**Abstract.** The evaluation of classifier performance in a cost-sensitive setting is straightforward if the operating conditions (misclassification costs and class distributions) are fixed and known. When this is not the case, evaluation requires a method of visualizing classifier performance across the full range of possible operating conditions. This talk outlines the most important requirements for [c](#page-3-0)ost-sensitive classifier evaluation for machine learning and KDD researchers and practitioners, and introduces a recently developed technique for classifier performance visualization – the cost curve – that meets all these requirements.

## **1 Introduction**

Methods for creating accur[ate](#page-0-0) classifiers from data are of central interest to the data mining community [2,15,16]. The focus of this talk is on binary classification, *i.e.* classification tasks in which there are only two possible classes, which we will call *positive* and *negative*. In binary classification, there are just two types of error a classifier can make: a *false positive* is a negative example that is incorrectly classified as positive, and a *false negative* is a positive example that is incorrectly classified as negative. In general, the [cos](#page-3-1)[t o](#page-3-2)f making one type of mis[cla](#page-3-3)ssification will [be](#page-3-4) different—possibly very different—than the [co](#page-2-0)st of making [the](#page-2-1) other type.<sup>1</sup>

Methods for evaluating the performa[nc](#page-3-5)[e of](#page-3-6) classifiers fall into two broad categories: numerical and graphical. Numerical evaluations produce a single number summarizing a classifier's performance, whereas graphical methods depict performance in a plot that typically has just two or three dimensions so that it can be easily inspected by humans. Examples of numerical performance measures are accuracy, expected cost, precision, recall, and area under a performance curve (AUC). Examples of graphical performance evaluations are ROC curves [18,19], precision-recall curve[s \[6](#page-3-7)], DET curves [17], regret graphs [13], loss difference plots [1], skill plots [4], prevalence-value-accuracy plots [21], and the method presented in this talk, cost curves [7,11].

<span id="page-0-0"></span>Graphical methods are [espe](#page-3-8)cially useful when there is uncertainty about the misclassification costs or the class distribution that will occur when the classifier is deployed. In this setting, graphical measures can present a classifier's actual performance for a wide variety of different operating points (combinations of costs and class distributions),

We assume the misclassification cost is the same for all instances of a given class; see [12] for a discussion of performance evaluation when the cost can be different for each instance.

whereas the best a numerical measure can do is to represent the average performance across a set of operating points.

Cost curves are perhaps the ideal graphical method in this setting because they directly show performance as a function of the misclassification costs and class distribution. In particular, the x-axis and y-axis of a cost curve plot are defined as follows.

The x-axis of a cost curve plot is defined by combining the two misclassification costs and the class distribution—represented by  $p(+)$ , the probability that a given instance is positive—into a single value,  $PC(+)$ , using the following formula:

$$
PC(+) = \frac{p(+)C(-|+)}{p(+)C(-|+) + (1 - p(+))C(+|-)} \tag{1}
$$

where  $C(-|+)$  is the cost of a false negative and  $C(+|-)$  is the cost of a false positive.  $PC(+)$  ranges from 0 to 1.

Classifier performance, the y-axis of a cost curve plot, is "normalized expected cost" (NEC), defined as follows:

$$
NEC = FN * PC(+) + FP * (1 - PC(+) )
$$
 (2)

where  $FN$  is a classifier's false negative rate, and  $FP$  is its false positive rate. NEC ranges between 0 and 1.

**Fig. 1.** Japanese credit - Cost curves for 1R (dashed [line\)](#page-3-9) and C4.5 (solid line)

<span id="page-1-0"></span>To draw the cost curve for a classifier we draw two points,  $y = FP$  at  $x = 0$  and  $y =$ *FN* at  $x = 1$ , and join them by a straight line. The cost curve represents the normalized expected cost of the classifier over the full range of possible class distributions and misclassification costs. For example, the dashed line in Figure 1 is the cost curve for the decision stump produced by 1R [14] for the Japanese credit dataset from the UCI repository and the solid line is the cost curve for the decision tree C4.5 [20] learns from the same training data. In this plot we can instantly see the relation between 1R and C4.5's performance across the full range of deployment situations. The vertical

[d](#page-3-6)ifference between the two lines is the difference between their normalized expected costs at a specific operating point. The intersection point of the two lines is the operating point where 1R's stump and C4.5's tree perform identically. This occurs at  $PC(+)$  = 0.445. For larger values of  $PC(+)$  1R's performance is better than C4.5's, for smaller values of  $PC(+)$  the opposite is true.

Mathematically, cost curves are intimately related to ROC curves: they are "pointline duals" of one another. However, cost curves have the following advantages over ROC curves (see [11] for details):

- Cost curves directly show performance on their y-axis, whereas ROC curves do not explicitly depict performance. This means performance and performance differences can be easily seen in cost curves but not in ROC curves.
- When applied to a set of cost curves the natural way of averaging two-dimensional curves produces a cost curve that represents the average of the performances represented by the given curves. By contrast, there is no agreed upon way to average ROC curves, and none of the proposed [av](#page-3-10)[e](#page-3-11)[rag](#page-3-12)ing methods produces an ROC curve representing average performanc[e.](#page-2-2)
- Cost curves allow confidence intervals to be estimated for a classifier's performance, and allow the statistical significance of performance differences to be assessed. The confidence interval and statistical significance testing methods for ROC curves do not relate directly to classifier performance.

For these reasons, we have gained insights into classifier performance using cost curves that would likely not have been possible using other methods [8,9,10] and other data mining researchers are using cost curves in their analyses [3,5,22,23].
