Input Unit (Human Interface). The input unit of the ventilator, also called the human interface, is the interface between the user and the device. It allows the medical personnel via the control unit to set the values which are appropriate for the respective patient, according to the operating philosophy of the device; for example, the frequency and inspiration-to-expiration ratio can be used to set the inspiration and expiration time, as widely used in anesthesia. In volume-controlled ventilation, the controlled ventilation stroke is determined by the specification of the volume to be administered and the inspiratory pause time or also by the volume and the inspiratory flow.

Today, the parameters are usually entered indirectly. In other words, each adjustment is only carried out by the control unit and applied to the patient if confirmed again by the user. This is a means of detecting erroneous settings before they are applied.

Control Unit. The control unit converts the set values preset by the input unit into machine data. It controls the valves and defines the times at which the inspiration valve, the expiration valve, and the fresh gas decoupling valve are opened or closed. It also triggers the drive unit to administer the tidal volume during inspiration to the patient. These activities depend on the respective operating mode.

Fig. 30.6 Subcomponents of a ventilator

Today, anesthesia ventilators are operated as time-time-cycled devices in controlled ventilation modes. In such time-time-cycled devices, the switchovers from both inspiration to expiration and from expiration to inspiration take place at defined times, independently of the condition of the patient's lungs.

Breathing System. In clinical practice there are two different types of breathing systems: the rebreathing system and the non-rebreathing system.

Non-rebreathing systems are used in intensive care ventilators. With this system, the fresh gas is supplied directly to the patient's lungs. The exhaled gas is released, without diversion, into the ambient air.

Rebreathing systems are used in anesthesia because of the costs of the gases in anesthesia devices (Fig. 30.7). By recirculation of the expiratory breathing gas into the inspiration gas flow, the anesthetic agents contained in the gas are used to best effect. This allows for a reduction of the delivered doses of inhalation narcotics. In this way, the fresh gas volume per minute can be reduced far below the minute volume.

Since the exhaled gas contains CO_2 , this system requires the integration of a CO_2 absorber to ensure that the patient is supplied with CO_2 -free gas. The absorber is the characteristic feature of a rebreathing system. The soda lime (primarily $\text{Ca}(\text{OH})_2$) contained in the absorber bonds the CO_2 in the exhaled air. At the same time, the chemical reaction produces heat and moisture, which contributes to gas heating and humidification.

The inspiratory concentration of the breathing gas delivered to the patient depends significantly on the set fresh gas concentration and the concentration of the expiratory gas.

Fig. 30.7 Principle of a rebreathing system

Today, rebreathing systems have become standard in anesthesia because they consume less gas, therefore having lower operating costs and being less environmentally harmful, and provide for improved gas climatization.

The systems are classified as follows depending on the magnitude of the fresh gas flow:

- High flow, approximately 3–6 l/min
- Low flow, approximately 1 l/min
- Minimum flow, approximately 0.5 l/min.

However, the lower the fresh gas flow setting, the higher the degree to which the system must be sealed and the greater the demands placed on device monitoring.

Bellows Unit with Drive. The bellows unit is the main component of a ventilator. It is used to supply the patient with the required tidal volume. The bellows can be pneumatically emptied using compressed air, for example, in the case of Ventilog, AV1, and Julian devices, or also electronically using a motor, for example, in the case of Cicero, Fabius or Primus devices.

In a pneumatically driven ventilator (also called the *bellows-in-bottle principle*), the bellows is fastened in a pressure-tight chamber. The application of compressed air in the chamber causes the bellows to be emptied in the inspiratory phase, and the gas contained in the bellows is delivered to the patient. In the expiratory phase, the pressure in the chamber is reduced, so that the pressure returns to ambient pressure again and the bellows returns to its initial position.

The bellows may be moved back and forth by means of an electric motor with connected gears, which results in the contained gas being emptied. This effect can also be implemented with a piston cylinder unit, which can be compared to a large syringe. The piston is moved back and forth via a spindle by a step motor. Since the cylinder has a defined cross-sectional area and the drive via the spindle is very precise, this provides for very accurate information on the currently delivered volume being administered. As drive gas is not needed when an electric drive is used, costs are reduced accordingly.

Fresh Gas Supply. As shown in Fig. 30.2, the O₂/N₂O mixture from the dosing unit is added to the anesthetic agent vaporizer. After passing through the vaporizer, the gas mixture consisting of O₂, N₂O, and the anesthetic agent is also called fresh gas. This gas mixture is delivered to the inspiration side of the breathing system. The fresh gas can be supplied in two different ways:

- Continuous (conventional system)
- Discontinuous (fresh gas decoupled system).

Continuous Fresh Gas Supply into the Inspiration Line. This conventional system (Fig. 30.8), implemented, for example, in Sulla 808 with Ventilog 2 or Narkomed devices, features the characteristics that the manual ventilation bag is not included in the gas flow during controlled ventilation and that gas flows continuously into the breathing system independently of inspiration and expiration.

During inspiration, fresh gas is delivered to the patient in addition to the volume from the bellows. Therefore, the volume delivered to the patient consists of the bellows volume plus the fresh gas volume. Therefore, the system has the following characteristics:

- The minute volume is fresh gas flow dependent. This means that, if the fresh gas flow is reduced from, e.g., 5 l/min to 2 l/min, without adjusting the ventilation, the minute volume (MV) is reduced by 1.5 l at an inspiration/expiration ratio of 1 : 1, i.e., $MV \text{ change} = 1/2(5 \text{ l/min} - 2 \text{ l/min}) = 1.5 \text{ l/min}$.
- If a large flow is present, the pressure curve in the plateau phase of volume-controlled ventilation shows a continuous pressure rise. The pressure curve exhibits a second pressure peak as a result.
- If a very small fresh gas flow is present, with descending bellows, a negative pressure phase is produced at the start of expiration because the

conventional system is not equipped with a gas reservoir. Therefore, to avoid this effect, a sufficiently high fresh gas flow must be maintained.

Today, some devices on the world market feature a steady state in which a fresh gas compensation eliminates this fresh gas flow dependency. By measuring the volume, for example, during inspiration, consisting of a fresh gas and a ventilator part, a control algorithm can be used to reduce the part from the bellows unit in such a way that the total of the fresh gas and bellows parts corresponds to the set volume.

Discontinuous Fresh Gas Supply into the Inspiration Line. This system (Fig. 30.9) is also called a fresh gas decoupled system and is implemented, for example, in Cicero and similarly in Fabius and Primus devices. A characteristic feature of this system is that the fresh gas flow can only flow into the inspiration line of the breathing system during the expiratory phase of the patient. During the inspiratory phase, the gas flows into a reservoir bag (manual ventilation bag), which allows the bellows to be filled during the expiratory phase.

Due to this discontinuous fresh gas supply, the system has the following characteristics.

- The minute volume is independent of the fresh gas flow, i. e., if the flow is adjusted from, e.g., 5 l/min to 2 l/min, the minute volume remains unchanged. This characteristic makes fresh gas decoupling essential for low-flow anesthesia applications.
- Due to the decoupling between drug dosing and the patient, the pressure curve is not affected by the fresh gas flow; in particular, no negative phase is present for low flow.
- The reservoir bag is included in the system during controlled ventilation and is filled and emptied with the rhythm of ventilation. This feature also allows recognition of fresh gas decoupling in volume-controlled ventilation.

Monitoring the Ventilator. Monitoring of device parameters is essential to make malfunctions in individual components (such as the ventilator including the breathing system) identifiable and transparent and to provide the user with the option of intervening. Three sensors – for pressure, volume, and CO₂ – are responsible for monitoring the correct functioning of the ventilator and the breathing system. Usually, these sensors are integrated into general device monitoring and also perform additional patient monitoring tasks.

Fig. 30.8 Conventional breathing system with continuous fresh gas supply

Fig. 30.9 Fresh gas decoupled system through discontinuous gas supply

Volume measurement can be used to check the set tidal volume. The correct ventilation frequency can be determined from the volume, pressure or CO₂ measurement. The pressure measurement warns against too large pressure in the breathing system (stenosis) and is designed to protect against the risk of barotrauma. The inspiratory CO₂ measurement detects an exhausted

soda lime absorber. The expiratory CO_2 measurement and the pressure measurement warn against disconnections (as the set lower pressure limit is no longer periodically reached in both directions in the case of disconnection).

Ventilation Modes in Anesthesia

Today, four main ventilation modes are used in anesthesia.

Manual Ventilation. Manual ventilation enables the anesthetist to initiate anesthesia, to ventilate the patient, and to wake up the patient from anesthesia for spontaneous breathing.

Controlled Ventilation. This is the main form of ventilation in anesthesia, because a muscle relaxant is often used during anesthesia, having the side-effect that the breathing musculature is also paralyzed. A distinction is made between two forms: volume-controlled ventilation and pressure-controlled ventilation. Both are used for different applications. Volume-controlled ventilation is primarily used for patients with healthy lungs, whereas pressure-controlled ventilation is used for patients with pulmonary problems, neonates, and pediatric patients.

Spontaneous Breathing Support (Pressure Support)

The use of muscle relaxants is not necessary in many operations, and a laryngeal mask is used instead of a tube to secure the airways. The patient can breathe spontaneously with stable spontaneous breathing frequency, however, the musculature is weakened depending on the drugs administered. Pressure support is designed to assist the breathing musculature which has been weakened by the drugs and to help the patient take deeper breathes.

Mixed Ventilation

In cases where operations are performed without use of muscle relaxants, but the doses of hypnosis and analgesic drugs are so high that spontaneous breathing frequency is not stable, there may be periods without spontaneous breathing. During such periods, minimum ventilation must be maintained to ensure that the patient is provided with sufficient oxygen. The patient's breathing is basically spontaneous. The ventilator, which has a low safety frequency setting, delivers controlled ventilation cycles synchronously with the patient's inhalation efforts.

To assist patients in overcoming the difficulties caused by the tube and the side-effects of the drugs, spontaneous breathing is supported by pressure support.

During the anesthesia termination phase with muscle relaxants, where the concentration of the drugs is gradually reduced and spontaneous breathing returns, mixed ventilation can be used to help support emerging spontaneous breathing and ensure minimum ventilation. This allows the anesthetist to use his hands for other tasks. Usually, one hand is busy providing manual ventilation.

Volume-Controlled Ventilation

Volume-controlled ventilation, also called intermittent positive pressure ventilation (IPPV), is a time-cycled, volume-controlled ventilation mode. In this controlled ventilation mode, the ventilator administers the preset tidal volume (e.g., 10 ml/kg body weight) with a fixed defined constant inspiration flow with the specified frequency (e.g., for adults, 10 /min).

The pressure in the breathing system and in the lung results from the set parameters and the resistance and compliance of the patient's lungs (Fig. 30.10).

High pressure peaks can occur depending on the settings. Therefore, a maximum pressure limit P_{\max} must be set which ensures that the flow is automatically reduced when the pressure limit has been reached. Additionally, pressure monitoring is also essential. An advantage of the IPPV mode is that the patient is always provided with a defined minute volume even with changes in lung properties.

Fig. 30.10 Pressure and flow curve for volume-controlled ventilation

This mode is primarily used for patients with healthy lungs and is very popular in anesthesia. It is also used when volume constancy and thus maintenance of arterial CO₂ partial pressure within strict limits is a primary objective of ventilation, for example, in traumatic brain injury. Since cerebral perfusion is dependent on CO₂, the volume must be kept constant to set the optimal intracerebral pressure.

Pressure-Controlled Ventilation

Pressure-controlled ventilation (PCV) is a time-cycled, pressure-controlled ventilation mode. In this controlled ventilation mode, the ventilator delivers a ventilation stroke at a constant preset pressure level, e.g., 15 mbar, with a decelerating inspiratory flow pattern during the entire inspiration time at a specified frequency (Fig. 30.11). The administered volume cannot be preset and results from the applied pressure and lung compliance. Depending on the pressure setting, the delivered volume may be too large or too small. Therefore, expiratory volume monitoring is essential. The main advantage of this mode is that the pressure values which have been set for the patient are never exceeded. This mode is primarily used for neonates, infants, and children, where the thorax is not stable and also the endotracheal tube is not blocked, resulting in a leak. It is also helpful for patients with inhomogeneous lungs, where it is necessary to prevent overinflation of the normal areas. This mode is also suitable for venti-

Fig. 30.11 Pressure and flow curve for pressure-controlled ventilation

lating patients with bronchopleural fistulas. PCV is also increasingly used for ventilation with laryngeal masks.

Spontaneous Breathing Support (Pressure Support)

Pressure support is a pressure-supported ventilation mode which can be used in cases where spontaneous breathing is present but insufficient (Fig. 30.12). It sup-

Fig. 30.12 Pressure and flow curve for supported spontaneous breathing (pressure support, PS)

ports each individual breath taken by the patient. This mode is also called *assisted spontaneous breathing* (ASB) or the *inspiratory help system* (IHS). In a similar way to how the anesthetist senses the restarting of spontaneous breathing in the patient at the breathing bag and supports it manually, the device can support insufficient spontaneous breathing. The device takes over part of the breathing work; however, the patient controls the start and end of inspiration. The start of inspiration is detected using a trigger system. The device then provides a flow and thus creates a pressure rise which increases up to the preset support pressure and also remains constant. Expiration starts as soon as the inspiration flow falls below a specific value (e.g., 25% of the maximum flow). By reducing the support pressure, the support provided by the device is reduced and the patient is induced to take over more breathing work.

Mixed Ventilation (SIMV/PS)

The basic idea of synchronized intermittent mandatory ventilation (SIMV) (Fig. 30.13) is that the patient basically breathes spontaneously and the ventilator intermittently delivers controlled ventilation strokes (volume controlled or pressure controlled) with a very low safety frequency synchronously with the patient's inhalation efforts. This prevents mechanical ventilation strokes from taking place during spontaneous expiration. No spontaneous breathing is possible during a controlled stroke.

Fig. 30.13 Pressure and flow curve for mixed ventilation SIMV (VC) with PS

SIMV is a mixed form between pure spontaneous breathing and controlled ventilation. The ventilation strokes of the device are synchronized with the patient's breathing, for which the trigger function of the machine is used. The ventilation stroke is triggered when the patient tries to inhale again at the end of the spontaneous breathing phase and thus triggers the trigger pulse. The consequence of these is a minimum ventilation which results from the product of tidal volume (VT) and the frequency. The patient can breathe freely and spontaneously between these controlled strokes. In these spontaneous breathing phases, the patient can be additionally supported with pressure support by a suitable pressure setting, thus relieving him of part of his breathing work.

30.3.3 Monitoring

The third significant component of an anesthesia device is monitoring. It has two main purposes: firstly, to constantly monitor the correct administration of drugs and the correct functioning of the ventilator, and secondly, to constantly monitor the effects of the anesthesia on the physiological functions of the patient. The corresponding monitoring values are used to determine whether the device is functioning properly and whether the patient is being anesthetized and ventilated as desired.

In the event that the limits of a previously defined range are exceeded, the corresponding audible and visual alarm of the monitored parameter is triggered. To meet the two most important tasks, namely the measurement and monitoring of a specific parameter, different system components in the monitor are required.

Measuring Unit

Using a sensor, this unit converts the physical values, such as pressure, flow, oxygen concentration, temperature or absorption, into a measurable electrical signal; for example, a sensor is used to create an electrical current from the breathing gas flow.

Display Unit

This unit shows the measured result after it has been converted into the corresponding units, such as volume in ml. The display can be shown as a digital numerical sequence or as a curve.

Monitoring Unit

This unit checks whether the actual values are within the target range. To achieve this, lower and upper limit values are defined for the monitoring unit by the user.

The monitoring unit compares the currently measured value with the lower and upper limit value. If limit values are exceeded, an alarm is issued to allow the user to intervene.

The output values from the different sensors can be collated in such a way that the screen can be arranged differently with curves, data, and alarm displays.

Tasks of Different Sensors

Generally, anesthesia devices are equipped with nine sensors, including five device monitoring sensors for monitoring drug dosing and the ventilator:

- Oxygen
- Pressure
- Volume
- Carbon dioxide (CO₂)
- Anesthetic agent

and four patient monitoring sensors for monitoring patient health during uncomplicated operations:

- Electrocardiogram (ECG)
- Noninvasive blood pressure (NIBP)
- Oxygen saturation (SpO₂), and
- Body temperature.

Display of Dosed Gases

The gas dosing unit and the anesthetic agent vaporizer deliver the drugs into the fresh gas flow of the breathing system. Due to the rebreathing system, the inspiratory concentrations of oxygen, nitrous oxide, and anesthetic agent differ from the concentrations set on the dosing devices. This difference increases when the fresh gas flow is reduced. To determine the concentrations being delivered to the patient, the inspiratory concentrations of oxygen, nitrous oxide, and anesthetic agent (isoflurane, sevoflurane or desflurane) need to be measured and displayed.

Monitoring the Device Components

Five different sensors with upper and lower alarm limits ensure that the device components are constantly monitored. The purpose of this type of monitoring is to allow qualified and trained medical personnel to intervene immediately in the event that the device fails to function properly.

Oxygen measurement is used to monitor gas dosing, to identify, for example, whether the O₂ and N₂O lines have been mixed up. Measuring the nitrous oxide concentration is another way of checking this. Oxygen

measurement is also used to detect hypoxia, if, for example, too low an O₂ concentration was set. Anesthetic agent measurement is responsible for monitoring the anesthetic agent vaporizer and ensuring that it is functioning correctly. CO₂ measurement allows detection of rebreathing if, for example, an inspiration or expiration valve is defective. Inspiratory CO₂ measurement monitors the CO₂ absorption by the soda lime and indicates the point when the soda lime has to be replaced at the latest. Expiratory CO₂ measurement monitors adequate ventilation and thus also breathing system integrity to ensure that the device and patient are not disconnected.

Pressure and volume measurement are used to monitor the proper functioning of the ventilator. Volume measurement indicates whether the ventilator is working properly, in particular whether the set volume is actually delivered. Pressure measurement ensures that disconnection is detected and also that the physician is alerted if the pressure is too high, to prevent barotrauma.

Patient Monitoring

The different sensors designed to monitor both the device and the patient allow the physician to assess the state of the patient. The inspiratory oxygen concentration and the mean pressure produced during ventilation are used to determine patient oxygenation. The difference between the inspiratory and expiratory O₂ concentrations provides an indication of the patient's O₂ uptake. Volume measurement together with the expiratory CO₂ measurement is used to set the patient's ventilation correctly. The expiratory anesthetic agent concentration provides a reference point for the depth of anesthesia. The difference between the inspiratory and expiratory anesthetic agent concentration values provides an indication of the patient's anesthetic agent uptake.

The difference between the peak pressure and plateau pressure in volume-controlled ventilation indicates the airway resistances. Patient and device compliance, on the other hand, are reflected in the plateau pressure in volume-controlled ventilation.

The oxygen saturation sensor shows the blood oxygenation level and also provides information on the heart's pump function. Monitoring the blood circulation is also necessary for patient monitoring. The heart's pump function can be observed by measuring the heart rate via evaluation of the oxygen saturation level as well as by measuring the noninvasive blood pressure. The ECG indicates whether and how the heart is electrically activated.

Fig. 30.14 Principle of a fuel cell for measuring oxygen concentration

For operations on the heart, and in neurosurgery and other related areas, enhanced monitoring with invasive blood pressure measurement is required in addition to the form of monitoring described before (Chap. 48).

30.3.4 Sensor Principles for Device Monitoring

Fuel Cell for Oxygen Concentration Measurement

The inspiratory oxygen concentration measurement monitors the oxygen delivery. A method often used for O_2 measurement is the fuel cell (Fig. 30.14).

The electrochemical reaction system of the fuel cell is accommodated in a housing which is sealed by an extremely thin membrane. This membrane prevents the alkaline electrolytes from escaping from the housing but allows oxygen molecules to diffuse through.

The O_2 concentration in the gas determines the O_2 concentration in the electrolyte of the fuel cell. The alkaline electrolytic solution contains a lead anode and

a gold cathode. After the oxygen molecules of the gas to be measured have passed through the membrane, basically the following electrode reactions take place. On the gold cathode, oxygen releases electrons from the cathode material, forming OH^- ions and positively charging the cathode. On the anode, lead reacts with the OH^- ions to form lead oxide and water. During this process, the anode is negatively charged. If the cathode and anode are connected with each other, an electrical current proportional to the oxygen concentration is produced.

The lifetime of this system is limited by two processes: lead is transformed to lead oxide, and water as the catalyst in the cell diffuses out.

Paramagnetic Sensor for Oxygen Concentration Measurement

The gas mixture used in anesthesia consists of oxygen, nitrogen, nitrous oxide, carbon dioxide, and the volatile anesthetic agent. Only the oxygen molecule has a paramagnetic moment, which can be influenced by a magnetic field. Therefore, oxygen can be measured selectively in this gas mixture. The measurement principle (Fig. 30.15) is based on the thermal conduction of oxygen. The thermal conduction of a gas depends on the degrees of freedom of the molecules, with more degrees of freedom contributing more to the thermal conduction. A magnetic field is used to reduce the degrees of freedom of the oxygen molecules. The oxygen molecules are aligned like tiny magnets and their freedom of movement is restricted.

Therefore, the thermal conduction depends on the external magnetic field and has a small but measurable influence on the overall thermal conduction of the gas mixture. A heating element is brought to a constant temperature in a magnet and conducts heat to the gas in the cuvette. A nearby temperature sensor measures

Fig. 30.15 Principle of a paramagnetic sensor cell for measuring oxygen concentration

the temperature, which depends on the thermal conduction of the gas. The magnetic field is periodically turned on and off at a specific frequency and the temperature sensor consequently measures small temperature fluctuations whose amplitude is proportional to the oxygen concentration.

This paramagnetic thermal-conductive oxygen analyzer has a short time constant, no moving parts, and long lifetime durability.

Piezoresistive Sensor for Pressure Measurement

Inspiratory and expiratory pressure measurements can be used to create pressure–time diagrams to make ventilation more transparent. This ensures that disconnections and apnea phases can be detected and also that warnings are issued if the pressure is too high.

An electrical pressure signal can be produced from a mechanical–electrical (piezoresistive) converter (Fig. 30.16). For this purpose, a pressure cell is sealed with a movable membrane. The membrane is attached to a solid-state device, whose electrical resistance depends on the elongation of the membrane. The electronic pressure measurement is determined by the actual stretching of the membrane. The stretching of the membrane causes the solid-state device to bend, leading to a variation in resistance. In this way, the current prevalent pressure is uniquely correlated with the measured resistance.

Hot-Wire Principle for Volume Measurement

The expiratory volume measurement detects the total quantity of exhaled gas. In particular, in the case of pressure-controlled ventilation, volume measurement is the only way of obtaining information on the volume delivered to the patient. An additional inspiratory measurement can be used to display the inspiratory and expiratory flow curve.

Fig. 30.16 Principle of a piezoresistive sensor for pressure measurement

Fig. 30.17 Principle of a hot-wire anemometer for flow and volume measurement

The hot-wire anemometer method is a purely electrical method for volume measurement (Fig. 30.17). An extremely thin platinum wire is heated to a temperature of approximately 180 °C using an electrical current. When gas flows past this wire, the wire is cooled. The greater the volume per time flowing past the wire, the more the wire is cooled. If the temperature of the platinum wire is kept constant by a control circuit, the required heating current can be used as an indication for the gas flow. A high flow requires a high electrical current to keep the temperature of the heating wire constant; a lower flow requires a small electrical current to reach the same temperature. The volume is obtained by integrating current over time electronically.

Infrared Absorption Measurement for CO₂, N₂O, and Anesthetic Agent Concentration Measurement

Infrared absorption spectroscopy (Fig. 30.18) is based on the physical principle that polyatomic gases absorb infrared radiation at characteristic frequencies. The level of absorption depends on the concentration of molecules.

For measurement, the molecules are channeled into a cuvette with a defined length and illuminated with an infrared light source. The detection element (the detector) detects the remaining residual radiation after absorption. If the light source has an intensity of I_0 and the beam is weakened by the molecules to the intensity I , then the concentration can be calculated according to the Lambert–Beer law

$$\text{Concentration} = \text{Absorption constant} \times \ln(I_0/I) .$$

CO₂ and N₂O are determined in the 4 μm range always using *one* specific light frequency for each gas. Today, the anesthetic agents halothane, enflurane, isoflurane,

Fig. 30.18 Infrared (IR) absorption for measuring CO₂, N₂O, and anesthetic agent concentrations

sevoflurane, and desflurane are identified by measuring the absorption at three wavelengths in the range 8–9 μm for determination of the corresponding concentration.

Sensor Principles for Patient Monitoring

The principles of ECG, oxygen saturation, blood pressure, and body temperature measurement are described in Chap. 48.

30.4 Safe Operation Prerequisites

30.4.1 Connection Prerequisites

The proper functioning of the anesthesia device is only guaranteed in rooms equipped with appropriate supply connections. Therefore, it must be ensured that the anesthesia device as a life-support system is connected to the hospital's internal emergency power system. It is equally important to ensure that oxygen, compressed air, and, where used, nitrous oxide from the central supply at a suitable pressure (e.g., 5 bar) are always available. If there is no redundancy, it must be ensured that backup cylinders are readily available to maintain anesthesia in the event of disruption to the central supply system. For cardiological procedures, it is also required that the device be connected to the central ground in the operating room. It must also be considered that mobile telephones can disturb the proper functioning of these devices.

Since nitrous oxide and anesthetic agents (isoflurane, sevoflurane, desflurane) are used in the device, being intended only for patient inhalation and not for inhalation by operating room personnel, it is necessary to provide for an anesthetic gas scavenging system to remove the gas. Since no device is totally leak-tight and, for example, anesthetic gases are released into the environment when mask anesthesia is used, a recirculation system with a suitable air exchange rate is required to keep unwanted levels in the workplace to a minimum.

30.4.2 Training and Continuing Medical Education

Training provides users with the knowledge of the procedures required to operate the device as designed. The instructions for use form the basis of training because they contain the main source of information for users. However, in addition to receiving initial training and studying the instructions for use, users should also receive further instruction and training on a regular basis to ensure safety. All training and advanced training programs must be directed towards instructing users how to use the respective anesthesia workstation properly, enabling them to make best use of the functions and to apply the knowledge and skills they have acquired to ensure safe operation in routine and emergency situations.

30.4.3 Cleaning

Anesthesia devices can be a source of infection. Therefore, these devices must be prepared according to defined protocols before use on the patient. The following points are important:

- All breathing-gas-conducting parts must be disinfected for each patient as standard. This can be achieved, for example, by replacing the corresponding parts of the breathing system and

ventilator for each patient. Nowadays, filters are often used on the Y-piece to meet these requirements.

- Parts for invasive use such as invasive pressure measurement lines or also endotracheal tubes must be sterilized.
- The surface of the machine must be disinfected at least once a day to reduce bacteria and to prevent the transfer of bacteria by hand from the machine to the patient.

To ensure devices are hygienic, it is essential that a fixed replacement regime is used and that this routine is verified by conducting hygiene tests at the site. If the test result is not satisfactory, the regime must be adapted accordingly.

30.4.4 Maintenance and Pre-use Check

The manufacturer integrates safety features into the device in the design, development, and production phases. The CE mark indicates that all applicable safety requirements of all pertinent EC directives which have to be observed for the medical device have been met. However, this does not guarantee the required safety during clinical use when the device is used for years, even if the device has been used as intended and operated within its design limits in accordance with the instructions for use. During operation, these types of devices are subject to

wear; i. e., the current state (actual state) differs increasingly from the desired state (target state). Therefore, users and operators are required to organize and carry out tests and checks on a routine basis, e.g., one or two times a year, to ensure device safety. It can be assumed that safety is maintained between two such regular inspections. However, users must always ensure before using any medical devices that they are functioning properly and operating correctly. Pre-use checks are designed to detect errors which may have been caused by disassembly, cleaning, disinfection, sterilization, transportation, and assembly.

31. Extracorporeal Blood Purification Systems

Extracorpore

Jörg Vienken

The increase in the number of chronic kidney disease patients has encouraged the development of hemodialysis as a routine therapy. Basic improvements in the dialysis system, from the membrane and the tubing system to the dialysis monitor, have laid the basis for this development. The understanding of underlying control variables and their settings in terms of optimal therapy has also led to reduction of side effects that used to occur and therefore improved the quality of life and reduced mortality [31.1]. Innovative processes associated with the analysis of individual physiological patient parameters use feedback systems and control realized in the dialysis machine. These are currently state of the art. Using bioimpedance procedures, precise monitoring of the water balance of patients is possible. Even patients with liver failure currently use extracorporeal blood purification procedures. In contrast to hemodialysis, one uses protein-permeable membranes with which albumin-bound toxins are filtered. Their purification of the filtrate is then achieved by adsorber columns. Clinical studies have confirmed the efficacy of this procedure.

Extracorporeal blood purification will, therefore, play a central role in renal and hepatic organ failure in the future.

-------------------------	-----

The pioneers in the field of blood purification systems could scarcely dream that by 2010 there would be 1.8 million patients with kidney disease who are undergoing standardized blood purification with dialysis procedures. This should be considered in the light of the fact that, at the beginning of research into extracorporeal blood circulation, seemingly

insurmountable technical difficulties existed. Routine treatment with an artificial kidney was even inconceivable. The famous clinician Franz Volhard held this to be even useless and dangerous in the 1920s.

The understanding of physiological processes in the body as well as the high state of technology now avail-

able for extracorporeal blood purification processes has led to an annual increase in dialysis patient numbers of 7 to 8% at this time, a figure growing faster than the world population, which is increasing at 1.2% per year. Linked to this are the increasing survival rates with dialysis patients since the beginning of the new millennium, which can be attributed to improvements in dialysis procedures, related therapies, and also with better prevention of kidney diseases [31.2].

31.1 Historical Perspective

31.1.1 Prologue

William Harvey (1578–1657) presented his idea of blood circulation for the first time to a skeptical audience in 1628. His ideas were so unusual, and so counter to prevailing wisdom, that his followers were ridiculed soon after by his contemporaries with the nickname *circulatores*. Circulatores were peddlers, stray dogs, and vagrants and the epitome of speculation and lack of seriousness. It was impossible to believe at the time what Harvey, and before him Giordano Bruno, asserted, that the blood flows through the organism in a circuit. Leonardo da Vinci had already reported that the heart pumped out blood at high pressure, but without coming up with the idea that the consequence of this observation must be blood circulation. This idea was advanced by William Harvey for the first time.

Objective scholars of the time shied away from the obvious consequences of blood circulation theory for physiology and pathology. One countered Harvey's thesis with the statement that "... if the blood circulates at the speed asserted by Harvey, absorbable and harmful matter would be distributed in a chaotic mess!" and tried in a last attempt to rescue the respected teacher Galenus of Pergamon (129–199) with his idea of a blood circulatory time of 12 to 15 h [31.3].

31.1.2 Blood Purification: The Search for Principles

How can bodily poisons be removed from the blood? With blood circulation such as advanced by William Harvey, this should have been simple. It meant that access to the blood for detoxification could be obtained anywhere in the body. Anyway, the now well-known physical principle of diffusion was not known at that

Blood purification processes can be regarded as one of the most successful treatment procedures in the area of organ replacement therapies. One can assume in the future that in the Western industrial countries, on average about 1000 patients with kidney disease per one million inhabitants will have to undergo hemodialysis (HD). This places high demands on the corresponding medical technology, but also with the payers who must ensure that all patients can receive this vital treatment.

time. Already in the early eighteenth century, René Dutrochet (1776–1847) had undertaken the first examinations of the transport of water through *biological dividing walls*, independent of the earlier and similar observations of Jean Antoine Nollet (1700–1770) and George Frédérique Parrot (1767–1852). The real progress, however, took place with the work of Thomas Graham (1805–1869) in Glasgow published as his Bakerian lecture on *osmotic forces*. In this publication, Thomas Graham coined the terms *dialysis* and *dialyzer* for the first time [31.4]. Graham's experiments were performed in 1854 with the aid of membranes made of bladders, which he later replaced with membranes made of parchment. Such membranes, however, were often fragile and uneven in terms of thickness and size. They were often contaminated with bacteria, and therefore unsuitable for precise scientific investigations.

In Zurich, and in parallel to Graham, Adolph Fick from the German city of Kassel in Hesse worked on the mathematical description of transport processes through membranes. These investigations led to the fundamental *Fick's laws*. They were published in 1855 and described selective material transport through a semipermeable membrane as a consequence of concentration gradients [31.5]. Fick's laws remain today the principle for the description of movement of molecules through membranes and therefore still form the basis for the clearance properties of dialysis membranes for blood purification.

31.1.3 Membranes, Transport Processes, and Dialyzers

It became important to pose the question about the optimum *membrane* material for transport investigations fairly early. The solution was devised by an agricul-

tural chemist named *Schumacher* of Bonn, Germany. He introduced a new type of membrane material called collodium. Collodium is a syrupy fluid that forms after evaporation of a solvent – acetone, ether, or alcohol. It subsequently constructs a membrane film upon drying [31.6]. From a chemical point of view, collodium, a cellulose nitrate, is therefore an ester of nitric acid. Due to its chemical configuration and its contents of nitrate groups, it explodes at a temperature of 186 °C and is also therefore known as *gun cotton*. *Schumacher* was a good chemist. He succeeded in casting extremely thin membrane skins of collodium with which he could study the processes that were significant for the transport of molecules through membranes. His work in 1860 carried the title *On Membrane Diffusion* [31.6]. That was the first time this term appeared in the scientific literature, and it prevailed as the driving force for many developments from biochemistry and medicine to reverse osmosis. Later, in 1921, *Eggerth* of Hoagland Laboratories in New York was able to make membranes of collodium with different permeabilities by using different concentrations of alcohol solutions as a solvent [31.7]. Many of the details given by *Schumacher* and *Eggerth* about which materials could be separated still form the basis for the technology of modern membrane production, both for the production of commonly used low-flux dialysis and for high-flux membranes.

Cellulose nitrate in the form of collodium and, after 1945, the regenerated cellulose from cotton became the dominant membrane material for HD up to the end of the twentieth century. The production of the famous Cuprophane membrane, which led the dialysis market for 50 years, however, was finally abandoned in 2006.

At the end of the nineteenth century, *Emil Abderhalden* (1877–1950) of Switzerland attempted to separate substances from the blood of pregnant women using dialysis. It appears that an American with German ancestors, *Johan Jacob Abel* (1857–1938) of Baltimore, had heard of these attempts and began to develop a dialysis machine that he described in a report on Monday, August 11, 1913 in the *London Times* as the *artificial kidney*. *Abel* is called the father of dialysis due to the term he introduced, even though he had not intended to use this treatment on patients with kidney disease or kidney failure. Rather, at the time he only applied animal trials on dogs to produce an *artificial urine* in order to isolate substances such as salicylates, phenolsulfonphthalein, and aromatic amino acids by dialysis and to then purify these substances [31.8]. In any case, *Johan Jacob Abel* should be respected for

the technical development of the first dialysis machine, which he called the *vividiffusion apparatus* [31.8]. This machine, built in 1913, was already very similar to today's capillary dialysis systems. At that time, *artificial kidneys* were made of a hollow glass cylinder in which the inflowing blood flowed over a header consisting of 8 or even 32 glass distribution tubes through approximately 20-cm-long membrane tubes made of collodium. These membrane tubes had a cross-section of about 2 cm. The end of the dialyzer consisted of a second distribution header as with the blood input area with which the blood was returned to the dog's blood circulation. The perfect design of the glass distribution headers must be attributed to the skillful biochemist *Benjamin B. Turner* (1871–1945), who was also the coauthor of the work along with *Abel*.

Abel is credited with having already carried out examinations about possible extractable substances from the colloidin (collodium) membranes he produced. It was shown that, under the circumstances, colloidin extracts could influence the blood and therefore render the experiment more difficult. In none of his experiments could differences in comparison to control experiments with saline solution be shown [31.8]. Studies of extractable substances from polymers for medical technology are now routinely carried out and are even the subject of ISO standards [31.9].

31.1.4 Preparatory Work for Extracorporeal Blood Circulation for Blood Purification

At the end of the nineteenth century the first studies were carried out on organ perfusion in order to determine isolated organ functions in vitro. A leader in this area was *Franz Hofmeister's* laboratory at the Physiological Institute of the University of Strasbourg. Strasbourg was also the way-station for the scientific careers of two scientists who later played a great role in the development of extracorporeal blood circulation. *Johan Jacob Abel* received his doctorate at Strasbourg in 1888. The second, the German *Georg Haas* (1886–1971), who was to work later in Giessen, was a close collaborator of *Hofmeister*.

One can rightly argue that the foundations for the theory and practice of extracorporeal circulation were laid in Strasbourg, from which *Georg Haas* profited later in carrying out the first extracorporeal blood purification in Giessen/Germany in the 1920s on patients with kidney disease.

31.1.5 Removal of Nephrotoxic Substances Through Dialysis as an Experimental Therapy

Johan Jacob Abel conducted his research exclusively on animals, whereas *Haas* conducted the first procedure on a human being [31.10]. The physician *Haas* began his experiments on dialysis in Strasbourg at the beginning of the First World War in 1914. No doubt, the main idea of HD for the select diffusion of crystalline blood substances on artificial exchange surfaces was born in *Haas*' laboratory at Hofmeister's institute [31.10].

In contrast to Abel, *Haas* began with the goal of removing uremic toxins for the treatment of renal failure. He described his first observations [31.11]:

Now, as to the therapeutic success of this case, we clearly had the impression of a detoxification process. Immediately following blood purification, the patient's mood was visibly better. Yes, I would say, superior. He was the talk of the ward during the night of the purification, and in the following nights he slept quite well without sleeping pills. Nausea and headaches, which were intractable in the days before blood dialysis, which had given an immediate indication for a procedure, had completely

disappeared. Above all, he had regained his appetite, which had been nearly absent before. The improvement in his status lasted about six days, until headaches, sleeplessness and vomiting reappeared.

Haas abandoned his experiments on the use of a dialyzer before the Second World War for a number of reasons. A major reason for this was the great demand for him as a director of the university hospital and the nursing school of St. Josef's Hospital in Giessen, and also the lack of recognition and acceptance by his colleagues, especially by *Volhard*, who was probably the most famous clinician of the time.

Only *Willem Kolff* in Kampen, the Netherlands, and later in the USA was able to conclude the work of *Haas* in the 1940s on his rotating drum kidney, from which kidney replacement therapy could be developed from an experimental to a standard therapy today [31.12]. Further technical developments in the area of membrane technology, e.g., through the use of capillary membranes instead of flat or tubular membranes, and also in the area of dialysis machines, e.g., through volume-control, analyzed and controlled through feedback systems incorporated into the extracorporeal blood circuit, additionally contributed to the success of extracorporeal treatment systems.

31.2 Blood Purification for the Therapy of Renal Failure

31.2.1 Principles, Control Variables, and Conditions for Hemodialysis

If the kidneys fail to perform their functions, then the body must be detoxified through extracorporeal blood circulation containing blood pumps and filters. Following intense investigations, the kidney patient must undergo a 4-h blood purification three times a week. In this procedure, blood is taken from a shunt between the veins and arteries of the patient's forearm. The blood then passes through blood tubes into the dialyzer (artificial kidney). The control of blood flow, its temperature, its blood pressure, blood volume, etc. are taken over by a monitor in the dialysis machine during the treatment process (Fig. 31.1).

The actual blood purification or blood washing then takes place in the dialyzer. This filter mimics the filtering unit of the natural kidney, the glomerulus. A typical dialyzer contains about 10 000 capillary membranes which are arranged in a bundle. These hollow fiber

membranes typically have an inner diameter of 200 μm . The wall of the capillaries consists of membranes with a thickness of about 40 μm through which the material exchange takes place (Fig. 31.2). The interstices between the capillary membranes are perfused with an isotonic rinsing solution (dialysis fluid or dialysate) in countercurrent flow to the direction of blood flow. This creates a concentration gradient for material from the blood because the dialysate only contains some electrolytes to maintain tonicity. Various blood toxins (uremic toxins) are filtered out of the blood into the dialysate path using these concentration gradients. They are thus removed and later disposed of. This blood purification procedure is called *hemodialysis* (Fig. 31.3a). The process of *hemodiafiltration*, which is used more and more for blood purification, additionally uses a process controlled by convective forces in addition to the diffusively controlled transport of uremic toxins. Here, high ultrafiltration volumes are used in order to provoke a *solvent drag*, whereby uremic toxins with higher

Fig. 31.1a–c Blood purification by hemodialysis is achieved in patients with kidney disease when blood is passed and filtered extracorporeally through a dialyzer. Treatment parameters, such as blood flow, dialysate flow, blood pressure, blood volume, pH, and the performance parameters, can be assessed and appropriately monitored by the dialysis machine. Patients (a) undergo this procedure three times per week for 4 or more hours nearly as a rule. Dialyzers (b) are the key functional elements of blood purification systems. Dialysis machines (c) (5008 machine from Fresenius Medical Care) are able to control a patient-specific therapy with the assistance of feedback systems. Even highly efficient blood purification systems, such as hemodiafiltration, can be operated cost-effectively, as the machine offers online availability of the necessary substitution solution directly from the dialysis fluid as a standard

molecular weights are filtered out in the secondary circuit (Fig. 31.3b). Obviously, high-volume ultrafiltration of the patient requires compensation of the lost volume by substitution with an infusion solution prior to or after the dialyzer (pre- or postdilution). In the past, such a substitution solution was very costly due to the requirements for microbiological and chemical purity. Modern dialyzers enable the introduction of highly pure substitution fluids online directly from the circulation of the dialysis fluid (Fig. 31.3c). Thus, *online hemodiafiltration* (OL-HDF) has developed into an accepted and affordable blood purification procedure.

Treatment of renal failure should be understood as a therapy under the premise of a systems approach. It simultaneously uses a dialysis machine, a tubing system, a dialyzer, and the circuit of dialysis fluids. All compo-

nents of this system act under synergistic conditions and have to be appropriately controlled in order to perform a blood purification therapy.

31.2.2 Dialysis Membranes

In nephrology, water is seen as a uremic toxin and must be removed by HD because patients with kidney disease are limited in their ability to excrete water. This process, known as ultrafiltration, specifies the chemical composition of the dialysis membrane. A membrane must be at least in part hydrophilic in order to allow water permeation. Consequently, a series of hydrophobic polymers such as polypropylene, polyethylene, etc. are excluded as membrane materials for HD. In many cases, it helps to blend originally hydrophobic polymers with hy-

Fig. 31.2 The dialysis membrane assumes the function of cleaning the blood from the filtration unit of the kidneys, the glomerulus. The capillary membranes assume the membrane functions in the walls of the capillaries. It is interesting to observe that the dimensions of the inner diameter of the glomerulus and the inner diameter of the capillary membranes are similar. A dialyzer contains more than 10 000 capillary membranes through which the patient's blood is passed. The dialysis fluid is passed in a countercurrent flow to the patient's blood

drophilic polymers. As an example, polysulfone (PSu) and polyamide (PA) can be rendered partially hydrophilic by the addition of polyvinylpyrrolidone (PVP) or polyethylene glycol (PEG), or, as in the case of polyacrylonitrile (PAN), by the addition of methallyl sulfonate.

The basic polymer and the additives of a dialysis membrane dictate its chemical and physical behavior. This includes resistance and stability against chemical sterilants and sterilization processes, its adsorptive characteristics for bacterial contaminants, and its removal characteristics for both uremic toxins and inflammatory mediators. In addition, the blood compatibility and biocompatibility of a membrane is influenced by its polymeric additives, e.g., in relation to blood coagulation, the activation of red and white blood cells, and the generation of vasoactive mediators such as bradykinin.

An ideal polymer membrane for dialysis should show physical stability and an excellent diffusive permeability and, if necessary, allow for high ultrafiltration

rates. High ultrafiltration rates enable the application of convective forces, which provoke solvent drag for large molecules in hemodiafiltration. It should have performance and biocompatibility characteristics that promote effective treatment conditions and avoid acute and chronic clinical sequelae.

Recent evidence indicates that an ultraclean dialysis fluid that is free of microbial contamination not only helps with acute inflammatory reactions but can also reduce or eliminate long-term complications of dialysis [31.13]. Therefore, it is particularly important to ensure no contamination in the dialysis fluid with chemical, bacterial, or other contaminants. The adsorption capability of a dialysis membrane for organic contaminants such as endotoxins is, therefore, of paramount importance. Membranes made of polysulfone show efficient adsorption capability for endotoxins. They offer additional protection for patients and are also approved for the filtration of dialysis fluid for online HDF [31.14].

Fig. 31.3a–c Schemes of blood purification procedures. **(a)** hemodialysis (HD); **(b)** hemodiafiltration (HDF), by which the high ultrafiltration rate is compensated by a substitute solution. **(c)** In the online HDF procedure, the substitution solution is directly obtained from the dialysis machine from the dialysate circulation. Endotoxin filters in the circuit guarantee the necessary purity of the substitution solution

Synthetic hollow fiber membranes have a diameter between 185 and 230 μm , with a wall thickness between 20 and 40 μm (Fig. 31.2). Typical polymers for the dialysis membrane are polysulfone (PSu, Fresenius Medical Care, and others), polyacrylonitrile (PAN, AN69, AN69ST, Gambro Hospal), polymethylmethacrylate (PMMA, Toray), and polyamide (PA, Gambro).

Membranes for dialyzers are now consistently offered as hollow fiber membranes made from synthetic polymers. Flat and tubular membranes indeed played a role only in the beginning of dialysis therapy, but the treatment of larger numbers of patients with the necessary voluminous dialysates would be inefficient, impracticable, and costly.

The cellulose membranes that have dominated the market in the past 50 years have nearly disappeared from the market due to their alleged lack of blood compatibility. Production of the Cuprophane and Hemophane membrane was abandoned in 2006 by its manufacturer, Membrana, in Wuppertal, Germany.

The range of dialyzers and filters with capillary membranes is far-reaching and difficult to grasp. Six hundred fifty different dialyzer types could be found on the market in 2010. These are equipped with membranes made of at least ten different polymers. Table 31.1 gives an overview of some of the most common filters.

31.2.3 Dialyzer Construction

The ideal dialyzer should be able to effectively remove soluble substances from the blood throughout the treatment period with consistent performance, have low blood priming volume, and contain a biocompatible

membrane [31.15]. In addition, it must be absolutely safe to use and ideally be steam-sterilized in order to avoid problems caused by possible sterilization byproducts (e.g., extracted oligomers followed by gamma irradiation, or residues of ETO (ethylene oxide) after gas sterilization). Furthermore, it should be made of a material that can be disposed of in an environmentally friendly way.

Capillary dialyzers consist of a housing made of polycarbonate or polypropylene (e.g., FX class from Fresenius Medical Care, Bad Homburg, Germany) with a hollow fiber bundle inside (Fig. 31.2). The fiber bundle is embedded on both ends in polyurethane (PUR) potting and attached in the housing in such a way that two compartments are formed, one for blood and one for dialysis fluid. Both compartments are separated from one another by the membrane. Material exchange between the compartments is therefore only possible across this membrane.

Table 31.1 Overview of some of the most common filters. Data from chosen dialyzers (manufacturer listed in alphabetical order)

Dialyzer manufacturer	Performance, clearance data					Technical data				
	KUF (ml/mmHg)	Urea (ml/min)	Creatinine (ml/min)	Phosphate (ml/min)	Vit B ₁₂ (ml/min)	Sterilization	Membrane material	Wall thickness (μm)	Lumen (μm)	Application
ASAHI PAN 650 SF	30	194	189	174	146	ETO	Polyacrylonitrile	35	250	HD/HDF/HF
BBraun Diacap HI PS15	50	190	178	176	127	γ-rays	Polysulfone – PVP – blend	40	200	HD/HDF
Fresenius Medical Care F8 HPS	18	252	224	193	118	Inline steam	Polysulfone low flux	40	200	HD
Fresenius Medical Care FX60	46	193	182	177	135	Inline steam	Polysulfone helixone	35	185	HD/HDF/HF
Gambro Polyflux-17S	71	191	179	176	136	Steam	Polyamide/PES/PVP	50	215	HD/HDF
Hospal Nephral-ST 400	50	189	176	156	111	γ-rays wet	PAN/AN69ST	42	210	HD/HDF/HF
Nikkiso FLX-15GW	50	190	179	175	143	γ-rays wet	Polyether sulfone	30	210	HD/HDF
Nipro 150FH	67	198	194	193	155	γ-rays wet	Cell.-tri-acetate	15	185	HD/HDF
Toray BK-1.6U	31	187	169	153	108	γ-rays wet	PMMA	30	200	HD/HDF

* Information from the manufacturer's data sheets

HD – haemodialysis; HDF – haemodiafiltration; HF – haemofiltration; PES – polyethersulfone; PAN – Polyacrylonitrile; PVP – Polyvinylpyrrolidone; PMMA – Polymethyl methacrylate

A sophisticated means of microtome cutting technique gives extremely smooth surfaces at the surface of the PUR potting at the ends of the bundles. The activation of blood coagulation pathways and of blood cells can thereby be significantly reduced. The inlet and outlet for the dialysis fluid are found in most dialyzers at the respective ends of the housing.

Housing Material

The housing material for earlier dialyzers was generally made of polymers such as polycarbonate, whereas for the new generations of dialyzer housings are made from polypropylene (FX-class from Fresenius Medical Care, Bad Homburg). Such polymers can be disposed of in an environmentally friendly manner. The housing and the fiber bundles must be structured in such a way that the volumes of the blood compartments are as small as possible in order to prevent the blood of the dialysis patient from being damaged.

Dialyzers and their housings are regarded as disposable and are not to be reused for the most part in Europe or the USA. In a recently published report, the EU commission stated that reuse of medical disposables has no proven advantage in cost, ecological impact, and performance over single-use devices [31.16].

Fiber Bundles

The performance characteristics of a dialyzer are primarily based on the size and type of the fiber bundle inside. The best performance, and hence the best exploitation of diffusive and convective transport from the blood to the dialysis compartment, can only be guaranteed if the flow of the dialysis fluid can occur around each fiber, even in the center of the membrane bundle. The latter is achieved with some newer housing options by a special design of the cap area and with a Moiré structured capillary membrane (FX-class, Fresenius Medical Care). The loosening of the membrane bundle is carried out through undulation of the capillary membrane in the sense of a Moiré structure or through irregular insertion of textile fibers or so-called spacer yarns into the bundle [31.17].

Potting Material and Sealing Compounds

The potting material affixes the capillary bundle and also makes it possible to separate the blood and dialysis fluid compartments. It consists in most cases of PUR. Epoxy resins can also be used. The amount of necessary sealing compound has been continuously reduced over the years. A reason for this was the observation that PUR has a high binding capacity and low degassing

kinetics for ethylene oxide (ETO) under ETO sterilization. In the case of contact of the potting compound with blood, such as in HD, ETO can be extracted from the dialyzer by human blood and be released into the circulating blood in the body. Blood proteins, such as albumin, have a high binding affinity to ETO. Once bound to albumin, the so-formed albumin–ETO complex provokes and stimulates the development of IgE antibodies by plasma cells. Serious allergic reactions among hypersensitive patients or among patients who have been primed by a previous contact with ETO can develop as a consequence [31.18, 19]. For this reason, the majority of dialyzer manufacturers have stopped the sterilization of their filters with ETO for safety reasons.

31.2.4 Performance Parameters

The treating physician checks the efficiency of the dialysis treatment for the removal of water, urea, creatinine, and phosphate in everyday clinical practice. In many countries, the Kt/V value is used as an indicator or measure for adequate dialysis. The *urea reduction rate* (URR) is also still used as a parameter in some hospitals.

The abbreviation Kt/V describes the clinically targeted dialysis dose, where K stands for urea clearance, t for the effective dialysis time, and V for the urine distribution volume of the body of the individual patient. The last corresponds at a first approximation to the water content of the body and adds to about 60% of total body weight.

Kt/V must be determined at regular intervals. It is recommended that it be determined at least once a month. In Germany and the USA, this measure serves as the basis for determining dialysis reimbursement by health insurers. Depending upon the dialysis unit and patient groups, the measurements are also made more frequently (once a week) or less often (every 6 weeks to every 3 months) [31.20, 21]. As an example, Table 31.2 provides conditions for the assessment of dialyzer performance. In addition, the development of technically better systems for online determination of urea clearance has led to carrying out these measurements automatically during dialysis treatment (e.g., OnLine Clearance Monitor, Fresenius Medical Care), and therefore the dialysis dose of Kt/V can be continuously monitored [31.22].

In stark contrast, predialysis measurements of urea levels with an estimation of dialysis efficiency besides Kt/V or URR are considered to be a bit imprecise and are not efficient over time [31.23].

Table 31.2 Conditions for the assessment of dialyzer performance

Clearance test parameter	Standard	Differences with some manufacturers
Type of test	In vitro	
Test medium	Dialyzer fluid, enriched with urea, creatinine, phosphate, and vitamin B ₁₂	
Concentration of test substances	Urea: 100 mg/dl Creatinine: 10 mg/dl Phosphate: 5 mg/dl Vitamin B ₁₂ : 5 mg/dl	
Test medium temperature	37 ± 1.5 °C (USA) 37 ± 1.0 °C (Europe)	
Test medium pH (important for the determination of phosphate)	7.4 ± 0.1 *AAMI Standard, Vol. 3, Dialysis RD16, 1996	
Blood flow (Q_B)	200 ± 4 ml/min	300 ml/min
Flow dialysis fluid (Q_D)	500 ± 10 ml/min	
Filtrate flow (Q_F)	0 ml/min (*EN 1283)	7, 10, and 60 ml/min
*AAMI: Association for the Advancement of Medical Instrumentation (USA)		

With a planned increase in dialysis efficiency, first the state of vascular access should be reviewed in order to maximize performance. In the next step, one should – if organizationally feasible – consider extending the dialysis time or increasing blood flow. If there are opportunities to improve urea clearance (K), as a rule it is recommended to use a dialyzer with increased performance, e.g., through the use of a larger membrane surface area.

The assessment of dialysis performance is still carried out on the basis of urea clearance, whereby urea serves as a low-molecular-weight molecule to quantify dialysis dosage. This does not imply that urea is considered to be a uremic toxin. Toxins with a molecular weight of 300–500 are known as low-molecular-weight entities. For the last few years, however, so-called mid-sized molecules, known as middle molecules, have come back as a central point of interest for nephrologists. In the 1970s to the 1980s, middle molecules were considered to be uremic toxins with a molecular weight of up to 5000. Today in nephrology, one includes in these molecular classes molecules up to a molecular weight of even 20 000. The small protein β_2 -microglobulin is a representative and model molecule for this class. It has a molecular weight of 11 818

and should not be removed by HD from patient blood by diffusion. Only high ultrafiltration, based on convective transport with high-flux membranes, allows for the efficient removal of this molecule. As a consequence, high-flux dialysis and hemodiafiltration were applied in order to remove these mid-sized molecules (HDF, Fig. 31.3b).

The European Uremic Toxin Working Group (EUTox) and its director, *Vanholder*, from Ghent/Belgium, recently published a list of molecules classified as uremic toxins [31.24]. Of the total 92 identified molecules and compounds, 68 belong to the class of low-molecular-weight substances, and another 23 are protein-bound. Twelve toxins are shown to have middle molecular weight, and the remaining 12 substances possess molecular weights of about 15 000. Toxic molecules with a molecular weight above albumin (66 000) should be filtered only to a limited extent during HD according to current doctrine.

UF Coefficient

The ultrafiltration coefficient (UF_{coeff}) of a dialyzer, often denoted as *flux*, determines the membrane's permeability for water. It is not only used as a measure of hydraulic permeability, but also serves as an indicator of the ability of a dialyzer to remove the medium- or high-molecular weight substances. The ultrafiltration coefficient of a membrane (UF_{coeff}) is defined as the product of hydraulic permeability (L_p) and the membrane surface (A) in the dialyzer

$$UF_{\text{coeff}} = L_p \cdot A$$

Ultra-filtration Hydraulic permeability Surface coefficient size (31.1)

Multiplying the ultrafiltration coefficients by the transmembrane pressure (TMP), one obtains the resulting ultrafiltration rate (Q_F , also called filtrate flow) during dialysis:

$$Q_F = UF_{\text{coeff}} \cdot TMP$$

Ultra-filtration rate Ultra-filtration coefficient Trans-membrane pressure (31.2)

The ultrafiltration rate per surface unit of the membrane is somewhat proportional to the fourth power of the average pore radius [31.25]. The pore size of dialysis membranes, which normally is in the area of 1.5 nm for low-flux membranes and of 3 nm for high-flux membranes, has no significant effect on the membrane's ultrafiltration coefficients.

It follows from (31.1) that the ultrafiltration coefficient is a direct function of the size of the membrane

surface. Therefore, one can simply compare the ultrafiltration coefficient of membranes with varying surfaces by dividing the values by the size of the *effective membrane surfaces*. This implies the surface of the membrane that lies within the two parts of the potting material. Because the size of the membrane surface is already an integral part of the definition of the required ultrafiltration coefficient of a membrane, the attending physician – with knowledge of the ultrafiltration coefficient – requires no additional information about the individual membrane’s surface area. This does not apply, however, for the membrane’s capability to remove dissolved substances. Figure 31.4 depicts the dependence of the ultrafiltration rate of the applied TMP for low-flux (Fig. 31.4a) and high-flux (Fig. 31.4b) membranes.

It is easy to see that for a given ultrafiltration, e.g., for 3 l/h, the necessary TMP with low-flux membranes

is significantly higher than with high-flux membranes. Lower TMPs have an additional advantage as they preserve the solid components of blood such as erythrocytes, leukocytes, and platelets. With high-flux membranes, lower TMPs are applied for high ultrafiltration rates and, thus, enable an easy realization of convective therapies for the removal of mid-sized molecules.

Standard Values

Table 31.2 captures the conditions under which the manufacturer of dialysis membranes measures the respective ultrafiltration coefficients. The relationship between TMP and ultrafiltration rate is linear for relatively low TMP values for all membranes. However, the deterioration of membrane function during clinical use limits the achievable filtrate flow through the formation of a secondary membrane layer consisting

Fig. 31.4a,b Ultrafiltration profiles of low-flux (a) and high-flux (b) dialysis membranes. Ultrafiltration is a function of transmembrane pressure (TMP) whereby the dependencies in low flux are linear; for high-flux membranes, they are exponential. TMPs to achieve an ultrafiltration rate of 3 l/h are significantly less if high-flux membranes are used. F4–F8 HPS denote to low-flux dialysers from Fresenius Medical Care (a) whereas F60–HdF100S refer to high-flux dialysers from this manufacturer

of blood protein and blood cells. Normally, one measures the ultrafiltration rate (Q_F) with several different TMP values. The ultrafiltration coefficient (UF_{coeff}) is then defined as the increase of the linear portion of the curve resulting from Q_F to TMP. Alternatively, some manufacturers calculate the ultrafiltration coefficients according to (31.2) from the ultrafiltration rate that is measured with a fixed TMP value.

Values for ultrafiltration coefficients can differ by up to $\pm 20\%$ from information provided by the manufacturer. If one would like to use the ultrafiltration coefficient derived from standard conditions in order to compare different dialyzers, the blood flow rate used (Q_B) must be identical with all comparable measurements. Information is often lacking. Most manufacturers provide the values for ultrafiltration coefficients measured at blood flows of $Q_B = 200$ ml/min, analogously to the corresponding rules for the measurement of clearance.

Lately, UF coefficients measured with blood flow rates of 300 ml/min have been used and are provided in product leaflets, as nephrologists prefer higher blood flows due to the higher performance that can thus be achieved.

31.2.5 Low-Flux, High-Flux, and High-Performance Dialyzers

The classification of low-flux, high-flux, and high-performance dialyzers using their ultrafiltration coefficients varies from country to country. In Europe, low-flux dialyzers are those that have an ultrafiltration coefficient under 10 ml/h mmHg [31.26]. In the USA, low-flux dialyzers are defined with ultrafiltration coefficients of less than 8 ml/h mmHg. High-flux dialyzers vary in their respective values in a large range, beginning from a minimum of 8–10 to over 50 ml/h mmHg. Some organizations and countries, however, set higher low limits as minimums: for example, the HEMO study group (American National Institute of Health, Hemodialysis (HEMO) Study Group) sets > 14 ml/h mmHg, in Germany the regulations have been > 20 ml/h mmHg [31.27] since 2000, and some other authors give > 40 ml/h mmHg for high-flux dialyzers. Some facilities and the Japanese authorities frequently and additionally rate the removal of β_2 microglobulin. Here, the sieving coefficient for this molecule should be greater than 0.6. The general classification is made, however, on the basis of ultrafiltration coefficients.

The ultrafiltration coefficients of high-flux dialyzers may also exceed 50 ml/h mmHg with some FX dialyzers from Fresenius Medical Care, the APS-SYNTRA,

or Polyflux series from the companies Asahi, Baxter, or Gambro when applied in hemofiltration (HF) or hemodiafiltration (HDF). These dialyzers are especially appropriate for convective blood purification procedures. Today one describes high-flux dialyzers with very high ultrafiltration coefficients as a rule as *hemofilters* or *hemodiafilters* as soon as they are used for convective therapy using a substitution fluid.

During the passage of blood through the dialyzer, water is continuously removed through filtration, which is associated by a continuous hemoconcentration along the length of the dialyzer. As a result, plasma oncotic pressure locally increases, so that a reduction of the in vivo ultrafiltration coefficient of the membrane follows. In addition, the hydraulic permeability, or water permeability, of a membrane (ρ) depends on the number and, above all, on the size of the pores as [31.28]

$$\rho = N \cdot \pi \cdot r_p^2.$$

Membrane porosity	=	N	·	π	·	r_p^2	.
		Number of pores				Pore diameter	(31.3)

All treatment parameters that promote or inhibit the pore-blocking effect therefore affect the in vivo ultrafiltration coefficient of the dialyzer. This includes both the actual filtrate flow and the blood flow. During dialysis, cellular components and proteins from the patient's blood are deposited on the dialysis membrane and build up a so-called secondary membrane layer. This phenomenon is described in biotechnology as *filter fouling*. With high filtrate flows, such as in the context of HF and HDF, hemoconcentration and, therefore, also the pore blockade can increase significantly. The resulting increase in plasma oncotic pressure then opposes the (much larger) mechanically generated pressure by blood pumps, which is needed for the removal of fluid during treatment. This phenomenon can be countered by increasing blood flow velocity. As a consequence, shear forces at the membrane surface increase and protein deposits are reduced.

Ultrafiltration Coefficient and Backfiltration

The phenomenon of backfiltration emerged with the advent of high-flux dialyzers. During clinical use, these filters may face a potential chemical or microbiological contamination from the dialysis fluid. Apart from heavy metals, mostly biological contaminants originating from cell wall components of gram-negative bacteria (endotoxins) may enter patients' blood through backfiltration. Since this observation has been described in 1991 [31.29], a *higher UF coefficient* and *backfiltration* have been inseparable terms.

Fig. 31.5 Pressure profiles for blood and dialysis fluid as a function of the length of a dialyzer. If the pressure of the dialyzer fluid exceeds that of blood, backfiltration can take place. Backdiffusion due to available concentration gradients between the dialysate and the blood compartment have also been observed even against an ultrafiltration flux over the entire length of the dialyzer

The term backfiltration describes the transition of fluid from the dialysate to the blood side of the dialyzer. At the blood inlet of the dialyzer, the TMP in the blood compartment exceeds the pressure in the dialysate compartment. As a consequence, ultrafiltration occurs from the blood into the dialysate. With increasing distance from blood inlet, however, the pressure in the blood compartment continuously sinks along the long

axis of the dialyzer to the point where the pressure in the dialysate compartment is higher than that in the blood compartment [31.29]. At this point, a reverse fluid filtration into the patient’s bloodstream can result (Fig. 31.5).

