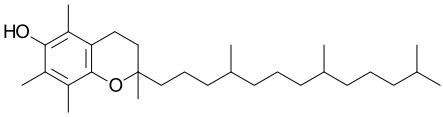
All-*trans*-retinyl β-glucuronide (**99**), another vitamin A glucuronide metabolite was prepared synthetically [185] and it was found to be equally effective in its growth-promoting activity as its aglycon [185,191]. The glucuronide, although converted to retinol in vivo, might also act physiologically in an intact form.

The mechanism of action for retinoid glucuronides is not established [192]. A novel action of the conjugates is suggested, because the glucuronides do not bind to cellular retinoic acid-binding proteins or to nuclear receptors for retinoic acid, although they are active prior to their hydrolytic cleavage.

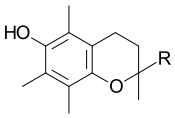
There exist other glycoconjugates of retinoic acid that have potential physiological application. Retinyl phosphate is mannosylated by rat liver microsomes using GDP-mannose in a way analogous to formation of mannophosphoryldolichol, however, the latter reaction is reversible compared to the former one [193]. Probably due to this irreversible reaction retinol is no longer available for its physiological functions in the organism. Besides retinoyl glucuronide, the corresponding galacturonide is formed in the organism at about 10–30% of the rate of the glucuronide formation [194]. Other mostly synthetic glycoconjugates such as retinoyl β-glucose, retinoyl adenosine, and retinoyl sucrose [195] show usually lower activities than RAG [196].

6.2.2 Tocopherol

Tocopherol (vitamin E) (**101**) (*Scheme 41*) is considered to be one of the most prominent antioxidants and radical scavengers in the organism, and it plays also an important role in fertility. It is generally accepted that it is incorporated into biological membranes and is especially effective as a lipid-peroxyl radical scavenger. Glycosylation of tocopherol is motivated mostly by the needs to increase its solubility. Therefore, an attachment of glucosyl unit(s) would be especially useful. Attachment of β-glucosyl, β-maltosyl, and β-oligomaltosyl units via the 6-OH group of tocopherol was achieved [197]. The biological applicability of such a compound



101 α-tocopherol



102 R = COOH
103 R = CH_2OH
104 R = CH_2O-α-Glc*p*

Scheme 41

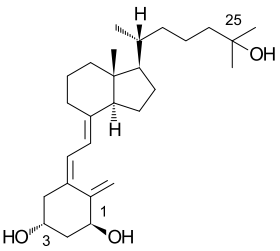
is, however, dependent on its deglycosylation in vivo because the free 6-OH group is essential for the redox properties of tocopherol.

Another probably more feasible strategy is based on the partly water soluble tocopherol derivative Trolox (**102**). The solubility of this compound in water is quite low, therefore enzymatic glycosylation of the corresponding alcohol (**103**) using α-glucosidase from *Saccharomyces* sp. was attempted [198]. The glycosylated product having the structure **104** is well water-soluble (> 1 g/mL) and its radical scavenging activity measured using the 1,1-diphenyl-2-picrylhydrazyl radical is nearly the same as that of α-tocopherol, Trolox, and ascorbic acid. Kinetic studies of the inhibition of the radical chain reaction of methyl linoleate in solution demonstrated that the peroxyl radical scavenging activity was not changed by the replacement of the phytyl side chain of tocopherol to the glucosyl group [199]. Its effectiveness was even higher than that of ascorbic acid when a liposomal suspension was exposed to a lipid-soluble radical generator 2,2′-azobis(2,4-dimethyl-valeronitrile) (AMVN). Also, formation of cholesteryl ester hydroperoxides in human plasma exposed to radical generators was considerably retarded by using compound **104**.

This is probably a good example for a positive influence of glycosylation by transforming a compound active almost solely in the lipid pool into the water pool of the organism. There is, however, one concern – glycosides bearing highly lipophilic moieties can act as nonionic detergents thus causing negative effects like hemolysis, etc. These potential problems must be addressed by thorough in vivo tests.

6.2.3 Calcitriol

Calcitriol (1α,25-dihydroxycholecalciferol, vitamin D_3, **105**) (*Scheme 42*) is involved in calcium metabolism. Glycosides of this compound occur in plants [200,201] and also as metabolites in mammal organisms. β-Glucopyranosides of **105** linked to the C-1, C-3, or C-25 hydroxyfunctions were tested in vivo (rats) and compared with the aglycon. These glycosides occur as potential sources of vitamin D in plants, e. g., *Solanum malacoxylon* [200] where



105

Scheme 42

they cause pathogenic calcifications in cattle grazing on this pasture. It was concluded that all three glycosides were equipotent but they were less active than the parental compound. The least active was the 3-β-glucopyranoside [150]. Their activity is probably a result of their hydrolysis [150,202] after administration *i.v.* or *p.o.*

Biological activity of the three β-glucopyranosides of **105** was studied in chicks and Japanese quails. While the 1- and the 3-glucoside showed no or only little effect on serum calcium, bone weight, calcium binding protein or calcium deposition in the egg shell, the 25-glucoside was found to be more than half as active as the aglycon **105**. The bioactivity of this glucoside parallels a higher binding constant to the intestinal calcitriol receptor compared to those of the two glucosides [203]. β-Glucuronides are the most prominent mammal metabolites of **105** [204].

7 Carbohydrate – Nucleic Acid Interactions

Traditionally, the glycan chains of the DNA-binding antibiotics have been viewed as molecular elements that control the pharmacokinetics of a drug, such as absorption, distribution, metabolism, and excretion. This notion changed a few years ago with the finding that the carbohydrate residues present in the calichenamycin antibiotics partially determine the selectivity of the process and even the calichenamycin aryltetrasaccharide (without possessing the enediyne ring) [39] binds well to the DNA.

Carbohydrate minor groove DNA [205,206] binders are neutral neoglycoconjugates, whose sugar residues are deoxygenated, thus showing a delicate balance between hydrophylic and hydrophobic domains (*Fig. 3*). There is rarely more than a single positively charged ammonium group in the respective carbohydrate and many of the sugars are of the 2,6-deoxyhexopyranose type. Often, the remaining hydroxy groups are further alkylated or acylated. Thus, the recognition process relies on just a few H-bonding interactions and is mostly driven by the hydrophobicity of the DNA-binding saccharides. This suggest that rather the complementary shapes, and hence specific van der Waals contacts between the carbohydrates and minor groove, may determine the site-selectivity displayed by many carbohydrate-containing minor groove binders [207]. Additionally, the relatively rigid carbohydrates may take advantage of the sequence-dependent flexibility of double stranded DNA to bind their target

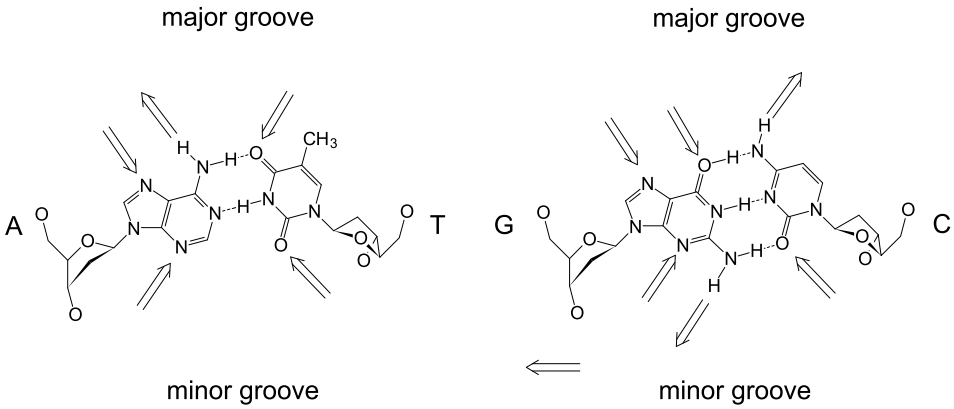


Figure 3
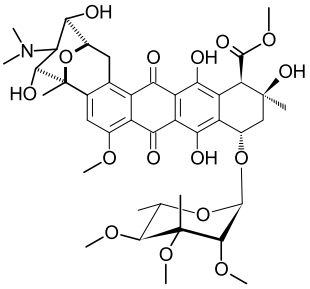
Substitution pattern of H-bonding donor and acceptor groups for adenine-thymine and guanine-cytosine base pairs in the major and minor groove

sites [208]. Furthermore, the hydrophobicity of DNA-binding carbohydrates may differentiate these from the hydrophilic and often negatively charged cell-surface saccharides, which are involved in protein recognition and may enhance the cellular uptake of the respective drugs.
Quite recently evidence has accumulated that some carbohydrates can be also effective DNA major groove binders. So far, there is only a limited number of examples of glycosides that have been found to interact with the DNA major groove [209]: neocarzinostatin (**32**, DNA cleavage agent); altromycin B (alkylating agent; nogalamycin **106** (*Scheme 43*), respinomycin (tandem-intercalative-groove binding ligands); neomycin-Hoechst33258 conjugate (dual-groove binding ligand).
Dual groove binding natural products such as nogalamycin have shown enhanced binding affinity over parent single carbohydrate (single groove binding) compounds (e. g., daunomycin **34**). Therefore, the application of synthetic chemistry and/or glycorandomization can result in novel ligands capable of dual groove recognition and increased binding affinity.



106 nogalamycin

8 Glycorandomization

The isolation of several sugar biosynthesis gene clusters and glycosyltransferases from different antibiotic-producing organisms, and the increasing knowledge about these biosynthetic pathways opened up the possibility of generating novel bioactive compounds through combinatorial biosynthesis. Recent advances in this area indicate that antibiotic glycosyltransferases show some substrate flexibility that can allow one to alter the types of sugar transferred to the different aglycons or, less frequently, to change the position of its attachment [211,212].

Recently, two complementary glycorandomization strategies have been described, namely, neoglycorandomization, a chemical approach based on a one-step sugar ligation reaction that does not require any prior sugar protection or activation, and chemoenzymatic glycorandomization, a biocatalytic approach that relies on the substrate promiscuity of enzymes to activate and attach sugars to natural products.

These "glycorandomization" approaches (occasionally referred to as "glycodiversification") are expected to foster our understanding of the role of sugars in a variety of glycoconjugates and the exploitation of these critical attachments. Neoglycorandomization that was developed by J. S. Thorson and coworkers relies on a broad variety of reducing monosaccharides without protection/deprotection methodology [212]. Neoglycorandomization is based on the selective formation of glycosidic bonds between reducing sugars and secondary alkoxyamine-containing aglycons [213] to form a library of "neoglycosides".

Sugars and acceptors containing secondary alkoxyamines are reacted with reducing sugars to generate oligosaccharide and glycopeptide mimics. Unlike primary alkoxyamines, which provide open-chain oxime isomers [112] secondary alkoxyamines react to form closed-ring neoglycosides. Presumably, such secondary alkoxyamines react with reducing sugars to form an intermediate oxo-imminium species, which then undergoes ring closure [113].

Chemoenzymatic glycorandomization [215,216] employs the inherent or engineered substrate promiscuity of anomeric kinases and nucleotidylyltransferases, and it attempts to provide activation pathways for the synthesis of nucleotide diphosphosugar donor libraries. In chemoenzymatic glycorandomization these activated sugar libraries, in turn, serve as substrates for inherently promiscuous natural product glycosyltransferases, thereby providing rapid chemoenzymatic means to glycodiversity. Such multienzyme, one-pot reactions offer an attractive alternative to the extensive synthetic manipulation typically required for chemical glycosylation strategies.

In the last three years a variety of examples has appeared supporting this robust methodology: Four glycosyltransferases from two distinct natural product biosynthetic pathways – calicheamicin and vancomycin – readily catalyzed reversible reactions, allowing sugars and aglycons to be exchanged. More than 70 differentially glycosylated calicheamicin and vancomycin variants were prepared. This study [217] suggests the reversibility of glycosyltransferase-catalyzed reactions and may be general and useful for generating exotic nucleotide sugars, establishing in vitro glycosyltransferase activity in complex systems. A monoglycosylated vancomycin library was prepared by the use of flexible glycosyltransferases with nucleotide diphosphosugar libraries [218].

High-level expression of three macrolide glycosyltransferases established a synthetic "tool kit" with such plasticity that 12 modified macrolide antibiotics (oleandromycin and erythromycin) have been readily created [219].

It is quite obvious that more interesting examples will follow bringing this method close to practical exploitation. Here, the basic knowledge of the role of carbohydrates in the biological activity of glycosides can be capitalized upon.

Abstract

Mucins are heavily *O*-glycosylated cell surface and secreted glycoproteins. In addition to orchestrating cell-extracellular matrix and cell-cell interactions in healthy organisms mucins are also the major carriers of altered glycosylation in carcinomas. Tumor-associated antigens displayed by cancer cells comprise oligosaccharide and glycopeptide motifs not encountered in the same locale or at the same frequency in healthy cells, and potentially confer a selective advantage to the tumor. Frequently tumor-associated antigens are under-glycosylated and prematurely sialylated, and it is these relatively simple saccharide and glycopeptide structures

that have been targeted to serve as drug candidates in most cases. A major goal is to assemble glycopeptide vaccine candidates based on partial mucin sequences and displaying tumor-associated antigens that can mount a potent immunological tumor-specific response when, in reality, the tumor has already coerced the immune system into a state of co-existence.

Keywords

Mucins; Vaccines; Cancer; Carbohydrates; Antigens; Glycosylation; Glycopeptides

Abbreviations and Symbols

Ac	acetyl
ADCC	antibody dependent cell-mediated cytotoxicity
APC	antigen presenting cell
Bn	benzyl
BCR	B-cell receptor
BSA	bovine serum albumin
CAN	cerium (IV) ammonium nitrate
CDC	complement dependent cytotoxicity
CTL	$CD8^+$ cytotoxic T-lymphocytes
DBU	1,8-diazabicyclo[5.4.0]undec-7-ene
DC	dendritic cell
DNA	deoxyribonucleic acid
EGF	epidermal growth factor
ELISA	enzyme-linked immunosorbent assay
ER	endoplasmic reticulum
Et	ethyl
Fmoc	9-fluorenylmethoxycarbonyl
GalNAc	*N*-acetyl galactosamine
GlcNAc	*N*-acetyl glucosamine
HPLC	high pressure liquid chromatography
IFN	interferon
Ig	immunoglobulin
IL	interleukin
KLH	keyhole limpet hemocyanin
MALDI-TOF MS	matrix-assisted laser desorption-time of flight mass spectrometry
MAPK	mitogen-activated protein kinase
MDa	MegaDalton
Me	methyl
MHC	major histocompatibility complex
MUC	mucin
NeuAc	*N*-acetyl neuraminic acid (sialic acid)
NMR	nuclear magnetic resonance
NOE	nuclear Overhauser effect
Ph	phenyl
ppGalNAcT	UDP-GalNAc-polypeptide-α-*O*-GalNAc transferase

PSA	prostate-specific antigen
RNA	ribonucleic acid
Su	succinimide
TAA	tumor-associated antigen
***t*-Bu**	tertiary butyl
TCR	T-cell receptor
TGF	transforming growth factor
$\mathbf{T}_H$	$CD4^+$ T-helper cell
TIPS	triisopropylsilyl
TSE	2-trimethylsilyl ethyl
UDP	uridine diphosphate
VNTR	variable number of tandem repeats

1 Introduction

Mucins are cell surface and secreted glycoproteins characterized by high levels of *O*-linked glycosylation, often over 50% carbohydrate by weight, which is generally densely clustered in repeating units of 20 or so amino acid residues (termed tandem repeats) of protein sequence rich in serine, threonine and proline [1]. The occurrence of tandem repeats is characteristic of "true" mucins and sets them apart from other heavily *O*-glycosylated proteins involved in, for example, lymphocyte homing and inflammation. The number of tandem repeats in any particular mucin expressed by the cells from different individuals is highly variable (a phenomenon termed polymorphism) hence the abbreviation VNTR: variable number of tandem repeats, that is often used to describe these repeating domains. Mucin molecules can also be cross-linked via intermolecular disulfide linkages between cysteine residues which results in a highly heterogeneous and hydrophilic matrix with molecular weights in excess of 1 MDa. Mucin molecules tend to have highly extended structures resulting from both intrinsic conformational preferences and intramolecular (hydrogen bonding) interactions typical of the α-*O*-glycopeptide linkage, and repulsive interactions between negative charges on densely clustered sialic acid residues. The highly charged and highly hydrated proteins form a viscous gel-like protective barrier between epithelial cells (other than skin cells that are water impermeable) and the external environment. Impressively, mucins which line the gastrointestinal tract allow endothelial cells to withstand the strongly acidic (pH 2) environment of the stomach and maintain a pH of 6–7 near the cell surface by binding bicarbonate secreted by gastric cells. In addition to the gastrointestinal tract, mucins are also secreted by epithelial cells of the tracheobronchial, respiratory, ocular and reproductive tracts, and serve to maintain tissue homeostasis, to trap and export invading pathogenic organisms as in nasal secretions as well as being implicated in numerous adhesion and signaling processes since, when bound to the cell surface, mucins can also mediate cell-cell interactions [2,3]. In this short review we aim to introduce the structure and occurrence of mucins and explain how their molecular characteristics influence their macroscopic physical properties and proposed biological activities. We will go on to describe their relevance to tumor development and metastasis and explain why mucins in particular have been targeted for vaccine development, primarily in the context of cancer treatment. In order to put the biological results in context we will describe the basic aspects of immunology

relevant to the design of mucin related anti-cancer vaccines and the general considerations for vaccine development. We will finally describe how anti-cancer vaccine candidates are prepared in the laboratory and summarize biological findings with such molecules.

2 Mucins: Structure, Function and Localization

Mucins are heavily *O*-glycosylated proteins. As the discovery of the number of ways in which proteins are modified by carbohydrates has increased, as a result of detailed glycobiological investigations, *O*-linked glycosylation has come to mean many things [4] but in the context of mucins it is specifically characterized by an α-*O*-glycosidic linkage between *N*-acetylgalactosamine (GalNAc) at the reducing end of the saccharide moiety and the hydroxyl groups of threonine and serine amino acid residues within the protein sequence [5]. The carbohydrate-rich VNTR domains in the wild-type mucin often contain densely clustered, short, branched oligosaccharide chains and the occurrence and role of glycosylation will be discussed in more detail in *Sect. 3* Mucins, for which 20 genes have been identified thus far [6], are often divided into two major classes: those that are membrane-associated (e. g. MUC1, MUC3, MUC4, MUC12) by virtue of a hydrophobic *C*-terminal transmembrane domain, and those which are constitutively secreted, for example MUC2, by specialized cells. The membrane associated mucins, though different in size, polymorphisms and sequence share several features (*Fig. 1*) [3,7].

Most membrane-bound mucins are proteolytically processed shortly after translation and MUC1 is translocated to the cell surface as a stable heterodimer (originating from a single encoded polypeptide) resulting in an *N*-terminal domain comprised mainly of the VNTR domain. The *C*-terminal domain possesses a hydrophobic transmembrane domain and a highly conserved short *C*-terminal cytosolic "tail" that can be phosphorylated on serine and tyrosine and is known to interact with elements of the cytoskeleton and β-catenin which is a mediator of the MAPK signaling pathway. Indeed activation of mucins, stimulated by ligand binding or a change in extracellular environment, with ensuing proteolysis of the MUC1 backbone and release of soluble mucin is accompanied with *C*-terminus internalization in complex with β-catenin suggesting transcription factor activity [2,8,9]. While it is feasible that the "normal" beneficial role for this function (association with intracellular signaling molecules) may be to protect epithelial cells from stress-induced apoptosis, this process has also been implicated in the hosts tolerance to cellular transformation (and chemotherapeutics) by over-expression of "oncoprotein" MUC1, allowing it to sequester various signaling proteins (such as c-Abl, c-Src, and EGF1 that interact with the cytosolic tail of MUC1 via their SH2 domains) at the cell membrane when they might otherwise initiate apoptosis [10]. In addition, membrane-bound mucins have extracellular EGF-like domains that are also implicated in signaling [11,12]. In this case association of the proteolytically released intramembrane domain of e. g. MUC4 (one of the best studied examples) exposes the EGF domain facilitating association with the integral membrane protein ErbB2 and initiates phosphorylation of ErbB2 which is involved in intracellular signaling through the MAPK pathway [2,11,13]. The roles for mucin-Erb interactions are largely speculative and poorly understood at the molecular level [2,3]. Secreted mucins, on the other hand, do not contain the *C*-terminal tail, or transmembrane domain and contain fewer EGF domains but instead (with the exception of MUC7) possess C and

N-terminal Von Willebrand factor D domains that are cysteine rich and facilitate intermolecular covalent cross-linking via disulfide bond formation. Apomucins are glycosylated as they traverse the Golgi apparatus and are localized exclusively at the apical cell surface by virtue of their transmembrane domain. Membrane associated mucins can also be secreted as a result of proteolytic processing of the cell surface protein or RNA splice variation that encodes the secreted protein.

3 Mucin Glycosylation

The repeating Ser/Thr/Pro rich sequence which is, in part, characteristic of each mucin is repeated from 10 to over 100 times (between 20 and 120 for MUC1) and although the num-

Figure 2
Modification of a peptide by ppGalNAcT glycosylates the peptide via an α-*O*-glycosidic linkage to serine and threonine (forming what is known as the T_N antigen). In healthy cells this structure is most commonly modified by core 1–core 4 forming glycosyltransferases. The core structure which predominates in any particular mucin depends on substrate and glycosyltransferase expression patterns but is generally core 2 in mucins with core 3 and 4 predominating in the gastrointestinal tract

Core 4

ber of repetitions varies from one individual to another (i. e. is polymorphic), the identity of the amino acids in tandem repeating sequences (in the VNTR domain) in typical mucins is generally known (◉ *Table 1*) [1].

The VNTR domain of a mucin can comprise 50–80% of the whole encoded protein sequence. The bulk of *O*-linked glycosylation occurs in these peptide sequences rich in serine, threonine and proline amino acid residues. The presence of proline appears important for efficient glycosylation by the enzyme UDP-GalNAc-polypeptide-α-*O*-GalNAc transferase (ppGalNAcT). The factors that influence whether a specific serine or threonine residue is glycosylated are poorly understood when compared to *N*-linked glycosylation but the recent disclosure of the crystal structure of ppGalNAcT, that adds the first *N*-acetylgalactosamine (GalNAc) residue of *O*-linked saccharides may yet provide insight into the origin of the apparent sequence context rules [14]. Peptides which are decorated with only this first sugar (GalNAc) give rise to what is known as the T_N antigen. Understanding the requirements for *O*-linked glycosylation is further complicated by the fact that at least fifteen ppGalNAcT enzymes exist, expression of which can be restricted to specific cell types and have been shown to exhibit different substrate specificities. ppGalNAcT I and ppGalNAcT II glycosylate "naked" (apomucin) peptide sequences whereas ppGalNAcT IV requires that the peptide is already glycosylated by ppGalNAcT I [15,16]. Despite the lack of a clear consensus sequence for *O*-linked glycosylation, the probability of serine and threonine residues being glycosylated can be predicted with some accuracy and Ser/Thr residues with proline located at the −1 and/or +3 positions are particularly favorable [17]. The T_N antigen is normally elongated to form one of the eight distinct "core structures" [5]. Core 1 and particularly core 2 are by far the most abundant core structures on mucins (◉ *Fig. 2*) in healthy cells though the prevailing core type is essentially the overall outcome of a competition between several glycosyltransferases for the same substrate. Core 3 and core 4 structures are also observed, though far less frequently, on mucins except in the intestinal tract [18]. Depending on the tissue type, the cores are often terminated by the addition of only a few saccharides, the blood group determinants for example, but usually with *N*-acetylglucsoamine, galactose, sialic acid, fucose and additionally with sulfate. The core structures from the breast epithelium are additionally elongated with polylactosamine repeating units and may comprise more than 15 monosaccharide residues. Typical mucin oligosaccharide structures are depicted in ◉ *Fig. 3*.

Normal mucin maturation is an iterative and dynamic process and shortly after expression the mucin that is displayed at the cell surface is only partially sialylated and a significant proportion of the oligosaccharides are neutral (uncharged). Maturation occurs as the cell surface membranes turnover and are recycled back to the *trans* Golgi where they undergo further sialylation before they are again transported back to the cell surface.

Once a peptide is glycosylated the attached *O*-linked saccharides make specific interactions with the peptide backbone that disrupt the formation of regular, or expected (based on protein sequence), secondary structure and promotes the formation of β-turns (◉ *Fig. 4*). The presence of a stable, defined, extended structure has been demonstrated by detailed NMR investigations of mucin and mucin-type glycopeptides which, in general display many more NOE's in the NMR spectrum than would normally be expected from a "randomly" glycosylated and unstructured short peptide sequence. The formation of α-helical conformations are particularly disrupted by *O*-glycosylated peptides. Specific to α-*O*-glycopeptides (the corresponding β-*O*-linked GalNAc does not exert the same influence) [19], the observed conformational pref-

Figure 4

Common β-turn motifs found in protein structures and possible hydrogen-bonding interactions between the carbohydrate and the peptide backbone that are believed to influence glycopeptide structure. Note that the turn-type structure is most clearly depicted in the central structure

erence has been attributed to stereoelectronic effects (the exo-anomeric effect in particular) and hydrogen bonding interactions between the N–H bond of the *N*-acetyl group of GalNAc and the amide carbonyl group of the proximal amino acid residue (◉ *Fig. 4*) in the underlying peptide sequence [20], and alternatively to hydrogen bonding interactions between the N–H bond of the *N*-acetyl group of GalNAc and the carbonyl group of the same (threonine) amino

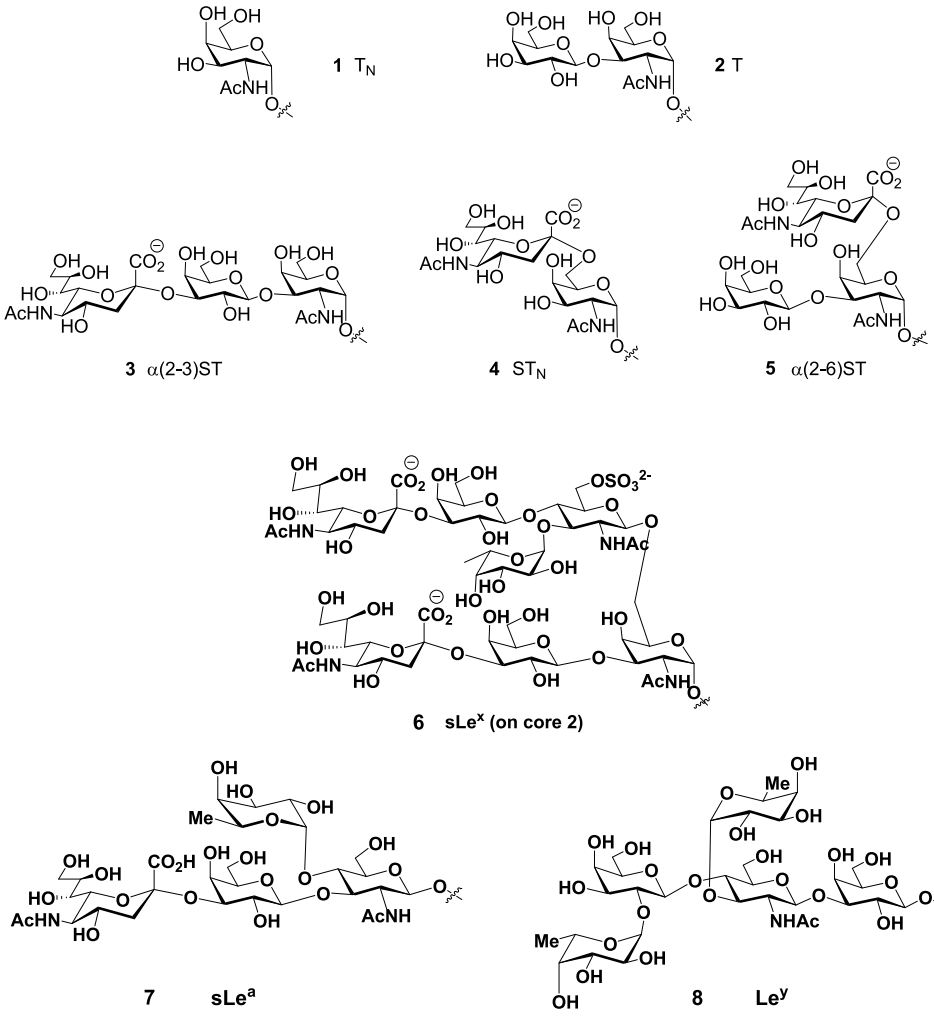

Figure 5

(a) Tumor-associated antigens are often under-glycosylated e. g. T_N (1), T (2), and α2,3-sialylT (3), and prematurely sialylated e. g. α2,6-sialyl-T_N (4), and α2,3-α2,6-disialyl-T_N (5). The premature sialylation on the 6-hydroxyl group of the *N*-acetylgalactosamine sugar precludes the formation of core 2 type structures. (b) Some Lewis antigens associated with cancer: (see ◉ *Table 2*) sLe^x (sialylLewis x, 6), sLe^a, (7) and Le^y (8) sLe^x (sialylLewis x, 6), sLe^a, (7) and Le^y (8)

acid residue [19,21]. Recent investigations suggest that H-bonding interactions are perhaps too weak for α-*O*-glycosylserine containing peptides and are not observed in conformational studies of model glycoamino acid diamides by NMR spectroscopy. This report suggests that inclusion of bridging water molecules may stabilize the extended conformation [22].

A detailed conformational analysis of glycopeptides corresponding to fragments of LI-cadherin (sequence: LAALD**S**QGAIV) containing native and cancer associated glycopeptide antigens was also described by Kunz and co-workers showing clear evidence for turn formation in peptides glycosylated on serine (bold) with the T_N (**1**), T (**2**), α2,3-sialylT (**3**), α2,6-sialyl-T_N (**4**), α2,3-α2,6-disialyl-T_N (**5**), and glycophorin structures (● *Fig. 5a*). Furthermore the report demonstrated dramatic and significantly different conformational effects depending on the identity of the appended saccharide. Peptides modified with T_N, T, and their mono and disialylated analogues all showed a more extended peptide structure relative to the unglycosylated peptide, and the larger (sialylated) saccharides orchestrating the formation of a more profound γ-turn motif. The T_N and T antigens, which are associated with tumors, imposed β type-III' and β type-II turn conformations on the peptide respectively [23]. In addition to the clear conformational preference of the appended saccharides it is additionally proposed that the charge repulsion originating from the large number of sialic acid residues in close proximity further dictates that mucins adopt an extended rod-like structure. Consequently the rod-like peptide sequence is often described as merely a scaffold on which saccharides are displayed. As mentioned above, the hydrophilic and charged nature of mucins dictates their physical properties, sequestering water molecules and ionic species they form a gel-like protective layer that coats the surface and are secreted from endothelial cells which are specialized for mucin production.

4 Mucin Glycosylation and Cancer

Mucins are the major carriers of altered glycosylation in carcinomas. The description of "abnormal" mucin expression and aberrant glycosylation in tumor cell lines is often attributed to the following key observations [3,24,25,26]. First, mucin expression is up-regulated in tumor cells or indeed present in tumor cells when the healthy cells are devoid of such mucin expression. This is exemplified by over-expression of MUC1 in many cancers, and with MUC4 expression in pancreatic cancer since the pancreatic epithelial cells do not normally express MUC4 [7]. Second, the carbohydrates present in the mucin are abnormal, often truncated. This is believed to stem from premature sialylation of the T_N antigen or T (also known as the T, Thomsen–Friedensreich) antigen which precludes further biosynthesis (i. e. prevents action of core 2 GlcNAc transferase) [27]. Additionally the T_N (**1**) or T (**2**) antigens themselves (or even the "naked" apomucin) may be present (● *Fig. 5a*). It has been proposed that the appearance of such antigens might result from mucin over-expression, the abundance of acceptor sites saturating the posttranslational apparatus. Indeed it has been demonstrated that over-expression of MUC1 (which is over-expressed in 90% of human breast carcinomas) is correlated with mammary gland transformation in vivo [12] and the truncated sialylT_N antigen (**4**, ● *Fig. 5a*) is a hallmark of this type of cancer and vaccines based on this epitope are in clinical trials for cancer therapy [25]. This hypoglycosylation of mucins can additionally arise from transformed cells which have lost core 2-forming β-1,6-GlcNAc transferase activity [28] or

Table 2

sT_N	X	X	X	X	X	X
T	X		X	X	X	
Le^y	X	X	X	X	X	X

over-express sialytransferases [27]. Depending on the physiological conditions, the peripheral sugars may vary and give rise to further tumor-associated antigens (◉ *Fig. 5b*). Expression of tumor-associated antigens is often a result of deregulation of glycosyltransferase expression or neoexpression of glycosyltransferases that are normally only observed during development giving rise to carbohydrate epitopes such as Le^a (Lewis a), Le^b, Le^x, Le^y (**8**), sLe^a (sialyl Lewis a), sLe^c, and sLe^x (**6**) which, though not unique to tumor cells, are the hallmark of various tumors as a result of their "wrong place-wrong time" appearance (◉ *Table 2*). Why specific sets of tumor-associated antigens predominate in particular carcinomas is unclear, however, it is likely that they have been selected from mixed populations to confer some advantageous properties to the tumor cell such as evasion from immunosurveillance machinery and increased adhesion through expression of selectin ligands (e. g. sLe^x) [29,30] that additionally facilitate tissue invasion and colonization of secondary sites [24].

Finally, in normal epithelial cells mucin expression is restricted to the apical domain (oriented towards the lumen) and consequently once proteolyzed or secreted the mucin is delivered to the lumen. However in many cancer cells the regulated apical expression of mucins appears corrupted with mucin expression (and secretion) also into intercellular spaces and into tissues and plasma. Indeed, soluble mucins are often observed in the blood of cancer patients. This seems to result in abnormal cell topology which inhibits normal cell-cell adhesive interactions (through increased negative charge and increased steric-bulk) facilitating tumor cell metastasis and evasion from the normal immune response. Pre-incubation of tumor cells with α-benzyl GalNAc which inhibits *O*-linked protein glycosylation (by diverting the biosynthetic machinery to the small molecule) reduces the metastatic potential of various tumor cell lines, directly linking glycosylation with malignancy [31]. A similar affect is observed when mucin expression is attenuated in cancer cell lines. For example, suppression of MUC1 over-expression in human pancreatic cancer cell line S2-013 using siRNA technology showed slightly increased adhesion in vitro (reduced over glycosylation) and reduced metastasis to secondary sites in vivo when re-administered to the pancreas of athymic mice [32].

Not all mucin over-expression is associated with carcinogenesis and much of what we know about mucins and their role in tumor development has been proposed as a result of knock-out studies in mice, where the expression of genes encoding various (apo)mucins has been completely abrogated. In contrast to the demonstrated relationship between MUC1 over-expression and tumor progression, in a recent study knock-out mice lacking the most abundant secreted

mucin in the gastrointestinal tract MUC2 were shown to have abnormal organ morphology and behavior [33]. Sixty-five percent of *muc2* null mice had developed tumors (that had originated from epithelial cells) in the colon, and the small and large intestine by the age of 1 year suggesting tumor suppressor activity for MUC2.

Given the importance of e. g. MUC1, and other cell-surface associated mucins in tumor development and metastasis [7] it is reasonable to presume that if altered mucin glycosylation accompanies tumor progression then any tumor-associated glycopeptide motif may be cancer cell specific and hence an immune response raised against aberrantly glycosylated MUC1, may serve to counter the spread of tumor cells. The replacement of regular core 1 and core 2 structures with their truncated T_N, T and sialylated T_N/T precursors is particularly prolific and it is these "unnatural" structures that have been the focus for much vaccine development since, potentially, they also allow antigenic elements of the peptide backbone, that would otherwise not be accessible in healthy cells to be targeted. The value of searching for vaccines against these epitopes is further validated by the clear demonstration of tumor-associated antigen (TAA)-specific glycopeptide conformations [23].

Because of the overwhelming evidence that aberrant mucin glycosylation is the hallmark of various cancers and may play a causative role in immune evasion and metastasis it is unsurprising that mucin based glycopeptides have been targeted for anti-cancer vaccine development. It should be noted that mucins are also *N*-glycosylated but targeting *N*-linked oligosaccharides on mucins has, to date, not received so much attention. However, over-expression of the glycosyltransferase GlcNAcT V which allows modification of *N*-linked glycans with *N*-acetyllactosamine repeats is associated with poor prognosis for cancer patients and is the focus of considerable investigation [25,34]. There are considerable advantages to pursuing mucin based vaccines. First, the vaccine itself may be otherwise non-toxic to healthy cells unlike many standard chemotherapy agents and is additionally non-radioactive so the potential for unpleasant side-effects may be reduced. However the use of cancer cell derived mucins as immunogens has been largely unsuccessful since they are heterogeneous. Generally containing a mixture of normal and tumor associated glycosylation, isolated mucins are very weakly immunogenic and recognized as "self." The remainder of this review will focus on how chemistry and biology have combined in an attempt to break this immunotolerance and to initiate a high quality cancer cell-specific response. The type of immune response generated has ramifications for the efficacy of the treatment. For example if B-cells are activated and antibodies are produced then they may only be beneficial in the clearance of non-adherent (e. g. metastasizing) tumor cells and circulating tumor cells after surgery since antibodies have limited capacity to penetrate the interior of solid tumors. Solid tumors also often shed their VNTR domains from the cell surface which neutralizes the effect of antibodies, though secreted mucins may still serve to activate B-lymphocytes (and hence T_H-cells) that express membrane-bound antibodies. Additionally, antibodies raised against tumor-associated antigens displayed by mucins (MUC1 in particular) have been shown to fail to recruit effector functions that kill cancer cells [35]. For reasons like this the use of antibodies raised against TAAs are often employed more widely as diagnostic agents or may possibly be utilized in antibody directed enzyme pro-drug therapy (ADEPT). A T-cell response, on the other hand, has the potential to invade cancerous tissue and is generally considered more selective than an antibody response and is consequently more desirable. Furthermore there is no requirement for additional effector molecules since activated cytotoxic $CD8^+$ T-cells can kill tumor cells directly through granule mediated exo-

cytosis. Carbohydrates are generally incapable of eliciting a cytotoxic $CD8^+$ T-cell response since, by themselves, carbohydrates are not presented by major histocompatibility complex (MHC) molecules though there is strong evidence that cells specialized for presenting tumor-associated antigens to T-cells are capable of presenting glycopeptides [36]. However, cancer cells have been shown to subvert the efficacy of a tumor specific T-cell response by attenuating the T-cells ability to transduce sufficient co-stimulatory signals [37]. The factors that need to be considered when initiating T-cell and B-cell responses to tumor-associated antigens are discussed briefly in the following section.

5 Generation of a Basic Immune Response

In order to discuss the current state of mucin-based vaccine technology within the context of generating an immune response, it is first necessary to understand a little about the way in which a basic immune response is initiated. For more detailed information regarding the induction and regulation of immune responses the reader is referred elsewhere [38,39]. The immune system is composed of two main branches: the innate and adaptive systems, that function together to protect the host against invading pathogens and the generation of potentially harmful cells within the body. This functionality is dependent upon the ability of the immune system to differentiate between healthy cells and those that require elimination. All nucleated cells in the body identify themselves to the immune system using antigens: short peptide fragments that act as "immunological identity cards." The adaptive immune system can be split into the humoral and cellular branches, and the implementation of either branch depends upon the successful recognition of antigens by lymphocytes. Antigens are continually exposed to scrutiny by both T- and B-lymphocytes, and those identified as foreign induce an immune response resulting in clearance. The adaptive immune response to a specific antigen becomes increasingly potent following each repeated encounter with the same specific antigen, and culminates in the development of long-lived antigen-specific immunological memory.

Cancer cells express many altered cell surface antigens that can potentially serve as targets for an anti-tumor immune response. However, as all cancers arise from the transformation of an otherwise healthy cell, many characteristics of the healthy cell are maintained, and consequently, the boundaries that enable the immune system to differentiate between "self" and "altered self" are often blurred. Immunological tolerance to "self" antigens is required to maintain tissue homeostasis and prevent the development of autoimmune disease. However, tolerance to "altered self" antigens facilitates disease progression. Hence, selectively breaking tolerance to promote tumor clearance is an area of intense research. The immune system often fails to clear tumors due to immunological tolerance towards altered self-antigens and cancer-mediated suppression of the immune response. Thus, whilst the immune system acts in a concerted manner to protect against invaders, the removal of well-established tumors is generally achieved through surgical intervention followed by chemotherapy or radiotherapy. However, during the early stages of cancer development, numerous encounters occur between T- and B-lymphocytes and developing cancer cells, and in some instances, successful elimination of these cells may occur. The activation of T- and B-lymphocytes during a basic immune response is summarized below.

6 Antigen Presentation

A T-lymphocyte (T-cell) response is triggered when antigens are acquired by professional antigen presenting cells (APCs). The APC family consists of B-lymphocytes (B-cells), monocytes, macrophages and dendritic cells (DCs), which are by far the most potent type of APC. Antigens are derived from endogenous and exogenous sources and both are assembled onto molecules of the MHC through "classically" segregated presentation pathways. Endogenous proteins synthesized in the cytosol are degraded in the proteasome into peptide antigens and transported to the lumen of the endoplasmic reticulum (ER), where they are assembled onto MHC class I molecules. The antigen-MHC complex is then transported to the surface of the APC (*Fig. 6*, *A–D*).

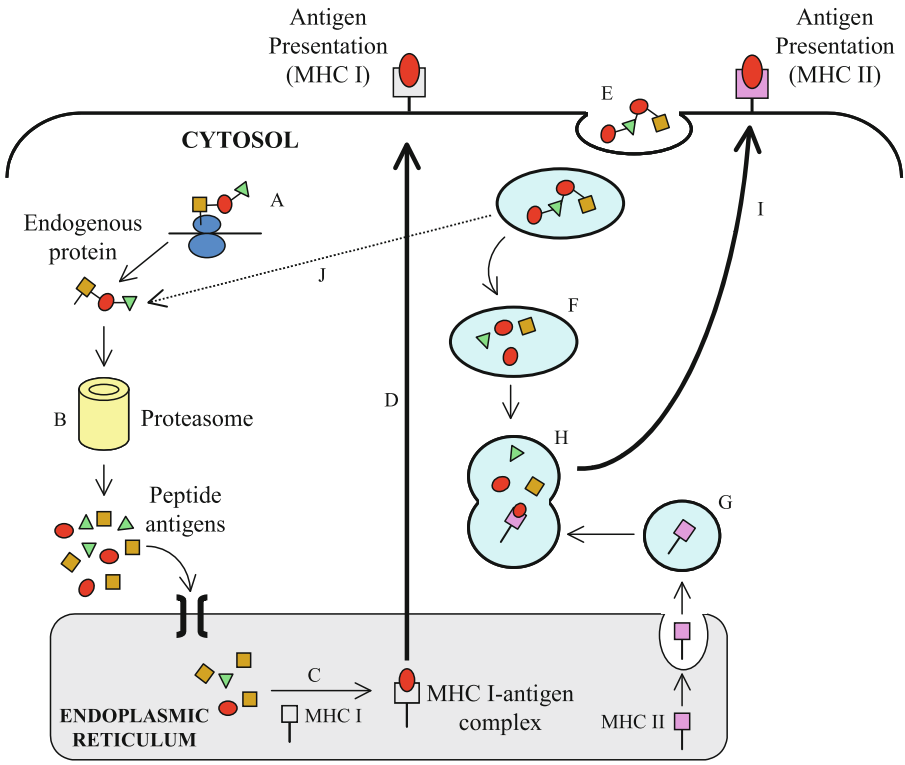

Figure 6

Pathways of antigen presentation by MHC class I/II molecules. *A–D*. Translation of cytosolic mRNA produces endogenous proteins that are degraded into antigen peptides by the proteasome. The antigens are imported into the endoplasmic reticulum and assembled onto MHC class I molecules that are subsequently transported to the cell surface. *E–I*. Pathogens and antigens are internalized by phagocytosis. Acidification of the intracellular vesicles triggers proteolysis generating peptide antigens that are assembled onto MHC class II molecules that are presented at the cell surface. *J*. Proteins derived from the phagocytosis of exogenous material can be presented on MHC class I molecules through the cross-presentation pathway. (Modified from Heath and Carbone [58])

Exogenous antigens are derived from intracellular vesicles following the phagocytosis of invading pathogens by macrophages or internalization of antigens by DCs and B-cells. Vesicular acidification triggers proteolytic processing of the captured proteins into antigenic peptide fragments (Fig. 6, *E–F*). Like class I, MHC class II molecules also reside in the ER lumen, although in contrast to class I, class II molecules are transported from the ER to the cytoplasm in vesicles which subsequently fuse with the acidified vesicles containing the processed antigen fragments. The antigens are then loaded onto the MHC class II molecule and the resulting MHC-antigen complex is presented on the APC surface (Fig. 6, *G–I*). Accordingly, MHC class I molecules are expressed on all nucleated cells that synthesize endogenous proteins with expression of class II molecules restricted to APCs that can phagocytose both pathogens and exogenous antigens. Antigen presentation by either class of MHC molecule can be crudely likened to a "Hot Dog in a bun," where the antigen is presented in an extended conformation (the "Hot Dog") bound by the vice-like structure of the MHC antigen binding groove ("the bun"). Antigens presented by MHC class I molecules are typically between 8 and 10 amino acid residues in length whilst those presented by class II antigens can be larger. DCs that have acquired antigen receive maturation signals from the site of infection and migrate to the lymphoid tissues where the antigen is presented to circulating T-cells. The T-cells interact with antigen-MHC complexes by virtue of antigen-specific T-cell receptors (TCR) expressed on their surface. Random variations in the amino acid sequence (and hence structure) of the antigen binding regions of the TCR generate specificity to a potentially limitless pool of antigens. Binding of TCRs to either MHC class I or II molecules is determined by the expression of co-receptors (CD8 or CD4) that define T-cell effector function. $CD8^+$ T-cells recognize antigens bound to MHC class I molecules and $CD4^+$ T-helper (T_H) cells interact with antigens bound to MHC class II. Binding of CD8 and CD4 receptors to MHC class I and II respectively increases the affinity of TCR binding to the MHC-antigen complex. Critically, activation of either $CD8^+$ T-cells or $CD4^+$ T_H cells is dependent upon at least two stimulatory signals which must be provided by the same APC.

7 Activation of $CD8^+$ T-Cells

At least two signaling events must occur to successfully initiate a $CD8^+$ T-cell response (Fig. 7*a*). First, the TCR must recognize a cognate antigen bound to MHC class I molecules presented by APCs. Several TCR-antigen interactions are required to stimulate efficient activation, with additional co-stimulatory signaling between CD28 on the T-cell and B7 molecules on the APC completing activation.

Signaling between CD28 and B7 acts to "validate" the authenticity of the antigen-TCR interaction. Indeed, T-cells that do not receive co-stimulation fail to initiate an immune response against a presented foreign antigen. This process is termed anergy, and once imposed, results in immunological unresponsiveness to the same antigen in subsequent encounters, even in the presence of co-stimulatory signaling. In the presence of co-stimulation, proliferation and differentiation of activated $CD8^+$ T-cells is driven by secretion of the cytokine interleukin-2 (IL-2). Binding of IL-2 to a cognate IL-2 receptor expressed on the activated cell stimulates clonal expansion into large populations of antigen specific cytotoxic T-lymphocytes (CTLs) (Fig. 7*b*). CTLs do not require co-stimulatory signals to initiate an immune attack, and

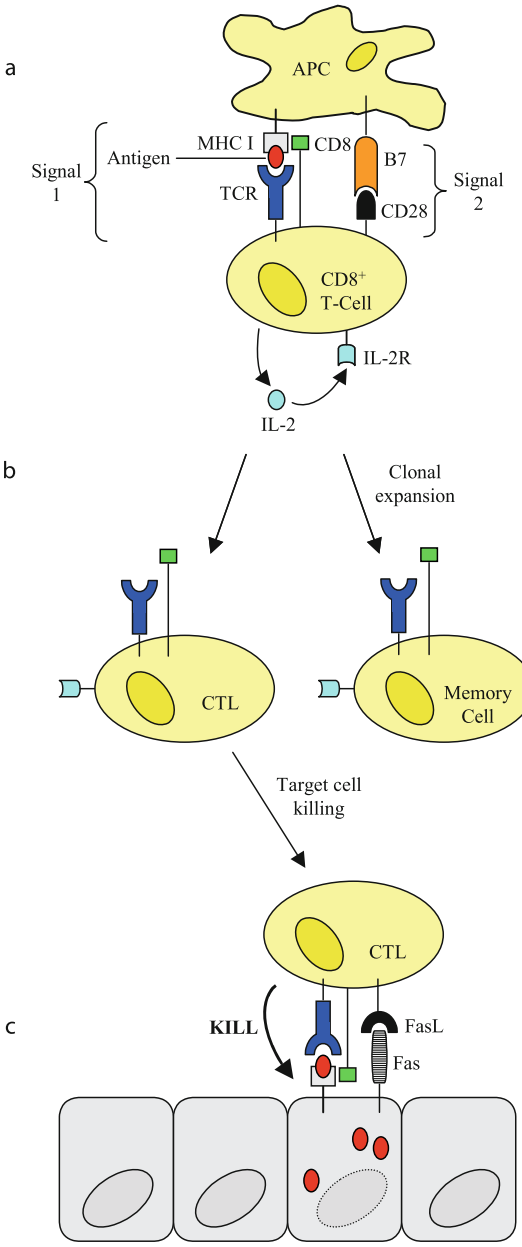

Figure 7

Activation of CD8+ T-cells. (a) APCs present antigens on MHC class I molecules that are recognized by the TCR and CD8 co-receptor respectively. Co-stimulation between B7 and CD28 is also required for activation and autocrine signaling via IL-2 drives clonal expansion. (b) Activated CD8+ T-cells develop into either CTLs or memory T-cells. (c) Killing of target cells by antigen-specific CTLs proceeds by either granule exocytosis or FasL-Fas interaction. (Modified from Janeway et al. [38] Figure 8.22)

are released into the body where they migrate to the peripheral tissues to search for target cells. A proportion of the expanded T-cell population may proliferate to form antigen-specific memory T-cells. The development of immunological memory (humoral or cellular) following a primary challenge against an encountered antigen enables a rapid and aggressive immune response to be re-generated against the same antigen should it be encountered in a subsequent infection, and thus forms the basis upon which the administration of prophylactic vaccines is founded.