Originally the volume of backfiltered fluid was calculated using the pressure relationships of blood and dialysate in the respective inlet and outlet positions. Today we know that these calculations often overestimate the volume of backfiltration, as the running pressure profiles of blood and dialysate are not similar along the long axis of the dialyzer. They don’t fall linearly, as was earlier assumed. This nonlinear form of profile course is especially characteristic of high-flux membranes [31.30]. It depends on the change in blood viscosity and on small variations in fiber diameter along the long axis of the dialyzer and is also a consequence of the continuously increasing oncotic pressure due to ultrafiltration of water. The danger of contamination of blood through backfiltration with high-flux membranes is countered by the high adsorption capabilities of polymers with aromatic structures containing benzene rings such as polysulfone and, to a lesser extent, polyamide (Fig. 31.6, [31.14]).

Clearance, Dialysance, and K_0A

The clearance of a dialyzer is defined as its volumetric removal rate for a substance dissolved in blood. It corresponds to the amount of this substance that the dialyzer removes from the blood over a unit of time, divided by the respective concentration in the streaming blood. The clearance is calculated as

$$K = Q_{Bi}[(C_{Bi} - C_{Bo})/C_{Bi}] + Q_F(C_{Bo}/C_{Bi}) \quad [\text{ml/min}] \quad (31.4)$$

Fig. 31.6 Polysulfone membranes are able to adsorb endotoxins that are transported from the dialysate side into the membrane. This was shown with an experiment using fluorescently marked endotoxins. These endotoxins were finally adsorbed within the membrane (after [31.14])

or

$$K = Q_{DFi}[(C_{DFi} - C_{DFo})/C_{Bi}]$$

Clearance diffuse portion

$$+ Q_F(C_{DFo}/C_{Bi}) \quad [\text{ml/min}] .$$

Convective portion (31.5)

If the adsorption of blood components at the membrane equals zero, the ultrafiltration rate (Q_F) is calculated from (31.4):

$$Q_F = Q_{Bi} - Q_{Bo} ,$$

Ultrafiltration rate Blood flow at blood inlet Blood flow at blood outlet (31.6)

where K is the urea clearance, Q the flow, and C the respective solute concentration. The subset indices B, DF, and F stand for blood, dialysis fluid, and filtrate. Fluids that stream into the dialyzer contain the additional index i, such as the out-streaming index o. The first two parts of the equations represent the clearance percentage caused by diffusion of a substance, while the last part represents the convective components of the mass exchange. If no ultrafiltration takes place, the last factors are removed. Under standard conditions with dialyzers, mostly the diffusive clearance values are given. This implies that the respective measurements are carried out without additional filtration.

Relevance of Diffusive Clearance Values

For low-flux dialyzers, diffusive clearance values give a reliable measure of clearance for diffusible substances. This does not apply, however, for high-flux dialyzers. For these types of filters, the pressure profiles of blood and dialysis fluid cross in the dialyzer. Even with a Q_F set at 0 ml/min, there is always a filtration of fluid from the blood into the dialysate (*internal filtration*) as well as a reverse filtration from the dialysis fluid into the blood compartment (*internal backfiltration*).

Measurements for the determination of diffusive clearance, i.e., clearance determination with $Q_F = 0$ ml/min, are always subject to the influence of internal filtration or backfiltration. Finally, internal filtration is affected by the concentration profile of soluble substances in the membrane itself as well as along the length of the capillary membrane.

Because the diffusion rate of substances is inversely proportional to the square root of the molecular weight, following the analyses of Einstein, measurements of only the diffusive clearance of substances such as vitamin B₁₂ (molecular weight 1355) and inulin (molecular weight 5200) are of limited practical

value. Various experiments have shown, however, that even under conditions of high dialysis flow rates and thinner membranes, these substances are mainly removed by diffusion. This also applies to drugs such as Vancomycin, which is often used in in vitro experiments in the place of vitamin B₁₂. Still, with increasing molecular size, the proportion of substances removed by convection plays an increasingly important role.

Effects of Flow Rates on Dialyzer Clearance – the K_oA Concept

The clearance of soluble substances is a direct function of blood flow, dialysate flow, and filtrate flow. For the determination of dialyzer performance in in vitro measurements, the flows in a dialyzer to be applied are given as fixed by the Standards Authorities. In clinical reality, however, these values depend greatly on the actual composition of patient blood. Different flow conditions will affect a dialyzer's clearance. Therefore, the factor K_oA has been introduced in order to get normalized values under various clinical conditions.

K_oA stands for the so-called mass transfer area coefficient of a dialyzer and serves to describe the clearance characteristics of a dialyzer under different blood and dialysate flow conditions. A standard formula applies for the conditions of $Q_F = 0$ ml [31.31]:

$$K_oA = [Q_B/(1 - Q_B/Q_D)]$$

Mass transfer area coefficient Factor considers the blood and dialysate flow

$$\cdot \ln[(1 - K/Q_D)/(1 - K/Q_B)] .$$

Factor considers the flow – adapted in vitro urea clearance (31.7)

Alternatively, one can also read the K_oA value from a nomogram (clearance versus K_oA), which is created from in vitro clearance values. Such diagrams are published by dialyzer manufacturers. The determination of K_oA values not only takes into account blood and dialysate flows but also offers other advantages over clearance measurements. With the help of K_oA measurements, a comparison of dialyzers is easily possible that accounts for different membrane surfaces: one simply divides the K_oA values by the individual surface dimensions (A) of the dialyzers.

Membrane Sieving Coefficients

The sieving coefficient (SC) of a membrane is determined from the clearance formula, which represents the convective portion of membrane transport (31.4).

Because the removal of mid-sized molecules occurs primarily by convective ultrafiltration (solvent drag), one defines the sieving coefficient as the relationship between the concentration of a substance in the ultrafiltrate (C_F) to the average value from the sum of concentrations in blood inlets (C_{Bi}) and outlets (C_{Bo}) in the dialyzer, divided by two:

$$SC = \frac{2C_F}{C_{Bi} + C_{Bo}}$$

Sieving coefficient = Concentration relationship feed to filtrate (31.8)

If the SC of a substance is *one*, it refers to an unlimited and unhindered passage of a substance through the membrane. With an SC value of *zero*, the membrane is impermeable to this substance. The area left to the SC curve represents the area for which molecules in so-defined molecular-weight ranges can pass through. To the right of the SC curve are molecules in a molecular-weight range that cannot pass through the filter (Fig. 31.7).

The SC is dimensionless and is mostly only given if the removal of mid-sized molecules is considered, or if high-flux membranes for use in convective treatment modes, e.g., HF or HDF, are applied.

Unfortunately, measurements of SCs have the disadvantage that they are difficult to recognize through the

Fig. 31.7 Sieving coefficient curves for low-flux and high-flux membranes, as well as membranes for liver replacement therapy, all made of polysulfone (PSu). Molecules whose molecular weight is located to the *left of the curve* can pass through the membrane, while molecules with molecular weight to the right cannot penetrate the membrane

elimination of molecules by membrane *adsorption*. The SC describes only the portion of the adsorbed molecules that is also found in the filtrate during therapy.

31.3 Dialysis Machines and Additional Equipment: Use and Conditions

In contrast to the complex physiological regulatory tasks of the natural kidneys, extracorporeal kidney replacement therapies, such as HD, HF and HDF are limited today to the correction of solute concentrations in a patient's blood induced by uremia, primarily correction of changes of metabolites, electrolytes and buffers, and the removal of excess body fluid. Despite the fact that knowledge of uremic retention substances has multiplied in recent years [31.32], the current therapy approach still applies a given exclusion range (cutoff point of the membrane). This is why unselective dialyzers or filters are still state of the art.

With regard to membranes' transport phenomena, renal replacement therapy is still almost exclusively concentrated on diffusive and convective solute transfer. This is also reflected in the design of dialysis machines and their therapeutic management. The use of adsorbents, which in 1980 was projected to be widely used for direct purification of whole blood, has not yet taken place despite different and repeated approaches, at least

in the framework of chronic kidney replacement therapy. Hemoperfusion with adsorber cartridges has only proven itself as an appropriate adsorbent therapeutic procedure in serious poisoning cases.

The technical possibilities for chronic hemodialysis have expanded since its inception in 1961 to a considerable degree, but not all approaches since this time have proven successful. For now, all trends in this area attempt to pursue a maximum removal of uremic retention substances combined with the goal of a reduced patient exposure to inflammatory stimuli. In order to protect patients from the influence of inflammatory stimuli, blood- as well as biocompatible disposables (dialyzers, blood tubing) are successfully used and manufacturing procedures, e.g., use of materials with low leachables and adequate sterilization procedures, have been optimized. Further, the use of chemically and microbiologically highly pure dialysis fluids (dialysates) has become a focus of dialysis therapy. Over the past 15 years, the medical device industry has made significant

progress in this area in both substance as well as cost of these products and, thus, enabled a successful therapy of kidney patients in the long term.

Modern dialyzers, which are appropriate for the OL-HDF form of therapy, combine all the aforementioned characteristics in terms of treatment effectiveness, biocompatibility, patient safety, and cost efficiency in an exemplary manner. The term *hemodiafiltration* (combining the terms *hemodialysis* and *hemofiltration*) therefore describes a form of therapy in which uremic retention substances are removed from the patient's blood through diffusive (dialysis) as well as through a large volume of convective (filtration) methods.

The parallel deployment of both these solute transport mechanisms makes it possible to effectively remove smaller-molecular-weight substances as well as the maximum removal of higher-molecular-weight substances. These most effective forms of treatment according to current standards to treat renal failure were first practiced by *Leber* et al. and described in [31.33].

The use of HF requires the substitution of large filter volumes (15–40 l, in special cases even more) in the form of sterile infusion solutions. The treatment costs resulting from this have prevented the significant spread of this procedure in the years between 1980 and 2000. A way out, as described above, is the so-called *online* production of the requested substitution solutions using cold filtration of the dialysate through the dialyzer itself. It was first described in the literature in 1978 by *Henderson* et al. [31.34]. Approval ambiguities and obstacles, however, have led to a very slow and limited deployment of this promising technique. Commercial manufacturers have offered equipment for this procedure since around 1984, but up to the late 1990s one could not establish a significant equipment base for the general use of HDF.

At least in Europe, however, new authorization rules have led to a continuously increasing inventory of such equipment. Since 2005, Fresenius has presented in its 5008 dialysis machine (Fig. 31.1c) a medical device that offers OL-HDF for the first time not just as an option, but as standard equipment in each unit. The decision to render OL-HDF as a modern standard procedure was based on the overall positive past experiences with this class of equipment and the results of the safety analyses related to these [31.35, 36].

In contrast to the otherwise preferred safe solution realized by a diversity of safety systems, e.g., by means of the combination of an operating and a protection system, the OL-HDF system uses redundant suitable filters with the appropriate return stop rate for viruses, bacte-

ria, endotoxins, and exotoxins. Such membrane filters (e.g., DIASAFE, Fresenius Medical Care) with effective surfaces $> 2 \text{ m}^2$ allow an operating clinical life of up to 3 months. Depending upon the technical execution of the individual device types, two or three filters are used that can be operated alternatively in multiple uses as well as in disposables. In the cost-saving version, only multiply-used filters are deployed, so that their integrity must be established through a strictly prescribed test before the beginning of treatment. Modern equipment conducts such tests within the context of an automated procedure prior to the start of treatment.

The now widespread availability of such systems for OL-HDF have led to an increasing market presence and thus to increasing treatment figures derived on the basis of tentative but mounting evidence about the clinical significance of this technique [31.37]. Retrospectively gathered clinical data indicate, even with cautious interpretation, that the use of effective HDF treatment over longer time periods demonstrates a reduction of patient mortality by roughly 30% [31.37]. Subject to a methodologically comprehensive study, these relationships are reason enough to regard HDF as the method of choice for extracorporeal treatment and clinical implementation for chronic renal failure. This particularly applies because technical developments in recent years have meant that appropriate substitution solutions that meet quality standards can be delivered directly from the dialysate (OL-HDF). This makes it possible to overcome the traditional cost barriers.

A central question in extracorporeal dialysis treatment concerns the need to set the necessary dialysis dose for individual patients whose individual treatment plan must be successfully implemented in individual procedures. This is judged primarily on the basis of urea generation in treatment-free intervals and the subsequent urea removal during treatment based on the adequacy of the treatment. The possibilities and limits of this approach, described as urea modeling, is multi-layered, and its discussion is beyond the scope of this chapter. Treatment planning has traditionally been carried out for the individual patient. It allows for the monitoring of the actually administered dialysis dose for individual treatment only on a sporadic basis, since this monitoring was associated with significant labor and laboratory costs.

Extensive analysis of the data in national and international databases, e.g., United States Renal Data System (USRDS), EDTA/ERA, etc., confirm both the relationship between dialysis dose and mortality as well as the fact that this ideal was not achieved in a signif-

icant number of individual treatments. It is explained by the notion that the proposed dialysis dose was not achieved for a variety of reasons. The now widespread introduction of technical systems to measure dialysis dose in real time through the dialysis machine itself allows for an almost complete review of treatment success, at least in this respect.

The technique used for this purpose mainly measures the conductivity differences in the dialysate before and after use of the dialyzer [31.35]. This allows for effective in vivo determination of urea clearance of the dialyzer and then performs the calculation of the relevant Kt/V dose parameter. The procedure is extremely cost-effective and can be done automatically by the device. The now widespread use of this technology in the devices made by many manufacturers can be considered as one of the main contributions to the quality of dialysis treatment in recent years.

Dialysis patients suffer complications in 20–30% of treatments; the complications include headaches, nausea, vomiting, and loss of consciousness due to a drop in blood pressure. The causes of these events are certainly multifactorial and may vary from patient to patient. However, the process of dialysis itself presents a massive intervention in the various homeostases of the organism, which determines the aforementioned symptoms. Since the mid-1980s, medical research and the industry have endeavored to adjust the intelligent rules systems of dialysis treatment to the individual physiological reactions of patients, so that the incidence of these complications can be reduced to a minimum. In connection with the hemodialysis procedure itself, technical solutions concentrate on approaches that impact the intradialytic cardiovascular stability of patients [31.38].

The relative change in blood-volume-controlled ultrafiltration and the regulation of intradialytic thermal energy of the body are clinically accepted monitoring parameters today. The use of these techniques allows for the reduction of the estimated incidence of dialysis-induced blood pressure drops in patient populations who are predisposed to this condition by about 30–50% [31.39, 40]. At present, studies have focused on easily measurable, but difficult-to-interpret, conductivity differences pre- and postdialysis to determine and, finally, to regulate the electrolyte balance of patients under dialysis. In contrast to the established procedure of automatic ultrafiltration regulation and the control of the thermal energy balance, there are still no reliable clinical data yet available. Without doubt, however, an assessment of this will be possible in the near future, so

that the clinician will be given these three effective ways to make dialysis treatment largely free of complications.

31.3.1 Determination of Fluid Status with Whole-Body Bioimpedance Spectroscopy

Limited renal function strongly influences the water balance of patients with renal failure. Fluid is withdrawn as part of the HD procedure through the ultrafiltration of fluid in order to normalize hydration. Many patients, however, suffer from chronic overhydration, as all current clinical methods are very insensitive to the objective determination of hydration status [31.41].

Pathological changes of the heart, e.g., left ventricular hypertrophy, are triggered by this overabundance of water and increase the mortality of affected patients. It is possible to prevent these dangerous changes in the heart through better hydration management or even to reverse them [31.42]. A clinically deployable diagnostic method to determine hydration status is therefore a prerequisite for this. Extensive analysis of different measurement methods have shown that in particular *whole-body bioimpedance spectroscopy* is an appropriate method [31.41, 43]. The results of these studies were the starting point of the body composition monitor (BCM, Fresenius Medical Care) for objective determination of hydration status.

31.3.2 Description of the Technology and Methodology

Using whole-body bioimpedance spectroscopy, the impedance response of patients is determined over a frequency range of a few kilohertz to the megahertz range (Fig. 31.8). The frequency range of beta dispersion is thereby sampled by a frequency sweep over 50 frequencies. In the lower kilohertz range, the measurement of current flows is only through the extracellular space; at high frequencies, however, both the extra- as well as the intracellular spaces are measured. By modeling as per *Cole* [31.44], the resistance of the extracellular space (R_{ECW}) and the resistance of total body water (R_{TBW}) are calculated.

In order to present a clinically applicable method, these resistances will need to be converted into easy-to-interpret and clinically relevant variables. This is achieved in two steps by the combination of the fluid model [31.45] with a body composition model [31.46] and makes it possible to differentiate overhydration from muscle mass. The clinically usable output vari-

Fig. 31.8 Calculation steps from measured resistances and reactances over the fluid volume for body composition. Extracellular resistance, or R_{ECW} , and the total resistance R_{TBW} are determined on the basis of Cole–Cole modeling using 50 measured resistances and reactances at 50 frequencies. This is possible as at lower frequencies (e.g., 5 kHz) the current flows only around the cells, while at very high frequencies (about 1000 kHz) they can cross the cell membrane. The two resistances thus calculated (R_{ECW} , R_{TBW}) are converted in the fluid model to extracellular (ECW) and intracellular water (ICW). In the next step, the determination of body composition is made (overhydration, lean tissue mass, fat mass) using the body composition model

ables are overhydration, *lean tissue mass*, and adipose tissue mass.

Using BCM, the standard hydration of a patient can be shown as a hydration target. This compares to the hydration status of a uremic patient with a patient with healthy kidney function and the same body composition. The attending physician decides whether to bring the patient to target with a positive or negative offset to standard hydration. It is possible to achieve the intended target after only weeks or months, because only a very cautious withdrawal of fluid can be tolerated by the patient. However, it is crucial that this long goal be kept

Fig. 31.9 Slow reduction of fluid status in a 73-year-old, heavily overhydrated patient over a period of 12 months

in mind even with a changing body composition of the patient (e.g., increased fat mass).

31.3.3 Validation of Clinical Data

The validation of the measured and calculated values is very important, as the BCM allows, for the first time, a quantitative calculation of the hydration status. Validation is carried out in several stages in comparison to then-available gold-standard reference methods.

This includes, for example, the indicator dilution method, total body potassium measurement, and dual x-ray absorptiometry. A complete overview of the validation studies conducted so far can be found in [31.46]. An analysis of 500 European hemodialysis patients further demonstrated that at least 25% of these patients were clearly overhydrated [31.47]. An overhydration of 2.5 l is already associated with a significantly increased mortality [31.48]. It is possible to reduce this overhydration through the design of long-term hydration management programs. Figure 31.9 shows the hydration process in a hemodialysis patient for whom a 7 l overhydration was reduced to 1.5 l within a year.

31.4 Blood Purification in Liver Replacement Therapy

In an issue of the American magazine *Newsweek*, hepatitis C virus (HCV) was termed an *insidious killer virus*, which has already infected several hundred million people globally [31.49]. HCV is responsible for

20% of acute and 70% of chronic liver inflammation. The associated hospital costs are immense. They amount in the USA alone to more than \$5.5 billion [31.50]. Liver transplantation, which is the only

possible therapy for many patients, is, however, not an alternative in the short term due to the insufficient supply of available donor organs, and the waiting list for liver transplants is steadily increasing.

Detoxification procedures on the basis of extracorporeal blood circulation have therefore become the basis for liver support systems. Initial work on membrane processes started in 1992 [31.51]. A basis for recent developments is the dual function of the liver, considered both as a detoxification organ and as an organ for synthesizing clotting factors, proteins, and hormones. Extracorporeal circulation for liver replacement therapy should ideally support or replace both functions.

31.4.1 Detoxification

In contrast to most uremic toxins, which are removed by dialysis because they are water soluble by nature, liver toxins are mostly protein (albumin)-bound and accordingly have hydrophobic (lipophilic) properties. Because of the relatively low-molecular-weight cutoff for typical hydrophilic dialysis membranes (membrane cutoffs are below the molecular weight of albumin), even modern dialysis membranes are not suitable for detoxification in liver replacement therapy. New therapeutic procedures such as molecular adsorbent recirculating system (MARS) (Gambro, Fig. 31.10) and the Prometheus System (Fresenius Medical Care, Fig. 31.11) use membranes that are able to remove albumin-bound liver

Fig. 31.10 Schematic principle of MARS. The blood of a patient with liver disease is transmitted over the *MARS flow filter*, whereby, according to the inventor, the albumin-bound toxins are led through the membrane into the secondary circuit. They are then bound to the *free* albumin molecules available in the secondary circuit. Two adsorbers in the secondary circulation, an active charcoal and an anion exchanger, clean this albumin solution online, so that free albumin molecules can continue to be used for further absorption of toxins

toxins from the bloodstream and discard them in a secondary circuit with the help of adsorbers [31.52, 53]. Following the postulated mechanisms of the respective

Fig. 31.11 In extracorporeal circulation of the Prometheus system, also known in the literature by the abbreviation FPSA – fractionated plasma separation and adsorption (Fresenius Medical Care, Bad Homburg, Germany) – albumin-bound liver toxins are depleted by a highly permeable plasma filter in the primary circuit. Albumin is then purified in two adsorber columns of the secondary circuits (prometh 01 and 02). It is then returned to the patient's bloodstream. Subsequent serial dialysis continues to provide the removal of small-molecule liver toxins, such as ammonia (NH_3)

inventors of MARS (see below), high-flux membranes are used here [31.52, 54] that allow the passage of albumin, while in the Prometheus system protein-permeable membranes are used [31.53, 55]. Clinical trials have already demonstrated the effectiveness of these procedures [31.52–57].

The MARS system (Fig. 31.10) has already been available since the 1990s [31.52, 54, 56, 57]. More than 10 000 patients with liver disease have been treated by the MARS system, and therefore, the largest database in the area of liver replacement therapy is available in this realm.

MARS (originally produced by the Teraklin company, Rostock, now offered by GAMBRO AB, Hechingen) is an extracorporeal blood purification system with a primary, a secondary, and a tertiary blood circuit. As in HD, the patient's blood is circulated for 4 to 6 h through a high-flux filter (MARSflux Filter). A buffered 5–10% commercial albumin solution (150 ml/min) is circulated in a closed secondary circuit, which cleans with two adsorber columns made of active carbon and an anion exchanger. Furthermore, the secondary circuit is supplemented by a tertiary circuit that contains an additional low-flux dialysis filter. This filter permits the diffusive removal of small molecular toxins.

With MARS it is possible [31.52, 56, 58] to separate albumin-bound toxins from the albumin in the blood and to transfer them through a not yet completely understood mechanism into the secondary circuit. Here, it is picked up by the then-circulating free albumin and is removed through the adsorber column. Thus, the secondary circuit always presents free albumin to take up toxins.

The Prometheus system [31.53, 55, 56] for extracorporeal liver replacement therapy (Fig. 31.11) contains, in contrast to MARS, an albumin-permeable filter whose SC curve has been shifted to higher molecular weights in comparison to dialysis, as shown in Fig. 31.7.

By shifting the SC curve to higher molecular weights, one obtains membranes with a cutoff of $> 200\,000$. Using this, the patient's own plasma and toxins bound to albumin can be filtered. Blood cells and large proteins, e.g., IgM, are retained, as their SC is 0.

Using the two adsorbers *prometh 01 and 02*, which are set in series in the secondary circuit, it is possible to clean the patient's own and toxin-laden albumin. Blood can then be led back into the patient. The adsorber particles consist of neutral resins (*prometh 01*) or are anion exchangers (*prometh 02*) with a large internal surface area (about $120\,000\text{ m}^2$ per cartridge with a particle diameter of about $400\ \mu\text{m}$). Lipophilic as well as elec-

trically charged toxins, such as bilirubin, can thereby be removed.

Anticoagulation is carried out in liver replacement therapy similarly to HD, with the administration of heparin. Recent studies in the field of HD have shown that anticoagulation with sodium citrate may better address the specific pathological conditions for liver patients [31.59–61]. For regional coagulation, which applies exclusively to extracorporeal blood circulation, two pumps replace the necessary heparin pump. The first pump advances a citrate solution (4% trisodium citrate) from the albumin filter into circulation. Citrate forms a chelate complex with ionized calcium and magnesium. Blood clotting can be reduced by minimizing $\text{Ca}^{2+}/\text{Mg}^{2+}$ volumes, at best to a concentration under 0.2 mmol/l , because these ions are cofactors in the coagulation cascade. In contrast to work in the older literature, which showed no dependence of activated clotting time (ACT) on Ca^{2+} levels in blood [31.62], observations by *Falkenhagen* at the Donau University in Krems, Austria [31.63] have shown that a lengthening of clotting time has been observed if one is able to reduce the Ca^{2+} level to below 0.2 mmol/l . The initial coagulation status after blood has passed through the extracorporeal circuit is achieved again if the patient is infused with a diluted solution of calcium ions through the second pump. It is important to know that the sodium citrate needed to reduce the calcium depends upon the hematocrit of the treated patient [31.58]. A significant and positive side effect of anticoagulation with sodium citrate solutions and the related reduction of calcium and magnesium concentrations is the lower complement activation [31.58].

In order to prevent hypercalcemia as well as hypocalcemia, it is necessary to measure and control calcium concentrations within defined intervals. The Prometheus system's CiCa device continuously adjusts the necessary physiological concentration of the calcium solution through the use of algorithms.

31.4.2 Synthetic Liver Function

Biological cells have characteristics that are so well designed that no engineer could copy them easily. It is feasible to treat liver patients by the supplementation of necessary proteins, hormones, and clotting factors, but the costs, also due to the related purity requirements, would be immense. Therefore, the use of liver cells in bioreactors for extracorporeal circulation should be seen as a possible solution. Liver cells can

be sensitive and be synthetically continuously active if the conditions of the cell culture in the bioreactor are at an optimum. In the past this has not been possible as the survival of isolated hepatocytes in vitro has been quite short (less than 1 week). The development of three-dimensional bioreactors in which liver cells can be cultivated in their entirety, i. e., all the cells present in the liver are grown, and are not just exclusively hepatocytes, allows for treatment periods of 1 to 2 months.

Thus, a bioreactor for extracorporeal treatment of patients with liver disease is a realistic therapeutic medium. Clinical applications of bioreactors with liver cells have so far not been satisfactory [31.64], but they offer promising prospects. However, a broad application of such bioreactors has not yet met the necessary European criteria for approval for a bioreactor for human therapies, as such a device would be categorized

as a *medicinal product* (pharmaceutical drug) due to its *principal mode of action*. The newly established regulations for advanced therapy medicinal products (ATMP) by the European Commission exclude the possibility of considering such a bioreactor a *medical device* [31.65]. As a consequence of this regulation, expensive clinical trials with large patient numbers would be required for approval. This creates difficulties for small and medium-sized enterprises (SMEs) for cost reasons.

Conclusion for Liver Replacement Therapy

It is possible that the two major liver functions, detoxification and synthesis, can be at least partially replaced through extracorporeal blood circuits, so that therapeutic success would be possible. Clinical trials with adsorber systems show promising results that have already led to approval for a detoxification system in liver replacement therapy.

Heart-Lung

32. Heart-Lung Machines

Ulrich Böckler, Andreas Hahn

During cardiac surgery and interventions on the large vessels, it is often necessary to disconnect the heart and lungs from the natural circulatory system and to stop them from working temporarily. When open heart surgery or coronary interventions are carried out, the heart and lung function is usually taken over by an external heart-lung machine (HLM). This procedure is also referred to as extracorporeal circulation (ECC) (Sect. 32.2) or cardiopulmonary bypass. The function and technical details of HLMs are described in this chapter.

32.1 Historical Development of Extracorporeal Circulation

The French physiologist Julien Jean César *Le Gallois* wrote down the first realistic principles of ECC in his monograph [32.1] in the early nineteenth century. He suggested replacing the function of the heart with a continuous injection of natural or, if possible, artificially produced blood.

This concept was, however, only implemented in 1828 by *Kay* [32.2] and, several years later, by *Brown-Séguard* [32.3]. In 1849, the German scientist *Loebell* [32.4] also experimented with isolated organ perfusion. He examined the secretions from explanted kidneys that had been artificially perfused. Ernst Bidder repeated these experiments using a pressurized container that served as a volume reservoir for artificial

perfusion. In 1867, *Schmidt* [32.5] from the Institute of Physiology in Leipzig refined this perfusion technique. He managed to influence perfusion flow and pressure during artificial perfusion using a container that could be elevated and lowered. However, the enrichment of blood with oxygen was yet to be achieved.

Artificial oxygenation of the blood during the perfusion of organs was not achieved until 1882 when *von Schröder* [32.6] invented a device for dispensing air directly into the bloodstream for oxygenation. However, this only partially met the basic requirement for artificial oxygen enrichment since extreme foaming made it unsafe to use this method at this point in time.

In 1885, *von Frey* and *Gruber* [32.7] developed the first forerunner of the modern HLM at the Institute of Physiology in Leipzig. It contained a film oxygenator with a rotating glass cylinder that oxygenated blood artificially. Von Frey and Gruber were the first to use a syringe pump with a corresponding valve control for perfusion in a closed system.

In 1890, *Jacobj* [32.9] from the Institute of pharmacology in Strasbourg (France) presented his invention, the hematisator, a blood pump that was capable of generating a pulsatile flow. Controlled by two valves, a rubber balloon was compressed rhythmically by a seesaw lever driven by a water motor. *Jacobj* was aware of the problems associated with the oxygenation processes of his time and focussed on a new technique. He used explanted isolated lungs, explaining that these were much easier to manage. This involved perfusion of two organs, and for this reason he would later name his device the double haematisator.

It was half a century later that *Gibbon* [32.10] finally achieved the revolutionary breakthrough. After 20 years of development, the surgeon from Jefferson Medical College in Philadelphia produced an HLM. He had constructed a pump oxygenator in 1934, which he used to take over the heart and lung function of cats that had had their pulmonary artery clamped for 25 min. Experiments on rabbit and monkey lungs carried out in the 1950s in the USA were less successful. In 1950, *Gibbon* received financial and technical support from the computer company IBM.

The rapid technical advancement and improved knowledge in the field of physiology made it possible to finally use the device on a human patient. *Gibbon*'s device, based on a roller pump and his screen oxygenator, was used for the first time in 1952. His first patient, however, died as a result of a misdiagnosis.

On 6 May 1953, *Gibbon* used the HLM successfully on a human for the first time. The 18-year-old female patient was suffering from a congenital atrial septal defect. The machine was used for 45 min in a partial bypass, including 26 min in a total bypass, completely taking over the heart and lung function. That year, *Gibbon* performed four further operations that were, however, unsuccessful.

Despite *Gibbon*'s major breakthrough in the history of cardiac surgery, scientists concentrated on the results published by in 1949 *Bigelow* [32.11], who stipulated that the body core temperature had to be lowered as a prerequisite for corrective surgery with circulatory arrest. Hypothermia slowed down the metabolism, which allowed the venae cavae to be clamped for a short time

without causing damage to the sensitive organs as a result of oxygen deprivation.

In 1953, *Lewis* [32.12] from Minneapolis successfully managed to close an atrial septal defect using surface hypothermia. Several years later, *Sealy* [32.13] combined profound hypothermia and partial cardiopulmonary bypass to perform corrective surgery.

In early 1954, *Lillehei* [32.14] made a name for himself with his concept of cross-circulation (Fig. 32.1). Artificial blood oxygenation and the use of an HLM were not required for this procedure. Cross-circulation involved the continuous reciprocal exchange of blood between two individuals. The donor, who had an identical blood type to the patient, served as the oxygenator for the patient's blood. The arterial donor blood was pumped into the recipient's circulation using a Sigmamotor pump.

On 26 March 1954, *Lillehei* carried out the first surgical procedure using cross-circulation. As a result, more complex congenital heart defects, such as ventricular septum defects and Fallot's tetralogy, could be treated surgically with success for the first time.

However, as the disadvantages of cross-circulation, such as reduced pump volume, outweighed the advantages when compared to the HLM, the procedure was

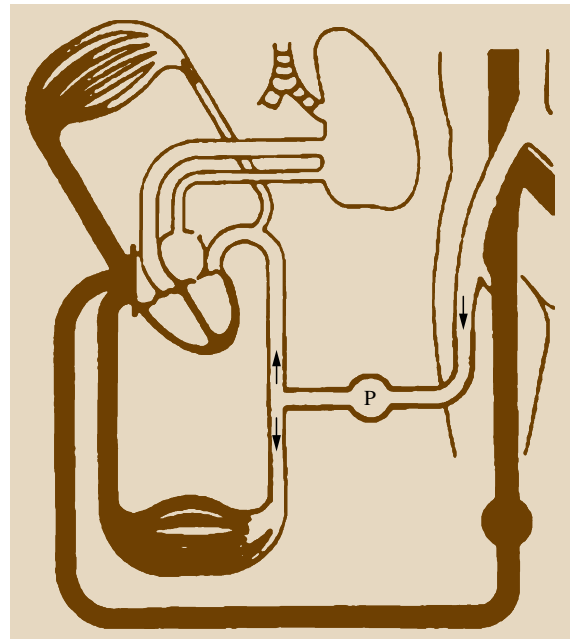

Fig. 32.1 Principle of cross-circulation according to *Lillehei* using a donor to oxygenate the patient's blood (after *Galetti* and *Brecher* [32.8])

not widely used. Cross-circulation also put both patient and donor at great risk and had a high mortality rate.

In 1955, *Kirklin* [32.15] carried out a further series of surgical procedures on patients with congenital heart defects at the Mayo Clinic in Rochester, MN, USA. He used the Mayo–Gibbon HLM, which had been improved in the intervening years. The biggest problems were the amount of fresh blood preserves (5–11 units) needed to prime the HLM and the risk of lethal embolisms caused by foaming blood, which meant that a controlled low blood flow through the oxygenator was a prerequisite. At first, Sigmamotor pumps were available as blood pumps. Later, Gibbon adopted the roller pumps first described by *Beck* in 1924 [32.16], which were utilized for transfusions. These roller pumps were later named after their advocate *De Bakey* [32.17].

32.2 Extracorporeal Circulation

ECC or perfusion is defined as a procedure carried out with the aid of an HLM.

In the early stages, cardiac surgery was mainly concerned with the treatment of congenital heart defects. Today, the main focus is on acquired heart defects. If heart disease cannot be treated with drug therapy or cardiologic intervention, cardiac surgery becomes necessary.

The term minimally invasive cardiac surgery relates to an alternative method in which the access path to the operation area is kept as small as possible to reduce the patient's surgical trauma. This primary surgical technique usually has a direct influence on the configuration of the HLM and on the way the perfusion is carried out. OPCAB (off-pump coronary artery bypass) as well as off-pump have also become established terms and refer

The development of different types of oxygenators such as bubble, film, disk, spiral coil, and membrane oxygenators in the mid-1950s led to further advances in cardiac surgery. The first commercially manufactured membrane oxygenator went on sale in 1967.

Alongside *Zuhdi's* [32.18] realization in 1961 that an HLM could be primed without blood, the use of an integrated heat exchanger to induce hypothermia by directly cooling the blood was an important development.

In 1962, the authors *Galetti* and *Brecher* [32.8] described the *ideal perfusion* as an intervention in which the heart and lung function is taken over completely by a machine with minimal detrimental effect on the body. Although advances in device technology and material science, new surgical techniques, and improved perfusion techniques have led to significant strides toward achieving this ideal, perfection has yet to be achieved.

to cardiac surgeries carried out without the support of an HLM.

ECC has evolved from its beginnings in the area of experimental organ perfusion to a routine procedure for open heart surgery. It will always be necessary when surgical intervention is carried out on an arrested heart or when assisted perfusion is required to support circulation on a beating heart.

The HLM can never be looked at in isolation. Additional components, mainly in the form of sterile disposables such as an oxygenator, heat exchanger, or reservoir, take on other important functions during ECC and are also described below. This is essential for understanding the extremely complex overall system of the HLM and its functions.

32.3 Structure and Function of the Heart–Lung Machine

The HLM is the basis of ECC and assumes two important organ functions once the cardiopulmonary bypass has been established:

- Pump function of the heart
- Gas exchange function of the lungs

A sufficient perfusion volume that corresponds to the normal cardiac output of the patient under anesthetic and an adequate perfusion pressure (50–90 mmHg) are

of particular importance during any ECC. The HLM must also ensure sufficient oxygenation, elimination of CO₂, and control of the blood temperature.

The following components make up the basic equipment of the ECC that is used during modern cardiac surgery:

- Blood pumps
- Oxygenator
- Tubing system with various tubing diameters

- Blood filters with various functions
- Cardiotomy reservoir
- Cannulae and intracardiac suction tubes

Because the HLM and the disposables must be regarded as a closed and functional unit, they must be set up in a certain way. ECC is always based on the same principle.

Venous blood is transferred from the venous vascular system (usually both venae cavae or the right atrium) to the cardiotomy reservoir using cannulae. The so-called arterial blood pump (roller pump or centrifugal pump) then actively pumps the blood from the cardiotomy reservoir through the so-called oxygenator and through another cannula back into the arterial vascular system (usually the aorta ascendens).

An additional arterial filter is located between the oxygenator and the arterial line leading back to the patient to filter-aggregated leukocytes and platelets, cell and tissue debris, denatured protein, air, and particle abrasion from the tubing system. Additional pumps are needed for cardiotomy and vent suction or as cardioplegia pumps.

During the intervention, cardiotomy suction tubes can be used to aspirate blood from the operation area in order to keep it free of blood.

Vent suction tubes aspirate directly from the heart chambers to prevent overextension of the arrested heart with excessive blood volume, which could cause extensive damage. The aspirated blood is collected, filtered, and defoamed in the cardiotomy reservoir and is usually fed back directly into the extracorporeal system.

Cardioplegia pumps are used to administer cardioplegic solutions into the aortic root or selectively into the two coronary ostia with volume, time, and pressure control.

32.3.1 Blood Pumps and Their Function

Blood pumps can generally be categorized into two groups, depending on their function:

1. Roller pumps
2. Centrifugal pumps

Essentially, both pump types should meet certain criteria when used with the HLM:

- Dosed delivery of liquids, with precise display of the actual flow rate
- Ideal ratio of size to delivered volume
- External control mechanism (e.g., for monitoring functions)

- Sufficient pressure or vacuum generation
- Minimal blood damage
- Adjustable occlusion settings (roller pumps only)
- Pulsatile flow generation
- High efficiency
- High reliability and safety
- Option for emergency operation (e.g., manual operation)

Roller Pumps

De Bakey blood pumps are based on the displacement principle and deliver blood through a tubing segment from the pump housing using rotating rollers. The roller pump consists of a rotating pump arm with two attached cylindrical rollers and a pump housing into which a semicircular silicone tubing segment is inserted and then secured using special tubing inserts.

The rotating rollers alternately compress the tubing segment and deliver the liquid contained in the tubing in accordance with the rotational speed and direction. The exact adjustment (occlusion) of the two rollers determines the delivery. When a central thumbwheel is turned, the occlusion rollers move outward symmetrically and occlude the inserted tube evenly. This reduces erythrocyte damage caused by shear stress or direct crushing.

Centrifugal Pumps

Centrifugal pumps do not use direct displacers and are therefore nonocclusive pumps. Such pumps use centrifugal forces to transport the blood instead of tubing compression. Because of the technical principle of operation, the centrifugal pump has a limited application. Although it can be used as an arterial pump, it has no application as a suction pump. Centrifugal pumps have the advantage of delivering limited amounts of air and causing less blood damage in the long run. The fact that an additional flow meter is required to determine the delivered flow is a disadvantage.

32.3.2 Oxygenator and Gas Exchange Function

The artificial lung, also called the oxygenator, takes on the lung function during ECC and is therefore responsible for the exchange of vital gases. So-called membrane oxygenators are now used as standard. They contain a semipermeable membrane in the shape of a microporous hollow fiber. This liquid-impermeable membrane separates the gas side from the bloodstream.

Due to the partial pressure gradients, O_2 and CO_2 diffuse through the microporous membrane. A correspondingly adjusted supply of air and O_2 on the gas side allows for selective and exact control of paO_2 and $paCO_2$ on the blood side.

Today, most membranes are made of polypropylene or polyethylene and permit operating times of 6–8 h.

32.3.3 Tubing Systems for Extracorporeal Circulation

The tubing system is used to connect the individual components of the extracorporeal system and forms a closed circuit with the vascular system of the patient. Depending on the location, either PVC or silicone tubing is used, which is available in different diameters and wall thicknesses. Tubing sizes range from a diameter of 1/8" and a wall thickness of 1/16" to 3/16" and 1/4" for pediatric applications (with correspondingly low flow rates). Tubing for adult applications is usually 3/8" or 1/2" with a wall thickness of 3/32", facilitating flow rates of more than 10 l/min. In order to achieve the desired flow when small tubing diameters are used, active pressure or suction (within certain limits) is used in the respective line.

Tubing with the smallest possible lumen and shortest possible length is used to keep the priming volume and system foreign surface as small as possible. In contrast to the pioneering days of ECC, modern medicine uses completely preassembled disposable systems manufactured under clean room conditions (Fig. 32.2).

Although the number of HLMS, components, and applications on the market is relatively small, there is practically no standardization and a wide range of customer-specific preassembled tubing systems is available.

32.3.4 Blood Filters

Blood filters are integrated into the ECC system mainly to avoid micro-embolisms caused by autologous influences, foreign particles, and microbubbles.

Depth Filters

Depth filters, made of Dacron wool or polyurethane foam, are inserted into cardiotomy reservoirs and are used mainly for particle filtration. The pore size can vary from 80–100 μm (coarse separation of particles) to 20–40 μm (micropore range).

Mesh Filters

Mesh filters are used as arterial blood filters and work on the principle of sieves. The pore size of mesh filters ranges from 20 to 40 μm . The material is a mesh of woven polyester strands. Unlike depth filters, mesh filters have little adhesive force. Their air retention properties are excellent as air bubbles can only pass the filter medium when a certain pressure difference (bubble point pressure) is reached.

32.3.5 Cardiotomy Reservoir

The cardiotomy reservoir collects and filters the blood aspirated from the operation area and feeds it back into the ECC as required. At the same time, it provides volume storage. The transparent housing facilitates continuous level control. A detailed scale makes it easy to quantify the level and detect corresponding changes in volume.

A minimum residual volume always remains in the reservoir during the entire ECC to prevent air delivery into the extracorporeal system. The blood flow or the blood–air mixture passes through a defoaming module

Fig. 32.2 Completely preassembled tubing system with infant oxygenator (Sorin Group S.p.A., Milan)

integrated into the reservoir and a combination of depth and mesh filters for optimal filtration.

The incoming and outgoing tubing can be plugged or screwed into the different types of connectors on the cardiotomy reservoir.

Hard-shell reservoirs that are exposed to air are used alongside pure venous reservoirs in the shape of a collapsible bag. The advantage of these soft-shell reservoirs is that the blood volume does not come in direct contact with air. In this case, the suction tubes are connected to a separate reservoir. These systems are referred to as *closed* or *semi-open*.

32.3.6 Cannulae

Cannulae are the interface between the ECC system and the vascular system of the patient. They are inserted into the relevant vessels by a surgeon, where they are secured and deaerated before their sterile connection to the tubing system of the HLM.

Arterial Cannulation

Arterial cannulae are used to return the oxygenated blood to the systemic circulation of the patient. The aorta ascendens is the most frequently used site. Depending on the type of intervention and surgical access path, an alternative site such as the femoral artery or iliac artery may be preferable or necessary.

The type and size of the selected cannula depends on both the required blood flow and the anatomic conditions.

Arterial cannulae are available in different sizes, with straight or bent tips, suture or flange collars, and optionally with wire reinforcement or length markings.

Venous Cannulation

Venous cannulae drain the patient's blood from the venous vascular system to the extracorporeal system.

The most commonly used cannula is the so-called two-stage cannula. The tip of the cannula with its side openings is placed in the vena cava inferior, and the blood from the vena cava superior and the right atrium is drained through the side openings in the second stage.

The type and size of the selected cannula is determined by conditions that are similar to those on the arterial side. However, venous cannulae are actually larger because the blood flow in the venous branch is usually caused by hydrostatic suction alone.

Two cannulae may be used on the venous side, if required, depending on the surgical access path or on the fact that the right atrium of the heart needs to be

bloodless. These drain the blood from the two large venae cavae or from the vena femoralis and vena jugularis separately.

Vent Catheters

A so-called vent suction tube is also inserted to protect the temporarily arrested heart and especially the left ventricle from overextension due to blood flowing back from the Thebesian veins and bronchial circulation.

Using this vent suction tube, excessive blood is drained usually via the auricle of the left atrium or a side port of the cardioplegia cannula into the cardiotomy reservoir of the HLM.

Cardioplegia Cannulation, Myocardial Protection

Cardioplegia is defined as a reversible, artificially induced arrest of the heart. This is required for most cardiac interventions to create an operation area free of movement for the surgeon or, if the heart muscle or vessels close to the heart need to be opened, to allow access to the heart valves or to the internal structures of the heart.

The induction of a cardioplegic heart arrest usually requires a process called myocardial protection. As the name implies, this involves protection of the arrested heart muscle. The most common method of plegia and myocardial protection is the administration of cardioplegic solutions. The administration of hyperkalemic solutions interrupts the conduction pathway and hence the mechanical activity of the heart.

Blood, electrolytes, colloids, and crystalloids are some of the base solutions available. Myocardial arrest, the administration of cold cardioplegic solution, and to a certain extent additional external cooling lead to drastically reduced oxygen consumption and thus represent the most important mechanisms for protecting the myocardial cells.

Immediately before the heart arrest is induced, the aorta ascendens is clamped between the aortic valve and the aortic cannula. The cardioplegic solution is then administered directly or indirectly into the coronaries. Depending on the nature of the surgery planned and other factors, there are two methods of administration. Antegrade administration delivers the solution via the aortic root or directly into the coronary ostia on the arterial side. Retrograde administration delivers the solution via the coronary sinus on the venous side.

A variety of different cannula types is available for both methods. If the aortic valve is sufficient, the cardioplegic solution can be administered via the aortic root

using an aortic root cannula. After the cardioplegic solution is administered, the cannula serves as an aortic root vent for left ventricular relief and deaeration. If the aortic valve is insufficient, the cardioplegic solution cannot be infused via the aortic root. With the aorta clamped, the incompletely closed aortic valve would cause a retrograde flow of the solution into the left ventricle. In this case, myocardial protection has to be carried out by direct selective catheterization of the coronary ostia using coronary perfusion cannulae.

In the case of retrograde administration, the cannula is inserted via the right atrium. The cardioplegic solution is then administered via the coronary sinus. This is an effective way of reaching the poststenotic areas of the heart muscle in particular as stenoses are not prevalent in the venous coronary system. This leads to optimum distribution of the cardioplegic solution and considerably improves myocardial protection.

32.4 Components of the Heart–Lung Machine

Section 32.4.1 lists the most important basic components of modern HLMS and provides a brief description.

32.4.1 Basic Components

Basic components are online gas and blood gas analysis in the form of measuring devices for the measurement and display of gas flows, gas concentrations in the gas flow, and saturation or partial pressures directly in the blood flow:

- Mobile console for mounting multiple pumps; includes the power supply, emergency power supply, and electronics.
- Adjustable mast system for mounting the holders for the oxygenator, filters, cardiotomy reservoirs, external pumps, and additional devices.
- Blood pumps
 - Large roller pump: pump with a longer tubing path in the pump housing that produces higher flow rates, required for the arterial blood flow, suction, or vent pump (Fig. 32.3).
 - Small roller pump: pump with a shorter tubing path in the pump housing for lower flow rates, e.g., for the perfusion of infants and children or for the administration of cardioplegic solutions, usually a double pump (Fig. 32.4, Table 32.1).
 - Centrifugal pumps: pumps for the arterial blood flow.

The infusion of cardioplegic solutions against the normal coronary vascular blood flow has proved particularly successful during coronary reoperations when inadequate native coronary flow is a factor, in the case of insufficient coronary artery development, as well as for patients who are at risk of embolization caused by arteriosclerotic material.

Intracardiac Suction Tubes

Intracardiac suction tubes are used to keep the operation area free of blood by aspirating blood from this area into the cardiotomy reservoir.

Cardiotomy suction is an important factor as it contributes greatly to blood damage. Shear stress at the tubing tips is not the only, or even most important, cause of blood damage; it is caused mainly by the constant mixing of blood and air, which leads to massive blood damage through hemolysis.

- Control and monitoring devices
 - Pressure monitor, including sensors, for measuring different pressures in the extracorporeal system and for controlling the flow rates accordingly.
 - Temperature monitor, including sensors, for measuring and displaying different system temperatures and, if required, patient temperatures.
 - Level monitor including sensors, for measuring and controlling the volume level in the cardiotomy reservoir and for regulating the arterial pump flow correspondingly.
 - Bubble monitor in the form of ultrasonic sensors that regulate the flow rate of the affected pump when air is detected in the system.
 - Pulsatile flow control for creating and controlling a pulsatile flow profile.

Fig. 32.5 Extract from a perfusion log with graphics and various patient and intraoperative data

- Cardioplegia control, including pressure and bubble sensor, for controlling cardioplegia delivery.
- Timer for measuring important times and intervals during perfusion such as total perfusion time, aortic clamping time, and reperfusion time.
- Display and control panel, providing access to all display and control elements described above as well as to additional system information and alarm management.
- Electronic or mechanical gas blender, for controlling and displaying the ventilation gases (air, O₂, and CO₂) that are delivered to the gas side of the oxygenator; vacuum controller, for the precise control and display of a permanent vacuum on the venous reservoir.
- Anesthetic gas vaporizer, allowing and displaying the administration of a precisely dosed amount of anesthetic gas to the oxygenator.
- Electronic documentation system that displays and stores all relevant data during perfusion. All data are stored centrally and displayed instantly as a perfusion report (Fig. 32.5), which allows for data evaluation at a later stage for statistical and scientific purposes.

Figure 32.6 shows a modern HLM.

32.4.2 Additional HLM Components

During ECC, the heat exchanger of the oxygenator indirectly regulates the patient's body temperature by heating or cooling the blood flow. Patients can also be placed on a water mattress that increases or decreases body temperature.

Heater–Cooler Device

For this purpose, the heater–cooler device delivers water with a temperature ranging from 2 to 42 °C. Two-chamber pumps ensure that the delivered water does not cause a buildup of overpressure in the circuits.

Modern heater–cooler devices feature several circuits with different temperatures. Two circuits supply the oxygenator and the heating/cooling mattress, while a third is connected to the heat exchanger in the cardioplegia system. The heat exchanger is supplied from two

Fig. 32.6 Industrial heart–lung machine with panel PC and data management system (Sorin Group, Munich)

independent tanks with different temperatures, which allows instant switching from cold to warm or vice versa.

Ideally, a remote control is integrated into the control panel of the HLM, which facilitates operation of the device and allows it to be placed outside the operating theater, leading to considerably lower noise levels in the OT.

Heater–cooler devices have always presented a hygiene challenge because the system parts that transport water inevitably become contaminated by germs. Regular water changes and the use of appropriate chemical cleaning agents are the two most effective cleaning and maintenance strategies.

32.5 Extracorporeal Circulation

Perfusion in ECC is an extremely complex process and plays a central role during cardiac surgery. The op-

eration and monitoring of the HLM is the exclusive responsibility of the perfusionist, who discusses ev-

ery action and decision with the operating surgeon and the anesthetist. Clear communication among these three parties is essential, especially at the beginning and end of ECC and in the event of irregularities and situations that require coordinated action.

The following section describes the course of a standard perfusion without making reference to the wide range of modified procedures.

32.5.1 Preparing the ECC

ECC begins with the selection of the required materials, followed by the setup, priming, and technical function test of the HLM.

The perfusionist mounts the components of the sterile disposable set in the relevant holders, inserts the tubing into the pump heads, and places temperature probes and bubble, flow, and pressure sensors in the appropriate positions. All connections are checked and secured as necessary.

The dry, sterile system is then primed with a mixture of different solutions and drugs, completely vented, and checked for leaks.

Using a checklist, the relevant settings, connections, functions, and alarms are checked and documented.

The arterial and venous lines are connected using the appropriate cannulae, which the surgeon has previously placed in the large vessels of the patient, connecting the blood circuit of the patient to the extracorporeal system.

The coagulation system is deactivated by the systemic administration of approximately 300–350 IU/kg of heparin before the cannulae are placed and the perfusion is started.

32.5.2 Carrying Out the Perfusion

The initiation of ECC is a major intervention that affects the entire organism and all vital functions of the patient. The following steps take place simultaneously at the start of perfusion.

- The perfusionist opens the venous line in consultation with the surgeon and the anesthetist and, by virtue of the hydrostatic differential, drains the blood from the venous vascular system of the patient into the venous reservoir of the HLM.
- The arterial pump is started and the blood flows from the HLM into the patient's arterial vascular system. The flow is increased until inflow and outflow are balanced. A previously calculated per-

fusion flow serves as a theoretical point of reference and corresponds to an artificial heart time volume.

- Depending on the blood flow, the oxygenator is supplied with a mixture of air, O₂, and anesthetic gas or CO₂ as required. This mixture is determined and controlled by mechanical or electronic gas blenders.
- The heater-cooler device supplies the heat exchanger in the oxygenator with warm or cold water and regulates the temperature.

The perfusionist continuously monitors and regulates the parameters and keeps them within the desired range.

- Perfusion flow.
- The HLM generates the blood flow that is required to perfuse the organs and the microcirculation sufficiently. This blood flow is first calculated by multiplying the body surface area with a so-called flow index (similar to the natural heart index). This theoretical index ranges from 2.4 and 3.0 l/m² body surface/min and depends on several factors, e.g., temperature, hematocrit value, body fat percentage, and depth of anesthesia. The perfusion flow must then be adjusted on the basis of parameters such as oxygen saturation, partial O₂ pressure, and other situational factors.
- Temperatures:
 - Blood temperature in the arterial and venous lines of the extracorporeal tubing system
 - Set and actualize temperatures of the heater-cooler device
 - Temperature of the cardioplegic solution
- Pressures in the extracorporeal tubing system.
- During perfusion, pressure measurements before and after the oxygenator and, if required, before the arterial cannula in the cardioplegia line or before the hemofilter result in an automatic flow adjustment of the assigned arterial pump (visual and acoustic alarm).
- Pressure monitors have two modes of operation:
 - Start-stop mode, i.e., the assigned pump is stopped when the set pressure value for the pump stop is reached and is restarted automatically only after the pressure has decreased;
 - Control mode, i.e., the pump slows down when the set pressure value for the pump control is reached and is only stopped when the stop pressure is reached.
- Perfusion times:
 - Total perfusion time
 - Aortic clamping time

- Reperfusion time
- Circulatory arrest times, head perfusion times, or hemofiltration times (where applicable)
- Level monitoring in the cardiotomy reservoir.
- Level monitoring protects against complete depletion of the reservoir, as this would cause delivery of air into the arterial branch of the extracorporeal system and lead to a severe air embolism in the patient’s aorta. The level sensor is positioned at the desired minimum level on the cardiotomy reservoir. If the liquid level in the reservoir reaches the level sensor, the level monitor automatically decreases the flow of the assigned arterial pump and triggers a visual and acoustic alarm.
- Level monitors have two modes of operation:
 1. Start–stop mode, i. e., the pump is stopped when the stop level is reached and is restarted automatically only after a release level has been reached.
 2. Control mode, i. e., the pump slows down when the control level is reached and is only stopped when the stop level is reached.
- Bubble detector. Bubble monitoring also protects against air delivery. The ultrasonic sensor detects air bubbles that exceed a certain size and automatically stops the assigned pump, triggering a visual and acoustic alarm at the same time. The system can also be set to generate acoustic and visual warnings if microbubbles below a certain size are detected. Similar to level monitoring, bubble monitoring protects the patient from severe air embolisms in the arterial vascular system.
- Cardiotomy suction strength. Optimum visibility in the operation area is essential during cardiac surgery. The surgeon or the assistant can use one or more cardiotomy suction tubes to keep the operation area free of blood. The perfusionist, who is in constant communication with the rest of the team, adjusts the suction strength to meet the needs of the surgeon.

32.5.3 Patient Monitoring and Therapy During ECC

Because the cardiovascular system of the patient and the ECC system form a unit during perfusion, the perfusionist must fully focus on the patient. This means that he or she is responsible for controlling and regulating the gas exchange and the resulting partial O₂ and CO₂ pressure, the acid–base balance, renal function, coagulation, perfusion pressure (MAP, CVP), temper-

ature, and a number of other blood gas values and electrolytes.

The perfusionist uses these parameters to get an overall view, interprets them in the relevant context, and reacts in an appropriate manner.

The section below describes a few essential aspects of the complex perfusion procedure in more detail.

Hemodynamics

The arterial blood pressure is the most important parameter of hemodynamic monitoring. During nonpulsatile perfusion, only the mean arterial pressure (MAP) can be measured, while pulsatile perfusion techniques also allow for measuring the systolic and diastolic pressure. Every clinic has its own standard regarding the ideal perfusion pressure. As a rule, the average perfusion pressure target is 60–90 mmHg for adults and 30–50 mmHg for pediatric applications.

Compared to perfusion flow, which is vital to adequate organ perfusion and microcirculation, perfusion pressure plays a relatively minor role.

The MAP is controlled by the two parameters pump minute volume (PMV) and total systemic vascular resistance (SVR). A reduction in PMV inevitably leads to a decrease in MAP, while the MAP increases subject to SVR when the PMV rises. The SVR can also be regulated with special drugs that dilate (vasodilators) or constrict the vessels (vasopressors) as well as with anesthetics.

O₂ Supply

The O₂ required for the organs needs to be delivered during ECC in a way that corresponds to the physiological gas exchange in the lungs. The supply of oxygen to the organism is determined by the arterial O₂ content (aO₂) and the flow (*Q*)

$$O_2 \text{ supply} = Q \times aO_2 . \quad (32.1)$$

O₂ consumption is calculated by multiplying the flow (*Q*) and the arteriovenous O₂ concentration difference (avDO₂)

$$O_2 \text{ consumption} = Q \times avDO_2 . \quad (32.2)$$

The oxygen supply to organs depends on the position of the sigmoidal O₂ binding curve or on the P₅₀ value. The P₅₀ value is the so-called half-saturation oxygen tension where 50% of the hemoglobin (Hb) is saturated with O₂.

The more limited the O₂ transport capacity during ECC, the greater the importance of the P₅₀ value for

the O₂ supply to organs and tissue. If there is a left shift in the O₂ binding curve (e.g., caused by hypothermia), then the P₅₀ value decreases due to an increased Hb–O₂ affinity. As a result, the O₂ delivery to organs and tissue deteriorates. In contrast, a right shift in the O₂ binding curve (e.g., due to a temperature increase or acidosis) leads to decreased Hb–O₂ affinity and an increased P₅₀ value, which facilitates O₂ delivery to tissue.

A simple and safe method to ensure adequate O₂ delivery during ECC is the continuous monitoring of the arterial saturation (SaO₂) and mixed venous saturation (SvO₂) on the HLM. Arterial O₂ saturation is an excellent parameter for judging the oxygenation performance, while the mixed venous O₂ saturation can indicate an imbalance between O₂ supply and O₂ demand.

Blood Gas Analysis and Management of the Acid–base Status. Two different methods can be applied to regulate the acid–base status during hypothermic ECC. Opinions differ as to which of the two methods represents a more physiological approach to the regulation of the acid–base balance.

The pH-stat measuring method is based on the fact that a pCO₂ value of 40 mmHg and a pH value of 7.40 are regarded as normal values, with the actual temperature not taken into account. The blood gas analysis carried out at 37 °C is adapted to the actual blood temperature. With the pH-stat method, the CO₂ partial pressure must be kept constant by feeding CO₂ into the oxygenator to replace the additional CO₂ dissolved in the blood. This corresponds to a state of respiratory acidosis and hypercapnia.

In contrast, the a-stat measuring method measures the pH value at 37 °C, but does not adjust this value in relation to the actual blood temperature of the patient. Under hypothermic conditions, this would mean a decreased pCO₂ value and an increased pH value and, as a consequence, hypocapnia or respiratory alkalosis.

It has not yet been established which of the two methods is superior for regulating the acid–base status in a hypothermic circuit. However, the a-stat method has a number of advantages over the pH-stat method:

- With the a-stat method, the cerebral blood flow correlates to the cerebral O₂ consumption during hypothermia, which means that the cerebral autoregulation is not affected.
- A physiological pH value is maintained in the intracellular space.

As the pH-stat method also offers advantages during deep hypothermia due to improved cerebral blood circulation and cooling, both methods may be used (pH-stat during the hypothermic phase and a-stat during the warmup phase).

Blood Coagulation. Systemic heparinization of the patient needs to be performed before starting ECC. The initial dose of heparin administered for the purpose of anticoagulation ranges from 200 to 400 IU/kg body weight. Anticoagulation efficiency during cardiopulmonary bypass is primarily determined from the activated clotting time (ACT).

To avoid coagulation complications at the start of ECC, part of the heparin dose is added during the priming of the HLM – this varies between 2500 IU and 10 000 IU for adults, depending on clinic and coagulation management. The initial dose is administered via central venous access or is injected into the right atrium or the aortic root.

Before the ECC can be started, the ACT value must be checked a few minutes after administration of the heparin. ECC should never be started if the ACT is < 400 s. If this is the case, the ACT has to be controlled again and, if required, additional heparin must be administered. If the AT III value is too low, AT III is substituted to ensure the anticoagulatory effect of the heparin.

During cardiopulmonary bypass, ACT values should stay over 400 s and heparin is substituted when the value falls below 400 s. After completion of the ECC, protamine is used as a heparin antagonist. The purpose of the antagonization is to restore a normal ACT (< 130 s). Unlike heparin, protamine is not administered as a bolus but as a short infusion given over the course of approximately 5–10 min. If protamine is administered too quickly, it can cause peripheral vasodilation in combination with hypotension and cardio depression. Once the administration of protamine has been started, cardiotomy suction is stopped to avoid complications from embolisms.

As a general note, the method briefly described above applies primarily to ECC systems without coating. Coagulation is a highly complex topic that cannot be adequately covered within the limitations of this article.

Hypothermia

Artificial lowering of the body temperature (induced hypothermia) during ECC slows down the metabolism of the organism, facilitating a reduction in tissue O₂ con-

Table 32.2 Hypothermia grade depending on body core or rectal temperature

Hypothermia grade	Temperature (°C)
Light hypothermia	37–32
Moderate hypothermia	32–28
Deep hypothermia	28–18
Profound hypothermia	18–4

sumption for the duration of hypothermia. Hypothermia is achieved by cooling flowing blood with a heat exchanger that is integrated into the oxygenator. Even a moderate drop in body core temperature, e.g., to 30°C, decreases O₂ consumption by approximately 50% because hypothermia has a protective effect on organs and leads to an improved ischemic tolerance in the various tissues.

Most modern surgeries are carried out under normothermic or light hypothermic conditions. Deep systemic cooling of the patient is called for in case of aortic arch surgery or a small number of complex surgical interventions on infants and may be combined with temporary circulatory arrest or low-flow perfusion when required.

Hypothermia is clinically graded according to the target temperature measured rectally or at the body core (Table 32.2).

Urine Production

During ECC, the renal function must be continuously monitored by measuring urine output. Urine output of 0.5–1.0 ml/kg body weight/h is considered adequate during ECC. Sufficient perfusion flows and pressures are required to ensure adequate diuresis. If the urine output decreases during ECC, the perfusion pressure should be increased with a higher perfusion volume or by administration of drugs. If renal function does not improve, diuresis can be treated with loop diuretics or substituted temporarily by a hemofilter.

32.5.4 Complications During Extracorporeal Circulation

Continuous advancements in the area of device technology, the introduction of quality assurance measures, the improvement and enhancement of monitoring functions, and, last but not least, the standardization of training ensure that the number of incidents during perfusion is kept to a minimum. However, the possibility of incidents can never be ruled out completely.

All incidents can be categorized as being caused by technical problems or human operation. Incidents with technical causes result mainly from defective devices or components, material fatigue, or manufactured products of inferior quality. Incidents caused by human operation are almost always the result of misinterpretation of situations and values or inappropriate reactions.

It is essential to protect and preserve the life and health of the patient under all circumstances and using all available means. Preventive measures for early detection of such incidents, appropriate training with regard to countermeasures, and clear communication among all parties can help prevent irreversible damage to the patient even in the case of a very serious incident, such as total failure of the arterial blood pump, rupture of tubing, or failure of the power or gas supply.

Incorrect Placement of the Arterial Cannula

Proper arterial cannulation of the relevant vessel (ascending aorta, femoral artery, etc.) and the correct choice of cannula (size, type) are vital for adequate body perfusion. Arterial perfusion cannulae that are too small and material defects are the most common causes of cannula-related complications. Complications that could have serious consequences for the patient at a later stage can also occur during cannulation and surgery. These include:

- Aortic dissection
- Displacement of the arterial cannula
- Dislocation of the arterial cannula

Incorrect Placement of Venous Cannula(e)

Because venous blood is usually drained from the patient into an HLM using the hydrostatic differential, the reflux of the blood depends on the central venous pressure and the resistance of the venous cannula(e) as well as on the tubing size of the venous line. Manufacturers' flow charts list the flow capacity of the individual cannulae and make it relatively easy to determine the correct size of cannula to meet the respective requirements.

A cannula of insufficient size may severely obstruct the venous reflux during a total cardiopulmonary bypass, which may cause blood stasis and dilation of the right heart. The drop in blood level in the oxygenator or reservoir then forces the perfusionist to reduce or adjust the pump minute volume depending on the situation. If such an event occurs, the cause of the error should always be addressed with measures such as recannulation

or additional cannulation so that adequate perfusion can continue.

Additional factors that can obstruct venous drainage are as follows:

- Dislocation of the venous cannula(e)
- Displacement of the venous cannula(e)
- Large amounts of air in the venous line (air block)
- Relocation of the venous line
- Luxation of the heart
- Hypovolaemia
- Insufficient hydrostatic differential

Arterial Air Embolisms

Systemic arterial air embolisms are among the most serious complications that can occur during cardiopulmonary bypass and can have many different causes. The most common causes of arterial air embolisms are insufficient reservoir levels, air embolization via cardioplegia cannulae, air application caused by incorrect flow direction in the vent suction tube, oxygenator malfunction, disconnection of the tubing system, material fatigue leading to rupture of the arterial pump tubing segment, and aggressive warming of the patient.

A large number of complications described in the literature could be added to this list. Depending on the amount and intensity of air delivery, an arterial air embolism can have catastrophic consequences for the patient, including irreversible organ damage. Arterial air embolisms can lead to hypoxic brain damage. For this reason, measures must be taken immediately after an embolism is detected in order to minimize subsequent damage.

If an air embolism occurs despite the applied preventive measures (level sensor, bubble sensor, arterial filter), immediate corrective action is required that must go well beyond removing the air from the systemic circuit:

- Immediate interruption of the cardiopulmonary bypass and positioning of patient in maximum Trendelenburg position (head-down position)
- Decannulation of the aortic cannula and deaeration via the incision point using a suction tube
- Removal of air from the arterial line and aortic cannula
- Hypothermic, retrograde perfusion via the superior vena cava until air can no longer be detected above the aortic root
- Intermittent compression of the two carotid arteries
- Hypertension using vasoconstrictors
- Drug therapy with steroids and barbiturates

- Antegrade, hypothermic perfusion (at $\approx 20^\circ\text{C}$)
- Hyperbaric oxygen therapy as a last resort

Oxygenator Failure

Inadequate oxygenator performance during cardiopulmonary bypass can have major consequences and lead to hypoxic organ damage. Various monitoring options (arterial O_2 saturation, arterial blood gases, and visual evaluation) allow for relatively fast interpretation of the oxygenator's gas exchange performance, enabling the user to take instant action if complications should occur.

The perfusionist can visually evaluate the returned arterial blood from the start of extracorporeal perfusion. If a significantly reduced arterial O_2 saturation and unacceptable arterial pO_2 values are measured at the beginning of the perfusion despite sufficient ventilation of the delivered gases, it must be assumed that the oxygenator failed because of an oxygenator module material defect or that the surface required for the gas exchange has been reduced by protein or thrombus deposits.

Depending on the remaining oxygenation capacity and the stage of the surgery, the oxygenator may have to be replaced. This requires a temporary interruption of perfusion (with the corresponding risk to the patient).

Incidences Caused by Technical Problems

In the past, an interruption to the power supply in the operating theater during ECC was a serious problem because both arterial pump and overall system were affected. Modern HLMs have a built-in independent emergency power supply. Using the emergency power supply (uninterruptible power supply, UPS), the overall system can be battery-operated for a period of approximately 20–130 min (depending on the load).

If the power supply or power pack fails, the UPS switches automatically to battery operation via an internal electrical switch. When the power supply returns, it switches back automatically.

An additional UPS control module monitors the battery charge status during power supply failure and displays the remaining battery life, which depends on the load. If a total roller pump failure occurs, the rotation and, hence, the required flow can be maintained with a hand crank. In modular systems, the defective pump can be replaced by a functioning pump, if required. In the case of centrifugal pumps, the pump head can be removed and inserted into a mechanical drive that is also operated using a hand crank.

If the central gas supply fails, the oxygenator is supplied with gas from transportable gas cylinders.

32.6 Differentiation of Heart-Lung Machines

Functionality, maximum reliability, safety and ergonomic aspects, optimum user-friendliness, and intuitive operation are factors for the design and development of HLMs.

The most important design feature that distinguishes HLMs is the modular or semimodular configuration.

In addition, the integration of blood gas analysis devices, flow sensors, electrical remote-controlled tubing clamps, and other systems is gaining importance.

32.6.1 Modular Systems

The modular concept of HLM systems (Fig. 32.7) offers maximum user flexibility. The overall system can be custom-tailored, resulting in HLM configurations that meet individual clinical requirements. Individual components, modules, and accessories can be added to the system at any time according to the requirements of

Fig. 32.7 Modular HLM

Fig. 32.8 Control panel for connecting monitoring, control, and measuring devices and the central display and control module (CDM). The control modules for the monitoring, control, and measuring devices can be arranged on the control panel as required

the user or replaced when defective. Modifications or system extensions that include additional monitoring, control, and measuring devices facilitate the use of the HLM for a variety of perfusion tasks.

Modular systems consist of a basic mobile console that supports 3–6 roller pumps, depending on the configuration. The modular roller pumps form the basis of the perfusion system. They are placed on the pump table of the console and connected to the power supply and electronic control via plug connectors. The control panel (Fig. 32.8) accommodates all modular monitoring, control, and measuring devices. As different types of surgery require various levels of monitoring, control panels accommodate a number of control modules.

The modular design also includes pumps that can be mounted in any position on the mast system, preferably separate from the control module. These pumps are also available for the semimodular systems described below. The main advantage of the freely positioned pumps are shorter tubing paths that lead to a reduction in the foreign surface and priming volume of the ECC system.

32.6.2 Nonmodular Systems

In contrast to modular designs, nonmodular systems are a configuration in which the number, type, and arrangement of the roller pumps as well as the scope of monitoring and control functions are predetermined by the concept and design (Fig. 32.9).

The system includes all important monitoring and control functions, such as bubble monitoring, level monitoring, pressure monitoring, cardioplegia monitoring, temperature monitoring, and timers. In such a system, the roller pumps are built into the housing and the standard monitoring functions are integrated fully into the HLM control panel without any option of re-configuration. In comparison to modular systems, the options for extending the system with additional roller pumps and monitoring, control, and measuring devices are limited. Another marked difference from modular systems is that the main components of the HLM can

Fig. 32.9 Compact HLM with semimodular configuration

only be replaced by authorized service technicians when technical defects occur.

32.7 Aspects of Technical Safety

HLMs should be designed, constructed, and manufactured with an emphasis on optimum safety. The user must always be in command of the system technology, especially when adverse events occur. For this reason, the main focus of any safety assessment must be on the detection of risks that are inevitable when technical devices are used or when man and machine interact. The most important safety requirement for an HLM is the maintenance of the patient's blood circulation. Perfusionists contribute greatly to the safety of such procedures.

The objective is to find solutions that prevent the occurrence of one or more adverse events. The minimum safety requirement is compliance with the laws and regulations (basic requirements) and the relevant standards.

Risk analysis is an important preventive measure that, based on EN ISO 14971, has developed into risk management. Risk management goes beyond the scope of pure risk analysis and requires decisions on the ac-

ceptability of risks and on the measures to reduce risks as well as a review of the measures taken.

If an adverse event occurs despite the measures that were taken, a targeted reaction is required. This means that a safe status must be determined and defined in such a way that any danger to the health and safety of patients and users is kept to an absolute minimum. Because the evaluation of probability of risks depends on their exact allocation, these must be classified:

- *Unintended adverse event*, such as a stopped pump – caused by a technical defect
- *Intended adverse event*, such as a stopped pump – caused by the detection of an air bubble in the tubing system

A life-sustaining system is not safe if the function is interrupted and an alarm is triggered. A temporary pump stop can be acceptable under certain conditions to avoid a risk caused by an adverse event such as air entering the tubing system.

The following standards are mandatory for the design of HLMs: Directive 93/42/EEC or MPG (Medical Device Act), EN 601-1, EN 601-1-1, EN 601-1-2, EN 601-1-4, EN 601-1-6, EN 62304.

All requirements must be determined at the start of the development process and must be implemented in system, device, and component specifications. A risk analysis must be generated for each function and for the overall system. Error control measures need to be stated and verified by prediction and testing.

All development tests as well as the entire product documentation have to be stored in a master file.

HLMs must always be constructed to be first-fault tolerant, i. e., a fault such as component failure caused by short-circuiting or interruption should never bring the device into an uncontrollable operational state. In any event, the error must be detected and indicated by an alarm and the function must be stopped.

The perfusionist then decides which measures to take so that the perfusion can continue. For example, if a pump stops due to motor failure, the affected tubing segment can be inserted into a backup pump or, in an emergency situation, the defective pump can be operated using a hand crank. If the level sensor on the cardiotomy reservoir or on the oxygenator fails, the perfusionist can monitor the level manually and stop or reduce the flow rate of the relevant assigned pump.

32.8 Prospects for Further Development

Cardiac surgery has developed greatly in recent years due to the increasing use of minimally invasive and video-assisted endoscopic and robot-assisted technology. The development of new, less invasive surgical techniques aims to reduce surgical trauma by reducing the size of surgical access and avoiding the use of an HLM. The implantation of vessel prosthetics without the use of an HLM is already established as a standard procedure in aortic surgery. In contrast, the trend toward implanting heart valves without ECC is still at an early stage of development.

Contrary to initial expectations, surgical interventions on a beating heart, especially in the area of bypass surgery, are still only being carried out at a small number of heart centers because of the complex and time-consuming nature of the surgery involved.

On the other hand, the use of extracorporeal systems outside heart surgery centers is increasing rapidly. Terms like ECMO or ECLS refer to minimalist systems consisting only of a pump and oxygenator that carry out

It goes without saying that HLMs must meet all applicable requirements for electrical safety, electromagnetic compatibility, explosion safety, and fire safety as well as the environmental requirements in the operating theater (e.g., temperature range). All devices must undergo stress testing under transport and storage conditions. In addition to these characteristics, users also evaluate cleaning and disinfection properties and look for adequate ergonomic design.

The operating instructions are an integral part of the device and are also inspected during the approval process. They contain information about safety and are therefore an important factor for the safe operation of the device. For this reason, they not only contain normal operating instructions but also information on error prevention as well as warnings regarding operational states that are not permitted or use in combination with devices that have not been tested or approved.

HLMs are Class IIb medical devices in accordance with MPG (Medical Device Act) and are subject to technical safety checks. The official transfer of ownership to the operator also includes an inspection that must be documented. Furthermore, the operator must be given formal instruction on the functions of the device as part of the transfer of ownership.

the main functions of the HLM, namely, the pump function of the heart and the gas exchange function of the lungs.

These systems can be used for several days or even weeks on account of the small number of components and the resulting minimum foreign surface. Along with the extended period of operation, the compact design makes the system practically autonomous and therefore independent of the operating-theater infrastructure. As a result, the use of these systems is on the increase in other departments, such as cardiological institutions. One of the main application areas of these mobile mini ECC systems will most likely be patient transport from clinic to clinic by road or air with partial or complete cardiopulmonary support that will present completely new possibilities and challenges.

Running parallel to the development of equipment technology is the advancement in the area of disposables such as tubing, oxygenators, filters, reservoirs, and cannulae. The focus here is on increased efficiency

and also on materials that have direct contact with and cause damage to blood cells. The aim is to use different coatings to create surfaces on the individual components and complete tubing sets that are almost biocompatible. A number of companies are offering various products that are, in some cases, a definite improvement, but to date no company has succeeded in producing a surface that is completely biocompatible with blood.

Application

33. Application of Shock Waves and Pressure Pulses in Medicine

Friedrich Ueberle

Since 1980 extracorporeal shock waves and pressure pulses are used to disintegrate kidney stones. Since then, ESWL – Extracorporeal Shock Wave Lithotripsy – is the most important treatment for kidney stones. In the past years, more medical applications for these special pulsed acoustic waves were developed, e.g. for orthopedic pain therapy (ESWT – Extracorporeal Shock Wave Treatment). Shock waves and pressure pulses have high peak pressures (up to 150 MPa) and very short time duration, typically 2–5 s. They are mostly generated by one of three principles: The electrohydraulic (spark gap) source, the electromagnetic (EMSE) source or the piezoelectric source. Some thousand pulses are released at a slow rate. They propagate through water into the body of the patient by an acoustic coupling means. In order to achieve the intended medical effects, they are focused on the treatment site. A number of physical parameters can be attributed to the effects of the pulses both on stones and tissue, the most important being the effective acoustic energy and the energy flux density. Stone disintegration is governed by direct wave effects, squeezing and cavitation. The waves also act on tissue, which may cause healing effects, but also some side effects. Targeting and treatment control is usually done by imaging systems using x-rays or ultrasound imaging. The result of the treatment can be described by efficiency quotients, which comprise stone-free rate as well as side effects.

33.1 Introduction – Historical Development

On 26 February 1980, for the first time, a patient with kidney stones was treated successfully with an extracorporeal shock wave lithotripter. Research and development for this moment had taken about 10 years from the first ideas to successful clinical application.

The first proposals to treat concretions with sound reach back to the 1940s. A British working group tried to disintegrate gallstones in vitro using continuous wave (CW) ultrasound at 400 kHz lasting between 5 and 60 s. Their success rate was about 80% [33.1].

Unfortunately, animal experiments in vivo resulted in heavy tissue damage, which was lethal for the animals. Consequently, further efforts were cancelled in 1956 [33.2–4].

The discovery that shock waves were able to penetrate soft tissue without harming it was made by chance in 1966 when a Dornier technician was touching a metal plate under fire, which was serving as a target in high-speed gas cannon experiments [33.5]. He felt a kind

of electric shock without suffering any visible damage. This phenomenon of transmitting shock waves through tissue was a subject of research by Dr. Hoff at Dornier Systems, Friedrichshafen, Germany, until 1971. During a scientific collaboration with the Dornier team, Prof. Häusler (Saarbrücken, Germany) raised the idea of disintegrating kidney stones using sound pulses generated by multiple sound sources, which would be transmitted through the body. Subsequent research activities soon led Prof. Häusler away from the originally unfocused high-speed projectiles generating shock waves when they hit a steel target. Instead, spark gaps (almost like spark plugs in a car) were used to generate shock waves by underwater discharge [33.6]. In 1972 urologist Prof. Schmiedt at the Klinikum Grosshadern of the University of Munich, with his team Chaussy (Munich) and Eisenberger (now Stuttgart), joined the working group. Research funding was secured from the German government (BMFT), which supported the subsequent animal experiments and later on the development of an efficient x-ray targeting.

After 3 years of clinical studies involving about 200 patients, the first series kidney stone lithotripter Dornier HM 3 was installed in Stuttgart in 1983. Soon the method was extended beyond kidney stones to the treatment of stones in the entire urinary tract. In 1985 experiments to disintegrate gall stones were started. This minimally invasive method is still in use today under certain circumstances, but it was made obsolete by the forthcoming minimally invasive surgical cholecystectomy in most cases.

Since its first introduction of noninvasive shock wave treatment, the medical applications of this energy have been continuously extended (Table 33.1). At present extracorporeal shock wave therapy (ESWT) for the treatment of soft tissue pain (e.g., tennis elbow pain, heel spur pain) is in clinical evaluation and approval worldwide. The sound sources used in ESWL

Fig. 33.1 The first series lithotripter Dornier HM3 was introduced in 1983. The patients were treated by the spark-gap source in a large bathtub filled with degassed water. Targeting was done using two crossed x-ray tubes

Table 33.1 Applications of shock waves and pressure pulses in medicine and biology. (Some applications are only in the experimental stage and may not be approved for clinical use in certain countries)

Application	Clinically applied since	Literature
Ureter stone lithotripsy	1980/1983	[33.10]
Gall stone lithotripsy	1985	[33.11]
Gall duct stone lithotripsy	1985	[33.12, 13]

Salivary stone lithotripsy	1989	[33.15]
Pseudarthrosis treatment	1989	[33.16]
Shockwave effect on tumors		[33.17]
Tendinosis calcarea treatment	1993	[33.18]
Pain therapy of tendons (tennis elbow, heel spur pain, shoulder pain)	1992	[33.19, 20]
Therapy of motion infringement	1994	[33.21]
Shockwave induced transfection of cells		[33.7, 8]
Peyronie’s disease treatment	1997	[33.22]
Coronary vessels treatment	2002	[33.23]

and ESWT are similar – no wonder, because the first clinical tests to treat soft tissue pain were undertaken using standard or slightly modified ESWL machines. Presently the use of shock waves for the application of biotechnological agents is under research. The first results are promising; as it turned out those shock-wave-induced cavitations are able to open up molecular

pathways into cells for a short time. During this time, molecules (e.g., genes, cytotoxics) are able to penetrate the cells [33.7–9].

Due to the close relationship between the ESW disciplines, the following technical description may be mostly restricted to the vocabulary and the knowledge learned from ESWL.

33.2 Definitions of Physical Terms: Acoustics – Sound Waves – Pressure Pulses – Shock Waves

33.2.1 Wave Forms Used in Acoustic Therapies

The simplest wave form is a sinusoidal wave comprising positive and negative pressures (overpressure and rarefaction pressure phases).

Each sinusoidal wave has one precisely defined frequency – in contrast to a shock wave. The wave is called

an ultrasonic wave if its frequency is above approximately 16 000 oscillations per second. If only one or a limited number of sinusoidal cycles are generated, which is common in ultrasound imaging systems, the result is called a sound pulse.

A pressure pulse typically consists of only one positive pressure wave, which decays in an exponential slope to ambient pressure within one to 5 μ s. Immedi-

Fig. 33.2 Acoustic waves propagate in fluid and gaseous media as longitudinal compression waves

ately a rarefaction period lasting a few microseconds follows. When the rise from ambient pressure to the positive pressure maximum takes place in a very short period of time (a few nanoseconds), the resulting signal is called a shock wave. After the pressure pulse or shock wave has passed, the medium has returned to ambient pressure conditions.

33.2.2 Sound Waves – Mechanical Waves in Media

A sound wave is a mechanical wave that propagates in a medium like gas, fluid, or a solid body. During

the passing of the wave, the molecular distances in the medium undergo a slight local change. In particular, in fluids and gases the waves propagate as longitudinal compression waves (Fig. 33.2).

In solids more wave forms like transversal waves, shear waves, surface waves, etc. can propagate.

Acoustic Properties of Media

Media differ by their mechanical properties like elasticity and compressibility. These properties determine the velocity of sound c , and the acoustic impedance $Z = \rho c$, which is calculated as a product of the medium density ρ and the sound velocity c . Table 33.2 shows

Table 33.2 Acoustic properties of some important media (after [33.24, 25])

Material	Density (kg/m ³)	Sound velocity (m/s)	Impedance (N s/m ³)
Air	1.293	331	429
Water	998	1483	1.48 × 10 ⁶
Fat tissue	920	1410–1479	1.33 × 10 ⁶
Muscle tissue	1060	1540–1603	1.67 × 10 ⁶
Bone tissue	1380–1810	2700–4100	4.3–6.6 × 10 ⁶

Table 33.3 Mechanical and acoustic parameters of some stone materials (more data, in particular for kidney stones, are published in [33.27])

Material	Pressure strength (MPa)	Tensile strength (MPa)	Vickers hardness (kg/mm ²)	Speed of sound (m/s)	Density (g/cm ³)	Impedance (10 ⁶ Rayl)	Disintegration energy (mJ/cm ³)	Comment

33.2.3 Definition of Shock Wave and Pressure Pulse

A shock wave is a mechanical wave in a fluid (or a gas) that rises from ambient pressure to peak positive pressure in a few nanoseconds (10^{-9} s). The cause for this almost instant rise is the nonlinear properties of fluids, which lead to a local increase of the velocity of sound in the positive pressure zone. During the propagation, trailing positive pressure parts of the wave approach on the leading front. The front steepens. This effect is saturated when the steepening is balanced by the energy loss by dissipation. Only in this saturated case is it physically valid to use the term shock wave. Besides the direct generation of a shock wave by a sound source, which moves at a higher speed compared to the velocity of sound in an ambient medium, shock waves are also generated by the steepening of a strong positive pressure pulse. This may happen, for example, in the converging sound field of a focused lithotripter source. Nowadays pressure amplitudes of 10 MPa to over 100 MPa (Mega-Pascal, 1 MPa = 10 bar, which equals ten times the atmospheric pressure) are used in pressure pulse therapies. As a shock wave – like all kinds of sound waves – propagates with a velocity, which is determined by the medium and the shock wave pressure, one can calculate a shock front thickness, which is the spatial distance between the point of ambient pressure and the point of peak positive pressure. In tissue, the shock front thickness is about 1.6 to 6 μm (micrometers, 10^{-6} m). Therefore, significant forces may act on a cell membrane that is only a few molecule layers thick when a shock wave

is passing. The pressure gradient, i. e., the change in pressure between two places, is maximized when shock waves occur instead of other kinds of acoustic wave forms, like sinusoidal high-power ultrasound.

It should be pointed out that in lay language the term shock wave frequently is used for all kinds of pressure signals, even if their rise times are much longer than a few nanoseconds. In this case the term pressure pulse, according to the IEC Standard 61846 [33.34], is more appropriate. The measurement problems of the fast pressure rise times will be discussed below.

33.2.4 Mechanical Effects of Sound Waves at Interfaces

When a sound wave passes an interface between media with different acoustic impedances, the propagation of the sound may be significantly changed. In most cases, knowledge of the magnitudes of the impedance of the different media (which is given by the product of density and sound velocity) is sufficient to characterize their properties.

Transmission and Reflection of Sound Waves

A fraction of sound energy is reflected into medium 1 at the interface when the media impedances are different, for example when the sound wave is passing from fat into muscle tissue. The remaining sound energy is transmitted into medium 2. The examples in Table 33.4 demonstrate the fraction of transmitted energy, depending on the properties of the tissues (e.g., muscle \rightarrow bone).

Another very important property of the reflected sound wave can be learned from the reflection formula: If the impedance of medium 2 is less than that of medium 1, then the algebraic sign of the reflected pres-

Fig. 33.3 A typical shock wave is characterized by a positive pressure pulse with an extremely short rise time t_r , followed by an exponential decay to ambient pressure. A trailing rarefaction phase lasting a few microseconds follows. Typical shock wave simulation (after [33.33])

Table 33.4 Examples of the amount of reflected and transmitted sound energy at the interface of two media calculated using the reflection formula for pressure $r = (Z_2 - Z_1)/(Z_2 + Z_1)$ with magnitudes of impedance Z_1 and Z_2

Interface	Reflected pressure (%)	Reflected sound energy (%)	Transmitted sound energy (%)
Water – fat tissue	–5	0.25	99.75
Fat tissue – muscle	11	1.2	98.8
Muscle – fat tissue	–11	–1.2	98.8
Muscle – bone	44–60	19–36	64–81
Muscle – model kidney stone	22	5	95
Model kidney stone – muscle	–22	5	95
Muscle – air	–99	98	2

sure becomes negative. The physical meaning of this is that a positive pressure is reflected as negative pressure back into medium 1. Almost the complete pressure amplitude is inverted during reflection at plane interfaces with a large difference in impedance. The pressure gradient at the interface takes twice the value of the gradient of the traveling wave in a homogeneous medium. No energy is transmitted to medium 2. These effects occur in particular at all interfaces from tissue to air, e.g., at the lung. As almost the complete energy is reflected at the interface, the tissue is no longer able to tolerate the resulting forces, and it tears. Thus, when

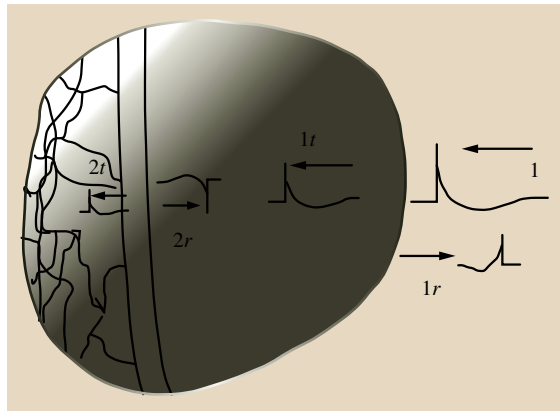

Fig. 33.4 If a sound wave impinges at the interface between two media, a part of the acoustic energy is reflected. If the acoustic impedance of the second medium is less than the impedance of the first medium, then the polarity of the wave is inverted. Positive pressures become negative and vice versa. At impacted stones the Hopkins effect can be observed. The concrement is damaged not at the sound entry side but at the adjacent side. The reflected pulse overlaps with the rarefaction portion of the impinging pulse, leading to high strain forces inside the stone. This effect explains findings on impacted concretions that are disintegrated from the back toward the front

the high-pressure path of a pressure pulse device is directed toward the lung, severe harm can occur. Similar problems can occur at the surface of other organs, e.g., gas in the intestine or at the skin/air interface on the opposite side of the body. If air bubbles are trapped at the impinging site of the sound waves, small bleedings (petechiae) frequently occur.

The effect of pressure inversion also occurs at another interface, which is important in lithotripsy: at the rear side of the stone, because the adjacent medium (e.g., kidney parenchyma) has lower impedance than the stone. Thus part of the leaving shock wave is inverted and reflected back into the stone. It overlays with the trailing rarefaction part of the shock wave, resulting in very strong traction forces at the rear side of the stone. These forces cause a spallation of the stone, occurring somewhere at the rear surface. This effect is named after its discoverer, Hopkins. In ESWL it can be observed in particular when stones are impacted, e.g., in the urethra or the shoulder (Fig. 33.5) [33.35, 36].

The Hopkins effect can be observed at impacted stones. The concrement is damaged not at the sound entry side, but at the adjacent side. The reflected pulse overlaps with the rarefaction portion of the impinging pulse, leading to high strain forces inside the stone. This effect explains findings on impacted concretions that are disintegrated from the back toward the front.

Refraction of Sound Waves at Boundaries

A wave that is impinging on an interface at an angle other than normal to the surface continues its path at a different angle. According to Snell's law, this angle depends on the speed of sound in both media. This refraction effect is used to design acoustic lenses for the focusing of sound.

Refraction can also occur at interfaces between tissues, and at the boundary between the coupling fluid of the sound source and the patient skin. Refraction is the main reason for a smearing of the sound focus inside

the body of the patient. Furthermore, refraction may be the cause of a potential aberration between the focus display of the localization device (x-ray or ultrasound imager) and the actual focus position of the pressure pulse source [33.37–40].

Diffraction of Sound Waves

Comparable to the diffraction of optical waves, diffraction of sound waves occurs at edges. Therefore, a certain portion of the sound not only propagates straight ahead but is bent around the edge.

Therefore, an edge-bending wave occurs at the fringe of any sound transducer as well as at interfering mechanical structures, e.g., an inline scanner device. This portion of the wave, which is unavoidable in sound sources of finite extensions, results in an inverted (rarefaction) pressure, which follows the primary transmitted pressure pulse. The maximum of this rarefaction portion occurs on the axis close to the focus, even if the sound source only transmits positive pressure pulses.

Absorption and Attenuation

Absorption and attenuation of sound waves lead to a loss of acoustic energy in every kind of tissue. The attenuation is usually frequency dependent ($0.5\text{--}0.7\text{ dB cm}^{-1}\text{ MHz}^{-1}$, which means a bisection of the pressure amplitude of 1 MHz after a 12 cm path length, or bisection of a 2 MHz wave after 6 cm). Thus, not only does the amplitude of a sound pulse change, but also the pulse itself changes its shape, resulting in less steep rise and decay [33.40]. Positive portions (P+) of the pressure pulses are reduced by 15–30% at penetration depths of 100 to 120 mm (typical for kidney stones) [33.42]. In contrast, the rarefaction amplitudes P– are only reduced by 6% [33.43]. This can be explained from the different frequency contents of the (steepened) positive portion and the nonsteepened rarefaction portion (e.g., 5–8 μs duration, Fig. 33.9). This rarefaction portion has a quasisinusoidal shape and contains frequencies in the range of 120 to 200 kHz, which are minor attenuated. As a contrast, the positive steepened signal portions have a saw tooth – like shape-containing frequencies up to the high megahertz range, which are particularly attenuated in tissue.

33.2.5 Mechanical Effects of Sound Waves Caused by Nonlinear Properties of the Media

So far, we have discussed the propagation of sound in a linear medium that does not change its properties no

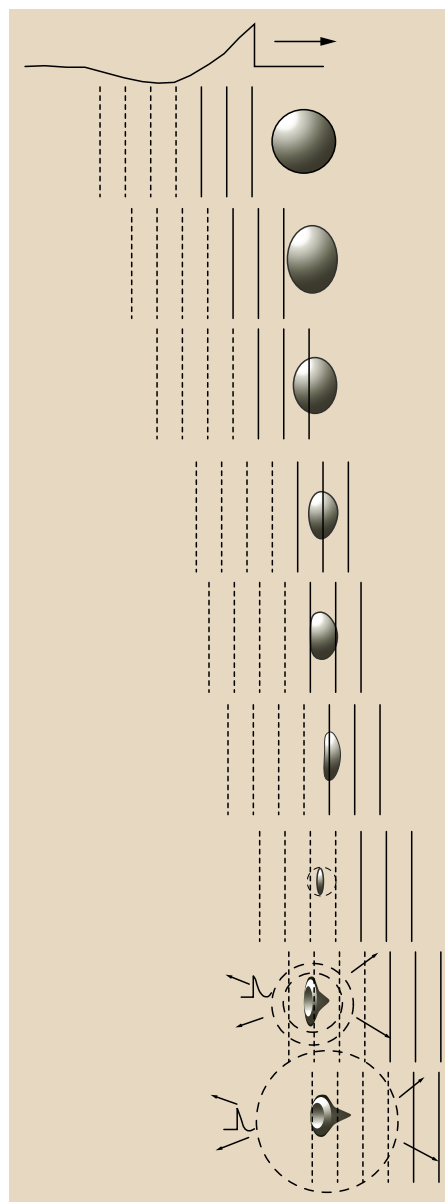

Fig. 33.5 If a cavitation bubble is hit by a shock wave, then it collapses. During the collapse a water jet is generated in the direction of the shock wave propagation or toward a nearby surface (after [33.41])

matter how high the pressure amplitudes are. Essentially all waves in a medium propagate nonlinearly. Therefore, we need to discuss some of the nonlinear effects in ESWL and ESWT.

Steepening of the Positive Pressure Portions of Sound Waves

High local positive pressures result in a strong local compression and thus a local increase in medium den-

sity. Simultaneously the velocity of sound increases due to the elastic properties of the medium. Thus, the trailing positive signal portions catch up with the leading portions during wave propagation. At the end of this process an ideally steep (shocked) front of the wave is built up, even if the wave starts as a sinusoid (assuming the starting positive amplitude is high enough to feed the nonlinear effects). The time and the source distance until the signal is fully steepened depend on the starting pressure of the sound wave, focusing (convergence) of the wave, and properties of the medium such as attenuation and nonlinearity coefficient.

In media with low attenuation (like water), already at rather low energy settings, steepening frequently occurs somewhere in front of the focus of the ESWL or ESWT devices. But the energies at higher frequencies, which are generated by steepening, are more strongly affected by attenuation in tissues. Therefore, it can be assumed that steepening in tissue needs a longer path length or higher starting pressures as in water.

Generation and Excitation of Cavitations

Cavitations are characterized by the occurrence of vacuum or gas-filled bubbles in a fluid medium. Stable cavitation bubbles are in a state of equilibrium when the vapor pressure inside the bubble is equal to the pressure of the fluid.

If the rarefaction pressure of the sound wave exceeds a certain threshold, which depends on the frequency of the wave and properties of the surrounding medium, then chemical bonding forces can be exceeded even in homogeneous media [33.24]. The bonds break up and cavitation bubbles occur. The theoretical cavitation threshold of tissues was estimated to be -16 MPa [33.33, 44], though cavitation events can be observed at significantly lower rarefaction amplitudes during lithotripsy. Most likely cavitation occurs close to stones and inside vessels [33.45].

The rarefaction portion of a sound wave is also responsible for another cavitation effect – micro bubbles, which may exist as remainders of larger collapsed bubbles start to grow during the rarefaction pressure portion of the sound waves. They may reach a stable size, up to three orders of magnitude larger than the original size. These bubbles may remain stable for several hundred microseconds.

After this stable phase, oscillations of the bubble occur until it is reduced to its final size. Every time during oscillation when the bubbles reach their minimum volume, they emit a shock wave to the surrounding environment, called a collapse wave. Afterwards, they

start growing again and the cycle is repeated. The number of oscillations as well as the maximum size of the bubble depends largely on the properties of the surrounding medium. Occasionally these bubbles may be observed for more than 1 s [33.37]. In large vessels, bubble clouds could be identified by ultrasound images [33.46]. Other research groups have used an external sensor to measure cavitation signals extracorporeally during lithotripsy [33.47].

When a shock wave hits a cavitation bubble, the excess external pressure leads to a shrinking of the bubble, while the bubble absorbs a part of the sound energy. When the exciting forces and energies are large enough, this leads to a forced bubble collapse. During the collapse, a part of the energy stored inside the bubble is released as a new acoustic wave to the surrounding medium. The maximum collapse energy is released when the original bubble radius is around $500\ \mu\text{m}$ (these values are valid for water and typical lithotripter shock waves). The bubble collapse takes place about $2\text{--}3\ \mu\text{s}$ after the shock wave has passed by. The collapse pressure amplitude is about $1/10$ of the original shock wave pressure and its duration is typically 30 ns. Thus, the acoustic energy of the collapsing bubble is 1000 times less than that of the exciting shock wave. Larger bubbles do not collapse that hard because they are slowed down by the rarefaction phase of the shock waves.

As a shock wave usually hits a bubble only from one side, the bubble collapse tends to be asymmetric, in particular close to interfaces. In this case, a water jet in the direction of the nearest surface is created (Fig. 33.5). The water jet can reach velocities as high as 400 to more than 800 m/s. Thus, the jet has enough power to perforate aluminum foils and plastic membranes.

During a bubble collapse, local effects may harm the tissue, which leads to small bleedings (petechiae) inside the tissue and at the skin. At cell level, an increase in the permeability of cell membranes is attributed to the effects of cavitation [33.9, 48].

Around the year 1990 researchers tried to find out if a bubble collapse would be able to create free radicals. To date, free radicals have only been identified in extracellular space. The question of whether free radicals caused by collapsing cavitation bubbles might also appear inside cells is still controversial [33.49, 50].

Trailing after the positive pressure pulses, the signal of every pressure pulse source also includes rarefaction portions. Due to these rarefaction portions, bubble seeds several micrometers in size grow to large bubbles of several hundred micrometers. Due to these bubble seeds, new active cavitation bubbles are created. How-

ever, the exact thresholds for this process are not defined. Depending on the water purity and gas content, values between -0.5 and -20 MPa can be found. For tissue a theoretical cavitation threshold of -12 to -16 MPa was estimated [33.51]. Furthermore, the duration of the rarefaction signals additionally plays an important role. The shorter the signal duration, the higher rarefaction pressures are tolerated by the tissue. In animal experiments with lithotripter pulses, the first damage occurred at about -1.5 MPa in mouse intestine [33.52]. Notably, lung tissue is very susceptible to damage [33.53].

Bubbles can be observed by high-speed photography at quite a large distance in front of the focus on the axis of a lithotripter pressure pulse source in water [33.54]. Recent measurements during stone treatments also demonstrated the occurrence of cavitation around the stone [33.55].

The amount of cavitation occurring in different tissues apart from the kidney is largely unknown. In water, bubbles may reach several millimeters in size. In tissue cavitation bubbles behave much differently. Most likely cavitation occurs in vessels and capillaries with a diameter of about $100\ \mu\text{m}$. These vessels contract immediately after the first shock waves [33.56]. It can be expected that the maximum bubble size is limited by the diameter of the vessels [33.53, 56, 57]. The collapse of

such small bubbles is significantly less powerful. Even a minor static excess pressure of 0.1 MPa is able to suppress cavitation completely [33.58].

It is of vital importance to restrict the maximum pulse repetition rate in order to avoid undesired side effects due to cavitation and its interaction with the trailing shock wave [33.59]. Besides reduced tissue damage, the number of shocks needed to disintegrate a given stone mass is also reduced when the pulse repetition rate is limited to $60/\text{min}$ or even less [33.60].

33.2.6 Thermal Effects Caused by Pressure Pulses

The pulse duration of a clinical pressure pulse or a shock wave is very short; as a rule, the time duration of the complete wave is only 3 to $5\ \mu\text{s}$. Nevertheless, a peak power of more than one megawatt per pulse can be reached. The average sound energy per pulse in the focal region is 10 to $150\ \text{mJ}$. Depending on the pulse intensity, the energy setting of the device, the pulse repetition rate, the stone material, and the heat conduction properties of the surrounding medium, the stone may warm up during the course of a treatment. In vitro, a maximum temperature elevation of $1.5\ ^\circ\text{C}$ was measured [33.61].

33.3 The Acoustic Field of a Lithotripter – Basics of Measurement Technology

The following description of the acoustic field of lithotripters will be restricted to those parameters that are most relevant in practice. They are defined in the international measurement standard IEC 61846 Pressure Pulse Lithotripters [33.34, 62]. The correlation of these parameters to stone comminution is shown in Table 33.5. The most relevant parameter for stone comminution is the acoustic energy that hits the stone, i. e., the energy distributed in the cross-sectional area of the stone [33.63, 64]. The biological importance of the pressure pulse parameters is less understood and will be discussed in a later chapter.

To evaluate the pressure pulse parameters, measurements must be made in degassed water according to the International Standard IEC 61846 (because no internationally acknowledged standard tissue phantom is defined). Sound waves are less attenuated in water as compared to tissue and the nonlinearity parameters of water are different from those of tissues. Therefore, the

measurement results cannot be directly applied to the situation in an individual patient. If a wave propagates in tissue, then the sound signals are influenced by the tissue layering, the attenuation of sound, and the nonlinearity parameters. As a rule, the greater the attenuation of the amplitudes, the greater the reduction of the amplitudes of higher frequencies in the pressure pulse signals. Thus the rise time of the pulses increases, resulting in an individual change in focal geometry [33.39, 40].

33.3.1 Sensors and Measurement Technology

New sensors for shock waves and pressure pulses continue to be developed. The most important parameters for these sensors are as follows:

- Small effective diameter to allow for measurement of parameter changes in small-scale highly focused

- fields, where the pressure amplitudes may vary by > 50% within a range of 2–5 mm;
- Broadband from < 100 kHz to > 10 MHz with low sensitivity variation (< 3 dB) [33.76, 77];
- Resistant to at least several thousand pulses;
- Known linearity over a broad pressure range (less than –10 MPa to more than 50 MPa);
- Constant calibration and easy recalibration during use;
- Appropriate price per pulse;

Table 33.5 Hydrophones used for lithotripter measurements. A comparison of the wave forms of the most frequently used hydrophones is given in Fig. 33.6

Sensor type	Advantages (+)/disadvantages (–)	In use since	Literature/ comments
Piezoceramic sensor	+ Simple handling + Long service life – No good signal reproduction	1970	Used as hydrophone for quality control (long term stability of lithotripters)
PVDF membrane	+ Good signal reproduction – Cavitation damage – Short service life – Very high prize – Large sensor head dimensions	Ca. 1982	[33.65] [33.66] Focus hydrophone according to IEC 61846; Reference hydrophone according to FDA
Contact-free PVDF membrane	+ Long service life – Relatively large effective aperture	1992	[33.67]
PVDF needle (IMOTEC)	+ Long service life + Reasonable price per pulse – P-reproduction varies – Cavitation damage	1987	[33.68, 69] Mostly used hydrophone in the past years; field hydrophone according to IEC 61846
Fiber optic hydrophone using the reflected light at the fiber tip, which is modulated by a transient change of water density by the pressure pulse	+ Good signal reproduction + Long service life + Reasonable price per pulse + Good P-reproduction + Easy calibration – Fragile fiber needs frequent maintenance – Handling requires much training	1988	[33.70] Focus Hydrophone and field hydrophone according to IEC 61846
Fiber optic hydrophone based on interferometer principles	+ Good signal reproduction + Good P-reproduction + Can be used in vivo – Handling only by trained personnel – Fragile fiber needs frequent maintenance – Service life?	1998	[33.71, 72]
Light spot hydrophone (LSHD), using the reflected light at a glass–water interface, which is modulated by a transient change of water density by the pressure pulse	+ Good pressure signal reproduction + Good reproduction of rarefaction pressure + Robust and durable, glass block can be easily exchanged, usually only slight adjustments of the glass block position required after damage, without the need to leave the measurement position + Calibration can be checked at any time – Large sensor head dimensions	2004	[33.73]
Steel ball sensor	– No good signal reproduction + Long service life + Reasonable price per pulse	1991	[33.74] Quality control hydrophone and measurement of cavitation signals
Capacitive steel block sensor	– Signal fidelity low + Very durable + Low price per measurement	1990	[33.75] For quality control

- Hydrophones must satisfy the requirements of IEC 61846 for a focus hydrophone or field hydrophone depending on the intended use;
- High adhesion to water to avoid cavitation at the hydrophone surface.

With a hydrophone made of plastic material like PVDF the last point in particular is very difficult to achieve. Rarefaction pressures of more than approximately -5 to -10 MPa often cannot be measured with sufficient reliability with such hydrophones due to the signal distortions caused by cavitation.

An additional major source of problems is the low cavitation resistance of the PVDF membrane hydrophone electrodes. They are very sensitive to pits caused by cavitation jets, which results in electrical interruption of the sputtered leads and significantly decreased sensitivity.

PVDF needle hydrophones are made of a PVDF-coated steel needle. Therefore they are less sensitive to damage [33.68]. In recent years, this type of hydrophone has frequently been used as a standard shock wave hydrophone because of its comparably long service life and reasonable price [33.26, 30, 69], but it has significant disadvantages. The metal needle is mechanically excited by shock waves and thus generates additional signals interfering with the trailing parts of the pressure pulse, in particular with the rarefaction part. Therefore, the reproduction of rarefaction portions and most of the signal energies are not reliable with this type of hydrophone (Fig. 33.6).

Hydrophones made of glass fibers are particularly advantageous because the adhesion of water to glass is

higher than the cohesion of water itself [33.70]. Thus, as cavitation at the probe surface is less likely, rarefaction pressures can be measured with high reliability. If any cavitation events occur at an optical hydrophone due to gas bubbles in the fluid, they can be identified by a rapid leap in the hydrophone output voltage, as the reflectivity of the laser light will change instantaneously in the presence of a gas bubble. As an alternative to the fragile glass fiber, the active surface of the light spot hydrophone (LSHD) is composed of a thick glass block, which also is able to tolerate very large rarefaction pressure amplitudes without causing cavitation [33.73].

In conclusion, because of all these problems and the extremely high price of fragile PVDF membrane hydrophones, the state of the art in measurement technology are optical hydrophones such as the fiber-optic hydrophone and the LSHD.

33.3.2 Measurement Parameters of Lithotripter Sound Fields

International Standard IEC 61846 describes the measurement parameters in detail. Further requirements, in particular for ESWT devices, are specified in a consensus paper of the Technical Working Group of the German Society for Shock Wave Lithotripsy (DGSL) [33.78]. The DIGEST (German and International Shock Wave Therapy Society) also accepted the parameters and gave further advice on their application.

The correlation of the parameters with the comminution of stones and with biological effects shall be discussed in the following sections.

Fig. 33.6 Comparison of the focal wave form of a pressure pulse source at different energy settings, measured using three different hydrophone types. The amplitudes were calibrated to read the same p_+ value. While the rise time and the p_- amplitude are reproduced comparably, the pressure-time curves and thus the energy flux density values measured by the PVDF needle probe are significantly different. In contrast, the PVDF membrane hydrophone and the fiber-optic hydrophone display almost the same curves

Pressure – Time Parameters of Single Waves: Pressure, Intensity, Energy Flux Density, Pulse Duration, Rise Time

The *amplitudes* of the *positive* and the *rarefaction pressure* are read from oscilloscope recordings of single pressure pulses (Figs. 33.2 and 33.6). The significance of the peak positive pressure values for the efficacy of lithotripters were often overestimated in the past. The actual pressure value seems not to have a high correlation to stone comminution as long as the pressure exceeds a certain (stone-material-dependent) threshold.

The *rise time* is determined as the difference in time between the 10 and 90% points of the positive pressure amplitude. In order to determine a typical shock wave's rise time of $< 5\text{--}10$ ns, it is necessary to use oscilloscopes and sensors with a frequency bandwidth of 500 MHz and sampling rates of 1 GSample/s. Additionally, the effective sensor area has to be adjusted exactly parallel to the shock wave front. Otherwise, parts of the sensor receive the wave with a temporal delay and thus the rise time of the wave appears to be longer. On the other hand, rise time has not been identified up till now as a very important parameter in the usual ESWL and ESWT regimes (< 5 ns to > 250 ns); thus the measurement efforts can be slightly relaxed. Measuring with a reduced bandwidth (e.g., 20 MHz) will reduce the noise, thereby enhancing the measurement quality.

The *pulse width* is defined as the signal duration between those points in time when a level of 50% of the maximum positive pressure amplitude is reached. When the wave form is complicated, this pulse width definition may lead to misinterpretations, e.g., if the wave has a long duration but contains one high short-time peak, its pulse width may be largely underestimated. These kinds of waves occur in regions outside the focus of a lithotripter.

The *pulse intensity integral* (PII) is a measure of the average power per pulse. A synonymous, more common term in lithotripsy is *energy flux density* (ED) per pulse. The unit of ED is J/mm^2 . Usually a manufacturer's technical specifications of the ED state the maximum value measured in the focus. There is a high correlation of ED to the depth of a crater that is eroded out of model stones after a number of shocks. On the other hand, in vitro experiments with perfused pig kidneys also showed the relevance of ED+ (ED of the positive portion of the pressure pulse) in determining the risk of tissue damage [33.79].

Spatial Parameters of Signals in the Pressure Pulse Field

When the location of the measurement is only several millimeters away from the focal maximum, the shape of the pulses changes significantly [33.80]. The rise time of the signal increases quickly at positions other than the focal maximum [33.81]. The pressure-time curves before and after the focus depend on the kind of pressure pulse source. In the case of spark-gap sources, a shock wave is found before the focus. In the case of electromagnetic shock wave emitter (EMSE) and piezo sources that emit less steep signals, the shock front may only occur several millimeters before the focal region, depending on the energy setting. It should be noted that the steepness of the front is of minor significance for the disintegration of stones [33.82].

Axial and Lateral Pressure Distribution, Full Width Half Maximum or (–6 dB) Width

Axial and lateral distributions of the positive pressure in the focal region usually are plotted in a graphic representation (Fig. 33.7). From these curves single values are extracted as a compact description of the focus according to the standard IEC 61846. According to the standard, the *full width half maximum* (FWHM) values of the axial and lateral pressure distributions are stated. The FWHM values give the spatial distance between those points where the pressure amplitude has 50% of the focal peak value. The term –6 dB width is used frequently instead of the term FWHM.

The *focal volume* is calculated from these axial and lateral –6 dB values under the simplifying assumption that the focal region is shaped like an elliptical cigar that extends along the direction of the wave propagation path.

However, the medical significance of these (standardized) values is not clear. All those values are based on measurements relative to the peak positive focal pressure, which depends on many technical design parameters. Besides the energy setting, the peak pressure mainly depends on the aperture angle of the source (the angle of a cone between source aperture and focus) – the larger the aperture angle, the higher the focal peak pressure and the smaller the focal FWHM values.

The correlation between pressure-based values and stone comminution effect is low. In contrast, it is shown below that the effective energy is very important for stone comminution. Also, in most publications, biological effects are described in terms of intensity and ED values [33.79, 83].

33.3.3 Energy Parameters of the Sound Field

The ED is calculated by integrating the squared pressure pulse signal; therefore, ED is also called the PII. Lateral from the axis, the ED values decrease at about the same rate or faster than the peak pressure values because ED depends on the square of the pressure.

The focal energy is calculated by integrating the ED values in the -6 dB focal area. So the term *focal energy* specifies the energy that is evaluated in a circle around the focal spot (point of maximum pressure) with a diameter of the FWHM [(1) in Figs. 33.7 and 33.8].

Effective energies are calculated by integrating over a certain effective area, which is defined from certain effects. An important effective area is a circle with a radius of 6 mm around the focus, which is a typical stone radius in ESWL. It is important to note that a comparison of the energies of different pressure pulse sources is only possible based on the same effective areas, as a comparison based on the focal energies within the

FWHM would be misleading when the focal dimensions are different.

The *total energy in the focal area* is approximated by $E_{5\text{MPa}}$. This energy is calculated by integrating the EDs over the focal area, which is delimited by the radius where the pressure just exceeds 5 MPa.

The total energy of larger sources (EMSE, piezo) is about the same as the emitted primary acoustic energy. In contrast, in sources that use reflecting mirrors for focusing purposes, the total energy additionally depends on the portion of the (spherical) wave that is reflected by the mirror. Thus in reflector systems the total energy sometimes is less than half of the primary acoustic energy. The nonfocused portion also hits the patient but does not contribute significantly to stone comminution. It is possible that the unfocused wave portions contribute to the dynamics of cavitation bubbles.

In general, the larger the aperture angle of the system, the larger is its focal pressure as well as the focal ED at a given level of primary acoustic energy. In contrast, the lateral focal dimensions decrease with increasing aperture angle. Thus, a pressure pulse source

Fig. 33.7 Many spatial pressure field parameters are derived from measurements of the axial and lateral p^+ distributions, according to the standard. In contrast, for the assessment of the disintegration efficacy, the effective energy $E_{12\text{mm}}$ in the circle delimited by a 6 mm radius and the effective energy $E_{5\text{MPa}}$ in the circle delimited by the 5 MPa pressure value are much more important

Fig. 33.8 Energies (circles) are calculated by spatial integration of the energy flux density values (diamonds). In circular symmetric pressure pulse sources, the energy can be calculated by integration over a certain radius. Biologically effective areas are delimited by the radius where the ED threshold (0.1 mJ/mm^2) for the generation of stress fibers or the detachment of endothelium (0.3 mJ/mm^2) occurs. Radii important for the stone comminution are 6 mm, and the 5 MPa limit. (1) Focal energy flux density (ED) (2) Radius r_2 delimiting the area where ED is larger than 0.3 mJ/mm^2 ; (3) Radius r_3 delimited by the half-maximum focal pressure value FWHM. Integrating inside this area calculates the focal energy; (4) Radius r_4 that encloses ED values larger than 0.1 mJ/mm^2 ; (5) Radius r_5 (here: 6 mm) that delimits the area of a typical model stone or stone concretions. Integration yields the energy $E_{12 \text{ mm}}$, which is relevant for stone comminution. Integration up to the boundary of the measured area yields the total focal energy. Usually this value is well approximated by an integration in the area delimited by the 5 MPa pressure values (not shown in the figure)

with a large aperture angle may have a high focal ED even though the total energy is low.

A significant pressure pulse effect on biological tissues and on stones can only occur if the energy thresholds of the material are exceeded. These energy thresholds are difficult to evaluate; some values will be given below.

Primary Acoustic Energy and Electrical Energy

The primary acoustic energy is concentrated in the focal area by focusing. Depending on the type of the pressure pulse source, it is not possible to focus the complete primary acoustic energy as in systems with a point source focused by a mirror. An (additional) portion of the energy can be shaded by inline scanners or other structures in the sound field [33.30].

The electrical energy necessary to drive the sound source is usually stored in a capacitor. It is calculated from the capacitance multiplied by the square of the charging voltage. Only a fraction of this electrical energy is transformed into acoustic energy; the rest is dissipated as heat in the source. Different source types have differing electroacoustic efficiencies and use dif-

ferent capacitor voltages. Therefore, neither voltage nor primary energy is appropriate for comparing different sources.

Spatial Distribution of Rarefaction Pressure

In the early years of lithotripsy, the measurement of the rarefaction pressure amplitudes in regions close to the focus was unsatisfactory. Already at low rarefaction pressures of several megapascals cavitation may occur [33.24], in particular at the surface of a PVDF hydrophone. In addition, some hydrophones are less sensitive to rarefaction pressures. Furthermore, the trailing rarefaction signal parts sometimes interfere with reflections of the wavefront at the hydrophone. Since the introduction of the fiber-optic hydrophone as well as the LSHD, the reproduction of rarefaction pressures has been significantly more reliable, as the adhesion at the water–glass interface is strong. Thus, the occurrence of cavitation on a glass surface is unlikely. If cavitation occurs nevertheless due to the presence of cavitation nuclei on the glass surface, the onset of cavitation can be immediately identified by a signal jump in the hydrophone output.

The primary acoustic signal generated by an EMSE or a spark-gap source does not contain significant rarefaction pressures. Nevertheless, rarefaction occurs in the focal region along the axis. It is caused by the diffraction wave at the rim of the sound source or reflector. This rarefaction wave appears to be a mirror image of the positive pressure wave, which is emitted by the outer ring of the aperture.

In the design phase of a pressure pulse source the suppression of rarefaction signal portions is one important point. As the rarefaction signal is not affected by nonlinear steepening, its amplitude in the focus remains lower than the steepened positive pressure amplitude (ca. 1/10 to 1/5). The usual duration of the rarefaction signal is about the same as the duration of the primary pressure pulse (2–5 μ s).

Due to nonlinear effects, the positive pressure focus is axially shifted away from the geometric focus of the source by some small amount. In contrast, the focus of nonsteepened signals is shifted slightly closer to the source. Therefore, the maximum of the rarefaction pressure may occur several millimeters before the positive pressure maximum.

The piezo source generates a trailing additional rarefaction pressure signal that merges with the edge diffraction wave in the focus. This additional rarefaction pressure can be minimized by certain electrical and mechanical design features.

33.3.4 Significance of the Pressure Pulse Parameters in Lithotripsy

In the early years of urethral stone lithotripsy, most of the sound field parameters shown in Table 33.6 could not be measured with sufficient accuracy and usually were not published. Either the peak positive pressure or the capacitor voltage of the spark-gap source was used to characterize the treatment parameters. Of course, as soon as different generator types (electrohydraulic, EMSE, piezoelectric) appeared, this led to confusion and misinterpretation. The characterization of clinical study parameters based on capacitor voltages does not provide sufficient information to compare different treatment regimes and devices. One of the major advantages of the international measurement standard IEC 61846 is that it improves the comparability of data and study results.

Table 33.6 shows the correlations between different standardized physical parameters and the comminution of stones. It can be concluded that the effective energy impinging on the stone is the most important param-

eter for the eroded volume (i.e., $E_{12\text{mm}}$ and $E_{5\text{MPa}}$), whereas the pulse intensity distribution determines the depth and shape of the eroded craters. The 5 MPa value, which was used to determine the boundary of the eroded area, is a fair estimate of the disintegration threshold of stone materials (ca. 2 to 10 MPa [33.84, 85]).

All energy values include a dose effect. The number of shocks S_z per stone volume V increases proportionally as the effective acoustic energy per shock E'_{eff} decreases, given by $E'_{\text{eff}}/V = \text{const}_{\text{Material}}/S_z$ [33.28]. The material constant ($\text{const}_{\text{Material}}$) depends on the stone composition, and its value for model stones is ca. 2 mJ/ml [33.63].

Stone comminution only occurs when a certain threshold energy per shock E_0 is exceeded, which is material dependent. Thus the effective energy that contributes to comminution is $E'_{\text{eff}} = E_{\text{eff}} - E_0$. The endpoint of comminution is reached when all concretions are crushed to less than 2 to 3 mm because these fragments can pass the urethra spontaneously without causing many problems.

Other parameters like peak pressure, rise time, and pulse width seem to play minor roles in lithotripsy – at least as long as they are in the typical ranges shown in Table 33.6.

The most important parameters for other treatment modalities have not yet been identified. In pain therapy (ESWT), thresholds of the ED seem to play a major role (see below). Therefore, in the future it may become important to introduce energies based on different areas whose boundaries are determined by ED (PII) threshold values [33.81, 86, 87]. These threshold values need to be evaluated by biological and other model experiments.

According to the standards, the –6 dB focal dimensions are calculated from those positions where the positive pressure has decreased to 50% of the focal maximum value. Thus, all those focal dimensions strongly depend on the focal peak pressure. This has a number of implications. The stronger the focusing of a sound source, the higher is its peak pressure and consequently the smaller its focal diameter becomes. However, as the disintegration, and thus the effective focal diameter, does not depend on peak pressure but on a threshold value (e.g., 5 MPa), this implies that the statement of a –6 dB focal extent is not a valid measure for the efficacy of a lithotripter or an ESWT device. Nevertheless, there is an ongoing discussion about which device is better: one with a small or one with a large focus (see below).

Symbol	Parameter	Unit	Typical value range	Significance	Comment
Focal parameters				According to standard IEC 61846 measured at the location where $p+$ is maximum in the sound field (acoustic focus) [33.34]	
$p+$	Peak positive pressure	Megapascal, MPa	7 to > 80 MPa (ESWT) 20 to > 100 MPa (ESWL)	Low correlation to stone disintegration* (0.704**) (0.54***)	
$p-$	Peak rarefaction pressure	Megapascal, MPa	-3 to -15 MPa	Correlation to disintegration unknown* (0.394**)	Significant for the creation of transient cavitation
T_r	Rise time (measured from 10 to 90% of $p+$)	Nanoseconds, ns	< 5–500 ns	Low correlation to stone disintegration* (0.006**)	Varies significantly in the sound field lateral of the focus
T_w	Pulse width (measured from 50 to 50% of $p+$)	Nanoseconds, ns	< 150–> 500 ns	Important to determine the integration limits of PII and energy parameters	
P_{II+} , ED+	Pulse intensity integral or energy flux density of the positive signal portion	Millijoules per millimeter squared, mJ/mm ²	< 0.02–0.8 mJ/mm (ESWT), < 0.1–> 1.2 mJ/mm (ESWL)	Correlates to the depth of a crater in stone material as well as to effects on cells*	Lateral distribution of P_{II+} correlates to lateral distribution of $p+$ [33.81]
P_{II} , ED	Pulse intensity integral or energy flux density of the complete wave (until the absolute value is less than 10% of the peak amplitude)	Millijoules per millimeter squared, mJ/mm ²	< 0.03–1.0 mJ/mm ² (ESWT), < 0.1–> 1.2 mJ/mm ² (ESWL)	Correlates very good to the depth of a crater in stone material (0.99***) as well as to effects on cells*. Correlates fairly to the eroded volume. (0.801**) (0.75***)	Lateral distribution of P_{II} correlates to lateral distribution of $p+$ [33.81]
Field parameters					
w_x, w_y, w_z	Focal extensions measured from pressure distributions in X, Y (lateral) and Z (axial) directions between the locations of 50% of $p+$	Millimeters, mm	Lateral: < 2–> 8 mm Axial: < 15–> 100 mm	Low correlation to stone disintegration*	Often misinterpreted as significant for Disintegration power of a source
V_f	Focal volume, usually approximated by $V_f = \pi/6 w_x w_y w_z$	Cubic millimeters, mm ³	< 100–> 1 000 mm ³	Correlation to stone disintegration unknown	Often misinterpreted as significant for disintegration power and sensitivity towards misplacement of a target (see below)
$E+, E$	Focal energy derived by integrating the P_{II} distribution to the lateral focal extensions w_x, w_y . The time integration limits either include the positive signal portion for $E+$ or the complete signal for E	Millijoules, mJ	$E+$: 0.5–180 mJ E : < 1.5–230 mJ	Low correlation to stone disintegration* (0.442**) (0.62***)	Parameter must not be used to compare different pressure pulse sources, if their focal width w_x, w_y is different
E_{eff+} , E_{eff}	Effective energy derived by integrating over a predetermined area, e.g. a circle with 12 mm diameter: E_{12mm} or a circle including pressures > 5 MPa: E_{5MPa}	Millijoules, mJ	$E+$: 0.5–65 mJ E : < 1.5–80 mJ	Highest correlation of all energy parameters to disintegrated stone volume (T_{total0} : $r = 98$ **) (E_{5MPa} : $r = 0.97$ ***)	Most important parameters to determine stone disintegration, see text

Table 33.6 Parameters describing the sound field of a pressure pulse source [33.34, 78]. The correlation of the parameters with stone disintegration and biological effects marked * were taken from [33.26, 82] and [33.89]. The ** numbers in brackets are correlation coefficients, composed of experiments with six different pressure pulse sources [33.90]. The correlation coefficients marked *** were taken from [33.26], those marked **** are from [33.82]. The parameters are shown in Figs. 33.2 and 33.6–33.10 ◀

Instead of using the -6 dB focal width for the characterization of a lithotripter, a more relevant parameter will be proposed: the *disintegration diameter*. This value is determined by the diameter of the area that is bordered by an increase, by a factor of 2, in the number of shocks necessary for the disintegration of a typical concretion, as compared to the shock number in the focus (Fig. 33.9). Model stone (12 mm diameter) measurements with different lithotripters have demonstrated that the disintegration diameter does not depend on the standardized (-6 dB) focal dimensions. The disintegration diameter seems to depend only weakly on the pressure pulse source design (spark gap or EMSE); in particular there is only weak dependence on the aperture angle of the source (angles between 54° and 74° were tested). The disintegration diameter turned out to be 18 to 22 mm [33.88]. The experimental setup and measurement results are shown in Figs. 33.9 and 33.10.