8 CTL-Mediated Killing of Target Cells

CTLs can eliminate target cells by inducing programmed cell death (apoptosis) by two contact dependent mechanisms, the first of which is granule exocytosis. When a CTL encounters a target cell, an interface is formed between the TCR and the MHC class I-antigen complex. Formation of this interface stimulates the CTL to synthesize cytotoxic granules: specialized lysosomes containing factors that promote apoptosis. Once synthesized, the granules migrate to the junction between the effector and target cell where their contents are released. The target cell is breached by perforin, a small monomeric protein that inserts into the plasma membrane and polymerizes to form a pore through which the pro-apoptotic factors are delivered. Apoptosis is triggered by the release of powerful serine proteases called granzymes that degrade multiple substrates resulting in death of the target cell. Once apoptosis is initiated, the CTL can detach and engage new target cells. CTLs can eliminate target cells using a second contact dependent mechanism mediated between Fas ligands (FasL) on the CTL and Fas molecules expressed on the target cell. Once a FasL-Fas interaction is established, a proteolytic cascade is initiated that culminates in the activation of caspase enzymes, thereby promoting apoptosis (◉ *Fig. 7c*).

9 Activation of CD4$^+$ T_H Cells

Unlike CD8$^+$ T-cells, CD4$^+$ T_H cells do not exhibit cytotoxic effector functions, and are thus unable to destroy infected cells or those that display altered self-antigens. However, CD4$^+$ T_H cells are crucial in activating and directing the effector functions of other immune cells. Activation of CD4$^+$ T_H cells occurs in a similar manner to CD8$^+$ T-cells, the critical difference being the class of MHC molecule to which the antigen is bound. Recognition of an MHC class II-antigen complex by the CD4$^+$ TCR together with co-stimulatory signaling through B7 and CD28 drives activation, and autocrine signaling via IL-2 stimulates clonal expansion (◉ *Fig. 8a*).

The expanded population of T_H cells proliferate into either T_{H1} or T_{H2} subsets (◉ *Fig. 8a*), which are distinguished by the different cytokines they produce (◉ *Fig. 8b*). T_{H1} cells secrete numerous cytokines including IL-2 and interferon gamma (IFN-γ) that activate macrophages and CD8$^+$ T-cells. Cytokines secreted by T_{H2} cells include IL-4 and IL-5, which are involved in the stimulation of antibody responses (◉ *Fig. 8c*). In general, the cytokines secreted by one subtype of T_H cells are inhibitory to the development of the other, resulting in an effector response driven by either T_{H1} or T_{H2} but not both simultaneously. Thus, the secreted cytokine milieu determines if the overall CD4$^+$ T_H cell response is cellular or humoral which, as we will see, has important ramifications for vaccine development.

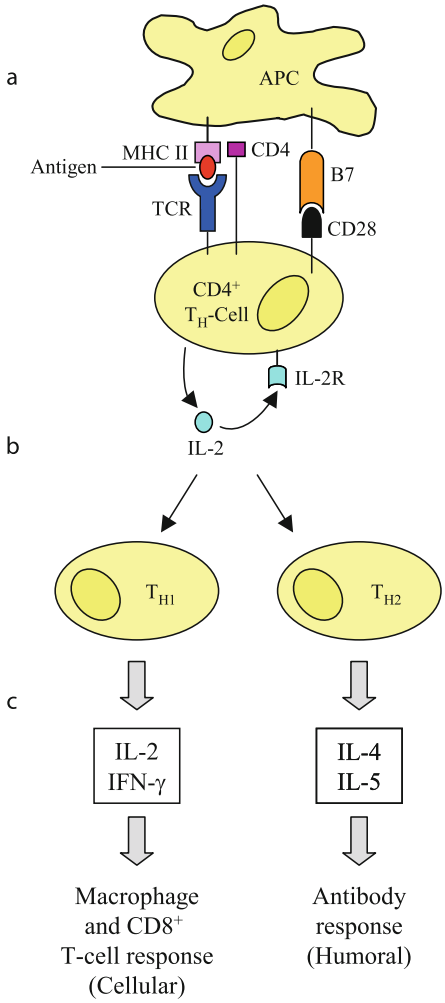

Figure 8
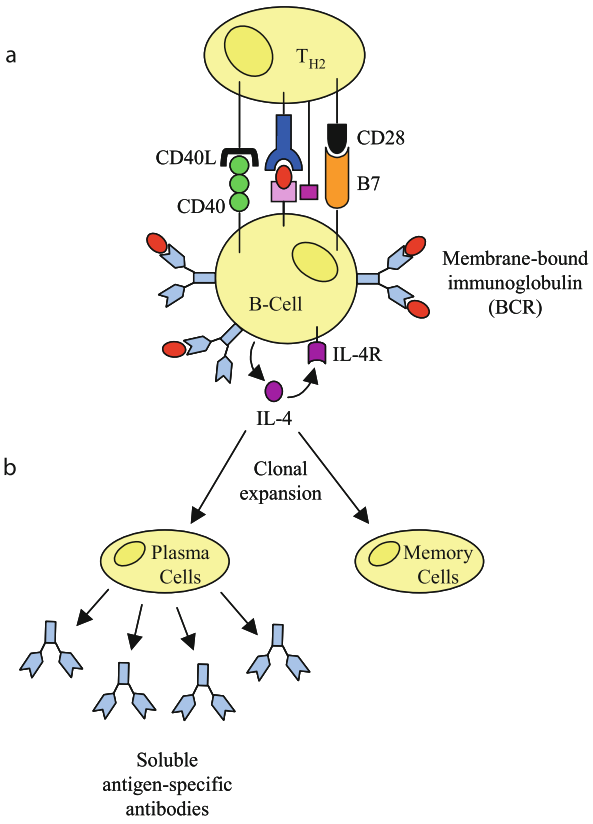
Activation of CD4⁺ T_H cells. (a) CD4⁺ T_H cells recognize antigen presented on MHC class II molecules. Co-stimulation and autocrine signaling are required to complete activation and drive clonal expansion. (b) Activated CD4⁺ T_H cells may proliferate into either T_{H1} or T_{H2} cells. (c) T_{H1} and T_{H2} cells secrete a variety of cytokines that stimulate the generation of either cellular or humoral immune responses. (Modified from Janeway et al. [38] Figure 8.10)

10 Activation of B-Cells

As previously mentioned, B-cells are APCs that must first acquire antigen to become activated. In contrast to the TCR expressed by T-cells, the B-cell receptor (BCR) consists of antigen specific cell surface immunoglobulins (IgM and IgD). Each B-cell expresses a BCR that is specific for a different antigen. Antigen specificity in the B-cell population within the body

derives from variations in the amino acid sequence of the antigen-binding region of the BCR molecule, which allows a huge number of potential antigen structures to be recognized. In contrast to $CD8^+$ T-cell and $CD4^+$ T_H cell activation, which proceed after each receives stimulatory signals from the same APC, the stimulatory inputs required for B-cell activation are provided from two different sources. The first is provided by antigen binding to a cognate BCR, which is subsequently internalized by receptor-mediated endocytosis. The antigen is processed and bound to MHC class II molecules that are transported to the B-cell surface. An activated $CD4^+$ T-cell provides the second signal upon recognition of the antigen-MHC class II complex. Co-stimulatory signaling between CD40L on the T-cell and CD40 on the B-cell completes activation, with secretion of IL-4 driving clonal expansion (◉ *Fig. 9a*).



◘ Figure 9
Activation of B-cells. (a) Binding of soluble antigen to a BCR is followed by receptor-mediated endocytosis and presentation by MHC class II molecules. An antigen-specific T_{H2} cell binds the antigen with its TCR and provides additional stimulation through CD28 and CD40L. Clonal expansion of activated B-cells occurs after autocrine signaling through IL-4. (b) Activated B-cells may proliferate into memory B-cells or plasma cells that secrete a large amount of antigen-specific antibodies

Activated B-cells undergo proliferation and may differentiate into antibody secreting plasma cells that facilitate antigen clearance, or become committed to a pool of long-lived memory B-cells (◉ *Fig. 9b*). Whilst the specificity of secreted antibodies derives from the complementarity determining regions of the molecule, the constant region of the molecule triggers different effector responses depending upon the antibody isotype. Binding of secreted antibody to a cognate epitope may target a cell for destruction either by antibody dependent cell-mediated cytotoxicity (ADCC), or by complement-dependent cytotoxicity (CDC).

11 Mucins, Immune System Evasion and Cancer Development

Cancers avoid immunological detection in a variety of ways including down-regulating the expression of immuno-stimulatory antigens, MHC molecules and co-stimulatory receptors required for immune cell activation [40]. These strategies are usually accompanied by a concomitant over-expression of immuno-modulatory cytokines [40] such as transforming growth factor-beta (TGF-β), which imposes numerous immuno-suppressive effects [41]. TGF-β-specific impairment of murine DC migration and antigen presentation has been observed [42] whilst expression of perforin, granzyme A, granzyme B, FasL and IFN-γ by CTLs is also inhibited [43]. A TGF-β-dependent increase in MUC4 expression is observed in pancreatic adenocarcinoma [11], an effect which is likely to contribute to cancer development, as MUC4 silencing with antisense MUC4 RNA was observed to suppress the growth of pancreatic tumor cells [13]. Premature termination of glycosylation is a hallmark of cancer-associated mucins, and the presence of such structures facilitates immune evasion, thereby contributing to disease progression. Addition of recombinant MUC1 displaying *O*-linked sialylated core 1 (sialyl-T) oligosaccharides to human DC impaired maturation and activation capacity in vitro [44]. Moreover, secretion of sialyl-T_N-MUC1 by numerous pancreatic tumor cell lines abrogated DC-mediated T-cell activation [45]. Secretion of MUC1 by ovarian, pancreatic and breast cancer cells blocked T-cell activation directly [46], and induces T-cell anergy that was reversible by addition of IL-2 [47].

One of the ways in which the immune system eliminates unwanted cells from the body is by CDC. CDC proceeds following the secretion and binding of specific classes and isotypes of immunoglobulins (IgM, IgG1 and IgG3 in humans) from B-cells to target cells. Blood serum from patients vaccinated with QS-21 and keyhole limpet hemocyanin (KLH) conjugated to either clustered T, sT_N, a 32 amino acid MUC1 peptide displaying *O*-linked T_N or the unglycosylated MUC1 peptide alone produced antigen-specific antibodies of the appropriate classes and isotypes to mediate complement fixation [35]. These antibodies bound to MCF-7 cancer cells expressing sT_N, T, MUC1, GM2, globoH, and Le^Y in vitro but failed to induce lysis by CDC. In contrast, parallel experiments revealed that antibodies generated against the expressed glycolipid antigens directed CDC efficiently [35]. From these observations it was proposed that the extended rod-like structure of glycosylated mucins projecting away from the cell surface may hinder the recruitment of certain immune system components towards cells that express them [35]. However, alternative immunoglobulin-dependent mechanisms of target cell clearance are not inhibited by the molecular architecture of cancer-associated mucins, as antibodies from breast cancer patients vaccinated with a KLH-MUC1 peptide conjugate promoted ADCC on MUC1 expressing cancer cells in vitro [48]. In contrast to CDC however,

the observed ADCC occurred by recruitment of natural killer cells to eliminate targeted cancer cells [48] rather than the components of the complement cascade.

The spread of cancer occurs following metastasis from the site of transformation and requires that cancer cells disengage from the primary tumor and adhere to new cells and target tissues elsewhere in the body. Galectin-3 is a galactoside-binding lectin expressed on the surface of endothelial cells. Addition of recombinant galectin-3 facilitated the adhesion of MUC1 positive, but not negative breast and colon cancer cells to human umbilical vein endothelial cells in vitro [49]. The observed adhesion was largely dependent upon an interaction between galectin-3 and the MUC1 cancer-associated T antigen, as removal of T from the surface of cancer cells reduced binding. Furthermore, the distribution of MUC1 on the surface of the cancer cell was altered following galectin-3 addition, and the observed adhesion to endothelial cells markedly reduced by co-incubation with antibodies specific for E-Selectin and CD44H, suggesting that the galectin-3-T interaction facilitates the adhesion of cancer cells to epithelial targets by unveiling adhesion molecules previously masked by cancer-associated MUC1 [49].

However, an oncogenic capacity of tumor-associated MUC1 is not restricted to the hypo-glycosylated extracellular domain. In response to damage of cellular DNA, the tyrosine kinase c-Abl is targeted to the nucleus of the cell where it promotes apoptosis. The cytoplasmic domain of MUC1 confers resistance to apoptosis in response to DNA damage by binding to c-Abl, thus preventing its import into the nucleus [10]. The MUC1-c-Abl interaction therefore allows DNA damage to accumulate, which may contribute to cancer development and/or progression. The induction of cellular apoptosis acts as a safeguard whereby potentially deleterious cells undergo programmed destruction before they can cause harm to the body. Activation of the anti-apoptotic Bcl-$_{XL}$ and phosphoinositide 3-kinase pathways was observed in MUC1 transfected rat 3Y1 fibroblast cells in vitro [50]. Moreover, MUC1 circumvents apoptosis in response to treatment with the chemotherapeutic agent cisplatin [51], pro-apoptotic drugs 1-β-D-arabinofuranosylcytosine and gemcitabine [50] and in response to hypoxic stress [52]. Collectively, these observations demonstrate the involvement of cancer-associated mucins not only in the process of immune evasion, but also in the process of cellular transformation itself.

12 Considerations for the Design of Mucin-Based Vaccines

The paramount feature of any synthetic vaccine molecule is safety. Vaccines must exhibit a negligible level of toxicity and have very few side effects. The molecule should be inexpensive to produce, soluble and chemically stable. Since the number of antigen-TCR interactions influences the efficiency of T-cell activation, the in vivo stability of the vaccine and rate of biological clearance must also be considered. Synthetic vaccines against cancers that express aberrantly glycosylated mucins are generally comprised of one or more TAAs that may be covalently conjugated to a carrier molecule. These immunogenic molecules serve to modify the chemical properties of synthetic antigens (e. g. improved solubility) and facilitate transport across membranes within the body. For a molecule to be an effective carrier, several criteria must be satisfied. Firstly, it must be safe to use with minimal toxicity and side effects, it must be soluble and easily produced with minimal molecular heterogeneity. The molecule must be amenable to chemical modification and conjugation to target antigens and lastly, it must be immunogenic to seed cross-reactivity to the conjugated antigen.

On healthy cells, the MUC1 peptide backbone is shielded from immune detection by an elaborate network of carbohydrates displayed upon the molecule. Hypo-glycosylation of mucins on cancer cells exposes cryptic peptide motifs and generates mucin-based glyco-antigens (e. g. T, T_N, sT_N) that can serve as TAAs in vaccine design. Consequently, synthesis of mono and multi-valent peptide and glycopeptide vaccines is an area of intense research. The synthesis of ever more complex multi-valent vaccines may pave the way forward in a multi faceted approach to cancer therapy, exploiting an array of peptide and glycopeptide TAAs that generate a simultaneous immune response against multiple targets. Multi-valent vaccines aim to provide the immune system with molecules that represent the antigenic architecture expressed on the surface of transformed cells. However, as the total number of aberrantly glycosylated mucins expressed on cancer cells may not be known, the number of mucin-based TAAs identified thus far may act as a limitation to vaccine efficacy. Furthermore, to facilitate the induction of a potent immune response, the design of synthetic vaccine molecules must proceed in a way that allows completely intact TAAs to be presented by APCs following internalization and proteolytic processing.

Tumors can be considered as a mixed population of cells, each of which is genetically unstable, resulting in the generation of a large number of heterogeneous cell surface antigens. It is postulated [53] that cancer progression stems directly from this antigenic heterogeneity and is, paradoxically, facilitated by an active immune system that destroys highly immunogenic cells whilst leaving those that do not invoke an immune response to proliferate. This process is termed immuno-editing and may inadvertently provide the growing tumor with a means of escape from clearance. Critically, antigenic heterogeneity may facilitate tumor adaptation against therapeutic agents that do not promote rapid clearance. The process of immuno-editing has profound implications in relation to the design of mucin-based vaccines. In many cases, structural characterization of mucin-type antigens prior to chemical synthesis requires that an established tumor be surgically removed. However, it is likely that many of the aberrant structures selected for synthesis and incorporation into vaccines are those that, due to immuno-editing, exhibit the lowest intrinsic levels of immunogenicity. Poor immunogenicity notwithstanding, expression of these "edited" antigens are nonetheless likely to be restricted to cancer cells alone, and as such should not be overlooked in vaccine design. Indeed, attempts to break tolerance using synthetic vaccines that display poorly immunogenic altered "self" antigens often rely upon the use of immunological adjuvants, molecules that, when mixed and co-administered with a vaccine boost the immune response against the associated antigen. Due to the poor immunogenicity of some TAAs, the choice of adjuvant can be critical in determining the effectiveness of the induced immune response. In many cases however, the use of vaccines in an adjuvant setting directs a sub-optimal induction of immune responses. Characterization of the adjuvant-mediated augmentation of immune responses to synthetic MUC1 [54], and glycosylated MUC2 [55] conjugate vaccines revealed high antigen-specific antibody titers with no direct evidence of CTL activation.

The generation of an immune response is most efficient when antigens are presented to T- and B-cells by APCs in a wholly biological context. Direct presentation of antigens by APCs negates the requirement for immunological adjuvants and provides an environment rich in essential co-stimulatory molecules. DCs can be isolated from the blood of cancer patients and provided with mucin-based antigens in vitro that allow processing and presentation to occur in the absence of immuno-subversion by established tumors. Thus, a pool of antigen presenting

DCs are generated that can be re-introduced to the patient (adoptive transfer). Adoptive transfer of DCs pulsed with lysate obtained from tumors that express cancer-associated mucins may potentially provide a means of exploiting a large number of hitherto unidentified mucin-based TAAs. As discussed above (see ❯ *Sect. 4*), premature termination of mucin glycosylation is a cancer-specific phenomenon that produces a pool of altered self TAAs. An interesting question that arises from this observation is "are these TAAs derived exclusively from the exposure of mucin core peptide sequences following the premature termination of glycosylation?" Murine DCs were observed to internalize, process and present MUC1 glycopeptides on MHC class II molecules in vitro [36], demonstrating that *O*-linked carbohydrate groups are not removed during antigen processing and suggesting that the poor immunogenicity of MUC1 stems not from the inability of MHC molecules to bind glycopeptides, but rather, from a reduction in the interaction between TCRs and MHC-glycopeptide complexes caused by carbohydrate presentation [36].

Furthermore, lymph node lymphocytes isolated from colorectal carcinoma patients and stimulated with MUC1 transfected B-cells in vitro produced CTLs that lysed MUC1 expressing targets cells [56]. Significantly, target cell lysis was enhanced by inhibiting *O*-linked glycosylation with phenyl-*N*-acetyl-α-D-galactosaminide, and was blocked completely by co-incubation with anti-T monoclonal antibodies [56]. Lysis was similarly titrated by addition of a Galβ1-3GalNAc disaccharide [56], demonstrating in vitro at least, that CTL recognition of mucin-based carbohydrate antigens can contribute to the clearance of MUC1 expressing cells.

13 Processing of Mucin-Based Vaccines

The apparent dichotomy in antigen presentation pathways (❯ *Fig. 6*) has important implications for mucin-based vaccines and serves to highlight the challenges faced in vaccine design. As vaccines are essentially exogenous antigenic molecules injected into the bloodstream, any resulting immune response is likely to proceed through the "classical" pathway of presentation by MHC class II molecules to $CD4^+$ T_H cells. This pathway excludes the presentation of vaccine-derived antigens by MHC class I molecules and hence, the production of antigen-specific immunoglobulins is frequently observed with activated CTLs being generally excluded from the immune response.

However, certain subsets of DCs can prime $CD8^+$ T-cell responses against exogenous antigens presented on MHC class I molecules in a process called cross-presentation [57] ❯ *Fig. 6*, *J*). Cross-presentation of exogenous antigens to $CD8^+$ T-cells is well documented in viral immunity (reviewed in [58]), and a more detailed understanding of the molecular events that transpire during antigen processing may enable specific features of synthetic mucin-based vaccines to be modified to facilitate the processing of exogenous mucin-based antigens by this pathway, thus increasing the chances of generating cancer associated mucin-specific CTLs to sites of cancer development in vivo.

Interestingly, several reports demonstrate that direct recognition of MUC1 peptide sequences by cognate TCRs can occur without a requirement for proteolytic processing of antigen or presentation by MHC molecules [59,60,61,62]. It is generally believed that the highly ordered, repetitive rod-like structure of the MUC1 VNTR domain enables direct TCR recognition

by virtue of multiple antigenic motifs that allow numerous TCR interactions to occur, thus bypassing the requirement for MHC-based stabilization of a limited number of TCR-antigen complexes. Generation of so-called "MHC-unrestricted" MUC1-specific CTLs that eliminate MUC1 expressing myeloma, breast and pancreatic cancer cells has been demonstrated in vitro [59,60,61,62]. Significantly, MHC-unrestricted lysis of MUC1 expressing cancer cells was abrogated in vitro by the addition of anti-MUC1 peptide antibody [60], suggesting that aberrant glycosylation arising from the cancerous state unmasked previously shielded antigenic peptide sequences that subsequently allowed this distinct and unusual form of direct recognition to occur. Although encouraging, it must be noted that MHC-unrestricted recognition of cancer-associated mucins by CTLs is uncommon, and has yet to be observed in response to the administration of a mucin-based vaccine.

Although the immune system functions in part to destroy deleterious cells as they arise in the body, cancers still develop in immuno-competent hosts. Cancers that over-express hypo-glycosylated mucins generally fail to induce potent immune responses due to a lack of intrinsic immunogenicity, the emergence of tolerance and the avoidance of immunological detection as discussed above. However, despite the prevalence of poorly immunogenic, aberrantly glycosylated mucins in many cancers, mucin-based immune responses in cancer patients have been observed [63,64], albeit infrequently. Thus, there is currently a great demand for mucin-based vaccine technologies that augment immune responses against hypo-glycosylated TAAs to facilitate tumor clearance. The synthetic methodologies commonly used to produce such vaccines are summarized below.

14 Chemical and Enzymatic Synthesis of Mucin-Based Vaccines

As discussed previously the heterogeneous nature of cancer cell-derived mucins (containing both normal and tumor-associated saccharides) generally makes them poor vaccine candidates and as a result chemists, for the most part, have provided pure samples of defined glycopeptides for structural and biological evaluation. Since the pioneering syntheses of Kunz [65], Lemieux [66], Meldal [67,68,69,70], Paulsen [71], and Schmidt [72], the synthesis of glycopeptides displaying "simple" *O*-linked saccharides such as the T_N and T antigens has become largely routine and is discussed in detail in various recent reviews [73,74,75,76,77,78]. Indeed simply glycosylated amino acids (e. g. GalNAc Ser/Thr) in suitably protected form for use in solid phase peptide synthesis (SPPS) are commercially available, and incorporation of simple saccharides into large proteins such as mucins [79,80] and mucin-like proteins [81] has been described. Consequently, rather than focusing on the construction of specific glycopeptide TAA's, this section highlights notable syntheses of these antigens (*Fig. 5*) and their union with mucin-derived peptide fragments resulting in homogeneous glycopeptide and glycopeptide-conjugate vaccine candidates poised to break immune tolerance. Specific examples will only be employed to emphasize an overall strategy.

While the assembly of oligopeptides and oligonucleotides is routine and has become highly automated, the automated synthesis of oligosaccharides is still in its infancy despite some notable advances [82,83,84]. The situation becomes even more complex when the protecting group requirements for both the oligosaccharide assembly, and peptide assembly combine in the same molecule to stretch this aspect of chemical synthesis to its limits. Conse-

quently most glycopeptides are prepared using a combination of SPPS and solution-based techniques and often not entirely in automated fashion because close monitoring of coupling reactions is usually desired in order to reduce the quantity of precious glycosylated building blocks required. The oligosaccharides and glycosylated building blocks are often prepared using standard solution-based techniques. In the past researchers have attempted to simplify the synthetic requirement by utilizing glycopeptide mimics that may be linked to a peptide

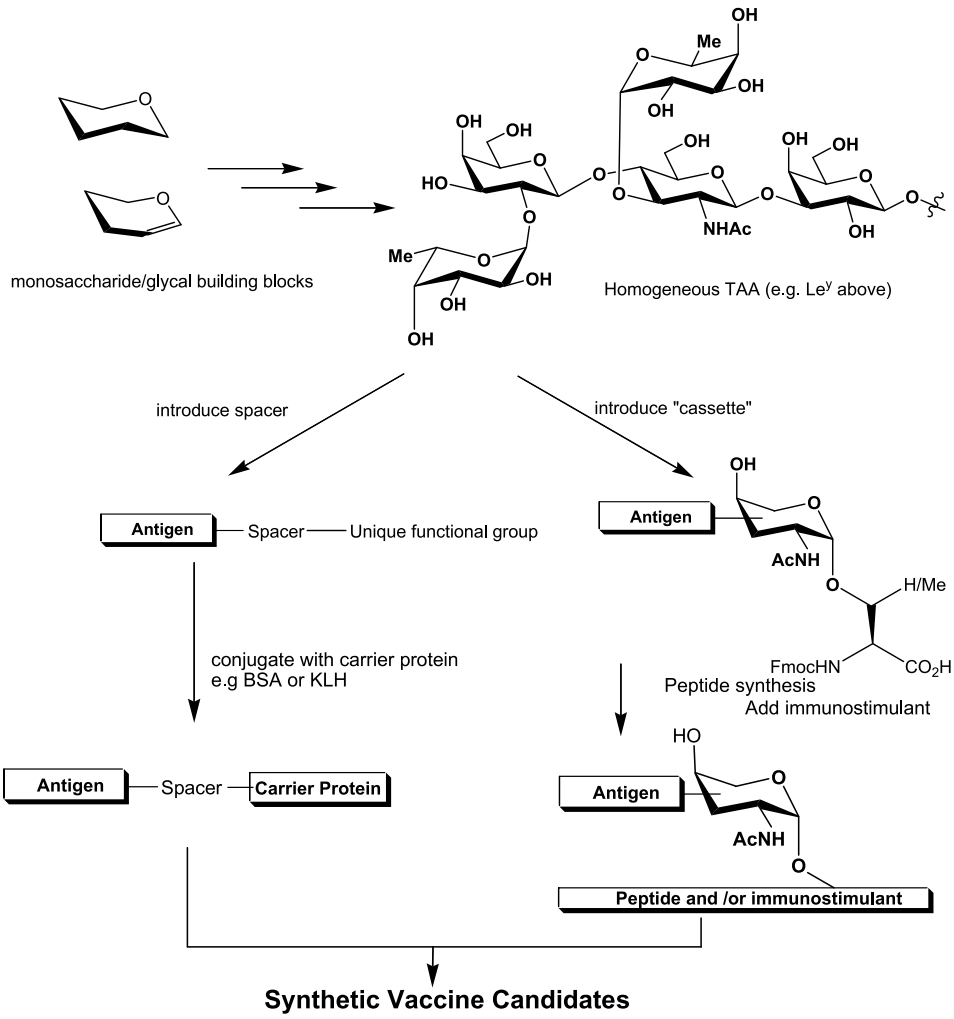


Figure 10

Common strategies for the assembly of tumor-associated antigen and glycopeptide vaccines. Synthetic TAAs and glycopeptide mimics displaying TAAs are either linked to large immunogenic carrier proteins that facilitate the display of hundreds of copies of antigen simultaneously, or alternatively glycopeptides may be adorned with additional functionality to include immunostimulants such as T-cell epitopes or inflammatory lipids

backbone of a carrier protein via an, often unnatural, linker or spacer motif (◉ *Fig. 10*). This can be particularly advantageous where the display of multiple copies of antigenic saccharides is required to arouse the strongest immunological response [85,86,87,88,89,90,91], and is also believed to more appropriately represent the multi-valent, clustered, environment in which tumor associated saccharides are displayed at the cell surface [92,93]. Additionally, it is considered to be particularly useful when the carrier protein is also considerably antigenic, such as Bovine Serum Albumin (BSA) or KLH which, in itself, stimulates the immune system, possibly through proteolytic processing and display on MHC class II, facilitating the recruitment of $CD4^+$ T-cell help. KLH can display hundreds of copies of oligosaccharide or glycopeptide antigen per protein molecule. Vaccines of this type will be discussed in more detail in ◉ *Sect. 15* The caveat in this approach is that elements of any unnatural linker motif, acting alone or in concert with the saccharide appendage, could give rise to the "incorrect" immunological response [89,94] and although widely practiced (with considerable success [95]) there is a desire to prepare homogeneous samples of oligosaccharides that are linked to native peptide sequences e. g. of MUC1 via regular α-*O*-glycosidic linkages to serine and threonine such that antigenic motifs which comprise elements of the saccharide and the underlying peptide backbone can be investigated. This makes sense because, often, TAAs are truncated saccharides arising from premature "capping" of core structures with sialic acid (◉ *Fig. 5a*) and the underlying peptide is believed to be more exposed. Obviously the use of unnatural spacers and linkers between the saccharide and peptide backbone precludes this type of investigation though are still useful for investigations of "saccharide-only" antigens, especially where the attached oligosaccharide is sufficiently sterically demanding so as to conceal any underlying non-natural structural elements. There are two general modes by which the synthesis of naturally occurring mucin-type glycopeptides might be envisaged. The first is the convergent union of pre-assembled saccharides with the appropriate peptides. Whilst this is commonplace in the assembly of *N*-linked glycopeptides it is far less common in *O*-linked glycopeptide synthesis due to the difficulties in controlling the stereochemistry of the new glycosidic linkage and the compatibility between glycosidation reactions (requiring strictly anhydrous conditions) and the solubility of peptides. Instead a "building block" or "cassette" approach is adopted where fully protected glycoamino acids are prepared and then introduced into regular SPPS. The added bulk of the glycoamino acid has ramifications for glycopeptide synthesis and the most sterically demanding glycoamino acids can give rise to low coupling yields in solid-phase glycopeptide assembly. However, it is possible that simple glycoamino acids can be introduced and then modified by using appropriate enzymes, provided that the appropriate enzymes are available [96]. These methods are shown schematically in ◉ *Fig. 10* and specific examples will be discussed below in more detail.

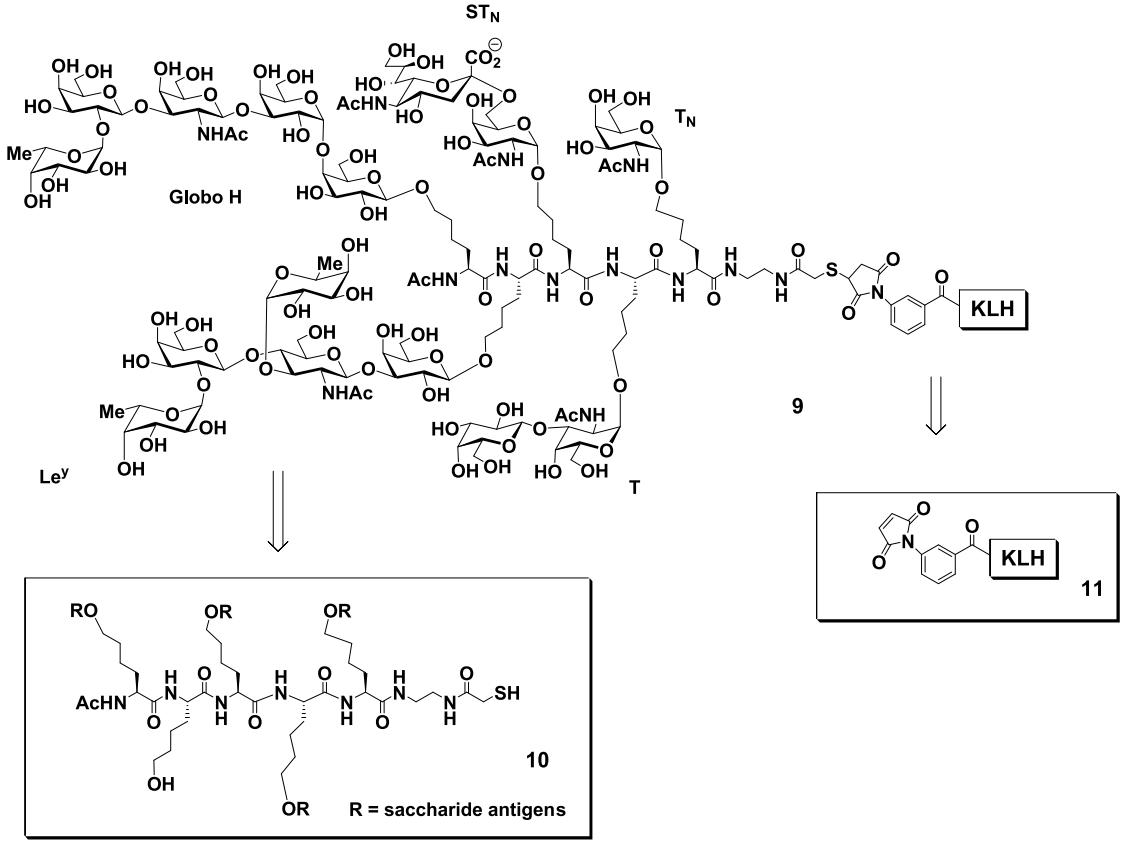
15 Multivalent Antigen Display on Immuno-Stimulatory Carrier Proteins: Eliciting an Antibody Response

Oligosaccharides often interact strongly with their receptors in a multi-valent fashion hence the term avidity, (arising from the sum of many individual interactions) rather than affinity (which

is more commonly employed to describe the interaction between a specific substrate-ligand pair) that is used to describe saccharide-protein interactions [92,93]. Following on from this it is known that numerous copies of specific cell surface oligosaccharides (or "glycans") direct fundamental processes such as cell-cell adhesion in this fashion since interactions between single synthetic or isolated oligosaccharides and their ligands are relatively weak (mM–μM range). Therefore in the development of therapeutic anti-cancer vaccines it has been essential to develop multi-valently displayed samples to more accurately replicate the situation at the surface of a cancer cell. Immuno-stimulatory proteins and short non-immunogenic linker motifs have been used for this purpose for decades since the chemistry is relatively well developed [97] and most often employs simple, non-specific, reductive amination type-reactions between antigen-displayed aldehyde functional groups and the ε-amino groups of lysine residues contained within, for example, KLH. In this way many problems associated with glycopeptide synthesis (such as the increased demand for protecting groups) are circumvented allowing the work to be conducted in non-specialist laboratories. Historically, the latent aldehyde functionality at the reducing end of isolated and synthetic oligosaccharides has been utilized in this way for conjugation to proteins but is less frequently employed nowadays as it irreversibly destroys the cyclic structure of the terminal sugar at the reducing end.

In a recent and impressive study the Danishefsky laboratory prepared a unimolecular pentavalent vaccine, displaying five different tumor-associated antigens (GloboH, Le^y, sT_N, T_N and T antigens) concomitantly, on a short peptide scaffold comprised mainly of an unnatural amino acid (ε-hydroxynorleucine) and subsequently conjugated to KLH (**9**, ➤ *Fig. 11a*) [98].

This approach is designed to elicit a multi-faceted response to several tumor-associated antigens simultaneously. Interestingly the choice of unnatural amino acid arises more from the shortcomings in chemical synthesis encountered along the way, rather than entirely by design. However its increased flexibility compared to the native α-*O*-glycopeptide linkage to serine and threonine undoubtedly facilitates chemical synthesis by relieving steric crowding in the clustered glycopeptide sequence. Alternative synthetic vaccines prepared using dendrimeric non-immunogenic lysine core-based multiple antigenic glycopeptides (MAG's) have also benefited from the use of similarly flexible homoserine-based glycoamino acid building blocks [87]. Initially the Danishefsky group had investigated the construction of allyl glycosides of antigens since they could be converted to aldehydes upon treatment with ozone. However, since the allyl glycoside was not fully compatible with the global reductive debenzylation of the pre-assembled saccharide at the end of the synthesis [99] an n-pentenyl glycoside (a well-known glycosyl donor [100]) was employed instead. Although more stable to the reductive debenzylation, the n-pentenyl glycosides, when employed as glycosyl donors, failed to provide access to the natural glycoamino acid (GalNAc-Ser/Thr) cassettes directly so an ozonolysis/Horner–Emmons/asymmetric hydrogenation sequence was ultimately preferred for the preparation of antigens containing the native GalNAc-α-*O*-glycosidic linkage. These neoglycoamino acid building blocks could be readily employed in SPPS [85]. A key step in the vaccine assembly was the conjugation between the neoglycopeptide (**10**) and maleimide modified KLH (**11**). To facilitate this, the neoglycopeptide was equipped with a diaminopropyl spacer that was subsequently linked to a 2-mercoptoacetate moiety employing the pentafluorophenyl (pfp) active ester. Unmasking of the thiol functionality (with NaOH) allowed reaction with maleimide-activated-KLH (**11**). This approach appears generally useful with GalNAc-α-*O*-ε-hydroxynorleucine derivatives, containing the native α-*O*-glycosidic linkage such as the



a

Figure 11

(a) A unimolecular penta-valent glycopeptide vaccine 9assembled by ligation between neoglycopeptide-thiol 10 and maleimide modified KLH 11. The component parts are readily prepared fromglycal precursors

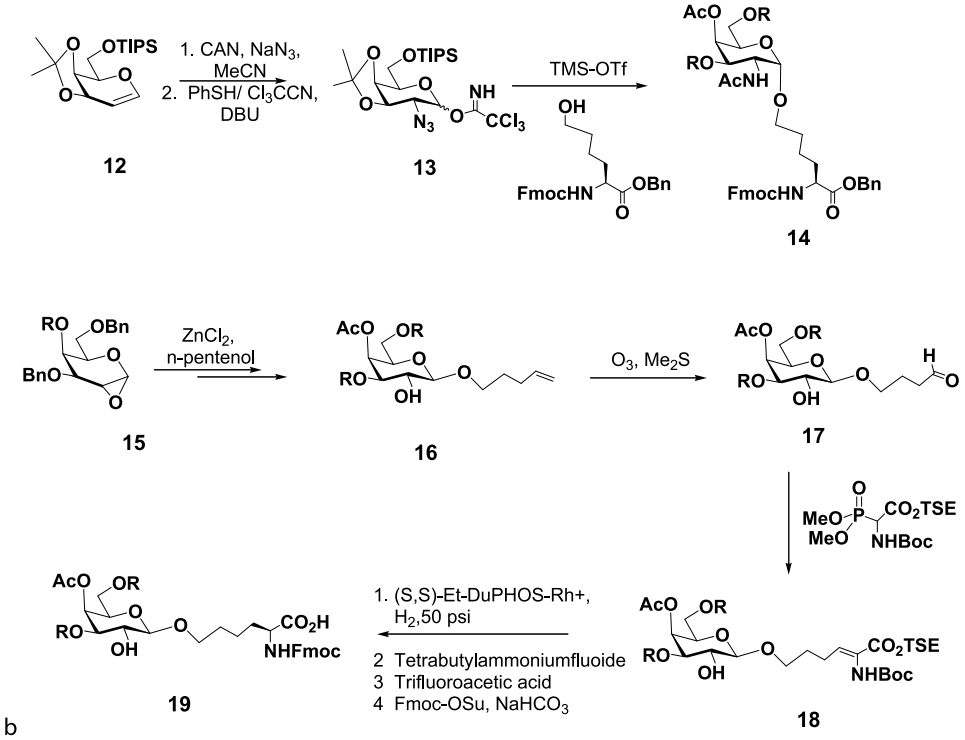


Figure 11 (continued)
(b) A Glycal 12 can be converted to a suitable glycosyl donor (13, X = leaving group) following Lemieuxs' azidonitration. Glycosidation with suitably protected ε-hydroxynorleucine, facilitated by the 2-azido group on the sugar, affords the α-*O*-linked tumor-associated antigens. For β-*O*-linked products the terminal glycal epoxide (e. g. 15) is opened with-n-pentenol. The n-pentenyl glycoside 16 provides access to the glycoamino acid cassette 19 following ozone-mediated double bond cleavage, Horner–Emmons reaction with a suitable phosphonate reagent and Rhodium-catalyzed asymmetric reduction of the carbon–carbon double bond

T_N and T antigens (**1** and **2**, ❯ *Fig. 5a*) and sialylated analogues being readily prepared by glycosylation of the activated 2-azido-2-deoxy sugars (**13**, ❯ *Fig. 11b*). Antigens containing β-*O*-glycosidic linkages are also readily prepared through solvolysis of the appropriate glycal epoxides [101]. All carbohydrate components are prepared from readily available glycals, emphasizing the power of glycal assembly methodology [102]. More recently [103] preliminary immunological findings with this class of KLH-linked antigen has been disclosed and the findings are discussed in more detail in the following section.

In another recent example Kunz and co-workers assembled glycopeptide vaccine **23** corresponding to fragments of the VNTR domain of MUC1 (❯ *Fig. 12*) modified with the sT_N antigen (**4**, ❯ *Fig. 5a*). Assembled glycopeptide **20** was displayed on BSA using diethylsquarate (3,4-diethoxy-3-cyclobutene-1,2-dione, **21**). The preformed sqauric monoamide **22** was conjugated to BSA in approximately 60% yield after 24 h [104].

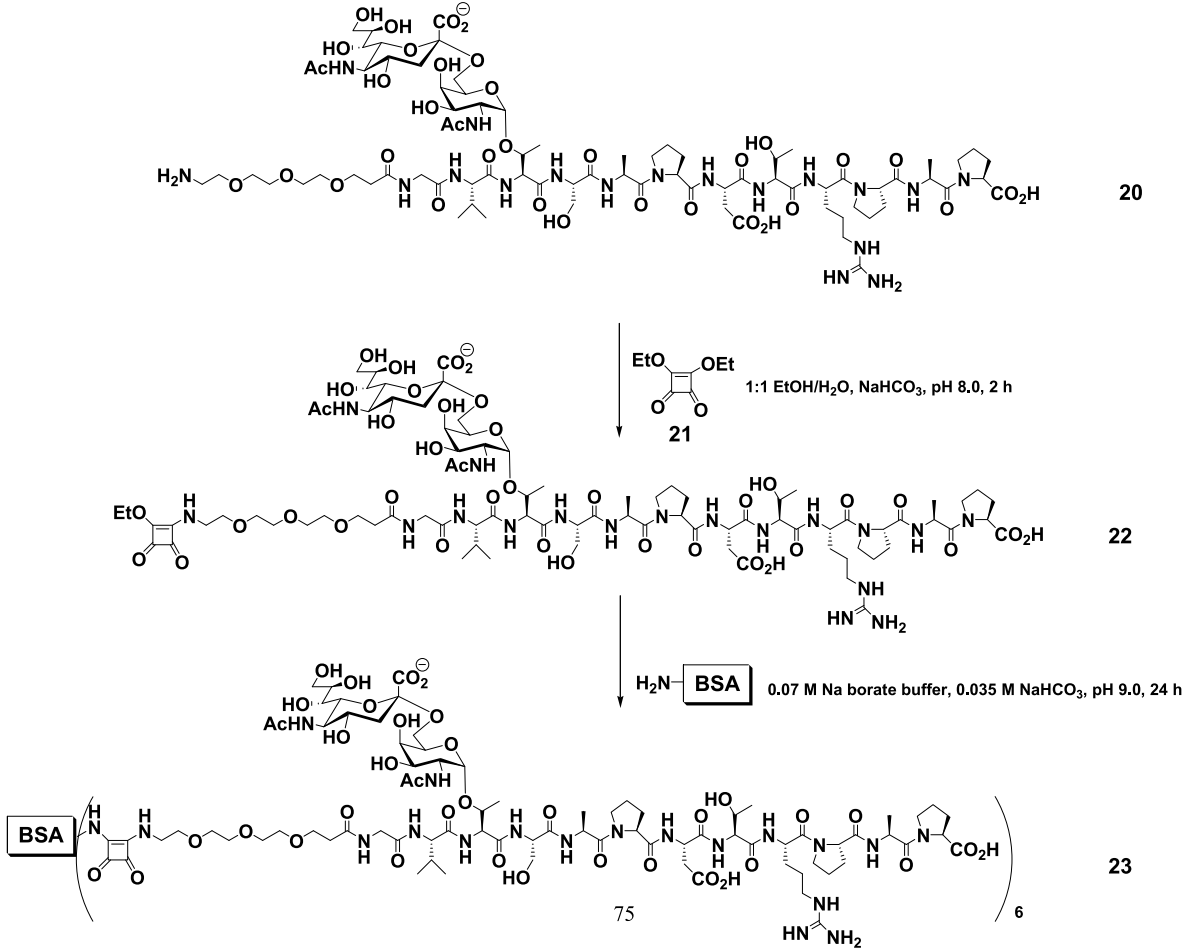

Figure 12

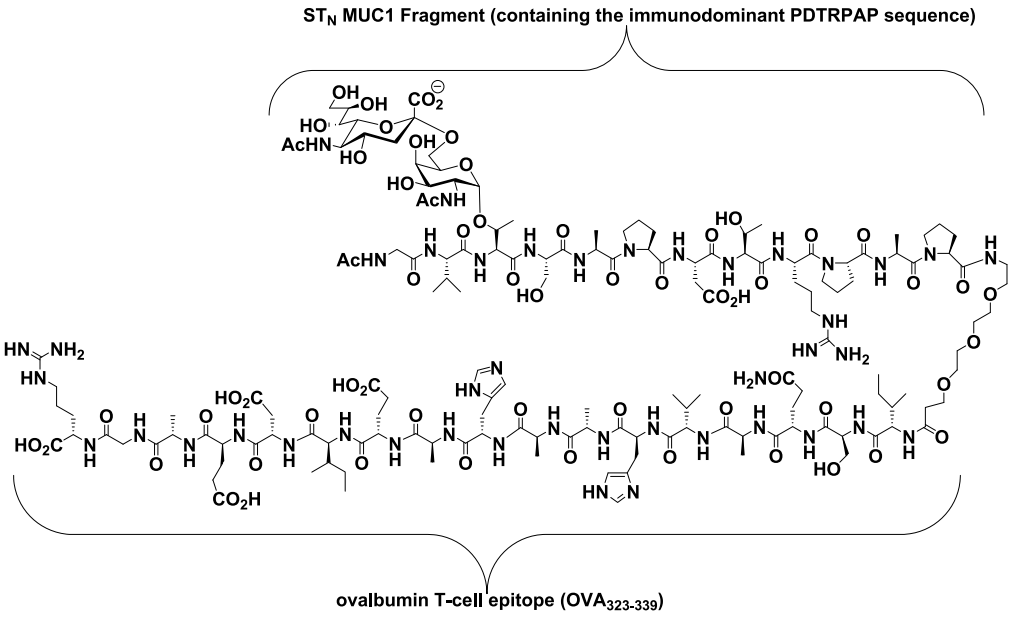
16 Synthetic Glycopeptides Designed to Elicit a CD4$^+$ T-Helper (T_H) Response

A major goal in vaccine design is to enlist strong T-cell help from CD4$^+$ T_H-cells to activate naïve B-lymphocytes and establish immunological memory such that tumor cells can be cleared if they attempt to re-establish themselves in a host after vaccination. In an attempt to invoke a T_H-cell response Kunz and co-workers describe a strategy where various TAAs are displayed on fragments (usually containing the immunodominant peptide motif: PDTRPAP, from the VNTR domain) of MUC1. The MUC1 fragment is linked via a non-immunogenic spacer to a known T-cell epitope (i. e. is known to be presented by MHC molecules). In this example (*Fig. 13*) the epitope is a fragment of ovalbumin ($OVA_{323-229}$) [105] though T-cell epitopes from Tetanus toxin have also been employed in the past [106].

It can be envisaged that exposing B-cells (in peripheral blood lymphocytes, or whole organisms!) to these glycopeptides may result in internalization of the immunogenic saccharide antigen after recognition by cell-surface bound immunoglobulins. After proteolytic processing, the T-cell epitope can then be displayed on MHC class II to T_H-cells, facilitating the release of sufficient co-immunostimulatory cytokines to allow B-cell maturation and antibody secretion. In this case the vaccines were used to immunize transgenic mice whose T-cells over-express a receptor specific for the ovalbumin sequence. The synthesis of such vaccines follows a similar route regardless of the antigen being presented and begins with the assembly of a suitably protected T_N displaying glycoamino acid (*Fig. 14a*) [69,70]. This protected glycoamino acid is commercially available though can be prepared on gram scale in few steps from readily availably starting materials. In the literature various glycosyl donors (glycosyl halides, thioglycosides, trichloroacetimidates) have all been effective in reactions with suitably protected serine and threonine residues. The versatility of this building block has been demonstrated in many glycopeptide syntheses and can be readily elaborated to various tumor associated glycopeptide carbohydrate antigens. *Figure 14b* highlights the synthesis of cassettes **27**, **28** and **31** from **24** by Kunz and co-workers, corresponding to the sT_N (**4**), ST (**5**), T (**2**) and T_N (**1**) antigens respectively [23]. Following assembly of the sT_N cassette it was incorporated into a MUC1 fragment. The peptide was cleaved from the resin employing a fluoride cleavable linker which allows the glycopeptide *C*-terminal acid, to be obtained in an otherwise fully protected form. This peptide was coupled to the pre-assembled ovalbumin sequence via a triethyleneglycol spacer and the fully deprotected vaccine was obtained in 42% yield, based on loading of the first amino acid of the ovalbumin fragment, after preparative HPLC purification.

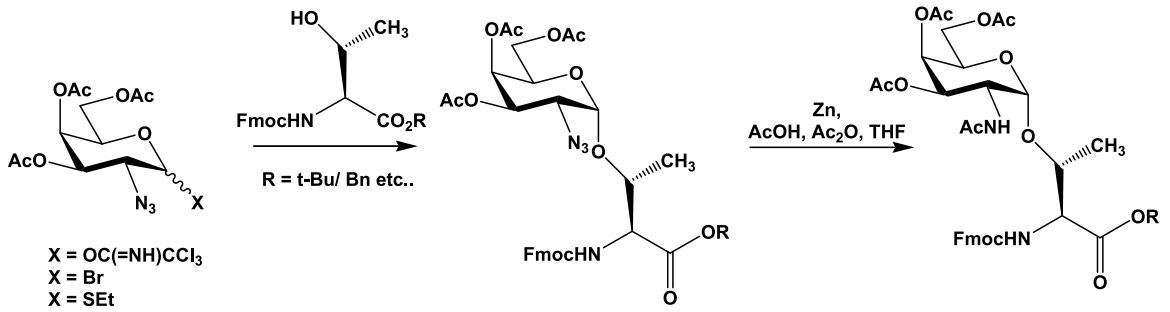
Boons and co-workers envisaged a similar strategy for the construction of a vaccine containing the T_N antigen (**32**, *Fig. 15*) [107]. Their vaccine contained the threonine-linked T_N antigen, conjugated to a T-cell epitope (comprised of a 20mer "YAF" peptide derived from the outer membrane protein of *Neisseria meningitides*) via a short 1,3-diaminopropyl linker. Furthermore the vaccine construct contained an S-[(R)-2,3-dipalmitoyloxy-propyl]-*N*-palmitoyl-(R)-cysteine (Pam_3Cys) motif that is known to function as an adjuvant, stimulating the secretion of pro-inflammatory cytokines that stimulates antigen presenting cells and the development of T_H-cells. This vaccine was prepared by coupling the three pre-assembled components. First the T-cell epitope was prepared using standard SPPS and the lipid modified cysteine residue **33**



76

Figure 13

Glycopeptide vaccine recently described by Kunz and co-workers comprising the immunodominant (PDTRP) sequence of the VNTR domain of MUC1, adorned with the sT$_N$ antigen and connected to a T-cell epitope (OVA$_{323-339}$) known to be presented to MHC class II molecules



a

Figure 14

(a) Glycoamino acid building blocksor "cassettes" such as 24 are readily prepared via glycosidation of suitably protected serine and threonine residues with common glycosylhalide trichloroacetimidate or thioglycoside donors. Following reduction of the azido group (which helps separation of α and β anomers) andcarboxyl deprotection the building blocks are ready for solid phase peptide synthesis or the T_N antigen 24 can be elaborated tovarious glycoamino acids

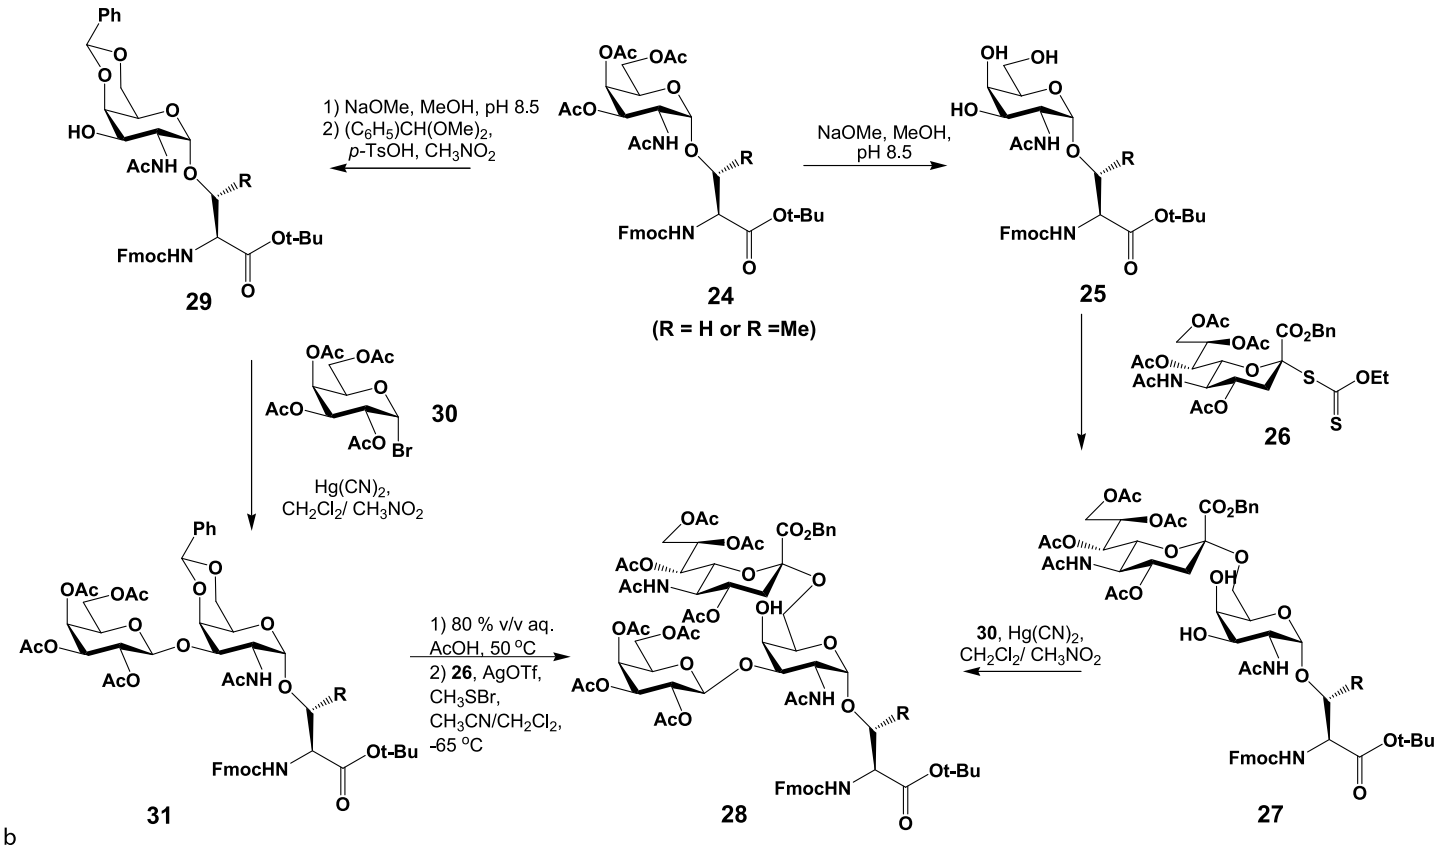


Figure 14 (continued)

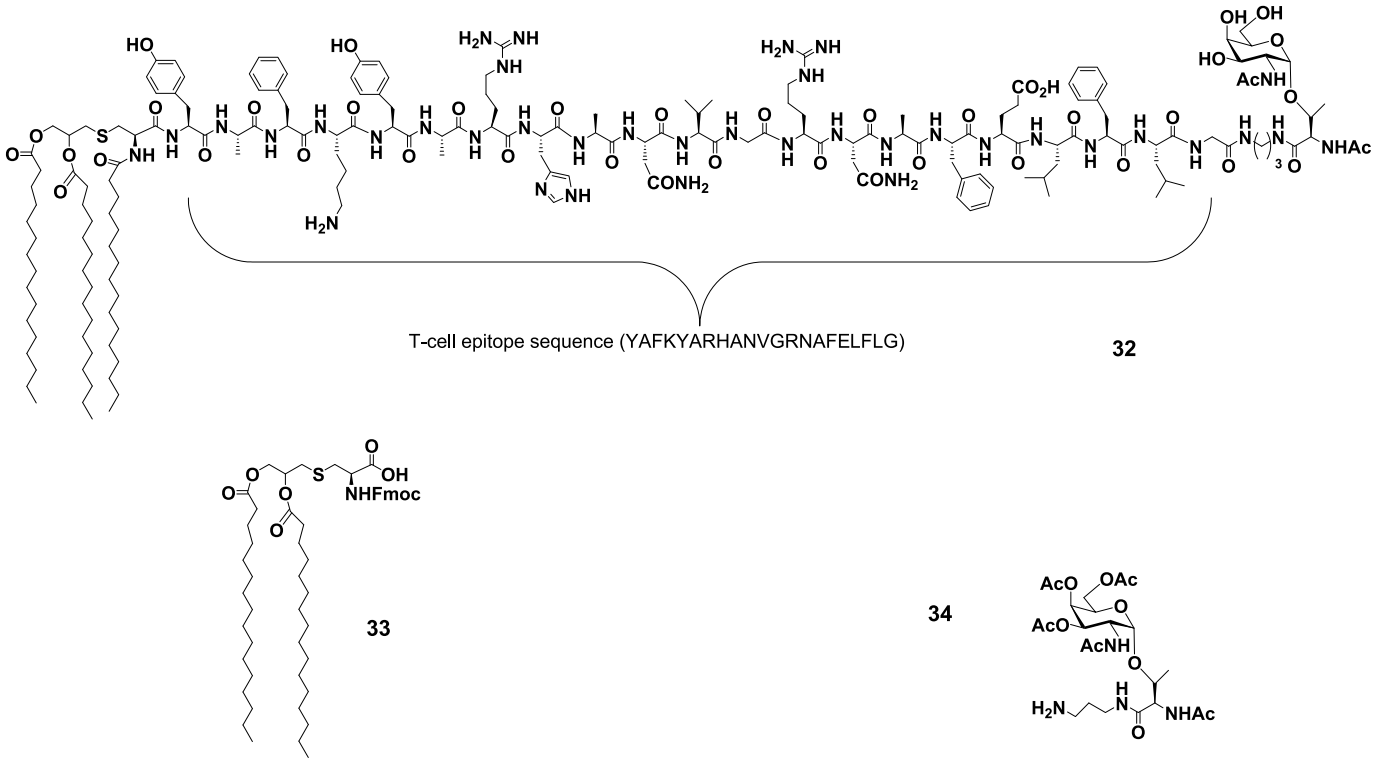

Figure 15

Synthetic glycopeptide vaccine (32) described by Boons and co-workers is assembled by first coupling the pre-assembled T-cell epitope to the lipidated cysteine residue 33 on solid phase. Following addition of the final palmitoyl group the lipopeptide is cleaved from solid support to present only the *C*-terminal acid to the T_N cassette 34. Glycolipopeptide 32 is finally obtained after protecting group removal and purification [107]

was finally coupled. Following adjustment of the cysteine protecting group and degree of lipidation the vaccine precursor was cleaved from the solid phase, as before to free only the *C*-terminal acid, though employing a different linker (HMPB-MBHA resin). Finally, the T_N cassette **34** was coupled and the vaccine was obtained after removal of protecting groups, size exclusion and reverse-phase HPLC. The Danishefsky group have also employed the use of the Pam_3Cys motif in various vaccine constructs (though not in concert with a T-cell epitope) though have favored more the KLH-conjugated constructs as a result of their higher observed IgG titers [74].

17 Enzymatic and Chemo-Enzymatic Synthesis of Mucin-Based Vaccine Candidates

Enzymatic assembly of tumor associated glycopeptide antigens is highly desirable since the obstacles that are characteristic of carbohydrate chemistry, the requirement for many protecting group manipulations and stereoselective glycosidation, are overcome due to the exquisite regio- and stereoselectivity of enzymes. Additionally the transformations can be conducted in aqueous solution. The drawbacks are not so much the cost of the required glycosylnucleotide donors (UDP-Gal, UDP-GalNAc, CMP-NeuAc, UDP-GlcNAc) since substrate recycling protocols are well developed in many instances, but more the general availability of suitable glycosyltransferases. Many glycosyltransferases are not commercially available. However recent reports have shown that ppGalNAcT enzymes, that transfer the first GalNAc residues to "naked" mucins, when working either alone or in concert with additional transferases can produce mucin associated antigens suitable for immunological study [108,109]. In one study, Freire et al. showed that MUC6 fragments from the tandem repeat domain could be over-expressed in *E. coli*. Interestingly MUC6 is over-expressed in MCF-7 breast cancer cell lines but its expression is normally restricted to gastric tissues of healthy individuals. The purified, unglycosylated, fragments obtained were then glycosylated with recombinant bovine ppGalNAc T I and the products, adorned with the T_N antigen, could be prepared in quantities of up to 3 mg. Peptides were also glycosylated with MCF-7 breast cancer cell extracts and could be similarly glycosylated (i. e. with T_N). The degree of glycosylation of MUC6 peptides was greater when using the breast cancer cell extract (T_N occupying 54–58% of the potential *O*-glycosylation sites) than with the recombinant ppGalNAcT I (T_N occupying 42% of the potential *O*-glycosylation sites). However, the degree of peptide glycosylation by bovine ppGalNAcT I depended significantly on the size of the MUC6 peptide fragment, 42% (as stated above) for glycosylation of a peptide corresponding to half a tandem repeat yet up to 64% glycosylation site occupancy for the whole tandem repeat. These peptide fragments were used to immunize mice and the results are described in more detail in the following section. In a further study [108], a synthetic peptide comprising 60 amino acids (three MUC1 tandem repeats) was fully glycosylated (five GalNAc residues per tandem repeat) employing recombinant ppGalNAcT enzymes (*Fig. 16*). Furthermore the T_N antigen was elaborated to T and sT_N antigens by the action of recombinant β-1,3-GalT and α-2,6-NeuAcT (a.k.a. ST6GalNAc I) respectively. The reactions were simply conducted in aqueous buffered solutions and monitored by reversed-phase HPLC and MALDI-TOF mass spectrometry. As enzymes become more avail-

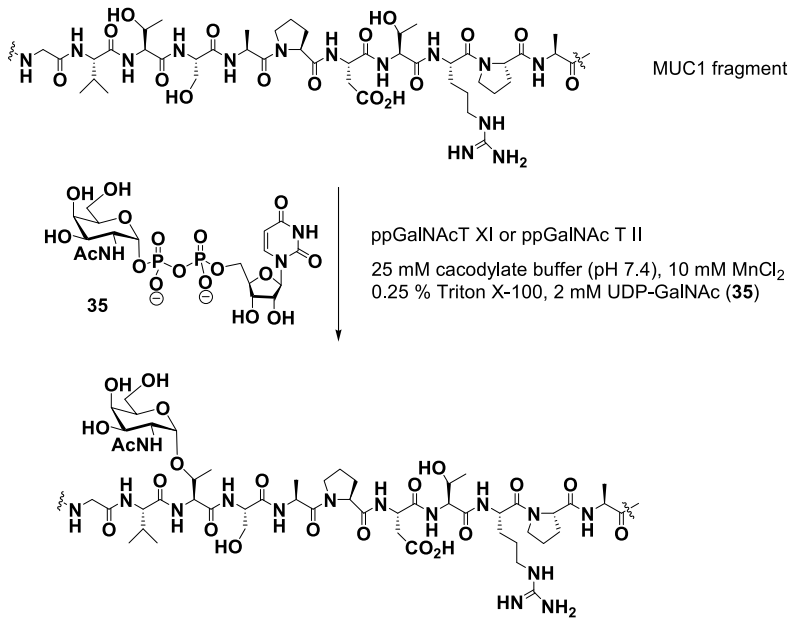

Figure 16
Peptide *O*-glycosylation employing glycosyltransferases utilizes the activated glycosyl nucleotide donor UDP-*N*-acetylgalactosamine (35) to modify mucin fragments with complete regio and stereocontrol in the absence of protecting groups

able the assembly of mucin based vaccines employing this approach, possibly in concert with chemical protein synthesis, is sure to become more commonplace.

For over a decade mucin-type glycopeptides have been amenable to automated synthesis employing the cassettes approach [110], and more recently many tumor associated glycopeptide antigens have been prepared using semi-synthetic methods in combination with glycopeptide substrate immobilization on water soluble polymer supports [111]. Along with technological advances in glycopeptide synthesis e. g. microwave assisted peptide synthesis [112] it might also be possible to decrease the time taken (increase the yield of oligosaccharide and glycopeptide antigens) to discover new tumor-associated antigenic motifs, and to prepare pure homogeneous samples for immunological investigations. Some immunological findings employing the glycopeptides highlighted above are summarized in the final section of this review.

18 Immunological Evaluation of Mucin-Based Vaccines

Aberrantly glycosylated mucins over-expressed on the surface of cancer cells reveal peptide sequences and prematurely sialylated carbohydrate moieties that would otherwise be inaccessible or absent in the healthy uncancerous state. Consequently, this provides a source of peptide and glycopeptide-based, mucin-associated antigens from which synthetic vaccines

can be constructed. The majority of synthesized vaccines are accordingly based on the solvent exposed peptide sequences and cancer-specific mucin-based antigens within the VNTR region, although additional sequences outwith the VNTR region have also yielded encouraging results. The remainder of this section seeks to evaluate the impact of such vaccines in preclinical murine studies and in clinical trials. A summary of the experimental results obtained from these investigations is also presented (● *Table 3*).

19 Unglycosylated Mucin Peptide Vaccines

The process of cellular transformation adversely affects the molecular machinery involved in the post-translational modification of mucin peptides, such that glycosylation is prematurely terminated by the addition of sialic acid to the developing carbohydrate chains. Consequently the mucin peptide backbone is often under-glycosylated, and core peptide sequences that would otherwise be inaccessible are exposed in the disease state. Many unglycosylated, mucin-based peptide vaccines are therefore based on these exposed sequences, as it is the accessibility to these motifs that differentiates between healthy and cancerous cells in vivo. Preclinical evaluation of these peptide vaccine formulations relies heavily upon the use of murine models and immortalized cancer cell lines. However, human MUC1 is highly immunogenic in wild-type mice. Introduction of human MUC1 into wild type murine models is therefore not immunologically representative of the human situation, where an absence of an immune response is frequently observed due to immunological tolerance to cancer-associated MUC1 antigens. For this reason, transgenic (Tg) mouse models were developed, where genetic engineering allows the human MUC1 glycoprotein to be expressed as a "self" molecule in mice from birth. In such models, immunological tolerance to "self" (the human MUC1 glycoprotein) and "altered-self" (human MUC1 decorated with prematurely sialylated cancer-associated antigens) is established from the outset, and thus provides a more representative immunological model in which to assess the efficacy of vaccines designed to break tolerance to human, cancer-associated mucin antigens.

The production of CTL precursors and extremely low titers of MUC1-specific antibodies was observed following vaccination of mice transgenic for human MUC1 (MUC1.Tg), with an unglycosylated MUC1 peptide (5 × PAHGVTSAPDTRPAPGSTAP: see [113] ● *Table 3*)-glutathione-*S*-transferase fusion protein (MUC1-GST) or unglycosylated MUC1-GST conjugated to oxidized mannan [113]. The use of oxidized mannan in these vaccine formulations acts as an immunological adjuvant, and is observed to favor the induction of cell-mediated, rather than antibody-based immune responses against the conjugated molecule [114]. Using an alternate strategy, MUC1.Tg mice were vaccinated with *Vaccinia* virus engineered to express both human MUC1 and the cytokine IL-2. In this system, MUC1 expression occurs through a virus-mediated introduction of mucin DNA into the recipient cell. As a result, production of human MUC1 is orchestrated by the host (murine) translational machinery, and is therefore endogenous. Consequently, the processed MUC1 antigenic fragments are presented on the surface of murine cells by MHC class I molecules. The generation of CTL precursor cells was also observed using this system [113]. Importantly, whilst the production of a fully blown anti-MUC1 immunological response was not observed, these results demonstrate that the stim-

PV = Peptide vaccine. GPV = Glycopeptide vaccine. AT = Adoptive transfer.

[a] The position of attatched glyco-antigens is indicated by highlighting the relevant amino acid residue in square brackets.

GST = Glutathione-S-transferase. Ox. Man = Oxidized mannan. CTL = Cytotoxic T-lymphocyte. CTLp = Cytotoxic T-lymphocyte precursors. ND = Not detected. NT = Not tested. $OVA_{323-339}$ = Ovalbumin peptide fragment 323-339. KLH = Keyhole limpet hemocyanin. T_N (c) = T_N antigen in trimeric cluster. IL-2 = Interleukin-2. GM-CSF = Granulocyte-macrophage colony-stimulating factor. SB-AS2 = An oil-in-water emulsion of 3-deacylated-monophosphoryl lipid A and QS-21. Pam_3Cys = S-[(R)-2,3-dipalmitoyloxy-propyl]-N-palmitoyl-(R)-cysteine. CFA = complete Freund's adjuvant. QS-21 = a water-soluble triterpene glucoside plant extract from the Soap Bark tree *Qillaja saponaria*. GPI-0100 = A semi-synthetic saponin based on QS-21. Ig = Immunoglobulin

ulation of an immune response against human MUC1 can proceed without the induction of autoimmunity against "self" antigens expressed in the transgenic model.

In a small clinical study, nine high-risk breast cancer patients were immunized with 1.5 unglycosylated synthetic MUC1 VNTR domains (VTSAPDTRPAPGSTAPPAHGVTSAPDTRPA: see [115] ❯ *Table 3*) conjugated to KLH and administered with the adjuvant QS-21 [115]. Analysis of peripheral blood after vaccination revealed elevated levels of MUC1-specific IgM and IgG that were sustained for up to 137 weeks following a single vaccination [115]. The observed switch in immunoglobulin isotype from antigen-specific IgM to IgG is importantly, only observed following the stimulation of B-cells by T_H-cells. The presence of antigen-specific IgG in post-vaccination blood plasma is therefore indicative of an activated $CD4^+$ T_H-cell response in vivo. IgM produced by seven of the nine patients in the study bound to MCF-7 tumor cells (expressing sT_N, T, GM2, globoH and Le^Y) in vitro, although none of the patients presented evidence of CTL activation [115]. Low but detectable increases in MUC-1 specific IgG responses were observed in a phase I clinical trial on 16 patients with resected or advanced pancreatic cancer that received a synthetic unglycosylated vaccine comprised of 100 amino acids from the MUC1 VNTR region (5 × GVTSAPDTRPAPGSTAPPAH: see [116] ❯ *Table 3*) and the immunological adjuvant SB-AS2 [116].

An unglycosylated peptide comprised of 60 amino acids from the VNTR region of human MUC1 (3 × PDTRPAPGSTAPPAHGVTSA: see [117] Table 3) was expressed and purified from bacterial culture and conjugated to oxidized mannan. The resulting vaccine was evaluated in a phase III clinical trial on 31 patients with early (stage II) breast cancer [117]. Patients received either placebo or vaccine with an observed cancer recurrence rate of 27% and 0% respectively after 5.5 years [117]. Of the patients treated with vaccine, 69% generated anti-MUC1 antibody responses and 40% generated a MUC1-specific T-cell response as evidenced by an increase in secretion of interferon-gamma (IFN-γ) in vitro [117].

In another study, a computational analysis of the human MUC1 amino acid sequence was performed to identify those regions most likely to interact with a polymorphic variant of MHC class I molecule [118]. Interestingly, several peptide sequences located outside of the VNTR region were identified as capable binding partners ($ATWGQDVTSV_{92-101}$, $ALLVLVCVLV_{1162-1171}$, $TISDVSVSDV_{1135-1144}$, $ALAIVYLIAL_{1172-1181}$, $VLVALAIVYL_{1169-1178}$ and $YLIALAVCQC_{1177-1186}$). The identified peptide sequences were constructed synthetically and all were observed to stimulate an increase in secretion of IFN-γ from T-cells, indicative of activation in vitro [118]. Furthermore, the most potent MHC binding peptide (ATWGQDVTSV) was modified to produce an agonist epitope (ALWGQDVTSV: see [118] ❯ *Table 3*) that exhibited improved characteristics as a MUC1 antigen when compared to the natural MUC1 peptide sequence identified in the computational screen [118]. The cytolytic efficiency of generated CTLs was quantified using an in vitro ^{111}In release assay, in which the amount of ^{111}In released from labeled target cells expressing MUC1-based antigens is proportional to lysis mediated by CTLs. Use of this assay importantly demonstrated that pulsing the agonist peptide into autologous DCs from patients with pancreatic cancer produced CTLs that lysed MUC1-expressing cancer cells more efficiently than CTLs generated from the natural MUC1 peptide sequence [118]. These results not only demonstrate that the immunogenicity of MUC1 is not restricted to the VNTR region of the molecule, but also that amino acid substitutions in the mucin peptide backbone can generate an immune response of increased potency against a naturally expressed cancer-associated mucin.

The results presented here demonstrate that immunoglobulin and cellular immune responses are observed with unglycosylated mucin-based peptide-only vaccines. Whether antibodies or T-cells become the predominant species in the immune response is most likely dependent upon the choice of immunological adjuvant and/or carrier protein used in the vaccine formulation.

20 Mucin-Based Glycopeptide Vaccines

In addition to exposed peptide motifs, the generation of aberrantly sialylated carbohydrate moieties provides yet another means of differentiating between cells expressing normal or cancer-associated mucins in vivo (see *Sect. 4*). Chemical synthesis allows a potentially unlimited number of vaccine formulations to be constructed incorporating one, or a combination of antigenic mucin-based carbohydrate structures.

In a pre-clinical study, mice were vaccinated with phospholipid-based liposomes containing a synthetic lipidated glycopeptide vaccine (see [107] *Table 3*) comprised of the T_N antigen (as a B-cell epitope), the MHC class II restricted outer membrane peptide fragment from *Neisseria meningitidis* (YAFKYARHANVGRNAFELFL) as a T-cell epitope, and the lipopeptide adjuvant Pam_3Cys with and without QS-21 [107]. Use of this multi-component vaccine aimed to achieve an immunoglobulin-dependent (and therefore) B-cell mediated recognition of the T_N antigen followed by T_H-cell recruitment through the T-epitope. In this situation, secretion of cytokines from the T_H-cell to the B-cell would then be envisaged to stimulate B-cell clonal expansion and differentiation into plasma cells that would subsequently produce soluble T_N antigen-specific antibodies. Encouragingly, analysis of post-vaccination sera by enzyme-linked immunosorbent assay (ELISA) using a T_N-BSA conjugate as bait revealed the production of T_N-specific IgM and IgG, with the highest titers observed from those mice that received QS-21 [107], suggesting that a T_H cell-mediated stimulation of B-cells had indeed occurred.

A similar immunological scenario was envisaged by Kunz and co-workers, who used a polar, non-immunogenic spacer molecule to couple a synthetic glycopeptide vaccine composed of the MUC1 glycopeptide (GV[T]SAPDTRPAP) displaying sialylated T_N attached to threonine (bold), and an ovalbumin peptide sequence (residues 323-339: ISQAVHAAHAEINEAGR [105] *Table 3*). This vaccine was administered to mice expressing TCRs transgenic for $OVA_{323-339}$ together with complete Freund's adjuvant. Analysis of blood serum by ELISA using MUC1-sT_N-BSA as bait revealed that sT_N-specific antibodies had been produced. Most importantly, co-incubation with either un-glycosylated MUC1 peptide or MUC4 peptide displaying sT_N neutralized antibody binding [105], suggesting that the immunoglobulins generated were only specific for MUC1 peptides decorated with a cancer-specific mucin-based antigen (sT_N).

Multi-valent vaccines aim to recreate the antigenic architecture that predominates on the surface of cancer cells following premature termination of glycosylation. A synthetic bivalent vaccine comprised of a glycosylated MUC2 peptide with a C-terminal cysteine residue (PTTTPITTTTTVTPTPTPTGTQTPTTTPISTTC: see [55] *Table 3*) conjugated to KLH and a globoH-KLH conjugate was evaluated in a clinical trial with biochemically relapsed prostate cancer patients, when administered with either QS-21 or GPI-0100 as immunological adjuvants [55]. The MUC2 peptide component was constructed synthetically and glycosylated

by treatment with ppGalNAcT II and ppGalNAcT IV glycosyltransferases. Analysis of post vaccination blood sera by ELISA using glycosylated MUC2 peptides conjugated to human serum albumin identified MUC2-specific IgM, IgG1 and IgG3 [55]. The highest antibody titers were derived from the administration of vaccine in combination with the QS-21 adjuvant. Of the nine patients who received the glycosylated MUC2-globoH-KLH vaccine, only one produced IgG1 and IgG3 capable of directing CDC against MCF-7 cells in vitro [55]. Similarly poor induction of CDC has been reported elsewhere [35,48,119].

In a recent study, the heterogeneous nature of cancer-associated antigens was addressed by Danishefsky and co-workers, in which a fully synthetic prostate cancer-specific vaccine incorporated multiple antigens (T, T_N, sT_N, Le^Y and globoH) displayed on a single polypeptide backbone (See [103] ❯ *Table 3*). This uni-molecular penta-valent vaccine was conjugated to either KLH or Pam_3Cys and administered to mice with QS-21. ELISA was used to compare antibody titers with those obtained from a control model that received each individual mono-valent antigen conjugated to KLH (T-KLH, T_N-KLH, sT_N-KLH, Le^Y-KLH and globoH-KLH). Mice that received the individually pooled mono-valent formulations induced high titer IgM responses against T_N, Le^Y and globoH. However, immunoglobulin class switching was not observed in response to any antigen using this formulation. In contrast, notable IgG titers were raised against T, T_N and sT_N following treatment with the uni-molecular penta-valent formulation coupled to KLH [103], whilst the Pam_3Cys conjugate generated IgG against T only, and at a significantly lower titer. Thus, the simultaneous administration of multiple carbohydrate antigens in a KLH-coupled, uni-molecular format served to recruit T_H-cells as part of the immune response against multiple antigens expressed by a specific (prostate) cancer. Importantly, IgG from sera generated against the penta-valent-KLH conjugate bound to MCF-7 cells (expressing globoH, Le^Y, sT_N, T and T_N), LSC cells (expressing Le^Y, sT_N and T_N) and DU-145 cells (expressing Le^Y and T) in vitro. In addition, the same study [103] describes the construction of additional uni-molecular penta-valent vaccine formulations (incorporating T, sT_N, T_N, GM2 and globoH), and increasingly elaborate hexa-valent molecules (displaying T, sT_N, T_N, Le^Y, GM2 and globoH) designed to specifically target breast and prostate cancer. Pre-clinical studies with these multivalent formulations are presently ongoing.

The efficacy of a fully synthetic mucin-based glycopeptide vaccine: α-*N*-acetylgalactosamine-*O*-serine/threonine (T_N) conjugated to either KLH or the B-cell activator palmitic acid (See [119] ❯ *Table 3*), was analyzed in a phase I clinical trial conducted with 15 patients presenting biochemically relapsed prostate cancer [119]. Patients presenting consecutive elevations in prostate-specific antigen (PSA), a biomarker that can be used to indirectly monitor disease progression, were eligible for trial. The vaccine was administered in a trimeric "clustered" formulation in combination with the adjuvant QS-21. Post vaccination blood sera were isolated and analyzed for immunoglobulin production and PSA levels. The highest antibody titers (IgM, IgG1 and IgG3) were observed with QS-21 as the adjuvant source, but presented a limited capacity to induce CDC in vitro (1 out of 15 patients). In contrast, patients that received $(T_N)_3$-palmitic acid produced IgM and very low titers of IgG. Notably, following treatment with $(T_N)_3$-KLH/QS-21, 33% of patients exhibited a reduction in PSA levels greater than 50%, whilst 46% presented PSA levels that remained stable after vaccination [119]. Importantly, 6/15 patients produced T_N-specific antibodies capable of binding to T_N expressing LSC colon carcinoma cells in vitro, whilst five patients enrolled in the trial remained disease free for 55 months [119].

In an alternative approach, a chemo-enzymatic strategy was used in the production of a multivalent mucin-based vaccine formulation. A MUC1 synthetic peptide comprised of 3 VNTR domains (3 × VTSAPDTRPAPGSTAPPAHG) was synthesized and glycosylated in vitro with purified recombinant human glycosyltransferase enzymes (GalNAc-T II, GalNAc-T IV and GalNAc-T XI: see [108] ❯ *Table 3*), such that 5 *O*-linked glycan groups were coupled per VNTR repeat. The extent of *O*-linked glycosylation with T_N was determined by MALDI-TOF analysis. The GalNAc-substituted MUC1 glycopeptide was then additionally sialylated (to form sT_N) with recombinant mouse ST6GalNAc-I, and coupled to KLH [108]. Wild type mice and mice transgenic for human MUC1 were vaccinated with these chemo-enzymatically derived formulations ($MUC1_{60}T_{N15}$ or $MUC1_{60}sT_{N15}$) with Freund's adjuvant to stimulate an immune response, and blood sera was analyzed by ELISA for the generation of antigen-specific immunoglobulins. Significantly, the transgenic model yielded MUC1 specific IgM and IgG1 with the $MUC1_{60}T_{N15}$ vaccine, and IgM, IgG1, IgG2A and IgG2B in response to administration of $MUC1_{60}sT_{N15}$, demonstrating immunoglobulin class switching in response to the administration of either vaccine. Whilst high MUC1-specific immunoglobulin titers were observed in both wild type and transgenic models, the highest values were observed when human MUC1 was expressed as self in the transgenic model, thus indicating that immunological tolerance can be broken. Furthermore, immunocytochemical analysis of sera produced following vaccination with $MUC1_{60}T_{N15}$ demonstrated positive staining of T_N-expressing T47D human breast cancer cells [108].

Interestingly, the immunogenicity of glycopeptides corresponding to the MUC1 VNTR domain was positively enhanced by substitution of amino acid residues involved in MHC binding [120]. Wholly synthetic, multi-component glycopeptide libraries modeled on human MUC1 were generated and administered with complete Freund's adjuvant to BALB/c mice. Lymph node T-cells were isolated from mice vaccinated with one such library containing the "MHC-anchor modified" glycopeptide APP(A)**MHG(V)LTSAP(D)ITRPA** (where the native residue in brackets is substituted for the residue in bold, and where GalNAc is attached to the boldface threonine). Characterization of the murine lymph nodes revealed the presence of T_H-cells that readily proliferated in response to the native, unmodified MUC1 glycopeptide in vitro [120]. Significantly, an equivalent response was not observed using the native unmodified MUC1 glycopeptide, clearly demonstrating that glycopeptide antigenicity was positively augmented by the engineered amino acid substitutions. Furthermore, use of the same glycopeptide library produced T_H-cells that proliferated following exposure to human breast cancer cell lysate in vitro [120], suggesting that the substitution of MHC anchoring amino acid residues does not adversely affect the presentation (and recognition) of the associated carbohydrate epitope. Hence, modification of peptide sequences lying within and outside of the VNTR domain with single or multiple amino acid substitutions can augment the immunogenicity of the corresponding peptide and glycopeptide antigens [118,120].

The majority of experimental results presented here demonstrate that a predominant antibody response is induced following the administration of mucin-based glycopeptide vaccines. The involvement of T-cells is observed however (as evidenced by immunoglobulin class switching from IgM to IgG mediated through T_H-cell stimulation of B-cells), although the production of antigen-specific $CD8^+$ CTLs is not a predominant feature of the observed immune responses. However, it must be noted that many of these vaccine formulations are designed specifically to induce an immunoglobulin response, where it is hoped that these formulations may serve by

eliminating the small number of remaining cells and circulating micrometastases that sometimes remain following the surgical removal of established tumors. However, when considering the structural nature of cancer-associated mucins and the ability of antibodies to mediate clearance by mechanisms such as CDC, perhaps a cautionary note of warning may be prudent where the administration of such vaccines is concerned.

21 Adoptive Transfer of Mucin-Based Antigens

Dendritic cells (DCs) are the most potent of antigen presenting cells, and function solely to present antigens to $CD8^+$ and $CD4^+$ T-cells via MHC class I and class II molecules respectively. Generating pools of activated, antigen-specific T-cells is often hampered in vivo by a cancer-driven subversion of the immune system. Adoptive transfer therapy has the potential to provide a way around this problem. DCs are removed from the cancer patient and cultured ex vivo with a source of cancer-specific antigen(s). During this time, internalization and presentation of antigen occurs on the DC cell surface, after which the cells can be re-administered to the donor patient to stimulate the production of cancer-specific T-cells in vivo. Alternatively, they can be used ex vivo to stimulate proliferation of antigen-specific T-cells which are cultured and re-introduced in large numbers back into the donor. The adoptive transfer of autologous (patient donated) DCs pulsed with cell lysates from MUC1-positive tumors or with nucleic acids encoding mucins or mucin-based peptides therefore aims to provide the recipient with a source of mucin-based antigens or antigen-specific T-cells from which potent, antigen-specific immunity can be derived. A number of in vitro human cell culture studies and pre-clinical in vivo murine studies demonstrate the feasibility of such an approach.

A murine model transgenic for human MUC1 that developed spontaneous pancreatic tumors expressing hypo-glycosylated MUC1 produced MUC1-specific $CD8^+$ CTLs in a natural immune response that failed to halt disease progression [121], an observation most likely explained by an inability of the immune system to distinguish "self" (healthy) from "altered self" (cancerous). Encouragingly however, the adoptive transfer of these unresponsive cells into healthy MUC1.Tg mice provided immunity against injected MUC1-positive tumor cells [121]. The significance of these results is twofold. First, they demonstrate that MUC1-specific CTLs can be produced naturally in response to the presence of MUC1-expressing tumors, and secondly, they serve to highlight that disease progression frequently occurs by cancer-mediated immune subversion despite the induction of an antigen-specific cellular immune response.

In another study, wild type mice were vaccinated with murine DCs transfected with MUC1 RNA from human breast cancer cells. In this system, human cancer-associated MUC1 RNA is translated by the murine DC cellular apparatus and presented on MHC class I molecules. Using this strategy, anti-MUC1 CTL-based immunity against a challenge with MC38 MUC1-positive, but not negative tumor cells was observed in vivo [122]. Critically, complete tumor clearance was observed in wild type mice with pre-established MUC1-expressing tumors following vaccination. However, introduction of these DCs into mice transgenic for human MUC1 did not provide immunity against MUC1-positive tumor cells due to pre-established immunological tolerance to mucins in the transgenic system. Importantly, a cellular anti-MUC1 immune response was observed in the transgenic model, but only when interleukin-12

(IL-12) was included in the treatment [122]. IL-12 is a multifunctional cytokine that (amongst other functions) is known to promote the expression of co-stimulatory molecules on DCs. The use of IL-12 with the adoptive transfer of murine DCs in this experimental system thus demonstrates that immunological tolerance to human MUC1 can be broken in vivo.

Vaccination of murine DCs pulsed with a synthetic peptide of 7 VNTR domains (7 × GVTSA-PDTRPAPGSTAPPAH: see [123] ❯ *Table 3*) into both wild type and MUC1.Tg mice induced only T-cell based immunity with a 90% rejection rate of injected murine T-cell lymphomas expressing human MUC1 [123]. The incorporation of 7 VNTR domains (rather than 1 or 2) was considered important for efficacy as previously, a synthetic MUC1 peptide composed of 7 VNTR domains was observed to be efficiently internalized and processed by DCs [124]. Using this formulation, MUC1-specific $CD8^+$ and $CD4^+$ T-cells were produced by the wild type mice (where human MUC1 is immunogenic) whereas significantly, only MUC1-specific $CD8^+$ T-cells were produced in the transgenic model [123]. These results demonstrate that whilst $CD4^+$-based immunological tolerance against human MUC1 was not broken in the transgenic system, tumor clearance can still proceed in the face of established immunological tolerance through a $CD8^+$ CTL-based mechanism. Furthermore and most importantly, these observations highlight that tumor clearance can proceed in the absence of an immunoglobulin or $CD4^+$ T-cell response in vivo.

In an in vitro study, DCs were pulsed with lysate from breast carcinoma cell lines MCF-7 (expressing sT_N, T, GM2, globoH and Le^Y) or MDA-MB-231 (expressing MUC1 TAAs as evidenced by binding of monoclonal antibody SM3 that recognizes the exposed peptide sequence PDTRP), and with tumor necrosis factor alpha and prostaglandin-E_2 as immunological adjuvants [125]. The pulsed DCs were then used to stimulate peripheral blood mononuclear cells in vitro. As a result, both activated $CD4^+$ T_{H1} cells and importantly, $CD8^+$ T-cells were obtained, indicating that presentation of MUC1 antigen to MHC class II molecules and cross-presentation (see also ❯ *Sect. 13* and ❯ *Fig. 6 J*) to MHC class I molecules had occurred [125].

Moreover, fusion of isolated MUC1-positive metastatic human colorectal carcinoma cells with autologous DCs provided a source of aberrantly glycosylated mucin together with the appropriate co-stimulation required to activate cellular immune responses in vitro [126]. Stimulation of patient-derived peripheral blood mononuclear cells with carcinoma-DC fusions generated antigen-specific CTLs that destroyed autologous MUC1-positive carcinoma cells in vitro [126].

A trial of 14 patients presenting advanced or metastatic cancer of the breast or lung (of which nine patients were MUC1-positive and five MUC1-negative) was conducted with DCs pulsed with either synthetic MUC1 peptide (TRPAPGSTAPPAHGVTSAPDTRPAPGSTAP: see [127] ❯ *Table 3*) or lysate from autologous cancer cells cultured in vitro [127]. Of the nine MUC1-positive patients, seven responded to vaccination and acquired antigen-specific immunity that caused a reduction in tumor size and prolonged survival in comparison with the MUC1-negative patients. However, following treatment, long-term immunity was found to be unsustainable in a number of patients. All of the MUC1-positive patients (four out of the seven that responded to vaccination) that received DCs pulsed with autologous tumor cell lysate subsequently relapsed. The three patients immunized with DCs pulsed with MUC1 peptide were alive at 3, 19 and 42 months post-vaccination at the time of trial [127].

A phase I clinical trial was conducted with a MUC1 peptide containing 3 VNTR domains and additional MUC1 flanking sequence (AHGVTSA[3 × PDTRPAPGSTAPPAHGVTSA]PESR-

PAPGSTAPAAHGVTSAPESRPAPGSTAPPAV: see [128] ❯ *Table 3*). The peptide was conjugated to oxidized mannan as an adjuvant and pulsed to autologous DCs that were administered to ten patients with advanced MUC1-positive adenocarcinomas [128]. Following treatment, vaccine-specific $CD4^+$ and $CD8^+$ T-cell responses were observed in all patients that were sustained for 1 year, whilst continual treatment led to disease stabilization in two of the ten patients [128].

The use of peptides to pulse DCs in adoptive transfer experiments is not restricted to the use of a single amino acid sequence. In one study, a computational screen of MUC1 was performed to identify peptide sequences that would bind to MHC class II (HLA-A2) molecules. Two peptide sequences were identified: STAPPVHNV from the VNTR domain and LLLLTVLTV from the leader sequence of the molecule [129]. Both of these peptide sequences were synthesized and used to pulse DCs, which were then further pulsed with the T-helper epitope PADRE to stimulate a $CD4^+$ T-cell response (See [130] ❯ *Table 3*). The efficacy of these "triple-pulsed" DCs was evaluated in a clinical trial on 20 patients presenting MUC1 positive metastatic renal cell carcinoma [130]. Following five vaccinations, patients additionally received treatment with IL-2. Post-treatment, MUC1 antigen-specific CTLs were produced that lysed target cells in ^{51}Cr release assays and caused disease stabilization in four patients and regression in six [130].

In spite of the immunological tolerance observed in murine studies, consideration of the above results demonstrate that humoral and cellular immune responses can be generated from the adoptive transfer of cancer-associated mucins in vitro and in vivo. In the clinical setting, the most promising results appear to be those obtained with DCs pulsed with synthetic MUC1 peptides rather than tumor cell lysate. One possible explanation for this observation may lie in the purity of the antigen preparation. The presence of a heterogeneous pool of TAAs derived from whole-cell preparations may result in the generation of large numbers of DCs, of which only a small proportion actually present the required antigen.

22 Concluding Remarks

The central challenge of mucin-based vaccine technology remains to break immunological tolerance to one or more cancer-specific antigens, such that immunoglobulins and cytotoxic T-lymphocytes can combine to rapidly clear established tumors from cancer patients. The combined use of both chemistry and biology in addressing this challenge has thus far provided encouraging data in preclinical trials, where in the majority of experiments, mutually exclusive immune responses producing either immunoglobulins or cytotoxic T-lymphocytes against specific antigenic targets is observed. Translation of these formulations to the clinical setting highlights that whilst positive progress is undoubtedly being made, a consistently effective vaccine formulation has yet to be produced. However, encouragement must be drawn from these initial clinical observations, which will undoubtedly pave the way forward towards the generation of more effective treatments. Re-addressing the "either-or" nature of vaccines to harness the full capacity of the immune system, so that both cancer-cell specific immunoglobulins and cytotoxic T-lymphocytes can be brought to bear against established tumors in the clinical setting remains the ultimate goal.

Abstract

Capsular polysaccharides (CPS) and lipopolysaccharides from bacteria are employed for the production of vaccines against human diseases. Initial development of CPS as a vaccine was followed by the development and introduction of conjugate polysaccharide-protein vaccines. The principles leading to both developments are reviewed.

Keywords

Polysaccharide vaccine; Conjugate vaccine; Meningitis; Pneumonia; *Haemophilus influenzae* type b

Abbreviations

ADH adipic acid dihydrazide
CPS capsular polysaccharides
CRM_{197} cross reacting mutant from diphtheria toxin
DT diphtheria toxoid

In: *Glycoscience*. Fraser-Reid B, Tatsuta K, Thiem J (eds)
Chapter-DOI 10-1007/978-3-540-30429-6_69:

Hib *Haemophilus influenzae* type b
Im imidazol
KLH keyhole limpet hemocyanine
LPS lipopolysaccharide
Nm *Neisseria meningitidis*
Sp *Streptococcus pneumoniae*
TT tetanus toxoid

1 Introduction

A variety of glycans with important structural and functional roles are produced as part of bacteria cell walls. Capsular polysaccharides (CPS), teichoic acids, and lipopolysaccharides (LPS) are the three most important and represent the bacterial first line of defense against complement and bacteriophages. The carbohydrate portion of this glycoconjugate contains the major antigenic determinants that distinguish various serotypes of bacteria [1].
It has long been known that the presence or absence of CPS correlates in many cases with disease and that bactericidal and opsonic antibodies directed against them protect the host from invasive disease caused by encapsulated bacteria [2]. Antibodies directed against the LPS play also a major role in protection against infection by avoiding bacterial colonization of specific mucosa or organ [3].
The interest in polysaccharide-based vaccines was originated already in the 1930s and associated mainly with bacterial meningitis and pneumonia. In 1945, a Sp-vaccine made from CPS of four serotypes was studied [4] but the advent of chemotherapeutics and antibiotics diminished the interest in this area of study. A resurgence of interest in preventative medicine occurred only after several decades due to the increase in bacterial antibiotic resistance and the occurrence of meningitis epidemics.

2 Vaccines Based on Capsular Polysaccharide

Haemophilus influenzae, *Neisseria meningitidis*, and *Streptococcus pneumoniae* are the leading cause of bacterial meningitis, pneumoniae, and sepsis. Although six types of *Haemophilus influenzae* [5], 13 groups of *Neisseria meningitidis*, and more than 90 serotypes of *Streptococcus pneumoniae* [6] are known, only a limited number are clinically important. A single type b of *Haemophilus influenzae* is associated with more than 90% of all Hi pneumonia and meningitis. This is a typical pathogen of children under five years with a peak of incidence occurring mainly in the first year of age [7]. The Hib-Meningitis is associated with a high rate of sequelae among survivors.
Serogroups A, B, C, W135, and Y are responsible for more than 90% of meningococcal meningitis. The disease affects the early infancy but also occurs in older children and particularly adolescents [8]. In the so-called "meningitis belt" of Africa, a well-characterized epidemic pattern is observed for group A with some occurrence of group C.
Pneumococcal infections can occur at all ages, but they have two peaks of incidence in the first years of life and in the elderly [9]. At least 23 serotypes are associated with the disease,

Table 1
Commercially available polysaccharide vaccines

Bacteria	Vaccine	Company	Valency	CPS
Streptococcus pneumoniae	PneumovaxII	Aventis-MSD	23	1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, 33F
	Pnu-immune	Wyeth	23	
Neiseria meningitidis	AC Vax	GSK	2	A, C
	Mengivax (A + C)	Aventis	2	
	Menomune	Aventis	4	A, C, W-135, Y
	Mencevax	GSK	4	
Salmonella typhi	Typhim Vi	Aventis	1	Vi

but its distribution is associated not only with age but also with geographical regions [10]. An important international collaborative effort is actually been made for establishing the burden of disease worldwide and the serotypes associated with them [11].

The potential of CPS as human vaccines for prevention of meningitis and pneumonia was ascertained by the fact that protective immune response is serotype-specific [4,12] and is directed mainly against the capsular polysaccharides; other cellular components are recognized by protecting antibodies to a significantly lower extent [13].

For Hib, Nm, and Sp the CPS expression correlates with increasing virulence [14,15]. The capsules themselves are highly hydrated shells surrounding the bacterium and mediating the adherence of the bacterium to biological and inorganic surfaces. The capsule inhibits or interferes with recognition of the bacteria cell wall by antibodies, adherence of complement, and ingestion of bacteria by host cells and killing of the bacterium after phagocytosis [16]. The polyanionic properties of the vast majorities of CPS help them in modulating the passage of molecules and especially ions to the bacterial cell envelope.

Capsular polysaccharides purified from bacteria are almost non-toxic and considerably less toxic than the whole-cell and elicited anti-polysaccharide antibodies at a single dose of 10–50 μg [17]. The antibodies provide type-specific immunity lasting for several years in healthy humans [18]. The simplicity of polysaccharides as vaccines and its low toxicity prompted development of the first polysaccharidic pneumococcal vaccine (tetravalent) marketed as early as 1946 [19]. Polysaccharide vaccines were only really introduced during the 1970s to counteract the emergence of bacterial resistance to antibiotics.

In 1974 vaccines against *Neisseria meningitidis* [20] followed by *Streptococcus pneumoniae* [21,22] in 1977 and later *Haemophilus influenzae* type b [23] were licensed (see *Table 1*).