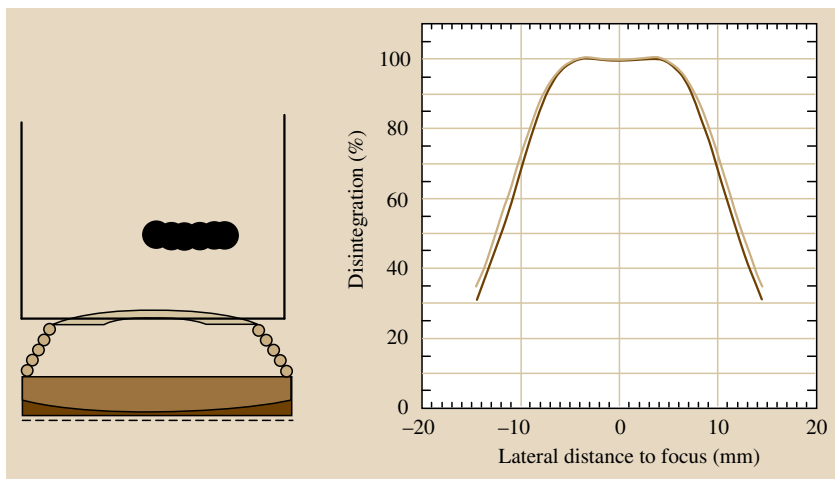

Fig. 33.9 The number of pulses for the comminution of a 12 mm stone to concretions < 2 mm in size is doubled when the stone is displaced by ± 11 mm beside the focus. The experiment was carried out with different pressure pulse sources (spark gap, aperture angle 54° , and EMSE 62°). Nevertheless, the measured differences in disintegration are minor. The *disintegration diameter* $f'x$, which is defined by a decrease in the disintegration efficacy of 50%, which means doubling of the number of pulses is 22 mm in both sources

33.3.5 Which Physical Effects Play a Significant Role in Stone Comminution?

A number of effects that contribute to stone comminution were published recently:

- Direct action of the pressure pulse forces on a stone leads to cracks due to stress and to the growth of cracks [33.91].
- Strongly focused waves lead to a cone-shaped erosion of the stone [33.92].
- Spallation effects are caused by the reflection of the pressure pulse at the rear side of the stone, including polarity reversal of the reflected wave (Hopkins effect) [33.91]. The reflected pulse overlaps with the rarefaction portion of the impinging pulse, leading to high strain forces inside the stone. This effect explains findings on impacted concretions that are disintegrated from the back toward the front.
- Cavitation effects are responsible for the expansion of cracks. They also induce extremely high amplitude collapse pressure pulses of a few nanoseconds' duration directly on the stone surface, and, due to water jets with speeds of 200 to 800 m/s, they are able to drill pits into the stone surface [33.71, 91]. Homologous craters can be identified in microscopic images at the stone front facing the wave.

Fig. 33.10 The focal pressure distributions of stronger and weaker focusing sources mainly show large differences in the area of ± 2 mm around the focal maximum. Thus the standardized (-6 dB) focal width F_x of the strongly focused source (circles) is only 2.5 mm, the standardized (-6 dB) focal width F_x of the next weaker focused source (triangles) is 6 mm, and that of the weakest focused source is 18 mm (diamonds). Nevertheless, the effective disintegration diameter of all three sources is almost identical (18 to 22 mm), as the disintegration threshold of ca. 10 MPa is reached at almost the same diameter with all three sources

- Clusters of cavitation bubbles collect around the stone. During collapse, they act as a water hammer [33.93].
- Due to different velocities of wave propagation inside and outside the stone, mechanical strains are created by the passing waves, which lead to binary fraction of the stones (fraction into two pieces) due to growing micro cracks [33.84].

The contribution of each effect to the final stone comminution is not yet clear. It can be estimated that the importance of every effect varies depending on the surrounding medium around the stone (fluid, in part or completely impacted, e.g., in the shoulder tendon or in the urethra). If a reasonably low static positive pressure restricts cavitation, then stone comminution is reduced by ca. 20%, i.e., the number of shocks necessary to crush the stone into pieces smaller than 2 mm increases by 20%. If the stone is surrounded by a medium of higher viscosity, e.g., castor oil, then the number of shocks also increases and the final concretions remain larger. This occurs due to the suppression of cavitation in the oil [33.94]. At higher surrounding static pressure or impacted stones, the additional static forces can lead to slower growth of cracks [33.84].

Different stone materials need typical energies for the cracking of a unit volume into pieces smaller than 2 mm [33.30, 95]. The typical energy value of model stones made of plaster, which are frequently used for lithotripter test purposes, is about 2 mJ/ml [33.63]. At the same time, the pressure must exceed at least 2 to 10 MPa [33.84, 85]. Disintegration takes place at those parts of the stone where the pressure threshold is exceeded. The amount of transgression seems to be of minor importance, which can be seen from the low correlation between peak pressure and disintegration. The amount of disintegrated stone volume per shock depends on the effective energy per shock.

However, when treating patients the influences of the tissue as well as the geometrical conditions of the sound path play a fundamental role in overall treatment success. These influences will be discussed in a later section of this paper.

33.3.6 Effect of the Pressure Pulses on Tissue

It is of great interest to distinguish between unintended side effects (e.g., bleeding during lithotripsy or irritation of nerves after ESWT), and desired effects. While the

Table 33.7 Energy flux density thresholds for biological effects of pressure pulses on cells

ED, PII (energy flux density)	Finding	Note	
0.3 mJ/mm ²	Complete detachment of endothelial cells, occurring at the entrance side of the pressure pulse Most likely caused by positive pressure	Thrombosis, occlusion of a vessel ED based on PVDF needle hydrophone measurements	[33.83]
0.22 mJ/mm ²	Rounded mitochondria in attached cells	ED based on PVDF needle hydrophone measurements	[33.83]
0.1 mJ/mm ²	Stress fiber formation in adhering endothelium	Reaction to shear forces, likely a reaction to cavitation forces. ED based on PVDF needle hydrophone measurements	[33.83]
0.045 mJ/mm ²	Bleeding of intestine	Mouse model, ED values were estimated from the published signals	[33.52]
0.007 mJ/mm ²	Skin damage	Mouse model, ED values were estimated from the published signals	[33.52]

mechanisms of stone comminution in ESWL are largely known, the healing effects in ESWT are not well understood in a biophysical sense. The shock wave might generate micro defects, which lead to rebuilding processes in the diseased tissues. The focusing of shock waves on soft tissue leads to a release of substance P and the triggering of cellular cascades [33.96].

The following mechanisms are identified:

- A dose effect, which increases with an increasing number of pressure pulses [33.52];
- An energy-dependent effect, which increases with increasing energy per shock;
- The effect of cavitation, which is mainly attributed to a shock wave–bubble interaction [33.97, 98].

The biological pressure limits that can be found in the literature were mostly determined for side effects of shock waves during lithotripsy. Other side effects of lithotripsy have rather biological causes, e.g., by obstruction of the urethral pathways. Altogether severe side effects that require treatment like kidney or subcapsular hematoma occur only in a small number (0.1–0.7%) of treatments [33.99, 100]; a transient hematuria is a more or less frequent effect that is accepted as a common side effect. Cavitation has been identified as the main cause of damage.

The ED thresholds for the generation of stress fibers and stronger effects on cells were evaluated using a human umbilical cord model [33.83, 101]. The effects and associated ED values are shown in Table 33.7. It should be noted that the ED values were determined using PVDF needle type hydrophones and integrating over the complete pressure signal. The large potential errors of this kind of sensor were already mentioned

in the measuring technology section above. From the lateral ED distributions of a pressure pulse source it is possible to estimate the biologically effective zones using the threshold values. These zones can be characterized by the diameter of areas comparable to the disintegration diameter given above. Presently the values serve as a coarse guide to the adjustment of devices. In order to assign these values to real treatment situations, they still need to be verified with a better pressure pulse measurement technology and more realistic tissue models. Recent experiments with perfused pig kidneys showed a strong correlation between damage and the ED+ values, while no good correlation to other shock wave parameters were found [33.79].

The limits of unwanted bone damage are only indirectly known. Microscopic and macroscopic fractures were found in most cases at extremely high energy settings, which are rarely used in lithotripsy [33.7, 102–104].

No significant long-term side effects of ESWT or damage that could be shown by diagnostic means have been reported in the orthopedic literature to date, although some damage has been demonstrated in animal tests. Still, there are a number of directions that it is vital to verify if ESWT really is the appropriate treatment for the diagnosed disease [33.105].

The pressure limit for skin damage was determined at 0.6 to 1.6 MPa and for intestinal bleeding at 1.6 to 4 MPa [33.52]. Thermal effects were excluded; thus the most likely damage mechanism is cavitation. The pressure pulses affected blood and other abdominal tissue much less. The ED values may be estimated from published graphical measurement data. The values are between ED = 0.007 and 0.045 mJ/mm².

33.4 Generation of Pressure Pulses for Extracorporeal Lithotripsy (ESWL) and Extracorporeal Shock Wave Therapy (ESWT)

In practice, all ESW sources are composed of a pulsed electrical energy source, an electroacoustical converter, and means for the focusing of the pulsed acoustic waves. Focusing is necessary to target the pressure pulse application area. With pointlike sources (e.g., spark gaps, laser discharges) and cylindrical sources, a focusing mirror is the first choice. Lenses are usually applied to focus plane sources (e.g., EMSE), while spherical curved sources (EMSE, piezo) are self-focusing.

At the end of each section, specific differences between the source concepts are discussed in terms of the generation of the pressure pulses and their effect on the wave fronts. However, it must be pointed out that it is not yet possible to make statements on the medical and biological relevance of these parameters.

33.4.1 Point Sources and Extended Pressure Pulse Sources

Depending on the generation principle, one must differentiate between point sources and extended sources. Point sources generate spherically expanding acoustic waves. Extended sources generate planar waves, cylindrically propagating waves, or spherically converging waves, depending on the source shape.

All those propagation modes of the primary sound waves require different means for focusing. Although, due to the nonlinear propagation, from the pressure signal measured in the focus of any source it is not possible to determine the kind of source and the focusing means. As will be discussed below, specific differences rather occur in the sound field outside the focus.

33.4.2 Generation of Spherical Pressure Pulses and Shock Waves

Spark-Gap Source (Electrohydraulic Source)

The first kidney lithotripter devices were equipped with spark-gap sources. This classical principle is still in use today. Comparable to the spark plugs of a car motor, a high voltage (usually 12 to 30 kV) applied to two electrodes a few millimeters apart generates an underwater spark, thereby generating an expanding plasma bubble, which leads to a compression of the surrounding water. After the electrical energy pulse has faded, a vapor bubble remains, which expands further with easing velocity and finally collapses after several hundred microseconds.

The effective primary compression wave is only generated during the existence of the plasma bubble. As this bubble expands at a speed that is greater than the velocity of sound in the surrounding medium, the wave front of this compression wave is extremely steep from the beginning and thus represents a shock wave by physical definition (Fig. 33.11). Its rise time is about 1 to 3 ns.

When the secondary collapse of the vapor bubble occurs, another, much weaker, shock wave develops.

The high voltage is stored in a capacitor of 40 nF to some 100 nF. Its complete energy content is transferred to the plasma bubble at the instant of the spark generation. The acoustic part of this energy is only a fraction of less than 1%.

Ellipsoidal Reflector for the Focusing of Spherical Waves. A rotational ellipsoid has the properties to concentrate in the second focus every acoustic event that happens in its first focus. If a target, e.g., a stone, needs to be placed in the second focus (the so-called *therapy focus*), then the ellipsoid must be cut somewhere at a suitable location (Fig. 33.12). The remaining mirror encloses a certain spatial angle of the spherical wave emerging at the first focus. Thus, this part of the spherical wave is focused, while the remaining part penetrates the tissue unfocused. The unfocused wave reaches the second focus earlier than the focused wave. Its maximum amplitude is less than 1 to 2 MPa, which is significantly less than the amplitude of the focused wave.

Nonlinear steepening results in an increasing axial shift of the pressure maximum of the focused wave by ca. 2 to 5 mm beyond the geometric focus F_2 .

Special Properties of the Spark-Gap Source. The small preliminary unfocused pressure pulse reaches the focus ca. 40 μ s before the main focused shock wave. Almost 1 ms after the focused signal a third, rather weak, pressure pulse may occur, which is generated by the collapse of the primary vapor bubble. It should be noted that this vapor bubble is generated due to the spark-gap principle and should not be confused with the occurrence of cavitation bubbles somewhere else in the field.

Pressure pulses generated by spark gaps usually have the properties of shock waves, which means that the pressure rise at the wave front is extremely rapid. Thus during the propagation in tissue the shock wave is particularly affected by the attenuation of its higher fre-

Fig. 33.11 Primary pressure pulse of an electrohydraulic spark gap source. *Small image:* enlarged view of the pressure pulse front with a steep rise typical for shock waves (rise time value delimited by the properties of the hydrophone used)

quencies. It can be assumed that part of the wave energy is completely attenuated before it reaches the focus. Due to the steepening process the high-frequency parts are constantly renewed, which again leads to further energy loss.

Recent Developments in Electrohydraulic Pressure Pulse Sources. The treatment concept of the first lithotripter generation included the use of a new electrode for every patient. This has the undisputed advantage that the electrode wear is well known over the course of treatment. Due to the increasing burn-up of the electrode tips, there are some disadvantages:

- An increasing electrode gap is the cause of an increasing ignition delay. During this delay part of the electrical charge drains off the capacitor. Thus, this part of the primary electrical energy is no longer transformed into acoustic energy.
- Due to the irregular erosion of the electrode surface, which is a side effect of the burn-up, the actual path of the spark, as well as the instant of ignition, fluctuates from shock to shock. This results in a fluctuation of the primary spherical pressure pulse amplitude, as well as a variation of the exact location of the spark. Therefore, the focal pressure varies largely from shock to shock – sometimes up to $\pm 30\%$.
- It is difficult to determine the true focal dimensions. According to the IEC standard, the measurement has to be repeated several times to get statistically relevant data. However, due to the statistical evaluations, the focal widths appear to be larger, while the peak pressures and EDs seem to be smaller.

Newer developments try to reduce the longer ignition delay due to increasing electrode gaps by increasing the conductivity of the surrounding fluid. For this purpose sometimes an electrolyte is used [33.106]. Due to these measures, the pressure variation from shock to shock is significantly reduced, treatment efficacy increases, and

the measured values of the focal dimensions become notably smaller.

Other manufacturers have developed adjustable electrodes. As the electrodes are placed in the center of explosions, the demands for safety and positional accuracy of the tips with respect to the ellipsoid focal spot play a very important role.

A very different approach was published by a Czech research group. They used a metal cylinder covered by a thin porous ceramic layer. A high number of ignition paths penetrate the pores of the ceramic layer in the direction of the surrounding highly conductive water. This setup represents an electrohydraulic cylindrical wave source, which may be focused using a rotational symmetric paraboloid mirror [33.107].

Explosives and Laser-Generated Shock Waves. As early as 1986, a Japanese lithotripter was built that used tiny explosive pills in the first focus of a rotational symmetric elliptic mirror. The device was used for the treatment of kidney stones, and reports about its application in ESWT therapy were published.

Fig. 33.12 The primary spherically expanding shock wave of the spark-gap source in the focus F_1 is refocused in the focus F_2 by a rotationally symmetric ellipsoidal reflector

The laser-generated thermal and dielectric breakdown of a fluid was also under research for the generation of shock waves [33.108]. Although this method is able to generate highly precise and reproducible pressure pulses, the high cost of applicable lasers makes this approach less feasible for commercial lithotripters. Therefore, the method is mostly used in academia for the generation and excitation of cavitations.

33.4.3 Generation of Planar Sound Waves

Electromagnetic Shock Wave Emitter

The principle of the electromagnetic shock wave emitter (EMSE) was published first in 1962 [33.109]. The source uses a flat coil that is energized by an electric current impulse of several kilo-Amperes. This results in

Fig. 33.13 The shape of the primary pressure pulse of the electromagnetic pressure pulse source (EMSE) is the square of the driving current pulse [33.109]. The wave contains only weak high-frequency components. Therefore, it is only slightly attenuated in tissue. A shock front occurs by steepening during propagation to the focus

Fig. 33.14 The electromagnetic pressure pulse source (EMSE) generates effective plane high-energy pressure pulses, which are focused by an acoustic lens. In the focus, they have shock wave properties if the primary pressure pulse amplitude is large enough and the tissue attenuation is not too high

a strong magnetic field extending over the area of the coil. The coil is covered by a thin insulator. On top of it is placed a highly conductive membrane. Due to the magnetic field of the coil, eddy current flows inside the membrane, which in turn creates a magnetic field with opposite polarity. Due to the two magnetic fields, the membrane is repelled (Fig. 33.14). Thus, the water is compressed in the volume above the membrane, which generates a positive pressure pulse with the shape of a squared semisinusoid (Fig. 33.13). The pressure distribution above the membrane is approximately constant. The duration of the pulse is $\approx 2\text{--}5\ \mu\text{s}$.

A capacitor again is used for the storage of the driving electrical energy. Its capacity is several hundred nanofarad to one microfarad, which is significantly more than the capacitor of a typical spark-gap source. Therefore, the charging voltage can be less; typical values for an EMSE are ca. 8 to 20 kV. Nevertheless, the electroacoustic efficacies of EMSE and spark gap (and piezo) are not comparable due to the different principles. Thus, a comparison of charging voltages or even electrical energies does not give useful information on the efficacy of different sources.

Acoustic Lenses for the Focusing of Sound Waves

Acoustic lenses are used for the focusing of planar pressure pulse sources like the EMSE or planar piezoelectric transducers. Depending on the velocity of sound of the lens material, its shape differs. If the velocity of sound is higher than that of the surrounding water, the lens shape becomes concave (e.g., perspex lenses). If the velocity of sound is less than that of the water, the lens shape becomes convex (e.g., silicon lenses).

Special Properties of the Electromagnetic Shock Wave Emitter

The primary acoustic signal of the EMSE has the shape of a squared sine half-wave at first. Its rise time is several hundred nanoseconds. Thus, it only contains a small amount of higher-frequency energy and is therefore only slightly attenuated in tissue. The higher spectral components occur during the propagation to the focus caused by the steepening process, when the primary acoustic pressure is high enough (ca. $> 1\ \text{MPa}$) and the propagation path is long enough.

Steepening by a Shock Tube

In order to generate a steep signal in front of the lens, a long tube can be inserted between the EMSE and the lens. During propagation inside the tube, the rise time

of the wave gets shorter, and a shock wave develops. Disadvantages of the shock tube are its large length of 20 to > 50 cm, its weight, and the fact that some of the waves that travel along the wall are coupled inside the wall and thus are lost. Therefore, shock tubes are not used in newer shock source designs.

Steepening by Focusing

On the way to the focus, the pressure pulse steepens due to the collimation of pressure. Thus as a rule with appropriately designed systems (distance lens – focus, primary pressure) shock waves develop in water in the focal area. In contrast, it is hard to prove that the same steepening occurs in tissue *in vivo*. As the tissue properties (e.g., attenuation, nonlinearity, and layering) are different in every patient, an exact prediction of the steepness in the focal area is not possible. Nevertheless, experiments *in vivo* demonstrate that the waves may be fully steepened.

Pressure pulses with a focal pressure of less than 25 MPa are usually unable to generate fully steepened signals at the usual geometries (focal distance 5 to 10 cm), even in plain water. At typical ESWT apertures (80–90° angle) shock waves can be observed in lens-focused EMSE systems at higher energy settings.

In an ESWL system with a self-focusing spherical calotte (EMSE of 12 cm aperture), shock waves were measured to develop even at relatively low focal pressures ($\approx 20\text{--}30$ MPa) due to a long propagation path and relatively high primary pressures [33.92].

Cylindrical EMSE

In this special EMSE, the coil is wound in a cylindrical shape and is covered by a cylindrical membrane. The pressure pulse is emitted radially symmetrical. It has about the same shape as the pressure pulse of the flat membrane EMSE. The waves of the cylindrical EMSE are focused by a section of a rotationally symmetric parabolic reflector [33.110].

Piezoelectric Pressure Pulse Source

In a piezoelectric pressure pulse source the transformation of electrical energy into acoustic energy is done by a number of polarized ceramic platelets, made of lead-zirconate-titanate, that elongate or contract due to a charge transferred by an electrical impulse (up to ca. 5 kV).

Usually several dozen to several thousand ceramic platelets are used that are arranged adjacent to each other on a plane or on a spherical carrier (the first sources were cuts of a sphere with a diameter of 50 cm)

[33.111, 112]. The platelets are excited simultaneously and emit a plane wave front, which converges in case the carrier is curved.

The time signature of the pressure pulse depends largely on the coating material of the front and rear side (backing) of the transducer. It also depends on the electrical excitation signal. If the backing is well matched to the properties of the piezo material, then the shortest pressure pulse is shaped as a sinusoidal wave composed of a single positive pressure and a trailing negative portion [33.111, 112]. The time duration of the signal thus depends on the length of the piezoelectric elements (e.g., 5 mm [33.113]). Usually it is chosen between 1 and 2 μs per half wave.

Pulse shapes that comprise a number of positive and negative portions can also be generated by adequate construction of the transducer. By oscillating between positive and rarefaction pressures, strong cavitation occurs in the focal area, which results in gross tissue damage. Possible applications for these kinds of signals could be the disintegration of tumors [33.114–116] and the transfection of cells in biotechnological and medical applications [33.8, 9].

Self-Focusing Assemblies – Spherical Sound Sources

Piezoelectric elements are favorably arranged on a spherical surface. Thus, all pressure pulses emitted from each single element arrive at the center of the sphere at the same instant, which results in the formation of a focal maximum. The smaller the aperture angle of the radiating surface, the closer the maximum pressure is shifted toward the source. This shift is compensated by an outward shift due to nonlinear steepening. When the sound waves are fully steepened, then the geometrical focus and the positive maximum often appear at the same position.

Self-focusing arrangements can also be found in EMSE sources using a spherically curved spiral coil and a corresponding membrane [33.80, 92].

New Approaches to Increase the Efficiency of Piezoelectric Pressure Pulse Sources

The primary peak pressure of a single-layer piezoelectric generator is < 1 MPa and thus lower than the primary pressure of an EMSE source. Therefore, the sound intensity at the piezo transducer surface also is less, so a larger area is necessary to achieve the necessary focal energies.

New approaches [33.117, 118] are based on layered transducer structures that are composed of two layers

of piezo elements with time-delayed excitation. Basically, the front layer is excited in phase when the sound waves of the rear layer penetrate it. This approximately doubles the surface pressure, so the energy is quadrupled [33.117]. Therefore, the diameter of the transducer can be reduced to ca. 30 cm (for ESWL), which makes new system concepts of the lithotripter feasible. A layered arrangement may be obtained by bonding the front and rear sides of a metal sphere with piezo elements. For ESWT purposes handheld transducers of < 10 cm diameter are available using double-layer technology.

Special Properties of the Piezoelectric Pressure Pulse Source

Like the EMSE, a piezoelectric transducer generates primarily not shock waves but triangular rising signals. As the spectrum of these piezo pulses only contains minor high-frequency components, about the same propagation and attenuation conditions apply for both piezo and EMSE sources.

Additionally, the typical pressure pulse signal of a piezo transducer includes a rarefaction portion that has about the same amplitude as the positive portion. This generated rarefaction part adds up to the rarefaction generated by the edge diffraction wave in the focus. However, as the rarefaction part does not steepen dur-

ing propagation, the focal amplitude of the rarefaction portion of the focus signal has less amplitude than the positive pulse, which may have developed a shock front.

An optimal signal shaping of the piezo pulse by electrical and mechanical means is mandatory. If the transducers are allowed to oscillate and to emit multiple positive and rarefaction pressure periods, then this leads to tissue damage by cavitation [33.112, 114]. Such transducer configurations are used for the targeted destruction of tissue, but not for lithotripsy. For lithotripsy, successful efforts were undertaken to generate both monopolar positive pressure pulses and to minimize the edge diffraction waves [33.119, 120].

Due to the many possibilities for pulse shaping, piezoelectric transducers offer a wide field for the evaluation of different bioeffects. A bioeffect study of pressure pulses starting with a rarefaction phase demonstrated that these inverse pulses caused significantly larger damage in agar models and in rabbit liver [33.121]. In contrast, other authors reported clearly less hemolysis when the rarefaction pressure was generated using a reflector with pulse-inverting properties as compared to a standard spark-gap arrangement [33.55, 122]. Stone comminution in the rarefaction case was significantly less at comparable reflector geometries [33.123].

33.5 Extracorporeal Lithotripsy (ESWL) and Extracorporeal Shock Wave Therapy (ESWT) in Practice

33.5.1 System Components of a Lithotripter

A typical lithotripter system as in Figs. 33.1 and 33.15 is composed of the following components:

- Pressure pulse source with high-voltage pulse generator and coupling means (water circuit and bellows)
- Source positioning means
- Localization means including video monitor
- Enclosure with power supplies, control computer, electrical high-voltage generator, etc.
- Patient stretcher with supplies for leg rests, arm rests, etc.
- ECG monitor for triggered pressure pulse release

Coupling Means

Between the pressure pulse source and the patient a water path is usually inserted that is enclosed in a bellows

at the patient's side. The water pressure can be adjusted to support the coupling. Between the bellows and the skin an ultrasound coupling gel is used. It is important to avoid the trapping of air bubbles in the gel layer in order to prevent disturbance of the pressure pulse propagation and possible skin petechiae due to cavitation effects.

Localization

During lithotripsy of urinary stones, gallstones, and shoulder calcification, as well as for bone treatment (pseudarthrosis), the target can be effectively visualized using ultrasound or x-ray systems.

During ESWT of tennis elbow pain, heel spur pain, etc., the treatment spot cannot be identified by these means and the doctor needs the cooperation of the patient. Usually he asks the patient to identify the exact localization of the maximum pain spot and directs the pressure pulses at this spot during treatment. In most cases, ultrasound images are able to show soft tissue

structures like tendons and thus are appropriate for treatment control.

Some systems offer dual imaging. This means the simultaneous use of x-ray and ultrasound imaging for the precise localization of the target and for a real-time ultrasound control of the treatment. Thus a continuous treatment control with minimal radiation is possible. However, for anatomical reasons, ultrasound localization is not possible with all stones and treatment situations (e.g., deep ureter stones, or if the stones are hidden behind rib shadows). Therefore, most lithotripters are equipped with an x-ray device, or lithotripters at least have provisions to add an external x-ray C-arm.

The requirements for both the precision and accuracy of localization are very high. As discussed above, the effective spot in the focal plane has a maximum diameter of 18–22 mm. The axial extent of the effective focus often has comparable dimensions. Thus the cross hair of the localization display needs to point to the focus with the highest precision with deviations of preferably less than 1 mm. To assure the quality of the localization device adjustment, a focus phantom is used that can be attached to the therapy head. It shows the exact therapy focus position in the localization display and should be used frequently to verify the correct adjustment of therapy head focus and localization systems.

X-ray Localization

In general a localization device must be able to display the volume around the focus from all spatial directions. In older lithotripters this task was solved with two x-ray systems whose central axes crossed in the therapy focus. Newer lithotripters have a movable x-ray arm that swivels isocentrically around the therapy focus. With the x-ray tube in an upright position perpendicular to the patient stretcher (AP position), the target is positioned horizontally to the position of the focal marker. Afterward, the x-ray tube is swiveled isocentrically around the therapy focus into an oblique position (in the cranial–caudal, CC, plane at ca. 30°). In this plane the vertical position of the target is adjusted to the focal marker (Fig. 33.16) by elevating the patient stretcher or the therapy head. Instead of the CC plane, sometimes a lateral position is used.

During treatment, frequent localization controls are necessary even at the expense of some additional x-ray dose (which is quite low in modern systems), particularly if it is suspected that the patient has moved.

Fig. 33.15 A modern lithotripter, which can be used as a urological work station at the same time. The figure shows all system components such as the pressure pulse source including source positioning mechanics and attached ultrasound outline system, the x-ray system attached to a rotating C-arm, including a monitor cart, the patient stretcher, which can be moved in three orthogonal axes, and the control console (Dornier Lithotripter S)

Variations of the X-ray Localization

The first lithotripters (Fig. 33.1) used two independent x-ray systems for localization, which were adjusted in a fixed position with respect to the shock wave focus. Both x-rays crossed the patient from an oblique angle, which made the orientation difficult. To account for these problems, the patient could be moved in planes parallel to the x-ray imaging planes.

Newer lithotripters sometimes use the so-called inline x-ray targeting method. In this case one of the x-ray projections is taken through a radiation-transparent opening in the center of the shock source. Under certain conditions, the relatively small image sector may be disadvantageous. To avoid excess radiation due to the penetration of the water path, an air-filled balloon can be inflated inside the shock source when an x-ray is taken.

If no direct access of the x-ray projections through (or along) the pressure pulse source is possible due to its large size, offline x-ray targeting can be used. In this case the x-ray arm is arranged at a position that is shifted along the long patient stretcher axis by some distance. For targeting, the patient is moved to the x-ray center position by a defined shift of the stretcher. For treatment, he is shifted back to the focus position. It is understood that the requirement for mechanical

Fig. 33.16a,b During x-ray targeting at first the AP direction is used (a). The target is adjusted to the therapy focus by moving the patient in the horizontal x - y -plane (b). Afterward, the C-arm is tilted 30° (CC) and the target is adjusted to the therapy focus in the z -direction by elevating the patient stretcher or the therapy source ◀

apy head. Instead, an electronic navigation system using ultrasonic or camera-based sensors measures the mutual positions of the x-ray device and therapy head. The attending physician is informed of the position of the therapy focus via numerical displays or a video overlay in the x-ray image [33.124].

Another system is significantly less expensive but just as accurate. It uses laser spots projected from the therapy head onto small target marks at the x-ray device. With the help of these laser spots, it is possible to use almost every x-ray C-arm device available at the hospital for targeting purposes.

Ultrasound Targeting

Depending on the arrangement of the ultrasound transducer, inline and outline systems are distinguished.

The inline ultrasonic transducer is built into the center of the pressure pulse source along its axis. Usually it can be moved axially and rotated around its axis. The advantage of the inline scanner is the use of the same propagation path and entrance window as the path of the therapy waves. The disadvantage of the inline arrangement is the shading of parts of the therapy wave and the occurrence of diffraction waves at the transducer housing. The resulting loss in therapy energy needs to be compensated by a higher primary pressure pulse energy.

Moreover, the ultrasound image may be impaired by the water path between transducer and patient inside the coupling bellows, causing multiple reflections and artifacts. To minimize these problems, the inline transducer is usually moved toward the patient for localization and retracted during the pressure pulse release.

In the ultrasound outline system the transducer is fastened at a mechanical arm, which can be rotated isocentrically around the therapy focus. Thus it is possible to choose the optimum windows for coupling the therapy source and the imaging transducer to the patient. As the localization transducer axis does not comply with the therapy source axis, the attending physician needs to have a good anatomical orientation. The outline transducer has the advantage that it allows one to visualize the anatomy in standard imaging planes, which is important for the correct assessment of the state of the disease and the tracking

precision of such arrangements is extremely high, particularly as the stone position and the progress of stone comminution cannot be tracked online by x-ray without moving the patient.

In recent devices localization systems have been built that do not require a mechanical link to the ther-

of treatment success. Additional advantages are the easy exchange of the transducers for optimum adaptation to the treatment situation and the artifact-free ultrasound image. Misalignments of a few millimeters between the localization display and the therapy focus, caused by the different sound pathways, can sometimes occur [33.38]. Such declinations can usually be compensated by the real-time monitoring of the treatment progress, as the exact site of the stone hits can be estimated from the ultrasound images by trained persons.

Sensor-based navigation systems have also been used for the adjustment of the ultrasound imaging system. The position of the therapy focus is displayed as an overlay in the ultrasound image. In principle, the ultrasound transducer could be used freehand, but for continuous treatment monitoring a mechanical holding arm is necessary.

33.5.2 Approaches to Online Disintegration Tracking During Treatment

Early on, attempts were made to track the disintegration progress online. As piezotransducers are capable of receiving ultrasonic signals, the echoes of test signals or high-energy pulse echoes from the focal region can be received by piezo lithotripters. A distinction between cavitation and stone signals is feasible by evaluating the polarity of the echoes [33.37]. By overlaying the signals of the lithotripsy pulse echo and standard ultrasonic

images the focal echoes could be amplified in order to implement a hit-or-miss monitoring [33.125].

Recent clinical trials demonstrated a highly significant indication of a hit or miss by evaluating the time duration of a Doppler shift when test signals were sent shortly after the pressure pulses. It was also feasible to track the progress of stone comminution by changes in the Doppler signals [33.126].

Nevertheless, none of these methods is (yet) used in actual clinical lithotripsy. In particular, solutions that interrupt the excitation of high-energy pressure pulses in the absence of stone echoes from the focus lead to irregular triggering of the shocks (comparable to the effects when respiration triggering was used), which is very irritating for both the patient and the physician [33.79]. Therefore, to date, a regular, continuous triggering of the pressure pulses is preferred and seems tolerable even if a certain number of pulses are missing the stone (up to ca. 30%).

A continuous and well-targeted shock wave application could be achieved by using an online target-tracking method. Mechanical tracking is hard to realize due to the large moved mass of the therapy head. A possible option would be the use of electronic focusing, e.g., by a phased array composed of a number of synchronized small single sources (16–128). Such designs were published as acoustic mirrors. They were used in clinical trials, but the high technological expenditures, and thus high price, prevented further steps toward widespread introduction [33.127].

33.6 The Patient

33.6.1 Patient Bedding for ESWL and ESWT Treatment

The treatment of stones usually is done with the patient in a lying position, which facilitates analgesia, supervision of blood pressure and ECG, and, in some cases, the use of sedation or anesthesia.

ESWT treatment may be done in a sitting or lying position, depending on the treatment site. A lying position may be advantageous for avoiding blood circulation problems, in particular if treatment is done under local anesthesia.

The extremities can be supported by appropriate holders. In this way the limbs can be positioned in a comfortable treatment position. These tools help to avoid decoupling of the target and pa-

tient movements due to reflexes caused by fear or pain.

33.6.2 Stone- and Patient-Related Influences

In the section on stone disintegration, the mechanisms were discussed from a physical view. The starting point was idealized conditions, which only occur when measurements are made in a water bath. In order to account for the influences of the patient, the Technical Working Group of the Deutsche Gesellschaft für Stoßwellenlithotripsie (DGSL) started the design of a patient phantom [33.78]. Probably due to the large number of parameters to be taken into account, the development is yet to be completed.

During actual stone treatment a number of real-world influences play a significant role in treatment outcome, the necessary pulse energy, and the overall energy dose. These influences are as follows:

1. Attenuation due to absorption in tissue;
2. Dissipation of energy and losses due to nonlinear distortions of the pressure pulses;
3. Reflections at tissue boundaries (skin, fat, muscle, kidney capsule, urethra, etc.);
4. Shadowing by bone structures (ribs, spine, pelvic bone) [33.30];
5. Shadowing by components installed inside the pressure pulse source propagation path, e.g., inline ultrasound transducers [33.30, 110];
6. Shadowing by gas-filled structures (e.g., gas in intestines or bubble layers in the coupling gel);
7. Shadowing and absorption by sludge, viz., already comminuted stone mass [33.63];
8. Aberration at boundaries by the diffraction of sound (which also leads to a declination of localization);
9. Influence of the medium surrounding the stone (tissue, urine, biles, etc.) on the excitation and enhancement of cavitation [33.30, 57, 71, 91];
10. Impacted stones, e.g., in the urethra [33.128, 129], or shoulder calcifications [33.35], which require markedly higher energy doses for complete disintegration as compared to free-floating stones in the kidney. In environments of higher viscosity (e.g., PVA) 8 to 10 times more pressure pulses are needed for the complete destruction of a stone as compared to water [33.30];
11. Gas bubbles in the pressure wave path (e.g., in the coupling gel between bellows and patient, or in greasy layers at the skin), which significantly increase the attenuation in the propagation path;
12. Different stone compositions, which can multiply the necessary pulse count for comminution [33.27];
13. Mispositioning due to localization errors, which may lead to misalignments of stone and focus in the range of centimeters;
14. Motions of the organ and the stone due to breathing, which typically lead to an excursion of around 30 mm; thus the stone leaves the focal region in ca. 30% of cases [33.130];
15. Uncontrolled patient movements, which may lead to gross mispositioning; thus frequent localization control is necessary (despite the moderately increased x-ray dose).

These influences can create a strong cumulative influence on the total number of pressure pulses per treatment: The number of pulses of one treatment usually is 5 to 10 times higher (1000 to > 5000 pulses per treatment at a retreatment rate of 10 to > 40%) than the number of pressure pulses needed for a comparable model stone in an idealized in vitro model using degassed water (e.g., to disintegrate 0.9 ml model stone material into pieces < 2 mm, 50 to 500 pressure pulses are needed [33.131]).

33.7 Assessment of the Clinical Efficiency of Lithotripters

For the assessment of the clinical efficiency of lithotripters the disintegration efficacy is not the only important parameter. Patient-related factors also need to be taken into account. These factors include the need for sedation, analgesia, or anesthesia, as well as auxiliary posttreatment measures like, e.g., endourological interventions to remove urinary tract obstruction or multiple lithotripsies (retreatments, re-ESWL). All these factors have been combined in the definition of the clinical efficiency quotient (EQ) [33.132, 133]

$$EQ_A = \frac{\% \text{ stone-free patients}}{100\% + \% \text{ retreatments} + \% \text{ auxiliary measures post ESWL}}$$

Modern treatment strategies also include auxiliary measures before lithotripsy, like catheterization or pushing

a ureter stone up the urethra back into the calyx. These measures can be included in the equation as an additional addend in the denominator of the above equation, which is then termed EQ_B .

Some first-generation lithotripters had EQs from 25%, whereas modern lithotripters reach up to 67% [33.134]. Thus both the increased stone-free rate (usually controlled after 3 months) as well as the continuing reduction of auxiliary measures and the lower pain level of the newer sources play a major role. But different authors often publish significantly different EQs for the same lithotripter type (e.g., HM3: 0.25 to 0.67). It is interesting to note that just this lithotripter, which was introduced as the first device 25 years ago, still is deemed the most efficient lithotripter by some doctors [33.135]). According to a recent study, both the applied treatment strategy (energy, pressure pulse count,

localization, anesthesia) and the training and experience of the physician play a crucial role in treatment efficacy [33.136]. Another reason for large differences in the EQs may be different patient populations used in the studies (e.g., exclusion or inclusion of ureter stones, restriction of stone size, etc.).

Due to the progress of measurement technology, physical data of the pressure pulse sources can be measured with satisfactory quality today. Thus a pressure pulse dosimetry should be introduced, taking into account the number of pulses per treatment times the effective energy per pulse $E_{12\text{mm}}$ [33.64].

With respect to the ESWT, the sum of effective energies per pulse or the sum of EDs is under discussion [33.86].

33.7.1 The Controversy About the Right Focal Size

Statements on the focal size traditionally (and according to the standard) refer to the axial and lateral (−6 dB) focal extent. Unfortunately, these values have no visible correlation to the disintegration efficacy, as shown above. Even recent publications that compare the devices of different manufacturers with smaller and larger focal extents do not reveal the effective energies $E_{12\text{mm}}$ or $E_{5\text{MPa}}$ which have significant correlation to the stone comminution efficacy. This is due to the lack of obligation to state such parameters. In a consensus report [33.78] driven by the DGSL, technical experts agreed on an adequate data set in Germany, but the actual implementation has only taken place for ESWT devices on the DIGEST Web site. There the technical data of ESWT devices are published, which were consistently measured using fiber-optic hydrophones or other acknowledged focus-type hydrophones according to IEC 61846.

For lithotripters such a database does not yet exist. Comparisons of devices using model stones may give a certain orientation [33.137], but they are not accepted by all manufacturers. An international standard of these kinds of tests is lacking.

A comparison of clinical and technical data of devices with a wide focus and lower peak pressure and devices with a smaller focal width but significantly higher peak pressure on the basis of the EQ values is difficult due to incomplete data sets. Still, two examples shall be given.

The clinical EQ_As are 0.65 and respectively 0.62 in the case of a wide-focus, low-amplitude device (18 mm lateral −6 dB width at max. 33.8 MPa) compared

to a small-focus, high-amplitude type (approximately 6 mm lateral −6 dB width at ca. 90–100 MPa), and thus would be comparable [33.84]. But in another publication concern was raised that the patient populations might have had too large differences to justify comparison of the data [33.79].

Another comparison of the EQ_As between a low-pressure, wide-focus spark-gap lithotripter (33 MPa at 16 mm −6 dB width) and a high-pressure, small-focus EMSE (90 MPa at 5.4 mm −6 dB width) using data from different publications reveals that the published EQ_A values are (up to) 0.67 (low-pressure source) versus 0.71 (high-pressure source) [33.64, 138], but the patient populations are also not clearly reported.

In conclusion, from the available data a clear advantage of one of the philosophies – wide-focus, low-pressure or small-focus, high-pressure – cannot yet be demonstrated.

So far the side effects of different lithotripters are rarely taken into account. This may be in part because the fraction of severe side effects seems to be too low to make statistically significant statements (at least for the devices that are actually on the market). The supporters of the wide-focus lithotripters point to very limited side effects and, in the case of the first example above, the complete absence of analgesia or anesthesia despite high efficacy at a low overall pressure pulse number. The reason might be the exceptionally low rarefaction amplitude of less than 5 MPa, which avoids tissue-damaging cavitation almost completely [33.84].

The supporters of the high-pressure, smaller-focus philosophy point to the positive experience in several million successful treatments, where subcapsular hematoma as the most frequent severe complication occurred in only 0.1–0.7% of cases, and other organs were affected even less [33.139].

Due to the unsolved controversy, recently some manufacturers have started to offer lithotripters with adaptable focal properties. In earlier devices this was achieved by exchangeable reflectors. In recent lithotripters, the pulse duration of the EMSE pulse can be modified; or it is possible to switch the delay times between the two layers in one piezo lithotripter, resulting in different focal properties. Recommendations by the manufacturers suggest using the larger focus for kidney stones and the smaller one for targeting ureter stones.

33.7.2 Side Effects and Safety

Direct side effects of the ESWL include pain, urinary tract infections, obstruction of urinary pathways, hema-

turia, cardiac rhythm disturbances, kidney hematoma, subcapsular hematoma, and harm to surrounding organs. Only the last three side effects are estimated to be severe. Delayed complications include loss of kidney function, hypertension (controversial), steinstrasse, residual fragments, and recurrent stones. Most of these complications are very rare, some are rated differently by different authors, and almost all can be minimized by properly following the treatment guidelines of the urological societies [33.140].

ESWT side effects are reported to be low at low-energy treatments like tennis elbow: transient skin reddening, pain, small hematoma, and seldom migraine [33.141]. In higher-energy regimes also large area hematoma were observed in single cases.

Sound energy is almost completely reflected at gaseous tissues. In particular, at the lung severe damage can occur. Therefore, it is mandatory during therapy planning to exclude lung tissue from the pressure pulse path, even at large distances from the focus. The safety distance of the focus from lung tissue depends on the design parameters of the pressure pulse source.

The effects of pressure pulses on nerves remain undetermined. It was demonstrated that nerves could be activated by cavitation [33.48]. But there are no actual results on nerve damage available. As a safety measure, the inadvertent insonification of nerves in the vicinity of the focus or at the propagation axis should be avoided. Signs of numbness or other neurological reactions should be watched carefully. In the meantime, patents can be found that claim the insonification of nerves with high-intensity sound pulses.

Increased hematoma were reported when blood-thinning medication was taken. These medications should therefore be discontinued in time before the

pressure pulse treatment. The Deutsche Gesellschaft für Stosswellenlithotripsie specifies discontinuing blood-thinning medication at least 10 d before treatment [33.142].

Pregnant women should not be exposed to x-rays. Additionally, the effect of shock waves and pressure pulses on the development of the fetus is not well understood (including indirect effects caused by pain during treatment).

In patients with heart pacers, it must be ascertained that the pacers are not influenced by the strong electromagnetic pulses of the therapy source as well as acoustic pulses during treatment; otherwise, treatment should be cancelled.

While lithotripters of the first generation generally used ECG triggering, in newer generation lithotripters the pulse repetition frequency can be chosen from 60 (seldom 30) up to a maximum repeat rate of 120 to (rarely) 240 pulses per minute. Due to the excitation of cavitation, the disintegration effect of the pulses is reduced at increasing pulse repetition rates, whereas the danger of kidney hematoma increases [33.59, 64, 143]. Recent animal experiments also point to reduced kidney trauma at slower pulse repeat rates.

In general the ECG must be watched in patients with a predisposition for cardiac rhythm disturbance. If necessary, the release of the pressure pulses should be triggered by ECG. The same holds if heart tissue is somewhere near the axis of pressure pulse wave propagation.

International Standard IEC 601-2-36 describes the general requirements for the safety of lithotripters. Medical guidelines are given by local urological or orthopedic societies and are constantly updated to incorporate the recent state of knowledge.

33.8 Associations and Societies for Lithotripsy and Pressure Pulse Therapy

Some societies were founded in Germany that deal with all aspects of pressure pulse lithotripsy (ESWL) and pressure pulse therapy (ESWT). The Deutsche Gesellschaft für Stosswellenlithotripsie (DGSL) within the scope of the Deutsche Gesellschaft für Urologie DGU is particularly competent for lithotripsy and related applications of therapeutic energy applications in urology. The DGSL develops consensus papers and guidelines for treatment and quality assurance. The

society watches actual technical and medical developments of extracorporeal and intracorporeal lithotripsy and related topics.

The Deutsche und Internationale Gesellschaft für Stosswellentherapie (DIGEST) is dedicated to the needs of pain therapy and the treatment of pseudarthrosis by pressure pulses [33.144]. The International Society for Musculoskeletal Shockwave Therapy (ISMST) also supports the development of ESWT applications.

High-Frequency Surgery

Bernhard Hug, Reiner Haag

High-frequency surgery (HF surgery) has been the dominant form of electrosurgery for many years. HF surgery can be defined as the application of electrical energy in surgery for effecting a thermally induced change or destruction of tissue cells with the aim of hemostasis (stopping bleeding), cutting tissue, or sealing it. In HF surgery, high-frequency alternating current (preferably 0.3–4 MHz) is delivered by special applicators (or active electrodes) to the tissue to be treated, where a thermal tissue interaction takes place due to the electrical resistance of the tissue.

In contrast, in the case of the electrosurgical operating method galvanocautery – which is insignificant today – a direct current is or was used to heat a cautery (Greek *kauter*) directly as a surgical instrument in order to transfer heat from it to the tissue. Today, this method is only applied for a small number of indications, i. e., whenever a flow of current through the body tissue is to be avoided (e.g., ophthalmology) [34.1, 2].

Today, HF surgery has become an indispensable tool for all surgical disciplines, whether for in-patient care or private medical practices.

A considerable advantage of cutting tissue using HF-assisted surgery, as compared with conventional cutting techniques using a scalpel or scissors, is that hemostasis takes place at the same time the cut is made due to the respective vessels becoming sealed. Other advantages lie in the prevention of cross-contamination, mechanical tissue protection, and the possibility of en-

dosopic application. When applying the method for a targeted hemostasis of bleeding vessels, selective hemostasis – as opposed to the alternative vessel ligation – can be achieved quickly and simply by boiling off (coagulating) spatially limited tissue without having to use any foreign substances.

Due to the history of its development, a large number of synonymous terms are used for HF surgery. Although some of the terms are based on totally different techniques historically, in most cases the same application method is meant today. With no claim as to its completeness, a list of some of the internationally common terms is given as follows: HF surgery, RF surgery, radiosurgery, electrosurgery, cautery, electrocautery, diathermy, endothermy, trans-thermy, electrotony or – frequently in the USA – also referred to as *Bovie* after an American pioneer in HF surgery.

34.1 Development of High-Frequency Surgery

The development of this method originates from the advantageous of the therapeutic application of heat. In the papyri written by the Egyptians in the second millennium BC (Papyrus Ebers, Papyrus Edwin Smith), information can already be found on the selective, therapeutic use of heat. The treatment of battle wounds using heated stones, opening festering inflammations using small sticks of wood heated in hot oil, or cauterizing wounds using the *fire drill* (glowing piece of charcoal) were recommended there. Even Hippocrates, who is often referred to as the *father of medicine* (≈ 400 BC), used the *ferrum candens* (cautery) in just the same way as Arabian or Roman physicians to reduce bleeding during amputations with glowing cauteries or knives. Even into the nineteenth century the *ferrum candens*, heated in different ways, was the method of choice in surgery.

New techniques have always been readily adopted in medicine. Thus, the predecessor of the electric battery developed by Count Volta around 1800 (voltaic pile) had only been known for a few years when the era of electrosurgery was heralded – any ideas about electric street lighting were still a long way off. In this connection, the recommendations of the Englishman Humphrey Davy (1807) for using electricity to decompose organic parts played a less decisive role than the suggestions of the Munich physicist Karl August Steinheil, according to which the Viennese dental surgeon Moritz Heider deadened a dental nerve using an electrically heated platinum wire. Throughout Europe physicians especially were now working on the new method; the Finnish physician Gustav Crusell then coined the term galvanocautery. Other pioneers worthy of note during this period are the Frenchmen Alphonse Amussat, Charles Sedillot, Auguste Nelaton, and Leroy d'Etoiles and the Englishmen John Marshall, Thomas Harding, George Waite, and Robert Ellis. Although he cannot be regarded as the originator of galvanocautery, Breslau physician Albrecht Theodor Middeldorpf (1824–1883) took much credit for the new method by standardizing surgical methods and described them in great detail in his book *Galvanocautery: A Contribution Towards Operative Medicine* in 1854. The basic instruments used in galvanocautery originate from him, i.e., the galvanocautery and the galvanocautery cutting loop – ligatura candens. One of the most famous surgeons of that time, Theodor

Billroth (1826–1894), who even recognized Middeldorpf as the inventor of galvanocautery, wrote in 1878 in his *Handbuch der allgemeinen und speziellen Chirurgie* (Manual of General and Specialized Surgery) [34.3]:

Middeldorpf not only invented galvanocautery; in his book he also completely exhausts it, so it seems to me, by inventing the most practical battery and the most practical instruments, and he additionally formulated the indications for the usability of this operating method with the utmost precision.

One of the few from the first group of German surgeons whose work on this topic deserves special mention after Middeldorpf was Victor von Bruns. Technical improvements of the ligatura candens trace back largely to him, specifically the contractible, loop-shaped platinum wire (snare) that was heated using direct currents of 10–20 A at voltages of 3–6 V. It was now possible to operate on places that were difficult to access and allow the glowing heat to take effect after having previously applied the cold wire without any hindrance – ideal conditions for applying the method endoscopically, and it was ultimately in the endoscopic area that galvanocautery was able to establish itself. In general surgery, hot cautery prevailed, not electrically as in the form of galvanocautery, but in the form of the thermocautery invented by Claude A. Paquelin. Differently shaped, hollow pieces of platinum were heated until they glowed and were then kept glowing by blowing in a mixture of petrol and air that burned on the glowing platinum surface. That thermocautery was the preferred method wherever it was possible to work with open access for laparotomies (open surgery) may be due to the fact that galvanocautery was complicated and expensive. In addition, handling the batteries existing at that time (mostly of a zinc-platinum type) was expensive and required intensive maintenance.

The requirements for implementing electric current not only as a form of energy for operating a modern *ferrum candens*, but also for applying it directly for use in the tissue, were similarly developed during the mid-nineteenth century. From the electrophysiological experiments conducted by Duchenne de Boulogne, whose results were published in 1855, the fact was established that low-frequency, alternating currents lead to muscle contractions and nerve irritation and are thus

useless for surgical purposes. At the end of the nineteenth century, though, Nikola Tesla and Jacques-Arsene d'Arsonval showed that alternating currents in a frequency range of 2 kHz to 2 MHz lead to heating the tissue without causing any stimulation of the muscles or nerves. In 1899 Walther Nernst demonstrated the relevance of these results and proved the inherent working principle. He formulated the Nernst law of electrical nerve stimulus threshold named after him, which established the correlation between the threshold value of the electric current intensity necessary for stimulating a nerve and the frequency of the alternating current producing the stimulus.

These fundamental findings formed the basis for Clive Rivière being able to report on successes in the spark treatment of tumors and tuberculous skin diseases in Paris in 1900. The era of HF surgery had begun. First, a device designed by d'Arsonval was used; its damped oscillations with high-voltage peaks enabled tissue to be destroyed by sparks arcing to the tissue. Simon Pozzi referred to this method as fulguration (Lat.: *fulgur*, lightning), a term used up to the present day to describe the virtually noncontact form of power transmission to a patient. In addition to Pozzi's work, de Keating-Hart's work was trendsetting. He used a fulguration device (Fig. 34.1) – as also recommended by Professor Czerny – for the irradiation of malignant tumors in combination with resection in Marseille and Paris (Broca Hospital).

Electrodesiccation (according to William L. Clark) has also been known since 1907. For this method, needle electrodes are used; they are positioned on or inserted into the tissue, and under the influence of an HF current the tissue cells subsequently reach the boiling point and dehydrate. In 1909, Eugène L. Doyen reported a two-pole method for the *electrocoagulation* of malignant tumors. The term *voltisation bipolaire* was then introduced. The applications for this method were limited to begin with, due to the generators available (Oudin resonators and spark-gap generators with a spark frequency < 3 kHz). For, as Nernst had already demonstrated, the lower frequencies are accompanied by strong faradic tissue stimulation. Even though spark-gap generators with frequencies of up to ≈ 1 MHz had been available since 1907, and their application could also be extended to neurosurgical indications, it was not possible to cut tissue (electrotomy) to a satisfactory extent using this given technology. It was later demonstrated that unmodulated or slightly modulated HF currents are required to successfully achieve the desired

Fig. 34.1 Fulguration device as invented by de Keating-Hart for *cancer fulguration*. For ≈ 10 min strong *fulguration spark bundles* were applied to the tumor tissue. Excessive heating was prevented by a flow of carbon dioxide conducted coaxially via the electrode (after [34.4]). Short explanation: a mains supply, b transformer, c Leyden jar, d variable resistor, e regulating screw for solenoid, f solenoid, g resonator, h connector for applicator, i adjusting screw for spark gap, k CO₂ gas cylinder, l applicator, m circuit breaker, n grounding cable

effect, which could not be generated from spark-gap generators. Such current generation was not possible until tube generators came into use, in the form used by George A. Wyeth (endotherm) in the mid-1920s. However, the hemostatic effect of these generators was not as strong as that offered by spark-gap generators. For a long time, two separate generators were therefore used for electrotomy and hemostasis (cutting with tube generators, coagulating with spark gap). The patent application of American inventor *William T. Bovie* in 1931 [34.5] marked another milestone in the development of HF surgery. Bovie proposed to offer surgeons the option of different kinds of HF surgical currents using the same generator with the same applicator. A technical level had now been reached where faradic (neuromuscular) stimulation was largely avoided and

Fig. 34.2 Advanced HF surgical unit with a menu-guided user interface. The treatment parameters are clearly arranged on a screen next to the respective patient output

smooth cutting was possible. Whereas in the USA both Bovie and his collaborator, neurosurgeon Harvey Cushing, deserve special mention for this new application, in Germany it was *von Seemen* (1898–1972), from Alsace, who wrote a guidance paper [34.6] on the topic during his time in Munich.

In subsequent years, the developments of HF surgery were concentrated more on the use of higher frequencies and thus on treatment using radiated electric or magnetic fields. In this context, parts of the body to be moderately heated were exposed to the electrical influence of a capacitor field (*Schliephake* [34.7]) or the magnetic influence of a coil field (*Esau* [34.8]). The shortwave devices (27.12 MHz) and decimeter devices (433.92 MHz) available in the 1930s and 1940s were completed by microwave devices (2.45 GHz) after the magnetron in radar technology became available after World War II. Although some of the shortwave devices were also suitable for surgical applications, it was HF hyperthermia – i. e., the artificially produced, temporary, and localized *fever* – that was the main focus of attention. It was probably due to the high price of tubes that these devices did not gain in popularity until after 1945. For surgical applications, most devices still contained a spark-gap generator for coagulation and a tube generator for cutting tissue. It was not until 1955 that the first fully electronic, universal device built on a tube principle was offered for HF surgery. The development of modern transistor technology in the 1970s offered a technological evolution of the technical design of the device. With this tech-

nology, devices could be built considerably smaller and more compact. However, as regards new potential applications, the method did not offer any new developments. Then, however, in the mid-1970s, the development of the so-called argon beamer marked an important milestone. Based on a *plasma scalpel* principle, as suggested by Americans *Shaw* [34.9], *Goucher* [34.10], and *Incropera* [34.11], for vaporizing tissue, *Morrison* [34.12] developed the *argon beamer* which has been used in basically the same way up to the present day. Whereas with the plasma scalpel a high-energy plasma beam – comparable to a cutting torch – was directed toward tissue, the argon beamer merely uses an ionized argon beam as a conducting medium in order to deliver the HF energy to the tissue without contact. And while the plasma scalpel was not of any real medical significance, the argon beamer firmly established itself in various medical applications.

Microprocessor-controlled HF surgical units have been in use since the early 1990s. As a result, feedback control technology has opened up completely new possibilities. A large number of different types of therapeutic current could be developed and adapted to specific indications and applications. Due to the great variety of application options, each with its process-specific treatment parameters, using these new devices soon became quite complex, however. Future developments took this into account, and today units with a display screen and a menu-guided user interface (Fig. 34.2) are offered to facilitate use.

34.2 Physical and Technical Principles

34.2.1 Bioelectrical and Biothermal Effects on Tissue

When electric current flows through biological tissue, three different effects occur, depending on the type of current, current intensity, and frequency.

Electrolytic Effect

With direct current and low-frequency alternating currents, the electrolytic effect dominates, i. e., ion migration takes place in the tissue. Positively charged ions travel to the negative pole (cathode) and negatively charged ions to the positive pole (anode). This effect is used in medicine in ionophoresis for transporting certain drugs into the body. In HF surgery this effect is undesirable as the tissue's cytochemical content can become damaged.

Faradic Effect

When alternating currents flow through biological tissue with a frequency of up to 20 kHz, the faradic effect

occurs. Currents within this frequency spectrum stimulate nerves and muscle cells, which can lead to muscle contraction. This stimulus effect peaks at frequencies between 10 and 100 Hz (Fig. 34.3). The faradic effect is currently used effectively in stimulation-current diagnostic procedures and the stimulation-current therapy (e.g., for muscle paralysis). In HF surgery this effect is undesirable as muscle contractions are painful, and possibly even dangerous for the patient, and are a hindrance for the surgeon.

Thermal Effect

With HF alternating currents, both the electrolytic and faradic effects are largely prevented in biological tissue, and thus the thermal effect dominates. The frequency of the alternating current is then at least 300 kHz, hence the term HF surgery. This desired thermal effect is mainly used for two different applications, namely, for cutting and, much more frequently, coagulating. The amount of heat created in the tissue mainly depends on the specific resistance of the target tissue, the current density, and

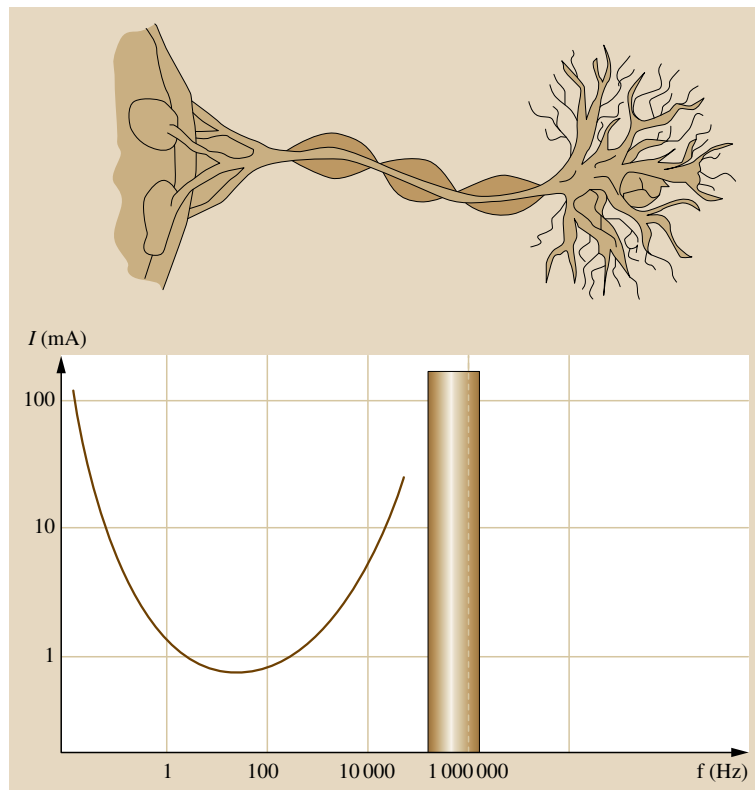

Fig. 34.3 The Nernst law of electrical nerve stimulus threshold, which states the frequency-dependent threshold value of the current intensity necessary for stimulating a nerve

the duration of exposure. The thermal effect is achieved through conversion of electrical energy into thermal energy.

Heat can be produced in every conductive or current-carrying matter. The conversion of electrical energy into thermal energy takes place effectively without loss of energy.

According to Joule's law, the following correlations result

$$Q = Pt = UIt = I^2Rt = \frac{U^2t}{R} \quad (J = Ws), \quad (34.1)$$

where Q is the heat, P the power, U the voltage, I the current, R the resistance, and t the time.

The HF power P_{coag} required for coagulation can be calculated approximately by using both the heat quantity Q_{coag} and the coagulation time t_{coag}

$$P_{\text{coag}} = \frac{Q_{\text{coag}}}{t_{\text{coag}}} \quad (W). \quad (34.2)$$

The heat quantity Q_{coag} depends on the quantity m_{coag} of the tissue to be coagulated, on its specific heat capacity c_{coag} , and on the temperature difference Δt_{coag} within the coagulum (of $\approx 37^\circ\text{C}$ to $60\text{--}100^\circ\text{C}$) between the start and end of the coagulation period

$$Q_{\text{coag}} = m_{\text{coag}}c\Delta t_{\text{coag}} \quad (Ws). \quad (34.3)$$

In Q_{coag} only the heat quantity required for coagulation is represented. Depending on the coagulation technique used, an additional quantity of heat Q_{env} also must be taken into account to represent the unintentional dissipation of heat in the surrounding current-carrying tissues. Though Q_{env} is negligibly small for bipolar coagulation applications in comparison with Q_{coag} , in monopolar coagulation techniques Q_{env} can at times be very large relative to Q_{coag} if unfavorable circumstances obtain. These unfavorable circumstances include, e.g., monopolar coagulation techniques where a large part of the HF current flows past the tissue to be coagulated, for example through the irrigation fluid used in transurethral resection (TUR) procedures. The heat quantity Q_{env} always poses a risk of undesired secondary effects, and it is absolutely necessary to take this into account during use. This also explains why a higher power value is required in monopolar applications as opposed to bipolar applications.

Apart from the heat quantities Q_{coag} and Q_{env} , the heat quantity Q_{AE} – which is the heat created within the active electrode during coagulation – also must be taken into consideration for some coagulation procedures. The temperature of the active electrode should

not rise during coagulation because this creates a layer of coagulum that can stick to the active electrode; if the active electrode were to directly contact the coagulum, the electrode would unavoidably be heated.

Thus the entire heat quantity created is calculated

$$Q_{\text{tot}} = Q_{\text{coag}} + Q_{\text{env}} + Q_{\text{AE}} \quad (Ws), \quad (34.4)$$

where Q_{coag} is the heat quantity required for coagulation, Q_{AE} the heat quantity active electrode, Q_{env} the unintended surrounding heat quantity, Q_{tot} the total heat quantity, t_{coag} the coagulation time, P_{coag} the power for coagulation, Δt_{coag} the temperature difference, m_{coag} the quantity of tissue to be coagulated, and c_{coag} the specific thermal capacity.