2.1 Anti-CPS Response and the Structure of the CPS

The anti-CPS antibody response recognizes linear epitopes on the polysaccharides [24]. The response is strong, but of relative low avidity, with a production mostly of IgM and IgG2

antibodies, which are not good activators of complement. The IgM is rapidly cleared but the IgG2 response lasts for a few years. Typically the antibody response drops to about a quarter of its initial value after four years in adults, and more rapidly in children [25].

Polysaccharides are T-independent antigens [26] and as a general rule the response to polysaccharides occurs 3–18 months after birth in humans, but it depends on the CPS structure; generally, children less than 2 years of age respond poorly. Immunological memory is not induced and as a result no boosting of the antibody response takes place on reimmunization. The affinity maturation and isotype switching of the antibody repertoire is absent.

Considering their relative simplicity of production and the low toxicity, this pattern of immunological response was generally acceptable in "the absence of better vaccines" and is acceptable now only for vaccines used to protect the elderly from pneumonia or high risk groups over short periods, for example during epidemics.

Some of the capsular polysaccharides are good immunogens and others are poor immunogens although there is no general rule associating structure with immune response. For example, the capsular polysaccharide of group A Meningococci [27,28] is a good immunogen in infants starting at the age of 3 to 6 months and produces protective levels of IgG antibodies. One or two-dose regimes of group A or bivalent A + C vaccine may be useful to protect infants during epidemics, although without offering a long-term protection [29]. Pneumococcal capsular polysaccharides of serotypes 3 and 18C induce also a good antibody response in infants as young as 6 months, but only older children respond to the CPS from serotypes 19F and 23F [30]. The capsular polysaccharide of serotype 6 is a poor immunogen at all ages [31]. *Haemophilus influenzae* type b capsular polysaccharide elicits long-lived and complement-mediated bactericidal antibodies in adults [13].

The structure of the repeating unit from the CPS used in polysaccharide vaccine is provided in ❯ *Table 2*. Some of them, particularly those from *Neisseria meningitidis* with a simpler repeating unit, were solved primarily using one-dimensional ^{13}C NMR spectroscopy and were amongst the first complex polysaccharide structures elucidated using these techniques.

Capsular polysaccharides are characterized by the presence of a strict repeating unit as for example in *Haemophilus influenzae* type b where a phosphodiester bond is a bridge between ribosyl-ribitol without any additional substituent. In other CPS the structure becomes heterogeneous by incomplete substitution or multiple *O*-acetylation sites. The repeating unit in *Neisseria meningitidis* is linear and composed only of a mono or disaccharide. All have a small repeating unit, are of relatively low-molecular weight and contain either phosphate or Neu5Ac as the anionic group. The repeating unit of *Streptococcus pneumoniae* capsular polysaccharides have a more complex structure (between 2–7 monosaccharide residues), often contain uronic acids but not sialic acid and are substituted with a wide range of groups, including *O*-acetyl, pyruvate acetal, and glycerol phosphate groups.

O-Acetyl groups are immunologically relevant in several CPS. For example, de-*O*-acetylation reduces or completely abolishes the recognition by anti-CPS sera in Nm serogroup A [32] and also in Sp capsular polysaccharides from serotype 1 [33], 11A [34], 15F [35], and 34 [36]. In a few cases the *O*-acetyl group can be removed without significant loss of activity toward serotype-specific serum. The most remarkable is Nm serogroup C. About 15% of meningococcal group C isolates produce a non-acetylated polysaccharide but antibodies induced by this CPS are still protective against infections caused by strains expressing *O*-acetylated CPS [37]. The fine specificity of antibodies reveals that both polysaccharides could be used in the produc-

tion of glycoconjugate vaccine with similar efficiency [38]. Sp serotype 20 is also recognized by anti-Sp20 serum after de-*O*-acetylation [39].
Other substituents in CPS are also immunodominant in most cases. For example, the pyruvate groups are immunodominant in serogroup 4. Its removal clearly changes immunological properties of the CPS [40]. Phosphates are very frequent in Sp CPS mainly as a phosphodiester bridge, but it could also be part of a backbone as free phosphate, glycerol 1-phosphate, glycerol 2-phosphate, ribitol phosphate. As a backbone the substituents become immunodominant and their loss abolishes the recognition, for example after dephosphorylation of Sp23F [65].
Lipopolysaccharides are also considered T-independent antigens [66]. LPS share some common features with CPS as for example direct stimulation of B-cells in the absence of T-cells, weak immunogenicity and protective capacity of the anti-LPS antibody response. While CPS initiate the immune response binding directly to the IgM receptor on B-cells and crosslinking them through their numerous repeating epitopes and are nontoxic, LPS are potent B-cell mitogens and are highly toxic [67], a fact that precludes its direct use as human vaccine.
Vaccination of infants and young children with CPS failed in producing serotype-specific antibody and general vaccination of humans of all-age with LPS is unacceptable due to its toxicity [68]. This failure is the main driving force behind the development of conjugate vaccines.

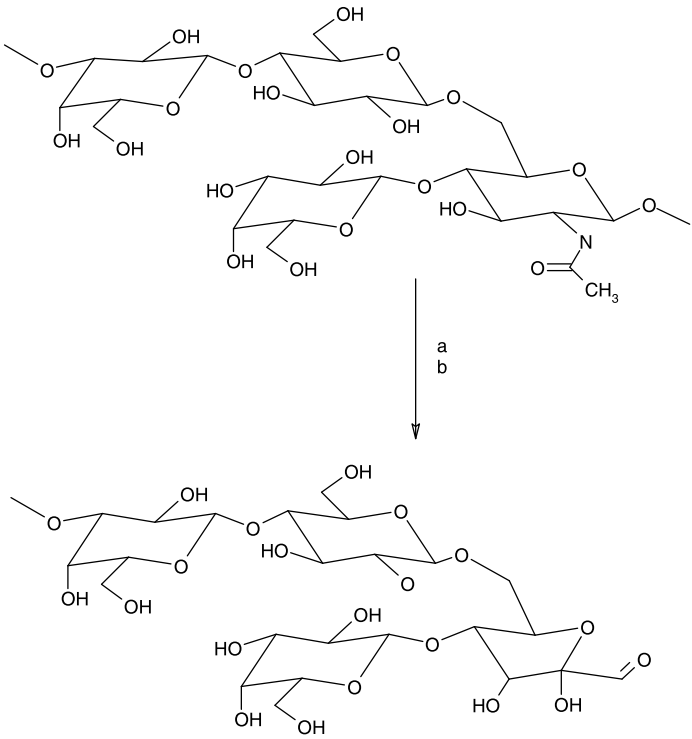
3 Glycoconjugate Vaccines

Polysaccharides are ideally located on the surface of bacteria and are a source of the most highly conserved protective epitopes. One of the challenges in vaccine development during the final quarter of the 20th century was to develop a better anti-carbohydrate immune response for CPS and LPS. Conjugation of polysaccharides to proteins provided a solution to some of the limitations found for natural compounds.
The concept of hapten and hapten-protein conjugate was introduced in the 1920s by Karl Landsteiner to provide a chemically defined system for studying the binding of and individual antibody to a unique epitope on a complex protein antigen [69]. According to this concept small organic molecules (haptens) were chemically coupled to a large protein (carrier) giving a hapten-carrier conjugate. Animals immunized with such a conjugate produce specific antibodies not only against the carrier protein (unaltered epitopes) but also for the hapten determinant.
Avery and Goebel applied this concept to cellobiouronic acid [70], and also to the Sp serotype 3 CPS. Both conjugates to horse serum globulin were able to induce polysaccharide specific antibodies and remarkably they conferred immunity to challenge by live *Streptococcus pneumoniae* serotype 3.
The development of conjugate vaccine as a pharmaceutical was initially undertaken for *Haemophilus influenzae* type b [71] and later, after the impressive success was extended to other CPS from *Streptococcus pneumoniae* [72] and *Neisseria meningitidis* [73]. The development of glycoconjugate vaccines from group B *Streptococcus* [74,75], *Salmonella typhi* [76], *Staphylococcus aureus* [77] CPS are also under different investigation stages. The development of conjugate vaccine from the carbohydrate portion of lipopolysaccharide is less straightforward and although the concept was proved at experimental level for *Vibrio cholerae* O1 [78] and O139 [79], *Shigella sonnei* and *flexneri* 2a [80], the vaccines are in earlier stages

of development-application and the concept is not fully proven in clinics. It is impossible to cover all aspects of the development of glycoconjugate vaccine in this chapter. For a detailed inventory of research the reader can consult excellent reviews on this matter [81,82].
Basically, the success in development of carbohydrate-protein conjugate vaccines as pharmaceuticals [83] is defined by the adequate selection of: (a) polysaccharide modification strategy, (b) the carrier protein and its modification, (c) the conjugation methods and by the establishment of analytical methods for the evaluation of the final glycoconjugate.

3.1 Polysaccharide Modification Strategy

Molecular weight is an important property for CPS vaccines as the immune response is induced by interaction of repeating epitopes with IgM B-cell receptors and their crosslinking. In glycoconjugate vaccines, the immune response proceeds by a different mechanism involving T-cells. Therefore, the length of the carbohydrate chain in a CPS-protein conjugate is not as important and restricted as for the CPS vaccines. The epitope recognized by antibodies to CPS is generally located in a linear small fragment of the capsular polysaccharide and consequently polysaccharide-protein conjugates prepared from CPS with a broad range of molecular weight have been shown to be excellent immunogens experimentally and in clinical practice [59]. T-cell dependency is more pronounced for conjugates with small-sized fragment polysaccharides. For example, small dextran molecules (4 KDa) were better immunogens in mice than for large ones ($\leq$ 40 KDa) [84,85]. Glycoconjugates from high molecular weight polysaccharides are immunogenic in humans at lower dose [86].
Very short oligosaccharides of one or two repeating units may not always raise antibodies specific for the polysaccharide [87,88] and usually are excluded from the preparation of glycoconjugate vaccines. Apart from that, fractions selected with a broad spectrum of size could be considered and for instance were employed successfully in the glycoconjugate vaccines developed so far. In the design of a glycoconjugate vaccine, the selection of the polysaccharide size is actually dictated by the conjugation technology and the removal of free CPS from the final product rather than by immunological consideration. Molecular sizing of the polysaccharides can be seen as a simple and effective means to ensure consistency of the final conjugate [89]. Therefore, partial depolymerization is usually performed before activation even if the intention is to use high molecular weight polysaccharides for conjugation.
For high and low molecular weight polysaccharides the strategy for conjugation differs markedly, specially for the type of activation: In large polysaccharides the activation modified randomly internal sites situated along the chain. Small oligo- or polysaccharide fragments could be selectively modified by terminal activation at one or both ends of the carbohydrate chain [90].
The methods for depolymerization more frequently employed are acid [91] or enzymatic hydrolysis [92] and ultrasonic irradiation [93,94]. The mixture of fragments is separated into fractions of selected molecular sizes by methods such as ion exchange chromatography [95] or gel filtration or ultrafiltration [96]. In some particular cases, endoglycosidases could provide selective cleavage of a specific bond. For example, Sp serotype 14 could be fragmented by the catalytic hydrolysis of endo-β-galactosidase from *Flavobacterium keratolyticus* [97].



Scheme 1
(a) NaOH, (b) $NaNO_2$

Defragmentation and activation could be performed simultaneously. For example, partial de-*N*-acetylation and nitrous acid deamination of the Sp serotype 14 CPS [98] proceeds with a rearrangement leading to a terminally activated oligo or polysaccharide according to the *Scheme 1*.

For some polysaccharides as for example Nm group C [99] and *H. Influenzae* type b [100] the periodic oxidation occurs selectively at a position leading to fragmentation of the CPS.

Depolymerized CPSs are further modified for activation. The following examples of *Haemophilus influenzae* type b CPS modification illustrate very well the broad spectrum of present technology [101] (see *Scheme 2*).

Method A. A high molecular weight polysaccharide was activated by reaction with cyanogen bromide at basic pH, in a similar fashion Sepharose is activated for affinity chromatography. The reaction takes place at all possible hydroxy groups to produce O–CN randomly

Scheme 2
Modification of Hib capsular polysaccharide for conjugation. (a) CNBr/OH–; (b) Adipic acid dihydrazide; (c) Carbonyldimidazole/OH–; (d) Butanediamine; (e) p-nitrophenylbromoacetate; (f) Sodium periodate; (g) Acetic acid; (h) Ethylendiamine, sodium cyanoborohydride

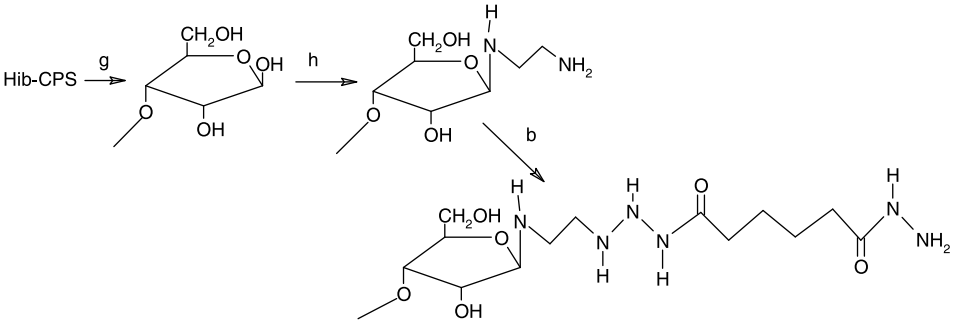
METHOD D



distributed all along the chain [102]. A spacer was introduced with adipic acid dihydrazide (ADH). The reactive group for conjugation is a very reactive hydrazide.

Method B. A high molecular weight polysaccharide was size-reduced and further transformed into a tetrabutylamonium salt for solubilization in dimethylformamide or dimethylsulfoxide [103]. The reaction sequence for activation is rather complex and includes activation of hydroxy groups with carbonylimidazol followed by introduction of a spacer with a terminal bromoacetate function.

Method C. The polysaccharide was directly oxidized by sodium periodate. The oxidation is restricted to the ribitol moiety leading to simultaneous fragmentation and terminal activation. As a result a fragment was obtained having aldehyde functions at both ends [100].

Method D. The polysaccharide was hydrolyzed with acetic acid to fragments having between 5 and 15 repeating units. After purification, ethylendiamine reacts at the terminal reducing end introducing a terminal amino function. Similarly to method A, the reaction with ADH introduced a spacer having terminally a very reactive hydrazide function [104].

The modification of the polysaccharide depends strongly on the structure. For example the meningococcal group C polysaccharide is partially acetylated at positions 7-8. Acetylation preclude the periodic oxidation, therefore the oxidation occurs only at those units with a free diol. The oxidation similarly to Hib polysaccharide breaks the structure producing size-reduced and terminal activated polysaccharide. The same process for Sp serotype 19F could take place at several internal bonds without size-reduction generating aldehydes randomly distributed along the chain (see ❯ *Scheme 3*). The control of the processes is essential in both cases to achieve the introduction of an ideal number of active groups. Over-activation will affect the structure of the CPS and reduce their recognition; under-activation will reduce the yield on the conjugation step or will produce less stable conjugates since the carbohydrate-protein attachment is effected only through a low number of sites.

3.2 Selection of the Protein Carrier and its Modification

Several highly immunogenic bacterial proteins have been proposed as carriers for conjugate vaccines. The list includes bacterial pili, outer membrane proteins (OMPs), and excreted toxins of pathogenic bacteria [105], preferably in toxoid form. Tetanus and diphteria toxoids, which are readily available and accepted for human use, are the preferred carrier despite the lot-to-lot variations during the detoxification procedure.

Alternative recombinant carrier proteins have been developed, for example CRM_{197} a non-toxic analogue of diphtheria toxoid [106,107] and a 42 KDa outer membrane protein from *Haemophilus influenzae* [108].

The lysine amino function is usually employed for conjugation but in some cases the amino group was modified to a thiol, for example, 25% of free amines in Nm Outer Membrane Protein were modified with *N*-acetylhomocysteine tiolactone [103].

The development of tetravalent meningococcal and 13-valent pneumococcal conjugate vaccine pointed to the future need of new carrier proteins. Experimentally or in very early clinical development are several proteins. Examples are *Bortedella pertussis* fimbriae [109], recombinant 64 KDa Nm OMP [110], Nm porin [111], and Sp pneumolysin [112].

3.3 Conjugation Methods

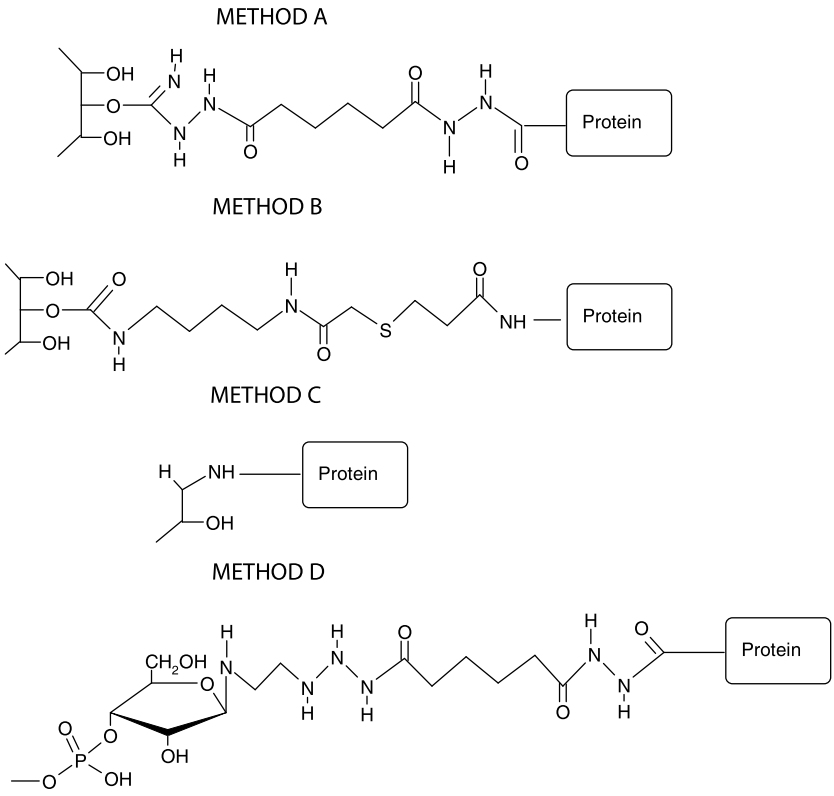
The polysaccharide modification strategy, the selected protein carrier and the conjugation methods are interdependent. The structure of the carbohydrate-protein conjugate could be very diverse ranging from a neoglycoprotein type made from smaller fragments of the CPS linked

to a protein through a single point to a multicomponent lattice-type which contains several molecules of both components each linked at a multiple point.

A wide variety of glycoconjugation methods were explored and are covered in the numerous reviews on the subject [113]. Carbohydrate-conjugates to bovine or human serum albumine are usually obtained as the very first step in conjugation research. Such conjugates serve not only as a model but also for studying the antigenicity of the conjugate polysaccharide, i. e. the ability of being recognized by antibodies of the unmodified CPS.

For the development of polysaccharide-protein conjugates as pharmaceuticals it is necessary not only to perform covalent coupling of both molecules but also to fulfill [83] some the following important requirements:

- The linkages formed during the conjugation process should be stable and also immunologically and pharmacologically acceptable.
- The integrity of both components has to be maintained.
- The residual reagent should be eliminated. Any residual reagent left should be below acceptable levels related to toxicity.



Scheme 4
Structure of conjugates made by methods (a)–(d)

- Neoepitopes formed either as a result of the conjugation or after active group capping could not be immunologically relevant.
- The product must be as defined as possible to facilitate their control.
- The conjugates have to be reproducible and water soluble.
- The immunogenicity of the conjugate must be optimized in terms of polysaccharide size, loading of the protein carrier, and CPS–protein ratio.

The direct introduction of active groups on the polysaccharide and the protein could seriously affect the efficiency of the coupling by steric hindrance [114]. By direct attachment, the saccharide epitopes could be shielded by the secondary structure of the protein. To avoid this problem, a spacer arm is frequently introduced either on the modified CPS or on the protein carrier during the design of a glycoconjugate. The conjugates represented in *Scheme 4* have been shown to be highly stable. They contained aliphatic amines [115], amides [116,117], or thioethers [118].

3.4 Glycoconjugate Vaccines from Lipopolysaccharides

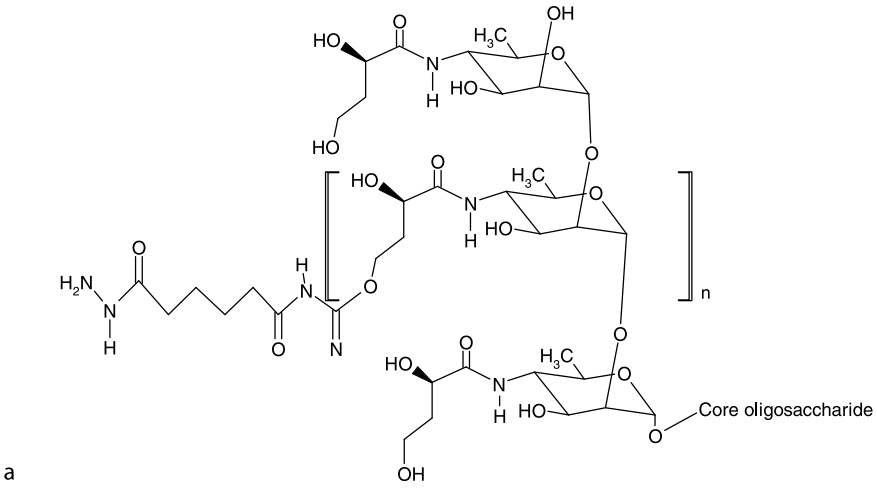
Anti-lipopolysaccharide response plays an important role in protection against disease [3] by interfering with colonization. The use of intact LPS as vaccines however, is precluded by their toxicity, which must be reduced as a critical first step before any further manipulation is done to improve the anti-LPS immune response. If detoxified and the LPS retains the epitopes it could be conjugated to a protein carrier to develop a better anti-carbohydrate response in a similar fashion to CPS.

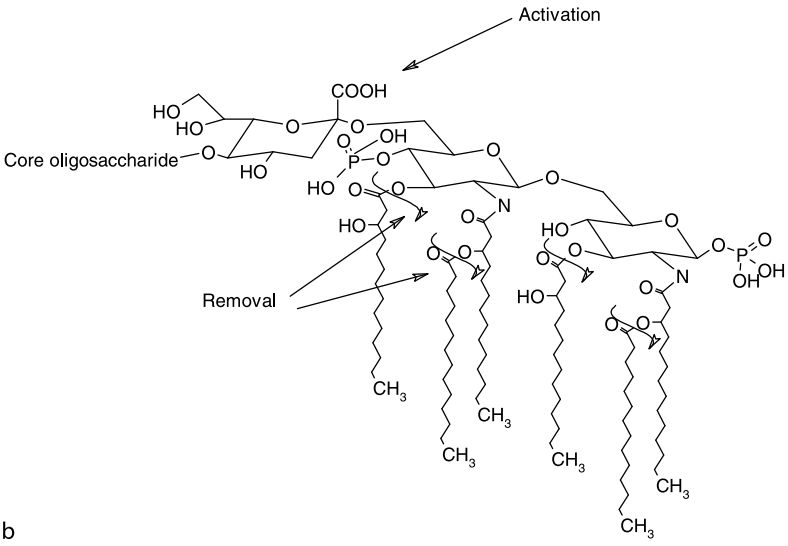
The general simplified structure of the LPS contains three domains; (a) *O*-polysaccharide chain, responsible for serotype specificity, (b) core polysaccharide, a conserved, usually short oligosaccharide chain containing KDO and (c) lipid A, which is responsible for the toxicity and is composed of GlcNAc-disaccharide substituted by several fatty acids linked as esters or amides.

The modification and activation of LPS for conjugation to a protein is more complex than for CPS. The first step is detoxification by fragmentation of the lipid A moiety either by the cleavage of the acid-sensitive KDO-lipid A linkage or by saponification of fatty acids. Acid hydrolysis completely eliminates lipid A and could be used in the absence of acid-sensitive monosaccharides for isolation of the *O*-polysaccharide. Saponification of fatty acids by base hydrolysis or hydrazinolysis also reduces the toxicity to acceptable levels.

LPS with a long *O*-polysaccharide chain could be regarded as CPS for conjugation and is usually activated by random modification of the polysaccharide chain. Examples illustrating the complexity and potential of LPS for glycoconjugate vaccines are shown in *Scheme 5*. Detoxification by hydrazinolysis conserved the structure better than NaOH saponification for *Vibrio cholerae* O1 LPS [119,120]. The remaining detoxified LPS is then activated by Method A (*Scheme 2*) and conjugated to cholera toxin B-subunit, a pathogen related carrier. Immunization of 38 human volunteers with two doses of vaccine [78] induces anti-LPS IgM, IgG responses, and vibriocidal titers comparable to those immunized with whole-cell vaccine.

A number of bacteria display LPS with short *O*-polysaccharide chains. These short *O*-polysaccharide chains are more conserved and could potentially afford a broader protection. Once detoxified, the strategy for conjugation differs from that previously used for LPS O-polysac-





Scheme 5

(a) Structure of the *O*-polysaccharide from *V. cholerae* O1 Inaba after detoxification followed by modification using Method A. (b) Structure of LPS from non-typable *Haemophilus influenzae*. The sites and type of modification are shown

charide. Random activation of such a small carbohydrate is impossible without affecting the integrity of the molecule and its recognition. Terminal activation is more suitable and is used for example in the modification of non-typable Hi-LPS [121]. The detoxified LPS are activated via the residual KDO-COOH by ADH and carbodiimide. Finally, the conjugation is performed in a similar fashion as described in Method D (*Scheme 2*).

3.5 Properties of Conjugates

Carbohydrate-protein conjugates stimulate the immune response through a very complex process. In a simplified model it involves the binding of the glycoconjugate to the surface immunoglobulin of the follicular B cell population with appropriate specificity for the saccharide hapten [122]. The glycoconjugate is endocyted and the carrier is fragmented into peptides. Selected peptides that bind to major histocompatibility complex class II molecules are displayed on the cell surface and recognized by peptide-specific T-cell receptors on the T-cell [123]. The cognate interaction between PS-specific B-cell and T-cell is modulated by interaction not only of MHC II-TCR, but also by CD40-CD40L and CD28-B7-1/-2 [124]. The interaction induces activation of the B-cell with differentiation into antibody secreting cells, germinal-center formation, class switch recombination, and somatic hypermutation. Memory B cells generated during this T cell-dependent process can be activated by subsequent stimulation with either PS-protein conjugates or by the CPS alone or by the whole-bacteria.

Glycoconjugate vaccines are considered biological pharmaceuticals. With the upsurge of recombinant biological pharmaceuticals, an evolution from traditional bioassay to physicochemical characterization is taking place. This evolution influences strongly the development of more and more complex glycoconjugate formulations as one of the limiting steps was the inability to fully characterize the products or their combination. Actually, modern physicochemical methods allow glycoconjugates to be characterized with a degree of precision previously not possible [125,126]. A combination of methods such as circular dichroism, size exclusion chromatography, high performance anion exchange chromatography, mass spectrometry, and NMR spectroscopy [127,128] are used.

The first glycoconjugate vaccine introduced into clinical practice was *Haemophilus influenzae* type b in the 1990s. After initial introduction in industrialized countries, the vaccination coverage was extended slowly to cover 26% of children worldwide. The World Health Organization recommended the inclusion of anti-Hib in the extended program of immunization [139].

Glycoconjugate vaccines induce a strong IgG immune response in infants with memory and also prevent nasopharyngeal Hib colonization. Few vaccines in history have induced such a dramatic decline in incidence over such a short period as have the Hib conjugates [140]. At present, six different glycoconjugate vaccines are commercially available (see *Table 3*). The formulations contain the vaccine either alone or in a preferred pentavalent combination containing conjugate anti-Hib, anti-hepatitis B and the classical Diphtheria, Pertussis, and Tetanus combination [141].

The spectacular success of anti-Hib conjugate vaccine prompted the development and introduction of other glycoconjugate vaccines. Several meningococcal group C-tetanus toxoid conjugates based on periodate oxidize polysaccharides were licensed. Glycoconjugates for other meningococcal groups were also developed and are now available in bivalent AC or tetravalent A, C, Y, and W135 combination. The development of multivalent glycoconjugate vaccine introduces further complexity. A challenge for modern technology was the development of multivalent glycoconjugate vaccine against *S. pneumoniae.* Prevenar, a licensed heptavalent vaccine containing serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugate to recombinant CRM_{197} protein induced a dramatic decline in bacterial pneumoniae in the US and other countries [134]. However, this vaccine could not be considered universal because serotype distribution of Sp depends strongly on geographical regions [142]. Vaccines containing more than ten

Table 3
Commercially available conjugate vaccines

Menactra	Nm A,C, Y and W_{135}	DT	Sanofi Pasteur	[138]

serotypes are in an advanced stage of development [108,143] and this shows the level attained by modern technology.
Vaccination with Prevenar reduced seven serotypes of Sp included in the conjugate vaccines. An increase in circulation of serotype 19A, not included in a vaccine, warns of the possibility of a replacement phenomenon [144]. Capsular polysaccharide serogroup seems not to be a fixed attribute of a strain for Nm [145] and Sp [146], as the exchange of single gene cassettes involved in CPS biosynthesis is a frequent process that could affect the speed of a replacement phenomenon.
Glycoconjugate vaccines from other capsular polysaccharides are in preclinical or clinical evaluation steps for Group B *Streptococcus*, *Salmonella typhi*, Shigellosis, Cholera, and *Staphylococcus aureus*.

3.6 Synthetic Carbohydrate-Protein Conjugate Vaccines

The production of CPS by bacteria fermentation-extraction-purification procedures presently reaches a very efficient level. Purified CPS or LPS should be chemically modified for conjugation to a protein by a very complex procedure and give a final product that needs to be as defined as possible. If the production or purification of the carbohydrate material from the natural source is difficult and one bears in mind the complexity of producing a consistent glycoconjugate from a natural polymer then opportunities for modern synthetic carbohydrate chemistry are at hand.
The field is actually in a good position to contribute to the development of bacterial polysaccharide glycoconjugate vaccines. Numerous fragments of capsular polysaccharides, lipopolysaccharides, or other bacterial carbohydrates have been synthesized and their protein conjugates obtained [87].
They supply valuable information on the influence of saccharide size and structure on immunogenicity. The use of synthetic oligosaccharides in the development of glycoconjugate vaccines for human use is, however, a very complex task far beyond a laboratory synthesis of a given oligosaccharide and oligosaccharide-protein conjugate.

Anti-Hib vaccine was the first glycoconjugate to be developed up to clinical use in humans. The structure of the Hib-CPS was an attractive target for synthetic carbohydrate chemistry in the 1990s. Accordingly, several syntheses of Hib-oligosaccharides and their protein conjugates were developed. An important step was the demonstration that a tetrameric oligosaccharide-tetanus toxoid conjugate induced anti CPS responses with an increasing IgG/IgM ratio in adult mice and monkeys [147] and that the synthesis of an oligosaccharide fragment having three repeating units coupled to T helper synthetic peptides raised protective antibodies against Hib infection in an infant rat model [148].

For anti-Hib vaccine, synthetic chemistry was compelled to reach the efficiency level attained during the production of the glycoconjugate vaccine from natural CPS. The contribution of several groups [149] to the synthesis of Hib-oligosaccharides paved the way for further improvement. A simplified synthesis of the repeating disaccharide unit and chain elongation process in one step through a polycondensation reaction were essential achievements before further developments and clinical evaluation were possible (see ❯ *Scheme 6*). The synthetic

Simplified structure of synthetic oligosaccharide fragment-protein conjugates using thiol-maleimido chemistry. (a) Conjugation of synthetic Hib-CPS fragment to thiolated Tetanus Toxoid. (b) Conjugation of *Plasmodium falciparum* synthetic pentasaccharide to KLH

oligosaccharide fragment with a terminal spacer arm activated through a maleimido function could be coupled to thiolated-TT with good yields and reproducibility [150] (see *Scheme 7*). The clinical evaluation in infants showed a comparable high efficiency for the vaccine containing the synthetic antigen against Hib infection [133] allowing licensing and use of the vaccine in infants since 2004.

Activity in the field has increased in the last few years and other projects targeting the synthesis of CPS or LPS fragments are in development. Citing only some of them, vaccines against

shigellosis [151,152], cholera [153], and Sp [154] are in preclinical or early clinical evaluation. While these projects afford valuable information on the antigen-antibody recognition, their feasibility and competing advantages over natural sources of antigens for the production of glycoconjugate vaccines remains to be demonstrated. Other projects as for example malaria [155] which identifies a pentasaccharide as an important carbohydrate antigen associated with the toxic effect of Plasmodium have additional opportunities (see *Scheme 7*). In this particular case the improved syntheses as well as the difficulties in isolating the carbohydrate from natural sources are positive circumstances.

4 Future Prospects

The impact on health care of polysaccharide-based vaccines for bacterial diseases in the last 15 years attracted much attention to this research field [156]. The evolution is not only toward the development of new vaccines for unsolved diseases but also for increasing the efficiency of existing vaccines. Noteworthy, a fully designed synthetic molecule induces in laboratory animals an improved anti-carbohydrate response [157]. Although there are several explored and potential designs for this new generation anti-carbohydrate vaccine, the selected example (see *Scheme 8*) contains three separate parts in a fully synthetic molecule: (a) carbohydrate antigen, (b) universal T-helper peptide, (c) lipopeptide with a dual function; anchored to a liposome and support as a ligand for toll-like receptors. Constructions like that will certainly impact the future technology.

Diverging with the previous tendency but with similar promise is the production of carbohydrate-protein glycoconjugates directly in a single bacterium. *Escherichia coli* was engineered to do three operations that usual technology performs separately. The recombinant bacteria produce the polysaccharide and the protein carrier and also transfer the polysaccharide to a protein carrier with the help of oligosaccharyltransferase in a way similar to the *N*-linked glycosylation in higher organisms [158].

Nomenclature of Carbohydrates

(Recommendations 1996)

International Union of Pure and Applied Chemistry
and
International Union of Biochemistry and Molecular Biology

Joint Commission on Biochemical Nomenclature*

Prepared for publication by
Alan D. McNaught

The Royal Society of Chemistry, Thomas Graham House, Science Park, Milton Road, Cambridge CB4 4WF, UK

*Members of the Commission (JCBN) at various times during the work on this document (1983–1996) were as follows:

Chairmen: H.B.F. Dixon (UK), J.F.G. Vliegenthart (Netherlands), A. Cornish-Bowden (France); ***Secretaries:*** A. Cornish-Bowden (France), M.A. Chester (Sweden), A.J. Barrett (UK), J.C. Rigg (Netherlands); ***Members:*** J.R. Bull (RSA), R. Cammack (UK), D. Coucouvanis (USA), D. Horton (USA), M.A.C. Kaplan (Brazil), P. Karlson (Germany), C. Lièbecq (Belgium), K.L. Loening (USA), G.P. Moss (UK), J. Reedijk (Netherlands), K.F. Tipton (Ireland), S. Velick (USA), P. Venetianer (Hungary).

Additional contributors to the formulation of these recommendations:

Expert Panel: D. Horton (USA) (*Convener*), O. Achmatowicz (Poland), L. Anderson (USA), S.J. Angyal (Australia), R. Gigg (UK), B. Lindberg (Sweden), D.J. Manners (UK), H. Paulsen (Germany), R. Schauer (Germany).

Nomenclature Committee of IUBMB (NC-IUBMB) (those additional to JCBN): A. Bairoch (Switzerland), H. Berman (USA), H. Bielka (Germany), C.R. Cantor (USA), W. Saenger (Germany), N. Sharon (Israel), E. van Lenten (USA), E.C. Webb (Australia).

American Chemical Society Committee for Carbohydrate Nomenclature: D. Horton (*Chairman*), L. Anderson, D.C. Baker, H.H. Baer, J.N. BeMiller, B. Bossenbroek, R.W. Jeanloz, K.L. Loening, W.A. Szarek, R.S. Tipson, W.J. Whelan, R.L. Whistler.

Chapter-DOI 10-1007/978-3-540-30429-6_70 © IUPAC (1996) *Pure and Applied Chemistry* **68**, 1919–2008

Corresponding Members of the ACS Committee for Carbohydrate Nomenclature (other than JCBN and the expert panel): R.F. Brady (USA), J.S. Brimacombe (UK), J.G. Buchanan (UK), B. Coxon (USA), J. Defaye (France), N.K. Kochetkov (Russia), R.U. Lemieux (Canada), R.H. Marchessault (Canada), J.M. Webber (UK).

Correspondence on these recommendations should be addressed to Dr Alan D. McNaught at the above address or to any member of the Commission.

Preamble

These Recommendations expand and replace the Tentative Rules for Carbohydrate Nomenclature [1] issued in 1969 jointly by the IUPAC Commission on the Nomenclature of Organic Chemistry and the JUB-IUPAC Commission on Biochemical Nomenclature (CBN) and reprinted in [2]. They also replace other published JCBN Recommendations [3,4,5,6,7] that deal with specialized areas of carbohydrate terminology; however, these documents can be consulted for further examples. Of relevance to the field, though not incorporated into the present document, are the following recommendations:

- Nomenclature of cyclitols, 1973 [8]
- Numbering of atoms in *myo*-inositol, 1988 [9]
- Symbols for specifying the conformation of polysaccharide chains, 1981 [10]
- Nomenclature of glycoproteins, glycopeptides and peptidoglycans, 1985 [11]
- Nomenclature of glycolipids, in preparation [12]

The present Recommendations deal with the acyclic and cyclic forms of monosaccharides and their simple derivatives, as well as with the nomenclature of oligosaccharides and polysaccharides. They are additional to the Definitive Rules for the Nomenclature of Organic Chemistry [13,14] and are intended to govern those aspects of the nomenclature of carbohydrates not covered by those rules.

2-Carb-0 Historical Development of Carbohydrate Nomenclature [15]

2-Carb-0.1 Early Approaches

In the early nineteenth century, individual sugars were often named after their source, e. g. grape sugar (Traubenzucker) for glucose, cane sugar (Rohrzucker) for saccharose (the name sucrose was coined much later). The name glucose was coined in 1838; Kekulé in 1866 proposed the name ‘dextrose’ because glucose is dextrorotatory, and the laevorotatory ‘fruit sugar’ (Fruchtzucker, fructose) was for some time named ‘laevulose’ (American spelling ‘levulose’).

Very early, consensus was reached that sugars should be named with the ending '-ose', and by combination with the French word 'cellule' for cell the term cellulose was coined, long before the structure was known. The term 'carbohydrate' (French 'hydrate de carbone') was applied originally to monosaccharides, in recognition of the fact that their empirical composition can be expressed as $C_n(H_2O)_n$. However the term is now used generically in a wider sense (see ❯ *2-Carb-1.1*).

2-Carb-0.2 The Contribution of Emil Fischer

Emil Fischer [16] began his fundamental studies on carbohydrates in 1880. Within ten years, he could assign the relative configurations of most known sugars and had also synthesized many sugars. This led to the necessity to name the various compounds. Fischer and others laid the foundations of a terminology still in use, based on the terms triose, tetrose, pentose, and hexose. He endorsed Armstrong's proposal to classify sugars into aldoses and ketoses, and proposed the name fructose for laevulose, because he found that the sign of optical rotation was not a suitable criterion for grouping sugars into families.

The concept of stereochemistry, developed since 1874 by van't Hoff and Le Bel, had a great impact on carbohydrate chemistry because it could easily explain isomerism. Emil Fischer introduced the classical projection formulae for sugars, with a standard orientation (carbon chain vertical, carbonyl group at the top); since he used models with flexible bonds between the atoms, he could easily 'stretch' his sugar models into a position suitable for projection. He assigned to the dextrorotatory glucose (via the derived glucaric acid) the projection with the OH group at C-5 pointing to the right, well knowing that there was a 50% chance that this was wrong. Much later (Bijvoet, 1951), it was proved correct in the absolute sense.

Rosanoff in 1906 selected the enantiomeric glyceraldehydes as the point of reference; any sugar derivable by chain lengthening from what is now known as D-glyceraldehyde belongs to the D series, a convention still in use.

2-Carb-0.3 Cyclic Forms

Towards the end of the nineteenth century it was realized that the free sugars (not only the glycosides) existed as cyclic hemiacetals or hemiketals. Mutarotation, discovered in 1846 by Dubrunfaut, was now interpreted as being due to a change in the configuration of the glycosidic (anomeric) carbon atom. Emil Fischer assumed the cyclic form to be a five-membered ring, which Tollens designated by the symbol <1,4>, while the six-membered ring received the symbol <1,5>.

In the 1920s, Haworth and his school proposed the terms 'furanose' and 'pyranose' for the two forms. Haworth also introduced the 'Haworth depiction' for writing structural formulae, a convention that was soon widely followed.

2-Carb-0.4 Nomenclature Commissions

Up to the 1940s, nomenclature proposals were made by individuals; in some cases they were followed by the scientific community and in some cases not. Official bodies like the Interna-

tional Union of Chemistry, though developing and expanding the Geneva nomenclature for organic compounds, made little progress with carbohydrate nomenclature. The IUPAC Commission on Nomenclature of Biological Chemistry put forward a classification scheme for carbohydrates, but the new terms proposed have not survived. However in 1939 the American Chemical Society (ACS) formed a committee to look into this matter, since rapid progress in the field had led to various misnomers arising from the lack of guidelines. Within this committee, the foundations of modem systematic nomenclature for carbohydrates and derivatives were laid: numbering of the sugar chain, the use of D and L and α and β, and the designation of stereochemistry by italicized prefixes (multiple prefixes for longer chains). Some preliminary communications appeared, and the final report, prepared by M.L. Wolfrom, was approved by the ACS Council and published in 1948 [17].

Not all problems were solved, however, and different usages were encountered on the two sides of the Atlantic. A joint British-American committee was therefore set up, and in 1952 it published 'Rules for Carbohydrate Nomenclature' [18]. This work was continued, and a revised version was endorsed in 1963 by the American Chemical Society and by the Chemical Society in Britain and published [19]. The publication of this report led the IUPAC Commission on Nomenclature of Organic Chemistry to consider the preparation of a set of IUPAC Rules for Carbohydrate Nomenclature. This was done jointly with the IUPAC-JUB Commission on Biochemical Nomenclature, and resulted in the 'Tentative Rules for Carbohydrate Nomenclature, Part I, 1969', published in 1971/72 in several journals [1]. It is a revision of this 1971 document that is presented here. In the present document, recommendations are designated 2-Carb-*n*, to distinguish them from the Carb-*n* recommendations in the previous publication.

2-Carb-1 Definitions and Conventions

2-Carb-1.1 Carbohydrates

The generic term 'carbohydrate' includes monosaccharides, oligosaccharides and polysaccharides as well as substances derived from monosaccharides by reduction of the carbonyl group (alditols), by oxidation of one or more terminal groups to carboxylic acids, or by replacement of one or more hydroxy group(s) by a hydrogen atom, an amino group, a thiol group or similar heteroatomic groups. It also includes derivatives of these compounds. The term 'sugar' is frequently applied to monosaccharides and lower oligosaccharides. It is noteworthy that about 3% of the compounds listed by Chemical Abstracts Service (i. e. more than 360 000) are named by the methods of carbohydrate nomenclature.

Note. Cyclitols are generally not regarded as carbohydrates. Their nomenclature is dealt with in other recommendations [8,9].

2-Carb-1.2 Monosaccharides

Parent monosaccharides are polyhydroxy aldehydes H-[CHOH]$_n$-CHO or polyhydroxy ketones H-[CHOH]$_n$-CO-[CHOH]$_m$-H with three or more carbon atoms.

The generic term 'monosaccharide' (as opposed to oligosaccharide or polysaccharide) denotes a single unit, without glycosidic connection to other such units. It includes aldoses, dialdos-

es, aldoketoses, ketoses and diketoses, as well as deoxy sugars and amino sugars, and their derivatives, provided that the parent compound has a (potential) carbonyl group.

1.2.1 Aldoses and Ketoses

Monosaccharides with an aldehydic carbonyl or potential aldehydic carbonyl group are called aldoses; those with a ketonic carbonyl or potential ketonic carbonyl group, ketoses.

Note. The term 'potential aldehydic carbonyl group' refers to the hemiacetal group arising from ring closure. Likewise, the term 'potential ketonic carbonyl group' refers to the hemiketal structure (see ❯ *2-Carb-5*).

1.2.2 Cyclic Forms

Cyclic hemiacetals or hemiketals of sugars with a five-membered (tetrahydrofuran) ring are called furanoses, those with a six-membered (tetrahydropyran) ring pyranoses. For sugars with other ring sizes see ❯ *2-Carb-5*.

2-Carb-1.3 Dialdoses

Monosaccharides containing two (potential) aldehydic carbonyl groups are called dialdoses (see ❯ *2-Carb-9*).

2-Carb-1.4 Diketoses

Monosaccharides containing two (potential) ketonic carbonyl groups are termed diketoses (see ❯ *2-Carb-11*).

2-Carb-1.5 Ketoaldoses (Aldoketoses, Aldosuloses)

Monosaccharides containing a (potential) aldehydic group and a (potential) ketonic group are called ketoaldoses (see ❯ *2-Carb-12*); this term is preferred to the alternatives on the basis of ❯ *2-Carb-2.1.1* (aldose preferred to ketose).

2-Carb-1.6 Deoxy Sugars

Monosaccharides in which an alcoholic hydroxy group has been replaced by a hydrogen atom are called deoxy sugars (see ❯ *2-Carb-13*).

2-Carb-1.7 Amino Sugars

Monosaccharides in which an alcoholic hydroxy group has been replaced by an amino group are called amino sugars (see ❯ *2-Carb-14*). When the hemiacetal hydroxy group is replaced, the compounds are called glycosylamines.

2-Carb-1.8 Alditols

The polyhydric alcohols arising formally from the replacement of a carbonyl group in a monosaccharide with a CHOH group are termed alditols (see ❯ *2-Carb-19*).

2-Carb-1.9 Aldonic Acids

Monocarboxylic acids formally derived from aldoses by replacement of the aldehydic group by a carboxy group are termed aldonic acids (see ❯ *2-Carb-20*).

2-Carb-1.10 Ketoaldonic Acids

Oxo carboxylic acids formally derived from aldonic acids by replacement of a secondary CHOH group by a carbonyl group are called ketoaldonic acids (see ❯ *2-Carb-21*).

2-Carb-1.11 Uronic Acids

Monocarboxylic acids formally derived from aldoses by replacement of the CH2OH group with a carboxy group are termed uronic acids (see ❯ *2-Carb-22*).

2-Carb-1.12 Aldaric Acids

The dicarboxylic acids formed from aldoses by replacement of both terminal groups (CHO and CH_20H) by carboxy groups are called aldaric acids (see ❯ *2-Carb-23*).

2-Carb-1.13 Glycosides

Glycosides are mixed acetals formally arising by elimination of water between the hemiacetal or hemiketal hydroxy group of a sugar and a hydroxy group of a second compound. The bond between the two components is called a glycosidic bond.
For an extension of this definition, see ❯ *2-Carb-33*.

2-Carb-1.14 Oligosaccharides

Oligosaccharides are compounds in which monosaccharide units are joined by glycosidic linkages. According to the number of units, they are called disaccharides, trisaccharides, tetrasaccharides, pentasaccharides etc. The borderline with polysaccharides cannot be drawn strictly; however the term ‘oligosaccharide’ is commonly used to refer to a defined structure as opposed to a polymer of unspecified length or a homologous mixture. When the linkages are of other types, the compounds are regarded as oligosaccharide analogues. (See ❯ *2-Carb-37*.)

Note. This definition is broader than that given in [6], to reflect current usage.

2-Carb-1.15 Polysaccharides

'Polysaccharide' (glycan) is the name given to a macromolecule consisting of a large number of monosaccharide (glycose) residues joined to each other by glycosidic linkages. The term poly(g1ycose) is not a full synonym for polysaccharide (glycan) (cf. [20]), because it includes macromolecules composed of glycose residues joined to each other by non-glycosidic linkages.

For polysaccharides containing a substantial proportion of amino sugar residues, the term polysaccharide is adequate, although the term glycosaminoglycan may be used where particular emphasis is desired.

Polysaccharides composed of only one lund of monosaccharide are described as homopolysaccharides (homoglycans). Similarly, if two or more different kinds of monomeric unit are present, the class name heteropolysaccharide (heteroglycan) may be used. (See 2-Carb-39.)

The term 'glycan' has also been used for the saccharide component of a glycoprotein, even though the chain length may not be large.

The term polysaccharide has also been widely used for macromolecules containing glycose or alditol residues in which both glycosidic and phosphate diester linkages are present.

2-Carb-1.16 Conventions for Examples

1.16.1

Names of examples are given with an initial capital letter (e. g. 'L-*glycero*-β-D-gluco-Heptopyranose') to clarify the usage in headings and to show which letter controls the ordering in an alphabetical index.

1.16.2

The following abbreviations are commonly used for substituent groups in structural formulae: Ac (acetyl), Bn or $PhCH_2$ (benzyl), Bz or PhCO (benzoyl), Et (ethyl), Me (methyl), Me_3Si (not TMS) (trimethylsilyl), Bu^tMe_2Si (not TBDMS) (*tert*-butyldimethylsilyl), Ph (phenyl), Tf (triflyl = trifluoromethanesulfonyl), Ts (tosyl = toluene-*p*-sulfonyl), Tr (trityl).

2-Carb-2 Parent Monosaccharides

2-Carb-2.1 Choice of Parent Structure

In cases where more than one monosaccharide structure is embedded in a larger molecule, a parent structure is chosen on the basis of the following criteria, applied in the order given until a decision is reached:

2.1.1

The parent that includes the functional group most preferred by general principles of organic nomenclature [13,14]. If there is a choice, it is made on the basis of the greatest number of

occurrences of the most preferred functional group. Thus aldaric acid > uronic acidketoaldonic acid/aldonic acid > dialdose > ketoaldosdaldose > diketose > ketose.

2.1.2

The parent with the greatest number of carbon atoms in the chain, e. g. a heptose rather than a hexose.

2.1.3

The parent with the name that comes first in an alphabetical listing based on:

2.1.3.1. the trivial name or the configurational prefix(es) of the systematic name, e. g. allose rather than glucose, a *gluco* rather than a *gulo* derivative;

2.1.3.2. the configurational symbol D rather than L;

2.1.3.3. the anomeric symbol α rather than β.

2.1.4

The parent with the most substituents cited as prefixes (bridging substitution, e. g. 2,3-*O*-methylene, is regarded as multiple substitution for this purpose).

2.1.5

The parent with the lowest locants (see [14], p. 17) for substituent prefixes.

2.1.6

The parent with the lowest locant for the first-cited substituent.

The implications of these recommendations for branched-chain structures are exemplified in ❯ *2-Carb-18*.

Note 1. To maintain homomorphic relationships between classes of sugars, the (potential) aldehyde group of a uronic acid is regarded as the principal function for numbering and naming (see ❯ *2-Carb-2.2.1* and ❯ *2-Carb-22*).

Note 2. To maintain integrity of carbohydrate names, it is sometimes helpful to overstep the strict order of principal group preference specified in general organic nomenclature [13,14]. For example, a carboxymethyl-substituted sugar can be named as such, rather than as an acetic acid derivative (see ❯ *2-Carb-31.2*).

2-Carb-2.2 Numbering and Naming the Parent Structure

The basis for the name is the structure of the parent monosaccharide in the acyclic form. ❯ *Charts I* and ❯ *IV* (❯ *2-Carb-10*) give trivial names for parent aldoses and ketoses with up to six carbon atoms. ❯ *2-Carb-8.2* and ❯ *2-Carb-10.3* describe systematic naming procedures.

2.2.1 Numbering

The carbon atoms of a monosaccharide are numbered consecutively in such a way that:

2.2.1.1. A (potential) aldehyde group receives the locant 1 (even if a senior function is present, as in uronic acids; see ❯ *2-Carb-2.1*, note 1);

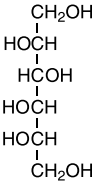
Chart I
Trivial names (with recommended three-letter abbreviations in parentheses) and structures (in the aldehydic, acyclic form) of the aldoses with three to six carbon atoms. Only the D-forms are shown; the L-forms are the mirror images. The chains of chiral atoms delineated in bold face correspond to the configurational prefixes given in italics below the names

2.2.1.2. The most senior of other functional groups expressed in the suffix receives the lowest possible locant, i. e. carboxylic acid (derivatives) > (potential) ketonic carbonyl groups.

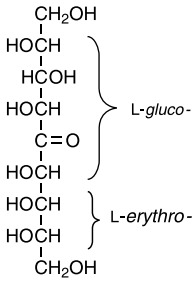
2.2.2 Choice of Parent Name

The name selected is that which comes first in the alphabet (configurational prefixes included). Trivial names are preferred for parent monosaccharides and for those derivatives where all stereocentres are stereochemically unmodified.

Examples:



L-Glucitol
not D-gulitol



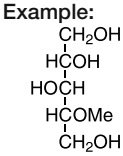
L-*erythro*-L-*gluco*-Non-5-ulose
not D-*threo*-D-*allo*-non-5-ulose

2.2.3 Choice Between Alternative Names for Substituted Derivatives

When the parent structure is symmetrical, preference between alternative names for derivatives should be given according to the following criteria, taken in order:

2.2.3.1. The name including the configurational symbol D rather than L.

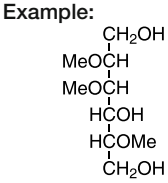
Example:



4-*O*-Methyl-D-xylitol
not 2-*O*-methyl-L-xylitol

2.2.3.2. The name that gives the lowest set of locants (see [14], p. 17) to the substituents present.

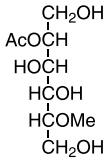
Example:



2,3,5-Tri-*O*-methyl-D-mannitol
not 2,4,5-tri-*O*-methyl-D-mannitol

2.2.3.3. The name that, when the substituents have been placed in alphabetical order, possesses the lowest locant for the first-cited substituent.

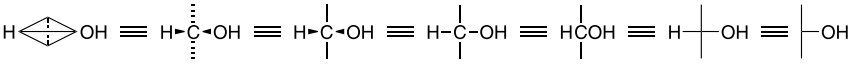
Example:



2-*O*-Acetyl-5-*O*-methyl-D-mannitol
not 5-*O*-Acetyl-2-*O*-methyl-D-mannitol

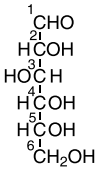
2-Carb-3 The Fischer Projection of the Acyclic Form

In this representation of a monosaccharide, the carbon chain is written vertically, with the lowest numbered carbon atom at the top. To define the stereochemistry, each carbon atom is considered in turn and placed in the plane of the paper. Neighbouring carbon atoms are below, and the H and OH groups above the plane of the paper (see below).



Conventional representation of a carbon atom (e.g. C-2 of D-Glucose) in the Fischer projection. Representation (e) will be used in general in the present document

The formula below is the Fischer projection for the acyclic form of D-glucose. The Fischer projections of the other aldoses (in the acyclic form) are given in *Chart I* (*2-Carb-2.2*).



D-Glucose

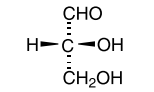
Note. The Fischer projection is not intended to be a true representation of conformation.

2-Carb-4 Configurational Symbols and Prefixes

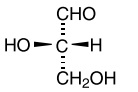
2-Carb-4.1 Use of D and L

The simplest aldose is glyceraldehyde (occasionally called glyceral [21]). It contains one centre of chirality (asymmetric carbon atom) and occurs therefore in two enantiomeric forms, called D-glyceraldehyde and L-glyceraldehyde; these are represented by the projection formu-

lae given below. It is known that these projections correspond to the absolute configurations. The configurational symbols D and L should appear in print in small-capital roman letters (indicated in typescript by double underlining) and are linked by a hyphen to the name of the sugar.



D-Glyceraldehyde

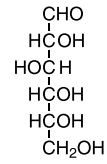


L-Glyceraldehyde

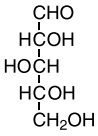
2-Carb-4.2 The Configurational Atom

A monosaccharide is assigned to the D or the L series according to the configuration at the highest-numbered centre of chirality. This asymmetrically substituted carbon atom is called the 'configurational atom'. Thus if the hydroxy group (or the oxygen bridge of the ring form; see ❯ *2-Carb-6*) projects to the right in the Fischer projection, the sugar belongs to the D series and receives the prefix D-.

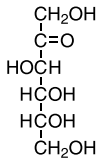
Examples:



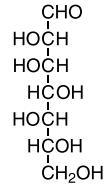
D-Glucose



D-Xylose

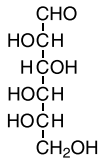


D-*arabino*-Hex-2-ulose
(D-Fructose)

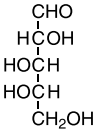


D-*glycero*-L-*gulo*-Heptose

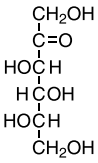
D-Monosaccharides



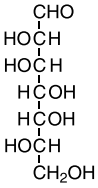
L-Glucose



L-Arabinose



L-*xlyo*-Hex-2-ulose
(L-Sorbose)



L-*glycero*-D-*manno*-Heptose

L-Monosaccharides

2-Carb-4.3 Configurational Prefixes in Systematic Names

In the systematic names of sugars or their derivatives, it is necessary to specify not only the configuration of the configurational atom but also the configurations of all CHOH groups.

This is done by the appropriate configurational prefix. These prefixes are derived from the trivial names of the aldoses in ❯ *Chart I* (relevant portions of the structures are delineated in bold face). In monosaccharides with more than four asymmetrically substituted carbon atoms, where more than one configurational prefix is employed (see ❯ *2-Carb-8.3*), each group of asymmetrically substituted atoms represented by a particular prefix has its own configurational symbol, specifying the configuration (D or L) of the highest numbered atom of the group.
The configurational prefixes are printed in lower-case italic (indicated in typescript by underlining), and are preceded by either D- or L-, as appropriate. For examples see ❯ *2-Carb-4.2* and ❯ *2-Carb-6.2*

Note. In cyclic forms of sugars, the configuration at the anomeric chiral centre is defined in relation to the 'anomeric reference atom' (see ❯ *2-Carb-6.2*).

2-Carb-4.4 Racemates and *meso* Forms

Racemates may be indicated by the prefix DL-. Structures that have a plane of symmetry and are therefore optically inactive (e. g. erythritol, galactitol) are called *meso* forms and may be given the prefix '*meso*-'.

2-Carb-4.5 Optical Rotation

If the sign of the optical rotation under specified conditions is to be indicated, this is done by adding (+)- or (−)- before the configurational prefix. Racemic forms are indicated by (±)-.

Examples:

- **D-Glucose or (+)-D-glucose**
- **D-Fructose or (−)-o-fructose**
- **DL-Glucose or (±)-glucose**

2-Carb-5 Cyclic Forms and Their Representation

2-Carb-5.1 Ring Size

Most monosaccharides exist as cyclic hemiacetals or hemiketals. Cyclic forms with a three-membered ring are called oxiroses, those with a four-membered ring oxetoses, those with a five-membered ring furanoses, with a six-membered ring pyranoses, with a seven-membered ring septanoses, with an eight-membered ring octanoses, and so on. To avoid ambiguities, the locants of the positions of ring closure may be given; the locant of the carbonyl group is always cited first, that of the hydroxy group second (for relevant examples of this see ❯ *2-Carb-6.4*). Lack of ring size specification has no particular implication.

Note. The 'o' of oxirose, oxetose, and octanose is not elided after a prefix ending in 'o'.

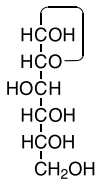
Example:

- **Nonooctanose, not nonoctanose.**

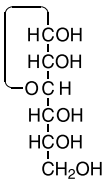
If it is to be stressed that an open-chain form of an aldose is under consideration, the prefix '*aldehydo*-' may be used. For ketoses, the prefix is '*keto*-'.

2-Carb-5.2 The Fischer Projection

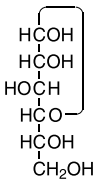
If a cyclic form of a sugar is to be represented in the Fischer projection, a long bond can be drawn between the oxygen involved in ring formation and the (anomeric) carbon atom to which it is linked, as shown in the following formulae for cyclic forms of α-D-Glucose (see 2-Carb-6 for the meaning of α and β):



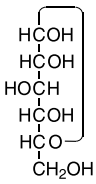
α-D-Glucooxirose



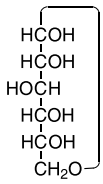
α-D-Glucooxetose



α-D-Glucofuranose



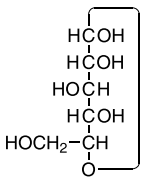
α-D-Glucopyranose



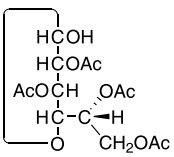
α-D-Glucoseptanose

2-Carb-5.3 Modified Fischer Projection

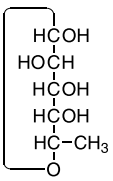
To clarify steric relationships in cyclic forms, a modified Fischer projection may be used. The carbon atom bearing the ring-forming hydroxy group, C-*n* (C-5 for glucopyranose) is rotated about its bond to C-(n − 1) ((C-4 for glucopyranose) in order to bring all ring atoms (including the oxygen) into the same vertical line. The oxygen bridge is then represented by a long bond; it is imagined as being behind the plane of the paper.
Examples are given below.



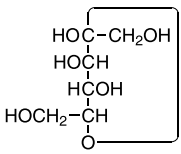
α-D-Glucopyranose



2,3,5,6-Tetra-*O*-acetyl-α-D-galactofuranose



β-L-Fucopyranose

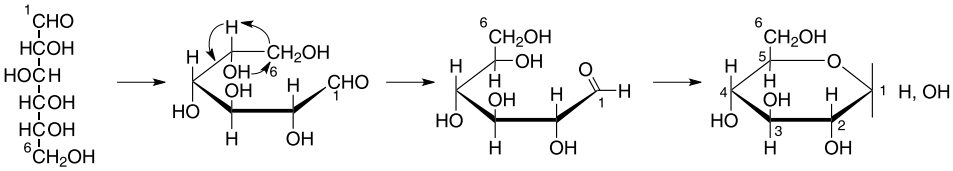


β-L-Fructofuranose

Thus the *trans* relationship between the hydroxymethyl group and the C-1 hydroxy group in α-D-glucopyranose, and the *cis* relationship between the methyl group and the C-1 hydroxy group in β-L-fucopyranose, are clearly shown. Note that representation of ketoses may require a different modification of the Fischer projection, as shown in the fructofuranose example above. Here C-2 is rotated about the bond with C-3 to accommodate the long bond to C-2 from the oxygen at C-5.

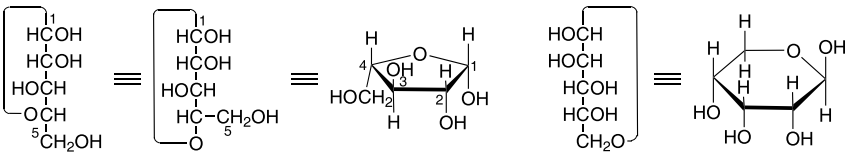
2-Carb-5.4 The Haworth Representation

This is a perspective drawing of a simplified model. The ring is orientated almost perpendicular to the plane of the paper, but viewed from slightly above so that the edge closer to the viewer is drawn below the more distant edge, with the oxygen behind and C-1 at the right-hand end. To define the perspective, the ring bonds closer to the viewer are often thickened.
The following schematic representation of pyranose ring closure in D-glucose shows the reorientation at C-5 necessary to allow ring formation; this process corresponds to the change from Fischer to modified Fischer projection.



Haworth representation of D-glucopyranose

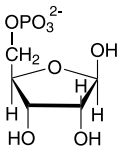
The orientation of the model described above results in a clockwise numbering of the ring atoms. Groups that appear to the right of the modified Fischer projection appear below the plane of the ring; those on the left appear above. In the common Haworth representation of the pyranose form of D-aldohexoses, C-6 is above the plane.
Generally, the configuration at the centre that yields the ring oxygen determines whether the rest of the carbon chain is below or above the plane of the ring.
Examples (for the use of α and β see ❯ *2-Carb-6*):



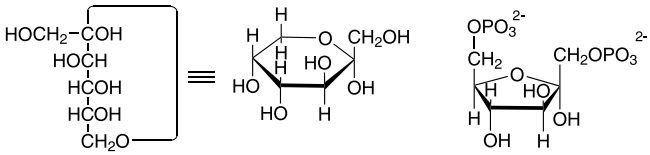
Fischer modified Fischer Haworth

β-L-Arabinofuranose representations

β-D-Ribopyranose

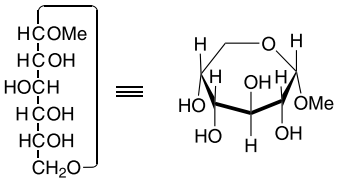


β-D-Ribopyranose 5-phosphate

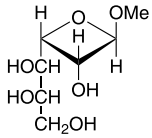


α-D-Fructopyranose

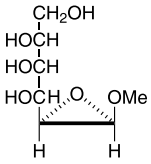
α-D-Fructofuranose 1,6-bisphosphate



Methyl α-D-glucoseptanoside



Methyl α-L-altrooxetoside



Methyl β-D-altrooxiroside

Note. In writing Haworth formulae, the H atoms bound to the carbon atoms of the ring are often omitted to avoid crowding ofthe lettering in the ring. For the sake of clarity, the form with H atoms included is preferred in this document.

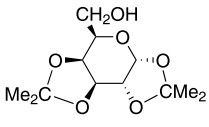
2-Carb-5.5 Unconventional Haworth Representations

It is sometimes desirable to draw Haworth formulae with the ring in other orientations (see ❯ *Chart II*), when there are bulky substituents to be represented, or when linkages in oligo- or poly-saccharides are to be shown. If the ring is inverted [as in (g)-(l)], the numbering runs counterclockwise.

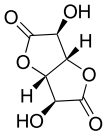
2-Carb-5.6 The Mills Depiction

In some cases, particularly where additional rings are present, structural formulae can be clarified by use of the Mills depiction. Here the main hemiacetal ring is drawn in the plane of the paper; dashed bonds denote substituents below this plane, and thickened bonds those above.

Examples:



1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose



D-Glucaro-1,4:6,3-dilactone

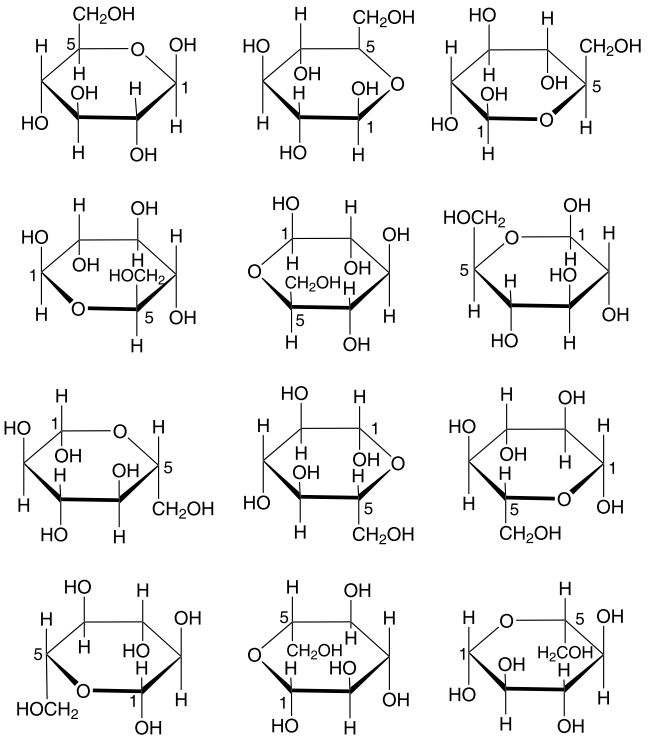


Chart II

***β*-D-Glucopyranose in the twelve possible Haworth representations (the hydrogen atoms are frequently omitted)**

2-Carb-5.7 Depiction of Conformation

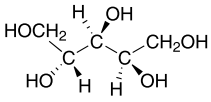
The Haworth representation implies a planar ring. However, monosaccharides assume conformations that are not planar: these may be represented by Haworth conformational formulae. The nomenclature of conformations is described in 2-Carb-7. For example, *β*-D-glucopyranose assumes a chair conformation:

β-D-Glucopyranose in a chair conformation

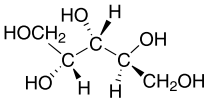
Note. The hydrogen atoms bonded to carbon are frequently omitted, but their inclusion may be necessary to make a stereochemical point.

2-Carb-5.8 Conformations of Acyclic Chains

Conformational depictions of acyclic sugar chains are conveniently expressed by locating certain atoms in the plane of the paper and orientating the remaining atoms or groups appropriately above and below that plane, as shown for D-arabinitol and xylitol (it should be recognized that the favoured conformation does not necessarily have all the carbon atoms in the same plane):



D-Arabinitol



Xylitol

2-Carb-6 Anomeric Forms; Use of α and β

2-Carb-6.1 The Anomeric Centre

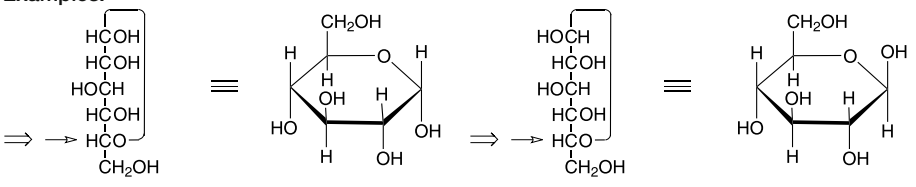
The new centre of chirality generated by hemiacetal ring closure is called the anomeric centre. The two stereoisomers are referred to as anomers, designated α or β according to the configurational relationship between the anomeric centre and a specified anomeric reference atom.

2-Carb-6.2 The Anomeric Reference Atom and the Anomeric Configurational Symbol (α or β)

The anomeric reference atom is the configurational atom (see 2-Carb-4.2 and 2-Carb-4.3) of the parent, unless multiple configurational prefixes (see 2-Carb-8.3) are used. If multiple configurational prefixes are used, the anomeric reference atom is the highest-numbered atom of the group of chiral centres next to the anomeric centre that is involved in the heterocyclic ring and specified by a single configurational prefix. In the α anomer, the exocyclic oxygen atom at the anomeric centre is formally *cis*, in the Fischer projection, to the oxygen attached to the anomeric reference atom; in the β anomer these oxygen atoms are formally *trans*.

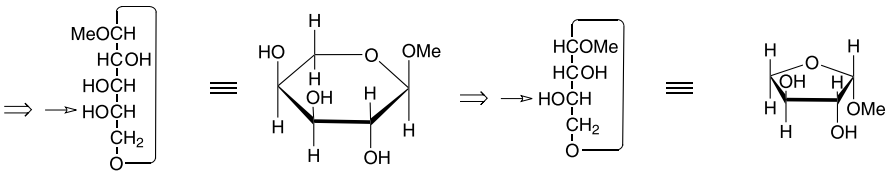
The anomeric symbol α or β, followed by a hyphen, is placed immediately before the configurational symbol D or L of the trivial name or of the configurational prefix denoting the group of chiral carbon atoms that includes the anomeric reference atom.

Examples:



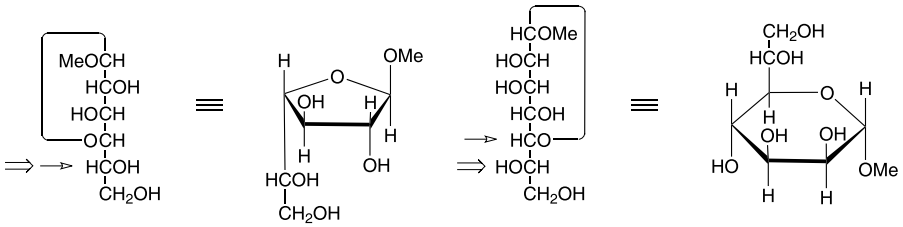
α-D-*gluco*
α-D-Glucopyranose

β-D-*gluco*
β-D-Glucopyranose



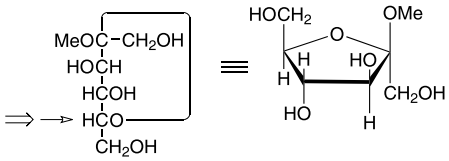
α-L-*arabino*
Methyl α-L-arabinopyranoside

β-L-*threo*
Methyl β-L-threofuranoside

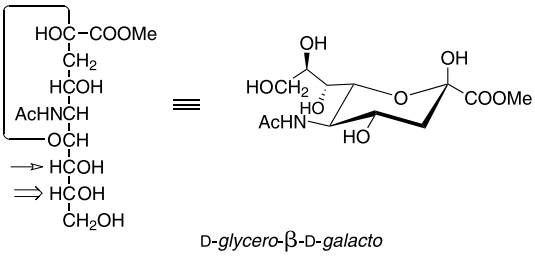


β-D-*galacto*
Methyl β-D-galactofuranoside

L-*glycero*-α-D-*manno*
Methyl L-*glycero*-α-D-*manno*-heptopyranoside



β-D-*arabino*
Methyl β-D-fructofuranoside



D-*glycero*-β-D-*galacto*
Methyl 5-acetoamido-3,5-dideoxy-D-*glycero*-β-D-*galacto*-non-2-ulopyranosonate (see 2-carb-14.2)

→ denotes the anomeric reference atom; ⟹ denotes the configurational atom.

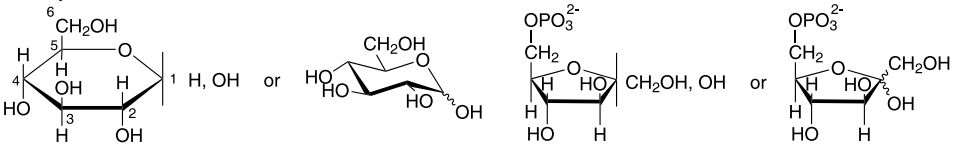
Note. For simple aldoses up to aldohexoses, and ketoses up to hept-zuloses, the anomeric reference atom and the configurational atom are the same.

2-Carb-6.3 Mixtures of Anomers

In solution, most simple sugars and many of their derivatives occur as equilibrium mixtures of tautomers. The presence of a mixture of two anomers of the same ring size may be indicated

in the name by the notation α, β-, e. g. α, β-D-glucose. In formulae, the same situation can be expressed by separating the representation of the ligands at the anomeric centre from the α and β bonds [see examples (a) and (c)], or by use of a wavy line [(b) and (d)] (particularly if hydrogen atoms are omitted).

Examples:



a b c d

α,β-D-Glucopyranose

α,β-D-Fructofuranose 6-phosphate

2-Carb-6.4 Use of α and β

The Greek letters α and β are applicable only when the anomeric carbon atom has a lower locant than the anomeric reference atom. In the case of dialdoses (cf. ❯ *2-Carb-9*), some diketoses (cf. ❯ *2-Carb-11*) and aldoketoses (cf. ❯ *2-Carb-12*), ring closure is also possible in the other direction, i. e. of a carbonyl group with a higher locant than the reference carbon atom with a hydroxy group having a lower locant. In this case, the configuration of the anomeric carbon atom is indicated by the appropriate symbol *R* or *S* according to the sequence rule (cf. Section E in [13]).

Examples:

(6*R*)-D-*gluco*-Hexadialdo-6,2-pyranose

(6*S*)-1,2-*O*-Isopropylidene-α-D-*gluco*-hexadialdo-1,4:6,3-difuranose

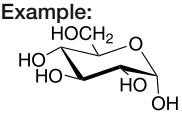
Note that locant numerals (potential carbonyl first) may be needed before the ring-size suffix in such cases.

2-Carb-7 Conformation of Cyclic Forms[1]

2-Carb-7.1 The Conformational Descriptor

The conformation, i. e. the (approximate) spatial arrangement of the ring atoms of a monosaccharide in the cyclic form, may be indicated by an italic capital letter designating the type of ring shape, and numerals, distinguishing the variants. The conformational descriptor is joined to the end of the name of the monosaccharide by a hyphen.

Example:



α-D-Glucopyranose-$^4C_1$

2-Carb-7.2 Notation of Ring Shape

The appropriate letters are as follows. Five-membered rings: *E* for envelope and *T* for twist; six-membered rings: *C* for chair, *B* for boat, *S* for skew, *H* for half-chair, and *E* for envelope. Examples are given in ❯ *Chart III*.

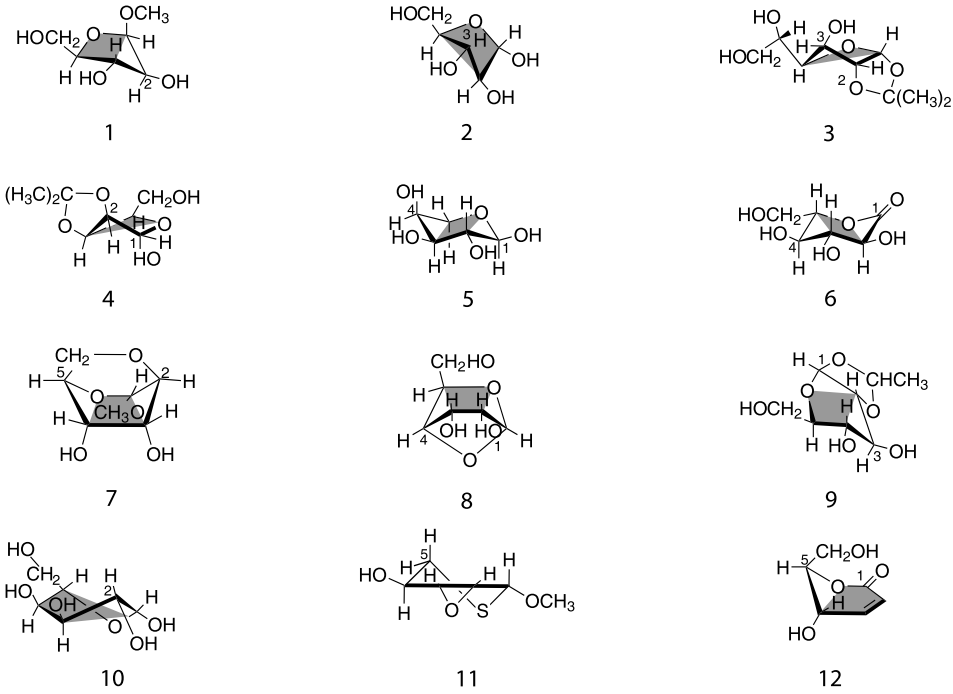
2-Carb-7.3 Notation of Variants

The variants are distinguished by the locants of those ring atoms that lie outside a reference plane (defined below) and are listed for some examples in ❯ *Table 1*. The locants of ring atoms that lie on the side of the reference plane from which numbering appears clockwise (i. e. the upper side in the normal Haworth representation of furanoses and pyranoses) are written as superscripts and precede the letter; those that lie on the other side are written as subscripts and follow the letter. Heteroatoms (e. g. O, S are indicated by their subscript or superscript atomic symbols. ❯ *Table 1* gives the notations and ❯ *Chart III* some examples.

Six-membered rings

Chairs. The reference plane is defined by two parallel ring sides, so chosen that the lowest-numbered carbon atom in the ring is exoplanar (examples **5** and **6**).
Boats. The reference plane is defined by the two parallel 'sides' of the boat (examples **7** and **8**).
Skews. Each skew form has two potential reference planes, containing three adjacent atoms and the remaining non-adjacent atom. The reference plane is so chosen that the lowest-numbered carbon atom in the ring, or the atom numbered next above it, is exoplanar, in that order of preference (examples **9** and **10**).
Half-chairs. The reference plane is defined by the four adjacent coplanar atoms (example **11**).
Envelopes. The reference plane is defined by the five adjacent coplanar atoms (example **12**).

[1] This is an abridged version of the document 'Conformational Nomenclature for Five- and Six-membered Ring Forms of Monosaccharides and their Derivatives. Recommendations 1980' [3].



1 Methyl β-D-arabinofuranoside-E_2

2 α-D-Arabinofuranose-^3E

3 1,2-*O*-Isopropylidene-β-L-idofuranose-$^3T_2$

4 2,3-*O*-Isopropylidene-α-D-luxofuranose-$^2T_1$

5 α-L-Arabinopyranose-$^4C_1$

6 L-Glucono-1,5-lactone-$^1C_4$

7 Methyl 2,6-anhydro-α-D-altropyranoside-$^{2,5}B$

8 1,4-Anhydro-α-D-allopyranose-$B_{1,4}$

9 1,2-*O*-Ethylidene-α-D-glucopyranose-$^1S_3$

10 β-L-Altropyranose-$^2S_0$

11 Methyl 2,3-anhydro-5-thio-β-L-lyxoyranoside-^5H_S

12 2,3-Dideoxy-D-*erythro*-hex-2-enono-1,5-lactone-^5E

Chart III
Drawings of the conformations listed in Table 1. The reference plane is stippled

Five-membered rings

Envelopes. The reference plane is defined by the four adjacent coplanar atoms (examples 1 and 2).

Twists. The reference plane is defined by three adjacent ring-atoms, so chosen that the exoplanar atoms lie on opposite sides of the plane (examples 3 and 4).

Note 1. Many of the possible conformations are not likely to contribute significantly to the chemistry of a particular monosaccharide, but must be stabilized by formation of additional rings, as in anhydrides or other derivatives. Some others may occur as transition-state intermediates.

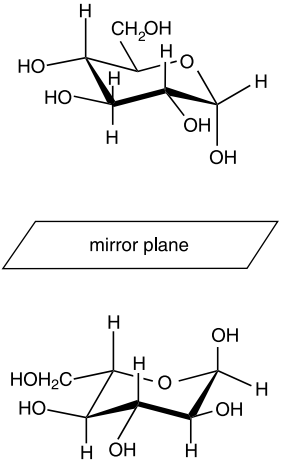
Note 2. A more precise specification of conformation can be achieved by use of the Cremer-Pople puckering parameters [22].

Table 1
Conformationsand their notations; some examples are shown in Chart III

Type of sugar	Conformation	Atoms of reference plane	Above plane	Below plane	Notation	Example
Aldofuranose	envelope	O-4,C-I,C-3,C-4	–	C-2	E_2	**1**
Aldofuranose	envelope	C-I,C-2,C-4,O-4	C-3	–	${}^3E$	**2**
Aldofuranose	twist	C-1,O-4,C-4	C-3	C-2	${}^3T_2$	**3**
Aldofuranose	twist	C-3,C-4,O-4	C-2	C-1	${}^2T_1$	**4**
Aldopyranose	chair	C-2,C-3,C-5,O-5	C-4	C-1	${}^4C_1$	**5**
Pyranoid lactone	chair	C-2,C-3,C-5,O-5	C-1	C-4	${}^1C_4$	**6**
Aldopyranose	boat	O-5,C-1,C-3,C-4	C-2,C-5	–	${}^{2,5}B$	**7**
Aldopyranose	boat	C-2,C-3,C-5,O-5	–	C-1,C-4	$B_{1,4}$	**8**
Aldopyranose	skew	C-2,C-4,C-5,O-5	C-1	C-3	${}^1S_3$	**9**
Aldopyranose	skew	C-1,C-3,C-4,C-5	C-2	O-5	${}^2S_0$	**10**
Aldopyranose	half-chair	C-1,C-2,C-3,C-4	C-5	S-5	${}^5H_s$	**11**
Pyranoid lactone	envelope	C-1,C-2,C-3,C-4,O-5	C-5	–	${}^5E$	**12**

2-Carb-7.4 Enantiomers

The conformational symbols for enantiomers are different. It is therefore important to state in the context whether the D or the L form is under consideration. Enantiomers have the same reference plane (see 2-Carb-7.3), and it should be noted that the mirror image of α-D-glucose-${}^4C_1$ is α-L-glucose-${}^1C_4$.



Mirror images: α-D-glucopyranose-${}^4C_1$ (upper) and α-L-glucopyranose-${}^1C_4$ (lower)

2-Carb-8 Aldoses

2-Carb-8.1 Trivial Names

The aldoses with three to six carbon atoms have trivial names which are given, together with the formulae in the Fischer projection, in ❯ *Chart I* (❯ *2-Carb-2.2*). (See also the alphabetical listing of trivial names in the Appendix.)
The trivial names form the basis of the configurational prefixes (see ❯ *2-Carb-4.3*).

2-Carb-8.2 Systematic Names

Systematic names are formed from a stem name and a configurational prefix or prefixes. The stem names for the aldoses with three to ten carbon atoms are triose, tetrose, pentose, hexose, heptose, octose, nonose, decose. The chain is numbered so that the carbonyl group is at position 1.
The configuration of the CHOH groups of the sugar is designated by the appropriate configurational prefix(es) from ❯ *Chart I*. When used in systematic names, these prefixes are always to be in lower case letters (with no initial capital), and italicized in print. Each prefix is qualified by D or L (❯ *Chart I* shows only the D structures).

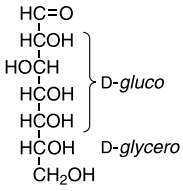
Examples:
D-*ribo*-Pentose for D-ribose
D-*manno*-Hexose for D-mannose

The trivial names are preferred for the parent sugars and for those derivatives where all stereocentres are unmodified.

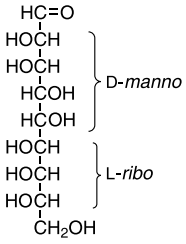
2-Carb-8.3 Multiple Configurational Prefixes

An aldose containing more than four chiral centres is named by adding two or more configurational prefixes to the stem name. Prefixes are assigned in order to the chiral centres in groups of four, beginning with the group proximal to C-1. The prefix relating to the group of carbon atom(s) farthest from C-1 (which may contain less than four atoms) is cited first.

Examples:



D-*glycero*-D-*gluco*-Heptose
not D-*gluco*-D-*glycero*-heptose

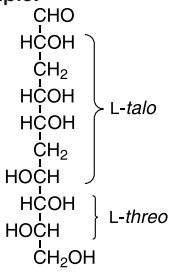


L-*ribo*-D-*manno*-Nonose
not D-*manno*-L-*ribo*-nonose

2-Carb-8.4 Multiple Sets of Chiral Centres

If sequences of chiral centres are separated by non-chiral centres, the non-chiral centres are ignored, and the remaining set of chiral centres is assigned the appropriate configurational prefix (for four centres or less) or prefixes (for more than four centres).

Example:



3,6-Dideoxy-L-*threo*-L-*talo*-decose

Note 1. This convention is not needed for parent aldoses, only for deoxy aldoses, ketoses and similar compounds (see ❯ *2-Carb-10.4* and ❯ *2-Carb-11.2*).

Note 2. Since all aldoses up to the hexoses have trivial names that are preferred, the systematic names apply only to the higher aldoses. However, the configurational prefixes are also used to name ketoses (see below) and other monosaccharides.

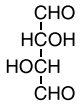
2-Carb-8.5 Anomeric Configuration in Cyclic Forms

For the specification of α and β in cyclic forms see ❯ *2-Carb-6*.

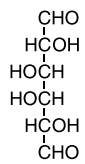
2-Carb-9 Dialdoses

Systematic names for individual dialdoses are formed from the systematic stem name for the corresponding aldose (see ❯ *2-Carb-8.2*), but with the ending 'odialdose' instead of 'ose', and the appropriate configurational prefix (❯ *Chart I*). A choice between the two possible aldose parent names is made on the basis of ❯ *2-Carb-2.2.2*.

Examples:



L-*threo*-Tetrodialdose

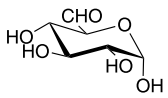


galacto-Hexodialdose

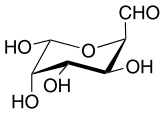
Note. The prefix '*meso*-' could be included in the latter case, but it is not needed to define the structure.

If a cyclic form is to be named, the locants of the anomeric centre and of the carbon atom bearing the ring oxygen atom must be given (in that order) (cf. ❯ *2-Carb-6.4*). If there is more than one ring size designator, they are placed in alphabetical order (e. g. furanose before pyranose).

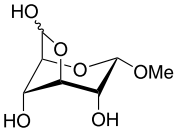
Examples:



α-D-*gluco*-Hexodialdo-1,5-pyranose



(6*R*)-D-*gluco*-Hexodialdo-6,2-pyranose



Methyl α-D-*gluco*-hexodialdo-6,3-furanose-1,5-pyranoside

2-Carb-10 Ketoses

2-Carb-10.1 Classification

Ketoses are classified as 2-ketoses, 3-ketoses, etc., according to the position of the (potential) carbonyl group. The locant 2 may be omitted if no ambiguity can arise, especially in a biochemical context.

2-Carb-10.2 Trivial Names

Ketoses with three to six carbon atoms are shown in ❯ *Chart IV*, with trivial names (and three-letter abbreviations) in parentheses. (See also the alphabetical listing of trivial names in the Appendix.)

The trivial names 'D-erythrulose' for D-*glycero*-tetrulose, 'D-ribulose' for D-*erythro*-pent-2-ulose, and 'D-xylulose' for D-*rhreo*-pent-2-ulose contain stereochemical redundancy and should not be used for naming derivatives. Sedoheptulose is the accepted trivial name for D-*altro*-hept-2-ulose.

2-Carb-10.3 Systematic Names

The systematic names are formed from the stem name and the appropriate configurational prefix.

The stem names are formed from the corresponding aldose stem names (❯ *2-Carb-8.2*) by replacing the ending '-ose' with '-ulose', preceded by the locant of the carbonyl group, e. g.

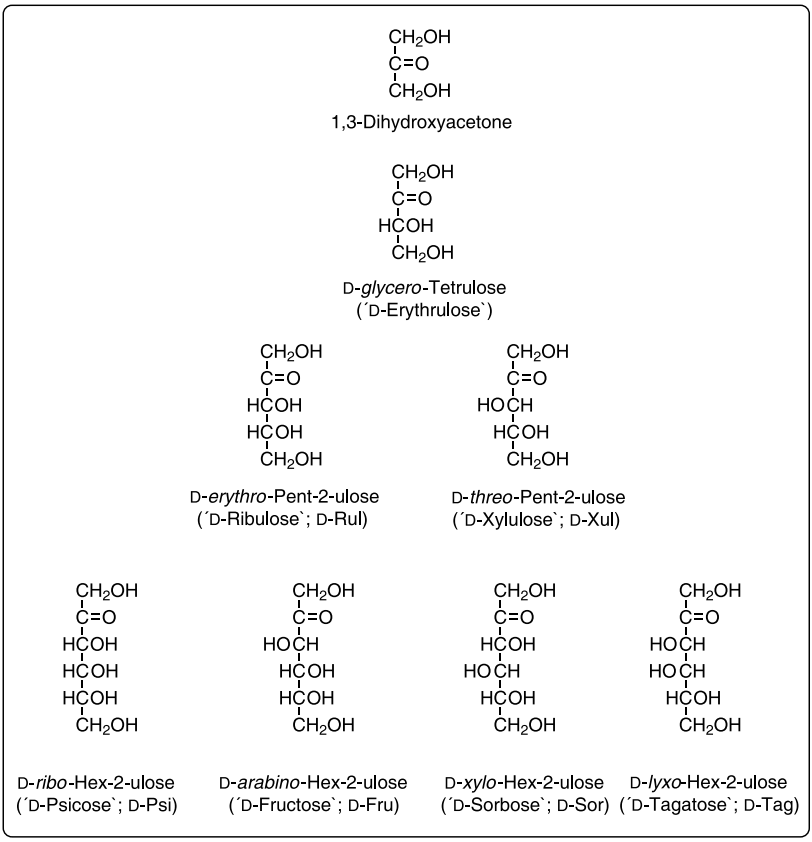


Chart IV
Structures, with systematic and trivial names, of the 2-ketoses with three to six carbon atoms

hex-3-ulose. The chain is numbered so that the carbonyl group receives the lowest possible locant. If the carbonyl group is in the middle of a chain with an odd number of carbon atoms, a choice between alternative names is made according to ❯ *2-Carb-2.2.2*.

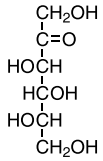
Note. In Chemical Abstracts Service (CAS) usage the locant for the carbonyl group precedes the stem name, e. g. 3-hexulose.

For examples see ❯ *2-Carb-10.4.*

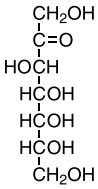
2-Carb-10.4 Configurational Prefixes

For 2-ketoses, configurational prefixes are given in the same way as for aldoses (see ❯ *2-Carb-8.2* and ❯ *2-Carb-8.3*).

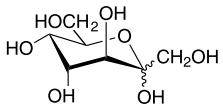
Examples:



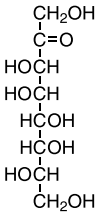
L-*xylo*-Hex-2-ulose
(L-Sorbose)



D-*altro*-Hept-2-ulose
(D-Sedoheptulose)



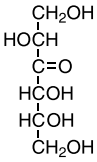
D-*altro*-Hept-2-ulopyranose



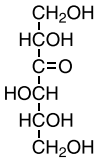
L-*glycero*- D-*manno*-Oct-2-ulose

For ketoses with the carbonyl group at C-3 or a higher-numbered carbon atom, the carbonyl group is ignored and the set of chiral centres is given the appropriate prefix or prefixes according to ❯ *Chart I* (cf. ❯ *2-Carb-8.4*).

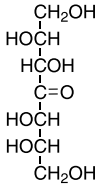
Examples:



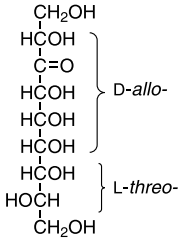
D-*arabino*-Hex-3-ulose



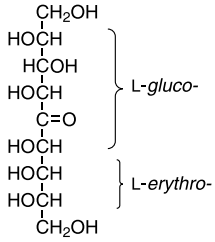
D-*xylo*-Hex-3-ulose
not L-*xylo*-hex-4-ulose



L-*gluco*-Hept-4-ulose
not D-*gulo*-hept-4-ulose



L-*threo*-D-*allo*-Non-3-ulose



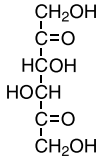
L-*erythro*-L-*gluco*-Non-5-ulose
not D-*threo*-D-*allo*-non-5-ulose

2-Carb-11 Diketoses

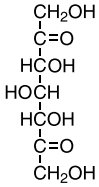
2-Carb-11.1 Systematic Names

The systematic name of a diketose is formed by replacing the terminal '-se' of the stem name by '-diulose'. The locants of the (potential) carbonyl groups must be the lowest possible and appear before the ending. The stem name is preceded by the appropriate configurational prefix. If there is a choice of names, a decision is made on the basis of 2-Carb-2.2.2. In cyclic forms, locants may be needed for the positions of ring closure; that of the (potential) carbonyl group is cited first.

Examples:



L-*threo*-Hexo-2,5-diulose

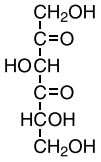


meso-*xylo*-Hepto-2,6-diulose

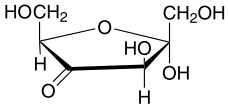
2-Carb-11.2 Multiple Sets of Chiral Centres

If the carbonyl group(s) divides the sequence of chiral centres, the configurational prefixes are assigned in the normal manner (see 2-Carb-8.4) for all chiral centres; the non-chiral centres are ignored.

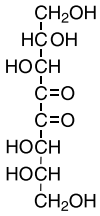
Examples:



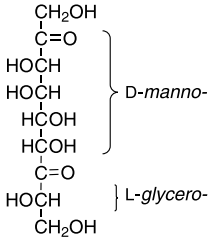
D-*threo*-Hexo-2,4-diulose



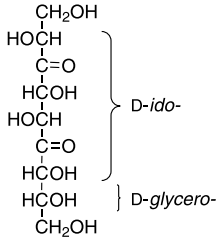
α-D-*threo*-Hexo-2,4-diulo-2,5-furanose



L-*altro*-Octo-4,5-diulose
not L-*talo*-octo-4,5-diulose



L-*glycero*-D-*manno*-Nono-2,7-diulose



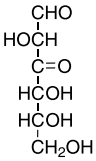
D-*glycero*-D-*ido*-Nono-3,6-diulose

2-Carb-12 Ketoaldoses (Aldoketoses, Aldosuloses)

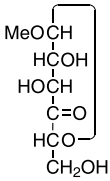
2-Carb-12.1 Systematic Names

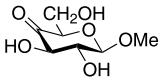
Names of ketoaldoses are formed in the same way as those of diketoses, but with use of the termination '-ulose' in place of the terminal '-e' of the corresponding aldose name (2-Carb-8.2). The carbon atom of the (potential) aldehydic carbonyl group is numbered 1, and this locant is not cited in the name. The locant of the (potential) ketonic carbonyl group is given (as an infix before '-ulose') unless it is 2; it may then be omitted (in this text, this locant is always retained for the sake of clarity). In cyclic forms, locants may be needed for the positions of ring closure; that of the (potential) carbonyl group is cited first. The position of the ring-size designator (e. g. pyrano) depends upon which carbonyl group is involved in ring formation (see examples).

Examples:

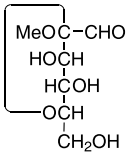


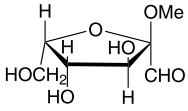
D-*arabino*-Hexos-3-ulose





Methyl β-D-*xylo*-hexopyranosid-4-ulose





Methyl α-L-*xylo*-Hexos-2-ulo-2,5-furanoside

2-Carb-12.2 'Dehydro' Names

In a biochemical context, the naming of aldoketoses as 'dehydro' aldoses is widespread. Thus D-*xylo*-hexopyranos-4-ulose would be termed 4-dehydro-D-glucose. This usage of 'dehydro' can give rise to names which are stereochemically redundant, and should not be employed for naming derivatives.

Note. In Enzyme Nomenclature [23] dehydro names are used in the context of enzymic reactions. The substrate is regarded as the parent compound, but the name of the product is chosen according to the priority given in 2-Carb-2.2.

Examples:

D-Glucose + O_2 = 2-dehydro-D-glucose + H_2O_2 (EC 1.1.3.10)

Sucrose + acceptor = β-D-fructofuranosyl 3-dehydro-α-D-allopyranoside + reduced acceptor (EC 1.1.99.13)

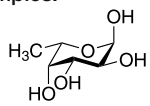
L-Sorbose + $NADP^+$ = 5-dehydro-D-fructose + NADPH (reaction of sorbose dehydrogenase, EC 1.1.1.123)

2-Carb-13 Deoxy Sugars

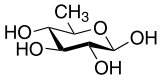
2-Carb-13.1 Trivial Names

Several deoxy sugars have trivial names established by long usage, e. g. fucose (Fuc), quinovose (Qui) and rhamnose (Rha). They are illustrated here in the pyranose form. These names are retained for the unmodified sugars, but systematic names are usually preferred for the formation of names of derivatives, especially where deoxygenation is at a chiral centre of the parent sugar. (See also the alphabetical listing of trivial names in the Appendix.)

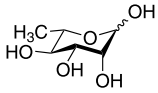
Examples:



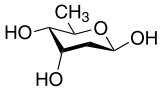
α-L-Fucopyranose
6-Deoxy-α-L-galactopyranose



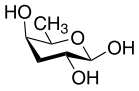
β-D-Quinovopyranose
6-Deoxy-β-D-glucopyranose



L-Rhamnopyranose
6-Deoxy-L-mannopyranose



2,6-Dideoxy-β-D-*ribo*-hexopyranose
(β-Digitoxopyranose)



3,6-Dideoxy-β-D-*xylo*-hexopyranose
(β-Abequopyranose)

3,6-Dideoxy-β-D-*arabino*-hexopyranose
(β-Tyvelopyranose)

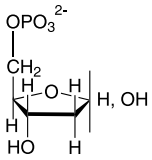
Other trivial names that have been used include ascarylose for 3,6-dideoxy-L-*arabino*-hexose, colitose for 3,6-dideoxy-L-*xylo*-hexose and paratose for 3,6-dideoxy-D-*ribo*-hexose.