The HF power P_{S} required for cutting can similarly be calculated approximately by using both the heat quantity Q_{S} and the cutting duration t_{S} as

$$P_{\text{S}} = \frac{Q_{\text{S}}}{t_{\text{S}}} \quad (W). \quad (34.5)$$

When cutting, a tissue volume proportional to the length, the average depth, and the width of the cut is heated so strongly that its water content vaporizes. The heat quantity required for vaporizing the water content in tissue (Q_{S}) consists of the heat quantity Q_{100} to heat tissue fluid from 37 to 100°C plus the heat quantity Q_{D} to evaporate the boiling tissue fluid.

$$Q_{\text{S}} = Q_{100} + Q_{\text{D}} \quad (Ws). \quad (34.6)$$

In analogy to the heat balance during coagulation, the heat quantity for the unavoidable heating of the tissue not involved in the cutting and the heat quantity for the unavoidable heating of the active cutting electrode also have to be taken into consideration during cutting.

Thus the total heat created is calculated as

$$Q_{\text{tot}} = Q_{\text{S}} + Q_{\text{U}} + Q_{\text{AE}} \quad (W), \quad (34.7)$$

where P_{S} is the power for cutting, Q_{S} the heat quantity required for cutting, Q_{D} the heat quantity for vaporizing the water content of the tissue volume, Q_{100} the heat quantity from $37\text{--}100^\circ\text{C}$, V_{S} the cut-tissue volume, and t_{S} the cutting time.

The current density J plays a key role in HF surgery; only if the current density is sufficiently high (normal: $1\text{--}6\text{ A/cm}^2$) can the desired cutting or coagulation effect be achieved.

The current density decreases quadratically with distance r

$$J \propto \frac{I}{r^2} \quad (\text{A/cm}^2). \quad (34.8)$$

Table 34.1 Specific resistance ρ of biological tissue (0.3–1 MHz), modified as described by *Reidenbach* [34.13]

Tissue	Specific resistance ρ (Ω cm)
Blood	160–300
Muscle, kidney	160–260
Spleen	270–300
Heart	200–230
Liver	200–380
Brain	670–700
Lung	160–1000
Fat	1600–3300

When tissue properties are homogeneous, the temperature-increase capabilities are reduced by the distance r at the fourth power

$$\Delta t \propto \frac{l}{r^4} \quad (\text{K}). \quad (34.9)$$

Biological tissue itself mainly behaves like an ohmic resistor (Table 34.1). Whereas the specific resistance in muscle tissue and well-vascularized tissue is relatively low, tissues with little fluid content such as bones, cartilage, and fat tissue have a high specific resistance, which in turn translates to a relatively low current flow. In muscle tissue, the resistance is $\approx 150\text{--}300\ \Omega$, whereas in fat tissue it lies between 500 and 1000 Ω .

Regardless of the method used to heat the tissue (HF current, laser, IR coagulator, ultrasound, ferrum candens, etc.), the thermal effects can be classified qualitatively as shown in Table 34.2.

34.2.2 Coagulation

The term coagulation (Lat. *coagulare*) generally describes the precipitation, flocculation, or coagulation of a material, i. e., the transition of colloidal mater-

ials (colloid: from Greek *kolla*, glue, and *eidōs*, form, appearance) from a solution state to a gel state. This process could also be described simply as a tissue's boiling point. During this process, the tissue is heated relatively slowly by HF electric current such that intracellular fluid and extracellular fluid vaporize and cause the tissue to shrink. The resulting *tissue glue* and the tissue shrinkage generated lead to the contraction of the perforated blood vessel and subsequent hemostasis. In many cases, such as with small vessels, this fast and effective coagulation can replace expensive fibrin glues or extensive ligatures. In daily use of HF surgery, the term coagulation is used not only for the tissue reaction described above but also more widely for a certain operating mode of HF surgical units. Depending on the quality and quantity of the HF current and technique used, a distinction is made between contact coagulation, forced coagulation, desiccation, fulguration (also referred to as spray coagulation), argon-assisted coagulation, and vessel sealing (Sect. 34.4.2).

34.2.3 Electrotomy (Cutting)

Even though the biophysical process occurring during a cutting procedure has not yet been fully explored in detail to date, it can be plausibly explained by a phenomenological description and through theoretical considerations. In doing so, two totally different initial situations must be taken into account. On the one hand, the cutting electrode is already in contact with the tissue at the beginning of the cutting procedure, while on the other hand the cutting electrode gradually approaches the tissue in an activated condition. Using a HF alternating current, it is possible to produce relatively high, but very concentrated, current densities in tissue using knife-shaped or needle-shaped electrodes with small electrode surface areas. As a result, the tissue

Table 34.2 Thermal tissue damage depending on temperature

Temperature	Tissue reaction
Up to ca. 40 °C	No significant cell changes
From ca. 40 °C	Reversible cell damage (depending on the duration of exposure)
From ca. 49 °C	Irreversible cell damage
From ca. 60–65 °C	Coagulation: Collagens are transformed into glucose, the tissue containing collagen shrinks and produces a hemostasis of the bleeding vessels
From ca. 90–100 °C	Dehydration/desiccation (drying out): Transition of intracellular and extracellular fluids to the vaporous state. Glucose can produce a sticking effect due to dehydration; the coagulum shrinks
From ca. 200 °C	Carbonization: The tissue carbonizes as in a 4th degree burn; unpleasant smell of the burnt tissue; the healing process can be impaired
Several hundred °C	Vaporization (evaporation of the tissue): Emission of plume and gases

heats up to over 100 °C in a flash, resulting in a vapor pressure increase and the rupture of cell membranes. The resulting isolative vapor between the electrode and the tissue subsequently prevents the unhindered ohmic current flow into the tissue; a cutting voltage builds up between the electrode and the tissue, creating sparks between them. The energy transfer subsequently takes place through these sparks. As extremely high energy densities occur in their very small base points having a size of just a few microns ($r = 10\text{--}20\ \mu\text{m}$), the targeted tissue cells vaporize. It is irrelevant whether this process takes place openly under atmospheric conditions or in an electrically nonconducting liquid. This model concept is also supported by the work being done by the study group headed by *Thiel* and *Fastenmeier* [34.14].

If, on the other hand, one approaches tissue with an electrode that is already active, the voltage present ignites sparks at a certain proximity to the tissue. These

sparks, which are indispensable for a cutting process, create a bridge over the *last* air gap before subsequently producing the steam layer that maintains the process as described above. However, in the first scenario, the reduced current flow into the tissue occurring at the beginning of the desired cutting application leads to a delay in starting the cut. This was overcome in the past using a pulse-type power increase when activating the current (to facilitate starting the cut); today, power control technology is used to compensate the phenomenon.

Cutting tissue with an *HF knife* involves no mechanical effort. The cutting electrode virtually glides through the tissue, similar to a hot wire gliding through butter or wax. As a result of the high temperature generated at the edge of the cut, the danger of contamination is reduced. In addition, hemostasis is produced simultaneously with the cut. The precisely controllable cut can be utilized by the surgeon both for open surgery and endoscopically.

34.3 Technology and Techniques

34.3.1 HF Generator Technology

The main task of an HF generator is to convert the electric current of the commercial power supply into HF current. The reliability of the electrical (galvanic) insulation between the mains circuit and the patient circuit has absolute priority to ensure safety. The current generation of microprocessor-controlled HF generators was developed on the basis of a careful analysis of the tissue effects created, taking into account also the various special requirements of the different surgical disciplines. Thus, HF surgical devices are now available with which consistent cutting and coagulation effects can be achieved. This provides, for example, a gentle coagulation effect without any carbonization, or reproducible cutting properties largely unaffected by external conditions such as the cutting speed or electrode size. The output power levels of automatically controlled HF surgical units are also considerably lower than those of conventional devices. Before 1975 devices were still being offered with an output power of up to 1000 W, even though no more than 150 W was typically required at the time (as also today), even for applications with a relatively high power requirement (applications in liquid environments) [34.15]. This former trend toward higher output power was reversed by appropriate standardization (IEC 60601-2-2) [34.16], whereby the maximum HF output power for HF surgical devices was limited to 400 W.

A series of monitoring features implemented in today's devices, such as neutral electrode monitoring, overdose protection circuits, visual and audible activation indicators, tissue impedance monitoring and HF leakage current compensation, translate into an increase in safety for the patient and surgeon. For all the manufacturers of HF surgical devices, international standards stipulate that controlling devices with an HF output power of over 50 W must be equipped with a monitoring system that detects a break in the neutral electrode contact and is able to prevent an energy output if a fault occurs. However, it is recommended to use devices that not only detect a cable break but additionally monitor the correct application and pad positioning of the neutral electrode on the patient.

The patient output circuit (applied part) must not have any direct connection to ground when using HF surgical devices. In other words, a *floating* (insulated) applied part must be used. HF devices are therefore not constructed as devices with an applied part of type B protection rating against electric shock but are defined as type CF (defibrillation-proof). In a completely floating output – devices with an applied part of type CF (cardiac floating) – neither of the two patient HF leads has an HF ground contact by design, whereas in the case of devices with a type BF (body floating) protection rating, the neutral electrode connection is designed to

have ground contact via a capacitor. For application on the open heart and for the combination with intracardial catheters, HF surgical devices with an applied part of protection type CF, and thus defibrillation-proof output, are available.

Since capacitive leakage currents – i. e., HF currents diverted to ground due to partial capacitances, e.g., generated by the housing, leads, and patient – can occur in an uncontrolled fashion and cause patient burns, standardized limits must not be exceeded. Since the leakage currents become higher with an increase in frequency, the application of HF surgery virtually has an upper limit. Low frequencies, on the other hand, lead to nerve and muscle stimuli, as Nernst has demonstrated. Considering this, IEC 60601-2-2 only recommends working with frequencies over 300 kHz, and, due to the potential for leakage current, it recommends not using frequencies above 5 MHz.

However, the Faraday effect can also occur in the above-mentioned higher working frequencies. Their effects are derived from the rectifying process of sparks – which are absolutely vital in electrotomy, for example. In order to avoid faradic irritation, a so-called *antifaradization capacitor* of low capacity is positioned in the patient circuit. At certain areas, however, the occurrence of muscle twitching cannot be completely eliminated (e.g., stimulation of the obturator nerve during resection in the urinary bladder).

34.3.2 HF Application Technique

The various types of application can basically be divided into monopolar, monoterminally, and bipolar methods. The monopolar application technique is used most frequently.

Monopolar Technique

In the monopolar technique, an active and a so-called neutral electrode must be connected to the HF surgical device. The physical effects required for electrosurgery (cutting, coagulation) are produced at the active electrode. The neutral electrode, which compared to the active electrode covers a far greater surface area, is normally placed on the thigh or upper arm of the patient. The contact area between the neutral electrode and the skin of the patient is large, in order to ensure that the current density (current per unit area) remains relatively low. In contrast, the active electrode only has a small contact area, which is why it produces a very high current density. The selective heating of tissue using the high temperature generated by the active electrode

Fig. 34.4 Monopolar circuit with large-surface neutral electrode attached to the thigh of the patient

would not be possible without such a high current density and the target tissue resistance.

The neutral electrode is also referred to as a plate electrode, passive return electrode, dispersive electrode, indifferent electrode, or, incorrectly, also as a grounding electrode. When the surgeon touches the tissue with the monopolar active electrode of an activated HF surgical device, HF electric current flows to the patient and generates the desired physical effect (Fig. 34.4) directly at the point of contact between the tissue and the relatively small-surfaced active electrode.

Monoterminally Technique

With this technique, the circuit is closed via the patient's body capacitive contact to ground (Fig. 34.5). No neutral electrode is used in this case. Basically, this is a special form of the monopolar mode. This technique is only safe for small working currents and is therefore only suitable for minor surgical interventions, e.g., in dentistry and in dermatology. For this application technique, only units with a maximum HF output power of 50 W should be used. Since in this working mode the HF current is intended to flow back to the HF unit via ground, an increase in electromagnetic interference with other electrical units can occur.

Units with an output power greater than 50 W must not be used monoterminally, as incorrect operation could cause severe patient burns.

Bipolar Technique

The bipolar technique is best described as the integration of both electrodes (active and neutral) in a single instrument, such as bipolar forceps with branches or

Fig. 34.5 Monoterminial circuit. The grounding of the HF unit on the HF side allows the reverse flow of current via a grounded treatment chair to which the patient is capacitively coupled

tines that are insulated from each other (Fig. 34.6). In this case, the current flows into the tissue via one electrode and back to the HF surgical unit via the other. This means that the current only flows in the narrowly defined tissue area between the two electrode tips. The bipolar technique offers an increase in safety particularly in the case of fine dissection in neurology. A separate neutral electrode is not necessary for operation.

In comparison with the monopolar technique, this offers the following advantages:

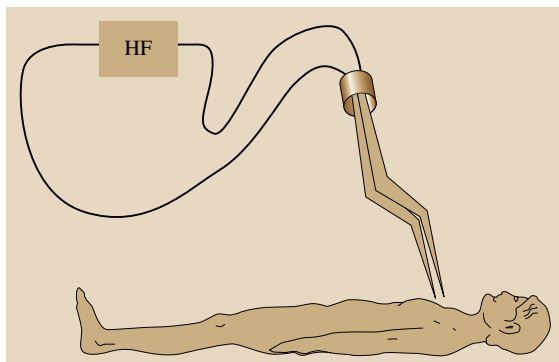

Fig. 34.6 Bipolar circuit. The current flow remains limited to the tissue grasped between the two tips of the forceps

- The current only flows through the tissue held between the two electrodes where the thermal effect is intended.
- The danger of patient burns by touching conductive objects during the operation is negligible.
- There are no stray currents.
- It has reduced influence on cardiac pacemakers and units that are connected to the patient in addition to the HF unit (e.g., for monitoring).

Whereas the bipolar technique mainly used to be applied in neurosurgery, it is successfully used today in ENT (ear, nose, throat), gynecology, and particularly for minimally invasive surgery (MIS). The bipolar technique is primarily used for coagulation with bipolar forceps and for sealing vessels and tissue. Despite several attempts to apply it in other areas, bipolar cutting continues to be limited to a few *special cases* thus far. The basic problem in using the bipolar mode for the cutting function is that the spark formation required for targeted cutting relies on the constant presence of an active electrode and a nonactive electrode. With the bipolar technique, both electrodes are more or less the same size. This means that the active/nonactive function can change during the cutting process and the whole process will come to a halt. An exception to this is bipolar cutting in a conductive saline solution for transurethral resections (Sect. 34.4.1). However, in this case one would correctly have to describe this as a semibipolar technique, as the two electrodes are of a significantly different size and it is always clear which of the two electrodes is to assume the function of the active electrode. Basically, the neutral electrode – as we know from the monopolar technique – is highly reduced in size here and held at very close proximity to the active electrode.

34.3.3 Leakage Currents

When applying HF surgery in flexible endoscopy and MIS, one should keep in mind that a capacitive current can flow due to the high frequency. This is the case whenever a capacitive reactance is present (capacitor effect).

The capacitive reactance follows the relationship

$$X_C = \frac{1}{2\pi fC} \quad (\Omega), \quad (34.10)$$

where C is the capacity of a capacitor, f the frequency on the capacitor, and X_C the capacitive reactance. In practice this effect is best known as capacitive coupling.

Capacitive coupling refers to a physical effect that always occurs when HF current flows from one electrically conductive medium to another while separated by an insulator. This can take place because an insulator for HF current does not have the same insulating properties as an insulator for low-frequency current (e.g., 50 Hz mains frequency). However, since our knowledge of the properties of insulative materials is based on those commonly used in the low-frequency range, the user expects these materials to have a similar insulating behavior when HF current is applied. The user is therefore not aware of the capacitively coupled current. This capacitive coupling depends on a series of factors:

- The distance between the two electrical conductors: the smaller the distance, the higher the capacitive current
- The cross sections of the electrical conductors: the larger the cross sections, the higher the capacitive current
- The level of the electric voltage: the higher the electric voltage, the higher the capacitive current

- The frequency level: the higher the frequency, the higher the capacitive current
- The form of the electric voltage: voltage characteristics with few harmonics cause a lower capacitive current than voltages with a high harmonic content.

For applications in open surgery, the capacitive coupling effect plays a small role. In the case of laparoscopic surgery and in flexible endoscopy, however, capacitive coupling is a more frequent phenomenon due to the long instruments used in these procedures. Since leakage currents are unavoidable, undesirable, unnoticeable, and unpredictable, it is particularly important for users to bear in mind that capacitive coupling can occur when using such instruments. In practice, this means that a current can also flow through a plastic insulating layer such as is present, e.g., in trocars or MIS instruments and that in the event of concentrated contact with the tissue, a current density can be produced that is high enough to cause a burn.

34.4 Types of Current and Their Application

The effect that an HF current can cause in the tissue is determined mainly by its application time, voltage level, and the degree of amplitude modulation. The frequency (0.3–5 MHz) does not play any decisive role in this case. However, the crest factor is an important parameter here. It describes the relationship between the peak value and the effective value of an alternating electric current and thus indicates how strongly a current is modulated in its amplitude. Thus, a sinusoidal alternating voltage with an effective value (U_{eff}) of 230 V (mains voltage), for example, has a peak value (U_{p}) of ≈ 325 V; the crest factor (C_{F}) here is 1.41 ($\sqrt{2}$). For the same output power, the output voltage must be higher for a current with a high crest factor. As to its influence on the tissue effect, the following holds true: the higher the crest factor, the more pronounced the coagulation effect; the lower the crest factor, the greater the cutting effect. Due to the sinusoidal forms of current used in HF surgery, the value of the crest factor cannot fall below 1.41

$$\text{Crest factor } C_{\text{F}} = \frac{U_{\text{p}}}{U_{\text{eff}}}, \quad (34.11)$$

with $C_{\text{F}}(\text{sinus}) = 1.41$, $C_{\text{F}}(\text{symmetrical rectangle}) = 1$.

34.4.1 Cutting Currents

It is only possible to cut tissue using HF alternating current if the electric voltage between the active electrode and the tissue is sufficiently high to generate electric sparks (Fig. 34.7). When an active electrode penetrates the tissue, electric sparks are automatically produced wherever the distance between the active electrode and the tissue is small enough. However, sparks do not occur until a minimum voltage of ≈ 200 V is exceeded. If this voltage increases, the spark intensity increases

Fig. 34.7 Dissection: HF surgical cutting (electrotomy) is based on sparking between the cutting electrode and the tissue

Fig. 34.8 HF surgical cuts with different crest factors. An unmodulated current produces a pure cut that only shows a very low thermal effect at the cutting edge (*top*). A modulated current causes a blend cut, whereby its thermal effect produces a narrow coagulation halo at the cutting edge (*center*). Strongly modulated current produces a cut with high eschar formation (super blend cut). The powerful thermal effect involved creates a wide coagulation margin along with slight carbonization on the cutting edge (*bottom*)

proportionally. Depending on the appearance of the cutting surfaces, a distinction is made between a *pure cut* and a *blend cut*. For a pure cut, where the cutting surfaces do not show any discoloration as a result of the heat effect, an HF current with a crest factor of ≈ 1.4 is used. For a blend cut, where the cutting surfaces show a brownish discoloration, an HF current with a crest factor of between 2 and 4 is used, depending on the required degree of coagulation. The more pronounced the eschar formation on the cutting surfaces, the greater the hemostatic effect accompanying the cut. A current with a crest factor higher than 4 no longer allows for satisfactory cutting. With the introduction in 1920 of tube generators, unmodulated currents did not initially provide sufficient hemostasis during cutting. Therefore, a spark-gap-based fulguration current was superimposed on (or mixed into) the cutting current. This is described as a mixed or blend current – a term that is still commonly used to describe unmodulated current today. A term frequently used for a smooth cut is *pure cut*, for an average eschar formation *blend cut*, and for a greater eschar formation *super blend cut* (Fig. 34.8).

Various parameters impacting the quality of the cut are minimized today using feedback control technology. The following factors play a considerable role here:

- Size and shape of the cutting electrode: for HF generators, it makes a great difference whether a large-blade electrode or a microneedle is used for cutting.
- Type of cut and cutting speed.
- The cutting quality depends on whether cutting is superficial or deep, incision speed is fast or slow.
- Tissue properties: if the cutting electrode penetrates tissue with a low electrical resistance (muscles, vessels), the output voltage sometimes breaks down; for tissue with a high electrical resistance (fat), this effect is less pronounced.

Depending on the circumstances, different control algorithms are used based on the output power, the output voltage, and the spark intensity. The aim here is to offer the user reproducible cutting properties that are independent of external conditions to the greatest possible extent.

Controlled Cutting Currents

For voltage control and regulation, sinusoidal voltages ranging between 200 and 650 V are used. In this case, the output voltage level also has an influence on the spark intensity and, consequently, on the degree of coagulation achieved during the cutting process (apart from the degree of modulation, the spark intensity thus also influences the degree of coagulation). No cut is possible below 200 V, as no spark ignition can occur between an active electrode and tissue at this voltage. On the other hand, voltages of over 650 V lead to an undesirable carbonization of the tissue and excessive wear of the active electrode. In homogeneous tissue, the voltage control compensates for variable cutting depths, cutting speeds, and electrode sizes. However, since mostly heterogeneous tissues (or different types of tissue) are cut during surgical interventions, *constant voltage regulation* alone is not sufficient. Low-impedance tissue (e.g., muscle) requires a much lower cutting voltage for a certain cutting effect than high-impedance tissue (e.g., fat). A purely voltage-controlled cutting process can therefore come to a halt when cutting through fat tissue. In order to prevent this, the control algorithm in modern HF generators uses another control criterion – e.g., the output power. The output voltage is *allowed* to fluctuate but the output power is kept constant. If an increase occurs in the tissue impedance (cut transition from muscle tissue into fatty tissue), the output voltage is increased

in order to keep the amount of power delivered to the tissue constant. This guarantees a consistent cutting effect even in heterogeneous tissue with highly variable tissue impedances.

The spark intensity has already been established as a main factor in the cutting process. As the existence of sparks inevitably has a retroactive effect on the generator itself, this can be utilized for control technology. On the one hand, sparks cause harmonics in the current, while on the other hand, sparks have a rectifying effect. This was already mentioned above in connection with faradic stimulation that can occur in electrotomy. During cutting, electrical variables are generated that are directly related to the spark intensity and thus may impact the cutting process. If one of these variables is regulated, the spark intensity can be kept constant. In this way, the cutting quality can similarly be reproduced and is largely independent of the cutting speed and type of tissue. However, spark regulation alone is not sufficient as an overall control algorithm to compensate for all the aspects involved. If the contact area of the active electrode is reduced – e.g., at the end of a cut when the electrode is lifted from the tissue – both a *constant power* algorithm and a *constant spark* algorithm try to maintain the process right to the end, even though the effective electrode area becomes steadily smaller. As a result, the tissue response would be far too strong. However, this phenomenon can then be controlled again by the *constant voltage* algorithm. An all-inclusive control algorithm, in contrast, links the three individual criteria to form one complex in which the best control algorithm is used as the situation demands in terms of impedance, voltage, and current. In this case, the required output power level is as low as possible, but as high as necessary.

Microneedle, lancet, and blade electrodes are used as cutting electrodes in open surgery; in transurethral, hysteroscopic, and cystoscopic resections, rigid loop electrodes are used, whereas hook electrodes are the best option in laparoscopic surgery.

Fractionated Cutting Currents

HF surgical interventions in gastroenterology present a particular challenge. The focus here is on endoscopic polypectomy (removal of an adenoma or a tumor on the mucous membrane, mostly in the intestines), mucosectomy (surface removal of gastric or intestinal mucosa), and papillotomy (widening of the biliary and pancreatic duct orifice in the duodenum, also referred to as sphincterotomy). In these indications, collateral thermal damage should be as superficial as possible, but as

large as necessary for sufficient hemostasis. The wall thicknesses of the target organs fluctuate considerably according to their position and elastic properties (stomach 2–8 mm, colon 0.5–4 mm), which make a resection very difficult due to the constant risk of perforation. Another factor to be considered is that not only is an open breakthrough to be classified as a perforation, but also a coagulation penetrating the wall. From a physical point of view the initial conditions are very unfavorable for electrotomy, particularly in polypectomy. Typically, prior to HF activation, the polyp is completely trapped within the polypectomy snare loop and held under tight mechanical tension. This results in a tissue contact situation that is very unfavorable to the electric cutting process as this process cannot take the form of a smooth cut due to the constant mechanical pressure that the cutting electrode exerts on the tissue. Once the cutting process has begun, the cut will continue in a jerky, hesitant manner. In order to provide an adequate clinical effect in this situation, a very HF power must first be applied in order to *condition* the tissue prior to cutting. However, this leads to the accompanying coagulation effect that is a great deal stronger than the required cutting power needed for the cutting process – which is much lower (by several orders of magnitude) than the initial cutting power needed for starting the cut. As a result, a highly inhomogeneously coagulated resection surface is produced which is too pronounced at the outer edges (risk of perforation) and too weak in the middle (risk of bleeding).

This problem is solved by temporarily discontinuing the cutting process right after it has been started. The short initial cutting phase is followed directly by a pure coagulation phase without any cutting effect. Thereafter, cutting pulses of varying intensity, automatically adjusted to the requirements of the procedure, are successively delivered to the tissue pre-coagulated between the pulses. The result is a *fractionated*, step-by-step cutting process by which a homogeneously coagulated resection surface is achieved. Depending on the type of polyp (sessile or pedunculated), the degree of coagulation can be controlled by selecting the most appropriate type of current.

In the case of endoscopically assisted manipulation of a cutting electrode during papillotomy, the surgeon frequently must correct the direction of the cutting electrode as he must assess the tissue condition regularly while cutting in order to determine whether the cutting length obtained is sufficient. In this case it is very helpful if the cutting procedure is not continuous but

pulsed. This means that the pulse-type cutting procedure used progresses *millimeter by millimeter*, giving the physician a chance to decide during the cutting pauses whether to continue or discontinue the procedure.

Argon-Assisted Cutting

If argon gas is used in combination with the normal cutting mode of the HF surgical unit, this method is referred to as argon-assisted cutting. For this purpose a special applicator is used. An active cutting electrode with argon gas flowing coaxially around it during the cutting procedure protrudes from the applicator shaft. Argon-assisted cutting is performed with the normal cutting voltages provided by the HF surgical unit, i. e., the argon gas is not ionized and is therefore not electrically conductive. The cutting site is surrounded by an inert argon-gas atmosphere, which adopts the function here of a protective gas atmosphere. Due to the argon gas, less oxygen reaches the cutting surface, leading to:

- A reduction in plume formation – the surgeon thus has a clearer view of the operating site
- Less carbonization – this means a faster healing process.

Argon-assisted cutting is particularly suitable for breast and liver surgery.

Fig. 34.9 TUR application. Via a rigid resectoscope, bladder or prostate tissue is resected transurethrally with a loop electrode, using the HF surgical monopolar mode with an electrically insulating sugar solution, or the bipolar mode with an electrically conductive NaCl solution

Bipolar Cutting

Generally the same physical laws governing the monopolar cutting process apply to bipolar cutting as well. Therefore, the current qualities and the possibilities created by control technology as shown for monopolar cutting currents can basically also be applied in the bipolar mode of application. The restrictions mentioned in connection with bipolar cutting in Sect. 34.3.2 are primarily due to the limitations of the application instruments available. Although great efforts were taken from the mid to late 1990s to improve the performance of bipolar cutting instruments and enhance the range of available products, none of the instruments have thus far been able to establish themselves as a real standard. The attempts at integrating additional electrodes in an instrument (in tripolar or multipolar arrangements) have also not led to the hoped-for breakthroughs.

Bipolar Transurethral Resection (Bipol-TUR)

The transurethral resection (TUR) of the hypertrophic prostate (TUR-P), resections in the bladder (TUR-B) in urology, or the transcervical resection of the endometrium in gynecology are standard procedures that are traditionally carried out by HF surgery using the monopolar technique in electrically nonconductive irrigation fluid (Fig. 34.9). A sugar solution serves as an irrigation medium (sorbitol + mannitol) that, however, due to irrigation pressure, can be washed into the circulation as a result of intraoperative bleeding. This absorption of hypotonic irrigation fluid can subsequently provoke a change in the electrolyte composition (hyponatremia) that – better known as TUR syndrome – leads to a brain or pulmonary edema and must be treated in intensive care. Since this risk increases with the length of the surgery, the duration of the surgery is limited.

When applying the bipolar TUR, as opposed to monopolar resection, a physiological saline solution can be used as an irrigation medium. With this medium the TUR syndrome is avoided. In bipolar TUR instruments, the two electrodes are combined within the resectoscope; either the shaft of the resectoscope functions as the nonactive electrode or it is arranged as the opposite electrode in close proximity to the active loop electrode. In both cases, the arrangement is quasibipolar, as described in Sect. 34.3.2. Since saline is electrically conductive, however, resection poses a problem because this fluid creates an electrical shunt, causing the electric current to be discharged from the cutting electrode and bypass the target tissue – which means that the required cutting voltage cannot be achieved. In order to overcome this situation, a very high power

must be produced at the loop electrode, at least for a short time. The high power level causes the irrigation fluid to evaporate abruptly along the entire cutting electrode, thus forming a plasma layer along the loop electrode. It is obvious that the energy required for forming the plasma will be dependent on the surface size of the loop electrode. The plasma layer produced in this way can then be maintained at a considerably lower power level. The loop is then ready for resection and any tissue in contact with it can be cut immediately – there is no problem *starting the cut* and no need to avoid the pressure exerted by the loop (as described above).

The method offers the following advantages:

- Reduced risk of the TUR syndrome
- Statistically significant but low risk of an obturator nerve stimulation. Due to the bipolar arrangement, the current does not flow through the body to the neutral electrode attached to the thigh but only in close proximity to the resection site
- Less blood loss
- Lower risk for pacemaker patients due to lower interference
- No thermal damage to the tissue in deeper layers
- Slightly lower cost of irrigation fluid
- No neutral electrode needed.

34.4.2 Coagulation Currents

The aim of coagulation is to denature tissue using HF current, or to constrict vessels to an extent where *bleeding stops*. The coagulation effect mainly depends on the level and form of the output voltage, the current density in the tissue, the tissue resistance, the form and size of the active electrode, and the application time. To coagulate biological tissue, a temperature of $\approx 70^\circ\text{C}$ (158°F) is required.

If the coagulation temperature of $\approx 70^\circ\text{C}$ is exceeded, the glucose within the coagulate dehydrates and the tissue can stick to the active electrode. At even higher temperatures, a carbonization of the tissue can result (Table 34.2).

The demands made on an HF surgical unit are very complex for coagulation; it is therefore important to be able to utilize different coagulation modes in order to meet all surgical needs. The following modes should be available: contact coagulation, forced coagulation, desiccation, spray coagulation, argon-assisted coagulation, bipolar coagulation and bipolar vessel sealing. The user can then select the coagulation mode best suited

to the respective surgical intervention and optimize the intensity setting accordingly.

Contact Coagulation

A distinction is made here between two basically different forms of application:

- Direct application of the HF current to the tissue via an HF surgical instrument (handle) incorporating special contact coagulation electrodes such as ball or plate electrodes.
- Indirect application of the HF current to the tissue via an additional surgical instrument to which the current is transmitted from the HF surgical handle; a cutting electrode (needle or blade electrode) is usually used for this purpose.

The direct application mode is used to a far lesser extent than the indirect application mode. Among general practitioners, where very little cutting takes place, it plays a more significant role than in daily routine application in the OR. There, selective coagulation goes hand in hand with cutting and takes place in constant alternation, *cutting/coagulation*. The source of spontaneous bleeding can be quickly grasped and compressed, and thus mechanical hemostasis can be achieved using surgical dissecting forceps. The needed *boiling off* of the targeted tissue can then be attained by simply applying HF current to these forceps (therefore, indirect application). Since the surgeon holding the forceps in his hand is frequently in contact with the patient with his other hand, he can virtually become *part of the patient* from an electrical point of view since he is only insulated by very thin surgical gloves. The higher the coagulation voltage used for the application, the greater the risk of the glove failing to insulate and thus the risk for the surgeon. As a result, he would notice and feel the coagulating effect of the HF current at the instrument contact point on his hand. In order to minimize this risk, only HF voltages of $\approx 600\text{--}700\text{ V}$ should be applied when using the indirect form of application. To support the user here, specially optimized currents are offered today for use with clamp forceps (so-called clamp currents). In order to reduce the risk even further, electrically insulated instruments are suggested that protect the grasping area (Fig. 34.10).

The diversity of differing types of tissue (for instance, muscle, fat) and their states (bleeding, dry, intimate, loose electrode contact, etc.) to which HF current is applied is reflected in a very wide impedance

Fig. 34.10 Indirect contact coagulation via insulated surgical forceps. Alternatively, the HF surgical electrode can also be used in direct contact with the tissue for contact coagulation

spectrum ($\approx 50\text{--}1000\ \Omega$). A broadband adjustment of the HF generator, i. e., constant power output across a wide tissue impedance range, is therefore required here. Since the maximum output voltage is limited for indirectly applied contact coagulation, only coagulation currents with relatively low crest factors are permitted for use here. These currents have a partially cutting characteristic that many users intentionally use for cutting in situations where the cut is to be accompanied by a distinct hemostatic effect, or if the risk of contamination is relatively high (e.g., in visceral surgery).

So-called care coagulation represents a special form. In *care* coagulation (also referred to as *soft* coagulation) the peak voltage between the active electrode and the tissue remains restricted to values $< 200\ \text{V}$. At these low voltages, no electric spark can be produced between the active electrode and the tissue. Any risk of unintentional cutting effect or undesirable carbonization is thus eliminated. Another advantage of care coagulation is the lower degree of eschar on the active electrode, which therefore needs to be cleaned less often during a surgical intervention. Care coagulation is suitable for all surgical interventions where the active electrode is brought directly into contact with the tissue to be coagulated (e.g., in neurosurgery, gynecology, ENT and particularly in minimally invasive surgery (MIS)).

As the level of the current depends on the coagulation progress, this can be used as a criterion for switching off the power supply. During the coagulation process the tissue impedance decreases considerably during the initial phase, and thus the current increases. Once the intracellular and extracellular fluids have vaporized, however, the impedance increases rapidly due to dehydration and the current is abruptly reduced

to a minimum as a result. A dynamic sensor system registers this change and switches the generator off automatically as soon as a certain limit value is reached. One speaks of contact coagulation with an auto-stop function in this context. For the surgeon this means that optimal coagulation is still possible even if he cannot observe the tip of the electrode in the tissue. Using the auto-stop coagulation mode, the user can adjust the switching-off threshold and thus preselect different coagulation degrees. The overall speed of the coagulation process varies with the output voltage used. A higher output voltage dehydrates the tissue more rapidly, whereas a lower output voltage means that less power is applied to the tissue and more time is required. This also implies that, due to heat conduction, the coagulation can continue to spread until the process is completed. Depending on the power setting on the HF surgical unit, different coagulation depths can therefore be achieved with electrodes of the same size.

Desiccation

The term desiccation (Lat.: *desiccare*, to dry out) is used mainly to define a very special form of application rather than a specific form of current. In this case, a needle-shaped electrode is pricked into the tissue and left in place for as long as the current is applied. At the given current intensity, the tissue then boils off and dries out in the area immediately surrounding the needle. As desiccation is a process that takes place deep inside the tissue, and since the thermal tissue reaction cannot be controlled visually, this form of application is advantageously combined with the auto-stop function already described in Sect. 34.4.2.

In the treatment of tumors, desiccation is used to reach tissue volumes as large as possible. Therefore, a suitable current to be used is the care coagulation current or a special desiccation current that is offered today for HF-induced interstitial tumor therapy (HFITT). In HFITT, special monopolar, bipolar, or multipolar applicators are brought into the center of the tumor or metastasis under imaging control (MRI, x-ray, ultrasound). HF current is applied over a longer period of time (typically 20 min) and the spreading of the thermal lesion is observed using imaging. Once the coagulation edges have extended into the healthy tissue, the power supply is discontinued. In order to be able to generate the largest possible coagulation volume, the needle electrodes are partially cooled to prevent the tissue close to the needle from desiccating too early. If this tissue were to dry out too soon, any further energy transfer would be prevented due to the high impedance of the dried-out

tissue and the tumor could not be completely ablated. HFITT is mostly used today in tumor therapy for liver tumors and liver metastases.

Forced Coagulation

In this coagulation mode, high, pulsed, strongly modulated output voltages of up to 3 kV are used (crest factor 5–7). This coagulation current is referred to as *forced* because, thanks to its high voltage, it even overcomes high impedances and can therefore generate coagulation even in *unfavorable* situations. The term *forced* also emphasizes the exclusive coagulation character of the current. Due to the relatively high voltages, sparks can occur between the active electrode and the tissue during forced coagulation, and thus extensive coagulation can be achieved within a short period of time. This mode fulfills the requirements for a standard coagulation and enables the surgeon to work fast and effectively – but with the compromise that tissue carbonization might also possibly occur. If a forced coagulation is to be applied indirectly via a surgical instrument, the instrument must be electrically insulated. This current is also applied in a slightly modified form for transurethral and gynecological interventions using an electrically non-conductive irrigation liquid (Fig. 34.9). Here it is particularly important that the current does not tend to cut, as the coagulations are carried out using very thin wire loop electrodes with wire thicknesses of 0.3–0.4 mm. If a cutting coagulation current were used, the loop electrode would sink into the tissue as soon as slight pressure was exerted; this cannot be tolerated for a resection in the bladder, where the tissue walls are thin.

Spray Coagulation or Fulguration

Due to the type of apparatus available in Pozzi's day, fulguration, which is largely referred to today as spray coagulation (and in very few cases also as sideration), represented the first possibility for applying HF current to living tissue (Fig. 34.11).

For spray coagulation very high pulsed and extremely strongly modulated output voltages of several thousand volts (up to 8 kV) are used (crest factor up to 20). If the user approaches the tissue with a small-area electrode (needle electrode) under spray voltage, the air between the tip of the electrode and the tissue is ionized at a distance of 3–4 mm from the tissue. Via the ionized air in the electric field, a spark discharges to the tissue, followed by further spark discharges in a process of *spraying* energy to the tissue surface and coagulating a relatively large tissue area – hence the term spray coagulation. If a ball electrode is used instead of a needle

Fig. 34.11 Spray coagulation – also referred to as fulguration

electrode, a weaker electric field strength is produced at the blunt *electrode tip* at the same distance from the tissue. This only increases again as the distance to the tissue gets smaller; so when using a ball electrode, the ionization of the air with the accompanying spark discharge only takes place at a closer distance

$$\text{Electric field strength } E = \frac{\text{Voltage } U \text{ (kV)}}{\text{Distance } l \text{ (mm)}}$$

Using spray coagulation, tissue can therefore be coagulated without touching it (noncontact coagulation). Whenever surface coagulation is necessary or diffuse bleeding must be stopped, the application of spray coagulation is advantageous, e.g., for coagulating parenchymal tissue (liver, kidney, spleen, lung). And if direct contact with the tissue is to be avoided for heat reasons, or if energy application is not possible by contact coagulation due to high tissue impedance – e.g., for hemostasis on the osseous sternum in thoracic surgery – spray coagulation is frequently the only possible application form for hemostasis.

For endoscopic applications, spray coagulation currents of lower voltage (such as endo spray) are used (typically limited to 4 kV) as a result of the dielectric strength requirements applying to the instruments.

Argon-Assisted Coagulation (Argon Beam)

There are clinical situations that cannot be sufficiently dealt with using conventional monopolar and bipolar coagulation methods. Problematic, for instance, is the open or endoscopic coagulation of large tumoral or hemorrhagic areas, which can only be addressed via technically challenging techniques and with a considerable expenditure of time when using conventional methods. Any plume formation obstructing the view, carbonization of the tissue, or coagulated tissue sticking to the electrode should also be excluded, particularly where endoscopic application is concerned. Since

the mid-1980s, the argon beamer HF method has been available for hemostasis in open surgery and since the mid-1990s in flexible endoscopy as well. Today auxiliary argon-gas modules can be added to advanced HF surgical units to have the argon-beam type of current readily available whenever it is needed.

The argon beam is a monopolar coagulation method in which HF alternating current is transmitted to the tissue to be coagulated through ionized, and thus electrically conductive, argon gas (argon plasma). Like spray coagulation, this method requires a high voltage (e.g., > 2000 V) and a relatively short distance between the electrode and the tissue. Basically, the whole process is similar to that of spray coagulation but differs where the electric field strength required for ionizing the argon gas is considerably less than for air (argon 5 kV/cm, air 25 kV/cm). In comparison with spray coagulation, the applicator can therefore be held at a considerably greater distance from the tissue (Fig. 34.12). In addition, the characteristics of the thermally generated tissue eschar are distinctly different from the effect that can be achieved using spray coagulation. The argon beam produces a focused, controlled current distribution in the beam, which in turn leads to a smooth, homogeneous coagulation of the tissue surface. In addition to this, the argon-gas beam blows tissue fluids away from the site to be coagulated. This ensures that the energy reaches the tissue directly, not only a film of blood possibly covering the tissue.

Due to its physical and electrical composition, the plasma beam will automatically deflect from coagulated (high-resistance) areas toward bleeding or insufficiently coagulated (low-resistance) tissue areas of the applica-

tion site. Thus a precise and uniform coagulation effect is achieved with superficial thermal damage limited in both depth and width; the typical depth of penetration is limited to 2–3 mm.

Compared with conventional monopolar and bipolar methods, argon-assisted coagulation offers significant advantages:

- Fast, large-surface coagulation of superficial hemorrhages.
- Automatically flow of current to tissue that has not yet been (sufficiently) coagulated, thus producing an eschar of even depth without any gaps.
- Possibility of lateral coagulation.
- Reliable hemostasis with minimal traumatization of the organ.
- Contact-free (*noncontact*) application, therefore no electrode charring.
- Maximum penetration depth of 3 mm, thus lower risk of perforation during coagulation in thin-walled organs.
- Faster wound healing due to minimal necrosis and less carbonization.
- No vaporization.
- The argon flow blows any blood produced away to the side; thus, the source of the bleeding is reached directly, which in turn improves the coagulation effect.
- Reduced smoke plume generation (better view), less unpleasant odor.
- Shorter procedural times.
- Reduced complication rate.

The endoscopic application of the argon beam has proved its worth for many indications, among them the hemostasis of tumor bleeding or bleeding after dilatation or bougienage, the treatment of anastomosis and scar stenosis, as well as partially obstructive tumors or tumors close to walls. Tumor tissue and granulation tissue growing through a mesh stent after stent insertion can be devitalized by endoscopic argon-beam application.

Necrosis can be obtained with the argon beam in tumor tissue located in areas subject to a risk of perforation (duodenum, colon). For bronchoscopy, thin, flexible probes are available that have been specially adapted to the working channel of the bronchoscope. In the tracheobronchial system, the argon beam can be used to stop bleeding and treat intrinsic obstructive tumors. Due to the numerous advantages that this coagulation method offers, the argon beam has established

Fig. 34.12a,b Comparison of (a) argon-assisted and (b) spray coagulation

itself relatively quickly in the operating room. The areas of application are mainly limited at present by the special applicators required for the discipline/indication involved. It is to be expected that new developments of combination instruments will enable additional indications to be added using this method.

Bipolar Coagulation

As in bipolar cutting, the physical laws governing tissue interaction are the same for bipolar coagulation currents as for monopolar coagulation currents. Due to the integration of both poles in one instrument, however, only currents with a limited output voltage (max. 500–800 V) can be used for reasons of dielectric strength. Strongly amplitude-modulated currents with high crest factors and high-voltage pulses – as required for noncontact coagulation – are therefore ruled out for practical reasons. As a result, bipolar coagulation is nowadays performed exclusively as contact coagulation and desiccation. Indirect application of current via surgical instruments is not an option in this case, as the tissue must come into direct contact with the bipolar instrument. In the majority of cases, bipolar forceps are used, which are offered in a large variety of shapes and sizes specially adapted to the requirements of the surgical disciplines concerned.

Auto Start and Auto Stop Functions

As in the case of monopolar contact coagulation, there is also the possibility in bipolar coagulation of terminating the coagulation process automatically by using the automatic-stop (auto-stop) function. This function can be beneficial for coagulating hypertrophic nasal concha and myomas, for example. A bipolar needle arrangement is pricked into the tissue, and the target tissue is then ablated by the application of HF energy (desiccation). In addition to the auto-stop function, automatic activation without using the foot switch (auto start) is possible for bipolar coagulation. A tissue contact sensor registers when the tissue to be coagulated is pinched between the two electrodes and automatically activates the generator. To ensure that the surgeon has sufficient time for positioning and preparation before the generator is activated, individually programmable delay times can be selected as needed. The auto-start function is only recommended and permitted for open surgery. Jointly using the auto-start and auto-stop functions offers a high degree of operating convenience as the generator is automatically activated with the preselected delay time, automatically supplies the correct power, and automatically switches off as soon as the optimum coagulation

result is obtained. In addition, undesirable side effects such as tissue carbonization and electrode charring are avoided.

Nonstick Technology

Similarly to searing in a frying pan, tissue tends to stick to a metal contact surface when heated for coagulation via electrosurgical forceps. In an attempt to detach the forceps from the tissue, it is possible for tissue to be *torn off* and the source of the bleeding broken open again. The chemical–physical process that is ultimately responsible for the sticking is largely unknown. What can be observed, however, is that the effect is all the more pronounced the higher the temperature of the forceps tips rises, and it is particularly pronounced when sparks occur between the tissue and the electrodes of the forceps.

One possibility for limiting the electrode temperature is to dissipate the thermal energy produced at the electrode contact point as effectively as possible. This can be achieved, for example, by selecting a material for the electrodes with a high specific-heat storage capacity and a good thermal conductivity. While the stainless steel normally used for forceps has a relatively high heat-transfer capacity (0.5 kJ/(kg K), whereas it is only 0.235 for silver and 0.383 for copper), thus offering a relationship between the amount of heat applied and the temperature increase obtained that is very favorable for coagulation electrodes, the thermal conductivity of the material is rather poor. In fact, it is only 15 W/(m K) and as such 25 times lower than that for copper. As a result, the process of removing the heat from the contact point and conducting it into the body of the forceps is too slow – heat builds up. The best conductor of heat is silver with 418 W/(m K). For this reason, a special silver alloy is used for the distal electrode area (tissue contact area) of nonstick forceps – one that is mechanically robust and combines the excellent thermal and electrical properties of silver with biocompatibility. This allows the heat energy to be quickly transferred, via the distal tines of the forceps, from the tissue contact point to the stainless steel composite where the thermal energy is readily absorbed due to the heat capacity of the material.

With the method developed by *Reidenbach* [34.17], which has become known as electrohydrothermosation (EHT), fluid (e.g., NaCl) is run through the tines of the forceps to the electrode contact points on the tissue surface. This fluid surrounding the electrodes ensures that, due to evaporative cooling, the temperature does not exceed 100 °C. This temperature is sufficiently high

for the required tissue coagulation but does not cause complete drying out of the contact surfaces or even any tissue carbonization. Although the EHT method is very effective, it is very expensive, as special forceps and additional irrigation fluid are needed. In addition, some indications do not allow an irrigation fluid to be applied.

Nonstick forceps therefore are an attractive alternative. They are particularly advantageous for use in neurosurgery, and also wherever tissue adhesion to the forceps is not tolerated.

Bipolar Vessel Sealing

Although the bipolar application form had already been introduced at the beginning of the twentieth century [34.18] and the coagulation mechanisms effective for occluding or sealing blood vessels had been sufficiently investigated in the early 1960s [34.19], *only* smaller vessels with a diameter of $\approx 2\text{--}3\text{ mm}$ could be sealed reliably with the bipolar method until the end of the twentieth century. The development achieved by an American study group led by *Buyssse* [34.20] and *Ryan* [34.21] must therefore doubtlessly be regarded as a milestone in bipolar technology. At the end of the 1990s they introduced a system that enabled them to seal considerably larger vessels by using a specially controlled coagulation process applied via bipolar clamp forceps (Fig. 34.13).

While being heated, the tissue undergoes different stages. In the first phase, the connective tissue is coagulated, thereby maintaining the fiber structure; this is followed by amorphous coagulation – i. e., structures disintegrate – and finally its complete destruction in the form of carbonization with loss of substance. When sealing vessels, it is important to fuse the body's own

collagen and elastin (i. e., the basic fibrous connective tissue structure), thereby maintaining the morphological tissue structure. Mechanical pressure is necessary for connecting these fibers during heating in order to ensure that the vessel walls are in close proximity with each other. Insufficient pressure merely leads to thrombosis inside the vessel, which does not ensure a reliable vessel occlusion for larger vessels. Insufficient heating produces a weak seal or only fusion of the adventitial layers (the lax connective tissue surrounding the blood vessel). If heated too strongly, the physical properties of the connective-tissue fibers are destroyed. The amorphous coagulate would tend to break and detach from the remaining tissue; the fiber structure would be destroyed and thus the mechanical stability and elasticity lost. Ideal sealing can only take place if the physical properties of the tissue are retained. When sparks are applied to the tissue, however, temperatures of more than 1000 K are reached, destroying the integrity of the tissue.

Consequently, the bipolar vessel-sealing current must not be allowed to reach voltages that could cause sparking ($< 180\text{--}200\text{ V}$). To ensure that sufficient energy can be delivered into the tissue for adequate coagulation at such low HF voltages, the energy transfer process must be supported by control technology. To this end, one utilizes the fact that the tissue impedance drops again after the first desiccation phase directly after discontinuing the HF power supply, which in turn enables repeated energy transfer at permissibly low HF voltages. In other words, the tissue is coagulated by applying the energy in pulsed mode. The process is automatically stopped only after the intended sealing level has been reached.

Fig. 34.13 Reusable bipolar instruments. Bipolar clamp forceps for vessel sealing in open surgery. Prior to cutting the tissue it is sealed intensively using the forceps (*left*). Bipolar scissors enable the application of coagulating, bipolar HF current via the two scissor blades during mechanical cutting (*right*). In contrast to vessel sealing, the hemostatic effect achieved in the process is only sufficient for smaller vessels

Reliably sealed tissue typically has a translucent, parchmentlike appearance, with the thermally damaged area limited to the margins.

The main advantages of the method are as follows:

- No foreign material – such as sutures and clips – is left inside the patient
- Cost reduction by saving suture material
- Shorter operating times (gentler treatment of patients and lower costs)
- Bipolar procedure with its typical advantages (no aberrant currents, no heating of distant tissue structures, absence of a neutral electrode, electromagnetic compatibility).

34.5 Methodical Instructions for Application and Safety

Modern HF surgical units equipped with automatic monitoring functions combine operational ease of use and functional diversity with the highest possible safety and protection for the patients. As with all HF surgical units, their safety also depends on proper handling. There are some basic rules that need to be observed to ensure maximum safety. They are just as important as the instructions for use of the HF unit and should therefore be part of the standard procedure.

The following summary has been drawn up from practical experience. It focuses on four main areas:

1. Patient,
2. Neutral electrode
3. Instruments and cables
4. HF surgical unit.

34.5.1 Patient and User Safety

General Rules for Application

- The patient must be positioned in a dry and electrically insulated area. He should not come into contact with electrically conductive objects that are grounded or have a high capacity to ground, e.g., the operating table or infusion stands.
- During longer operations, the urine must be drained away through a catheter.
- If possible, any wet operating table covering, drapes, or towels should be replaced by dry ones.
- When positioning the patient, no skin-to-skin contact should occur at any points such as between the fingers and thighs.
- The cables of the active electrode handle and the neutral electrode should be positioned so that they do not touch either the patient or other leads.
- Do not coil the HF cable; use a plastic clamp and not a metal clamp to attach it to the surgical drape.
- A sufficient distance of at least 15 cm should be maintained between the active HF electrode and an ECG electrode.
- Proper precautions should be taken for patients with implantable devices such as pacemakers in order to avoid interference with or damage to the implanted device. We recommend consulting a cardiologist.
- Pay attention to potential metal parts in or on the patient's body. Body-piercing jewelry should be removed wherever possible.
- Take particular care with anesthetics, degreasing agents, and disinfectants! They must be completely evaporated and removed from the HF target area. An electric spark could ignite the alcohol they contain.
- Prior to HF application in the gastrointestinal tract, make sure that no combustible, endogenous gases are present. A quick insufflation/suction combination is suggested to minimize any possible concentration.
- If irrigation is insufficient during a TUR procedure, H₂O molecules can dissociate to H₂ and O₂ and accumulate in the upper part of the urinary bladder. A resection carried out in this gas mixture could cause an explosion.
- The active electrode handle should not be placed down on the patient; it should always be positioned in the instrument holster intended for this purpose.
- For surgical interventions where the HF current flows through organs or vessels with a relatively small cross section, undesirable thermal damage can be safely avoided by using the bipolar technique.
- Do not make an electrical connection to the instrument until just prior to the desired HF application. This is particularly important when using the foot switch for activation.
- Always set the acoustic signal loud enough so that all users may hear the tone indicating the activation of the HF generator.

Rules for Application when Using the Argon Beamer

If argon gas is used on the patient, the following applies:

- Argon-assisted coagulation is a monopolar form of HF current application. Consequently, the safety regulations for monopolar HF surgery must be observed.
- Do not blow any argon gas into open blood vessels.
- Do not press the tip of the applicator against tissue as this could cause a gas emphysema.
- High HF voltages are required for gas ionization; make sure that the electrical insulation of leads and applicators is fully intact and undamaged.
- Argon is heavier than air (1 : 1.38); it can accumulate close to the ground and displace oxygen.
- Argon gas cylinders are under high pressure (up to 200 bar). Handle these pressurized tanks with care!

Rules for Application in Endoscopy

Apart from the general application rules given above, the following points must be additionally observed in endoscopy:

- The HF unit must not be activated if the electrode is not in the field of view.
- The argon gas flowing into the respective body cavity increases the pressure already present there due to air or CO₂ insufflation. Only use insufflators with regulated pressure releases.
- Guide wires used in combination with an HF application must be electrically insulated (e.g., Terumo wires).
- Prior to HF application in the gastrointestinal tract, make sure that no combustible, endogenous gases are present.
- Do not introduce any combustible, oxygenated breathing gas into the tracheobronchial system prior to or during argon-beam application (if necessary, keep oxygen concentration levels below 30% and ensure intermittent activation of the HF current).
- When using a video endoscope, prevent chip destruction by making sure that the argon plasma is not directed at the camera chip.

34.5.2 Neutral Electrode

In the monopolar application mode, a thermal effect is required exclusively at the active electrode. However, no thermal reaction should take place underneath the neutral electrode (NE).

Table 34.3 Contact quality monitors (CQM) of different suppliers

Acronym	Supplier	Type
PCS	Martin	Patient control system
REM	Valleylab	Remote electrode monitoring
ARM	Conmed	Aspen return monitor
NESSY	Erbe	Neutral electrode safety system
PDM	Aesculap	Permanent dynamic monitoring
PACC	Integra	Patient contact control system

To prevent patient burns, potential heating in the NE application area must be kept below 6 °C (42.8 °F) (ANSI AAMI HF 18) [34.22]. This requires correct attachment of the NE and making absolutely sure that it does not detach during the course of an operation. Advanced HF surgical units offer NE monitoring technology that keeps proper NE attachment under constant control and disarms monopolar HF energy delivery if a problem is detected (use of contact quality monitors). However, this requires the use of a split neutral electrode. The acronyms used by different manufacturers for such monitoring technologies vary depending on their monitoring philosophies (Table 34.3).

The original assumption that the return flow of current from deep tissue layers was equally distributed across the surface of the neutral electrode was not correct. In fact, the current distribution shows a distinct current concentration at the edges of the NE (edge effect). This effect is caused by the layered structure of the human skin, with the dermis offering good conductivity lying over the poorly conducting fatty tissue layer. If rectangular neutral electrodes are used, the edge closest to the target site will offer the least resistance to the HF current, leading to a *hot spot*. An electrode as round as possible, with a sufficiently long peripheral edge directed toward the operating field, is therefore ideal.

Since an even distribution of the current in both halves of the NE is not possible due to the irregular flow of current on the surface of the tissue, monitoring systems based on an even current distribution have not proved successful in practice. In contrast, monitors that continually evaluate the dynamic impedances between the two halves of the NE offer the highest level of patient safety. Advanced monitors are capable of recognizing whether a single-part NE or a split NE is connected. Additionally, given sufficient safety awareness, users can choose to have nonsplit electrodes locked and thus barred from use.

Rules for Neutral Electrode Application

- Ensure that the insulation of the NE is undamaged.
- Connect the NE cable to the surgical unit and the NE with the utmost care.
- Occasionally check the NE alarm of the HF surgical unit for proper functioning.
- Attach the NE with the long edge directed toward the operating field.
- Position the NE on one of the suitable extremities (upper arm, thigh) as close to the operating field as possible.
- Ensure good tissue contact; this may require shaving any hair preventing proper contact.
- Keep fluids away from the NE area, as these can adversely affect both the adhesion and the electrical properties of the NE.
- Do not reuse disposable (single-use) NEs. For safety and hygiene reasons, disposable NEs should never be reused.
- Observe the expiration date of the NE.
- The NE must not be trimmed or reduced in size.
- In any circumstance, additional contact gel should never be applied to the NE.
- Bony or uneven surfaces, implant sites, places with thick layers of fat (such as the abdomen or buttocks), and scarred tissue are unsuitable for NE application.
- Use a contact quality monitor that requires the exclusive use of split NEs.
- Do not subject NE cables lying on the floor to any mechanical stress; in particular, avoid rolling the equipment trolley or even the C-arm over them.

34.5.3 HF Instruments and Cables

- Only use original accessories recommended by HF surgical unit's manufacturer. In case of doubt, request a certificate of compatibility from the manufacturer or dealer.
- Prior to each application, perform a visual check to ensure that the insulation of plugs, cables, and instruments is not damaged in any way. A short functional check of the instruments is recommended as well.
- During the operation, it is best to cleanse the electrodes with a moist cloth (swab). Do not scratch as this could damage the surface and insulation of the electrode.
- It is advisable always to keep the electrodes clean immediately following each use. Should the electrodes have any bits of old, dried tissue on them, soak them in a solution before cleansing.

- The manufacturer's instructions for reprocessing (cleaning, sterilization) must be duly observed.
- Disposable instruments must always be discarded immediately after the operation (multiple use is not permitted!).
- Keep reusable instruments in a safe place. Observance of the manufacturer's instructions for handling and care increases both the safety of the patient and the service life of the instruments.
- Accessories with visible defects must be checked or returned to the manufacturer for inspection or repair.

34.5.4 HF Surgical Unit

- The use of any HF surgical unit requires the user to be familiar with its correct handling.
- Only use HF units equipped with a contact quality monitor.
- The HF power setting should always be selected as low as possible and as high as necessary. Automatically controlled HF surgical units are the best option.
- The cutting or coagulation function should only be activated for as long as it is really needed.
- Always conduct a functional test before starting the operation. When the NE has been applied, briefly activate the HF current by pressing the active electrode handle button.
- Pay attention to error messages and alarm signals.
- Repeat training courses on the principles of HF surgery and their safe use each year (make use of training courses offered by the manufacturer).
- To avoid video disturbances in older systems, the HF cable should run as far away from the camera cable as possible.

34.5.5 Incidences During Application of HF Surgery

As part of the enforcement of the Medical Devices Act, the German Federal Institute for Drugs and Medical Devices (BfArM, Berlin) has evaluated the incidents reported in the field of HF surgery over a number of years. It concluded that the few complications reported were mainly caused by user errors and were not due to a malfunction of the medical devices. The BfArM has set guidelines from these user errors that have been taken into consideration in the above-mentioned rules.

In the few incidents reported, the damage mainly involved the NE. In this connection the BfArM made the following statement:

... A distinct accumulation of incidents can be observed for single-part neutral electrodes, for which there is no safety monitoring. The very few “burns” observed in conjunction with split electrodes are due to causes other than high current densities ... chemical burns due to disinfectants that have not evaporated.

Where injuries in the coccyx and dorsal areas were concerned, the BfArM made the following determination [34.23]:

... The users sometimes spoke of burns, but the investigations carried out by the manufacturer, or an assessment of the photos sent in, revealed that they were actually acid burns or inflammations. During the operation, the area above the sacrum is particularly subjected to a pressure load that leads to a slight perfusion of the respective skin areas.

It is therefore absolutely vital to ensure that HF units are only put into operation and used by qualified personnel who have received special training and are fully familiar with the device.

34.6 Outlook

The automatically controlled HF surgical units currently available are of a very high standard, both in terms of technical safety and usability. The growing number of technical possibilities will contribute to further improvement of these standards as well. In addition, application-specific improvements will mean that the handling of the HF surgical units will become even easier. Instrument recognition and the resulting automatic parameterization of the devices with suitable settings will play a role here. Only logical and meaningful changes to the automatic presettings will then be possible within predetermined limits (expert systems). Consequently, there will be no standardized interfaces for HF instruments but specific solutions provided by each manufacturer.

The integration of HF units into OR systems via communication networks will also contribute toward enabling the control of all the devices required for an operation using a common user interface. Touch-screen monitors and voice control are relevant keywords here.

As HF currents are being optimized increasingly toward specific applications, HF generators will be showing a trend toward the specialist user instead of the general user. Solutions with special devices and systems will be offered for the different specialist fields, e.g., gastroenterology, urology, neurosurgery – optimized in terms of costs as well as handling.

Argon-assisted applications will gain even greater importance in daily OR use. The range of applications has by no means been exhausted and is currently restricted only by the available applicators. Combination instruments – such as polypectomy snares, sclerosing needles, or biopsy forceps offering optional argon-

assisted coagulation – will enable the method to handle new indications.

Greater importance will be attached to the continuing development of surgical instruments, particularly with regard to specialized instruments and instruments for specific indications. It will be a tremendous challenge to increase the quality of the instruments and simplify their handling in daily use. Despite the enormous cost containment pressure that affects the public health sector on a global scale, there will be a trend toward the use of disposables. Hepatitis, AIDS, rabies virus, Creutzfeldt–Jakob disease (CJD), and bovine spongiform encephalopathy (BSE) are just a few of the dreaded, contagious diseases now running rampant around the globe – and new diseases continue to extend the list year after year. As a result, instrument processing becomes a growing challenge for hospitals.

Vessel sealing will play an important part particularly in laparoscopic surgery. Surgical sutures and ligatures are particularly difficult to use in a laparoscopic environment, and foreign material is unavoidably left in the patient. Reliable vessel sealing will radically change this field and help establish standardized surgical techniques. The large number of different methods used for tissue dissection will be greatly reduced as a result. Ultrasonic dissection and water-jet dissection leave much to be desired as regards their performance, and these procedures are also expensive. They will be replaced by bipolar, HF-induced tissue sealing. To ensure the greatest possible safety for patients, it will also be important for users, surgeons, and surgical staff to keep themselves well informed about the current and future developments taking place in the industry.

Medical Rad

35. Medical Radiation Therapy

Peter H. Cossmann

Historically speaking, medical radiation therapy is a relatively old medical branch as it originated two centuries ago with the discovery of x-radiation by W. C. Röntgen in 1895. Shortly after this historical event the first treatment attempts were carried out by some courageous physicians. Since then radiation therapy evolution has undergone several major leaps due to essential developments in mechanical engineering, electronics, and computer science.

An introductory part gives an overview of these developmental steps through history. This is followed by some basic information on the physical and technological principles of radiation physics. Here radiation types, radiation sources, and the interaction of radiation with biological tissue are covered and finally rounded out with a more detailed look at dosimetry.

Furthermore, the three therapy fields for radiation treatments are discussed: percutaneous therapy, brachytherapy, and radionuclide therapy.