Note. Sugars with a terminal CH_3 group should be named as *o*-deoxy sugars, as shown above, not *C*-methyl derivatives.

2-Carb-13.2 Names Derived from Trivial Names of Sugars

Use of 'deoxy-' in combination with an established trivial name (see ❯ *Charts I* and ❯ *II*) is straightforward if the formal deoxygenation does not affect the configuration at any asymmetric centre. However if 'deoxy' removes a centre of chirality, the resulting names contain stereochemical redundancy. In such cases, systematic names are preferred, especially for the naming of derivatives.

Note. The names 2-deoxyribose (for 2-deoxy-D-*erythro*-pentose) and 2-deoxyglucose (for 2-deoxy-D-*arabino*-hexose) are often used.



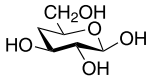
2-Deoxy-D-*erythro*-pentofuranose 5-phosphate

2-Carb-13.3 Systematic Names

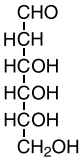
The systematic name consists of the prefix 'deoxy-', preceded by the locant and followed by the stem name with such configurational prefixes as necessary to describe the configuration(s) at the asymmetric centres present in the deoxy compound. Configurational prefixes are cited in order commencing at the end farthest from C-1. 'Deoxy' is regarded as a detachable prefix, i. e. it is placed in alphabetical order with any substituent prefixes.

Note. The treatment of 'anhydro' (see 2-Carb-26), 'dehydro' (see 2-Carb-17.3) and 'deoxy' as detachable prefixes follows long-standing practice in carbohydrate chemistry, but is in conflict with [14] (p. 12).

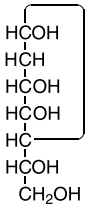
Examples:



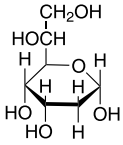
4-Deoxy-β-D-*xylo*-hexopyranose
not 4-deoxy-β-D-galactopyranose

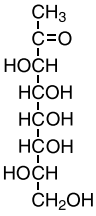


2-Deoxy-D-*ribo*-hexose not 2-deoxy-D-allose



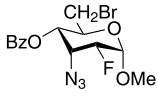
a





2-Deoxy-α-D-*allo*-heptopyranose

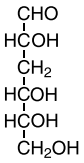
1-Deoxy-L-*glycero*-D-*altro*-oct-2-ulose



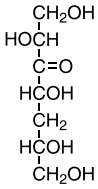
Methyl 3-azido-4-*O*-benzoyl-6-bromo-2,3,6-trideoxy-2-fluoro-α-D-allopyranoside

If the CH_2 group divides the chiral centres into two sets, it is ignored for the purpose of assigning a configurational prefix; the prefix(es) assigned should cover the entire sequence of chiral centres (see ❯ *2-Carb-8.4*).

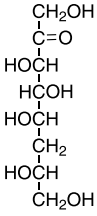
Examples:



3-Deoxy-D-*ribo*-hexose
not 3-deoxy-D-*erythro*-D-*glycero*-hexose



5-Deoxy-D-*arabino*-hept-3-ulose
not 5-deoxy-D-*glycero*-D-*glycero*-L-*glycero*-hept-3-ulose



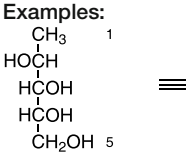
6-Deoxy-L-*gluco*-oct-2-ulose
not 6-deoxy-L-*glycero*-L-*xylo*-oct-2-ulose

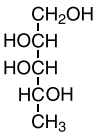
If the anomeric hydroxy group is replaced by a hydrogen atom, the compound is named as an anhydro alditol (❯ *2-Carb-26*).

2-Carb-13.4 Deoxy Alditols

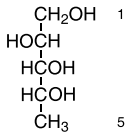
The name of an aldose derivative in which the aldehyde group has been replaced by a terminal CH_3 group is derived from that of the appropriate alditol (see ❯ *2-Carb-19*) by use of the prefix 'deoxy-'.

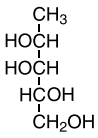
Examples:





1-Deoxy-D-arabinitol
not 5-deoxy-D-lyxitol





5-Deoxy-D-arabinitol
not 1-deoxy-D-lyxitol

The alditols from fucose and rhamnose are frequently termed fucitol and rhamnitol (see ❯ *2-Carb-19.1*).

2-Carb-14 Amino Sugars

2-Carb-14.1 General Principles

The replacement of an alcoholic hydroxy group of a monosaccharide or monosaccharide derivative by an amino group is envisaged as substitution of the appropriate hydrogen atom of the corresponding deoxy monosaccharide by the amino group. The stereochemistry at the carbon atom carrying the amino group is expressed according to 2-Carb-8.2, with the amino group regarded as equivalent to OH.

Some examples of *N*-substituted derivatives are given here; for a detailed treatment see 2-Carb-25.

2-Carb-14.2 Trivial Names

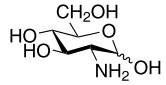
Accepted trivial names are as follows.

- D-Galactosamine for 2-amino-2-deoxy-D-galactose
- D-Glucosamine for 2-amino-2-deoxy-D-glucose
- D-Mannosamine for 2-amino-2-deoxy-D-mannose
- D-Fucosamine for 2-amino-2,6-dideoxy-D-galactose
- D-Quinovosamine for 2-amino-2,6-dideoxy-D-glucose
- Neuraminic acid for 5-amino-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-ulosonic acid
- Muramic acid for 2-amho-3-*O*-[(*R*)-1-carboxyethyl]-2-deoxy-D-glucose.

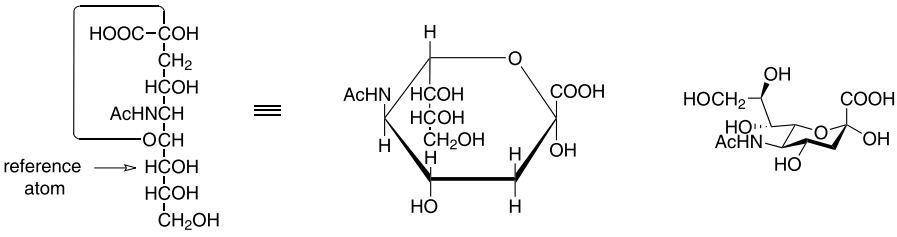
In the last two cases the trivial name refers specifically to the D enantiomer. (See also the alphabetical listing of trivial names in the Appendix.)

Such names as 'bacillosamine' for 2,4-diamino-2,4,6-trideoxy-D-glucose and 'garosamine' for 3-deoxy-4-C-methyl-3-methylamino-L-arabinose are not recommended, as they imply replacement of OH by NH_2 in a nonexistent parent sugar.

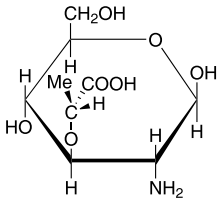
Examples:



2-Amino-2-deoxy-D-glucopyranose (D-glucosamine).



5-Acetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-non-2-ulopyranosonic acid (*N*-acetyl-α-neuramic acid, α-Neu5Ac), drawn in three ways (note that C-7 is the anomeric reference atom



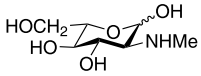
2-Amino-3-*O*-[(R)-1-carboxyethyl]-2-deoxy-β-D-glucopyranose (β-muramic acid)

For examples with nitrogen in the ring, see ❯ *2-Carb-34.1*.

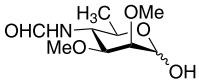
2-Carb-14.3 Systematic Names

The compounds are named by use of a combination of 'deoxy-' and 'amino-' prefixes. When the complete name of the derivative includes other prefixes, 'deoxy-' takes its place in the alphabetical order of detachable prefixes.

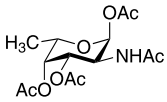
Examples:



2-Deoxy-2-methylamino-L-glucopyranose



4,6-Dideoxy-4-formamido-2,3-di-*O*-methyl-D-mannopyranose



2-Acetamido-1,3,4-tri-*O*-acethyl-2,6-dideoxy-α-L-galactopyranose

When the amino group is at the anomeric position, the compound is normally named as a glycosylamine (see ❯ *2-Carb-33.6*).

2-Carb-15 Thio Sugars and Other Chalcogen Analogues

Replacement of a hydroxy oxygen atom of an aldose or ketose, or of the oxygen atom of the carbonyl group of the acyclic form of an aldose or ketose, by sulfur is indicated by placing the prefix 'thio', preceded by the appropriate locant, before the systematic or trivial name of the aldose or ketose.

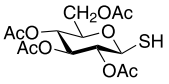
Replacement of the ring oxygen atom of the cyclic form of an aldose or ketose by sulfur is indicated in the same way, the number of the non-anomeric adjacent carbon atom of the ring being used as locant.

Selenium and tellurium compounds are named likewise, by use of the prefix 'seleno' or 'telluro'.

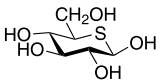
Sulfoxides (or selenoxides or telluroxides) and sulfones (or selenones or tellurones) may be named by functional class nomenclature [13].

Note. The appropriate prefix is thio, not thia; the latter is used in systematic organic chemical nomenclature to indicate replacement of CH_2 by S.

Examples:

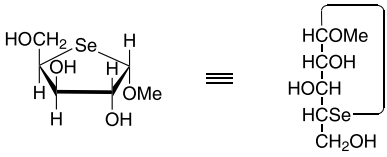


2,3,4,6-Tetra-*O*-acetyl-1-thio-β-D-glucopyranose

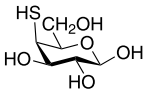


5-Thio-β-D-glucopyranose

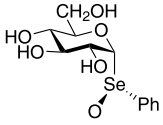
Methyl 2,3,4-tri-*O*-acetyl-1-thio-6-*O*-trityl-α-D-glucopyranoside



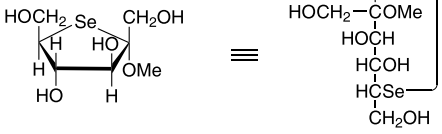
Methyl 4-seleno-α-D-xylofuranoside



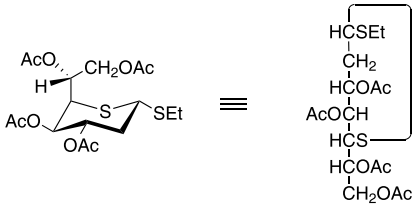
4-Thio-β-D-galactopyranose



α-D-Glucopyranosyl phenyl (*R*)-selenoxide



Methyl 5-seleno-α-D-fructofuranoside



Ethyl 3,4,6,7-tetra-*O*-acetyl-2-deoxy-1,5-dithio-α-D-*gluco*-heptopyranoside

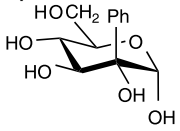
Note. It is common practice in carbohydrate names to regard 'thio' as detachable, and therefore alphabetized with any other prefixes.

2-Carb-16 Other Substituted Monosaccharides

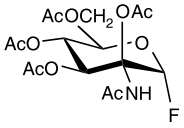
2-Carb-16.1 Replacement of Hydrogen at a Non-terminal Carbon Atom

The compound is named as a *C*-substituted monosaccharide. The group having priority according to the Sequence Rule ([13], Section E) is regarded as equivalent to OH for assignment of configuration. Any potential ambiguity (particularly when substitution is at the carbon atom where ring formation occurs) should be avoided by use of the *R*, *S* system to specify the modified stereocentre.

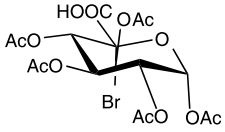
Examples:



2-*C*-Phenyl-α-D-glucopyranose



2-*C*-Acetamido-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl fluoride

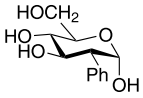


(5*R*)-1,2,3,4-Tetra-*O*-acetyl-5-bromo-α-D-*xylo*-hexopyranuronic acid
or 1,2,3,4-tetra-*O*-acetyl-5-bromo-β-L-idopyranuronic acid

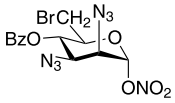
2-Carb-16.2 Replacement of OH at a Non-terminal, Non-anomeric Carbon Atom

The compound is named as a substituted derivative of a deoxy sugar. The group replacing OH determines the configurational description. Any potential ambiguity should be dealt with by the alternative use of the *R*, *S* system to specify the modified stereocentre.

Examples:



2-Deoxy-2-phenyl-α-D-glucopyranose or 2-deoxy-2-*C*-phenyl-α-D-glucopyranose
or (2*R*)-2-deoxy-2-phenyl-α-D-*arabino*-hexopyranose



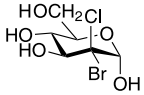
2,3-Diazido-4-*O*-benzoyl-6-bromo-2,3,6-trideoxy-α-D-mannopyranosyl nitrate

Note. Use of the symbol *C*- is essential only in cases of potential ambiguity, to make clear that substitution is at carbon rather than at a heteroatom (cf. 2-Carb-18.2); however, it may also be used for emphasis.

2-Carb-16.3 Unequal Substitution at a Non-terminal Carbon Atom

The compound is named as a disubstituted deoxy sugar. Configuration is determined by regarding the substituent having priority according to the Sequence Rule ([13], Section E), as equivalent to OH. Any potential ambiguity should be dealt with by the alternative use of the *R*, *S* system to specify the modified stereocentre.

Example:

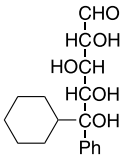


(2*R*)-2-Bromo-2-chloro-2-deoxy-α-D-*arabino*-hexose
or 2-bromo-2-chloro-2-deoxy-α-D-glucopyranose
(Br has priority over Cl)

2-Carb-16.4 Terminal Substitution

If substitution at the terminal carbon atom of the carbohydrate chain creates achiral centre, the stereochemistry is indicated by the *R*, *S* system.

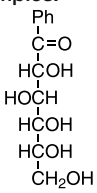
Example:



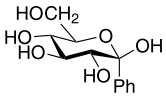
(5*R*)-5-*C*-Cyclohexyl-5-*C*-phenyl-D-xylose

Note. A monosaccharide with a terminal methyl group is named as a deoxy sugar, not as a *C*-methyl derivative. Substitution of aldehydic H by a ring or ring system is indicated simply with a *C*-substituent prefix.

Examples:



1-*C*-Phenyl-D-glucose
not 1-*C*-phenyl-D-*gluco*-hex-1-ulose

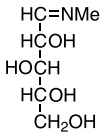


1-*C*-Phenyl-β-D-glucopyranose

2-Carb-16.5 Replacement of Carbonyl Oxygen by Nitrogen (Imines, Oximes, Hydrazones, Osazones etc.)

The imino analogue of a monosaccharide may be named as an imino-substituted deoxy alditol.

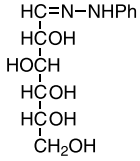
Example:



1-Deoxy-1-(methylimino)-D-xylitol

Oximes, hydrazones and analogues are named directly as oxime or hydrazone derivatives etc.

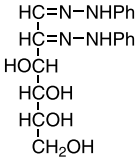
Example:



D-Glucose phenylhydrazone

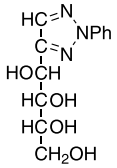
The vicinal dihydrazones formed from monosaccharides with arylhydrazines have been called arylosazones, but are preferably named as ketoaldose bis(phenylhydrazone)s

Example:



D-*arabino*-Hexos-2-ulose bis (phenylhydrazone)
or D-*arabino*-hex-2-ulose phenylosazone

The triazoles formed on oxidising arylosazones (commonly called osotriazoles) triazolylalditols.



D-*arabino*-Hexos-2-ulose phenylosotriazole
or (1*R*)-1-(2-phenyl-2*H*-1,2,3-triazol-4-yl))-D-erythritol
or 2-phenyl-4-(D-*arabino*-1,2,3,4-tetrahydroxybutyl)-2*H*-1,2,3-triazole

2-Carb-16.6 Isotopic Substitution and Isotopic Labelling

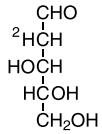
Rules for designating isotopic substitution and labelling are given in [13] (Section H). Parentheses indicate substitution; square brackets indicate labelling. The locant U indicates uniform labelling.

Examples:

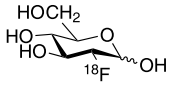
- D-(1-^{13}C)Glucose (substitution)
- D-(2-^{2}H)Mannose (substitution)
- L-[U-^{14}C]Arabinose (labelling)
- D-[1-^{3}H]Galactose (labelling)

When isotopic substitution creates a centre of chirality, configuration is defined as for other types of substitution (see ❯ *2-Carb-16.1* to ❯ *2-Carb-16.4*).

Example:



2-Deoxy-D-(2-^{2}H)lyxose (substituted)
or (2S)-2-deoxy-D-*threo*-(2-^{2}H)pentose



2-Deoxy-2-[^{18}F]fluoro-D-glucose (labelled)
or (2*R*)-2-deoxy-2-[^{18}F]fluoro-D-*arabino*-hexose

2-Carb-17 Unsaturated Monosaccharides[2]

2-Carb-17.1 General Principles

This section relates to the introduction of a double or triple bond between two contiguous carbon atoms of the backbone chain of a monosaccharide derivative. A double bond between a carbon atom of the backbone chain and an atom outside that chain, or a double or triple bond between two carbon atoms outside the backbone chain, will be treated according to the normal rules of organic nomenclature [13,14].

2-Carb-17.2 Double Bonds

Monosaccharide derivatives having a double bond between two contiguous carbon atoms of the backbone chain are named by inserting, into the name for the corresponding fully saturated derivative, the infix '*x*-en'. The infix is placed directly after the stem name that designates the chain length of the sugar. The locant *x* is the lower-numbered carbon atom involved in the double bond. Steric relations at a double bond are designated, if necessary, by the standard stereosymbols '(*Z*)-' and '(*E*)-' preceding the whole name ([13], Section E). For multiple double bonds, infixes such as '*x*, *y*-dien' are used (preceded by an inserted 'a' for euphony).

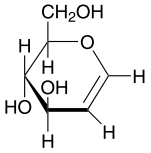
[2]This is based on the 1980 recommendations [5] Some examples have been omitted.

Note 1. The term 'glycal' is a non-preferred, trivial name for cyclic enol ether derivatives of sugars having a double bond between carbon atoms 1 and 2 of the ring. It should not be used or modified as a class name for monosaccharide derivatives having a double bond in any other position.

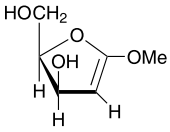
Note 2. Following the principle of first naming the saturated derivative, compounds having a C=CR-0-group as part of a ring system are named as unsaturated derivatives of anhydro alditols if R is hydrogen or carbon; if R is a halogen, chalcogen, or nitrogen-family element, the resulting name is that of a glycenose or glycenosyl derivative.

Note 3. The symbols (*Z*)- and (*E*)- may be omitted when the double bond is located within a ring system of six atoms or less, as steric constraints in such systems normally permit only one form.

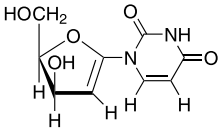
Examples:



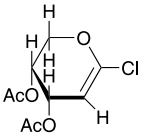
1,5-Anhydro-2-deoxy-D-*arabino*-hex-1-enitol (non-preferred trivial name D-glucal)



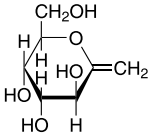
Methyl 2-deoxy-D-*threo*-pent-1-enofuranoside



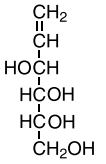
1-(2-Deoxy-D-*threo*-pent-1-enofuranosyl) uracil



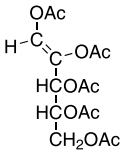
3,4-Di-*O*-acetyl-2-deoxy-D-*erythro*-pent-1-enopyranosyl chloride



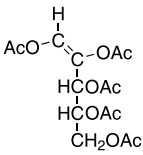
2,6-Anhydro-1-deoxy-D-*altro*-hept-1-enitol
(alphabetic preference over 2,6-anhydro-7-deoxy-D-*talo*-hept-6-enitol)



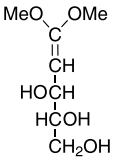
1,2-Dideoxy-D-*arabino*-hex-1-enitol



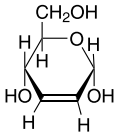
(*Z*)-1,2,3,4,5-Penta-*O*-acetyl-D-*erythbro*-pent-1-enitol



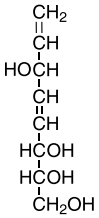
(*E*)-1,2,3,4,5-Penta-*O*-acetyl-D-*erythro*-pent-1-enitol



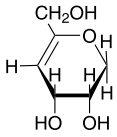
2-Deoxy-D-*threo*-pent-1-enose dimethyl acetal



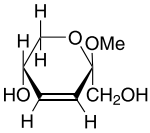
2,3-Dideoxy-α-D-*erythro*-hex-2-enopyranose



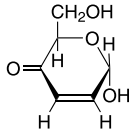
1,2,4,5-Tetradeoxy-D-*arabino*-octa-1,4-dienitol



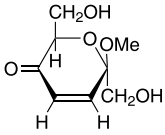
1,5-Anhydro-4-deoxy-D-*erythro*-hex-4-enitol
(enantiomeric precedence over 2,6-anhydro-3-deoxy-L-*erythro*-hex-2-enitol)



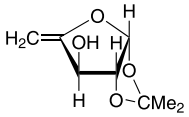
Methyl 3,4-dideoxy-β-D-*glycero*-hex-3-en-2-ulopyranoside



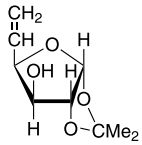
2,3-Dideoxy-α-D-*glycero*-hex-2-enopyranos-4-ulose



Methyl 3,4-dideoxy-β-D-*glycero*-hept-3-en-2-ulopyranosid-5-ulose



5-Deoxy-1,2-*O*-isopropylidene-β-L-*threo*-pent-4-enofuranose



5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose

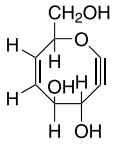
2-Carb-17.3 Triple Bonds and Cumulative Double Bonds

Monosaccharide derivatives having a triple bond or cumulative double bonds in the backbone chain are named by the methods of ❯ *2-Carb-17.2*, with the infix '*n*-yn' for a triple bond and infixes such as '*i*,*j*-dien' for cumulative double bonds.

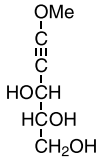
Note. This approach was not included in [5].

Alternatively they can be named on the basis of the corresponding fully saturated sugar by using the appropriate number of dehydro and deoxy prefixes (deoxy operations are regarded as formally preceding dehydro operations). The prefixes are placed in alphabetical order before the stem name.

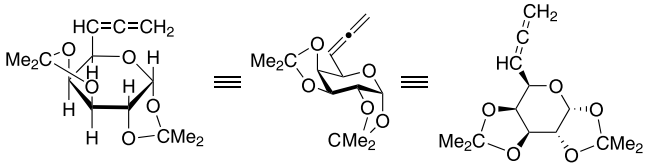
Examples:



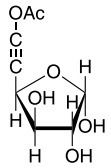
(*Z*)-1,7-Anhydro-2,5,6-trideoxy-D-*xylo*-oct-5-en-1-ynitol
or (*Z*)-1,7-anhydro-1,1,2,2-tetradehydro-2,5,6-trideoxy-D-*xylo*-oct-5-enitol



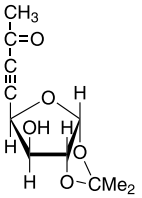
2-Deoxy-1-*O*-methyl-D-*threo*-pent-1-ynitol
or 1,1,2,2-tetradehydro-2-deoxy-1-*O*-methyl-D-*threo*-pentitol



6,7,8-Trideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-octa-6,7-dienopyranose
or 6,7,7,8-tetradehydro-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-octopyranose



6-*O*-Acetyl-5-deoxy-α-D-*xylo*-hex-5-ynofuranose
or 6-*O*-acetyl-5,5,6,6-tetradehydro-5-deoxy-α-D-*xylo*-hexofuranose



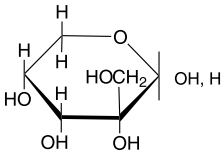
5,6,8-Trideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-oct-5-ynofuranos-7-ulose
or 5,5,6,6-tetradehydro-5,6,8-trideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-octofuranos-7-ulose

2-Carb-18 Branched-Chain Sugars[3]

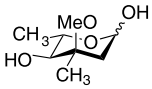
2-Carb-18.1 Trivial Names

Several branched monosaccharides have trivial names, some established by long usage. Examples are given below, together with systematic names for the (cyclic or acyclic) forms illustrated. (See also the alphabetical listing of trivial names in the Appendix.) Enantiomers of the sugars listed should be named systematically.

Examples:

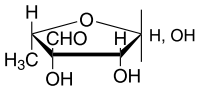


Hamamelose
2-*C*-(Hydroxymethyl)-D-ribopyranose

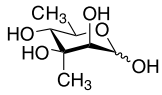


Cladinose
2,6-Dideoxy-3-*C*-methyl-3-*O*-methyl-L-*ribo*-hexopyranose

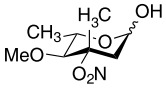
[3]This is a modified form of the 1980 recommendations [4]. Priority is now given to naming cyclic forms, since in most cases branched-chain monosaccharides will form cyclic hemiacetals or hemiketals.



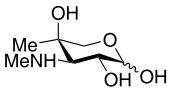
Streptose
5-Deoxy-3-*C*-formyl-L-lyxofuranose



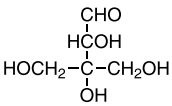
6-Deoxy-3-*C*-methyl-D-mannopyranose
(Evalose)



2,3,6-Trideoxy-3-*C*-methyl-4-*O*-methyl-3-nitro-L-*arabino*-hexopyranose
(Evernitrose)

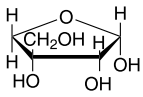


3-Deoxy-4-*C*-methyl-3-methylamino-L-arabinopyranose
(Garosamine)



D-Apiose (Api)
3-*C*-(Hydroxymethyl)-D-*glycero*-tetrose

Note. For the cyclic forms of apiose, systematic names are preferred, e. g.



3-*C*-(Hydroxymethyl)-α-D-erythrofuranose
[The name α-D-*erythro*-apiofuranose is ambiguous; Chemical Abstracts Service (CAS) uses the trivial name D-apio-α-D-furanose; Beilstein gives (3*R*)-α-D-apiofuranose]

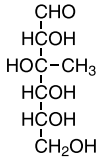
2-Carb-18.2 Systematic Names

A branched-chain monosaccharide is named as a substituted parent unbraxhed monosaccharide, as outlined in ❯ *2-Carb-16.1* to ❯ *2-Carb-16.4*.

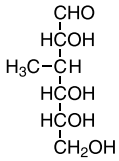
Note. *C*-Locants are essential only where there is potential ambiguity, to make clear whether substitution is at carbon or at a heteroatom (cf. ❯ *2-Carb-16*); however, they may also be used for emphasis.

2-Carb-18.3 Choice of Parent

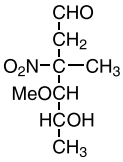
If the branched monosaccharide forms a cyclic hemiacetal or hemiketal, the chain which includes the ring atoms rather than any alternative open chain must be the basis of the name. Otherwise the parent is chosen according to the principles given in ❯ *2-Carb-2.1*.
Examples (see also ❯ *Chart V*):



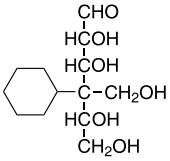
3-*C*-Methyl-D-glucose
(configuration determined by OH)



3-Deoxy-3-methyl-D-glucose
(configuration determined by CH_3)



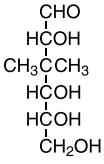
2,3,6-Trideoxy-3-*C*-methyl-4-*O*-methyl-3-nitro-D-*lyxo*-hexopyranose
(nitrogen has priority over carbon for determining configuration)



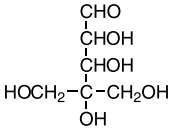
4-Cyclohexyl-4-deoxy-4-(hydroxymethyl)-D-allose
[oxygen (in CH_2OH) has priority over carbon (in cyclohexyl) at C-4]
or (4*R*)-4-cyclohexyl-4-deoxy-4-(hydroxymethyl)-D-*ribo*-hexose

If the two substituents at the branch point are identical, so that this centre has become achiral, the stereochemistry is specified as described in ❯ *2-Carb-8.4*.

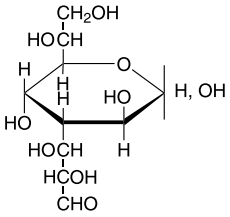
Examples:



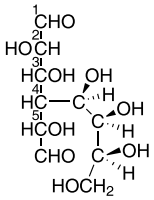
3-Deoxy-3,3-dimethyl-D-*ribo*-hexose



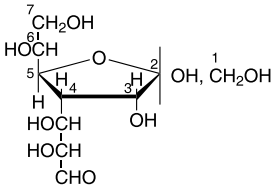
4-*C*-(Hydroxymethyl)-D-*erythro*-pentose



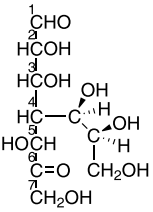
1



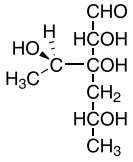
2



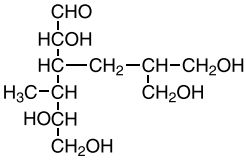
3



4



5



6

1 3-Deoxy-3-[(1*R*,2*S*)-1,2-dihydroxy-3-oxopropyl]-D-*glycero*-D-*altro*-heptopyranose
or 3-deoxy-3-(D-*threo*-1,2-dihydroxy-3-oxopropyl)-D-*glycero*-D-*altro*-heptopyranose
(not the alternative open-chain six-carbon dialdose or eight-carbon aldose, cf. **2**)

2 4-Deoxy-4-(L-*ribo*-1,2,3,4-tetrahydroxybutyl)-D-*altro*-hexodialdose

3 4-Deoxy-4-[(1*R*,2*R*)-1,2-dihydroxy-3-oxopropyl]-D-*allo*-heptulo-2,5-furanose
or 4-deoxy-4-(D-*erythro*-1,2-dihydroxy-3-oxopropyl)-D-*allo*-heptulo-2,5-furanose
(not the alternative ketoaldose, cf. **4**)

4 4-Deoxy-4-[(1*R*,2*S)*-1,2,3-trihydroxypropyl]-L-*talo*-heptos-6-ulose
or 4-deoxy-4-(L-*erytro*-1,2,3-trihydroxypropyl)-L-*talo*-heptos-6-ulose

5 4,6-Dideoxy-3-*C*-(D-*glycero*-1-hydroxyethyl)-D-*ribo*-hexose
(not the alternative pentose)

6 3,4-Dideoxy-3-[3-hydroxy-2-(hydroxymethyl)propyl]-4-*C*-methyl-L-mannose
(not the alternative *threo*-hexose)

◘ Chart V

Choice of parent in branchedchain monosaccharides. In the first names given for examples 1, 3 and 4, side-chain configuration is specified by use of *R* and *S*. This approach is generally preferred in all but the simplest cases, as less open to misinterpretation

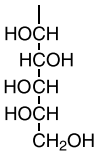
Note. Cyclization of the second example between C-1 and a CH_2OH group would necessitate a three-centre configurational prefix for the ring form.

Note. These recommendations may give rise to very different names for cyclic and acyclic forms of the same basic structures, resulting from different priorities. Thus, in ❯ *Chart V*, structures **1** and **2** are virtually identical, differing only by cyclization. The same holds for structures **3** and **4**.

2-Carb-18.4 Naming the Branches

Each branch will be named as an alkyl or substituted alkyl group replacing a hydrogen atom at the branch point of the parent chain. Within the branches, configurations around asymmetric centres can either be indicated using the *R*, *S*-system or, if they are carbohydrate-like and assignment is straightforward, by the use of the configurational prefix. For this purpose, and in the absence of a carbonyl group (or a terminal COOH or its equivalent) in the branch, the point of attachment of the branch (on the main chain) is regarded as to an aldehyde group.

Example:



L-*gluco*-1,2,3,4,5-Pentahydroxypentyl

If there is a carbonyl group in the branch (or a terminal COOH or its equivalent), its position (assigned lowest number when stereochemistry is being considered) is used to define the configurational prefix (see examples **1** and **3** in ❯ *Chart V*). Use of the *R*, *S* system is generally preferred, as less open to misinterpretation.
For an alternative approach to naming carbohydrate residues as substituents see ❯ *2-Carb-31.2* [which would give the name (1*R*)- or (1*S*)-L-arabinitol-1-*C*-yl for the above example, depending on the ligands at the branch point].

2-Carb-18.5 Numbering

The carbon atoms of the parent chain are numbered according to ❯ *2-Carb-2.2.1*. If a unique numbering is required for the branch(es) (e. g. for X-ray or NMR work), the carbon atoms may be given the locant of the appropriate branch point, with the internal branch locant as superscript, e. g. 4^2 for position 2 of the branch at position 4 of the main chain. This style of branch numbering is not to be used for naming purposes: e. g. the side-chain-methylated derivative of compound **5** is named 4,6-dideoxy-3-*C*-[(*R*)-1-methoxyethyl]-D-*ribo*-hexose, and not as a 3^1-*O*-methyl derivative.

2-Carb-18.6 Terminal Substitution

See ❯ *2-Carb-16.4*.

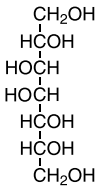
2-Carb-19 Alditols

2-Carb-19.1 Naming

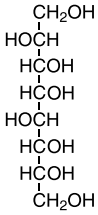
Alditols are named by changing the suffix '-ose' in the name of the corresponding aldose into '-itol'.

If the same alditol can be derived from either of two different aldoses, or from an aldose or a ketose, preference is ruled by ❯ *2-Carb-2.1* or ❯ *2.2.2* as appropriate.

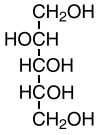
Examples:



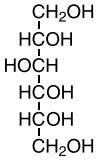
D-*glycero*-D-*galacto*-Heptitol
not L-*glycero*-D-*manno*-heptitol



D-*erythro*-L-*galacto*-Octitol
not D-*threo*-L-*gulo*-octitol

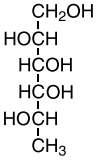


D-Arabinitol (Ara-ol) not D-lyxitol

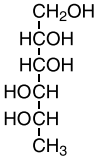


D-Glucitol (Glc-ol) not L-gulitol
(the trivial name sorbitol is not recommended)

The trivial names fucitol and rhamnitol are allowed for the alditols corresponding to the 6-deoxy sugars fucose and rhamnose.



L-Fucitol (L-Fuc-ol) or 1-deoxy-D-galactitol
not 6-deoxy-L-galactitol (cf. 2-Carb-2.2.3.1)



L-Rhamnitol (L-Rha-ol) or 1-deoxy-L-mannitol

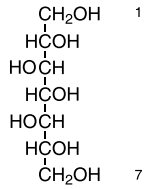
2-Carb-19.2 *meso* Forms

Alditols that are symmetric and therefore optically inactive – the *meso* forms – can be designated by the prefix *meso*-.

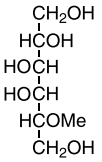
Examples:
***meso*-Erythriol**
***meso*-Ribitol**
***meso*-Galactitol**

The prefix D or L must be given when a derivative of a *meso* form has become asymmetric by substitution. It is also necessary to define the configurational prefixes as D or L in the case where there are more than four contiguous asymmetric carbon atoms.

Examples:



meso-D-*glycero*-L-*ido*-Heptitol
not L-*glycero*-D-*ido*-heptitol; cf. 2-Carb-2.2.3



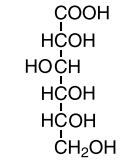
5-*O*-Methyl-D-galactitol
not 2-*O*-methyl-L-galactitol

2-Carb-20 Aldonic Acids

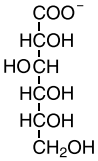
2-Carb-20.1 Naming

Aldonic acids are divided into aldotrionic acid, aldotetronic acids, aldopentonic acids, aldohexonic acids, etc., according to the number of carbon atoms in the chain. The names of individual compounds of this type are formed by replacing the ending '-ose' of the systematic or trivial name of the aldose by '-onic acid'.

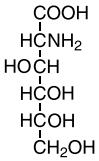
Examples:



D-Gluconic acid



D-Gluconate



2-Amino-2-deoxy-D-gluconic acid

2-Carb-20.2 Derivatives

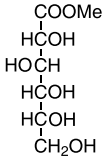
Salts are named by changing the ending '-onic acid' to '-onate', denoting the anion. If the counter ion is known, it is given before the aldonate name.

Example:
Sodium D-gluconate

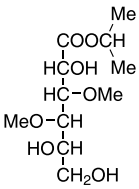
Esters derived from the acid function are also named using the ending '-onate'. The name of the alkyl (aryl, etc.) group is given before the aldonate name. Alternative periphrase names like 'aldonic acid alkyl (aryl, etc.) ester' may be suitable for an index.

Amides are designated by the ending '-onamide', and nitriles by the ending '-ononitrile'.

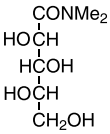
Examples:



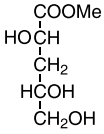
Methyl D-gluconate



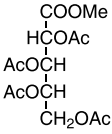
Isopropyl 3,4-di-*O*-methyl-L-mannonate



N,N-Dimethyl-L-xylonamide



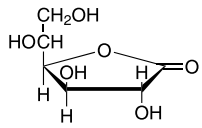
Methyl 3-deoxy-D-*threo*-pentonate



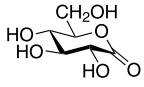
Methyl tetra-*O*-acetyl-L-arabinonate

Lactones are named with the ending '-onolactone'. The locants must be given (in the form '-ono-*i*, *j*-lactone): that of the carbonyl group (*i*) is cited first, and that of the oxygen (*j*) second (see examples below). Periphrase names (see alternatives in parentheses) appear widely in the literature but are not recommended. *Lactams* are named similarly by use of the ending '-onolactam'.

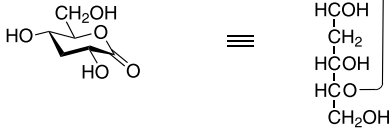
Examples:



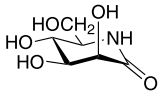
D-Glucono-1,4-lactone
(D-Gluconic acid γ-lactone)



D-Glucono-1,5-lactone
(D-Gluconic acid δ-lactone)



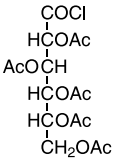
3-Deoxy-D-*ribo*-hexono-1,5-lactone



5-Amino-5-deoxy-D-mannono-1,5-lactam

Acyl halides are named by changing the ending '-onic acid' to '-onoyl halide;'.

Example:



Penta-*O*-acetyl-D-gluconoyl chloride

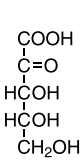
More complicated examples of general principles for naming acid derivatives can be found elsewhere [13,14].

2-Carb-21 Ketoaldonic Acids

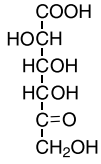
2-Carb-21.1 Naming

Names of individual ketoaldonic acids are formed by replacing the ending '-ulose' of the corresponding ketose by '-ulosonic acid', preceded by the locant of the ketonic carbonyl group. The anion takes the ending '-ulosonate'. The numbering starts at the carboxy group.
In glycosides derived from ketoaldonic acids, the ending is '-ulosidonic acid', with appropriate ring-size infix, e. g. '-ulopyranosidonic acid'.

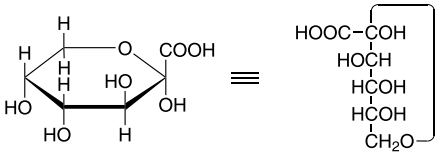
Examples:



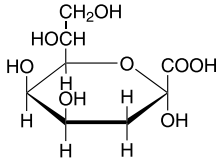
D-*erythro*-Pent-2-ulosonic acid



D-*arabino*-Hex-5-ulosonic acid



α-D-*arabino*-Hex-2-ulopyranosonic acid



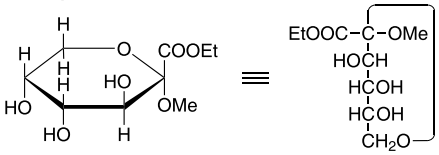
3-Deoxy-α-D-*manno*-oct-2-ulopyranosonic acid

Note. The last of the above examples is.one of the possible forms of the compound referred to by the three-letter symbol Kdo (formerly the abbreviation KDO, from the previously allowed trivial name ketodeoxyoctonic acid). Similarly the symbol Kdn for the C_9 sugar 3-deoxy-D-*glycero*-D-*galacto*-non-2-ulopyranosonic acid is widely used.

2-Carb-21.2 Derivatives

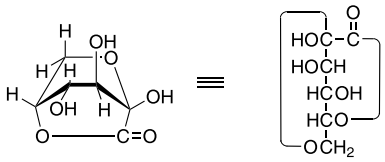
Esters, lactones, lactams, acyl halides etc. are named by modifying the ending '-ic acid' as described for aldonic acids (➤ *2-Carb-20.2*).

Examples:

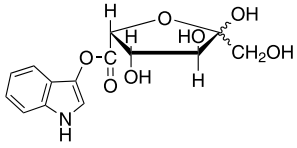


Ethyl (methyl α-D-*arabino*-hex-2-ulopyranosid)onate

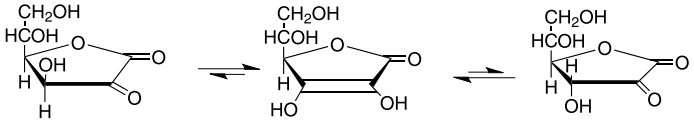
Note. The parentheses are inserted to distinguish between the ester alkyl group (cited first) and the glycosidic *O*-alkyl group.



β-D-*arabino*-Hex-2-ulopyranosono-1,5-lactone



Indol-3-yl D-*xylo*-hex-5-ulofuranosonate; trivial name isatan B



L-*xylo*-Hex-2-ulosono-1,4-lactone L-*threo*-Hex-2-enono-1,4-lactone L-*lyxo*-Hex-2-ulosono-1,4-lactone

(L-Ascorbic acid is the equilibrium mixture of all three isomers)

2-Carb-22 Uronic Acids

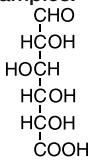
2-Carb-22.1 Naming and Numbering

The names of the individual compounds of this type are formed by replacing (a) the '-ose' of the systematic or trivial name of the aldose by '-uronic acid', (b) the '-oside' of the name of the glycoside by '-osiduronic acid' or (c) the '-osyl' of the name of the glycosyl group by '-osyluronic acid'. The carbon atom of the (potential) aldehydic carbonyl group (*not* that of the carboxy group as in normal systematic nomenclature [13,14]) is numbered 1 (see ➤ *2-Carb-2.1*, note 1).

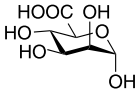
2-Carb-22.2 Derivatives

Derivatives of these acids formed by change in the carboxy group (salts, esters, lactones, acyl halides, amides, nitriles, etc.) are named according to ❯ *2-Carb-20.2*. The anion takes the ending '-uronate'. Esters are also named using the ending '-uronate'.

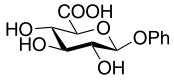
Examples:



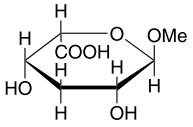
D-Glucuronic acid



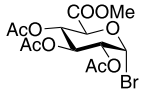
α-D-Mannopyranuronic acid



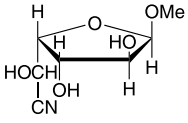
Phenyl β-D-glucopyranosiduronic acid
not phenyl β-D-glucuronoside or phenyl glucuronide



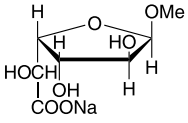
Methyl α-L-idopyranosiduronic acid



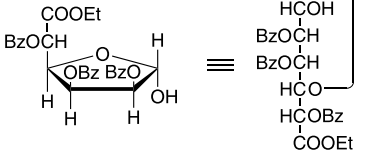
Methyl 2,3,4-tri-*O*-acetyl-α-D-glucopyranosyluronate bromide



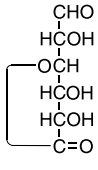
Methyl α-L-glucofuranosidurononitrile



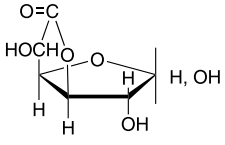
Sodium (methyl α-L-glucofuranosid)uronate



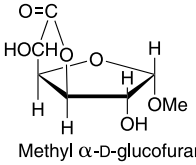
Ethyl 2,3,5-tri-*O*-benzoyl-α-D-mannofuranuronate



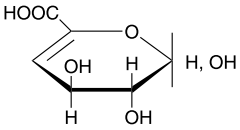
D-Glucurono-6,3-lactone



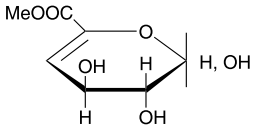
D-Glucofuranurono-6,3-lactone



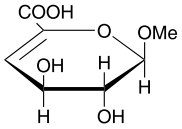
Methyl α-D-glucofuranosidurono-6,3-lactone



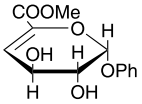
4-Deoxy-L-*threo*-hex-4-enopyranuronic acid



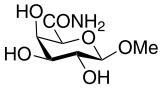
Methyl 4-deoxy-L-*threo*-hex-4-enopyranuronate



Methyl 4-deoxy-α-L-*threo*-hex-4-enopyranosiduronic acid



Methyl (phenyl-4-deoxy-β-L-*threo*-hex-4-enopyranosid)uronate



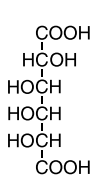
Methyl β-D-galactopyranosiduronamide

2-Carb-23 Aldaric Acids

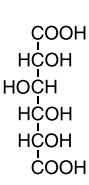
2-Carb-23.1 Naming

Names of individual aldaric acids are fonned by replacing the ending '-ose' of the systematic or trivial name of the parent aldose by '-aric acid'. Choice between possible names is based on 2-Carb-2.2.2.

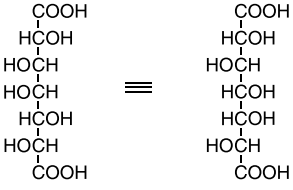
Examples:



L-Altraric acid
not L-talaric acid



D-Glucaric acid
not L-gularic acid

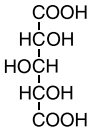


L-*glycero*-D-*galacto*-Heptaric acid
not L-*glycero*-D-*gluco*-heptaric acid

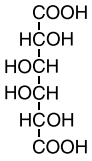
2-Carb-23.2 *meso* Forms

To the names of aldaric acids that are symmetrical, which therefore have no D- or L- prefix, the prefix '*meso*-' may be added for the sake of clarity. Examples: *meso*-erythraric acid, *meso*-ribaric acid, *meso*-xylaric acid, *meso*-allaric acid, *meso*-galactaric acid.
The D or L prefix must however be used when a *meso*-aldaric acid has become asymmetric as a result of substitution.

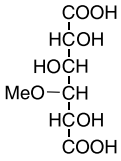
Examples:



meso-Xylaric acid



meso-Galactaric acid

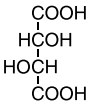


4-*O*-Methyl-D-galactaric acid
not 3-*O*-methyl-L-galactaric acid

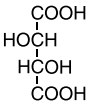
2-Carb-23.3 Trivial Names

For the tetraric acids, the trivial name tartaric acid remains in use, with the stereochemistry given using the *R*, *S* system. Esters are referred to as 'tartrates' (the second 'a' is elided).

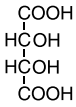
Examples:



(2*R*, 3*R*) - or (+)-Tartaric acid
or L-threaric acid



(2*S*, 3*S*) - or (–)-Tartaric acid
or D-threaric acid



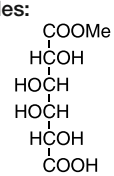
(2*R*, 3*R*) - or *meso*-Tartaric acid
or erythraric acid

Note. In the older literature, there is confusion about the use of D and L in the case of tartaric acids. It is therefore recommended to use the *R*, *S* system in this case.

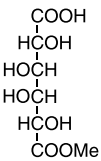
2-Carb-23.4 Derivatives

Derivatives formed by modifying the carboxy group (salts, esters, lactones, lactams, acyl halides, amides, nitriles etc.) are named by the methods of 2-Carb-20.2. Dilactones, half-esters, amic acids etc. are named by the methods of [13,14]. In cases of ambiguity, locants should be specified.

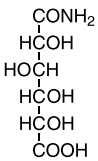
Examples:



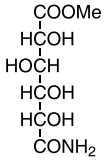
1-Methyl hydrogen D-galactarate



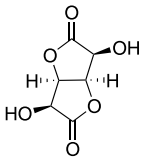
6-Methyl hydrogen D-galactarate



D-Glucar-1-amic acid



Methyl D-glucar-6-armate



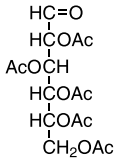
L-Mannaro-1,4:6,3-dilactone

2-Carb-24 *O*-Substitution

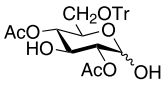
2-Carb-24.1 Acyl (Alkyl) Names

Substituents replacing the hydrogen atom of an alcoholic hydroxy group of a saccharide or saccharide derivative are denoted as *O*-substituents. The '*O*-' locant is not repeated for multiple replacements by the same atom or group. Number locants are used as necessary to specify the positions of substituents; they are not required for compounds fully substituted by identical groups. Alternative periphrase names for esters, ethers, etc. may be useful for indexing purposes. For cyclic acetals see 2-Carb-28.

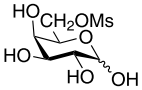
Examples:



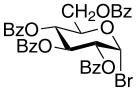
Penta-*O*-acetyl-*aldehydo*-D-glucose
or *aldehydo*-D-glucose pentaacetate



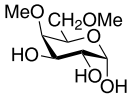
2,4-Di-*O*-acethyl-6-*O*-trityl-D-galactopyranose



6-*O*-Methanesulfonyl-D-galactopyranose
or D-galactopyranose 6-methanesulfonate



Tetra-*O*-benzoyl-α-D-glucopyranosyl bromide



4,6-Di-*O*-methyl-α-D-galactopyranose

Note. Acyl substituents on anomeric OH are designated (as above) by *O*-acyl prefixes. However, anomeric *O*-alkyl derivatives are named as glycosides (see 2-Carb-33).

2-Carb-24.2 Phosphorus Oxoacid Esters

24.2.1 Phosphates

Of special biochemical importance are the esters of monosaccharides with phosphoric acid. They are generally termed phosphates (e. g. glucose 6-phosphate). In biochemical use, the term 'phosphate' indicates the phosphate residue regardless of the state of ionization or the counter ions.

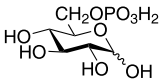
The prefix terms used for phosphate esters in organic nomenclature ([14], p. 65) are '*O*-phosphono-' and '*O*-phosphoato-' for the groups $(HO)_2P(O)$- and $(0^-)_2P(O)$- respectively, bonded to oxygen.

The term 'phospho-' is used for $(HO)_2P(O)$- or ionized forms in a biochemical context (see recommendations for the nomenclature of phosphorus-containing compounds [24]).

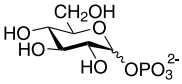
If a sugar is esterified with two or more phosphate groups, the compound is termed bisphosphate, trisphosphate etc. (e. g. fructofuranose 1,6-bisphosphate). The term diphosphate denotes an ester with diphosphoric acid, e. g. adenosine 5′-diphosphate.

Note. In abbreviations. a capital P is used to indicate a terminal $-PO_3H_2$ group or a non-terminal $-PO_2H-$ group (or dehydronated forms).

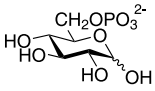
Examples:



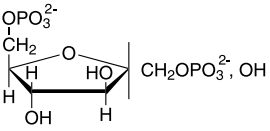
D-Glucopyranose 6-(dihydrogen phosphate)
or 6-*O*-phosphono-D-glucopyranose



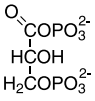
α-D-Glucopyranosyl phosphate
(biochemical usage: glucose 1-phosphate) (Glcl1P)



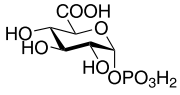
D-Glucopyranose 6-phosphate
(often shortened to glucose 6-phosphate)
or 6-*O*-phosphonato-D-glucopyranose
or 6-phospho-D-glucose (Glc6P)
(in a biochemical context)



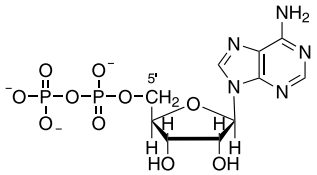
D-Fructofuranose 1,6-bisphosphate
(often shortened to fructose 1,6-bisphosphate)
or 1,6-di-*O*-phosphonato-D-fructofuranose
or 1,6-bisphospho-D-fructofuranose



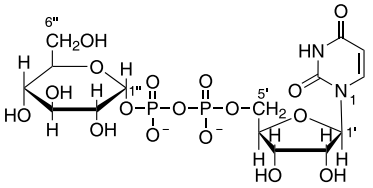
3-*O*-Phosphonato-D-glyceroyl phosphate
or 3-phospho-D-glyceroyl phosphate
or 1,3-bisphospho-D-glycerate (for biochemical usage)



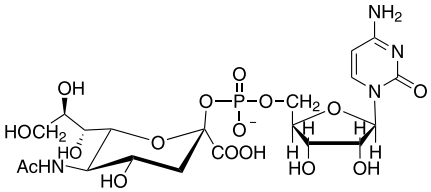
α-D-Glucopyranuronic acid
1-(dihydrogen phosphate)
(biochemical usage: glucuronate 1-phosphate) (GlcA1P)



Adenosine 5′-diphosphate (ADP) or 5′-diphosphoadenosine



Uridine 5′-(α-D-glucopyranosyl diphosphate)
(trivial name uridinediphosphoglucose) (UDP-Glc)

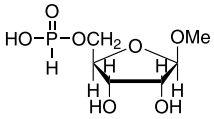


Cytidine 5′-(5-acetamido-3,5-dideoxy-D-*glycero*-β-D-galacto-non-2-ulopyranosylonic acid monophosphate) (CMP-Neu5Ac)

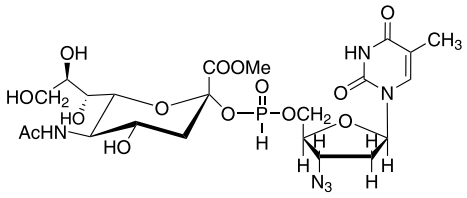
24.2.2 Phosphonates

The following examples illustrate the use of phosphonate terminology for esters of phosphonic acid, $HP(O)(OH)_2$. For formation of the alternative (substitutive) names, see 2-Carb-31.2.

Examples:



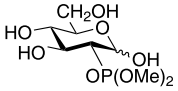
Methyl β-D-ribofuranoside 5-(hydrogen phosphonate)
or methyl 5-deoxy-β-D-ribofuranosid-5-yl hydrogen phosphonate



3'-Azido-3'-deoxythymidine 5'-[(methyl 5-acetamido-3,5-dideoxy-D-*glycerco*-α-D-*galacto*-non-2-ulopyranosylonate) phosphonate]

Derivatives substituted on phosphorus are named by standard procedures [13,14]; e. g. *P*-methyl derivatives are named as methylphosphonates.
Compounds with a phosphonate group linked by a P–C bond to a carbohydrate residue may be named as glycos-*n*-ylphosphonates (cf. ❯ *2-Carb-31.2*) or as *C*-substituted carbohydrates (cf. amino sugars, ❯ *2-Carb-14*).

Example:



2-Deoxy-2-dimethoxyphosphoryl-D-glucopyranose
(this usage of 'phosphoryl' is given in [13], Section D, Rule 5.68, and [14], p. 65)
or dimethyl 2-deoxy-D-glucopyranos-2-ylphosphonate

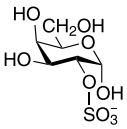
24.2.3 Phosphinates

Esters of phosphinic acid, $H_2P(O)(OH)$, are named by the same methods as used for phosphonates. For examples with two P–C bonds see ❯ *2-Carb-31.3*.

2-Carb-24.3 Sulfates

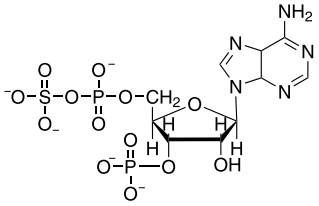
The prefix terms used for sulfuric esters are '*O*-sulfo-' and '*O*-sulfonato-', for the groups $(HO)S(O)_2$- and $(O^-)S(O)_2$- respectively, bonded to oxygen. Sulfates may also be named by citing the word 'sulfate', preceded by the appropriate locant, after the carbohydrate name.

Example:



α-D-Galactopyranose 2-sulfate
or 2-*O*-sulfonato-α-D-galactopyranose

The mixed sulfuric phosphoric anhydride (PAdoPS or PAPS) of 3′-phospho-5′-adenylic acid is named as an acyl sulfate:



3'-Phospho-5'-adenylyl sulfate (PAPS)

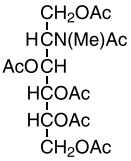
2-Carb-25 *N*-Substitution

Substitution, e. g. acylation, at the NH_2 group of an amino sugar can be dealt with in two different ways:

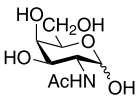
(a) The whole substituted amino group can be designated as a prefix, e. g. 2-acetamido- (or 2-butylamino-) 2-deoxy-D-glucose. For the purpose of the configurational prefix, the group is considered to take the place of the former OH group.
(b) If the amino sugar has a trivial name, the substitution is indicated by a prefix preceded by an italic capital *N*.

Note. In carbohydrate nomenclature, substitution at a heteroatom is normally indicated by citing the locant of the attached carbon atom, followed by a hyphen, and then the italicized heteroatom element symbol, e. g. 2-*O*-methyl, 5-*N*-acetyl. Substituents on the same kind of heteroatom are grouped (e. g. 2,3,4-tri-*O*-methyl), and substituents of the same kind are cited in alphabetical order of heteroatoms (e. g. 5-*N*-acetyl-4,8,9-tri-*O*-acetyl). The alternative format with superscript numerical locants (e. g. N^5, O^4, O^8, O^9-tetraacetyl), used in some other areas of natural product chemistry, is unusual in carbohydrate names.

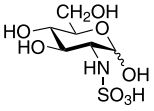
Examples:



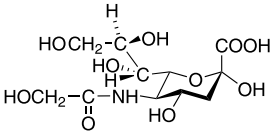
1,3,4,5,6-Penta-*O*-acetyl-2-deoxy-2-(*N*-methylacetamido)-D-glucitol



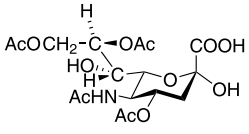
2-Acetamido-2-deoxy-D-galactopyranose
or *N*-acetyl-D-galactosamine



2-Deoxy-2-sulfoamino-D-glucopyranose
or *N*-sulfo-D-glucosamine



N-Glycoloyl-α-neuraminic acid (α-Neu5Gc)
(D is implied in the trivial name)



5-*N*-Acetyl-4,8,9-tri-*O*-acetyl-α-neuraminic acid
(α-Neu4,5,8,9Ac$_4$)

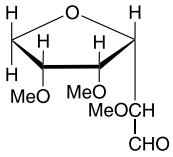
2-Carb-26 Intramolecular Anhydrides

An intramolecular ether (commonly called an intramolecular anhydride), formally arising by elimination of water from two hydroxy groups of a single molecule of a monosaccharide

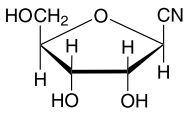
(aldose or ketose) or monosaccharide derivative, is named by attaching the (detachable) prefix 'anhydro-' preceded by a pair of locants identifying the two hydroxy groups involved.

Note. Detachable prefixes are cited in alphabetical order along with any substituent prefixes.

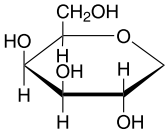
Examples:



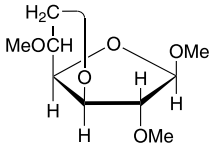
3,6-Anhydro-2,4,5-tri-*O*-methyl-D-glucose



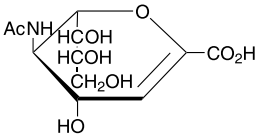
2,5-Anhydro-D-allononitrile



1,5-Anhydro-D-galactitol



Methyl 3,6-anhydro-2,5-di-*O*-methyl-β-D-glucofuranoside

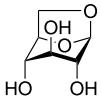


5-Acetamido-2,6-anhydro-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-enonic acid (Neu2en5Ac)

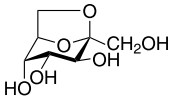
The compounds usually known as monosaccharide anhydrides or glycose anhydrides (earlier 'glycosans'), formation of which involves the anomeric hydroxy group, are named by the same procedure. In these cases the order of preference of ring size designators is pyranose > furanose > septanose. However, three- or four-membered rings should normally be cited as 'anhydro' if there is a choice.

Trivial names for anhydro monosaccharides, though established by usage, are not recommended because of possible confusion with polysaccharide names based on the use of the termination '-an'.

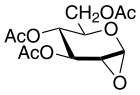
Examples:



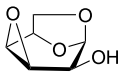
1,6-Anhydro-β-D-glucopyranose
not 1,5-anhydro-α-D-glucoseptanose
(older trivial name: levoglucosan)



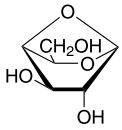
2.7-Anhydro-β-D-*altro*-hept-2-ulopyranose
(older trivial name: sedoheptulosan)



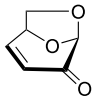
3,4,6-Tri-*O*-acetyl-1,2-anhydro-α-D-glucopyranose
not 3,4,6-tri-*O*-acetyl-1,5-anhydro-β-D-glucooxirose



1,6:3,4-Dianhydro-β-D-talopyranose



1,4-Anhydro-β-D-galactopyranose

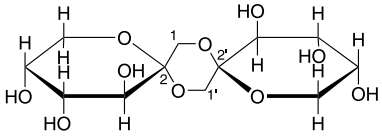


1,6-Anhydro-3,4-dideoxy-β-D-*glycero*-hex-3-enopyranos-2-ulose
(trivial name: levoglucosenone)

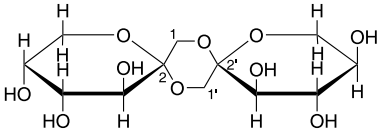
2-Carb-27 Intermolecular Anhydrides

The cyclic product of condensation of two monosaccharide molecules with the elimination of two molecules of water (commonly called an intermolecular anhydride), is named by placing the word 'dianhydride' after the names of the two parent monosaccharides. When the two parent monosaccharides are different, the one preferred according to the order of preference given in 2-Carb-2.1 is cited first. The position of each anhydride link is indicated by a pair of locants showing the positions of the two hydroxy groups involved; the locants relating to one monosaccharide (in a mixed dianhydride, the second monosaccharide named) are primed. Both pairs of locants immediately precede the word 'dianhydride'.

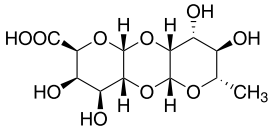
Examples:



α-D-Fructopyranose β-D-fructopyranose 1,2′:1′,2-dianhydride



α-D-Fructopyranose α-D-sorbopyranose 1,2′:1′,2-dianhydride

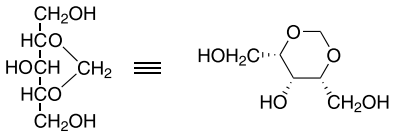


(α-D-Galactopyranuronic acid) β-L-rhamnopyranose 1,2′:1′,2-dianhydride

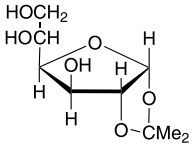
2-Carb-28 Cyclic Acetals

Cyclic acetals formed by the reaction of saccharides or saccharide derivatives with aldehydes or ketones are named in accordance with 2-Carb-24.1, bivalent substituent names (formed by general organic nomenclature principles) being used as prefixes. In indicating more than one cyclic acetal grouping of the same kind, the appropriate pairs of locants are separated typographically when the exact placement of the acetal groups is known.

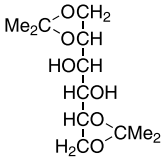
Examples:



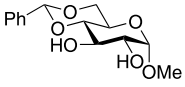
2,4-*O*-Methylenexylitol



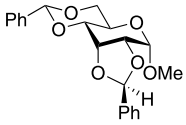
1,2-*O*-Isopropylidene-α-D-glucofuranose



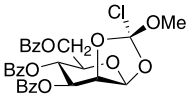
1,2:5,6-Di-*O*-isopropylidene-D-mannitol



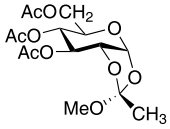
Methyl (*R*)-4,6-*O*-benzylidene-α-D-glucopyranoside



Methyl (*S*)-2,3:(*R*)-4,6-di-*O*-benzylidene-α-D-allopyranoside



3,4,6-Tri-*O*-benzoyl-[(*S*)-1,2-*O*-chloro (methoxy)methylene]-β-D-mannopyranose



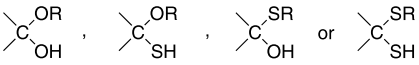
3,4,6-Tri-*O*-acetyl-α-D-glucopyranose (*R*)-1,2-(methyl orthoacetate)
or 3,4,6-tri-*O*-acetyl-[(*R*)-1,2-*O*-(1-methoxyethylidene)]-α-D-glucopyranose

Note 1. The last two examples contain cyclic ortho ester structures. These compounds are conveniently named as cyclic acetals.

Note 2. In the last four examples, new asymmetric centres have been introduced at the carbonyl carbon atom of the aldehyde or ketone that has reacted with the saccharide. When known, the stereochemistry at such a new centre is indicated by use of the appropriate *R* or *S* symbol ([13], Section E) placed in parentheses, immediately before the locants of the relevant prefix.

2-Carb-29 Hemiacetals, Hemiketals and Their Thio Analogues

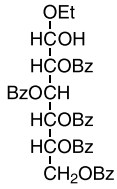
The compounds obtained by transforming the carbonyl group of the acyclic form of a saccharide, or saccharide derivative, into the grouping:



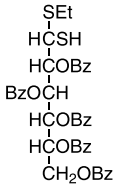
(R = alkyl or aryl)

are named as indicated in ❯ *2-Carb-30*, by using the terms 'hemiacetal', 'monothiohemiacetal', or 'dithiohemiacetal'(or the corresponding 'hemiketal' terms for ketone derivatives), as appropriate. The two isomers of a monothiohemiacetal are differentiated by use of *O* and *S* prefixes.

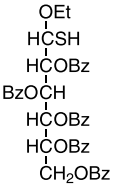
Examples:



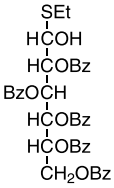
(1 *S*)-2,3,4,5,6-Penta-*O*-benzoyl-D-glucose ethyl hemiacetal



(1 *S*)-2,3,4,5,6-Penta-*O*-benzoyl-D-glucose ethyl dithiohemiacetal



(1 *R*)-2,3,4,5,6-Penta-*O*-benzoyl-D-glucose *O*-ethyl monothiohemiacetal

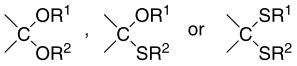


(1 *S*)-2,3,4,5,6-Penta-*O*-benzoyl-D-glucose *S*-ethyl monothiohemiacetal

Note. In these compounds carbon atom number 1 has become chiral. When known, the stereochemistry at this new chiral centre is indicated using the *R*, *S* system ([13], Section E).

2-Carb-30 Acetals, Ketals and Their Thio Analogues

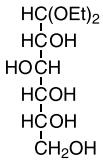
The compounds obtained by transfoming the carbonyl group of a saccharide or saccharide derivative into the grouping:



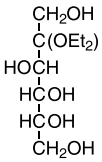
(R = alkyl or aryl)

are named by placing after the name of the saccharide or saccharide derivative the term 'acetal', 'monothioacetal' or 'dithioacetal' (or the corresponding 'ketal' terms for ketone derivatives) as appropriate, preceded by the names of the groups R^1 and R^2. With monothioacetals, the mode of bonding of two different groups R^1 and R^2 is indicated by the use of the prefixes *O* and *S*.

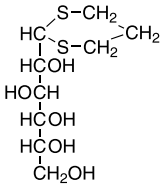
Examples:



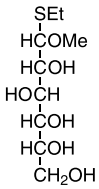
D-Glucose diethyl acetal



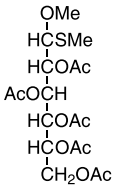
D-Fructose diethyl ketal



D-Glucose propane-1,3-diyl dithioacetal



(1 *S*)-D-Glucose *S*-ethyl *O*-methyl monothioacetal



(1 *R*)-2,3,4,5,6-Penta-*O*-acetyl-D-glucose dimethyl monothioacetal

Note. In the last two examples, carbon atom 1 has become chiral. When known, the stereochemistry at this new chiral centre is indicated by the *R*, *S* system, as specified in 2-Carb-29.

2-Carb-31 Names for Monosaccharide Residues

2-Carb-31.1 Glycosyl Residues

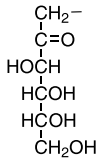
The residue formed by detaching the anomeric hydroxy group from a monosaccharide is named by replacing the terminal '-e' of the monosaccharide name by '-yl'. The general name

is 'glycosyl' residue. Terms of this type are widely used in naming glycosides and oligosaccharides. For examples (including glycosyl residues from uronic acids), see ➤ *2-Carb-33.2*. The term 'glycosyl' is also used in radicofunctional names, e. g. for halides such as the glucopyranosyl bromide in ➤ *2-Carb-24.1* and the mannopyranosyl fluoride in ➤ *2-Carb-16.1*, and esters such as the glucopyranosyl phosphate in ➤ *2-Carb-24.2.1* and the mannopyranosyl nitrate in ➤ *2-Carb-16.2*.

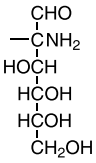
2-Carb-31.2 Monosaccharides as Substituent Groups

In order to produce names for structures in which it may be desirable for a non-carbohydrate portion to be cited as parent, prefix terms are required for carbohydrate residues linked through carbon or oxygen at any position on the main chain. These prefixes can be formed by replacing the final 'e' of the systematic or trivial name of a monosaccharide by '-*n*-C-yl', '-*n*-*O*-yl' or '-*n*-yl' (if there is no ambiguity). In each case the term '-yl' signifies loss of H from position *n*. At a secondary position (e. g. in 2-deoxy-D-glucos-2-y1, below) the free valency is regarded as equivalent to OH for assignment of configuration.

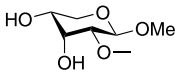
Examples:



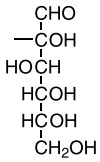
1-Deoxy-D-fructos-1-yl



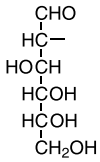
2-Amino-2-deoxy-D-glucos-2-yl



(Methyl β-D-ribopyranosid-2-*O*-yl)



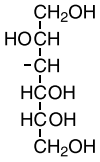
D-Glucose-2-*C*-yl



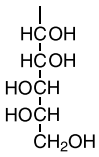
2-Deoxy-D-glucos-2-yl

The same endings can be used to form substituent prefixes for alditol residues.

Examples:



3-Deoxy-D-mannitol-3-yl

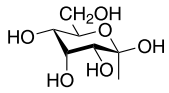


L-Arabinitol-1-*C*-yl (cf. 2-Carb-18.4)
(*R*/*S* to be specified at C-1)

The ending '-yl' without locants signifies loss of OH from the anomeric position (see 2-Carb-31.1). Loss of H from the anomeric OH is indicated by the ending '-yloxy', without locant. For examples see 2-Carb-33.

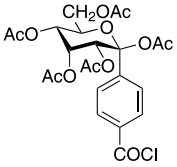
The situation in which the anomeric OH is retained but H is lost from the anomeric carbon atom is indicated by use of the ending '-yl' without locants in conjunction with the prefix '1-hydroxy-' (not by the ending '- 1-*C*-yl'). **N.B.** In this case, the anomeric prefix α or β refers to the free valency, not the OH group.

Example:

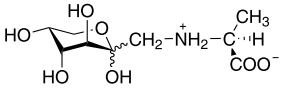


1-Hydroxy-α-D-allopyranosyl

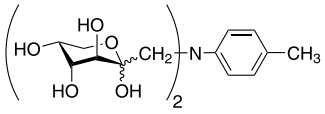
Examples of the use of substituent prefixes for carbohydrate residues:



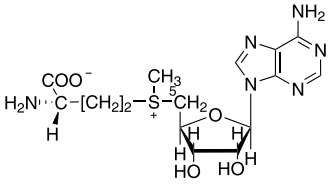
4-(1-Acetoxy-2,3,4,6-tetra-*O*-acetyl-α-D-allopyranosyl) benzoyl chloride



N-(1-Deoxy-D-fructopyranos-1-yl)-L-alanine

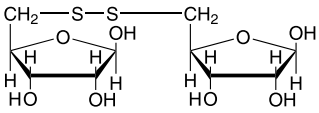


N,N-Bis-(1-deoxy-D-fructopyranos-1-yl)-*p*-toluidine

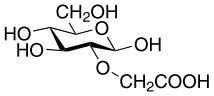


S-(5'-Deoxyadenosin-5'-yl)-L-methionine (AdoMet)

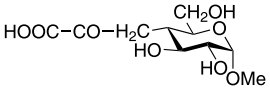
S-[(1-Adenin-9-yl)-1,5-dideoxy-β-D-ribofuranos-5-yl]-L-methionine
[trivial name *S*-adenosylmethionine (SAM)]



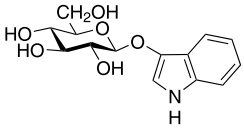
Bis(5-deoxy-β-D-ribofuranos-5-yl) disulfide
or bis(5-deoxy-β-D-ribofuranos-5-yl)disulfane



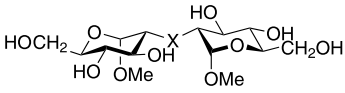
(β-D-Glucopyranos-2-*O*-yl)acetic acid
(more commonly named 2-*O*-carboxymethyl-β-D-glucopyranose; see 2-Carb-2.1, note 2)



(Methyl α-D-glucopyranosid-4-*O*-yl)pyruvic acid [or methyl 4-*O*-(oxalomethyl)-α-D-glucopyranoside]



3-(β-D-Glucopyranosyloxy) indole (or indol-3-yl β-D-glucopyranoside); trivial name indican



X=O

Methyl 2-*O*-(methyl 2-deoxy-α-D-glucopyranosid-2-yl)-α-D-glucopyranoside
or bis(methyl 2-deoxy-α-D-glucopyranosid-2-yl) ether

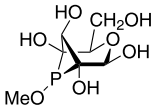
X=NH

Bis(methyl 2-deoxy-α-D-glucopyranosid-2-yl)amine

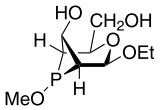
2-Carb-31.3 Bivalent and Tervalent Groups

The group formed by detaching one hydrogen atom from each of two (or three) carbon atoms of a monosaccharide is named by replacing the terminal '-e' of the monosaccharide name by '-diyl' (or '-triyl'), preceded by the appropriate locants.

Examples:



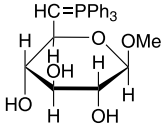
Methyl β-D-talopyranose-2-*C*,4-*C*-diylphosphinite
or 2-*C*,4-*C*-(methoxyphosphanediyl)-β-D-glucopyranose
or (2*R*,4*S*)-2-*C*,4-*C*-(methoxyphosphanediyl)-β-D-*threo*-hexopyrano



Methyl (ethyl 2,4-dideoxy-β-D-glucopyranoside-2,4-diyl)phosphinite
or ethyl 2,4-dideoxy-2,4-(methoxyphosphanediyl)-β-D-glucopyranoside

Residues formed by detaching two (or three) hydrogen atoms from the same carbon atom may be named similarly.

Example:



(Methyl 6-deoxy-β-D-glucopyranosid-6-ylidene)triphenyl-λ^5-phosphane
or methyl 6-deoxy-6-triphenyl-λ^5-phosphanylidene-β-D-glucopyranoside

Note. Names based on phosphane, rather than phosphine or phosphorane, are used in this document, as recommended in [14].

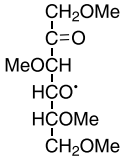
2-Carb-32 Radicals, Cations and Anions

Naming procedures described in this section follow the recommendations given in [25].

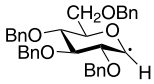
2-Carb-32.1 Radicals

Names for-radicals are formed in the same way as those for the corresponding substituent groups (see ❯ *2-Carb-31.2*).

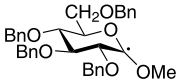
Examples:



1,3,5,6-Tetra-*O*-methyl-D-fructos-4-*O*-yl



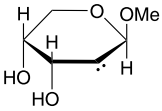
Tetra-*O*-benzyl-D-glucopyranosyl



2,3,4,6-Tetra-*O*-benzyl-1-methoxy-D-glucopyranosyl

Carbenes are named analogously by use of the suffix '-ylidene'.

Example:

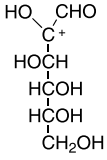


Methyl 2-deoxy-β-D-*erythro*-pentopyranosid-2-ylidene

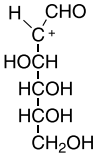
2-Carb-32.2 Cations

Cations produced by formal loss of H^- from a carbon atom are denoted by replacing terminal 'e' with the suffix '-ylium', in conjunction with appropriate locants and a 'deoxy-' prefix if necessary (cf. ❯ *2-Carb-31.2*).

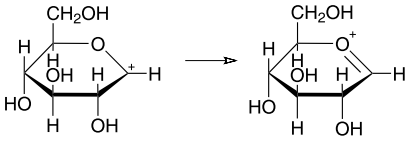
Examples:



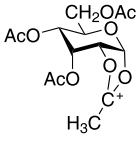
D-*arabino*-Hexos-2-*C*-ylium



2-Deoxy-D-*arabino*-hexos-2-ylium



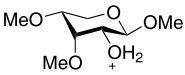
D-Glucopyranosylium



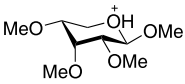
3,4,6-Tri-*O*-acetyl-1,2-*O*-ethyliumdiyl-α-D-allopyranose

Cations formed by hydronation of an OH group or at the hemiacetal ring oxygen are denoted by the suffix '-*O*-ium', with numerical locant.

Examples:



Methyl 3,4-di-*O*-methyl-β-D-ribopyranosid-2-*O*-ium

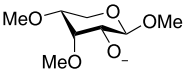


Methyl 2,3,4-tri-*O*-methyl-β-D-ribopyranosid-5-*O*-ium

2-Carb-32.3 Anions

Anions produced by formal loss of H^+ from an OH group are denoted by the suffix '-*O*-ate', with numerical locant.

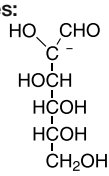
Example:



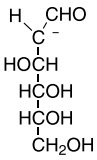
Methyl 3,4-di-*O*-methyl-β-D-ribopyranosid-2-*O*-ate

Anions produced by formal loss of H^+ from a carbon atom are denoted by the suffix '-ide', with appropriate locants and a 'deoxy-' prefix if necessary (cf. 2-Carb-31.2).

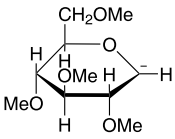
Examples:



D-*arabino*-Hexos-2-*C*-ide



2-Deoxy-D-*arabino*-hexos-2-ide

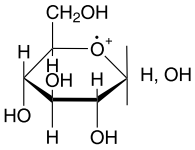


1,5-Anhydro-2,3,4,6-tetra-*O*-methyl-D-glucitol-1-ide

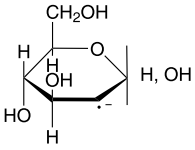
2-Carb-32.4 Radical Ions

Radical ions can be named by adding the suffix 'yl' to ion names. Alternatively, the words 'radical cation' or 'radical anion' may be added after the name of the parent with the same molecular formula, especially when the location of the radical ion centre is not to be specified.

Examples:



D-Glucopyranosiumyl, or D-glucopyranose radical cation



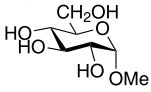
2-Deoxy-D-*arabino*-hexos-2-id-2-yl, or 2-deoxy-D-*arabino*-hexopyranos-2-ylidene radical anion

2-Carb-33 Glycosides and Glycosyl Compounds

2-Carb-33.1 Definitions

Glycosides were originally defined as mixed acetals (ketals) derived from cyclic forms of monosaccharides.

Example:



Methyl α-D-glucopyranoside

However, the term 'glycoside' was later extended to cover not only compounds in which, as above, the anomeric hydroxy group is replaced by a group -OR, but also those in which the replacing group is -SR (thioglycosides), -SeR (selenoglycosides), $-NR^1R^2$ (*N*-glycosides), or even $-CR^1R^2R^3$ (*C*-glycosides). 'Thioglycoside' and 'selenoglycoside' are legitimate generic terms; however the use of '*N*-glycoside' , although widespread in biochemical literature, is improper and not recommended here ('glycosylamine' is a perfectly acceptable term). '*C*-Glycoside' is even less acceptable (see Note to *2-Carb-33.7*). A glossary of terms based on 'glycose' is given in the Appendix.

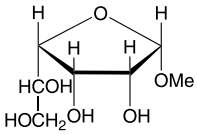
Particularly in naturally occurring glycosides, the compound ROH from which the carbohydrate residue has been removed is often termed the aglycone, and the carbohydrate residue itself is sometimes referred to as the 'glycone'.

Note. The spelling 'aglycon' is often encountered.

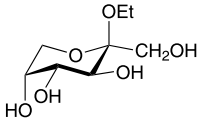
2-Carb-33.2 Glycosides

Glycosides can be named in three different ways:
(a) By replacing the terminal '-e' of the name of the corresponding cyclic form of the monosaccharide by '-ide' and preceding this, as a separate word (the intervening space is significant), the name of the group R (see examples below).

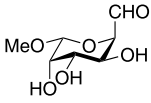
Examples:



Methyl α-D-gulofuranoside
not methyl-α-D-gulofuranosid



Ethyl β-D-fructopyranoside



Methyl (6*R*)-D-*gluco*-hexodialdo-6,2-pyranoside

Note. This is the 'classical' way of naming glycosides. It is used mainly when the group R is relatively simple (e. g. methyl, ethyl, phenyl).

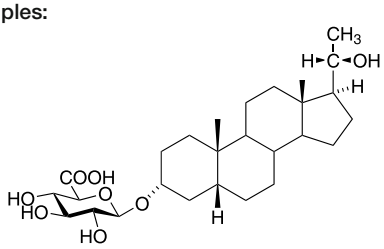
(b) By using the term 'glycosyloxy-', in the appropriate form for the monosaccharide, as prefix, for the name of the compound.

Note. This prefix includes the oxygen of the glycosidic bond. An example is given in 2-Carb-31.2; more are given below.

(c) By using the term '*O*-glycosyl-' as prefix to the name of the hydroxy compound.

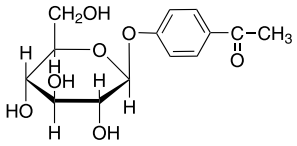
Note. This prefix does not include the oxygen of the glycosidic group. This is the appropriate method for naming natural products if the trivial name includes the OH group. The system is also used to name oligosaccharides (see 2-Carb-37).

Examples:

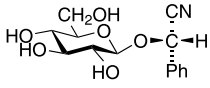


(20*S*)-20-Hydroxy-5β-pregnan-3α-yl β-D-glucopyranosiduronic acid
or (20*S*)-3α-(β-D-glucopyranosyloxyuronic acid)-5β-pregnan-20-ol;
for biochemical usage, pregnanediol 3-glucuronide

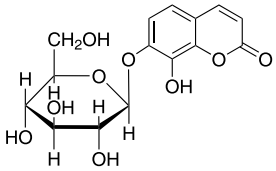
Note. A common biochemical practice would give the name (20*S*)-3α-(β-D-glucopyranuronosyloxy)-5β-pregnan-20-ol. This practice of naming glycosyl residues from uronic acids as 'glycuronosyl' is unsatisfactory because it implies the acceptance of the parent name 'glycuronose'. However the use of a two-word substituent prefix (glycosyloxyuronic acid), ending with a functional class name, remains inherently problematic, since it contravenes general organic nomenclature principles [13,14]. The latter practice has the advantage of retaining homomorphic relationships between glycoses and glycuronic acids.



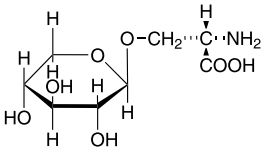
4-Acetylphenyl β-D-glucopyranoside
or 4′-(β-D-glucopyranosyloxy)acetophenone;
trivial name picein



(*S*)-*O*-β-D-Glucopyranosylmandelonitrile
or (*S*)-(β-D-glucopyranosyloxy)(phenyl)acetonitrile;
trivial name sambunigrin



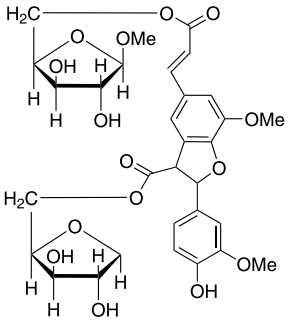
7-(β-D-Glucopyranosyloxy)-8-hydroxycoumarin;
trivial name daphnin



O-β-D-Xylopyranosyl-L-serine [(Xyl-)Ser]

Glycosides can be named as substituents by the methods of ❯ *2-Carb-31*.

Example:



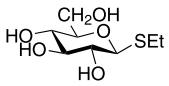
(Methyl 5-deoxy-β-D-xylofuranosid-5-yl) 2-(4-hydroxy-3-methoxyphenyl)-7-methoxy-
5-[2-(methyl β-D-xylofuranosid-5-*O*-ylcarbonyl)vinyl]-2,3-dihydrobenzofuran-3-carboxyl

2-Carb-33.3 Thioglycosides

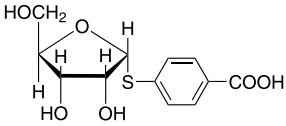
Names for individual compounds can be formed, like those for glycosides, in three ways, as follows.

(a) By using the term thioglycoside, preceded by the name of the group R.
(b) With the prefix 'glycosylthio-', followed by the name of the compound RH; this prefix includes the sulfur atom.
(c) With the prefix '*S*-glycosyl-' (not including the S atom), followed by the name of the thio compound. Sulfoxides and sulfones can also be named by functional class nomenclature [13,14].

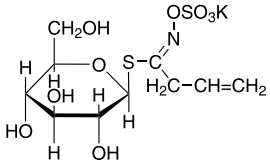
Examples:



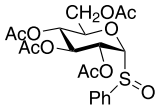
Ethyl 1-thio-β-D-glucopyranoside



4-(α-D-Ribofuranosylthio)benzoic acid
or 4-carboxyphenyl 1-thio-α-D-ribofuranoside



S-β-D-Glucopyranosyl (*Z*)-*O*-(potassium sulfonato)but-3-enehydroximothioate
(trivial name sinigrin)

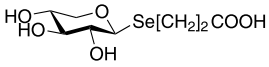


Phenyl tetra-*O*-acetyl-α-D-glucopyranosyl sulfoxide
or phenyl 2,3,4,6-tetra-*O*-acetyl-1-*thio*-α-D-glucopyranoside *S*-oxide

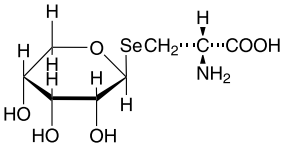
2-Carb-33.4 Selenoglycosides

Names are formed analogously to those for thioglycosides (2-Carb-33.3).

Examples:



2-Carboxyethyl 1-seleno-β-D-xylopyranoside
or 3-(β-D-xylopyranosylseleno)propanoic acid

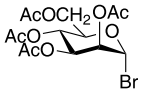


Se-β-D-Ribopyranosyl-D-selenocysteine
or (*S*)-2-amino-2-carboxyethyl 1-seleno-β-D-ribopyranoside
or 3-(β-D-ribopyranosylseleno)-D-alanine

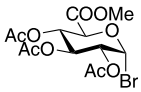
2-Carb-33.5 Glycosyl Halides

Compounds in which the anomeric hydroxy group is replaced by a halogen atom are named as glycosyl halides. Pseudohalides (azides, thiocyanates etc.) are named similarly.

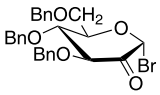
Examples:



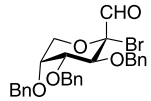
Tetra-*O*-acetyl-α-D-mannopyranosyl bromide



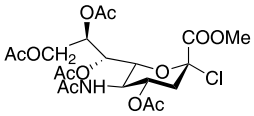
Methyl (2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl)uronate bromide
not methyl 2,3,4-tri-*O*-acetyl-1-bromo-1-deoxy-α-D-glucopyranuronate



3,4,6-Tri-*O*-benzyl-α-D-*arabino*-hexopyranosyl-2-ulose bromide



3,4,5-Tri-*O*-benzyl-α-D-*arabino*-hexos-2-ulo-2,6-pyranosyl bromide
or 3,4,5-tri-*O*-benzyl-*aldehydo*-α-D-*arabino*-hexos-2-ulopyranosyl bromide

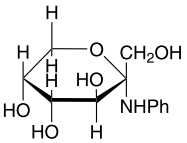


Methyl (5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-*glycero*-α-D-*galacto*-non-2-ulopyranosyl)onate chloride

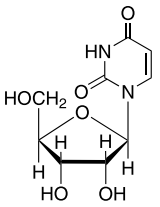
2-Carb-33.6 *N*-Glycosyl Compounds (Glycosylamines)

N-Glycosyl derivatives are conveniently named as glycosylamines. In the case of complex heterocyclic amines, such as nucleosides, the same approach is used.

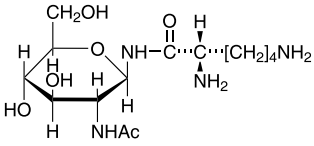
Examples:



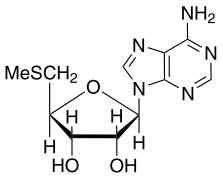
N-Phenyl-α-D-fructopyranosylamine
not aniline α-D-fructopyranoside



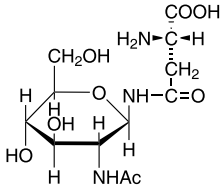
1-β-D-Ribofuranosyluracil (trivial name uridine)



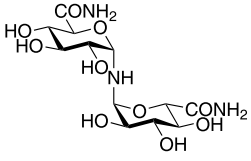
N^1-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)-L-lysinamide (Lys-NH-GlcNAc)
[trivial name N^1-(*N*-acetylglucosaminyl)-L-lysinamide]



9-(5-*S*-Methyl-thio-β-D-ribofuranosyl)adenine



N^4-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)-L-asparagine [(GlcNAc-)Asn]
or 2-acetamido-N^1-L-β-aspartyl-2-deoxy-β-D-glucopyranosylamine
(trivial name β-*N*-acetylglucosaminyl-L-asparagine)



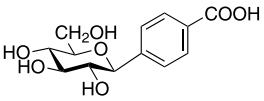
Bis(α-D-glucopyranosyluronamide)amine

2-Carb-33.7 *C*-Glycosyl Compounds

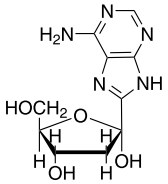
Compounds arising formally from the elimination of water from the glycosidic hydroxy group and an H atom bound to a carbon atom (thus creating a C-C bond) are named using the appropriate 'glycosyl-' prefixes (or other methods as appropriate, avoiding '*C*-glycoside' terminology).

Note. The term *C*-glycoside, introduced for naming pseudouridine (a nucleoside from transfer RNA), is a misnomer. All other glycosides are hydrolysable; the C-C bond of 'C-glycosides' is usually not. The use and propagation of names based on 'C-glycoside' terminology is therefore strongly discouraged.

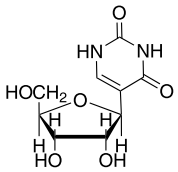
Example:



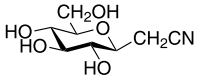
4-β-D-Glucopyranosylbenzoic acid
not 4-carboxyphenyl *C*-β-D-glucopyranosid



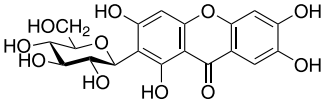
8-(2-Deoxy-β-D-*erythro*-pentofuranosyl)adenin
not adenine 8-(2-deoxyriboside)



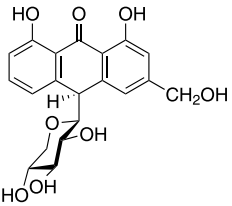
5-β-D-Ribofuranosyluracil; trivial name pseudouridine



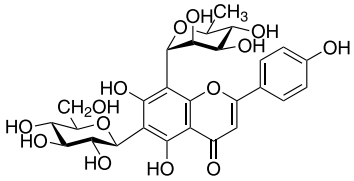
3,7-Anhydro-2-deoxy-D-*glycero*-D-*gulo*-octononitrile
or 2-*C*-(β-D-glucopyranosyl) acetonitrile
not cyanomethyl *C*-β-D-glucopyranoside



2-β-D-Glucopyranosyl-1,3,6,7-tetrahydroxyxanthen-9-one; trivial name mangiferin



(10*S*)-10-β-D-Glucopyranosyl-1,8-dihydroxy-3-(hydroxymethyl)anthracen-9(10*H*)-one; trivial names aloin A. (10*S*)-barbaloin



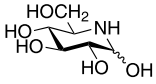
6-β-D-Glucopyranosyl-4',5,7-trihydroxy-8-α-L-rhamnopyranosylflavone; trivial name violanthin

2-Carb-34 Replacement of Ring Oxygen by Other Elements

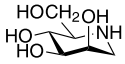
2-Carb-34.1 Replacement by Nitrogen or Phosphorus

Names should be based on those of the amino sugars (see ❯ *2-Carb-14*) (or the analogous phosphanyl sugars) with the amino or phosphanyl group at the non-anomeric position. Ring-size designators (furano, pyrano etc.) are the same as for the oxygen analogues.

Examples:

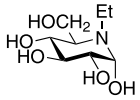


5-Amino-5-deoxy-D-glucopyranose; trivial name nojirimycin

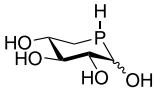


1-Amino-1,5-anhydro-1-deoxy-D-mannitol or 1,5-dideoxy-1,5-imino-D-mannitol; trivial name deoxymannojirimycin

Note the extension of the use of 'anhydro' in the above example to include the elimination of water between -NH_2 and -OH (Cf. ❯ *2-Carb-26*).

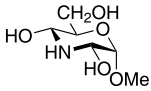


5-Deoxy-5-ethylamino-α-D-glucopyranose



5-Deoxy-5-phosphanyl-D-xylopyranose

Note. Use of the terms 'aza sugar', 'phospha sugar' etc. should be restricted to structures where carbon, not oxygen, is replaced by a heteroatom. Thus the structure below is a true aza sugar. The term 'imino sugar' may be used as a class name for cyclic sugar derivatives in which the ring oxygen atom has been replaced by nitrogen.



Methyl 3-deoxy-3-aza-α-D-*ribo*-hexopyranoside

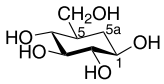
2-Carb-34.2 Replacement by Carbon

The (non-detachable) prefix 'carba-' signifies replacement of a heteroatom by carbon in general natural product nomenclature [26], and may be applied to replacement of the hemiacetal ring oxygen in carbohydrates if there is a desire to stress homomorphic relationships. If the original heteroatom is unnumbered, the new carbon atom is assigned the locant of the non-anomeric adjacent skeletal atom, with suffix 'a'.

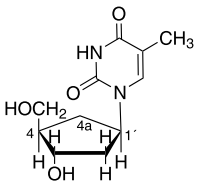
Note. The draft natural product rules [26] recommend that the new carbon atom takes the locant of the lower-numbered proximal atom. However, carbohydrate chemists regard the ring oxygen as formally originating from the non-anomeric (usually higher-numbered) position.

Additional stereochemistry (if any) at the new carbon centre is specified by use of the *R*/*S* system ([13], Section E).
Structures of this type can also be named as cyclitols [8].

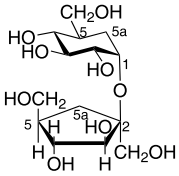
Examples:



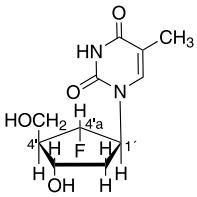
5a-Carba-β-D-glucopyranose



1-(2-Deoxy-4a-carba-β-D-*erythro*-pentofuranosyl)thymine
or 4'a-carbathymidine



5a-Carba-β-D-fructouranosyl 5a-carba-α-D-glucopyranoside



1-[(4a*S*)-2-Deoxy-4a-fluoro-4a-carba-β-D-*erythro*-pentofuranosyl]thymine
or (4'a*S*)-4'a-fluoro-4'a-carbathymidine

2-Carb-35 Carbohydrates Containing Additional Rings

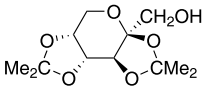
Internal bridging of carbohydrate structures by bivalent substituent groups creates additional rings, which can be named either by use of a substituent prefix representing the bridging group, or by fusion nomenclature. The following recommendations for the use of these two approaches are not thoroughly developed; they simply represent an attempt to rationalize ind codify current literature practice in the use of systems not in general well suited to carbohydrate applications. Bridging substituent prefix nomenclature (❯ *2-Carb-35.1*) is based on the system well established for simple cyclic acetals (❯ *2-Carb-28*), and fusion nomenclature (❯ *2-Carb-35.2*) on current literature usage and requirements for general natural product nomenclature [26].

2-Carb-35.1 Use of Bivalent Substituent Prefixes

Where the new bridge is attached to oxygen (or a replacement heteroatom, e. g. nitrogen in an amino sugar) already indicated in the name of the unbridged carbohydrate, the bivalent substituent prefix denotes substitution at two heteroatoms as outlined in ❯ *2-Carb-24.1* and ❯ *2-Carb-25* [method (b)]. Heteroatoms not directly bonded to the carbohydrate chain are regarded as part of the bridge.

Where the new bridge is attached through C-C bonds to the carbohydrate chain, the bridge prefix denotes a double *C*-substitution. Procedures are as outlined in ❯ *2-Carb-16*.

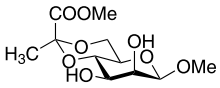
Examples:



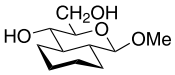
2,3:4,5-Di-*O*-isopropylidene-ß-D-fructopyranose

Note 1. The alternative fusion name (see ❯ *2-Carb-35.2*) is 2,2,2′,2′-tetramethyl-4,4′,5,5′-tetrahydro-(2,3,4,5-tetradeoxy-β-D-fructopyranoso)[2,3-*d*:4,5-*d*′]bis[1,3]dioxole; this is clearly less desirable on grounds of complexity.

Note 2. The use of prefixes ending in '-ylidene' for *gem*-bivalent substituent groups is traditional in the carbohydrate field, although no longer recommended in general organic nomenclature [14].

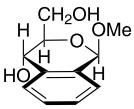


Methyl [(*S*)-4,6-*O*-(1-methoxycarbonylethylidene)]-β-D-mannopyranoside



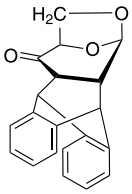
Methyl 2,3-(butane-1,4-diyl)-2,3-dideoxy-β-D-glucopyranoside

Note. The alternative fusion name (see 2-Carb-35.2) is hexahydro(methyl 2,3-dideoxy-*β*-D-glucopyranosido)[2,3]benzene

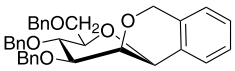


Methyl 2,3-(buta-1,3-diene-1,4-diyl)-2,3-dideoxy-β-D-*erythro*-hex-2-enopyranoside

Note. The alternative fusion name (see 2-Carb-35.2) is (methyl 2,3-dideoxy-*β*-D-*erythro*-hexopyranosido)[2,3]benzene



1,6-Anhydro-2,3-dideoxy-2,3-(9,10-dihydroanthracene-9,10-diyl)-β-D-*ribo*-hexopyranos-4-ulose

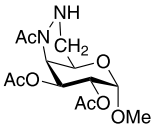


(1*S*)-1,5-Anhydro-3,4,6-tri-*O*-benzyl-1-*C*,2-*O*-(*o*-phenylenemethylene)-D-mannitol

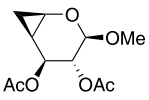
Note. The isomeric chromene would be named as a 2-*O*, 1-*C*-substituted system.