The main part covers equipment technology for the generation of radiation. In radiation therapy, ionizing radiation is used, which either results from radioactive decay processes or is generated by the acceleration of charged particles. The technologies described are x-ray equipment, cobalt unit, linear accelerator, brachytherapy sources/treatment units, and radioactive implants. A main focus is on the technology of linear accelerators, which serve as the daily workhorses nowadays.

Finally, special techniques and newer developments in teletherapy are discussed. Besides stereotactic and tomotherapy approaches, technological developments and refinements in the field of linear accelerator technology are described in more detail.

35.1 X-Radiation

1896 patient, Vienna: 70 years later

Fig. 35.1 First radiation treatment to remove a nevus pigmentosus et papillomatosus (after [35.1])

On 8 November 1895 at Würzburg University's Institute of Physics, W. C. Röntgen discovered a new type of radiation. In his first disclosure, Röntgen spoke of so-called x-rays because he didn't know what type of radiation he was dealing with. With this he laid the foundations for medical radiation therapy (RT). Therapy with ionizing radiation began in 1896 in Vienna, only a few months after Röntgen's discovery. Initial reports regarding the successful therapeutic application of X-radiation can be traced back to Freund, Sjögren, and Stenbeck. Based on newspaper reports of erythema and alopecia following exposure to x-rays, Professor Freund from Vienna had in 1896 treated a young girl suffering from nevus pigmentosus et papillomatosus with radiation. In 1966, the patient was presented at the German Radiology Congress. The result, which is illustrated in Fig. 35.1, clearly showed that the radiation had undeniably had the desired effect, which is to say that the hair

First successful treatments of cancer:
Stockholm, 1809

Fig. 35.2 First treatment of carcinomas of the lip and cheek using X-radiation (after [35.2])

on that patch had definitively disappeared. However, presumably also as a result of a lack of knowledge about adequate dosage, there was a significant side effect – considerable curvature of the spine in the radiation area. This illustrated in a striking manner where the main problem lies with this form of treatment: achieving a desired effect while avoiding undesirable side effects.

In 1899 in Stockholm, T. Sjögren and B. Stenbeck reported the first successful treatment of carcinomas of the lip and cheek using X-radiation. Figure 35.2 shows examples of the treatments of carcinomas of the lip and cheek using X-radiation.

35.2 Historical Development of Radiation Therapy

Initially, gas ion tubes consisting of a partially evacuated glass bulb with a cold cathode and anode were used as therapy systems. The first x-ray tube was a Hittorf tube as shown in Fig. 35.3.

The high voltage necessary for generating x-rays was produced using induction coils, which were, in principle, a transformer with a primary and secondary coil on a ferrite core. The cathode is in the form of a concave mirror, so that the cathode rays that emerge from the cathode perpendicular to the cathode surface meet at a point. At this focal point is the anticathode, a piece of sheet metal composed of platinum or tungsten that is in-

clined by about 45° and conductively connected to the anode. X-radiation is generated as a result of the metal ions and electrons impinging on the electrodes (cathode and anode), and there is simultaneous sputtering of the electrode material. The gas molecules present in the Hittorf tube are absorbed by the sputtered metal particles, and the vacuum in the tube increases. Ever higher voltages must be applied in order to ensure the flow of current. Because of the higher voltage, the x-rays become increasingly hard and finally the tube ceases to work. To make them usable again, gas had to be let into the tube. Soft x-rays are rays with a relatively

Fig. 35.3 Hittorf tube (cold cathode tube) (courtesy Electrosuisse Museum of Technology and Engineering, Fehraltdorf)

long wavelength, and thus with low penetrating power, which are generated by relatively low voltage (approx. 30 000–50 000 V). Hard x-rays have a short wavelength with a high penetrating power and with low absorbability (100 000–300 000 V). Modern x-ray tubes such as the so-called Coolidge tube are high-vacuum hot cathode tubes, which are pure electron tubes [35.3]. The hot cathode is a filament made from tungsten, which has a very high melting point. The tube has no special anticathode; rather, the anode serves as the anticathode facing the cathode. It is composed of copper, a good thermal conductor, and, because of the buildup of heat due to the cathode rays impinging on it, it is provided with a cooling attachment, e.g., a water cooling system. At the point where the cathode rays impinge upon it, the anode has a tungsten disc to protect it. A Coolidge tube of this kind is illustrated in Fig. 35.4.

Hot cathode tubes have various advantages over cold cathode tubes. Firstly, soft or hard X-radiation can be generated using variable voltages, and the intensity of this radiation can be regulated by adjusting the filament current. Their properties only change in the long term. Modern tubes are operated exclusively using alternating current (AC) power and a transformer. For this purpose, the voltage of 220 V is raised to 30 000–300 000 V.

Fig. 35.4 Coolidge tube (hot cathode tube) (courtesy Siemens, Erlangen)

The discovery of radium radiation by Curie in 1898 led by chance to a therapeutic application of radioactive substances, because in 1901 Becquerel acquired dermatitis from a radium source, and this dermatitis was no different to radiation dermatitis, which had been observed in connection with x-rays. Therapy for the treatment of dermatological conditions was consequently begun at the St. Louis Hospital in Paris using a radium source provided by Curie. Initially it was mainly the beta rays of radium that were used for therapeutic purposes. Subsequently, from 1906 onward, the radiation sources were encapsulated in order to utilize only gamma radiation. Radium was of great significance, particularly in gynecological RT, but it has since been completely superseded by methods of afterloading with synthetic radioactive emitters, partly for reasons of radiation protection. Telecurietherapy using synthetic radioactive substances began after the discovery of synthetic radioactivity by Joliot-Curie in 1934 and, among other things, once it was possible to produce ^{60}Co and ^{137}Cs in nuclear reactors. The first use of a telecobalt machine for RT followed in 1952. It continued to be used until the middle of the twentieth century, until the first clinical applications of a circular electron accelerator (betatron) were able to be realized. Use of the linear accelerator (linac), first developed in 1930, began in the early 1970s. Since then linacs have almost completely superseded the betatrons, and today they are the most important radiation source in the field of teletherapy.

35.3 Physical and Technical Principles of Radiation Physics

35.3.1 Types of Radiation

Radiation that can generate ions when passing through matter as a result of impact interactions is described

as ionizing radiation. A distinction is drawn between directly and indirectly ionizing radiation. Directly ionizing radiation consists of charged particles such as electrons, protons, α -particles, and heavy ions; their ki-

netic energy is sufficient to achieve impact ionization of an atom. In the case of indirectly ionizing radiation, charged particles are produced from uncharged particles such as photons or neutrons, which then transfer their energy once more to the surrounding atoms through impact ionization [35.4–6].

Photons – in the form of x-rays and γ -radiation – and also electrons are predominantly used in RT. In addition, protons – as well as isolated heavy ion radiation – are also increasingly being used, with the generation/application of heavy ions in particular having high technological requirements, which currently are not yet practicable except in a research center environment. In recent times, moreover, boron neutron capture therapy has again brought neutrons for therapeutic use into the discussion, this being a form of therapy that is limited to a few fields of application and that is furthermore technologically complex and therefore not yet very widespread.

Since RT works mainly with photons for deep therapy and electrons for superficial and semideep therapy, the following sections are limited to these types of radiation.

35.3.2 Radiation Sources

The generation of photons in the form of X- and γ -radiation is achieved either by means of deceleration/energy dissipation of accelerated particles in a target (Fig. 35.5) or by radioactive decay. The technical basis for this is x-ray tubes in the low to middle energy range (kV) and accelerators in the high energy range (MV). The latter are also used for the generation of high-energy electrons.

Radioactive substances serve as further radiation sources. The three possible types of decay are illustrated

α -decay	β -decay	γ -radiation
${}^A_ZX \rightarrow {}^{A-4}_{Z-2}Y + {}^4_2\text{He}$	${}^A_ZX \rightarrow {}^A_{Z+1}Y + \beta^- + \bar{\nu}$	${}^A_ZX^* \rightarrow {}^A_ZX + \gamma$
	${}^A_ZX \rightarrow {}^A_{Z-1}Y + \beta^+ + \nu$	

Fig. 35.6 Types of radioactive decay

in Fig. 35.6. Following α - or β -decay, the daughter nucleus is often in an excited state. The majority of these excited states have very short half-lives and, by emitting therapeutically usable γ -radiation, pass into a state of lower excitation or into the ground state.

35.3.3 Interactions with Matter

Photons are attenuated by matter on the one hand by absorption (photoelectric effect or pair production) and on the other by scattering (excitation or Compton effect). Absorption is dependent on the linear attenuation coefficient, a matter constant, and also on the layer thickness. In the case of the photoelectric effect, the photon transfers all its energy to an electron, and this photoelectron leaves the atomic shell. With photon energies above 1022 MeV, the photon can be converted into an electron–positron pair. In the case of elastic scattering of photons, the electrons in the atomic shell are excited and the energy is then emitted in another direction in the same quantity. The Compton effect involves inelastic scattering, i. e., the photon releases an electron from the shell with some of its energy and then continues to move in a different direction. Within an energy range of approx. 20 keV–20 MeV, which is to say practically in the entire energy spectrum of RT, the Compton effect is dominant for all human tissue. The interaction of photons with tissue takes place in two stages. In

Fig. 35.5 Schematic view of an x-ray tube

the first stage, charged particles are released (electrons), and in the second stage these particles either transfer their energy to the matter or release electrons. Since the effect of photons is indirect in this way, it is also referred to as indirectly ionizing radiation. The higher the energy of a photon, the deeper it is able to penetrate into the tissue before it releases an electron. In the case of photons generated by linear accelerators and having energies of 4–25 MV (ultrahard x-radiation), a higher dose is generated in the deep tissue than at the skin surface; this is known as the so-called buildup effect, which does not occur with x-rays in an energy range of 200–400 kV. The higher the energy, the less the photons are decelerated; they are scattered in a forward direction as well as other directions. In this way, a higher dosage is achieved using ultrahard x-rays for target areas that are situated deeper. At the same time, this leads to better protection of the skin and, as a result of the lower proportion of lateral radiation, to a more sharply defined lateral limit of the dosage.

The interaction of electrons with matter takes place exclusively by means of scattering processes. Elastic scattering leads to the particles changing direction. In the case of inelastic scattering, the particles change their direction and lose energy due to the excitation of the atomic shell, the ionization of atoms, or the generation of x-ray Bremsstrahlung. Electrons are electrically charged particles that transfer their energy directly to tissue, and this therefore involves directly ionizing radiation. This results in a relatively high exposure of the skin, a large area in which the maximum dose is deposited, and a rapid decrease in dose after the maximum dose, which means that the region behind the target area situated at the surface is better protected than with photons.

35.3.4 Dosimetry

Dosimetry, in the modern sense of the word, was unknown in the early stages of RT. The following three effects were used for the semiquantitative determination of the level of radiation: the redness of the patient's skin as a *biological dosimeter*, the blackness of a photographic plate, or the luminescence of various substances (usually barium cyanide). In order to estimate the dose, it was important to know the hardness of the radiation, as all three methods give different results with different mixtures of rays.

In the field of RT, *dose* is understood as meaning the energy that is absorbed by tissue when it is treated with radiation, since only the energy remaining in the

tissue can have a radiation effect. We talk of the so-called absorbed dose, measured in *gray*, with 1 gray corresponding to an energy of 1 Joule per kilogram of tissue.

In order to make the dosages used by different hospitals and clinics in international cooperation or used in publications more comparable, there are standards governing how they should be referred to. In the case of the reference point concept used for this purpose, reference is commonly made to ICRU Report 50 [35.7]. In everyday clinical practice, the *ICRU reference point*, or the *dose according to ICRU*, is therefore often spoken of.

Any material in which a signal is generated as a result of exposure to radiation can be used to measure the dose of ionizing radiation. In principle, any physical, chemical, or even biological effect that is caused by ionizing radiation can therefore be utilized.

To this day, ionization dosimetry is of the greatest significance among methods for radiation detection and measurement. It is based on the primary interaction process of radiation and matter, ionization. Ionization chambers in two designs are primarily used: cylinder chambers and flat chambers. Cylinder chambers, which are also known as compact chambers, consist of a cylindrical chamber wall of a conductive material and an axial, usually metal, electrode.

The main advantages of this dosimetry approach are that it is possible to use tried and tested electrical and electronic measurement technology and that the system possesses a very high degree of sensitivity, measuring accuracy, reproducibility, and long-term stability, is not damaged by radiation, and can be used in the entire range of applications of ionizing radiation while being less energy dependent [35.4]. The chambers are also convenient, user-friendly, and very robust. The ionization of solids, including semiconductors, is also routinely used in dosimetry. Mobile electrons and also mobile positively charged *holes* are generated in the semiconductor by means of radiation, i. e., it is made into an *n*-type or *p*-type semiconductor. The sensitivity in semiconductors is around 20 000 times greater than in ionization chambers with a measuring volume of equal size. The advantage of semiconductor detectors is their high spatial resolution, but in the longer term the sensitivity decreases as a result of irreversible radiation damage in the material. Recently, diamond detectors have also been used. They belong to the so-called conductivity detectors and, after obligatory preirradiation, exhibit detector currents that can exceed those of ionization detectors by several powers of ten – and with especially high spatial resolutions,

too. Scintillation detectors are based on the physical phenomenon of excitation and are predominantly used for the detection of radiation. The shell electrons that are raised to a higher orbit fall back to the ground state, emitting light; the light pulses emitted are usually amplified by the use of photomultipliers. Thermoluminescent dosimetry uses special ion crystals, known as thermoluminescent dosimeters (TLD), as detectors. These lithium fluoride or calcium fluoride crystals are selectively doped with foreign atoms, such as magnesium, manganese, or titanium, and are characterized by the fact that they do not immediately return to their ground state after excitation. A long-term luminous effect therefore remains following irradiation, which is termed luminescence. Some of the absorbed energy is stored in the crystals and can be retrieved in the form of the emission of light by controlled heating. TLDs exist in various forms and are suitable both for *in vivo* and also for phantom measurements. Simultaneous irradiation of several of these miniaturized dosimeters also enables the dose distributions to be measured. Spatial resolutions in the submillimeter range and with measuring accuracies of up to 1% can be achieved, although measuring accuracies of this level can only be achieved with a very large amount of experimental outlay.

Films are also very highly suitable as dosimeters, as was recognized at an early stage. Following irradiation with subsequent development, the films are densitometrically assessed with special equipment (densitometers, film scanners). The reproducibility of the process conditions, from the manufacture of the film through development to assessment, play a fundamental role in the accuracy of the measurement, and this means that films are of only limited suitability for routine use. Films are the dosimeters with the highest spatial resolution, as practically every individual silver particle acts as a dosimeter. Ultimately, however, the resolution is limited by the diameter of the light beam of a densitometer or by the CCD detector density of the film scanner used.

Ferrous sulfate dosimetry, also known as Fricke dosimetry, belongs to the group of chemical methods and was at the same time the first approach of what was known as gel dosimetry. The measuring process is based

on the fact that divalent iron in an air-saturated aqueous sulfuric acid solution is irreversibly oxidized by ionizing radiation to form trivalent iron. The amount-of-mass concentration of the trivalent iron ions is determined by means of extinction measurement. The method exhibits proportionality of amount-of-mass concentration and absorbed dose in a wide dose range, it is independent of the dose rate, and absolute determinations of the dose can be achieved with an accuracy of 1%. The method is thus also used by calibration service providers for the calibration of dosimeters. Gel dosimetry has in recent years been gaining increasingly in significance, as new gels that are less difficult to process have in the meantime become available. This group includes the BANG (bis acrylamide nitrogen gelatin) gels, which have been available for a short period of time. This involves a monomer that is incorporated into a gelatin matrix. When subjected to radiation, polymerization is induced, resulting in a change in the spin-spin relaxation time T_2 as a function of the respective locally absorbed dose. Magnetic resonance imaging (MRI) was initially exclusively used as an evaluation method; now there are also optical systems based on computer tomography (CT) that make use of the change in optical density that occurs simultaneously.

For the sake of completeness, calorimetry should also be discussed as another approach. It is based on the principle that, in the event of complete conversion of the absorbed energy into heat, it is possible for this energy to be directly and absolutely measured. In addition to graphite calorimeters, water calorimeters are increasingly being used in national standard laboratories, as the absorbed dose in water has since become the basis of clinical dosimetry. Owing to the high experimental outlay, calorimetry cannot be used in routine clinical applications.

In recent years in particular, various biological dose-measuring methods have also been further developed and used in clinical settings. In addition to the purely qualitative method already mentioned of assessing the redness of skin, which has of course been superseded, these methods include quantitative ring chromosome counting and fluorescence analysis of chemically labeled DNA strands.

35.4 Forms of Therapy

In general, modern RT can be divided into three forms: percutaneous RT, brachytherapy, and radionuclide ther-

apy. In percutaneous therapy, also called teletherapy, the radiation source is situated outside the body of the pa-

tient to be treated with radiation, and the rays penetrate through the skin and into the body. Examples are irradiation using a teletherapy unit or an accelerator. In brachytherapy, one or more small radiation sources are inserted into each region of the body that is to be treated with radiation. Irradiation thus takes place directly at the location of the tumor, that is, just a short distance from it (from the Greek *brachy*, short). Brachytherapy can be *intracavitary*, e.g., in the uterus, *intraluminal*, e.g., in the vagina, the esophagus or the bronchus, or *interstitial*, using needles or thin catheters implanted in the tumor or in the tumor bed for that purpose. In radionuclide therapy, radioactive substances are administered, which preferably accumulate in a certain organ or body part [35.6, 8, 9].

35.4.1 Percutaneous Therapy

In percutaneous therapy, a distinction is drawn, depending on the depth of the region to be radiation treated, between superficial therapy, semideep therapy, and deep therapy. Superficial therapy includes skin radiation therapy on the one hand and intraoperative radiation therapy on the other. These are performed using therapy systems specifically designed for the purpose, which are usually in an energy range of between 10 and 50 kV. Fields of application for semideep therapy are mainly the treatment of benign conditions such as inflammatory processes of the ligaments and joints. Photons in the range of 150 to 300 kV from so-called orthovoltage units are used for this, and sometimes low-energy electrons of linacs are also used. Deep therapy using high-voltage equipment is today performed mostly using linacs, which have virtually replaced the cobalt unit. The energy range for this so-called high-voltage therapy is between 1 and 25 MeV. Typical doses applied in teletherapy are approx. 2 Gy per radiation session; varying numbers of sessions ultimately lead to total doses of up to approx. 75 Gy.

35.4.2 Brachytherapy

In the field of brachytherapy, distinctions are made both on the basis of the dose rate used and the region being treated. If the dose rate is taken as the value of measurement, then a distinction is drawn between low-dose rate (LDR), medium-dose rate (MDR), high-dose rate (HDR), and pulsed-dose rate (PDR). According to the definition based on ICRU, the dose rates are 0.4 to 2.0 Gy/h for LDR, 2.0 to 12.0 Gy/h for MDR, and greater than 12.0 Gy/h for HDR, the usual dose

rates with modern HDR brachytherapy systems being between 100 and 300 Gy/h. The PDR is a relatively new variant, which for reasons of radiation protection appears to be establishing itself increasingly as a replacement for LDR approaches.

An alternative classification arises from the nature of the application: here, a distinction is drawn between contact, intracavitary, endoluminal, and interstitial therapy. In the case of contact therapy, therapies are administered close to the surface using specially shaped radioactive applicators or radioactive preparations inserted into boluses. In intracavitary therapy, cavities in the human body that are present naturally or are artificially created are used to insert radioactive substances. In endoluminal therapy, also referred to as intravascular therapy, radioactive sources are introduced into the vessel lumen either temporarily (HDR) or permanently in the form of stents (LDR). Interstitial therapy involves temporary or permanent insertion of radioactive emitters directly into the tumor tissue, these emitters being applied in catheters or hollow needles positioned in advance.

35.4.3 Radionuclide Therapy

Familiar radionuclide therapies include radioiodine therapy for the treatment of thyroid conditions. It has been used worldwide since the 1950s and belongs not to the specialist field of RT/radiooncology but to the discipline of nuclear medicine. Based on statistical studies of over 100,000 patients treated, it has been possible to guarantee that radioiodine treatment will not cause an increase in thyroid cancer or other malignant diseases in the body. The exposure to radiation that the body undergoes in the process corresponds to that of a thorough x-ray examination. Radioiodine therapy is carried out in the case of thyroid disorders (e.g., hyperthyreosis associated with Graves' disease, uni- or multifocal autonomy, latent hyperthyreosis) to reduce the size of large thyroid glands (*goitre*) and also for the follow-up treatment of thyroid carcinomas. For reasons of radiation protection, the therapy must be carried out on an in-patient basis, as the patients emit radioactivity in their excretions (urine, stools, perspiration, and saliva) and also in their respiratory air. All sewage from the therapeutic ward must be collected and must only be released into the public sewerage system once the radioactivity has decayed. The radioactive iodine is administered to the patient orally in an amount individually determined in advance by means of a radioiodine test. The ^{131}I isotope used for radioiodine therapy is

a beta minus emitter with subsequent gamma radiation. It emits 90% beta radiation and 10% gamma radiation. The beta radiation is therapeutically effective and has an average range into the tissue of just 0.5 mm. As a result, the exposure of the neighboring organs to the radiation is minimal. The nuclide has a half-life of around 8 d and a gamma energy of 360 keV. The amount of radioiodine required for RT is calculated, depending on the desired focal dose, from the maximum thyroïdal iodine uptake, the effective half-life and the thyroïd volume to be treated with radiation therapy. As a target dose, 150–200 Gy is applied for Graves' disease, 200–400 Gy for thyroïd autonomy, and 150–180 Gy for reducing the size of a goitre. In cases of hyperthyreoses, permanent elimination of the

metabolic disorder can be expected in roughly 80% of cases.

The radiation protection measurements and the posttherapeutic calculations of the radiation dose are performed with the aid of the gamma radiation that is emitted from the body. Gonadal exposure in radioiodine therapy of benign thyroïd conditions is 0.02–0.05 Gy. The gonadal dose that leads to a doubling of the spontaneous mutation rate is 0.2–2.0 Gy. The iodine beta radiation has the following radiobiological effects in the cell system of the thyroïd gland: restriction of function, loss of regenerative ability, and cell death. In addition to influencing function, the degeneration of individual thyroïd cells also results in a decrease in the size of the goitre, usually by approx. 40%.

35.5 Equipment Technology for the Generation of Radiation

In RT, ionizing radiation is used that either results from radioactive decay processes or is generated by the acceleration of charged particles. In addition to x-ray tubes, various other technologies are used for the acceleration of charged particles, such as linear and circular accelerators – apart from the betatron, which is no longer in use, circular accelerators include the microtron, the cyclotron, and the synchrotron. Since linacs and afterloading units are in particular used in clinical application for the generation of radiation, the chapters that follow will include in-depth discussion of these technologies.

35.5.1 X-ray Equipment

Today, a distinction is made between soft x-ray and hard x-ray therapy, the latter also referred to as orthovoltage therapy. The boundary between the two forms of therapy is at a tube voltage of 100 kV. The therapy distance – also called the focus-skin distance – is between 0 and 5 cm in the case of short-distance radiation, and otherwise between 10 and 30 cm, or in exceptional cases up to 50 cm. In addition to the classics from Siemens (Dermopan, Stabilipan 2) and Philips (formerly C. H. F. Müller, RT50, RT100, RT250), which are over 50 years old and are still in use in some places today, microprocessor-controlled systems with integrated patient databases are now used and cover a tube voltage range of 10 to 300 kV. A modern x-ray therapy unit is depicted in Fig. 35.7.

Therapeutic x-ray units consist of a cooled tube, which is integrated in a tube head fixed to a stand,

a generator, a control panel, a patient couch, and a set of applicators. Depending on the spectrum of use, systems with overhead installation or combined wall and floor installation are used as stands. As the currents of between 20 and 30 mA that are used are significantly lower than those of diagnostic x-ray tubes, there is less heat generated, and stationary, i. e., structurally simple, anodes can therefore be used. As the X-radiation generated has a broad, continuous photon energy distribution, basic filtering is performed, which eliminates the low-energy components and thus hardens the radiation. In addition to the traditional applicators – also called tubes – some modern devices of this type are also equipped, for contact therapy, with a collimator having adjustable diaphragms for field definition. In addition, individually manufactured lead cutouts are introduced into the tube

Fig. 35.7a,b X-ray therapy unit Gulmay D3225 (a) with control console (b) (courtesy Gulmay Medical, Camberley)

for the shaping of irregular fields. The use of a multi-leaf collimator is also a relatively new approach that is used instead of the aperture collimator. This is a device that enables irregular field shaping by means of manual positioning of the individual leaves, which move independently of one another.

35.5.2 Cobalt Unit

Cobalt units belong to the group of equipment known as teletherapy units, i. e., they are used for teletherapy. In order for sufficiently high dose rates to be achieved at a therapy distance of usually 80 cm, the sources must have a very high activity. So that the highly active source only has to be replaced very rarely, radionuclides are desirable that have a half-life that is as long as possible. Radionuclides used are therefore ^{60}Co and, only in rare cases, ^{137}Cs . In comparison with ^{137}Cs , ^{60}Co has a higher photon energy of approx. 1 MeV and therefore has therapeutic advantages, even though its much shorter half-life of 5.25 years generally means that it is necessary to replace the source after just 5–10 years. A modern cobalt unit is shown in Fig. 35.8. The tube head of the cobalt unit is connected to a stand by means of a support arm that can be rotated around a horizontal axis. This design is also known as a gantry and enables arc RT around a virtual point lying fixed in space, the so-called isocenter. The tube head itself consists of the source, a source valve or a rotary shutter, the lead shielding, diaphragms for field definition, a light-beam localizer, and a distance-measuring device. In addition to the support arm, the diaphragm can also be rotated. The treatment couch, which is fixedly connected to the system, can be moved linearly in all three spatial directions and can be rotated both isocentrically and eccentrically around its own axis.

35.5.3 Linear Accelerators

These days, modern linacs are available for the generation of therapeutic electron radiation with a maximum energy of 2–25 MeV and ultrahard photon radiation with a maximum energy of 4–25 MeV. There are several electron energy levels that can be set and – depending on the manufacturer – up to three photon energy levels. In addition, there is also a sort of special form, the *photon-only machines*, which have low maximum photon energies of between 4 and 6 MeV. They are mostly used as a replacement for cobalt units that have been taken out of service, which is to say that they can be installed in existing therapy rooms without any

Fig. 35.8 UJP Terabalt 80 cobalt unit (UJP PRAHA, Prague)

great additional measures being necessary in terms of radiation protection. Systems of this type manage without moving parts in the accelerator segment and also have accelerator tubes that are a maximum of 50 cm in length. This makes a significantly more compact and more simple design possible, without beam deflection or beam analysis, which lowers the costs accordingly.

Linacs are radiofrequency accelerators that accelerate electrons in straight accelerator tubes by means of radiofrequency waves of 3 GHz with a wavelength of 10 cm. The systems essentially consist of five sub-assemblies: the energy supply unit, the modulator, the accelerator unit, the tube head, and the control unit. Figure 35.9b shows a schematic representation of the structure of a modern high-energy linac. The modulator contains the source for the radiofrequency generation, as well as the control electronics and electrical power supply. The radiofrequency generators originally come from radar technology; they generate microwaves in magnetrons or klystrons and amplify them. Magnetrons are preferably used with low to medium electron energies and are less expensive than klystrons, but they also

Fig. 35.9a,b Varian Clinac 21 EX linear accelerator (a) with beam guidance (b) (courtesy Varian Medical Systems, Palo Alto)

have a significantly shorter operational life span than klystrons. With klystrons, which are used with relatively high electron energies, a distinction is made between single-chamber and two-chamber systems.

The accelerator unit is composed of an electron gun and an accelerator tube, as well as cooling units and vacuum pumps. The electron gun is either a directly heated hot cathode made from tungsten coils or an indirectly heated tungsten matrix. Unheated cathode grids, known as cold cathodes, are also used, which are coated with barium sulfate, for example. These coatings reduce the work function of the electrons such that they can be extracted simply by applying a high voltage. The extraction voltages are between 15 and 50 kV. Depending on the manufacturer, traveling waves or standing waves are used as the acceleration medium. In the traveling wave principle, the radiofrequency wave travels through the tube, taking the electrons with it; at the end of the tube the electromagnetic traveling wave is then broken up. In contrast to this, when operating with the standing wave, the electromagnetic longitudinal wave is reflected at the end of the tube such that a standing wave develops. Differences in design are mainly in the length of the accelerator tube, which is longer for traveling waves than for standing waves. On the other hand, in a traveling wave system there is a lower dependence of the acceleration power on the frequency and fewer high demands on the energy level of the electrons fired.

The tube head has the task of deflecting the pencil beam, which points in the direction of the accelerator tube and has a diameter of just a few millimeters, and of adapting it geometrically to the requirements. The necessary steps for this are:

1. Concentration, focusing, and deflection
2. Primary collimation
3. Homogenization
4. Beam monitoring (position and symmetry)
5. Dose monitoring and control of the dose rate
6. Field shaping

The components used for this are the 270° deflecting magnet, the beam-steering device, the primary collimator, the carousel with photon compensating filters and electron scattering foils, a double ionization chamber, collimator diaphragms, and a multileaf collimator. In the case of photons, the field is shaped by means of collimator diaphragms as well as a multileaf collimator (MLC), and in the case of electrons, so-called tubes are used for this purpose that collimate in a cascading fashion and at the lowest level provide the option for an individually shaped insert to be accommodated

for the generation of irregular field shapes. Diaphragm systems with variable, and if appropriate asymmetrical, apertures, which can also be operated dynamically, are used to delimit the radiation field. The limitation of such systems to rectangular-shaped fields has led to the integration of blocks that, despite having to be manufactured individually, can be used to generate virtually any desired irregular field shapes. More modern accelerator systems today also provide MLCs that – depending on the width of the leaves – make field configurations of virtually any shape possible. Depending on the manufacturer, these MLCs can also be operated dynamically. It is possible to modulate the field. This is done either by means of wedge filters or compensators, these being produced either in terms of software or hardware.

External wedge filters and also physical compensators are produced from heavy metal. The former are standard components of a linac, whereas the latter are manufactured individually for the patient. In modern linacs, they can also both be generated by dynamic operation of the collimator diaphragms and the multileaf collimator. In order to do this, the diaphragms and leaves move during the irradiation process, thereby modulating the intensity distribution within the field as desired.

35.5.4 Miniature Accelerators

A compact miniaturized version of the x-ray source first became a reality not that long ago, which makes possible a mobile system that can be transported from one operating theater to another. The source (Fig. 35.10b), which weighs a mere 2 kg, is a compact linac with an energy of 50 kV, which can be operated at voltages of 110–230 V and if necessary even with a battery of 9.6 V. The acceleration path is approx. 40 cm and dose rates of 2.8 Gy/min can be achieved at a distance of 1 m.

The structure of a system such as this is illustrated in Fig. 35.10a, b; the device is integrated in a stereotactic robot and thus permits intraoperative high-precision radiation. As a result of miniaturizing the source and the energy used, the radiation is also limited to a small volume. The investment in shelters and personal protection measures that are necessary in the case of conventional equipment (linacs, radioactive emitters) is therefore not necessary. As a result of the spatial restriction and isotropic distribution of the radiation, only the affected tissue around the tumor bed is irradiated and healthy tissue is spared. Heavy exposure of healthy tissue to radiation is, in contrast, a critical side effect of treatment

Fig. 35.10a,b Zeiss IN-TRABEAM miniature accelerator (a) with accelerator section (b) (courtesy Zeiss, Oberkochen)

with conventional methods of RT, as there are limits in radiation protection for medical reasons.

35.5.5 Brachytherapy Sources and Brachytherapy Equipment

In brachytherapy, closed radioactive sources are exclusively used, in which the radioactive substance is encased in a solid inactive shell or is embedded in it such that it is impossible for it to escape in normal use. In the field of LDR, radioactive wires are predominantly used that contain the isotope ^{192}Ir . The long treatment period of the forms of application initially used, combined with the high exposure to radiation of the staff, has led to remote-controlled afterloading processes being developed. To this end, various remote-controlled afterloading systems have been designed that work with ^{192}Ir , ^{137}Cs , or ^{60}Co as radioactive emitters. High dose rates, and as a result very short therapy times, can be achieved with the gamma emitter ^{192}Ir . The half-life of iridium is 74 d, and the mean gamma energy is 0.35 MeV. Iridium has therefore become prevalent, with the exception of a few applications. In the course of optimizing costs, however, multiple-source systems are now being offered that can be equipped with a ^{60}Co source of the same size but with approximately only a quarter of the activity. It is usually only necessary to exchange the emitter once in the first 10 years of operation, compared with 35 to 40 times in the case of conventional iridium emitters.

Figure 35.11 shows a modern multichannel afterloading device. Two different drive systems are used that drive the practically punctiform source by remote control from a vault into the applicator: steel cores

in the form of flexible shafts or solid wires. The former have a particularly high degree of flexibility and a relatively large diameter, whereas the latter are considerably less flexible, despite being very thin. The Ir source is a combined beta–gamma emitter whose gamma radiation component is used for the therapy. The encapsulated emitters are encased in one or two high-grade steel sleeves that on the one hand screen out the undesirable beta radiation fractions and on the other hand reduce the wear on the source experienced during transport through the guide tube and during movement in the applicators. An indexer system, such as the one illustrated in Fig. 35.11b, allows – depending on the manufacturer – up to 40 channels to be actuated sequentially, and thus allows spatially complex dose distributions to be generated in combination with corresponding applicator configurations. Prior to the actual radiation procedure, the radiation session is simulated

Fig. 35.11a,b Varian GammaMedPlus HDR afterloader (a) with indexer (b) (courtesy Varian Medical Systems, Palo Alto)

Fig. 35.12 ^{106}Ru applicator with a cutout for the cornea

with a nonradiative metal wire (dummy) in order to check the route in advance for any possible resistance resulting from extreme bends or connection problems in the connections to the indexer or applicator. In addition to the Ir-HDR devices, which have an initial source activity of 10 Ci, there are also PDR systems that have a very similar design.

These systems are designed for regular repeat RT and have an initial source activity of 1 Ci. Isolated systems exist for specific applications that also include the so-called Curietron. The Curietron is a remote-controlled afterloading unit for low to medium dose rates for the insertion of ^{137}Cs sources for intracavitary gynecological brachytherapy. Special systems are used for endovascular RT with afterloaders: the application of gamma rays is currently performed by means of ^{192}Ir , while different sources are used for beta rays. The clinically relevant application of beta rays is to date carried out using a ^{90}Y wire or using a $^{90}\text{Sr}/^{90}\text{Y}$ active line. The systems also differ with respect to their centering in the vessel lumen: some use a special centering balloon, while others are self-centering (radioactive

balloon catheters, radioactive stents). At this point it must be mentioned, however, that even so-called centered systems always remain eccentric with respect to what is known as the plaque, such that fluctuations in the dose in the vessel are unavoidable. In the future, the use of endovascular afterloading with gamma rays will probably include application in vessels with a relatively large diameter such as venous bypass vessels and peripheral vessels, whereas brachytherapy using beta rays will become the established treatment for coronary arteries, including in the case of in-stent restenosis.

35.5.6 Radioactive Implants

The use of radioactive implants is actually a subform of brachytherapy. Because this form of therapy has quite specific applications in the field of cancerous and vascular diseases, however, these will be discussed separately below.

Eye Applicators

In contact therapy for tumors of the eye, small dome-shaped plates are used that contain the beta emitter ruthenium (^{106}Ru) as the radionuclide. The nominal surface dose rate is 120 mGy/min and the activity varies between 10 and 50 MBq. These applicators (Fig. 35.12) allow radiation treatment of up to 100 Gy to a depth of up to 2 mm, without damaging adjacent sensitive structures.

Seeds

Permanent brachytherapy or seed implantation is a curative and at the same time particularly gentle form of RT for locally limited carcinoma of the prostate. Because it is highly effective, it is increasingly being used as an alternative to radical prostatectomy, which is the removal of the entire prostate gland. In this method, the radiation sources are introduced directly into the prostate in the form of tiny radioactive implants (seeds) with the aid of special cannulae.

Seeds of this kind are shown in Fig. 35.13a, and the situation following application is shown in Fig. 35.13b. Iodine (^{125}I) or palladium (^{103}Pd) is used as the radioactive source, which is applied to a support matrix and embedded in laser-welded titanium capsules. Significantly higher radiation doses can in this way be administered directly in the prostate, while sparing surrounding organs, than in the case of external radiation treatment. The implants remain in the prostate and emit the radiation directly into the tumor tissue, with the radiation slowly decreasing over several months (in the

Fig. 35.13a,b Iodine seed therapy of carcinoma of the prostate ((a) seeds, (b) fluoroscopic image, taken after application) (courtesy Eckert & Ziegler Bebig, Berlin)

case of ^{125}I , over about 12 months, and with ^{103}Pd over about 3 months). The prostate carcinoma is thus gradually destroyed, without the healthy tissue suffering any appreciable damage. Precise determination of the position during the application by means of ultrasound is essential when implanting seeds. Between 40 and 200 seeds with an activity of 20–80 MBq are typically implanted in a tumor. Therapy planning with the aid of ultrasound ensures that a dose of 144 Gy is achieved at the prostate surface. Two different forms of application are used: in addition to the application of individual isolated seeds, in the so-called rapid-strand technique the seeds are applied in a chain. As a result, a relatively low degree of mobility of the sources can in particular be expected.

Stents

Coronary heart disease is one of the most common causes of death in countries in the West. Healthy coronary arteries normally have a smooth, elastic wall. In patients with coronary heart disease, deposits of cholesterol, a natural component in blood, begin to collect on the vessel wall and reduce the blood flow, and a stenosis forms. Besides the option of operative therapy, known as a bypass operation, first and foremost nonoperative methods of dilating the constricted coronary vessels have become important for the treatment of vasoconstrictions. Balloon dilatation or percutaneous transluminal coronary angioplasty (PTCA) was introduced as early as 1979 as a nonoperative treatment method for coronary heart disease. Very small lesions form in the vessel wall as a result of dilating the coronary artery using a balloon. These lesions heal again without any problems. However, the cell growth induced by the healing process reduces the size of the cross section of the vessel once again (scar formation). In medicine, we then talk of a proliferation, i. e., extra

tissue growth. As a result, in around a third of cases of successfully dilated coronary arteries, a restenosis, that is, renewed vascular occlusion, appears after a short period of time. The main causes of restenoses are the contraction of the vessel wall following removal of the balloon catheter and the increased cell growth as a result of healing processes in the damaged vessel wall.

Since stents only prevent the contraction of the vessel walls following balloon dilatation, it has been necessary to look for new ways to prevent extra tissue growth. By using radioactivity, which is introduced by ion implantation into the surface of the stent, the intention is to prevent the proliferation of the tissue. Studies have shown that cell growth following balloon dilatation can be significantly reduced by treating the vessel wall with radiation. However, a certain minimum activity ($> 100 \text{ kBq}$) is necessary in order for the stent to be medically effective, i. e., for it to prevent cell growth. It has also been possible to demonstrate that a reduction in the rate of restenosis can also be achieved by temporary introduction of a strong source into the coronary vessel following stent implantation by means of HDR afterloading technology. Compared with radioactive stents, however, this method has the disadvantage that a very strong radioactive source (up to 400 MBq) must be introduced into the patient's body in order to deliver a correspondingly high dose of radiation to the vessel wall in a short space of time. The operating team and the patient are therefore subject to a higher level of radiation exposure than when using a radioactive stent whose activity is significantly lower ($< 1 \text{ MBq}$).

Figure 35.14 illustrates the effect of a radioactive coating. Following balloon dilatation with subsequent fitting of an inactive stent, the blood vessel slowly becomes constricted again (restenosis), whereas irradiation by means of a radioactive stent damages the cells of the vessel wall and as a result prevents the growth of

Fig. 35.14a,b The influence of a stent on cell growth; (a) without and (b) with radioactive coating (courtesy ETH, Zurich)

the outer wall and renewed vascular occlusion. The first radioactive stent was produced in 1992 at the Karlsruhe Research Center (Forschungszentrum Karlsruhe, FZK). This stent was produced from steel whose alloying elements had been activated.

The most important nuclides today in terms of stent coating are palladium (^{103}Pd) and phosphorus (^{32}P). The radioactive isotope of phosphorus was first introduced into the base material of the stent by means of ion implantation. This achieved a homogeneous distribution

through the entire stent and good adhesion to the base material. The effectiveness of this product was demonstrated in clinical studies. In order to supply a stent with palladium, a gold layer is first applied to the stent by means of electroplating. This acts as an adhesive layer for the palladium, which is likewise deposited on the stent by means of electroplating. The palladium is then covered with a final gold layer to prevent leaching. In this way, the undesirable low-energy X-radiation of the palladium is also absorbed.

35.6 Special Techniques and Newer Developments in Teletherapy

As a result of, among other things, the continuous progress in computerization, RT is achieving rapid development in the implementation of novel therapeutic technologies. Various approaches of this kind, based for the most part on the technology of linacs, are described below.

35.6.1 Intensity-Modulated Radiotherapy

Intensity-modulated radiotherapy (IMRT) involves modulation of the fields, which in principle can be realized technologically in two different ways: either by means of a physical compensator or with the aid of an MLC. Nowadays, field modulation is performed almost exclusively using MLCs; Fig. 35.15 shows a modern MLC with increased resolution, that is, with a reduced leaf width of 5 mm instead of the leaves 1 cm in width that are generally customary. Depending

Fig. 35.15 Multileaf collimator (courtesy Varian Medical Systems, Palo Alto)

on the manufacturer of the accelerator, there are two different application techniques: the step-and-shoot (SS) technique and the dynamic MLC technique (dMLC).

In the SS technique, different subfields – segments, as they are known – are superposed sequentially and field modulation is thus achieved, i. e., a defined MLC position is first assumed and some of the dose is then applied, followed by repetitions with other MLC layouts. In the dMLC technique, the individual leaves move during the entire period of radiation treatment. Because this technique operates using windowlike apertures that move smoothly across the field, it is also known as the sliding-window technique. A paradigm shift in the dosimetric therapy planning occurs as a result of IMRT. In previous advance planning, the planner interactively changes the field configuration until a satisfactory dose distribution has been achieved. The IMRT, in contrast, allows inverse therapy planning. Certain restrictions are defined in the planning system in the form of target doses (for the tumor) and maximum doses (for critical organs) as well as associated weighting factors. The planning computer then calculates from this the optimum field configuration in an iterative backward process.

Early on, IMRT was treated as a new silver bullet. However, experience has shown that, although the dose distribution can be significantly better adapted to the target volume with the use of this technique, the dose distribution is in the process spread over a relatively large region.

35.6.2 Breathing-Adapted Radiotherapy (BART)

Particularly in the thorax and upper abdominal region, the susceptibility of the target volume to respiratory displacement means that the regions to be treated with

radiation must be selected such that they are larger than the actual volume of the tumor in order not to jeopardize the control of the tumor. This sometimes results in very severe side effects. Newer approaches have now led to the possibility of controlling the irradiation via the breathing, i.e., only activating the therapy beam when the target volume is situated in the irradiation field. This therapeutic technique is also called gating. Various systems are used to monitor breathing that are either based on a spirometer, and therefore measure the respiratory volume, or else record the thoracic excursion using external measuring technology. Figure 35.16 shows a system that records the movements of the chest wall by means of an external marker box. Two breath coaching techniques are used to ensure that the patient's breathing is stable and constant. The patient is first of all assisted in maintaining a regular breathing cycle by means of digitized audio commands (*breathe in/breathe out*) over a loudspeaker. There are also various systems (prism glasses/mirror glasses, LCD glasses/LCD monitor) to help the patient stabilize the breathing depth and thoracic excursion using visual information (biofeedback). This is particularly important when tumors are being irradiated that move simultaneously with the thoracic wall.

35.6.3 Image-Guided Radiotherapy

Linacs have recently been developed that are equipped with dedicated image-guided radiotherapy (IGRT) systems. The fundamental concept of systems such as this is to provide imaging technology on the radiation unit that primarily serves to verify the position of the patient. In addition to a radiological mode, which allows digital x-ray images to be taken, there is a fluoroscopy mode for live fluoroscopic images and also a computed tomography mode, which allows a CT scan to be performed with a conical beam arrangement and is therefore called cone-beam CT (CBCT).

Figure 35.17 shows a system of this kind. It is composed of two different imaging systems. One uses MV therapeutic radiation and has been known for some time as portal imaging. The second system is based on traditional kV imaging and consists of an x-ray tube as well as a high-resolution detector. Systems of this type, which are all based on the most modern semiconductor technology (amorphous silicon), now have a resolution of up to 4 million pixels with detector surfaces of up to $40 \times 40 \text{ cm}^2$.

In the case of the kV imaging systems, a distinction is drawn between gantry-based systems (Fig. 35.17) and

Fig. 35.16 Varian RPM Gating breathing control system (courtesy Varian Medical Systems, Palo Alto)

room-based solutions. A room-based solution is illustrated in Fig. 35.18. Whereas the gantry-based systems rotate correspondingly as the gantry rotates and thus do not permit imaging that is simultaneous with the application of the dose, room-based systems allow ver-

Fig. 35.17 Varian Clinac iX linear accelerator with gantry-based imaging system onboard imager (courtesy Varian Medical Systems, Palo Alto)

Fig. 35.18 Brainlab ExacTrac room-based imaging system (courtesy Brainlab, Feldkirchen)

ification that, although limited to fixed solid angles, is simultaneous by means of fluoroscopy.

Either MV-based or kV-based monitoring images can be produced in order to verify the position of the patient on the basis of internal bone structures. These images can then be compared online with the existing reference images using digital superposition tools, known as matching, and this enables immediate repositioning based on a 2-D/2-D match, with the images having to be taken orthogonal to one another. The CBCT mode enables matching on the basis of three-dimensional data records that also show soft tissue structures. Such approaches are of particular advantage in the pelvis, as in this region the target volume that is to

be irradiated is not in a fixed position in relation to bony structures. The fluoroscopy mode provides a live fluoroscopic image and thus allows moving structures in the thoracic region, such as a lung tumor, to be analyzed in terms of their movements and allows any corrections to be made.

35.6.4 Dynamic Adaptive Radiotherapy

Dynamic adaptive radiotherapy (DART) is a new type of approach whose aim is to adapt the therapy continuously to the changing parameters. The previous approaches were based on the assumption that the anatomical relationships only change slightly during the course of therapy. However, IGRT has in particular demonstrated that this need not be the case. The concept of dynamically adapted radiotherapy is based on the fact that a new plan is drawn up with the help of regularly acquired CBCT data, this only being possible as an offline process with the technology currently available. This means that the therapy plan is adapted accordingly on the basis of the new data, such as the shrinkage of the target volume, for example. Among other things, this allows healthy tissue to be increasingly conserved. New avenues are now being pursued in which this approach is implemented online. This is particularly recommended when changes in the patient's anatomy or physiology have profound consequences in the case of highly conformal forms of therapy. Online adaptation presupposes fast acquisition of the CT data, followed by very extensive automatic contouring and accelerated calculation of the plan. Implementation places very high demands on the clinical workflow and, because of technical limitations that still exist and other limitations, is still in its infancy.

35.6.5 Stereotactic Radiosurgery/Radiotherapy (SRS/SRT)

High-precision radiation treatment in the cranial region places very high demands on the accuracy of the radiation field and also patient positioning. In order to achieve accuracies in the region of 1 mm or less, a special piece of therapy equipment, the so-called gamma knife, which is equipped with a stereotactic ring for fixing the cranium, was developed as early as the 1960s. Ultimately it is a cobalt unit, but with the special feature that it contains 201 sources all of which are collimated at one point. There are now more modern systems for intra- and extracranial stereotaxy that are either based on a conventional linac or consist of a compact linac

Fig. 35.19 Varian Novalis TX radiosurgery unit (courtesy Varian Medical Systems, Palo Alto)

Fig. 35.20 Accuray CyberKnife robotic radiosurgery system (courtesy Accuray, Sunnyvale)

fixed to a robotic arm. Figure 35.19 shows a system of this type that is based on a gantry-mounted linac, while Fig. 35.20 illustrates a Cyberknife. The latter is a completely new development, in which the linac is mounted on a robotic arm – in the same way as is used in the automotive industry. The two approaches have a similar level of precision, which is in the submillimeter range.

Unlike the gamma knife, these systems are equipped with additional imaging hardware that enables the position of the patient to be monitored. The imaging systems used are based on digital x-rays, except that they involve two permanently installed kV units, arranged at a defined angle with respect to one another, each consisting of an x-ray tube and a digital imaging panel. Depending on the technological concept, the imaging technology also includes cone-beam functionality.

35.6.6 Tomotherapy

In this generation of RT units, a linac is integrated in a gantry that is similar to a CT gantry. This approach is based on IMRT and IGRT. Similarly to an x-ray tube in a CT unit, the linac circles around the patient and

is also used for medical imaging in this case, with the result that the position of the tumor can be checked and the subsequent treatment can be performed without any complex recalculation and adaptation processes. The therapy itself is carried out on a cross-sectional basis, that is, in small slices – hence also the name tomography. Figure 35.21 shows the two systems currently in clinical use. Besides the Hi-ART system from the American manufacturer Tomotherapy, which was developed originally, there is now also a version by Mitsubishi/Brainlab that enables noncoplanar therapy techniques by inclination of the gantry and table. The latter version also contains a kV imaging system that is used in place of MV imaging (as in the Tomotherapy system). This more recent approach also allows online verification by means of fluoroscopy during the therapy.

Due to the highly conformal distribution of the radiation dose achieved with this technology, a further reduction in the side effects is expected, which means destruction of the tumor while providing even better conservation of the healthy tissue surrounding the tumor and of the organs at risk. However, many questions on this front still remain unanswered, as tomotherapy is still in the early stages of its development.

35.6.7 Intensity-Modulated Arc Therapy

Intensity-modulated arc therapy (IMAT) combines traditional arc therapy with intensity modulation. This means not only field aperture correction – also known as conformal arc therapy – but also true field modulation.

This combined technology places extraordinarily high demands on the linac control system since the dynamic leaf movements of the MLC have to be coordinated, i.e., synchronized, with the gantry rotation, and the control of the dose rate also has to be adjusted to it. Clinical introduction has since been successfully realized in the case of one manufacturer. Figure 35.22

Fig. 35.21 (a) Tomotherapy Hi-Art tomotherapy system and (b) Mitsubishi MHI TM 2000/Brainlab Vero (courtesy: a) Tomotherapy, Madison; b) Mitsubishi Heavy Industries, Tokyo and Brainlab, Feldkirchen)

Fig. 35.22 Varian RapidARC intensity-modulated arc therapy (courtesy Varian Medical Systems, Palo Alto)

shows a schematic representation of the course of therapy of this kind. As a result of this combined application form that allows even better optimized, highly conforming dose distribution, just as with the tomotherapy already discussed, better chances of recovery are expected with fewer side effects. In addition, one chief advantage is the faster application of the dose. On the one hand, this leads to a higher patient throughput, and on the other hand the therapy dose can be applied immediately and quickly following image verification, which means that movements by the patient or changes in the internal body topography (e.g., movement of gas in the intestine) during the radiation treatment are less likely.

35.6.8 Current Developments in Linear Accelerator Technology

Forms of therapy with intensity modulation of the treatment areas have now virtually become standard, and

until now, in the case of linacs, the pencil beam with a diameter of only a few millimeters has been expanded and modified by means of compensating filters such that a symmetrical beam geometry is obtained up to a field size of 40 cm × 40 cm. As a result, this beam profile that was complex to produce was then remodulated again by intensity modulation by means of an MLC in order to obtain the desired intensity distribution. A new approach is now to dispense with the compensating filters entirely, especially since compensating filters significantly lower the dose rates and it would therefore be possible to significantly shorten the duration of the therapy using systems without compensating filters. A new linac of this type is illustrated in Fig. 35.23. This system allows irradiation of intensity-modulated fields in an assembly that does not have compensating filters.

A further step in the direction of a comprehensively dynamic dose application that also makes it possible to compensate for the movements of target areas and patients makes it necessary to be able to dynamically adjust not only the MLC and the gantry rotation but also other relevant linac parameters, such as the position and rotation of the collimator, during the radiation process. This is now possible for the first time with the new system shown in Fig. 35.23.

Considering the comprehensive dynamically operated parameters, it is all the more important to have appropriate verification imaging available during the radiation process. Where there is a combination of respiratory triggering and IMAT, because of the complexity it makes sense to provide monitoring by means of fluoroscopy during the radiation process. An approach of this kind can be implemented for the first time using the linac depicted in Fig. 35.23.

This new development in the field of linac technology offers various functions, although the potential is still to undergo clinical testing. In particular, the ques-

Fig. 35.23 (a) Linear accelerator Varian True-Beam, (b) with beam generation and beam guiding components (courtesy Varian Medical Systems, Palo Alto)

tion remains unanswered regarding the extent to which the increase in the dose rates by up to four times compared with the dose rates of the systems previously

used has radiobiological consequences. Relevant clinical studies are necessary to clarify these and other aspects.

36. Mechanical Circulatory Support Systems

Mechanical C

Roland Hetzer, Ewald Hennig

Part D | 36

After many years of intensive interdisciplinary research and development, mechanical pump systems to support or replace the failing heart (Ventricular Assist Devices/VAD and the Total Artificial Heart/TAH) are firmly established in the treatment of end-stage heart failure.

Initially, the systems followed the pulsatile principle, i. e. pumps with valves imitated the function of the native heart. The later developed continuous-flow rotary blood pumps have the advantages of being considerably smaller and noiseless and working without valves. They have become the current standard in mechanical circulatory support (MCS).

The current state of technology and medical expertise allows the application of MCS systems with acceptable risks and quality of life. With small, mobile, implantable electromechanical blood pumps patients can return home and take part in *normal* life.

Today, MCS is considered a definitive, permanent therapy when contraindications rule out heart transplantation and in view of the growing shortage of donor organs. Because of their unlimited availability the systems will play a more important role in future medicine, whereby further improvements to the systems are required.

Today, after years of intensive interdisciplinary research and development and initial studies on application in humans, mechanical pump systems for supporting or

replacing the failing heart (ventricular assist devices (VAD) and the total artificial heart (TAH)) are firmly established in the treatment of end-stage heart failure.

36.1 Introduction – History

In 1951, Dennis performed the first open heart operation on a human being using a self-built heart–lung machine, followed in 1953 by Gibbon, who used extracorporeal circulation to correct an atrial septal defect (ASD) in open surgery. The machine was built by IBM engineers. This led to the development of pumps and gas exchangers (oxygenators) that were able to take over the function of the heart and lungs for a limited period. The application of machines such as the heart–lung machine (HLM) provided the basis for today’s open heart surgery.

In 1957, pioneers Kolff and Akutzu implanted the first total artificial heart (TAH) in a dog. The animal survived for 90 min. The first ventricular assist device (VAD) was implanted in 1963 by Liotta and Crawford, followed in 1966 by the first successful clinical application of a VAD to support the heart until it recovered (bridge to recovery, BTR) by Liotta and DeBakey.

After the first heart transplant (HTX) was performed successfully in 1967 by *Barnard* in Cape Town, the artificial heart no longer seemed so important [36.1]. However, in 1969, *Cooley* implanted an artificial heart designed by *Liotta* for human application to bridge a patient to transplantation (BTT), thereby opening up the new field of VADs and TAHs [36.2]. The first clinical application of a pneumatically driven TAH as a permanent implant was accomplished in 1982 by *Jarvik* and *DeVries* with a device they had developed further at the Institute for Artificial Organs in Salt Lake City (Kolff) [36.3].

However, media coverage of clinical courses that were fraught with complications had a negative impact on public opinion; it seemed that the TAH was not going to yield positive results in the near future.

In Germany, an artificial heart program led by *Bücherl* in cooperation with AEG, Siemens, MBB, and Hoechst was set up in Berlin in 1971 [36.4]. A range of different assist devices and heart replacement systems were developed, one of which is still in clinical use today (BerlinHeart EXCOR). The first clinical application of this extracorporeal pneumatic blood pump (*Bücherl* VAD) as a BTR in a patient after heart surgery took place in Berlin in 1985.

The artificial heart designed by *Bücherl* and *Hennig* (Berlin TAH) was implanted for the first time as a BTT in 1986. The newly established *Deutsches Herzzentrum Berlin* (DHZB, German Heart Institute Berlin) continued the program with the implantation of TAHs in 1987, and the application of cardiac support systems (ventricular assist devices) in 1988 [36.5].

With the successful, temporary application of VADs as a BTT these systems met with growing acceptance and a new era opened up in which it was possible to gain a wealth of experience in terms of indications, control of complications, technical advancements, and long-term care. This experience ultimately helped to make permanent application – the original goal – a clinical reality.

Following on from these first experiences with adults, the requirement for a system for children became apparent. Miniaturized devices that are also suited to the needs of small children and infants had been under development since the early 1990s [36.6].

Initially, these systems followed the pulsatile principle, i. e., pumps with valves imitated the function of the native heart; this dictated the size, weight, noise generation, and high energy consumption of these devices. The later developed continuous-flow rotary blood pumps, which are considerably smaller, work without valves, and are noiseless, are without these drawbacks. The first pump of this type, the *MicroMed* system developed by *DeBakey*, was implanted in a patient at the DHZB by *Hetzer* on 13 November 1998 [36.7]. Since it was shown that such a different blood flow is well-tolerated by the body, the rotary blood pump has developed to become the current standard in mechanical circulatory support.

Nowadays, left ventricular assist devices (LVADs) can provide patients with an acceptable quality of life over several years. With small, mobile, externally driven or implantable electromechanical LVADs, patients can be allowed to return home and take part in *normal* life. Some have been able to return to work [36.8]. Thus, today, it is legitimate to consider mechanical circulatory support (MCS) as a definitive, permanent therapy when contraindications rule out heart transplantation. In view of the growing shortage of donor organs, more and more often MCS systems are the alternative to heart transplantation. Because of their unlimited avail-

ability they will play a more important role in future medicine, whereby further improvements to the systems are required.

Another important aspect stems from the observation that long-term support of the heart in cases of myocarditis, after cardiac surgery, and also in cases of chronic cardiomyopathy resulted in complete recovery, allowing the pump to be explanted (bridge to recovery, BTR) [36.9,10]. This most fascinating route to recovery came about without detailed knowledge of the mechanisms of myocardial recovery or its predictability, and should be the subject of intensive research.

Chronic heart failure resulting from coronary artery disease is the fastest growing category of heart disease. The challenge facing future heart surgeons is to help these patients with a combination of organ-preserving surgery and, where appropriate, temporary or permanent mechanical cardiac support. So, in the future, MCS is likely to become a routine therapy, particularly in

older patients, comparable to the current situation with implantable pacemakers and defibrillators.

Of course, the increased use of VADs and TAHs raises a number of ethical, legislative, and regulatory questions; economic aspects must also be discussed. However, these cannot be covered in the following short composition. Here, proven MCS systems are described, with an emphasis on the systems available today (2010).

Based on the experience of the DHZB, the institution with the widest range of systems worldwide and the highest number of patients treated with medium- and long-term MCS systems, indications and specific concomitant therapies are presented [36.11].

It is not possible to give a detailed description of the numerous systems here; links are provided to the manufacturers' websites, which can also be used to follow the steady progress in the refinement of implants and the development of new concepts and to obtain the current application statistics.

36.2 Indications for Application of MCSS

In 2009 a total of 120 000 heart operations were performed in Germany. Over 65 000 coronary artery bypass surgeries and roughly 18 000 heart valve operations were carried out in 84 cardiac surgery centers. Around 95 000 of these heart operations were performed using the heart–lung machine.

In some cases, the patient cannot be taken off the heart–lung machine and an MCSS is applied as an emergency measure. Normally, patients are temporarily connected to the system, i. e., for a number of days or weeks, until their own heart is able to function efficiently.

A heart transplant (HTX) is the final, life-saving option available to patients with severe heart disease. Given the current indication criteria, about 1000 donor hearts are needed every year in Germany. In 2009, however, fewer than 350 hearts were transplanted. The discrepancy between the number of patients affected and the number of donor organs available is glaringly obvious. Patients who are on the waiting list for an HTX might go into life-threatening heart failure at any time. Application of an MCSS offers the last possible therapy option.

A range of different devices have been implanted at the *Deutsches Herzzentrum Berlin* under the leadership of Roland Hetzer to bridge the waiting time to possible recovery of the heart (BTR) or, if a suitable donor organ is available, to bridge the waiting time to a po-

tential subsequent transplantation (BTT). Since 2000, these devices have also been implanted for permanent support, known as *destination therapy* (DT), in patients who cannot or do not wish to receive a heart transplant.

Table 36.1 shows the range of devices used successively at the DHZB since 1988, with the corresponding number of implantations performed and the maximum observation period. Thirteen different systems have been implanted in a total of 1355 patients (as of 30 September 2010) with maximum therapy durations of more than 5 years. Over the resulting accumulated period of more than 590 patient years, the DHZB has gained the widest range of experience worldwide at a single institution.

Not included in this list is the number of patients who have received a *short-term device* as an emergency measure to prevent acute cardiogenic shock, in order to gain time before making a final decision (bridge to decision, BTD). These short-term devices include intra-aortic balloon pumps, catheter turbines, and certain types of extracorporeal circulatory support (ECMO, etc.).

Because the existing NYHA (New York Heart Association) classification of heart failure does not discriminate between different levels of cardiogenic shock, the US Assist Device Registry INTERMACS created a new system for the differentiated categorization of patients.

Table 36.1 Long-term circulatory support devices used at the DHZB

System	Date of first implant	No. of patients	Max. duration days / years

* No longer used at the DHZB

The INTERMACS levels are defined as follows:

1. Critical cardiogenic shock
2. Progressive decline
3. Stable but inotrope-dependent
4. Recurrent advanced heart failure
5. Exertion intolerant
6. Exertion limited
7. Recompensated heart failure.

Levels 1–4 correspond to NYHA Class IV. Currently, we do not consider INTERMACS levels 5–7 to be indications for MCS. Based on earlier experiences, different system configurations are indicated to achieve stabilization of the circulatory system.

Deep cardiogenic shock (level 1) always requires a biventricular assist device (BVAD) or a TAH. In primary left ventricular failure (levels 2, 3, 4) implantation of a left ventricular assist device (LVAD) may be sufficient. In cases of imminent right ventricular failure the additional support of the right ventricle is indicated, at least temporarily, more recently with the application of an implantable BVAD.

Today, the risk of right ventricular failure after LVAD implantation can be very reliably predicted by echocardiographic criteria. Potential contraindications include the presence of septic conditions, brain damage, and advanced malignancies, and the acknowledged impossibility of rehabilitation.

36.2.1 Bridge to Transplant

Patients listed for a heart transplant are at risk of developing unmanageable heart failure as the waiting time progresses, and they then require an MCSS to survive long enough to be able to receive the transplant. In the same way, patients who have received an MCS system as a result of acute heart failure may be listed for a transplant if they satisfy the criteria for an HTX.

Impaired organ function caused by heart failure prior to MCSS can often be relieved by stabilizing the patient's circulatory system. Congestion-induced pulmonary dysfunction and liver or kidney failure caused by the lack of perfusion are then no longer contraindications for subsequent HTX. The overall condition of the patient and, therefore, also the initial situation for a now elective heart transplantation is greatly improved.

36.2.2 Bridge to Recovery

In certain types of heart disease that lead to heart failure, such as some forms of myocarditis or in a small number of patients with dilative cardiomyopathy, recovery of the myocardial function can be achieved with temporary cardiac support using MCS over a period of days, weeks, or months. Afterwards the assist device can be explanted.

Even in cases of heart failure after cardiac surgery, the critical situation can be managed initially by effectively supporting the left ventricle, which is most often affected, with an LVAD.

36.2.3 Bridge to Bridge = Bridge to Decision

When cardiogenic shock leads to impaired organ function, particularly of the brain, and it is uncertain whether recovery is possible, an MCS system designed for short-term application should be used, which is generally less invasive and easier to connect. Stabilization of the circulatory system wins extra time for further diagnosis and potential improvement of the situation. If the organism recovers, then the switch can be made to a longer term or even permanent system.

36.3 Classification of MCSS

36.3.1 Physical Pumping Principles and Concepts

Blood pumps can function according to different hydro-mechanical principles, as pulsatile displacement pumps or as rotary pumps with continuous axial or radial flow. The pumps themselves can be located outside the body (extracorporeal) or inside the body (intracorporeal). All systems are dependent on external sources of power. In the case of implanted pumps, power is delivered via percutaneous leads. It is possible to supply power through the undamaged skin by induction with an external and an implanted coil.

TAHs are implanted to replace the explanted heart; the driving system can remain outside the body or it can be placed inside the thorax, forming a unit with the pump.

Depending on the objective of the therapy, systems can be designed for short-term (1–30 days), medium-term (up to 6 months), or long-term (5 years or more) application. In the case of long-term systems, the aim is to accommodate all the required system components such as the pumping chamber, activator (motor), power transmission and power storage, the control and monitoring unit and, where necessary, the volume-equalizing chamber inside the body. This aim has not yet been realized with the systems available today.

36.2.4 Permanent Support or Replacement of the Cardiac Pump Function (Destination Therapy)

The goal was to develop systems for permanent application, to either support or replace the heart. After extensive experience with so-called temporary MCS systems with application times of several years, a number of systems available today allow destination therapy. Patients who cannot receive a heart transplant due to known contraindications or who themselves refuse such a transplant can be offered life-prolonging support with extracorporeal or implantable VADs or with an older TAH model, with a reasonable outlook. With complete aftercare and regular monitoring of the device, including the replacement of wear and tear components, device application times of several years are called for and have, in the meantime, been realized.

36.3.2 Pulsatile Systems

Like piston pumps, blood pumps can be designed as displacement pumps with elastic blood chambers, activated by pneumatic, hydraulic, or mechanical compression devices, which are usually powered by electric motors. A disadvantage of this concept is that volume compensation must take place for every volume of blood moved, either through a connection to the free atmosphere (vented system) or to a volume-equalizing chamber implanted in the body. These pumps can generate a flow of blood that is similar to the natural blood flow, with periods of relaxation (filling, diastole) and ejection (emptying, systole).

To be able to direct the bloodstream, pulsatile pumps require valves that are similar to heart valves. Stresses placed on the numerous components are problematic with regard to the individual system's long-term fatigue resistance.

36.3.3 Nonpulsatile Systems – Rotary Blood Pumps

The first rotary blood pump used in the clinical setting was designed around 1982 by Wampler at Nimbus Corporation. This catheter-mounted, intra-aortic axial flow pump (hemopump) was about the size of an eraser on an ordinary pencil. It was inserted through a small incision in the femoral or external iliac artery, advanced

to the aorta, and positioned across the aortic valve. An Archimedes screw rotated 17 000 to 25 000 times per minute, drawing blood from the left ventricle and ejecting it into the descending aorta. This system now belongs to history [36.12].

Rotary blood pumps create a continuous flow and do not require valves. They are smaller than displacement pumps, making them easier to implant, do not require volume compensation, and normally only have one moving component, the rotor, with low mechanical load. As a result, the long-term operational safety of these pumps is significantly higher than that of pulsatile pumps. Contact-free positioning of the rotor by magnetic bearings or a combination of hydrodynamic and magnetic bearings means that there is no abrasion, so that, in theory, the life of the system is unlimited.

A distinction is made between axial and radial pumps, depending on the direction of the flow of blood

at the rotor. The different hydrodynamic designs determine speed range, positioning possibilities, and the possible outlet orientation (180° for axial, 90° for radial pumps), as well as the characteristics of the pump performance curve.

The electric motor for operating the pump is integrated. The rotor is usually used as a direct impeller, which transmits the required force to the blood, allowing a flow of 10 l/min under normal arterial afterload.

The rotating magnetic field generated in the stator, i. e., the coil assembly located in the pump housing can – depending on the design – produce speeds of over 10 000 rpm.

Initial concerns over the possible adverse effects of continuous, rather than normal, pulsatile perfusion on organ function have since been dispelled by clinical experience with thousands of implantations of this type of system and application times of up to several years.

36.4 Today's Systems

Table 36.2 gives an overview of the MCSS approved for clinical application in Europe and the United States in 2010.

A number of clinically proven systems not included in this list have been withdrawn from the market by the manufacturers either for economic or for technical reasons (Arrow LionHeart, Arrow CorAide, Ventracor VentrAssist).

The technical construction, flow dynamics, and the composition of the materials used for these variously activated electropneumatic, electromechanical, electromagnetic, and electrohydraulic systems are so complex that a detailed description is beyond the scope of this chapter [36.13].

Once again, detailed information can be obtained from the manufacturers' websites. Links to these websites are included in the system descriptions below. Only the functional principles are summarized here.

36.4.1 Pulsatile Systems

Extracorporeal Pulsatile MCSS for Short-Term Application

These relatively inexpensive and easily connectable systems are used in cases of acute failure of one or both ventricles, when the patient goes into cardiogenic shock, and when there is a chance of recovery if the heart is supported. If the patient's condition fails to improve, these systems can be replaced by longer term,

implantable devices. Up to now, extracorporeal systems are the therapy of choice for biventricular heart failure.

Abiomed BVS 5000 VAD. BVS 5000 manufactured by the company Abiomed (www.abiomed.com) is a pneumatically driven pulsatile pump used in intensive care to support the left, the right, or both ventricles. This device has been on the market since 1993 and has been used in over 6000 cases. It is primarily used for BTR therapy.

More recently, there has been a sharp drop in the number of applications of this 17-year old system, as its efficiency is limited by inflow problems caused by the required length of the tube lines and the fact that it has to compete with newer systems with better hemodynamic characteristics.

Abiomed AB 5000 VAD. AB 5000 is a smaller, pneumatically driven membrane pump. It can be used to provide left, right, or biventricular support. The recently developed mobile driving unit facilitates patient transport and also allows a certain degree of mobility. With a chamber volume of 80 ml, it can pump 6 l/min. The period of application is limited to 30 days.

Extracorporeal Pulsatile MCSS for Long-Term Application

The BerlinHeart EXCOR VAD system. EXCOR is a pneumatic extracorporeal system produced by BerlinHeart GmbH (www.berlinheart.de). With its wide range of

pumps offering stroke volumes of between 10 and 80 ml, apical, atrial, and arterial cannulas in numerous shapes and sizes, and stationary as well as small, mobile electropneumatic driving units, this system is unique in that it can be adapted to the needs of each individual patient, from newborns and infants right through to adults.

The blood pump consists of a transparent polyurethane housing, the interior of which is divided into a blood chamber and an air chamber by a highly flexible, triple-layer membrane. The membrane on the blood side is seamlessly integrated into the housing to prevent the adhesion of blood clots. All blood contact surfaces are coated with heparin (CARMEDA coating, Carmeda AB, Uplands Väsby, Sweden).

The polished titanium connectors fixate the Sorin tilting disc valve; the air chamber is equipped with a Delrin connector for the PVC air driving tube. Polyurethane tricuspid valves are used for the EXCOR pediatric pumps as their dynamic characteristics are better suited to small stroke volumes.

The pump can be connected to one or both ventricles (Fig. 36.1). Silicone cannulas that connect at the apex of the left ventricle or at the left or right atrium send

the blood from the heart to the pump from where it is directed back to the ascending aorta or the pulmonary artery through arterial silicone cannulas.

The IKUS stationary driving unit is used for large blood pumps (50–80 ml stroke volume) and for the EXCOR pediatric (10–30 ml stroke volume) system for children. In biventricular operating mode the pumps can be driven separately, with selectable synchronous pul-

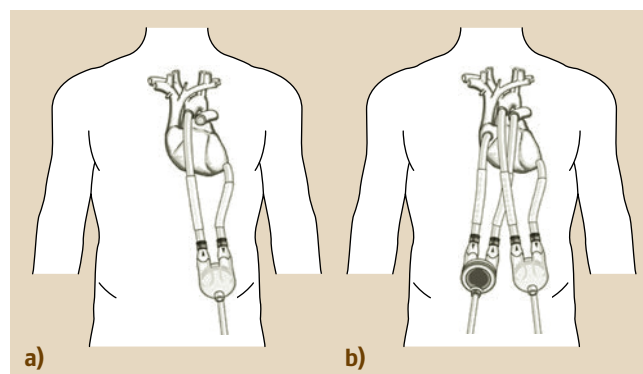

Fig. 36.1a,b Berlin Heart EXCOR as LVAD and BVAD with cannulation. (a) Apical – aortic; (b) atrial – pulmonary artery

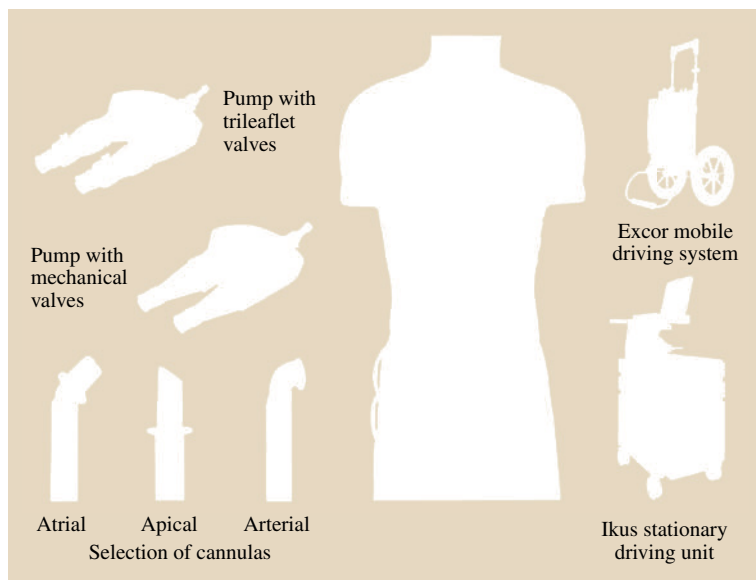

Fig. 36.2 EXCOR system overview

sation or counterpulsation, and the frequencies can be controlled independently.

For blood pumps of 50 ml and more the small driving unit EXCOR Mobile can be used, allowing the patient full freedom of movement without having to rely on an external power supply.

Figure 36.2 gives an overview of the BerlinHeart EXCOR system components.

Thoratec PVAD. The pump of the paracorporeal ventricular assist device (PVAD/Thoratec Corp., www.thoratec.com) consists of a rigid plastic housing containing a flexible, polyurethane blood sac, which is filled and emptied of blood by a compressed air pulse. Two Delrin tilting disc heart valves direct the blood flow. A stroke volume of 65 ml achieves a flow rate of 7 l/min. Polyurethane cannulas that can be connected to the left ventricular apex or to the left atrium direct the blood to the pump from where it is forced back into the ascending aorta through an arterial prosthesis. To provide right ventricle support, the right atrium and the pulmonary artery are cannulated.

Instead of a large stationary driving system, mobile patients can be fitted with a miniaturized unit with which they can be discharged.

Medos VAD. Like the EXCOR device, the Medos system (www.medos-ag.com) is a VAD for pulsatile cardiac support in children and adults. The pumps are available in a range of different sizes and, as is the case for all

other systems, are approved for single use only. This system is also driven by electropneumatic units with battery or mains supply.

Implantable Pulsatile MCSS for Long-Term Application

Implantable long-term MCSS are designed for BTR and BTT therapy but based on experiences gained to date in exceptional cases they may also be selected for DT therapy.

Thoratec P-IVAD. The original Thoratec PVAD was modified to produce an implantable model. The extracorporeal PVAD pumps described above were encased in titanium, so now they can be implanted inside the body. As a result, the length of the blood-transporting cannulas is reduced, and the number of transcutaneous injuries to the surface of the body is halved because only the thinner driving line has to be introduced for each pump. The risk of infection at these sites is lowered. Like the earlier PVAD, P-IVAD can be used as an LVAD, RVAD, or BVAD (Fig. 36.3).

Thoratec HeartMate XVE. The HeartMate XVE is an electromotorically driven LVAD displacement pump. Inside a titanium case, an elastic polyurethane (PU) membrane is moved by an electric motor and a cam-and-follower gearing in the direction of its longitudinal axis by a circular pusher plate, emptying the rigid blood chamber. Filling of the chamber takes place passively

due to the pressure of the inflowing blood. Two bio-prosthetic heart valves ensure the unidirectional flow of blood. The pump is operated by an external controller, which supplies power to the electric motor of the implanted pump through a percutaneous driveline. The volume of blood displaced by each pulse must be compensated. This is achieved through a tube connected from the inside of the pump of the driving chamber to the outside along the electric driveline (vent) [36.14].

The pump can be implanted into a pre-peritoneal pocket in the left upper abdominal wall or it can be implanted intra-abdominally (Fig. 36.4). In 2003, because of the positive results of long-term clinical trials, this system became the first LVAD to be approved by the FDA as DT in the United States.

WorldHeart Novacor LVAS. WorldHeart's Novacor LVAS is an implantable, electromagnetically driven LVAD [36.15] (www.worldheart.com).

A polyurethane blood sac with a seamless interior is symmetrically compressed by two pusher plates to propel the blood into the aortic vascular graft, and then released again to fill passively via the apical inflow cannula.

The pump is implanted through the peritoneum into the left upper abdominal wall and, like the HeartMate XVE, is connected to the external components by a percutaneous lead with an integrated venting tube (Fig. 36.5).

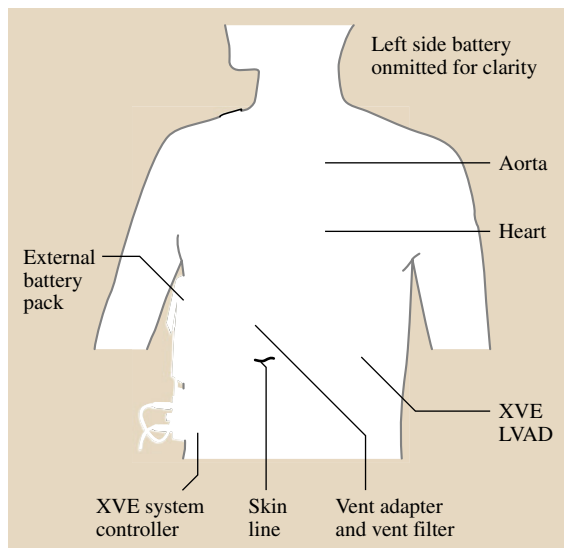

Fig. 36.4 Thoratec HeartMate XVE with external components

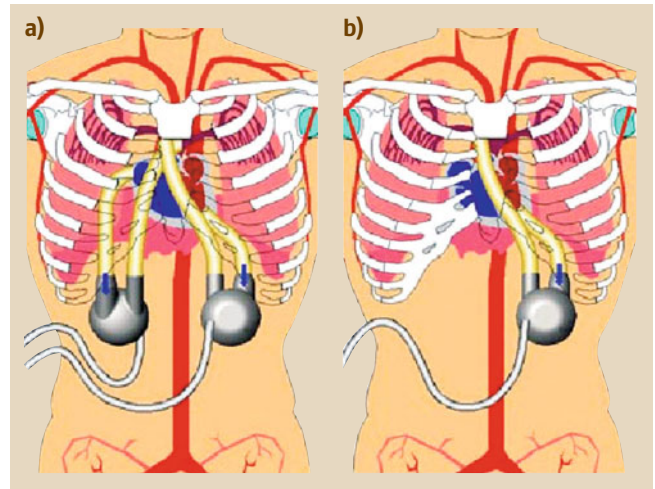

Fig. 36.3a,b P-IVAD. Position of the implantable pneumatic blood pump for biventricular (a) or univentricular (b) support

This system can automatically adjust its pumping rate to complement the residual function of the native heart, thus adapting to the respective circulatory requirement.

Implantable Pulsatile TAH for Temporary or Permanent Application

TAHs, or artificial ventricles for orthotopic cardiac replacement, occupy a special position among the implantable systems in clinical use today. For implantation of these devices the native heart is removed, as for

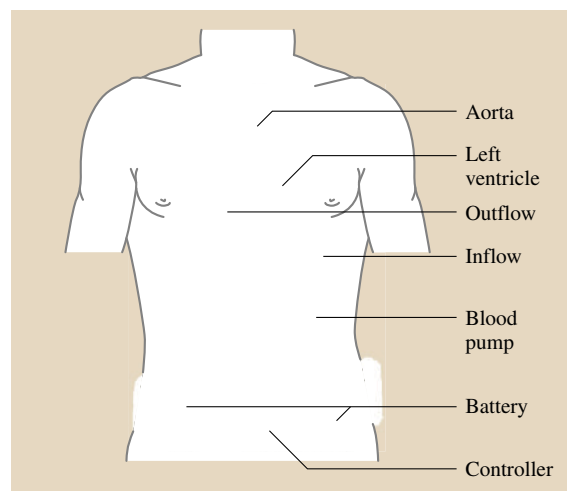

Fig. 36.5 WorldHeart Novacor LVAS with external components

a heart transplant, and replaced with two separate pumps or one dual-chamber mechanical blood pump connected to the atria and the great vessels (aorta, pulmonary artery).

SynCardia Systems, Inc. CardioWest Temporary Total Artificial Heart (TAH-t). This pneumatically driven TAH is a further development of the JARVIK 7 TAH first applied in the clinical setting in 1982. Worldwide this is the only FDA-approved and CE-certified arti-

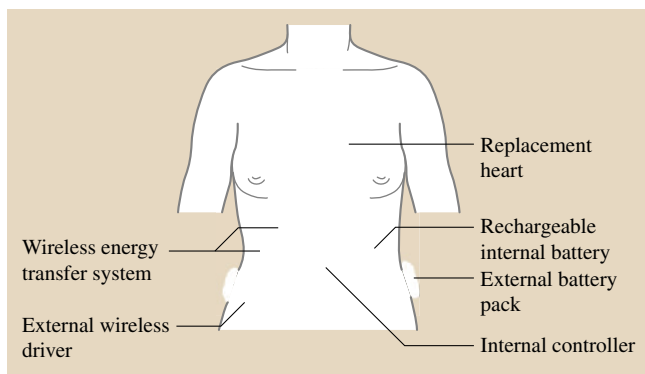

Fig. 36.7 Abiomed AbioCor. Totally implantable TAH with TET

ficial heart for temporary implantation as a bridge to transplantation (BTT) today (www.syncardia.com).

The displacement diaphragm pumps, which are pneumatically activated by an extracorporeal power console, are similar in structure to the EXCOR design and generate a flow rate of up to 9.5 l/min against normal circulatory afterloads (Fig. 36.6). The electropneumatic drive system is newly developed. The small mobile unit replaces the previous mobile driving system EXCOR TAH-t. Unfortunately, the pumps are so bulky that they only fit inside the thorax of relatively large patients. A smaller version is currently being developed and tested in animal studies.

Abiomed, AbioCor Implantable Replacement Heart. The electro-hydraulically driven Abiomed TAH is the first fully implantable TAH [36.16] (Fig. 36.7).

All components such as pumping chambers, drivers, the volume compensator, control unit, battery pack, and transcutaneous energy transmission systems (TETs) are implanted inside the body. This reduces the risk of infection since the skin does not have to be penetrated for the leads and venting tubes to be connected. However, the safety requirements for the many highly technical and sensitive components of this life-sustaining system are very stringent. After a preliminary clinical study was conducted in 2001, with questionable results, the first commercial application was attempted in 2009; the patient died one month later. Since then, no further implantations have been reported.

36.4.2 Nonpulsatile Systems (Axial and Centrifugal Rotary Blood Pumps)

Extracorporeal Systems for Short-Term Application

CardiacAssist, Inc. TandemHeart pVAD. The TandemHeart pVAD (CardiacAssist, Inc.; Pittsburgh, PA, www.cardiacassist.com) is a percutaneous LVAD with continuous flow for temporary ventricle support.

It is used to treat patients in cardiogenic shock as a BTD therapy. The components consist of a small blood pump driven via magnetic coupling by an electric motor. The rotor is hydrodynamically suspended. The blood is pumped from the left atrium through a transseptal venous cannula and directed back through the arterial catheter (Fig. 36.8). The hydrodynamically suspended rotor spins at a rate of 3000–7500 rpm and can deliver a continuous flow of up to 4.0 l/min.

Fig. 36.8 CardiacAssist PTVA (TandemHeart). Cannulation of the extracorporeal pump

Levitronix CentriMag. The Levitronix CentriMag (Levitronix LLC; Waltham, Mass., www.levitronix.net) is a VAD with a magnetically suspended impeller that, like the TandemHeart, is driven by magnetic coupling. It can be connected directly to the cannulation of the heart–lung machine, and with the appropriate connection technology can be applied as an LVAD, RVAD, BVAD, or in a set for extracorporeal membrane oxygenation. At 5500 rpm it can achieve a flow rate of up to 9.0 l/min, depending on the type of cannulation used. The system is also used as a temporary RVAD, in addition to an implanted LVAD, in cases of acute right ventricular failure or for left–right or biventricular support as a BTB (BTD).

Abiomed Impella. Impella catheter pumps support the heart with a flow rate of up to 5.5 l/min. The pumps can be connected directly in a minimally invasive procedure by insertion via a blood vessel or after thoracotomy, e.g., during cardiac surgery. With the Impella mobile console patients can be moved around the hospital or transported to another institution.

The LP2.5 systems, which were designed primarily for application by cardiologists, carry an electrically driven microaxial pump with a pigtail extension at the tip of a catheter and are inserted into the heart through the femoral artery via the aortic valve. They take the

blood from there and pump it into the aorta. With a flow rate of 2.5 l/min they stabilize the heart function for up to 2 days. The larger version LP5.0 delivers a flow rate of up to 5.5 l/min for up to 5 days.

The modification LD (left direct) is implanted by cardiac surgery. It supports the left ventricle with a maximum flow rate of 5 l/min. The blood is pumped directly into the aorta through a vascular prosthesis (left ventricle and pump in sequence). The pump weighs only 17 g.

The RD (right direct) works in a similar manner. To support the right ventricle the blood is conveyed from the right atrium into the pulmonary artery (right ventricle and pump in parallel). Both systems can be applied for up to 10 days.

Implantable Long-Term MCSS with Axial Flow

The axial pumps clinically available today are produced by various manufacturers and have similar system configurations. The pump is implanted into the thorax, while the electronic control unit, the power supply for stationary and mobile operation, the battery charger, and the monitor for setting the operating parameters (rotational speed, alarm limits) and surveillance of the function remain outside the body. A percutaneous lead connects the pump to the mobile external components; a Dacron velour cover fixes the lead in the tissue and protects the wound from infection. The pump itself is a small electric motor with hermetically encapsulated coils; the rotor (impeller) is located in a tight blood-conducting cylinder.

In systems with a mechanically suspended impeller, inflow and outflow stators inside the cylinder support the bearings. The rotor contains one or more small permanent magnets, so that it can be set in rotation by the rotating electromagnetic field of the coil. As it is the only moving component of the system, these constructions can provide high functional reliability and long-term durability.

There are, however, significant differences in the individual systems with respect to the following components:

- Anatomic design and the conduits to the heart and great vessels
- Finish of the titanium blood contact surfaces
- Fluid dynamic shape of the rotor
- Rotor suspension
- Design of the percutaneous driveline
- Performance diagrams (rotary speed – flow – differential pressure)
- Measurement and control technology

Fig. 36.9 Thoratec HeartMate II LVAS. Schematic of the interposition of the pump between left apex and aortic vascular graft

Fig. 36.10 Schematic of an implanted Berlin Heart INCOR system with external components

- Documentation of the operational parameters and their evaluation.

MicroMed Technology HeartAssist 5, Formerly DeBakey VAD. The HeartAssist 5, formerly MicroMed (www.micromedtech.com) DeBakey VAD, is a small, electrically driven implantable turbine, which in patients with terminal heart failure can pump up to

10 l/min at a rate of 12 000 rpm from the left ventricle into the ascending aorta. The rotor is held on both sides by ceramic bearings.

As the only rotary LVAD, blood flow is measured here directly using a Transsonic ultrasound flow probe that ensures reliable system monitoring.

An elaborate documentation and evaluation system allows early detection of imminent malfunctions and provides a subsequent detailed analysis.

Thoratec HeartMate II LVAS. The HeartMate II is similarly constructed, but it uses a different cannulation technology for the left ventricular apex. In contrast to the rigid, curved inflow cannula of the MicroMed system, the HM II apex connector is connected to the pump inflow by a flexible vascular graft. This has proven to be beneficial for pump positioning and for the ingrowth of the connector located in the myocardium (Fig. 36.9).

As this system is a little bigger than the HeartAssist 5, during implantation a pocket must be prepared in the abdominal wall to accommodate the pump housing. The rotor is held by two jewel bearings. With speeds between 8000 and 15 000 rpm the system can achieve flow rates of up to 10 l/min

Berlin Heart INCOR. A special feature of the BerlinHeart INCOR LVAD (Fig. 36.10) is the contact-free suspension of the turbine. A combination of permanent magnets in the stators and in the rotor, and electromagnets and position sensors in the stators make it possible to actively control the position of the rotor. This means that the bearings are free of wear and tear.

Position sensors allow the calculation of many of the operating parameters including the pulsating differential pressures (in front of and behind the rotor) according to the residual cardiac activity, the pulsating momentary flow and the filling state of the heart. As a result, valuable information on the circulatory status of the patient can be gained, which can contribute to therapy management.

Possible malfunctions such as flow obstructions or the formation of thrombotic deposits in the pump can be detected at an early stage and appropriate countermeasures can be initiated.

All blood contact surfaces of the pump are coated with heparin (the CARMEDA method).

Jarvik Heart, Inc., Jarvik 2000 Flow Maker. This LVAD (www.jarvikheart.com) differs significantly from the previously described systems in terms of positioning, technical structure, electronic concept, and

performance. The pump was deliberately designed only to support an insufficient but still functional left ventricle. By reducing the performance requirements it was possible to greatly simplify the design.

The body of the pump simultaneously serves as the apical connector; the pump is implanted intracardially. As with the DeBakey pump, the rotor is supported by mechanical bearings. The device is entirely without automatic monitoring or an electronically complex regulation system. The pump is implanted directly into the left ventricular apex through a left lateral thoracotomy and is secured with a sewing cuff. Blood is pumped through a vascular graft into the descending aorta (Fig. 36.11).

A unique feature of this system is the percutaneous connector for the electric driveline power cable. A titanium pedestal, similar to those that have been in use for many years in cochlear implants for infection-free power transmission, is mounted on the skull behind the left ear and connected to the power cable bundle, which runs subcutaneously to the pump. The external components can then be hooked up with the corresponding connector. Patients can shower, and the skin exit site will remain free of infection even with minimal care [36.17].

Implantable Long-Term MCSS with Radial Flow

TerumoHeart, Inc., DuraHeart Left Ventricular Assist System (LVAS). The DuraHeart (www.terumo-europe.com) is an implantable centrifugal pump made from titanium. In three hermetically separated chambers there are an electronic motor, a rotor magnetically coupled to the motor with an integrated permanent magnet, and a regulated electromagnetic system for contact-free magnetic suspension. Should the magnetic suspension fail, the device can fall back on hydrodynamic emergency bearing features, although these only function for a limited period.

Like all rotary pumps, the DuraHeart system propels the blood from a cannula implanted in the left apex through a vascular graft into the aorta. The complex magnetic suspension technology accounts for the large size of the pump (Fig. 36.12). For this reason it must be implanted in the abdominal wall.

HeartWare International, Inc., HVAD System. The HeartWare (www.heartware.com) HVAD is the smallest left ventricular assist device with radial flow currently available that has the capacity to take over the total pumping capacity of the left ventricle under normal

Fig. 36.11 Jarvik Heart 2000 Flow Maker. Schematic of the intracardial implantation; auricular pedestal for the electric driveline

Fig. 36.12 Terumo Heart DuraHeart LVAS blood pump with rigid apical cannula

physiological pressure. The pump has three main components:

- A front housing with inflow cannula
- A rear housing with a center post
- A wide-bladed impeller.

Each half of the housing has a separately connected stator coil assembly, making the motor redundant. Large permanent motor magnets can be embedded in the wide blades of the impeller. The combination of passive magnetic and hydrodynamic suspension without complex bearing electronics increases functional reliability,

Fig. 36.13 HeartWare HVAD system. Direct apical cannulation and aortic outflow graft to the ascending aorta

but also demands the highest level of manufacturing precision. The blood contact materials are titanium, a titanium nitrite coating of the rotor and center post, and zirconium ceramics.

Flow is calculated on the basis of power consumption, speed of rotation, blood viscosity, and with the help of empirical data of a performance chart. The variations in power consumption and the shape of the curve of the calculated flow displayed on a mobile monitor allow an evaluation of the operating conditions and the filling, or activity, of the supported heart.

During implantation a sewing ring is fixed to the apex. The pump with the inflow connectors is introduced here and thus lies directly at the heart, finding space in the pericardium (Fig. 36.13). The outflow graft can be connected to the ascending or descending aorta.

36.4.3 MCSS for Pediatric Patients

The first clinically available MCSS were designed in terms of performance and anatomic adaptation to fit the requirements of adults. Soon, however, there was a need to develop systems for small patients that could be adapted to body weights of 1–30 kg with flow rates of 1–4 l/min. Connections to the circulatory system had to be miniaturized and new types of valves were required for pulsatile pumps.

Berlin Heart EXCOR, an extracorporeal pneumatic system, was applied as the first pediatric system for BTT with a 50 ml pump in 1990 (DHZB). In 1992, the first implantation of a pediatric system, EXCOR Pediatric with a 10 ml pump took place at the DHZB. Today, a range of pumps (10, 25, 30 and 50 ml) with corresponding miniaturized cannulas are available. This system is also approved for clinical application in the USA. The company MEDOS now also offers a CE-certified pediatric assist system.

In 2004, in the USA, the National Institutes of Health contracted five research groups to develop cardiopulmonary assist devices for pediatric patients with body weights of 2–25 kg (contract HHSN268200448192C (NO1-HV-48192), *Pediatric Circulatory Support*).

The projects were: *PediaFlow VAD*; *PediPump*, an axial turbine for intravascular or extravascular placement; *Pediatric Jarvik 2000 Flowmaker*, a miniaturized version of the Jarvik 2000; and Thoratec's modified pneumatic *pVADs*. A compact heart–lung support system *pCAS* is also included in the program.

A very detailed description of a prescriptive design approach was published recently [36.18]. This explains the multi-disciplinary program of different departments

Fig. 36.14a,b PediaFlow. (a) First centrifugal design; (b) new axial design

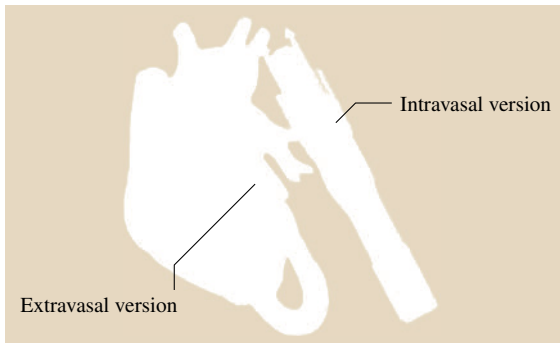

Fig. 36.15 Axial PediPump (extravasal and intravasal version), Cleveland Clinic, Foster–Miller Technologies

at the universities of Pittsburgh in collaboration with the industry to develop the PediaFlow VAD that resulted after 5 years in three different pump topologies with axial or radial flowpath. Judged on the basis of a multi-component analysis including criteria for anatomic fit, performance, biocompatibility, reliability, and manufacturability the mixed-flow magnetically levitated pump, the PF3, has been chosen as the best-suited design (Fig. 36.14).

The PediPump design is shown in Fig. 36.15.

Despite concentrated efforts, in 2010 none of these five NIH systems had yet reached the status of clinical application.

36.4.4 Summary

Whereas initially, in the 1980s, the market was led by pulsatile pneumatic extracorporeal systems, followed

by first-generation implantable electromechanical pulsatile VADs, today it is the second and third-generation nonpulsatile implantable systems for mechanical circulatory support that dominate the market (Table 36.3).

The new technology's initial *teething problems* were soon overcome, and new concepts and further miniaturizations with improved reliability and biocompatibility prevailed. Before long the implantation of rotary pumps was favored. The clinical success of these devices inspired manufacturers to continue developing new concepts. Figure 36.16 gives a scaled overview of the various systems available in 2010.

The number of applications of pulsatile displacement systems quickly fell in favor of continuous-flow systems. DHZB application statistics illustrate this trend. Since 1998, the proportion of pulsatile extracorporeal and intracorporeal systems applied has dropped almost linearly from 100 to 3%, while the total number of applications has doubled. Until recently, pulsatile extracorporeal systems and the temporary TAH were only unrivalled in the case of indications for BVAD. The fact that some rotary pumps with continuous flow can be implanted as BVADs has since been demonstrated by the first applications at the DHZB [36.19] and at the Medical University of Hannover [36.20]. A laboratory study funded by the Friede Springer Foundation made it possible to carry out the first clinical applications of these HVADs as BVADs.

Because the terms *nonpulsatile* or *continuous flow* are often misinterpreted, a brief explanation is given here. The flow of the rotary pumps at a constant rpm (revolutions per minute) is only nonpulsatile when the heart does not affect any changes in the inflow pres-

Table 36.3 Clinical implantable VADs 2010

Implantable ventricular assist devices – clinical 2010			
Manufacturer	First clinical	Volume (cm ³)	Weight (g)
First generation – volume displacement			
WorldHeart Novacor	1984	700	1800
Thoratec HeartMate I XVE	1991	600	1200
Second generation – rotary, mechanical bearings

Fig. 36.16 Scaled overview of today's clinical pulsatile and continuous flow VADs

sure to the pump, i. e., in the absence of contractions or when the heart is asystolic or fibrillating. Any change in differential pressure in the pump causes a more or less pulsatile flow at a constant rpm, corresponding to the pressure–flow characteristics of the pump design. In that case, the flow is normally continuous. The diastolic standstill typical to displacement pumps does not occur. These flow pulsations give rise to corresponding pressure amplitudes; the term *pulseless perfusion*, therefore, can only be used to a limited extent, particularly when the physiological effects of nonpulsatile VAD perfusion on organ function are being discussed. Ultimately, we still do not have any reliable long-term observations relating to this question.

Fig. 36.17 Circadian rhythm of the left and right pump flow in a patient with HeartWare BVAD; flow variations over 7 days with constant rotational speed ◀

Another example shows how the continuous flow in a biventricular VAD adjusts approximately to physiological conditions even without external regulation of the pump parameters (Fig. 36.17). Even at constant rpm, signs of some kind of autoregulation corresponding to the recognition of the body's perfusion requirements can be clearly recognized in the circadian biorhythm of the cardiac output of a patient with a BVAD giving *pulseless* support. This is an example of the interaction between the biotechnical hybrid system consisting of

an unregulated blood pump and the naturally regulated circulation [36.21].

It seems certain that the future of mechanical circulatory support belongs to rotary pumps. With ever smaller devices implantation will become less and less invasive. New fluid dynamic designs and optimized blood contact surfaces will ensure even greater biocompatibility, and the concomitant drug therapies still necessary today, for instance for controlling coagulation, might in the future be reduced or dispensed with entirely.

36.5 Complications

When describing the complications that follow the application of MCSS it must be taken into account that even today this therapy is only selected for patients in the final stage of an imminently life-threatening illness. The evaluation and classification of early postoperative complications is limited because existing concomitant circumstances in themselves represent complications or involve a high risk of complications.

Often, cause and effect cannot be clearly distinguished. For this reason, BTB or BTD (bridge to bridge; bridge to decision) can be implemented initially to stabilize and evaluate cardiogenic shock patients using less invasive (and less expensive) mechanical circulatory support before other more invasive therapies are applied. Based on our experience at the DHZB and supplemented by published data and data received through personal communication, the most commonly occurring problems in the various post-implantation periods are presented below.

36.5.1 Device Malfunction

Device malfunction can affect all components of the system:

- The blood pump, as the central component of the MCS system
- Connections to the patient's vascular system
- The pneumatic leads or electric cables that supply power to the pump
- The control units to which the pumps are connected
- In pneumatic systems, the driving unit where the pneumatic pressure pulse is generated
- The integrated system monitor/alarm system
- The power supply.

Blood pumps, as the key component of any life-sustaining VAD, are subject to special requirements

with regard to fatigue strength and reliability [36.22]. The membranes or blood sacs of pneumatically driven systems are subjected to high mechanical stress by the vast number of alternating load cycles that bend and stretch the material (ca. 40–50 million cycles per year). To improve safety, the membranes are designed as multi-layered membranes. As a result, the risk of rupture with blood escaping into the air chamber or the risk of an air embolism in the blood chamber is extremely low [36.23].

Mechanical valves are another potential source of trouble. Cracks can appear in the valve discs or in the retaining struts of the valve ring; jamming of the valve in the valve ring has also been observed. However, these defects have only occurred occasionally.

A more frequent observation is the formation of blood clots, resulting from either insufficient or unadjusted anticoagulation therapy, for instance in the event of infection or inadequate perfusion of the pump (e.g., hypovolemia). In such cases the pump can be exchanged.

Rotary pumps have only one moving part – the impeller. Depending on the type of suspension, this is either wear-free (magnetic suspension, hydrodynamic suspension) or very low-wear, so that operation times of more than 10 years can be expected.

Extracorporeal systems require comparatively long, percutaneous blood-conveying cannulas to connect the blood pump to the vascular system of the patient. In addition to the potential complications of infection at the skin exit site (Sect. 36.5.5), the patient's movements may, depending on the position of the blood pumps, cause the cannula to bend. If this happens repeatedly at the same site on the cannula, cracks may form, thus increasing the risk of bleeding and air embolisms.

In implantable systems the power electric driveline to the pump is the component subjected to the most me-

chanical stress. In many patients every movement, even the heartbeat itself, causes a slight movement of the pump, so that the power cable is permanently subjected to bending stress. If tensile stress occurs at the same time, whether accidentally, e.g., the bag containing the controller and the heavy batteries falls, or consistently as a result of a gain in weight, and therefore also circumference of the patient, the conducting wires break, causing the pump to malfunction or fail. Cable defects that necessitate the exchange of the pump have been repeatedly observed in various models.

The control and driving units normally have a redundant design, or at least an operating mode for emergencies. Patients are also equipped with replacement components and receive instruction on exchanging parts.

Even with systems that are durable, easy to operate, equipped with sophisticated alarm systems and, in some cases, emergency operating features or redundancies as well as good usability, patient operating errors can still lead to fatal accidents. Increasingly, VADs are being used to treat older patients who – sometimes for the first time during therapy – experience cognitive or manual function limitations that cannot be compensated, even with extensive and repeated instruction on operating the system.

36.5.2 Hemolysis

The use of mechanical pumps in the circulatory system is always associated with the risk of damage to the corpuscular components of the blood. Contact between the blood and foreign surfaces and the stress placed on the blood cells by the pressure-dependent and flow-dependent shear stresses generated by the pumping all have a damaging effect on the blood. This trauma can be minimized through the choice of materials and surface finishing, and by optimizing fluid dynamics in terms of the extent and exposure time of the mechanical load.

Depending on the particular system, our patients' serum lactate dehydrogenase (LDH) values lie in the 180 U/l (normal) to 400 U/l range. Any sudden increase in this regularly measured parameter indicates VAD-induced hemolysis. This may be caused by an obstruction in the pump inflow or outflow, resulting in a local increase in speed and a corresponding rise in shear stress. Possible aspiration of the pump with a partial or complete occlusion of the inflow causes turbulence around the rotor and a sharp increase in flow-dynamic stress on the blood, resulting in cell trauma.

It should be noted that hemolysis is not a problem generally associated with today's pumps, in contrast to the systems of the pioneering days. This is also proven by the fact that it is irrelevant whether a patient is fitted with one or two well-functioning pumps. However, patients with MCS systems can exhibit hemolysis due to other effects such as infection or medication.

36.5.3 Thromboembolism

Even with carefully monitored anticoagulation therapy that takes into account the varying requirements of the individual systems, blood contact with the biomaterials used (titanium, silicone, polyurethane, etc.) can result in the formation of blood clots. Unfavorable flow conditions in areas with stagnating blood flow and, therefore, poor washout contribute to this complication.

36.5.4 Bleeding

After implantation of an MCSS there is always a risk of secondary bleeding in the postoperative phase, requiring renewed surgical intervention. This bleeding tendency is exacerbated by the profound shock, which in itself induces coagulation disorders. In the later course there is a risk of bleeding due to over-anticoagulation, trauma, and infection.

36.5.5 Infection

Implantations of VADs and TAHs are associated with a high incidence of infection. An early infection rate of 5–20% is reported; in long-term applications this rate increases to up to 90% depending on the system. Circulatory failure and concomitant diseases promote infection.

Today's systems all require external access through the surface of the body to the vascular system (extracorporeal pumps: large-bore blood-conveying cannulas) or to the implants (leads). At the skin exit site, the cannulas or leads are coated with a porous synthetic material to give the injured tissue a chance to grow into it, thereby forming an infection barrier along the wound tunnel. However, generally speaking, the wound area around these access sites is always slightly inflamed and can become infected, even with meticulous care of the wound, thus providing a gateway for bacteria to enter the body. Infections can penetrate right through to the implant where they can no longer be controlled with medication.

Infections that spread as far as the inflow cannula at the tip of the left ventricle are particularly serious. This

can cause the cannula to migrate away from the chamber resulting in the formation of a mycotic aneurysm with the risk of rupture and recurrence, even after surgical intervention.

Years ago, inductive *transcutaneous energy transfer systems* (TETs) were developed to supply power and to transmit data and control signals through the undamaged surface of the body. An implanted coil, electromagnetically coupled with an external supply coil conveys the signals through the intact skin to a similarly implanted control and power storage unit, which activates the pump. The long-term capacity of the required implanted power storage unit still presents a problem today; after a limited number of loading and unloading cycles, a further operation is needed to exchange the unit.

36.5.6 Problems at Anastomoses

Impaired wound healing at the anastomosis of the apical cannula is common, but not often described. This problem was examined in over 200 autopsies in DHZB patients treated with 11 different long-term devices.

Even in the absence of infection, granulation tissue can quite often form around the cannula in the ventricle, spreading to such an extent that the cannula becomes obstructed or the tissue embolizes into the pump. This complication often occurs with pumps that have a rigid connection to the inflow cannula. When the pump is connected to the cannula with a flexible conduit there is obviously less opportunity for infection or granulation.

A microporous surface structure allows the cells of the myocardium to form a fixed neointima. In all cases, after only a short time, smooth metallic surfaces initially cause the formation of thrombotic deposits, which later develop into granulation tissue (Fig. 36.18). At the aortic anastomosis, in individual cases, aneurysms have sometimes been seen.

36.5.7 Right Ventricular Insufficiency

More recent publications report right ventricular insufficiency in 25–35% of LVAD patients immediately after implantation. The rate at the DZHB is somewhat lower at 15% [36.11].

If the problem of right ventricular insufficiency cannot be reversed by a sophisticated drug regimen, application of a temporary extracorporeal right ventricular support remains the only option. If there is a disturbance of gas exchange in the lung, the RVAD can be combined with an oxygenator.

36.5.8 Anatomic Obstruction of Flow

Cramped anatomic conditions in the thorax, e.g., due to small patient size or the more bulky blood pumps, can result in compression of the venous, blood-conveying vessels or a dislocation of the pump, resulting in apical cannula inflow obstruction. Therefore, pump function can already be impaired during surgery, and may even come to a complete standstill. Poor positioning can be identified by intraoperative transesophageal echocardiography (TEE) and surgical correction can then be performed.

36.5.9 Arrhythmias

Arrhythmias are common in patients with indications for an assist implantation. Many of our patients had already received an implantable cardioverter/defibrillator (ICD) prior to surgery.

In the event of ventricular arrhythmia, tachycardia or fibrillation, the pumping capacity of the left pump may also fall due to the then reduced right ventricular function and the pulmonary hypertension often present in these patients. This can lead to suction of the apical cannula and even pump failure. This situation may even require the implantation of an ICD. Patients with

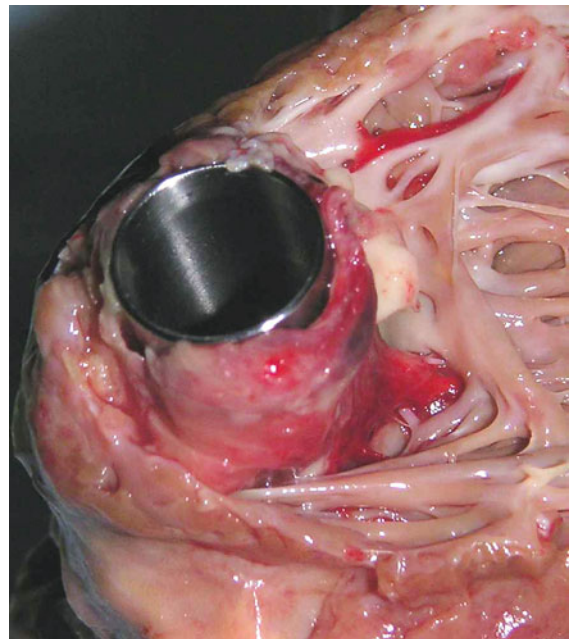

Fig. 36.18 Apical cannula of the DuraHeart in the left ventricle with thrombotic deposits and granulation tissue

BVADs and good flow conditions are not compromised by serious heart rhythm disturbances of this kind; some

of our patients with lasting cardiac fibrillation have survived for longer periods without symptoms.

36.6 Technical Follow-Up and Care

Patients who have been allowed to return home and who only visit the clinic as outpatients – in some cases at intervals of several months – require technical aftercare and monitoring. First and foremost, a 24-h/7-day-a-week hotline is needed to deal with acute problems.

The first attempts at establishing remote monitoring of the system function have been made. Similar to telemedicine centers, a dialog may be set up whereby patient data can be accessed and analyzed via cordless telephone networks and the Internet. Remote monitoring requires internal logging of the system parameter data; this enables the diagnosis and, if necessary, the temporal reconstruction of events when alarm signals are given.

The Thoratec HeartMate II records certain conditions, each with a corresponding set of parameters containing all real-time values. However, its memory storage is limited to 120 data sets.

With the DeBakey system two memory areas are constantly updated with high-resolution data. If an er-

ror occurs, the respective data are recorded in such a way that the beginning of an event is stored in the first area. The second area is overwritten with any newly occurring events so that in the clinic the first and last occurrences can be examined in detail.

With the BerlinHeart INCOR system an unlimited number of events can be recorded as long as the patient is connected to the home equipment monitor. A comparatively small amount of event-triggered data, only 400 parameter sets, can be stored in the control unit itself.

The HeartWare system stores data sets in 15 min intervals, covering a maximum of 30 days.

In the Terumo DuraHeart control unit detailed short-term storage and a long-term time protocol are combined over a 30-day period. In the event of a malfunction, the changes of specific signals are recorded.

Experience shows that optimal monitoring depends on detailed data storage that allows an analysis of past events.

36.7 Psychosomatic Syndromes and Quality of Life During Treatment with MCS

36.7.1 Psychosomatic Syndromes During MCS

The implantation of an MCSS means an intensive psychological stressor for the patients and induces emotional distress and various concerns. Patients are confronted with the threat of sudden death, very often experience a high degree of anxiety and depression before and after implantation of the assist device, and suffer in a psychological sense from a kind of self-infarction. The psychiatric–psychological reactions after surgery are very complex in nature due to the simultaneous impact of organic and emotional factors.

In the initial postoperative period organic factors are of specific importance:

- Psychotropic side effects of the extracorporeal circulation, cerebromicroembolic events, metabolic

disorders, pre-existing neuropsychological dysfunctions, and cerebrototoxic medication effects

- Besides these, initially acute psychological shock reactions resembling a *possum reflex* or states of pronounced psychovegetative activation and an excess of diffuse bodily sensations are observed.

In the following days or weeks processes of adaptation to the assist device develop and organic psychotropic factors gradually lose their significance in favor of emotional reactions and defence or coping processes. Patients tend to restore their psychic balance and to adapt to the new reality.

In psychological care multifaceted treatment modules are required to support patients adequately. It is necessary to attend to (often hidden) mental confusion, delirium, and short psychotic disorders, and to treat these states with basic supportive interventions and/or

neuroleptic medication or tranquilizers. Over time there is an increase in affective disorders such as depression, anxiety, or mixed disorders, as well as adjustment disorders. *Neurocognitive dysfunctions* are very often underdiagnosed: they comprise impairment of the ability to maintain attention and concentration, deficits in learning and short-term memory, and mental flexibility, and are often only to be detected by neurocognitive testing.

The most prominent reactions are depressive mood, hopelessness, feelings of inadequacy, anxiety, and sleep disorders with often rapid cycling from day to day. These affective and bodily sensations are often induced by assist-device-specific side effects such as noise, vibrations, altered cardiac rhythms, etc. Furthermore patients suffer from isolation from their family or partners and are confronted with the demands of the clinical setting. Deprivation effects emerge but on the other hand patients also feel themselves to be safe and secure in the department and realize that the threat to their lives has been overcome and that they can now look to the future.

In accordance with these conflicting psychological feelings patients are ambivalent and their reactions range from latent suicidal ideas or impulses to confidence, intensive future planning, or even euphoric states.

36.7.2 Profound Psychological Processes

All these psychosomatic reactions can be understood as transient regressive developmental processes.

The assist device implantation represents a breach of the body's boundaries. The internal world of the organs and abdominal cavities (anchored in the *body image*) is forced open, the body is invaded from the outer world, the motor of life has lost its vitality and has been violated. A new *replacement heart* is implanted, and this high-tech apparatus cannot be controlled by myself, it is controlled from outside the body and is under the care of initially unfamiliar people. In the intimate heart cavity – is my heart still there? What importance does it have now? Patients are forced to form a union between an internal and partly external life center, a union between living and dead matter.

This induces the regressive processes mentioned above and reactualizes very early developmental periods where rhythms, internal bodily sensations, and basic perceptual and affective patterns create the basis for the more complex and more mature self structuring processes.

36.7.3 Coping Skills

During treatment with the assist device *depressive withdrawal* is the predominant coping strategy during the initial period, as well as *denial and wishful thinking*. After some months on MCS patients rely upon *active problem-solving* i. e., they tend to reorganize their daily lives and overcome difficulties. They are engaged in fighting against their illness, encourage themselves and look for success and self-confirmation. They intensively seek *social support* from their family and friends and emphasize as the most important single strategy: *placing trust in the doctors*. In contrast, nearly half the patients hesitate to follow the doctors' advice to some degree.

36.7.4 Quality of Life

Quality of life, mostly measured with the SF-36 Questionnaire, is reduced during life with MCS and the mean scores in most of the studies are about 25% below the scores of chronically ill patients; there are no relevant differences comparing the physical and the psychological domains.

The patients have generally positive overall perceptions of the MCS but express several specifics pertaining to infections, sleep disturbances, pain related to the driveline, device noise, and fears of MCSS malfunction. An important concern relates to stroke and the correlated long-term impairment. These specific concerns are responsible for the reduced quality of life.

36.7.5 Therapeutic Consequences

It seems very important to offer patients continuous psychological treatment:

- To treat the transient psychosomatic or psychiatric disorders according to the current guidelines
- To analyze the sources for regressive behavior, feelings of guilt and suicidal ideas
- To support the patients in developing individual plans for active, self-contained behavior and for the caregivers to sustain support.

36.7.6 Summary

There is a high degree of psychosomatic or psychological disorders during the initial weeks after MCS implantation. Once the first emotional threat is overcome, and due to the reduction of external organic factors, we observe a rapid remission of psychological

syndromes and an increase in active problem-solving behavior instead of regressive withdrawal. Nevertheless, neurocognitive impairment remains an important issue for longer time periods.

36.8 Overview and Outlook

Artificial cardiac assist devices for longer-term application have been in clinical use since the 1980s and were initially employed in life-threatening situations as a bridge to subsequent heart transplantation, i. e., for a limited, foreseeable period. However, then came the development of systems that could function for several years and, for some patients who were not able to receive a transplant, the permanent use of these pumps became inevitable.

Technical improvements and higher numbers of temporary artificial heart implantations as a BTT do not inherently contribute to solving the donorship problem, nor do they contribute to improving the care of patients who today can only be helped to achieve better life expectancy with a heart transplant. In Germany, the number of organ donors is falling steadily. In 2009 over 1000 patients were listed for a heart transplant, but the number of donor organs was only 350. The increased use of bridging systems (BTT) merely leads to higher numbers of patients on the waiting list and lower chances of receiving a transplant.

Nevertheless, the concept of bridging to subsequent transplantation can be viewed as a historic achievement, because for the first time it became possible to use artificial cardiac assist devices in a meaningful and acceptable way. The only justifiable solution for the future is the provision of technically safe, long-term implantable systems that offer significant improvements in life expectancy without greatly limiting quality of life and that can, therefore, be seen as an alternative to transplantation [36.25].

Syncardia's current development of a scaled down version of the well-established temporary artificial heart CardioWest is only an interim solution that will enable its implantation in smaller patients. Due to the limited life of the membranes and the external pneumatic driving unit it will remain a BTT system.

Given the recognized need for a long-term implantable biventricular mechanical cardiac support or heart replacement, research groups around the world have for years been trying to refine TAH systems for clinical use – with a range of different concepts and

More detailed information on the psychiatric-psychosomatic disorders and coping mechanisms associated with mechanical circulatory support is available in [36.24].

often at enormous financial expense covered by state funding and industrial support – but so far without further clinical success.

ABIOCOR, the first fully implantable pulsatile electrohydraulic artificial heart system developed by the American company ABIOMED, Inc., was approved by the FDA for limited commercial clinical application, but considerable anatomic and also technical problems and the lack of clinical success have raised doubts about its continued development.

In Europe, two new projects on pulsatile implantable artificial hearts have recently been introduced; both are based on the initial developments of the 1980s. Just a short time ago, the French heart surgeon Alain Carpentier announced that, together with researchers from the aerospace company EADS, he had created a fully implantable artificial heart (Fig. 36.19). It is reported to have functioned well in animal trials with calves. The French artificial heart weighs 1 kg and is made of biolyzed tissue, titanium, and plastic. A special blood contact surface derived from porcine cartilage is designed to prevent the formation of blood clots. Details have not yet been released, but the device is certainly not small, as could be seen from a published video. According to the company CARMAT, which was established to produce the system, the de-

Fig. 36.19 CARMAT artificial heart, designed by A. Carpentier

Fig. 36.20 The ReinHeart, under development by RWTH Aachen University and R. Körfer

vice should be ready for clinical application in 4–6 years.

This year, together with the RWTH University in Aachen, Reiner Körfer presented a concept for a permanent artificial heart, ReinHeart. This is the continuation of the MiniACcor development project, which has been under way there for several years. ReinHeart is larger than the normal heart. It is expected to fit into the thorax of 80% of adults and should weigh no more than 800 g. Comparable to the native heart, the device consists of two chambers and four valves, as well as an electromagnetic linear drive (Fig. 36.20). These elements and further components are designed to be implanted into the body. It will take several more years of development before this system can be applied in the clinical setting.

It is now time to consider the realization of total heart replacement systems based on two rotary blood pumps of existing permanent LVAD systems and thus using the clinical experience gained from thousands of patients with these devices [36.26]. The long-term suitability of different second or third generation rotary blood pumps with contact-free magnetic or magnetic–hydrodynamic suspension of the rotor and accordingly high fatigue resistance and reliability has been demonstrated in clinical applications over periods of up to several years with acceptable complication rates.

With the support of the *Friede Springer Foundation*, investigations into the suitability of clinically proven LVADs for biventricular cardiac support or heart replacement were initiated in 2009 at the DHZB with the TAHROT study. Now, in the first stage of this study, rotary pumps are being implanted as BVADs in patients

Fig. 36.21 Anatomical positioning of two HeartWare HVAD blood pumps

with terminal biventricular heart failure at the DHZB (Figs. 36.21, 36.22).

The working area of the pump, which functions as an RVAD and was originally conceived as an LVAD, is transformed by banding the pulmonary outflow graft; this increased resistance moves the flow–pressure area (afterload of the RVAD) into that of the natural systemic circulation. The pump itself does not need to be redesigned (Fig. 36.23).

The development of even smaller rotary LVADs and possibly also BVADs shows promising progress. Three modified miniaturized systems from the company HeartWare are already being tested in animal experiments (Fig. 36.24). These new axial pumps are said to have a similar capacity but less than 50% of the weight of an HVAD, with a correspondingly small size. Implantation will be greatly simplified; a combination for total heart replacement seems very promising.

Thoratec, the world leader in the market for VADs, has new miniaturized axial (HM X) and centrifugal (HM III) rotary blood pumps in its development program (Fig. 36.25). The aim is to achieve long-term application with only minimal or no anticoagulation therapy.

To improve patient quality of life, a transcutaneous energy transmission system (TET) was developed to supply fully implantable blood pumps (Fig. 36.26). The TET allows two-way data and energy transfer through the intact skin, thereby ruling out the risk of infection at a skin exit site wound.

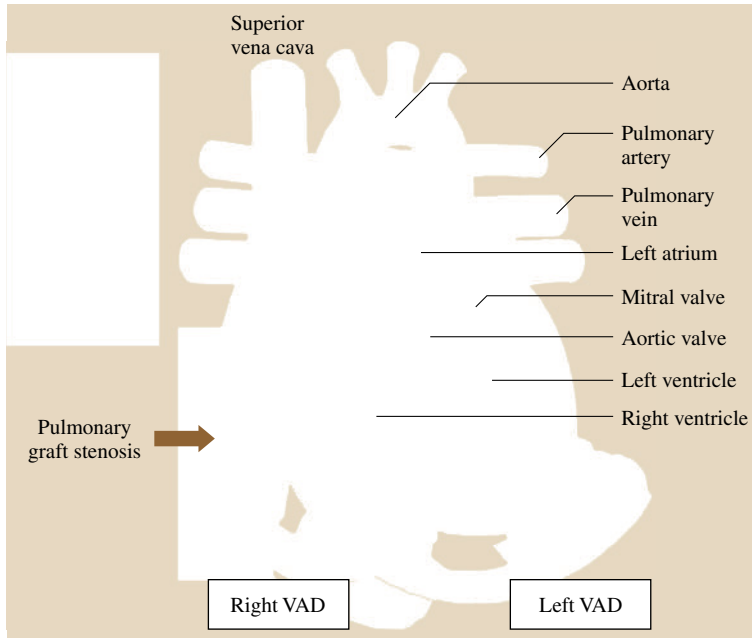

Fig. 36.22 Schematic of the left and right ventricular cannulation and the aortic and banded pulmonary artery conduits

On 10 December 2009, *Euromacs* (EUROMACS VAD registry; European Register for Mechanical Circulatory Support e.V.) was founded in Berlin to allow comprehensive pooling and documentation of all data on applications of MCSS in Europe. The evaluation of experience from a larger patient pool is

expected to result in a more rapid transfer of findings, both to hospitals and to system manufacturers. This collection of data will provide a valuable research tool.

The current state of technology and medical expertise allows the application of mechanical circulatory

support systems for a number of indications, extending right through to the permanent replacement of the heart function with acceptable risks and quality of life.

The provision of patient aftercare by specially trained technical and medical staff is of growing importance, on the one hand so that complications can be recognized and averted as they develop, and on the other hand, to give patients a sense of security in their day-to-day living with the device. Telemedical monitoring of external VAD patients will play a helpful role here. Given that MCSS can now be applied as an alternative to heart transplantation, the numbers of patients requiring outpatient care from the implant institutions are set to increase rapidly. Additional capacities will need to be created to satisfy the requirements for aftercare.

37. Neural Interfaces for Implanted Stimulators

Neural Interf

Xiao Liu, Andreas Demosthenous, Nick Donaldson

For a paraplegic, direct control of certain body parts is destroyed by the injury, leading to the loss of sensation and muscle control. However, most of the nerves and muscles below the injury site may still be functional and can be artificially stimulated by an appropriate neural stimulator to restore the lost functions or to facilitate rehabilitation. Thanks to CMOS technologies, the vast majority of stimulation electronics can be integrated onto a small silicon chip, able to drive many electrodes and generate complex stimulation patterns. However, it is of paramount importance that any advance in circuit functionality should not compromise electrical safety. This chapter looks into several safety issues, especially on the parts near the stimulation interface, i. e., stimulating electrodes, implantable cables, and stimulator output stages. Various methods and solutions for building reliable and robust stimulation interfaces are reviewed and compared in terms of system com-

plexity, physical size, level of safety, and circuit performance.

There is a large population worldwide suffering from neural disabilities and dysfunctions due to injuries and diseases. For example, *spinal cord injury* (SCI), which disrupts the normal pathways between the brain and the muscles or sensory cells, is one of the most disastrous medical conditions. The worldwide annual estimate of SCI is 2.5–57.8 new cases per million population [37.1]. SCI is not only physically and psychologically devastating for individual patients, but also puts a large economic burden on the society's health care system. Thus there is constant need for new technologies for treatment and to facilitate rehabilitation.

The simple fact that electrical changes, described either as ionic currents or neural voltage signals, are the cause of neural communications in the body makes it

possible to use electrical stimulation to mimic the normal neural activities of muscles. By placing stimulating electrodes within excitable neural tissue and passing electrical stimuli through these electrodes, it is possible to generate excitation or inhibition of neural targets. If the electrical stimulation targets nerves that innervate peripheral muscles, in order to replace or restore lost functions in neurologically impaired patients, it is referred as *functional electrical stimulation* (commonly abbreviated as FES).

In FES, the excitation of nerves and muscles is caused by artificial electrical stimuli rather than the voluntary neural driving signals. In the last few decades, FES has been approved as a useful method to restore neural functions in many applications. These include the restoration of hand grasp [37.2], standing and

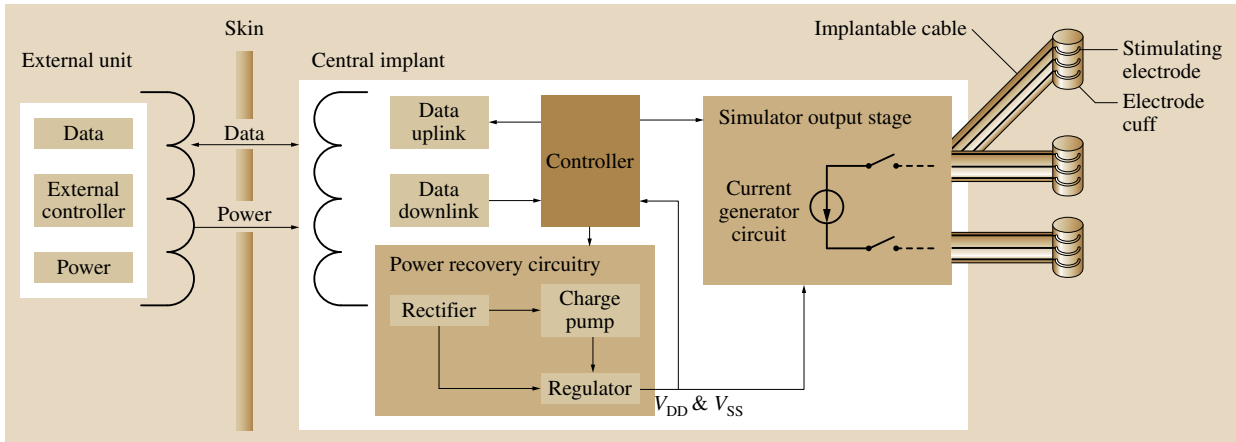

Fig. 37.1 A simplified block diagram of an implantable stimulation system

walking [37.3], bladder and bowel control [37.4], and breathing [37.5].