The prefix 'cyclo-' may be used for a single-bond bridge [14].

Examples:



Methyl 4-*N*-acetyl-2,3-di-*O*-acetyl-4,6-diamino-4,6-*N*-cyclo-4,6-dideoxy-α-D-galactopyranoside



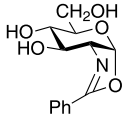
Methyl 2,3-di-*O*-acetyl-4,6-cyclo-4,6-dideoxy-β-D-galactopyranoside

2-Carb-35.2 Ring Fusion Methods

Fusion methods are employed as in general natural product nomenclature [26], except that the original carbohydrate ring is cited first, in parentheses (with terminal '-e', if present, replaced by '-o'). For designating stereochemistry, bonds in the new ring are considered as equivalent to OH, unless OH (or its equivalent) is still present at the ring junction. Substituents on the carbohydrate portion are included within the parentheses enclosing the fusion prefix. Substituents on the new ring (including 'hydro-' prefixes) precede the carbohydrate term(s). If there is a choice, the new ring is numbered in the direction used to define the fusion locants.

Note. General natural product fusion nomenclature [26] would require the carbohydrate portion to be cited last (e. g. oxazologlucopyranose), whereas it is cited first here and in the literature.

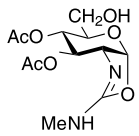
Examples:



2-Phenyl-4,5-dihydro-(1,2-dideoxy-α-D-glucopyranoso)[2,1-*d*]-1,3-oxazole

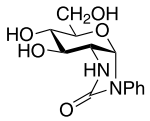
Note 1. The alternative name using a substituent prefix (see ❯ *2-Carb-35.1*) is 2-amino-1-*O*,2-*N*-(benzylylidene)-2-deoxy-α-D-glucopyranose.

Note 2. Literature fusion names for this type of compound use 'glucopyrano[2,l-d]oxazoline' terminology. However, names for partially hydrogenated heterocycles ending in 'oline' were abandoned by IUPAC in 1983 [27], in favour of 'dihydro.....ole'. Use of 'pyranoso' rather than 'pyrano' is recommended to avoid confusion with the normal fusion prefix from 'pyran' and to simplify rules for naming derivatives (e. g. glycosides).



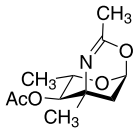
2-Methylamino-4,5-dihydro-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-glucopyranoso)[2,1-*d*]-1,3-oxazole

Note. The alternative name using a substituent prefix (see 2-Carb-35.1) is 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-1-*O*,2-*N*-[(methylamino)methylylidene]-α-D-glucopyranose.



3-Phenyltetrahydro-(1,2-dideoxy-α-D-glucopyranoso)[1,2-*d*]imidazol-2-one

Note. The alternative name using a substituent prefix (see 2-Carb-35.1) is 2-amino-1,2-*N*-carbonyl-1,Z-dideoxy-1-*N*-phenyl-α-D-glucopyranosylamine



2-Methyl-5,6-dihydro-(4-*O*-acetyl-1,2,3,6-tetradeoxy-3-methyl-α-L-*ribo*-hexopyranoso)[3,2,1-de]-4*H*-1,3-oxazine

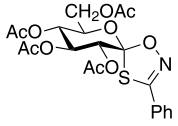
Note 1. The alternative name using a substituent prefix (see 2-Carb-35.1) is 4-*O*-acetyl-3-amino-2,3,6-trideoxy-1-*O*,3-*N*-(ethan-1-yl-1-ylidene)-3-C-methyl-α-L-ribo-hexopyranose

Note 2. This example would not normally be regarded as a fused system for nomenclature purposes, since it is not *ortho*- and *peri*-fused [13].

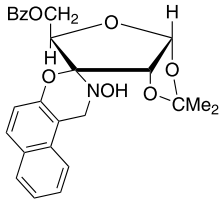
2-Carb-35.3 Spiro Systems

Spiro systems can be named by normal procedures [13]. For clarity, any anhydro or deoxy prefixes or chalcogen replacement prefixes (e. g. thio) referring to the spiro junction should appear next to the carbohydrate stem. The carbohydrate component is cited first. Configuration at the spiro junction is assigned by the *R*, *S* system.

Example:

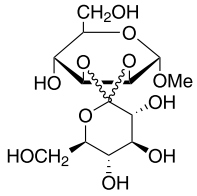


(1*R*)-2,3,4,6-Tetra-*O*-acetyl-3'-phenylspiro[1,5-anhydro-D-glucitol-1,5'-[1,4,2]oxathiazole]



(3*S*)-5-*O*-Benzoyl-1',2'-dihydro-1,2-*O*-isopropylidenespiro[3-deoxy-α-D-*elythro*-pentofuranose-3,3'-naphtho[1,2- e][1,3]oxazin]-2'-ol

The following spiro disaccharide example is best named by use of a *gem*-bivalent substituent prefix:



Methyl 2,3-*O*-D-glucopyranosylidene-α-D-mannopyranoside

Stereochemistry at C-1 of the glucose residue could be indicated as *R* or *S*, e. g. [(1*R*)-2,3-*O*-D-glucopyrano-sylidene]. . .

2-Carb-36 Disaccharides

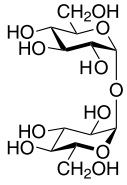
2-Carb-36.1 Definition

A disaccharide is a compound in which two monosaccharide units are joined by a glycosidic linkage.

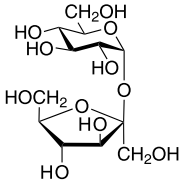
2-Carb-36.2 Disaccharides Without a Free Hemiacetal Group

Disaccharides which can be regarded as formed by reaction of the two glycosidic (anomeric) hydroxy groups with one another are named, systematically, as glycosyl glycosides. The parent (cited as the 'glycoside' component) is chosen according to ❯ *2-Carb-2.1*. Both anomeric descriptors must be included in the name.

Examples:



α-D-Glucopyranosyl α-D-glucopyranoside
[α-D-Glc*p*-(1↔1)-α-D-Glc*p*]
(trivial name α,α-trehalose)

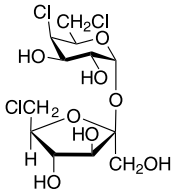


β-D-Fructofuranosyl α-D-glucopyranoside
[β-D-Fru*f*-(2↔1)-α-D-Glc*p*]
not α-D-glucopyranosyl β-D-fructofuranoside
(trivial names sucrose, saccharose)

Note. Such disaccharides are also known as non-reducing disaccharides.

If derivatives are named on the basis of the trivial name, the component cited first in the systematic name receives primed locants.

Example:



4,6,6'-Trichloro-4,6,6'-trideoxygalactosucrose
or 6-chloro-6-deoxy-β-D-fructofuranosyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside
('galactosucrose' is a trivial name for the 4-epimer of sucrose)

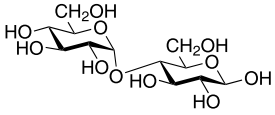
2-Carb-36.3 Disaccharides with a Free Hemiacetal Group

A disaccharide in which one glycosyl unit has replaced the hydrogen atom of an alcoholic hydroxy group of the other is named as a glycosylglycose. The locants of the glycosidic linkage and the anomeric descriptor(s) must be given in the full name.
There are two established methods in use for citing locants: either in parentheses between the glycosyl and glycose terms, or in front of the glycosyl prefix, as in the names of glycosides. The former (preferred) method is derived from that used to designate residues in oligosaccharides (see ❯ *2-Carb-37* and ❯ *2-Carb-38*).

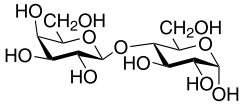
Note. The latter method is that used by Chemical Abstracts Service for disaccharides.

The *O*-locants used for the former method in the previous recommendations [1] are omitted here.

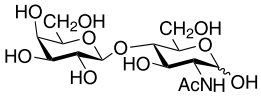
Examples:



α-D-Glucopyranosyl-(1→4)-β-D-glucopyranose
[α-D-Glc*p*-(1→4)-β-D-Glc*p*]
or 4-*O*-α-D-glucopyranosyl-β-D-glucopyrano
(trivial name β-maltose, not β-D-maltose)



β-D-Galactopyranosyl-(1→4)-α-D-glucopyranose
[β-D-Gal*p*-(1→4)-α-D-Glc*p*]
or 4-*O*-β-D-galactopyranosyl-α-D-glucopyranose
(trivial name α-lactose, not α-D-lactose)



β-D-Galactopyranosyl-(1→4)-*N*-acetyl-D-glucosamine (trivial name *N*-acetyllactosamine; LacNAc)

Note. Disaccharides with a free hemiacetal group are also known as reducing disaccharides.

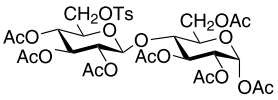
2-Carb-36.4 Trivial Names

Many of the naturally occurring disaccharides have well established trivial names. Some of these are listed below, together with the systematic names in both versions (see above).

Cellobiose β-D-Glucopyranosyl-(1→4)-D-glucose
4-*O*-β-D-Glucopyranosyl-D-glucose
Gentiobiose β-D-Glucopyranosyl-(1→6)-D-glucose
6-*O*-β-D-Glucopyranosyl-D-glucose
Isomaltose α-D-Glucopyranosyl-(1→6)-D-glucose
6-*O*-α-D-Glucopyranosyl-D-glucose
Melibiose α-D-Galactopyranosyl-(1→6)-D-glucose
6-*O*-α-D-Galactopyranosyl-D-glucose
Primeverose β-D-Xylopyranosyl-(1→6)-D-glucose
6-*O*-β-D-Xylopyranosyl-D-glucose
Rutinose α-L-Rhamnopyranosyl-(1→6)-D-glucose
6-*O*-α-L-Rhamnopyranosyl-D-glucose

The systematic names of trehalose, sucrose, maltose and lactose have been given already (with the formulae).
If derivatives are named on the basis of the trivial name, the component cited first in the systematic name receives primed locants.

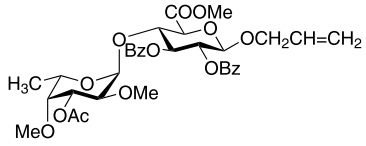
Example:



1,2,2',3,3',4',6-Hepta-*O*-acetyl-6'-*O*-tosyl-α-cellobiose
or 2,3,4-tri-*O*-acetyl-6-*O*-tosyl-β-D-glucopyranosyl-(1→4)-1,2,3,6-tetra-*O*-acetyl-α-D-glucopyranose

If the reducing terminal is a uronic ester glycoside, the ester alkyl group is cited at the beginning of the name, and the aglyconic alkyl group is cited with the name of the glycosidic residue.

Example:



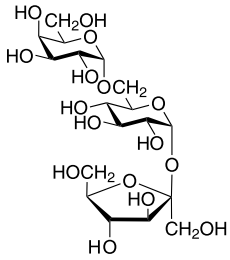
Methyl (3-*O*-acetyl-6-deoxy-2,4-di-*O*-methyl-α-L-galactopyranosyl)-(1→4)-(allyl 2,3-di-*O*-benzoyl-β-D-glucopyranosid)uronate

2-Carb-37 Higher Oligosaccharides

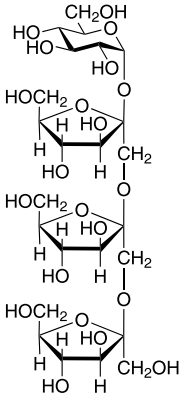
2-Carb-37.1 Oligosaccharides Without a Free Hemiacetal Group

Trisaccharides (for example) are named as glycosylglycosyl glycosides or glycosyl glycosy lglycosides as appropriate. A choice between the two residues linked through their anomeric positions for citation as the 'glycoside' portion can be made on the basis of ❯ *2-Carb-2.1*. Alternatively, a sequential (end-to-end) naming approach may be used, regardless of ❯ *2-Carb-2.1*. The names are formed by the preferred method of naming disaccharides (see ❯ *2-Carb-36.3*): the locant of the anomeric carbon atom, an arrow, and the locant of the connecting oxygen of the next monosaccharide unit are set in parentheses between the names of the residues concerned.

Examples:



β-D-Fructofuranosyl α-D-galactopyranosyl-(1→6)-α-D-glucopyranoside
(glucose preferred to fructose for citation as 'glycoside')
or α-D-galactopyranosyl-(1→6)-α-D-glucopyranosyl β-D-fructofuranoside
(sequential method)
[α-D-Gal*p*-(1→6)-α-D-Glc*p*-(1↔2)β-D-Fru*f*]
(trivial name raffinose)



β-D-Fructofuranosyl-(2→1)-β-D-fructofuranosyl-(2→1)-β-D-fructofuranosyl α-D-glucopyranoside
[β-D-Fru*f*-(2→1)-β-D-Fru*f*-(2→1)-β-D-Fru*f*-(2↔1) α-D-Glc*p*] (trivial name nystose)

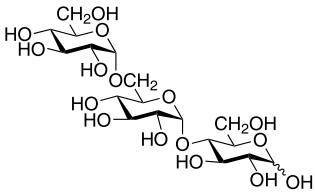
If derivatives are to be named on the basis of the trivial name, the component cited last in the systematic name receives locants with no primes, the preceding component singly-primed

locants, etc. However, naming of trisaccharide and higher oligosaccharide derivatives systematically is preferred, to avoid ambiguity.

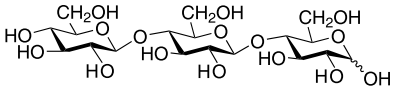
2-Carb-37.2 Oligosaccharides with a Free Hemiacetal Group

An oligosaccharide of this class is named as a glycosyl[glycosyl]$_n$glycose, i. e. the reducing sugar is the parent. Anomeric descriptors and locants are given as described in 2-Carb-37.1. The conventional depiction has the reducing sugar (glycose residue) on the right and the non-reducing end (glycosyl group) on the left. Internal sugar units are called glycosyl residues (the term 'anhydrosugar unit' is misleading and its use is discouraged). As the reducing end is often converted into the corresponding alditol, aldonic acid or glycoside derivative, the more general term 'downstream end' has been proposed for this end of the molecule.

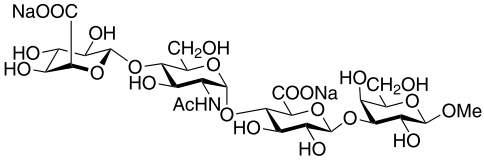
Examples:



α-D-Glucopyranosyl-(1→6)-α-D-glucopyranosyl-(1→4)-D-glucopyranose (trivial name panose)



β-D-Glucopyranosyl-(1→4)-β-D-glucopyranosyl-(1→4)-D-glucopyranose (trivial name cellotriose)

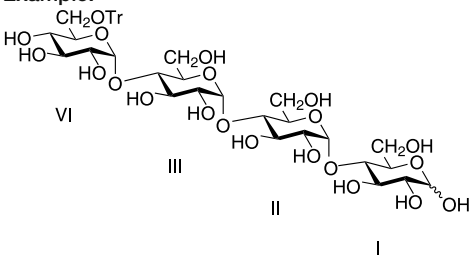


Methyl (sodium α-L-idopyranosyluronate)-(1→4)-(2-acetamido-2-deoxy-α-D-glucopyranosyl)-(1→4)-(sodium β-D-glucopyranosyluronate)-(1→3)-β-D-galactopyranoside
{Na_2[α-L-Ido*p*A-(1→4)-α-D-Glc*p*NAc-(1→4)-β-D-Glc*p*A-(1→3)-β-D-Gal*p*OMe]}

Higher oligosaccharides are named systematically in the same way. However, it is often preferable to give their structures by use of the symbolic approach outlined in 2-Carb-38.
Trivial names for linear oligosaccharides consisting only of 1→4 linked α-D-glucopyranosyl residues are maltotriose, maltotetraose etc. Similar names, based on the component sugar, are convenient for referring to other homo-oligosaccharides (e. g. xylobiose, galactotetraose), but such names should be used sparingly. Locants for naming substituted derivatives may be

obtained by assigning roman numerals to the residues in ascending order starting from the reducing end.

Example:



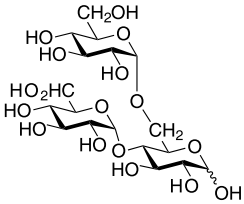
6^{VI}-*O*-Tritylmaltotetraose

Arabic numerals have also been used in this context, but confusion may result when component sugar residues have structural modifications (e. g. chain branches) requiring superscript locant numbers. The present recommendation follows long-established usage in glycolipids [21].

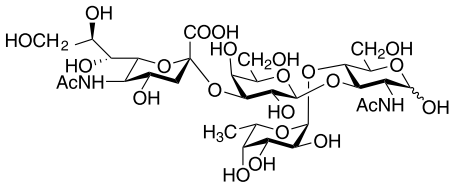
2-Carb-37.3 Branched Oligosaccharides

Terms designating branches should be enclosed in square brackets. In a branched chain, the longest chain is regarded as the parent. If two chains are of equal length the one with lower locants at the branch point is preferred, although some oligosaccharides are traditionally depicted otherwise, such as the blood group A trisaccharide exemplified below.

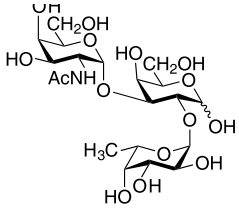
Examples:



α-D-Glucopyranosyl-(1→4)-[α-D-glucopyranosyl-(1→6)]-D-glucopyranose
[or 4,6-di-*O*-(α-D-glucopyranosyl)-D-glucopyranose]
(trivial name isopanose)



(5-Acetamido-3,5-dideoxy-D-*glycero*-α-D-*galacto*-non-2-ulopyranosylonic acid)-(2→3)-β-D-galactopyranosyl-(1→3)-[α-L-fucopyranosyl-(1→4)]-2-acetamido-2-deoxy-D-glucopyranose
or 5-*N*-acetyl-α-neuraminyl-(2→3)-β-D-galactopyranosyl-(1→3)-[α-L-fucopyranosyl-(1→4)]-2-acetamido-2-deoxy-D-glucopyranose
{α-Neu*p*5Ac-(2→3)-β-D-Gal*p*(1→3)-[α-L-Fuc*p*(1→4)]-D-Glc*p*NAc} (sialyl-Le^a trisaccharide)



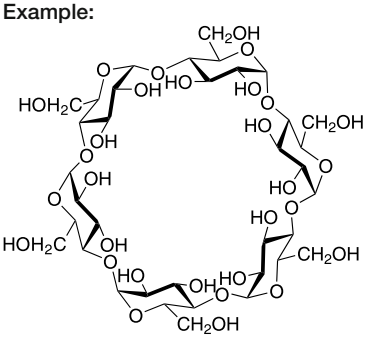
2-Acetamido-2-deoxy-α-D-galactopyranosyl-(1→3)-[α-L-fucopyranosyl-(1→2)]-D-galactopyranose
{α-D-Gal*p*NAc-(1→3)-[α-L-Fuc*p*(1→2)]-o-Gal*p*} (blood group A trisaccharide)

2-Carb-37.4 Cyclic Oligosaccharides

37.4.1 Semisystematic Names

Cyclic oligosaccharides composed of a single type of oligosaccharide unit may be named semisystematically by citing the prefix 'cyclo', followed by terms indicating the type of linkage [e. g. 'malto' for α-(1→4)-linked glucose units], the number of units (e. g. 'hexa' for six) and the termination '-ose'. The trivial names α-cyclodextrin (α-CD) for cyclomaltohexaose, β-cyclodextrin (β-CD) for cyclomaltoheptaose and γ-cyclodextrin (γ-CD) for cyclomaltooctaose are well established.

Example:



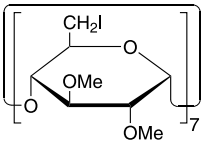
Cyclomaltohexaose (α-cyclodextrin, α-CD)

Structures with linkages other than (1→4) should be named systematically (see ❯ *2-Carb-37.4.2*).

Note. The cyclic oligosaccharides arising from enzymic transglycosylation of starch have been referred to as Schardinger dextrins. These names (and those of the cyclohexaamylose type) are not recommended, but the abbreviation CD is tolerated.

Derivatives with the same substitution pattern on each residue can be named semisystematically by assigning a single multiplicative prefix (e. g. hexakis, heptakis etc.) to the substituent prefixes as a group.

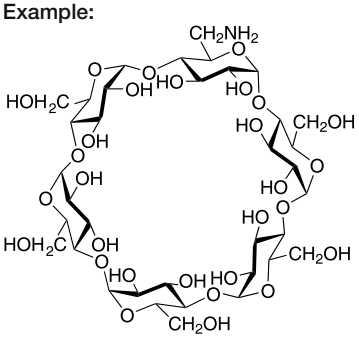
Example:



Heptakis(6-deoxy-6-iodo-2,3-di-*O*-methyl)cyclomaltoheptaose

Derivatives with different substitution patterns on the various residues can be named by the method of ❯ *2-Carb-37.2*, assigning a roman numeral to each residue.

Example:

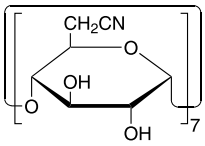


6'-Amino-6'-deoxycyclomaltohexaose

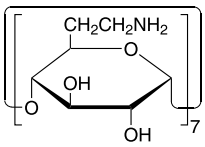
37.4.2 Systematic Names

Cyclic oligosaccharides composed of a single type of residue can be named by giving the systematic name of the glycosyl residue, preceded by the linkage type in parentheses, preceded in turn by 'cyclo-' with a multiplicative suffix (i. e. 'cyclohexakis-' etc.)

Examples:



Cycloheptakis-(1→4)-(6-deoxy-α-D-*gluco*-heptopyranosylurononitrile)



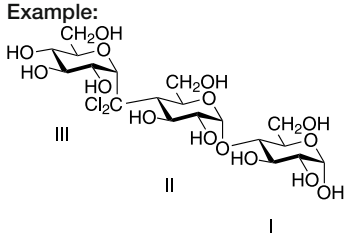
Cycloheptakis-(1→4)-(7-amino-6,7-dideoxy-α-D-*gluco*-heptopyranosyl)

The 1→6 isomer of cyclomaltohexaose should be named cyclohexakis-(1→6)-α-D-glucosyl, rather than cycloisomaltohexaose.

2-Carb-37.5 Oligosaccharide Analogues

Structures in which the linking glycosidic oxygen is replaced by -CH_2- may be named by use of the replacement prefix 'carba-' (cf. ❯ *2-Carb-34.2*) for emphasis of homomorphic relationships. The oxygen replaced is given the locant of the carbon atom to which it is attached in the residue with the lower roman numeral (cited as superscript) (ct ❯ *2-Carb-37.2*), with suffix 'a'.

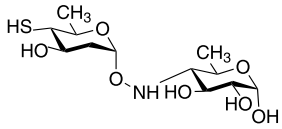
Example:



4'''a,4''a-Dichloro-4''a-carba-α-maltotriose

If the glycosidic oxygen link is replaced by -O-NH-, normal amino sugar nomenclature can be employed.

Example:



4-(2,6-Dideoxy-4-thio-α-D-*arabino*-hexopyranosyloxyamino)-4,6-dideoxy-α-D-glucopyranose

2-Carb-38 Use of Symbols for Defining Oligosaccharide Structures[4]

2-Carb-38.1 General Considerations

Oligosaccharide and polysaccharide structures occur not only in free form but often as parts of glycopeptides or glycoproteins [11] or of glycolipids [21]. It can be cumbersome to designate their structures by using the recommendations of ❯ *2-Carb-37*. The use of three-letter symbols for monosaccharide residues is therefore recommended. With appropriate locants and anomeric descriptors, long sequences can thus be adequately described in abbreviated form. Symbols for the common monosaccharide residues and derivatives are listed in ❯ *Table 2*. They are generally derived from the corresponding trivial names. Abbreviations for sub-

[4]The recommendations presented here are a modified version of the published 1980 recommendations [6]

Table 2
Symbols for monosaccharide residues and derivatives in oligosaccharide chains

Abequose	Abe	Iduronic acid	IdoA
Allose	All	Lyxose	Lyx
Altrose	Alt	Mannose	Man
Apiose	Api	Muramic acid	Mur
Arabinose	Ara	Neuraminic acid	Neu
Arabinitol	Ara-ol	*N*-Acetylneuraminic acid	Neu5Ac
2-Deoxyribose	dRib	*N*-Acetyl-2-deoxyneur-2-enaminicacid	Neu2en5Ac
Fructose	Fru	*N*-Glycoloylneuraminic acid	Neu5Gc
Fucose	Fuc	3-Deoxy-D-*manno*-oct-2-ulosonic acid	Kdo
Fucitol	Fuc-ol	Rhamnose	Rha
Galactose	Gal	3,4-Di-*O*-methylrhamnose	Rha3,4Mez
Galactosamine	GalN	Psicose	Psi
N-Acetylgalactosamine	GalNAc	Quinovose	Qui
β-D-GalaCtOpyranOSe 4-sulfate	β-D-Gal*p*4S	Ribose	Rib
Glucose	Glc	Ribose 5-phosphate	Rib5*P*
Glucosamine	GlcN	Ribulose	Ribulo (or Rul)
2,3-Diamino-2,3-dideoxy-D-glucose	GlcN3N	Sorbose	Sor
Glucitol	Glc-ol	Tagatose	Tag
N-Acetylglucosamine	GlcNAc	Talose	Tal
Glucuronic acid	GlcA	Xylose	Xyl
Ethyl glucopyranuronate	Glc*p*A6Et	Xylulose	Xylulo (or Xul)
Gulose	Gul	2-CMethylxylose	Xyl2*C*Me
Idose	Ido		

stituents (see 2-Carb-1.16.2), preceded by locants, follow the monosaccharide abbreviations directly.

2-Carb-38.2 Representations of Sugar Chains

For writing the structure of an oligo- or poly-saccharide chain, the glycose residue [the 'reducing group', i. e. the residue with the free hemiacetal group or modification thereof (e. g. alditol, aldonic acid, glycoside)] should be at the right-hand end. Also, when there is a glycosyl linkage to a non-carbohydrate moiety (e. g. protein, peptide or lipid) the glycosyl residue involved should appear at the right.
Numbering of monosaccharide units, if desired, should proceed from right to left.

2-Carb-38.3 The Extended Form

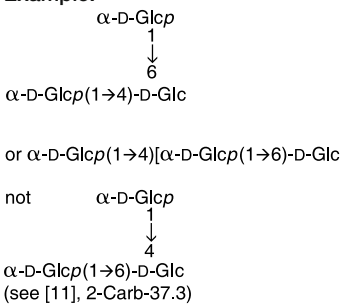
This is the form employed by the carbohydrate databank CarbBank, and is preferred for most purposes. Each symbol for a monosaccharide unit is preceded by the anomeric descriptor and

the configuration symbol. The ring size is indicated by an italic *f* for furanose or *p* for pyranose, etc. The locants of the linkage are given in parentheses between the symbols; a double-headed arrow indicates a linkage between two anomeric positions. In CarbBank, omission of α/β, D/L, or *f*/*p* means that this structural detail is not known.

Examples:
α-D-Gal*p*-(1→6)-α-D-Glc*p*-(1↔2)-β-D-Fruf for raffinose (see 2-Carb-37.1)
β-D-Glc*p*-(1→4)-β-D-Glc*p*-(1→4)-D-Glc for cellotriose (see 2-Carb-37.2)

Branches are written on a second line, or in brackets on the same line.

Example:



or α-D-Glc*p*(1→4)[α-D-Glc*p*(1→6)-D-Glc

(see [11], 2-Carb-37.3)

for 4,6-Di-*O*-α-D-glucopyranosyl-D-glucose

The hyphens may be omitted, except that separating the configurational symbol and the three-letter symbol for the monosaccharide.

2-Carb-38.4 The Condensed Form

In the condensed form, the configurational symbol and the letter denoting ring size are omitted. It is understood that the configuration is D (with the exception of fucose and iduronic acid which are usually L) and that the rings are in pyranose form unless otherwise specified. The anomeric descriptor is written in the parentheses with the locants.

Example:
Gal(α1-6)Glc(α1-2β)Fruf for raffinose

For most purposes, the short form (2-Carb-38.5) is preferred when abbreviation of the extended form is desirable.

2-Carb-38.5 The Short Form

For longer sequences, it is desirable to shorten the notation even further by omitting (i) locants of anomeric carbon atoms, (ii) the parentheses around the locants of the linkage and (iii) hyphens (if desired). Branches can be indicated on the same line by using appropriate enclosing marks (parentheses, square brackets etc.). Whenever necessary, configuration symbols and ring size designators etc. may be included, to make the notation more specific.

Example:
Galα-6Glcα-βFruf or Galα6Glcαβ*F*ruf for raffinose

The following examples show all three representations of the same structure:

a

extended form

β-D-Gal*p*-(1→4)-β-D-Glc*p*NAc-(1→2)-α-D-Man*p*-(1→
3
↑
1
α-L-Fuc*p*

b

condensed form in two lines

Gal(β1-4)GlcNAc(β1-2)Man(α1-
|
Fuc(α1-3)

or in one line

Gal(β1-4)[Fuc(α1-3)]GlcNAc(β1-2)Man(α1-

c

short form

Galβ-4(Fucα-3)GlcNAcβ-2Manα-
or Galβ4(Fucα3)GlcNAcβ2Manα-
or Galβ4GlcNAcβ2Manα-
|
Fucα-3

This last version is recommended as the most explicit representation of branching using the short form.

Note. These representations do not follow the recommendat ions for choice of main chain given in 2-Carb-37.3. Such deviations are common in depicting series of naturally occurring oligosaccharides where it is desirable to show homomorphic relationships.

2-Carb-39 Polysaccharides[5]

2-Carb-39.1 Names for Homopolysaccharides

A general term for a polysaccharide (glycan) composed of a single type of monosaccharide residue is obtained by replacing the ending '-ose' of the sugar name by '-an'.

Note. Examples of established usage of the '-an' ending are: xylan for polymers of xylose, mannan for polymers of mannose, and galactan for polymers of galactose. Cellulose and starch are both glucans, as they are composed of glucose residues.

2-Carb-39.2 Designation of Configuration of Residues

When the configurational series of the monomer residues is known, D- or L- may be included as a prefix to the name.

[5] This is a modified version of the 1980 recommendations on polysaccharide nomenclature [7]

Examples:

[4)-α-D-Glc*p*-(1→3)-α-D-Glc*p*-(1→]$_n$

A D-glucan (nigeran)

[5)-α-L-Ara*f*-(1→5)-α-L-Ara*f*-(1→5)-α-L-Ara*f*-(1→5)-α-L-Ara*f*-(1→]$_n$

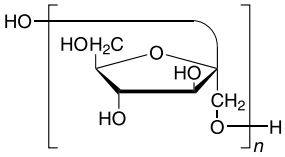
3 3
↑ ↑
1 1
α-L-Ara*f* α-L-Ara*f*

An L-arabinan (more specifically an α-L-arabinan)

2-Carb-39.3 Designation of Linkage

When the major linkage in a homopolysaccharide is known, it may be indicated in the name. The linkage designation shows the carbon atoms involved in the glycosidic bonds. When specific sugars are designated, notation for glycosidic linkages should precede the symbols designating the configuration of the sugar; thus, (1→4)-α-D-glucan.

Examples:

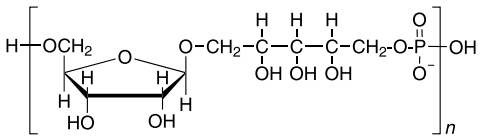


(2→1)-β-D-Fructofuranan (inulin has this structure, with a terminal α-D-glucopyranosyl group)

[4)-α-D-Glc*p*-(1→]$_n$

(1→4)-α-D-Glucopyranan (amylose)

Note. When the linkage between monosaccharide units is non-glycosidic (as in the phosphate derivative shown below), use of the glycan terminology is inappropriate; other methods of polymer nomenclature should be employed [20].



Poly[(β-D-ribofuranosyl-5-*O*-yl)(1-deoxy-D-ribitol-1-*C*,5-*O*-diyl)(oxidophosphoryl)]

[5)-β-D-Rib*f*-(1→1)-D-Rib-ol-5-*P*-(O→]$_n$

Such structures do not conform to the original strict definition of 'polysaccharide' but are generally classified as polysaccharides in current practice.

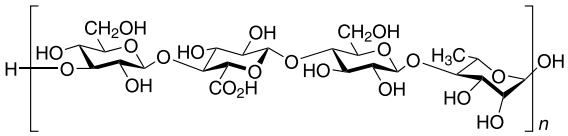
2-Carb-39.4 Naming of Newly Discovered Polysaccharides

Names assigned to newly discovered polysaccharides should end in '-an'.

Examples:

[6)-β-D-Glc*p*-(1→]$_n$

Pustulan (a glucan from the lichen *Umbilicaria pustulata*)



[3)-β-D-Glc*p*-(1→4)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→4)-α-L-Rha*p*(1→]$_n$

Gellan (a bacterial polysaccharide originally designated S-60)

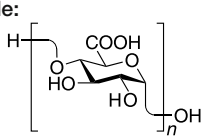
Note. The name ending in '-an' refers to the unsubstituted polysaccharide. Thus xylan occurs in nature in unacetylated and partially acetylated forms. Xylan designates the unacetylated material, and xylan acetate an acetylated derivative.

Well established names such as cellulose, starch, inulin, chitin, amylose and amylopectin are retained. 'Carrageenan' and 'laminaran' are now often used rather than the older names ending in '-in'.

2-Carb-39.5 Uronic Acid Derivatives

A polysaccharide (glycan) composed entirely of glycuronic acid residues is named by replacing '-ic acid' by '-an'. The generic name for this group of polysaccharides is 'glycuronan'.

Example:



(1→4)-α-D-galacturonan (pectin component)

Note. The term glycuronan is used instead of 'polyuronide'; the latter term is incorrect.

2-Carb-39.6 Amino Sugar Derivatives

A polysaccharide composed entirely of amino sugar residues is named by appropriate modification of the systematic amino sugar name.

Example:

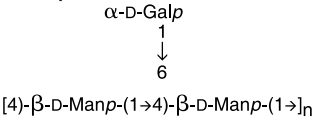
[4)-β-D-Glc*p*-NAc(1→]$_n$

(1→4)-2-acetamido-2-deoxy-β-D-glucan (chitin)

2-Carb-39.7 Polysaccharides Composed of more than one Kind of Residue

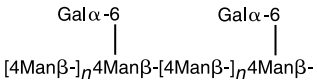
A heteropolysaccharide (heteroglycan) is a polymer containing two or more kinds of sugar (glycose) or modified sugar (e. g. aminodeoxyglycose or glycuronic acid) residue. When the polysaccharide has a principal chain ('backbone') composed of only one type of sugar residue, this residue should be cited last (as a 'glycan' term), and the other types of residue cited as 'glyco-' prefixes in alphabetical order. However, when no single type of sugar residue constitutes the principal chain, all sugar residues should be cited alphabetically as 'glyco-' prefixes, and the name should terminate with the suffix '-glycan'.

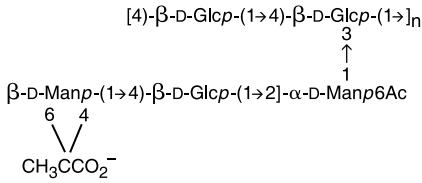
Examples:



A D-galacto-D-mannan (guaran)

Note. A less branched D-galacto-D-mannan could be shown in the short form as:



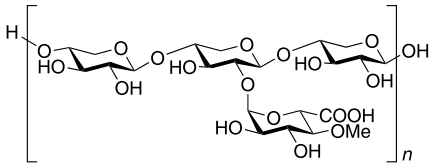


Xanthan

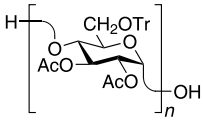
2-Carb-39.8 Substituted Residues

When substitution occurs in a polysaccharide (glycan), each type of substitutent is cited in the name at an appropriate position (in alphabetical order).

Examples:



(4-*O*-Methyl-α-D-glucurono)-D-xylan



2,3-Di-*O*-acetyl-6-*O*-tritylamylose

[4)-β-D-Glc*p*A-(1→3) -β-D-Glc*p*NAc-(1→]n

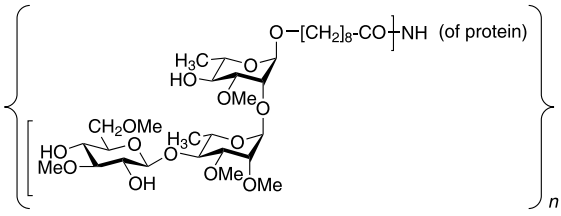
(2-Acetarnido-2-deoxy-D-gluco)-D-glucuronoglycan (hyaluronic acid or hyaluronan)

2-Carb-39.9 Glycoproteins, Glycopeptides and Peptidoglycans

Polymers containing covalently bound monosaccharide and amino-acid residues are termed glycoproteins, glycopeptides or peptidoglycans. It is not possible to give precise distinctions between these terms. In general, glycoproteins are conjugated proteins containing either oligosaccharide groups or polysaccharide groups having a fairly low relative molecular mass. Proteoglycans are proteins linked to polysaccharides of high molecular mass. Peptidoglycans consist of polysaccharide chains covalently linked to peptide chains. The nomenclature of these compounds is discussed in [11].

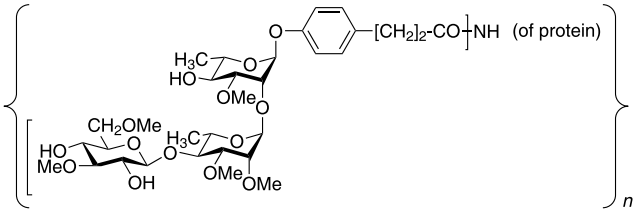
Synthetically produced or modified carbohydrate-protein conjugates are sometimes referred to as neoglycoproteins. The nomenclature for the carbohydrate-containing substituents in such structures is analogous to sequential oligosaccharide nomenclature (*2-Carb-37.2*)

Examples:



Poly-[(3,6-Di-*O*-methyl-β-D-glucopyranosyl)-(1→4)-(2,3-di-*O*-methyl-α-L-rhamnopyranosyl)-(1→2)-(3-*O*-methyl-α-L-rhamnopyranosyloxy)-(1-*O*→9)-nonanoyl-(1→N]-protein

{[β-D-Glc*p*3,6Me$_2$-(1→4) α-L-Rha*p*2,3Me$_2$-(1→2)-α-L-Rha*p*3Me-(1-*O*→9)-nonanoyl-(1→N]$_n$-protein}



Poly-[(3,6-Di-*O*-methyl-β-D-glucopyranosyl)-(1→4)-(2,3-di-*O*-methyl-α-L-rhamnopyranosyl)-(1→2)-(3-*O*-methyl-α-L-rhamnopyranosyloxy)-(1-*O*→4′)-(3-phenylpropanoyl)-(1→N^{Lys}]-protein

Appendix

Trivial Names for Carbohydrates and Derivatives with Their Systematic Equivalents and Symbols (Non-limiting List)

(a) Parent Monosaccharides

Glycerone (1,3-dihydroxyacetone)	1,3-Dihydroxypropanone
Gulose (Gul)	*gulo*-Hexose
Idose (Ido)	*ido*-Hexose
Lyxose (Lyx)	*lyxo*-Pentose
Mannosamine (ManN)	2-Amino-2-deoxymannose
Mannose (Man)	*manno*-Hexose
Psicose (Psi)	*ribo*-Hex-2-ulose

Quinovose (Qui)	6-Deoxyglucose
Quinovosamine	2-Amino-2,6-dideoxyglucose
Rhamnitol (Rha-ol)	1-Deoxymannitol
Rhamnosamine (RhaN)	2-Amino-2,6-dideoxymannose
Rhamnose (Rha)	6-Deoxymannose
Ribose (Rib)	*ribo*-Pentose
Ribulose (Rul)	*erythro*-Pent-2-ulose
Sorbose (Sor)	*xylo*-Hex-2-ulose
Tagatose (Tag)	*lyxo*-Hex-2-ulose
Talose (Tal)	*talo*-Hexose
Tartaric acid	Erythraric/Threaric acid
Threose	*threo*-Tetrose
Xylose (Xyl)	*xylc*-Pentose
Xylulose (Xul)	*threo*-Pent-2-ulose

(b) Common Trivial Names

Abequose (Abe)	3,6-Dideoxy-D-*xylo*-hexose
Amicetose	2,3,6-Trideoxy-D-*erythro*-hexose
Amylose	(1→4)-α-D-Glucopyranan
Apiose (Api)	3-*C*(Hydroxymethyl)-*glycero*-tetrose
Arcanose	2,6-Dideoxy-3-*C*-methyl-3-*O*-methyl-*xylo*-hexose
Ascarylose	3,6-Dideoxy-L-*arabino*-hexose
Ascorbic acid	L-*threo*-Hex-2-enono-1,4-lactone
Boivinose	2,6-Dideoxy-D-gulose
Cellobiose	β-D-Glucopyranosyl-(1→4)-D-glucose
Cellotriose	β-D-Glucopyranosyl-(1→4)-β-D-glucopyranosyl-(1→4)-D-glucose
Chacotnose	α-L-Rhamnopyranosyl-(1→2)-[α-L-rhamnopyranosyl-(1→4)]-D-glucose
Chalcose	4,6-Dideoxy-3-*O*-methyl-D-*xylo*-hexose
Cladinose	2,6-Dideoxy-3-*C*-methyl-3-*O*-methyl-L-*ribo*-hexose
Colitose	3,6-Dideoxy-L-*xylo*-hexose
Cymarose	6-Deoxy-3-*O*-methyl-*ribo*-hexose
2-Deoxyribose (dRib)	2-Deoxy-*erythro*-pentose
2-Deoxyglucose (2dGlc)	2-Deoxy-*arabino*-hexose
Diginose	2,6-Dideoxy-3-*O*-methyl-*lyxo*-hexose
Digitalose	6-Deoxy-3-*O*-methyl-D-galactose
Digitoxose	2,6-Dideoxy-D-*ribo*-hexose
Evalose	6-Deoxy-3-*C*-methyl-D-mannose
Evernitrose	2,3,6-Trideoxy-3-*C*-methyl-4-*O*-methyl-3-nitro-L-*arabino*-hexose
Gentianose	β-D-Fructofuranosyl β-D-gIucopyranosyl-(1→6)-α-D-glucopyranoside
Gentiobiose	β-D-Glucopyranosyl-(1→6)-D-glucose

Hamamelose 2-*C*-(Hydroxymethyl)-D-ribose
Inulin (2→1)-β-D-Fructofuranan
Isolevoglucosenone 1,6-Anhydro-2,3-dideoxy-β-D-*glycero*-hex-2-enopyranos-4-ulose
Isomaltose α-D-Glucopyranosyl-(1→6)-D-glucose
Isomaltotriose α-D-Glucopyranosyl-(1→6)-α-D-glucopyranosyl-(1→6)-D-glucose
Isopanose α-D-Glucopyranosyl-(1→4)-[α-D-glucopyranosyl-(1→6)]D-glucose
Kojibiose α-D-Glucopyranosyl-(1→2)-D-glucose
Lactose (Lac) β-D-Galactopyranosyl-(1→4)-D-glucose
Lactosamine (LacN) β-D-Galactopyranosyl-(1→4)-D-glucosamine
Lactosediamine (LacdiN) 2-Amino-2-deoxy-β-D-galactopyranosyl-(1→4)-D-glucosamine
Laminarabiose β-D-Glucopyranosyl-(1→3)-D-glucose
Levoglucosan 1,6-Anhydro-β-D-glucopyranose
Levoglucosenone 1,6-Anhydro-3,4-dideoxy-β-D-*glycero*-hex-3-enopyranos-2-ulose
Maltose α-D-Glucopyranosyl-(1→4)-D-glucose
Manninotriose α-D-Galactopyranosyl-(1→6)-α-D-galactopyranosyl-(1→6)-D-glucose
Melezitose α-D-Glucopyranosyl-(1→3)-β-D-fructofuranosyl α-D-glucopyranoside
Melibiose α-D-Galactopyranosyl-(1→6)-D-glucose
Muramic acid (Mur) 2-Amino-3-*O*-[(*R*)-1-carboxyethyl]-2-deoxy-D-glucose
Mycarose 2,6-Dideoxy-3-*C*-methyl-L-*ribo*-hexose
Mycinose 6-Deoxy-2,3-di-*O*-methyl-D-allose
Neuraminic acid (Neu) 5-Amino-3,5-dideoxy-D-*glycero*-D-*galacto*-non-2-ulosonic acid
Nigerose α-D-Glucopyranosyl-(1→3)-D-glucose
Nojirimycin 5-Amino-5-deoxy-D-glucopyranose
Noviose 6-Deoxy-5-*C*-methyl-4-*O*-methyl-L-*lyxo*-hexose
Oleandrose 2,6-Dideoxy-3-*O*-methyl-L-*arabino*-hexose
Panose α-D-Glucopyranosyl-(1→6)-α-D-glucopyranosyl-(1→4)-D-glucose
Paratose 3,6-Dideoxy-D-*ribo*-hexose
Planteose α-D-Galactopyranosyl-(1→6)-β-D-fructofuranosyl α-D-glucopyranoside
Primeverose β-D-Xylopyranosyl-(1→6)-D-glucose
Raffinose β-D-Fructofuranosyl α-D-galactopyranosyl-(1→6)-α-D-glucopyranoside
Rhodinose 2,3,6-Trideoxy-L-*threo*-hexose
Rutinose α-L-Rharnnopyranosyl-(1→6)-D-glucose
Sarmentose 2,6-Dideoxy-3-*O*-methyl-D-*xylo*-hexose
Sedoheptulose D-*altro*-Hept-2-ulose
Sedoheptulosan 2,7-Anhydro-β-D-*altro*-hept-2-ulopyranose
Solatriose α-L-Rhamnopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-D-galactose
Sophorose β-D-Glucopyranosyl-(1→2)-D-glucose

Stachyose	β-D-Fructofuranosyl α-D-galactopyranosyI-(1→6)-α-D-galactopyranosyl-(1→6)-α-D-glucopyranoside
Streptose	5-Deoxy-3-*C*-formyl-L-lyxose
Sucrose (saccharose)	β-D-Fructofuranosyl α-D-glucopyranoside
α,α-Trehalose	α-D-Glucopyranosyl α-D-glucopyranoside
Trehalosamine	2-Amino-2-deoxy-α-D-glucopyranosyl α-D-glucopyranoside
Turanose	α-D-GIucopyranosyl-(1→3)-D-fructose
Tyvelose (Tyv)	3,6-Dideoxy-D-*arabino*-hexose
Umbelliferose	β-D-Fructofuranosyl α-D-galactopyranosyl-(1→2)-α-D-galactopyranoside

(c) Trivial Names Formed by Modification of Non-standard Monosaccharide Parent Names

Acosamine	3-Amino-2,3,6-trideoxy-L-*xylo*-hexose
Bacillosamine	2,4-Diamino-2,4,6-trideoxy-D-glucose
Daunosamine	3-Amino-2,3,6-trideoxy-L-*lyxo*-hexose
Desosamine	3,4,6-Trideoxy-3-dimethylamino-D-*xylo*-hexose
Forosamine	2,3,4,6-Tetradeoxy-4-dimethylamino-D-*erythro*-hexose
Garosamine	3-Deoxy-4-*C*-methyl-3-methylamino-L-arabinose
Kanosamine	3-Amino-3-deoxy-D-glucose
Kansosamine	4,6-Dideoxy-3-*C*-methyl-2-D-methyl-L-mannose
Mycaminose	3,6-Dideoxy-3-dimethylamino-D-glucose
Mycosamine	3-Amino-3,6-dideoxy-D-mannose
Perosamine	4-Amino-4,6-dideoxy-D-mannose
Pneumosamine	2-Amino-2,6-dideoxy-D-talose
Purpurosamine C	2,6-Diamino-2,3,4,6-tetradeoxy-D-*erythro*-hexose
Rhodosamine	2,3,6-Trideoxy-3-dimethylamino-*lyxo*-hexose

Glossary of Glycose-Based Terms; Standard Forms [Common Biochemical Usage]

	Class	Amino sugar[a] {usually asacetamido (*N*-acetyl) derivative}	Uronic acid[b] *Uronate*	Ulosonic acid *Ulosonate*	The sialic acid family[b]
	Glycose	Aminodeoxy-glycose [Glycosamine]	Glycuronic acid *Glycuronate*	Glyculosonic acid *Glyculosonate* [Ketoglyconic acid]	Neuraminic acid Sialic acid
	Glycosyl	Aminodeoxy-glycosyl [Glycosaminyl]	Glycosyluronic acid *Glycosy-luronate* [Glycurono-syl]	Glyculosylonic acid *Glyculosylonate*	[Neuraminosyl][c] [Sialosyl][c]
	Glycoside	Aminodeoxy-glycoside [Glycosaminide]	Glycosiduronic acid *Gly-cosiduronate* [Glycuronide]	Glyculosidonic acid *Glyculosidonate*	[Neuraminoside] [Sialoside]
	Glycosidase (Glycoside hydrolase)	Aminodeoxy-glycosidase [Gly-cosaminidase]	Gly cosiduronase [Gly-curonidase]	Glyculosidonase	[Neuraminidase] [Sialidase]
	Glycosyl-trans-ferase	Aminodeoxy-glycosyltrans-ferase [Glycosaminyl-transferase]	Glycosylurona-tetransferas [Glycurono-syltrans-ferase]	Glyculosylonate-transferase	[Neuraminosyl-transferase] [Sialosyltrans-ferase]

[a]The biochemical usage is widely established in the literature. [b]The biochemical usage implies the parents 'glycuronose', 'sialose', and 'neuraminose'. [c]'Neuraminyl' and 'sialyl' have been used, but are likely to be interpreted as referring to acyl groups; the terms given are more consistent with the terms used for glycosides