A device that supplies the desired electrical stimuli for an FES application is known as a *neural stimulator*. During the last century, the design of neural stimulators has progressed enormously. These are categorized as surface stimulators (external stimulation unit with stimulating electrodes placed on the surface of the skin), semi-implantable stimulators (external stimulation unit with implanted stimulating electrodes), and fully implantable stimulators (implanted stimulation unit with implanted stimulating electrodes), depending on the location of the stimulating electrodes and the stimulation unit. Compared with surface stimulators, implantable stimulators offer several unique advantages:

1. Compared to surface stimulation, an implantable stimulator greatly simplifies the prestimulation and poststimulation procedure by avoiding the repeated placement and removal of stimulating electrodes. Thus implanted stimulators are more convenient for patients.
2. The implantation allows near-target placement of stimulating electrodes, providing better selectivity.
3. A full implantation avoids transcutaneous cables, which can introduce infection.

Implantable stimulators are currently widely used in clinical trials and have resulted in several successfully commercialized products for chronic applications. By 2004 there were more than 1000 different types of stimulation systems implanted into more than 200 000 patients [37.6].

The development of implantable stimulators has greatly benefitted from the advances in integrated circuit and system-on-a-chip (SOC) technologies, which offer a high-density integration of electrical components with small power consumption. The size of implantable stimulators has shrunk significantly over the years, making the devices easier to implant.

Figure 37.1 shows a simplified block diagram of an implantable stimulation system for FES applications. The complete stimulation system is composed of an external unit and an implanted device, outside and inside the human body, respectively. Figure 37.1 also shows the core modules in the external and implanted devices.

Due to the high power requirement (> 1 mW) of FES applications, the limited capacity of a small internal battery may not be sufficient for stimulations on a regular basis (daily). Thus, implanted devices are usually inductively powered at radio frequency during stimulation, or the internal battery is recharged during idle time (nonstimulation period, e.g., at night when the patient is sleeping) by an inductive link. The inductive power link is essentially a transformer made of two magnetically coupled coils. One of the coils is embedded in the implantable device while the external coil aligns with the internal coil for efficient power transmission. The received alternating voltage across the tuned coil is further rectified to DC voltage by a rectifier in the power recovery unit. Then the rectifier's output is further regulated to one or more stable DC voltage levels or pumped to an even higher voltage level before regulation if a supply voltage higher than the rectifier's output is required. The recovered DC sup-

plies provide the power required for the operation of other circuit modules in the implanted device, such as data uplink/downlink, digital control unit, and stimulator output stage.

The data downlink in the implanted device allows the implanted device to be remotely controlled by an external unit. The controller interprets the stimulation commands from the received data and guides the stimulator output stage to generate appropriate stimulation pulses. The stimulation commands usually accommodate a wide range of different stimulation profiles (e.g., the amplitude and duration of stimulus current) in order to meet the different requirements of each individual patient with specific SCI conditions.

Data downlink is only a one-way communication, conveying information from the external unit to the implanted device. It is also desirable to feed internal sensed information back to the external unit via a data uplink. Typical data transmitted to the external unit include humidity information inside the implant package,

electrode impedance, and status of the power supply. This information helps to study the efficacy of stimulation and monitor the status of the implant. The sensed information is analyzed by an external device that may modify the stimulation commands on the data downlink if necessary. Thus the duplex communication mode allows closed-loop control of an implanted device.

Another important module in implanted devices is the stimulator output stage, which is functionally the closest unit to the biological interface (the stimulating electrodes and the tissue). It is responsible for generation of electrical stimulation pulses according to the commands received from the control unit and delivers the stimulus to the tissue impedance.

In this chapter, we intend to describe some of the common principles in the design of integrated neural stimulators, emphasizing the safe stimulation interface between neural tissue and implantable electronics. The topic covers stimulating electrodes, implantable cable management, and stimulator output stage.

37.1 Stimulating Electrodes

37.1.1 Electrode–Electrolyte Interface and Circuit Model

An electrode is an interface between a biological environment and a stimulator. During stimulation, electrical currents in metallic conductors, such as the implantable electronic circuits, are carried by free electrons while electrical currents in biological tissue and body fluids are carried by the motion of ions. The electrode, which itself is a metallic conductor, carries current by

free electrons. At the electrode–tissue interface there is a transduction of charge carriers in order to continue the relay of current delivery.

To perform neural stimulation, at least two electrodes (known as a *dipole*), a positive anode and a negative cathode, are required. However, three or more electrodes are commonly used in order to confine the electrical field in a more localized volume of tissue for better selectivity [37.7]. Figure 37.2a shows the electrical circuit model for an electrode–electrolyte

Fig. 37.2a,b Electrical circuit modes for (a) an electrode–electrolyte interface (b) the interelectrode impedance for a dipole configuration

interface. The half-cell potential [37.8] for the electrode has been omitted from the model because the same electrode material is used to implement the dipole electrode configuration in which the electrodes' half-cell potentials are the same and have been cancelled out. In the model, C_{dl} represents the double-layer capacitor at the interface. Depending on the type of metal conductor used and the roughness of electrode surface, the C_{dl} value is on the order of $\mu\text{F}/\text{cm}^2$ [37.9]. R_{faradaic} represents the Faradaic resistance, which is in parallel with C_{dl} . Because of the double-layer capacitor effect, the impedance of the electrode is frequency dependent. At the same time, C_{dl} and R_{faradaic} themselves are both nonlinear time-varying components [37.10] that make the accurate modeling of electrode impedance difficult. Figure 37.2b shows the electrical circuit model for the interelectrode impedance in a dipole. R_s represents the electrolyte or tissue resistance between the two electrodes, known as *access resistance*.

The equivalent model shown in Fig. 37.2 is important from the safe stimulation point of view, because it shows that the stimulation reaction at the electrode–electrolyte interface is a combination of several electrochemical processes occurring at different pathways, each of which results in different charge delivery mechanisms. There are two primary mechanisms involved for passing current from one medium to the other: capacitive charging (also known as non-Faradaic) or the Faradaic process (also known as oxidation–reduction reactions, or electrochemical reactions).

Capacitive charging involves the redistribution of charged chemical species in an electrolyte. It charges and discharges the so-called electrode double-layer capacitance. Ions in the tissue are attracted or repelled by charge on the electrode to produce pulses of stimulus current (ionic). No charge actually crosses the electrode–electrolyte interface, but rather charge builds up on either side, such as on the two plates of a capacitor. For a perfect capacitive electrode, R_{faradaic} in Fig. 37.2 is infinite, indicating there is no net charge across the interface via the Faradaic process.

Since there is no net charge transfer across the interface in a capacitive electrode, both electrode and electrolyte maintain electroneutrality at any time. As long as the charge density is below the limit that a capacitive electrode can tolerate, only charge redistribution occurs and capacitive charging is considered safe in the neural environment. When the direction of the applied current is reversed, the charge redistribution is also reversed and the charge stored by the capacitor in the first phase is recovered.

In a Faradaic process, the charge is injected from the electrode to the electrolyte and vice versa. There is a reduction process that acquires additional electrons occurring at the negative electrode and an oxidation process that removes excess electrons at the positive electrode. One may generally think of capacitive charging as representing charge storage and the Faradaic process as representing charge dissipation [37.11] or leakage.

Unlike the capacitive electrode, the products formed in the electrolyte in Faradaic charge injection cannot be recovered upon reversing the direction of current if the products diffuse away from the electrode–electrolyte interface. Hence, Faradaic reactions are divided into reversible and irreversible reactions. The degree of reversibility depends on the relative rates of kinetics (electron transfer at the interface) and mass transport [37.11]. If the kinetic process is fast relative to the rate of mass transport, the Faradaic reaction is reversible. With fast kinetics, the electrochemical products formed at the interface do not diffuse away from the surface and are still stored near the electrode interface. If the direction of stimulus current is reversed, those products can be reversed to their original forms. However, in a Faradaic reaction with slow kinetics, the electrochemical products are able to diffuse away from the electrode in the lengthy time frame and there is no effective storage of charge at the electrode interface. If the direction of stimulus current is reversed, those products cannot be reversed to their original forms. Thus, such a Faradaic reaction is irreversible. Irreversible Faradaic reactions result in a net change in the electrochemistry of the environment that leads to electrode dissolution, gassing, variation in the pH of the electrolyte, etc. It potentially creates harmful chemical species that are deleterious to the surrounding tissue as well as damaging the electrode. Thus, an important principle in long-term electrical stimulation is that irreversible Faradaic reactions should be avoided. Another practical implication of this principle from a circuit's point of view is that all of the charge injected into the tissue in one phase of a stimulation pulse has to be recovered afterward, preferably before the beginning of the next pulse. This requirement, which is generally known as charge balancing, is a safety measure that avoids charge accumulation in the tissue and has to be incorporated into all stimulation circuits [37.9]. The reverse charge should be applied as soon as possible before the newly created chemical species diffuse away from the electrode. However, this is not to say that the recuperation phase should take place immediately after

the first stimulation phase. A small interphase gap between the two phases is often useful in maximizing the stimulation effect [37.12].

37.1.2 Safety Issues

The use of stimulating electrodes in a neural environment should ensure that desired physiological effects are obtained and maximized while negative effects remain below a dangerous level. This section will not discuss the general safety requirements that apply to all the implanted electrodes, such as biocompatibility, but rather electrode performance under stimulation.

During stimulation, a large amount of charge is passed through the stimulating electrodes. A good stimulating electrode should be able to carry enough stimulus charge for neural excitation without exceeding the safety limit of the electrode. The maximum net charge (Q_{\max}) that an electrode can tolerate without causing any irreversible electrochemical reactions at the electrode–tissue interface and the electrode itself is given by $Q_{\max} = qA$, where q and A are the geometric charge density and the surface area of the electrode, respectively. For example, platinum (Pt) electrodes have a charge density limit of $0.05 \sim 0.15 \text{ mC/cm}^2$ [37.13], while the limit for activated iridium oxide is up to 3 mC/cm^2 [37.14]. For any clinical application, the maximum charge density for the electrode must be higher than its practical usage, and it is suggested that as large a safety margin between the practical usage and the limit as possible be reserved for safe stimulation.

Besides the charge density, the charge per phase is also important in terms of safe stimulation. The stimulus charge per phase is calculated by the integration of the stimulus current over the stimulation phase (pulse width) and is simply equal to the product of current amplitude and pulse width if the stimulus current is constant. Statistical results showed a significant correlation between first-order tissue damage and charge

per phase [37.15]. McCreery found that the thresholds for cochlear neuron excitation and damage were 1 and 3 nC/phase, respectively. Stimulating at charges greater than 3 nC/phase resulted in damage in myelinated axons. Since the iridium electrodes used in McCreery's stimulation experiment were pretreated to have an electrode charge density much larger than the charge per phase during stimulation, the neural damage was unlikely due to the electrode dissolution. The severity of the tissue damage increased with higher charge per phase [37.15].

Thus it is always better for a stimulator to supply a charge per phase that is just above the excitation threshold. This not only saves power consumption but is also considered safer by providing a wide safety margin to the limit of neural damage.

However, meeting these two requirements is not enough to guarantee safety. Electrode dissolution or gassing at the interface may still occur, mainly due to charge imbalance. The charge imbalance here indicates stimulation pulses in which the charge in the stimulation phase is different from the discharge phase. The previous discussion on charge density and charge per phase assume stimulation pulses with balanced charge. There is a maximum amount of charge that an electrode can tolerate. The accumulated net charge will cause an increase in the electrode voltage. The region of safe electrode voltage is known as the *water window* beyond which gassing and electrode dissolution will occur. Taking a platinum electrode, for example, the lower and upper bounds of the water window are about +0.8 and −0.6 V, respectively, when using an Ag/AgCl reference electrode [37.13], or +1.2 and −0.8 V, respectively, when using a calomel reference electrode [37.16]. Once the practical electrode voltage exceeds the safety limit (the breakdown voltage) defined by the water window, unintended biochemical reactions will occur at the interface. The byproducts formed could result in deleterious reactions with nearby tissue.

37.2 Implantable Cable Management

37.2.1 Current Limitations

For most implanted stimulation systems, the small stimulating electrodes are placed at the stimulation site, near the targeted muscles or nerves, while the stimulator itself is placed at a more spacious or convenient loca-

tion. The stimulator is connected to the electrodes via implantable cables (Fig. 37.1). These cables are composed of several wires that carry stimulus current to or from the electrodes. Assuming a dipole electrode configuration, each stimulation channel will require two dedicated wires to provide a stimulation path. Thus an

N -channel stimulator will have $2 \times N$ wires between the stimulator and the electrodes. If each cable contains m wires, it will subsequently require $2 \times N/m$ cables. The cable count will be even higher if a tripole (two anodic electrodes and one cathodic electrode) configuration is used. Due to the surgical difficulty of implanting many cables, the number of stimulation channels is often limited by the maximum number of cables that can be implanted. In this section, two detailed examples are given to illustrate how this limitation affects the design of implant systems.

The first example that shows the importance of reduced cable count is the usage of a grommet in the Finetech–Brindley bladder control implant [37.17], which is one of the most successful implants in humans with both CE and FDA (US Food and Drug Administration) approvals [37.18]. The CE marking is a mandatory conformity mark placed on many products in the European Union (EU). A CE-marked medical device meets all the regulations and requirements in the EU for medical devices. The Finetech–Brindley implant is able to stimulate sacral anterior roots of patients with SCIs to empty their bladder or urinate on demand. In the implantation procedure of the Finetech–Brindley implant, silicone rubbers were used for adhesion and sealing. However, the adhesion of silicone rubbers to the surface of implant parts could be degraded by the presence of a thin fibrous membrane between them, which compromised the hermeticity of the sealing [37.19]. This can be disastrous if the implantable cables run through a subarachnoid space because any hole in the seal will allow cerebrospinal fluid leakage. The solution in the Finetech–Brindley bladder implant was to apply a small grommet encompassing all the implantable cables to the subarachnoid space. The gap between the threaded cables and the inner wall of the grommet was filled with silicone rubber. By having a grommet to encompass all the cables, the growth of fibrous tissue is kept on the outside of the grommet and the inside is not affected. Additionally, the suitable stress tension provided by the grommet helps to achieve a water-tight seal and solves the potential leakage problem. A high cable count not only requires a larger grommet for implantation, but also increases the complexity of cable insertion and the difficulty of filling all the gaps during implantation.

Another example is the sacro-lumbar anterior root stimulator implant (SLARSI) [37.20], a stimulator designed by the Implanted Devices Group, University College London, to stimulate certain root levels for leg movements and bladder control. Ten completely independent channels are available in the stimulator

(see detailed root-channel mapping in [37.20]). In the SLARSI, the stimulating electrodes are implanted in the spinal canal at the cauda equina, while the stimulator is placed in the abdomen. Besides the same possible leakage problem as in the Finetech–Brindley implant, the functions that can be provided by the SLARSI are also limited by the interconnecting cables. In SLARSI, the stimulating electrode pairs are configured in a pseudotripolar manner with the two anodes in every stimulation channel shorted together. Thus the number of wires required by this pseudotripole configuration is the same as a dipole configuration. Therefore, 10 channels will need 20 wires in total, requiring 5 four-wire *Cooper* cables [37.21]. More functions would be obtained for a SLARSI system with more channels, but at present this is impossible because the available space in the inner body for cable implantation is very limited and surgeons are reluctant to implant more than 5 cables entering the spinal canal through the dura.

Besides space constraints, complex cable management approaches are usually rejected by implant surgeons due to the high risk of mechanical failure and infection [37.22]. Usually, several wires are packed into an implantable cable. Each wire is used to deliver a stimulus current, a power-supply voltage, a data stream, or a clock, depending on the application. If the insulation fails on only one wire inside the cable and the stimulator is off at the time, it will still be safe because there is no applied potential (voltage difference) between the exposed part of the broken wire and the internal body. Hence, there will be no pathway for the current to flow from the exposed part of the broken wire in such a condition. However, if the stimulator is on, current could flow between the exposed part of the wire and the electrodes. When two or more wires are exposed in a failure, current will also flow between the exposed parts because of the voltage difference between them, causing electrolysis. These would be severe safety hazards for the tissue near the exposed area.

It is desirable for future implants to be able to stimulate at many sites [37.23]. For example, by applying FES on many muscles at the same time, the paralyzed patient will not be limited to restoring simple leg movement but may be able to transfer or walk again. Much effort has been devoted to increasing the functionalities of stimulators without complicating the implantation procedure while maintaining a high level of reliability. It is desirable to have a better stimulation system that is able to manage implantable cables in a more efficient way, reducing the cable count.

37.2.2 Solutions

One approach to reducing the number of wires is to have a separate device at each site, the *BIONs* method [37.26] shown in Fig. 37.3a [37.24]. *BION* is an abbreviation for bionic neurons. The term *BION* refers to a family of wireless, injectable microelectronic modules developed by researchers led by Loeb [37.26] at the University of Southern California. The *BION* microstimulator is available from Advanced Bionics Corp., Valencia, CA. Each *BION* contains all the units in a central implant, and since each is placed at the stimulation site, there is no wiring. However, *BIONs* are not a panacea, not only because of their high unit cost but also because there are sites in the body where *BIONs* would be too large or too nonspecific (current is not confined to the target nerve). Some *BIONs* contain rechargeable cells that significantly increase their total size.

Another approach to reducing the wire count is to connect some of the anodes on the electrode cuffs to a common wire, but this leads to cross-talk between the channels [37.27]. In that case, an N channel stimulator will require $N + 1$ wires for linking the electrodes with

Fig. 37.3a,b Different cable management solutions: (a) *BIONs* approach, (b) demultiplexer approach (after [37.24] with permission from IEEE 2007)

the stimulator, provided all the anodes are connected together.

The third approach is to introduce a demultiplexer [37.28, 29] into the wire routing, as shown in Fig. 37.3b. The demultiplexer controls the destination of the stimulus current and is able to drive multiple electrode cuffs. This approach reduces the number

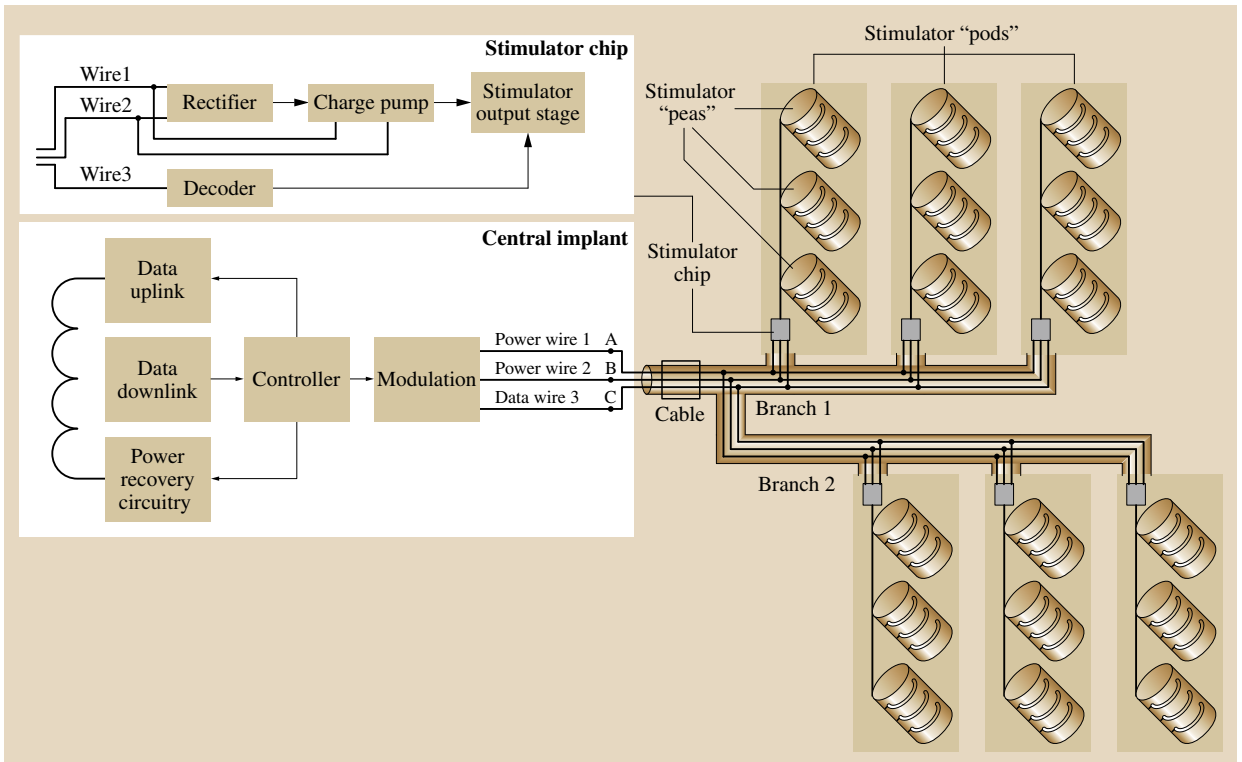

Fig. 37.4 Schematic illustration of branch-pod-pea structure (after [37.25] with permission from IEEE 2007)

	Branch	Pod	Pea						

Fig. 37.5 An example of a data packet sent in a data wire

of wires from the central implant, having short local wires between the demultiplexer and the electrode cuffs. However, stimulating many cuffs simultaneously will still require many wires between the central implant and the demultiplexers. Furthermore, in order to make the demultiplexer work, extra power wires and a data wire that contains the information for the cuff selection are required.

The fourth approach moves the stimulator output stage to the stimulation site. Thus, stimulus currents are no longer sent distantly to stimulation sites but generated locally at the stimulation site. When this is done, each stimulation channel only has to be allocated a few wires that are responsible for power and data (stimulation commands). To distinguish different stimulation channels, each channel will be assigned a unique address. This requires an extra address wire that identifies each individual channel. Thus different channels can be activated sequentially by appropriate stimulation commands from the data wire. The address can also be modulated together with the stimulation commands in the data wire. This reduces the total wire count, with a small price of longer data packets that contain both the selected channels and the stimulation commands. Although the required driving wire for each stimulation channel is increased from two (inward and returning wires) to three (two power wires and one data wire in serial bits), the same three wires can be shared by all stimulation channels. Figure 37.4 [37.25] shows the branch–pod–pea structure for the transmission of stimulation commands and power from the central implant to the stimulation sites. One stimulator chip is attached to each stimulator pod that contains several electrode cuffs (peas). All the stimulator chips share the same three wires as the input. In the data wire, the same bit stream is sent to all stimulator chips, but only the bits that specifically point to a certain pea are utilized (each pea in the pod is addressed). Figure 37.5 shows an example of a data packet sent in a data wire. The data

packet is processed only if the synchronization word in the packet matches the predefined sequence in the stimulator ASICs.

The address section in a multibit data packet locates the corresponding stimulator ASIC and the channel (i.e., the pea) to be stimulated. The rest of the data packet defines the amplitude and duration of the cathodic and anodic currents generated by the ASIC. The resolution of the current amplitude and phase duration decides the length of the data packet. A fine-controlled stimulus strength/intensity requires more bits in a data packet. Additionally, a long data packet usually features an error-check section, such as parity check, to check for errors from either transmission or data decoding. A data packet that fails the error check is discarded and not utilized by the stimulator ASIC. In this scheme, the stimulus current is generated onsite instead of in the central implant. Thus, it avoids sending different stimulus currents directly to the peas and using many implant cables. Therefore, the branch–pod–pea structure of the implant system greatly reduces the number of wires routed to the stimulation sites and is able to stimulate more stimulator peas. The feasibility of such a system requires the design of a stimulator output stage small enough to fit at a stimulation site, which is usually spatially tight. The integrated circuit method is an existing solution to minimize the size of many electrical components by providing high-density integration.

In order to ensure fail-safe operation, the current between interconnecting wires exposed in a failure has to be charge balanced. If the average voltage of each wire is identical, there may be current from one exposed wire to another at a certain time. But shortly there will be current in the reverse direction, which will neutralize the net charge. Since the charge is always balanced over a long time period, it will not cause any harm to nearby tissue. Thus, instead of dangerous DC, AC signals with the same DC components are transferred in the wires [37.7].

37.3 Design of Stimulator Output Stage

The stimulator output stage is the interface between the digital control unit and biological environment (i.e.,

stimulating electrodes and nerve tissue). The stimulator output stage delivers stimuli (stimulation pulses) to

the neural interface at a suitable frequency and is composed of a stimulus current generator and an output stage circuit (see below).

37.3.1 Stimulation Pulses

Stimulus waveforms are generally either monophasic or biphasic in shape. A monophasic stimulus (Fig. 37.6a) consists of repeating unidirectional pulses. Biphasic waveforms can be realized in various forms, as shown in Fig. 37.6b–d. Each of them contains a cathodic phase where stimulus current flows through neural tissue in one direction and an anodic phase in which the current flows in the reverse direction.

Monophasic pulses are more efficient in stimulation, requiring a smaller stimulus current to recruit muscle contractions than biphasic pulses. Additionally, the hardware used to generate biphasic pulses is more complicated than that for monophasic pulses. However, biphasic pulses are used almost exclusively in current implantable stimulators because they prevent or minimize damage to stimulating electrodes and the underlying tissue. It is important that the charge injected into the electrode–tissue interface in one phase should be equal to the charge that comes out of the interface in the following phase. Thus there is no net charge accumulation at the interface. In some literature, the net charge accumulation is measured by an equivalent DC current. The product of the DC current and the stimulation time gives the net charge for a certain period. The symmetrical cathodic and anodic phases in Fig. 37.6b are easy to generate, and the net charge is zero at the end of a stimulation pulse. However, a large anodic current that has the same amplitude as the cathodic current may elicit another stimulation response. This complicates the stimulation effect. Thus the anodic current is usually limited to a certain percentage of the cathodic current (Fig. 37.6c). In Fig. 37.6b, c the anodic phase is active and square in shape. It is also possible to have a passive anodic phase for charge balance. The passive phase is achieved by shorting the stimulating electrodes via a discharging switch in series with either a blocking capacitor or a capacitive electrode whose electrode–electrolyte interface serves as a good capacitor. In the passive phase, the anodic current is at its maximum at the start of the anodic phase and decreases exponentially with time. Passive discharge is able to achieve a high degree of charge balance if the passive phase is long enough. However, compared with active discharging, passive discharging requires a longer recuperation time, which limits the maximum stimulation frequency.

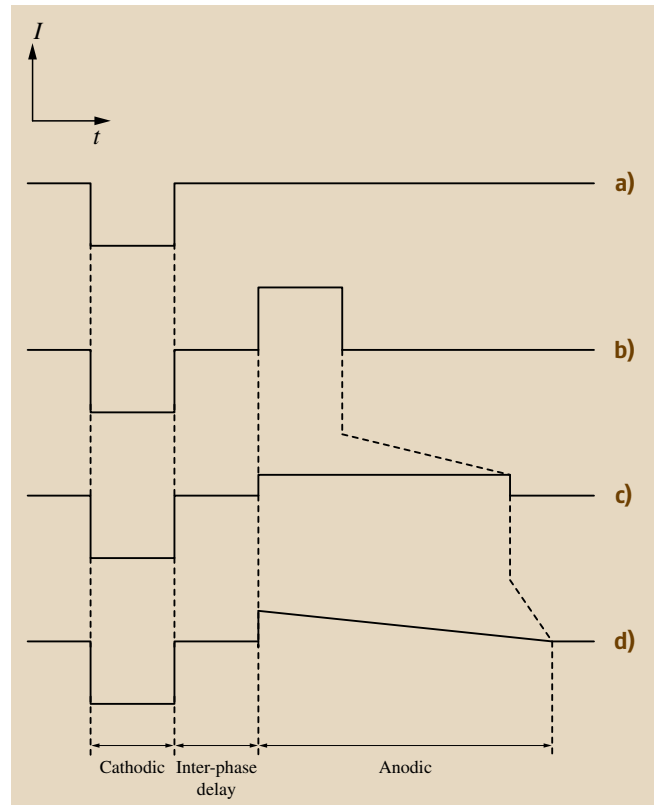

Fig. 37.6a–d Different stimulus shapes. Monophasic (a); biphasic (b)–(d)

However, for FES applications, which usually lie in the range of several Hertz to 50 Hz, passive discharging is able to achieve a charge balance as good as active discharging.

37.3.2 Current Generator Circuits

The current generator circuit is a key block in the stimulator output stage. It converts the digital control signals into an analog stimulus current or voltage and passes it to the output stage circuit, which is in direct contact with stimulating electrodes and nerve tissue. The current generator circuit could be either current mode [37.30] or voltage mode [37.31], realized by corresponding circuits as shown in Fig. 37.7a, b. In voltage mode the stimulation load is connected to a bipolar voltage source that generates both positive and negative voltages across the load, while in current mode a biphasic current from the source is supplied to the load.

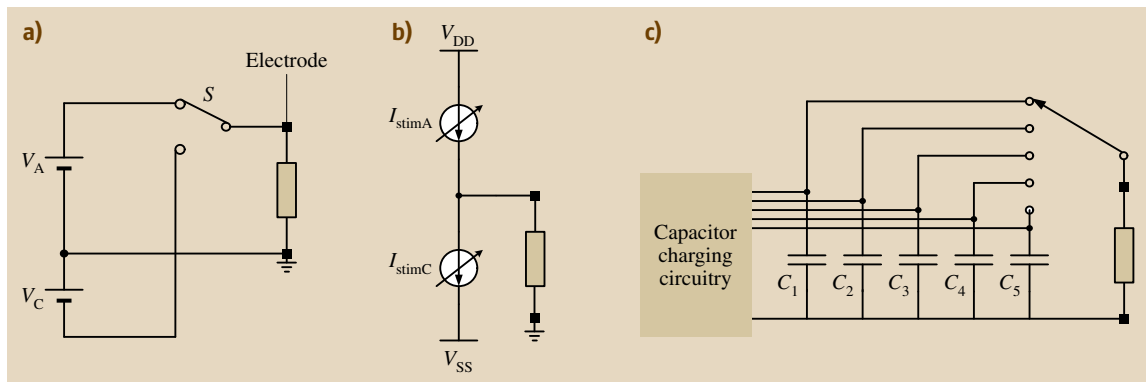

Fig. 37.7a–c Different stimulation modes: (a) voltage mode, (b) current mode, (c) charge mode

For voltage-mode stimulation, the switches on the stimulation path are realized by transistors whose voltage drop can be reduced to almost zero by increasing the transistor's aspect ratio (W/L). Thus it is possible that the total power consumed from the supply of voltage-mode stimulation is close to the load power itself, which results in an efficiency close to 1. For current-mode stimulation, besides the switches, there are also one or two current generator circuits. The number of current generators depends on the power-supply configurations. In order to provide a constant stimulus current, the current generator circuit should have a large output impedance, much larger than the load impedance. This is usually done by cascading several transistors in a stack. The current generator circuit realized by a cascode topology requires an additional voltage drop across the current generator circuit and dissipates substantial power in the output transistors. This is a waste of energy and reduces the voltage headroom available for the stimulation load. In current mode, the voltage supply rails and the stimulus current are usually kept constant during stimulation. Thus the power consumption from the supply (stimulus current \times supply voltage) is also constant. This wastes a significant amount of power at the beginning of stimulation. Since power efficiency is of importance in most implant applications, voltage mode seems to be the right option. However, the magnitude of the current delivered to the tissue is dependent on the interelectrode impedance (Ohm's law). Thus in voltage-mode stimulation, the stimulus current is affected by the interelectrode impedance variation. Hence it is difficult to control the exact amount of charge to the electrode and tissue because the charge is a product of the stimulus current and the stimulation time. Theoretically, voltage mode may find applications in which the interelectrode

impedance is fairly stable. But in practice, due to tissue growth over electrodes [37.32], the interelectrode impedance is difficult to predict. To address the safety associated with charge delivery, voltage-mode stimulators usually feature extra complexity to measure the charge flowing through the load, such as an integrator circuit. However, in current mode, the current generator circuit presents a much larger output impedance than the electrode–tissue impedance; the influence of interelectrode impedance variation to the stimulus current is small. Therefore, the amount of charge delivered per stimulus pulse is easily controlled. Hence, the safety level of current mode is higher than that of voltage mode.

Recently, some researchers have proposed another stimulation mode, known as charge mode. It combines some characteristics from both voltage-mode and current-mode stimulation. In charge mode, the load absorbs energy either from the electrode capacitance of previously charged electrodes [37.33] or from a bank of capacitors [37.34, 35], as shown in Fig. 37.7c. The capacitance provides neither constant current nor constant voltage, but rather transfers the charge to the load. It applies a voltage waveform that is an approximation of the waveform that would appear at the load if a current mode was applied. Since the charge is delivered to the electrode directly from intermediate voltage supplies (the capacitors), it avoids the substantial unnecessary power consumption in the current source circuit as well as providing large voltage headroom. However, the impedance of the energy-storage capacitors may be comparable to the electrode impedance, which limits the amount of charge that can be transferred. As a solution, it may be required to precharge the storage capacitors to a higher voltage level before sharing the charge with the stimulation load. Charge-mode stimula-

Table 37.1 Comparison of different stimulation modes

Performance	Voltage mode	Current mode	Charge mode
Voltage compliance	Low	High	Low
Power efficiency	High	Low	High
Safety on charge delivery	Low	High	Medium
Stimulation-induced neural response	Better	Good	Better
System complexity	Size	Small	Large
	Resolution	Low	High

tion saves power because some of the charge supplied to the stimulation load is recycled from some other capacitance instead of being taken directly from the power supply. Therefore, it achieves a power efficiency higher than current-mode but lower than voltage-mode stimulation due to extra losses during precharging and sharing [37.36]. Similar to voltage mode, the exact amplitude of stimulus current in charge mode is not controlled except for limiting the maximum amplitude. In charge mode, the charge supplied to the load is from intermediate sources, so the charge to the load does not exceed the charge on the capacitor source, which is limited by the capacitance and the voltage across the capacitance. Thus the charge to the load is somehow controlled. It provides a better safety standard than voltage mode, but not as good as current mode. The disadvantage of charge mode is that it requires large capacitors (which act as voltage sources) that tend to be bulky and occupy lots of physical space. Kelly et al. used five 1 μ F capacitors for a 15-electrode stimulation system [37.34], which would increase for more electrodes. It is also difficult to achieve fine resolution in both voltage-mode and charge-mode compared to current-mode stimulation since the former two are an approximate method of producing a current pulse, and increasing the resolution requires more voltage sources or capacitors.

Unlike current mode in which the stimulus current is constant and lasts for a certain period of time, voltage mode and charge mode are comprised of both high- and low-frequency components at the output spectrum. Since the true neural stimuli also contain high- and low-frequency components, voltage mode and charge mode are believed to be physiologically more efficacious in stimulation [37.35].

The ultimate goal of FES stimulation is to achieve more natural control of movement of paralyzed muscles. This certainly requires a multichannel stimulator that is able to stimulate many nerves. The size constraint excludes charge-mode stimulation because of the bulky storage capacitors. A more natural stimulation ef-

fect also requires a wide range of different stimulation strength that is best given in the current-mode configuration. Additionally, current-mode stimulation also gives the best safety standard in terms of charge delivery. Table 37.1 summarizes the performance of three different stimulation modes in terms of voltage compliance, power efficiency, safety on charge delivery, stimulation-induced neural response, and system complexity. The voltage compliance is the minimum voltage drop across the stimulus source. In current mode, the voltage compliance is the minimum voltage across the current generator circuit at which the current generator still provides a high output resistance [37.37].

Due to the aforementioned merits offered by current-mode current generators, current generator circuits are extensively used for implantable neural stimulators [37.30, 38–54]. The full-scale output current varies from about 100 μ A to 25 mA and the resolution from 3 to 8 bits, depending on the application. Desirable features for a current generator circuit for use in implantable stimulators are (1) small output voltage compliance, (2) high output impedance, (3) good linearity, (4) low power consumption, and (5) small silicon area. Table 37.2 summarizes the performance of current generator circuits in various topologies.

37.3.3 Safe Output Stage Circuits

A current generator is only responsible for generating stimulus currents while it is the output stage circuit that guides the stimulus current to the neural tissue in a safe manner. A safe stimulation pulse received at the tissue end should be charge balanced. However, perfect charge balance is difficult to obtain. Various factors, including semiconductor failures, software faults in the implant microcontroller, parametric shift after implantation, crosstalk between adjacent stimulation channels, and cable failures, can all lead to charge imbalance [37.55]. The outcome of charge imbalance is devastating because any excess charge accumula-

tion over time leads to damage at both the stimulating electrodes and neural tissue. The electrode itself could dissolve into the solution if overdriven. The metallic cations could form toxic products with the anions in the solution. Usually, a high level of charge imbalance also involves gassing at the electrode–tissue interface, which disturbs the normal pH balance in the solution. A shifted pH level can have a significant effect on cell function, such as destruction of tissue [37.56].

Charge imbalance can be corrected by actively monitoring the change at the neural interface or by the use of capacitive coupling.

Monitoring

Monitoring can be applied to at the stimulator–electrode–tissue interface (Fig. 37.8a). Approaches include using a window comparator to monitor the inter-electrode voltage [37.57], an on-chip sinusoidal wave-

Table 37.2 Summary of various current generator circuits for implantable stimulators

Current generator	Full-scale current	Power supply (V)	Resolution (bit)	Tracking error ^a	Linearity ^b
Binary-weighted transistors with single bias [37.46]	600 μ A	± 7	4	7.24%	No data

Binary-weighted transistors with single bias [37.53]	4 mA	5	5	source = sink	DNL: 0.10LSB; INL: 0.37LSB
Binary-weighted transistors with digital driving [37.54]	1 mA	5	4	active sourcing + passive sinking	DNL: 0.032LSB; INL: 0.065LSB
An array of unity current generator [37.52]	5 mA	3	8	active sourcing + passive sinking; 5% error between cathodes (sources)	1%
Identical transistors with binary-weighted bias [37.44]	400 μ A	± 5	8	5.74%	DNL: 2.11LSB; INL: -3.11 LSB
Active feedback [37.30]	600 μ A	± 6.5	6	1.2%	DNL: 0.15LSB; INL: -0.16 LSB
Voltage follower [37.51]	1.3 mA	No data	No data	source = sink	No data
Voltage-controlled resistor with analogue DAC [37.38]	210 μ A	5	5	< 1%	Degraded linearity in saturation region

^a Tracking error is the mismatch between sourcing (cathodic) and sinking (anodic) currents in one current generator circuit or between sourcing currents in different current generators.

^b Two parameters are commonly used to describe the linearity. The differential nonlinearity (DNL) defines the difference between the ideal step amplitude and the real step amplitude and the integral nonlinearity (INL) defines the maximum difference between the ideal output and the real output of the current source. Those nonlinearities are usually expressed in LSB units (where one LSB corresponds to the amplitude of an ideal step).

^c The same DAC current is guided to the stimulation load by a switch array as either cathodic or anodic current.

^d The silicon area refers to the silicon occupation for realizing one current generator circuit. In the case of actively biphasic stimulations, the current generator circuit includes both current source and current sink parts. If there are certain circuits shared globally by different current sources/sinks, such as a voltage bias generator, the silicon area for the global circuit is divided and proportionally allocated to each current generator circuit. The area data is not listed in the table if the literature data includes more circuits than the current generator circuit.

^e n in the formula is the number of channels among which the multi-bias generator is shared.

form to measure the interelectrode impedance [37.58, 59], and an integrator to monitor the stimulus charge delivered over stimulation periods [37.60]. The measured result is compared with a predefined reference value and the output is used as an input to control the next stimulation phase. Thus, in the next phase, the output stage circuit may be subsequently switched off to prevent neural damage or supply additional current in the desired direction to neutralize the net charge. The advantage of this approach is volume saving since the monitoring circuit can be integrated with the output stage circuit. However, the monitoring circuit increases the stimulator complexity, which itself increases the probability of semiconductor failure.

Capacitively Coupled Shorting

Capacitively coupled shorting places a blocking capacitor (known as a coupling capacitor in some literature [37.23, 61]) in the stimulation path. One end of the capacitor is connected in series with a stimulating electrode and the other end of the capacitor goes to the stimulation circuitry, which supplies the current, as shown in Fig. 37.8b. During capacitively coupled stimulation, the difference between the cathodic charge and the anodic charge (i.e., the net charge) is accumulated on the blocking capacitor. By periodically discharging the capacitively coupled load, the charge imbalance is corrected.

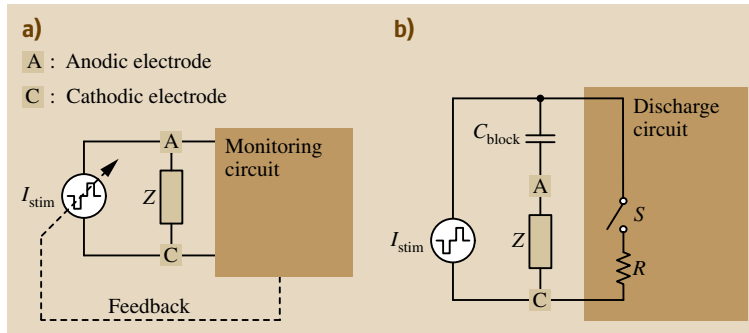

Fig. 37.8a,b Different safety features against charge imbalance in stimulator output stages: **(a)** monitoring and active control, **(b)** capacitively coupled shorting

The presence of the blocking capacitor provides several unique safety functions [37.62] to ensure safe stimulation. (i) Due to the *pass AC, block DC* characteristic of capacitors, they prevent direct current passing through the electrodes and tissue due to the absence of a complete DC stimulation path. (ii) The blocking capacitor helps to limit the maximum net charge and charge per phase during stimulation. For a given power supply V_{DD} , the worst-case charge density that a blocking capacitor C would allow is $V_{DD} \cdot C/A$, where A is the electrode area. If this is less than the maximal allowable charge density for the electrode material, the electrode cannot be overcharged by the stimulator.

Compared with monitoring techniques, the capacitive coupling approach with a blocking capacitor is relatively simple because of its unique safety features, which provide solutions to ensure charge balance and prevent excess stimulus charge in the event of failure.

However, for high-intensity stimulation, blocking capacitors are large in volume. For example, to recover partial leg movements, stimulus currents of about 1 mA intensity and 1 ms pulse width may be required. The aim is to minimize the voltage *wasted* across the blocking capacitor so that most of the power supply voltage can be made available to the load. To calculate the required capacitance, the following elementary equation may be used:

$$C = I_{\text{stim}} \frac{\Delta t}{\Delta V}, \quad (37.1)$$

where I_{stim} is the stimulus current amplitude, Δt is the stimulus current pulse width, and ΔV is the change in voltage across the blocking capacitor during stimulation. For this numerical example, to limit the capacitor voltage drop, to, say, 0.5 V, a 2 μF capacitor is required. Clearly, it is impractical to implement such a large ca-

pacitor on silicon due to the size and cost constraints, thus the use of off-chip surface mount capacitors. The blocking capacitor value may be reduced at the expense of a larger voltage drop across it, but this will result in a higher supply voltage. Due to the large physical size of blocking capacitors, stimulator designers would like to avoid their usage for applications with many channels.

In [37.63], a high-frequency current-switching (HFCS) stimulation scheme was proposed to mini-

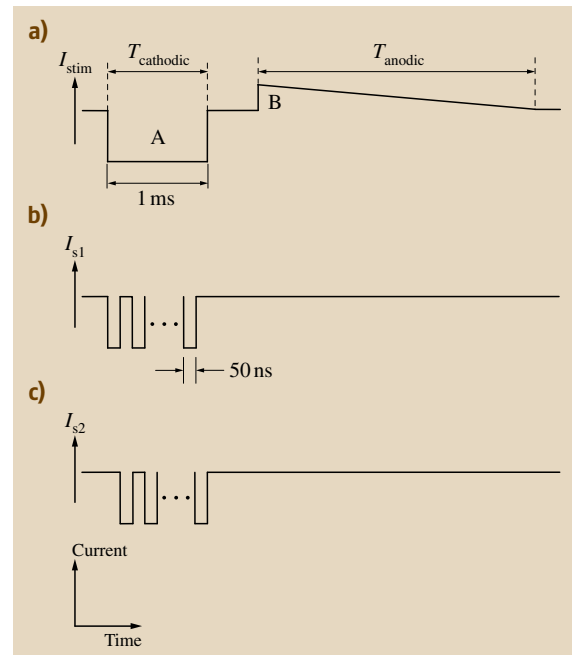

Fig. 37.9a-c Waveform illustration of HFCS technique. The long cathodic phase **(a)** is divided into two complementary high-frequency pulse trains **(b)** and **(c)** while the discharging phase remains a long and passive period (after [37.54] with permission from IEEE 2008)

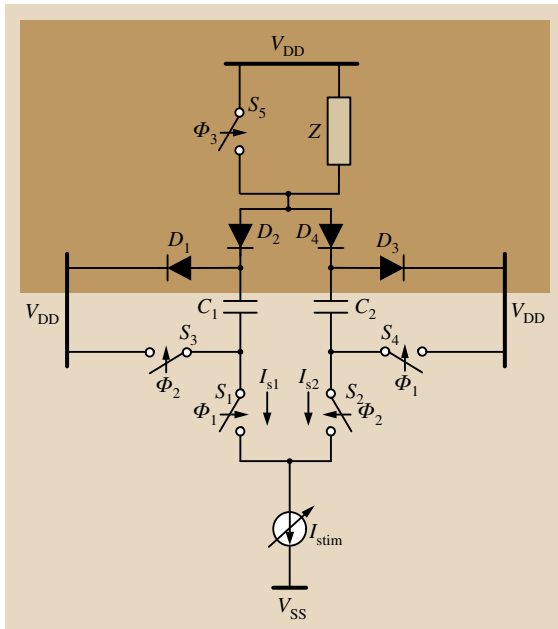

Fig. 37.10 Circuit diagram for HFCS output stage using parallel-blocking-capacitor configuration

mize the blocking capacitor from the microfarad range to tens of picofarad. It is based on the idea that a long continuous stimulation phase can be divided into two complementary high-frequency trains, as shown in Fig. 37.9 [37.54]. Thus, instead of a large off-chip capacitor that can accommodate a stimulation pulse in milliseconds, only two small capacitors that only need to accommodate pulses tens of nanoseconds in duration are required. According to (37.1), the output stage based on HFCS only requires subnanofarad capacitors. Thus, the complete stimulator output stage

37.4 Conclusions

One of the most important requirements for implantable stimulator design is its reliability at neural interfaces in both long-term and short-term usage. A safe stimulation system should maintain the original properties of implanted devices, stimulating electrodes and neural tissue. This is necessary to avoid any deleterious outcomes that might harm the stimulation environment. This chapter has provided an overview of the safe usage of stimulating electrodes, implantable ca-

Fig. 37.11 Circuit diagram for HFCS output stage using series-blocking-capacitor configuration

can be fully integrated on a single silicon chip. Figures 37.10 and 37.11 show two different circuit topologies to implement the HFCS output stages, namely, the parallel-blocking-capacitor configuration [37.54] and the series-blocking-capacitor configurations [37.64]. A complete multichannel stimulator output stage utilizing an HFCS technique is reported in [37.54] with a silicon occupation of only 6 mm^2 .

The charge balance of an HFCS stimulator relies on passive discharging using the capacitance of platinum electrodes. The measured direct current in the HFCS stimulator output stage under various FES stimulation profiles were all smaller than 12 nA , well below the safety limit for implantable stimulation [37.54].

bles, and stimulator output stages. Various methods and solutions have been discussed in terms of system complexity, physical size, level of safety, and circuit performance. As technology evolves, new solutions in circuit and system domains are expected to emerge. However, before any new solution can be applied in human beings, it must be subjected to thorough performance and reliability evaluations and in vivo and in vitro trials.

Cardiac Pacer

38. Cardiac Pacemaker Systems

Armin Bolz

Pacemaker technology is one of the largest milestones in Medical Technology. Over the past five decades millions of patients benefited from the advantages of this masterpieces of engineering.

Today all types of *bradycardia* and most *tachycardias* can be treated successfully. Pacemakers improve the quality of life significantly. They help to avoid syncope and dizziness. Pacemakers also support the heart and improve the *cardiac* output. State of the art pacemakers are no longer simple pulse generators but cardiac rhythm management systems.

38.1	Structure of a Pacemaker System	768
38.1.1	The Programming Device	768

Pathological changes in the excitation formation or conduction within the heart are divided into bradycardiac (decelerating) and tachycardiac (accelerating) clinical characteristics. If there are bradycardiac changes, the cardiac output is usually too low, causing the patient to suffer from dizziness, a low maximum stress level, and even problems with consciousness. In these cases, cardiac pacemaker therapy can allow the sinus rhythm to be restored and the symptoms can either be relieved or eliminated altogether.

The idea of electrically stimulating the heart dates back to the beginning of the last century with the work of Burns and Aldini (a nephew of Galvani). But it was 1927 by the time Hyman built the first functioning external pacemaker, a small electric clockwork-driven generator. In 1948, Shockley, Bardeen, and Brattain invented the transistor and made it possible to drastically reduce the size of electric switching units, which also advanced the development of pacemaker design. The first implantable pacemaker was implanted in 1958 by a Swedish doctor named Elmquist. This device was

made of 20 discrete components and weighed about 180 g. Pacemakers today weigh about 60 g and have the functionality of a small computer.

Pacemaker therapy is based on the delivery of current pulses, which lead to the artificial depolarization of some cardiac cells. They go across the conduction system of the heart, as well as across the *gap junctions* (intercellular ionic bonding channels, which serve to transmit the excitement directly from cell to cell), triggering a complete contraction of the heart. Based on this triggering effect of artificial pulses, this is referred to as the *all-or-nothing law*. In principle, the current pulses can be applied in four different ways:

Transcutaneous stimulation: In rare cases, the heart is stimulated via externally applied electrodes. In principle, this is possible, but this way is largely ineffective due to the relatively long distance to the heart. This requires high current intensity, which, in turn, triggers unwanted contractions in the skeletal muscles. External stimulation only makes sense in emergencies, e.g., when using an external defibrillator.

Esophagus stimulation: Esophagus stimulation is a minimally invasive procedure. Here, a catheter is advanced via the mouth or nose into the esophagus so that the electrodes come to rest near the atrium of the heart. This approach is mainly used for diagnostic purposes since the atrial position allows better differentiation of atrial and ventricular action. Stimulation within the esophagus does cause pain, however, which kept this method from gaining widespread practice.

Transient intracardial stimulation: In many cases, bradycardia is only temporary, requiring only temporary therapy (in general terms, this is referred to as transient stimulation). This is used for the following indications:

- Asystoles or external ventricular bradycardia with acute sinoatrial (SA) and atrioventricular (AV) blocks
- Acute conduction defect in the case of a recent anterior myocardial infarction
- Complicated pacemaker exchanges
- As a prophylactic during cardiological operations
- Acute poisoning, especially with pharmaceuticals, such as digitalis or antiarrhythmics

In these cases, a catheter is pushed into the right ventricle via a venous access. Alternatively, so-called

heartwires (flexible, insulated wires with a needle at both ends) are fixed in the heart through the chest wall. This is especially suitable for open-heart surgery, since there is already direct access. Pulses are generated via an external stimulator.

Intracardial stimulation using implants: Especially common, however, is permanent stimulation for the rest of the patient's life, for example, when the patient suffers from the following conditions:

- Considerable defects in the auricular stimulus conduction system, such as SA or AV blocks of the second or third degree or fascicular blocks
- Bradycardias and arrhythmias after cardiac infarction
- A sick sinus node (sick sinus syndrome)
- Carotis sinus syndrome (this clinical condition is characterized by an oversensitivity of the pressoreceptors in the carotis sinus, where, for example, heart activity is limited when one turns one's head)

Technically, all methods are very similar. Clinically, however, the use of implants is especially important, so in what follows, implant technology is discussed exclusively.

38.1 Structure of a Pacemaker System

A pacemaker system consists of an external programming device, the actual cardiac pacemaker, which contains a battery and electronic elements, as well as a pacemaker electrode (Fig. 38.1). The electrode is advanced almost exclusively via a venous access (e.g., the vena cava sup.) underneath the collarbone into the right half of the heart and anchored there. Afterward, the

pacemaker is connected and implanted subcutaneously in a pocket of skin.

38.1.1 The Programming Device

When the pacemaker is programmed, the system should be optimally adapted to the needs of the patient, and the

Fig. 38.1 Structure of a pacemaker system

lifetime of the battery should be maximized. With the long running times of today, it can't be assumed that the conditions on the day of implantation will remain constant over the entire lifetime of the pacemaker. It is therefore necessary to be able to adapt the pacemaker to changing conditions.

External devices that are usually based on a PC platform and drive manufacturer-specific short-range telemetric equipment are used for programming. This data transmission, usually based on inductive near-field coupling in a range below 100 kHz, allows the implant to be queried/reprogrammed. To do this, the programming head is first placed on the skin above the pacemaker housing. Afterward, the current pacemaker parameters, as well as diagnostic values (markers, event histograms, ECG, etc.), are transmitted out and evaluated. Finally, the updated parameters are reloaded into the implant. The most significant programmable parameters include the following:

- Stimulation frequency (lower and upper limits)
- Pulse amplitude and duration
- Input sensitivities
- Refractory periods
- Hysteresis (difference between the intervention and stimulation frequency)
- Av delay and hysteresis
- Pacemaker mode

The number of programmable parameters is meanwhile in the triple digits, and optimum pacemaker programming requires special knowledge, requiring supplemental education, even for cardiologists. For this reason, automatic functions are being increasingly implemented that allow the implant to adapt itself. In addition, Web-based expert systems are being considered, or are already in the test phase, that are supposed to ensure the constant availability of the most current knowledge. For more detailed information, one must refer to the respective pacemaker manuals or the corresponding special literature [38.1–4].

38.1.2 The Pacemaker

The pacemaker itself consists of a battery, the electronics, a hermetically enclosed titanium housing, and an epoxy resin connector for accommodating the electrode (Fig. 38.2). Nowadays, lithium-iodide batteries (open-circuit voltage about 2.8 V, capacitance about 1 Ah, inner resistance a few 100 and 50 k Ω) are usually used as a power source. With this type of battery, the anode is

Fig. 38.2 Cross-section of a DDD pacemaker (source: Biotronik)

made of lithium and the cathode of iodine. In addition to its extraordinarily low self-discharge ($< 1\%$ /year), the lithium-iodide battery offers high stability of the inner resistance beyond the discharge time. Only at the end of the service life does the open-circuit voltage rapidly drop. Lithium-iodide batteries thus offer the greatest possible reliability with their long lifetime, small dimensions, and light weight. Today, they have running times ranging from 5 to 10 years with this technology [38.3].

The trend toward primary cells, or rechargeable batteries, which are at the beginning of their technical development and are occasionally discussed even today, offer no major advantages. The supposed prolonged service life must be weighed against the drastic increase in aging-related failures after about 10 years, which makes an implant change recommendable after this time, anyway.

The electronics are usually designed as a hybrid, multichip module. The once-used thick film technique is being increasingly replaced by multilayer ceramics due to the increasing complexity of the circuits. Recently, brand new PCB technologies (e.g., Dycos-trate) have been attracting interest, which, thanks to their flexibility, allow electric connection technology to be considerably simplified, thus improving the device quality.

38.1.3 The Pacemaker Electrode

The pacemaker electrode or probe establishes the connection between the pacemaker and the heart. It consists of a connector, i.e., the plug for connection to the

Fig. 38.3 Schematic structure of a pacemaker electrode

pacemaker, the electrode conductor, and the electrode tip (Fig. 38.3). The connector configuration has been standardized according to the IS-1 standard [38.4], so that all modern electrodes can be connected to any pacemaker.

One of the main technical challenges is the high bending stress of about 40 million load changes per year. For this reason, electrode conductors nowadays are made of four individual coiled wires, which provide the highest possible reliability with high flexibility. With a coiled wire, the bending radius is reduced, which reduces the alternating load stress on the feed line material (usually MP35N stainless steel). For this reason, electrode breakage is no longer a major problem.

The newest developments in the area of multifocal stimulation (Sects. 38.3.6 and 38.3.7) sometimes require very thin electrodes. In these cases, so-called DFT wires are used, which are special wires with a sheath made of MP35N and a silver core. These guarantee low electrical resistances while also having high mechanical strength.

Special demands are placed on the insulation material. It must be biocompatible and also be able to withstand the mechanical and chemical loads in the

body. Right now, insulation made of silicone and polyurethane are being used [38.3, 4]. Polyurethane has a much lower friction coefficient, which is why it is especially preferred when implanting several electrodes via the same vessel. Clinical experience has shown, however, that when there is minor contamination, which can hardly be controlled in production, this can lead to hydrolysis, and thus to possible aging/brittleness, which ultimately leads to a life-threatening short-circuit. For this reason, several tens of thousands of electrodes from different manufacturers had to be removed/replaced a few years ago, which is why silicone is the preferred insulation material today.

Furthermore, a distinction is made between uni- and bipolar pacemaker electrodes (Fig. 38.4). Unipolar means that the electrode tip acts as the cathode and the pacemaker housing (or another counterelectrode with a large surface area) acts as the anode. Due to the considerably greater surface area of the pacemaker compared to the electrode tip, the housing is also called an *indifferent pole*. Bipolar probes also work with a cathodic tip. The anode, however, is also placed in the distal electrode area (about 2.5 cm away from the tip). Bipolar probes are somewhat thicker and more rigid than unipolar electrodes since they have two feed line coils. It is hardly possible to repair electrode breakage.

Important advantages of bipolar probe technology are the insensitivity to electric potentials whose origins lie outside the area where the electrode tip was implanted (potentials of the skeletal muscle, P-wave for ventricular probes, R-wave for atrial probes) and the lower risk of muscle contractions, even if higher energy is delivered [38.1, 3]. In addition, interference due to electromagnetic couplings in the feed lines cancel each

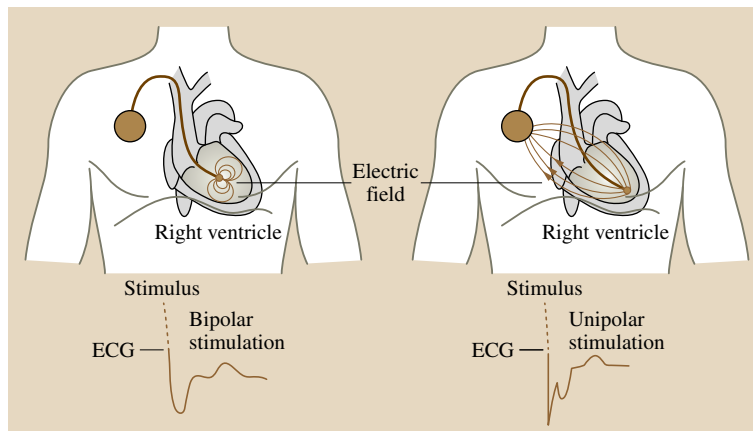

Fig. 38.4 Electric field distribution and ECG for uni- and bipolar stimulation

other out. A widespread compromise is the implantation of bipolar probes in the atrium of the heart (a smaller potential requires a higher sensitivity and the suppression of interference signals) and unipolar probes in the ventricle area.

The electrode head has direct contact with the endocardium. Its size, geometry, and surface structure are major determining factors for the stimulation and detection properties. A porous or fractal surface has proven advantageous [38.5]. The probe head is anchored using various fixation systems (Fig. 38.5). One distinguishes between electrodes with passive fixation (barblike anchor systems out of the insulation material of the electrode) and those with active fixation (system of screws on the electrode head). The former are preferred for electrode anchoring in the strongly divided surface of the right ventricle (trabeculae structure), and the latter is used for anchoring in the smoother right atrium. A hybrid type is the so-called J-electrodes, which ensure stable contact with the wall thanks to the J-shaped hook at the beginning of the electrode feed line. They are mainly used in the atrium. Probes without a fixation mechanism are used for transient pacemaker stimulation in emergency situations and can be easily removed again.

All described electrodes are fed transvenously to the right heart. They stimulate the inside of the heart and are therefore referred to as endocardial electrodes. Epicardial electrodes, which are applied to the outside of the heart, are no longer used for permanent pacemaker

Fig. 38.5a,b Passive (a) and active (b) anchorable probe heads of cardiac pacemaker electrodes. The top passive electrode is a so-called J electrode. Below this follow a bipolar and a unipolar standard electrode. The screw electrode, which must be actively anchored, is shown once with an extended tip (ready for screwing into the myocardium) and, next to this, with a retracted tip (to avoid complications when inserting the electrode in the heart)

therapy. At most, they play a minor role in pediatric applications.

Pacemaker electrodes are hollow on the inside. This allows a reinforcement wire (mandrin) to be inserted during implantation, which makes it easier to push in the electrode. The mandrin is removed again before the electrode is connected to the pacemaker.

38.2 The Functionality of a Cardiac Pacemaker

A cardiac pacemaker not only blindly stimulates at a defined rate but attempts to synchronize itself to the still-existing heart rhythm and only to intervene when needed. Its structure can thus be divided into three basic modules: (1) the input stage for detecting intracardial electrical signals, and thus physiological events, (2) the output stage for stimulating the heart, and (3) a control unit, which takes the physiological demands, such as the heart rate, synchronicity, etc., into account (Fig. 38.6). The complexity of the control unit is determined to a great degree by the type of illness and, therefore, the stimulation mode to be used. A special section is dedicated to this aspect (Sect. 38.3).

The Sensing Function

The input sensitivity of a pacemaker system describes its capability to detect electric signals from the heart in

the millivolt range and to interpret them as a contraction of the atrium/ventricle (perception, detection or sensing function). The fundamental structure of the input stage required for this is equivalent to that of an ECG amplifier [38.2], whereby the boundary conditions of an implant (size, supply voltage, energy requirement) sometimes demand special solution approaches.

To differentiate between physiological heart signals and interference signals, input filters are used in pacemakers. The filter characteristics have now been standardized (e.g., DIN 7505, Part 9) in order to establish binding safety standards. The greatest input amplification of a pacemaker after this stage lies between 30 and 70 Hz [38.6].

Furthermore, in clinical practice, an indirect measure for the frequency content of the electrical signal, the maximum slew rate, which is easy to determine by

Fig. 38.6 Fundamental block diagram of a cardiac pacemaker

means of differentiation, is used. In order for a signal to be detected as such by the pacemaker, it must exceed a certain slew rate. The limit values of the slew rate lie at 0.5 V/s for the atrium area and at 1 V/s in the ventricle.

Another parameter for defining the perception function is the signal's amplitude. The so-called perception threshold or sensitivity of a pacemaker is usually programmable. In the atrium, one strives for an amplitude of 2.5 mV . In the ventricle, values up to 10 mV are to be registered. Often, real signals lie considerably below this, however [38.1].

Another special feature is so-called *blanking*. The detection channel is connected to the same electrode as the output stage. The amplifier would be overdriven by the stimulation impulse and be put out of operation over a longer period of time. For this reason, shortly before delivering a pulse, the inputs are decoupled by a transistor, which is generally referred to as *blanking*. A few milliseconds after the stimulation pulse, the blanking switches are closed again.

Logical blanking follows physical blanking in the sense of a switch. This means that no detection events within a certain window after the pulse are evaluated by the following circuit. There are several reasons for this. For one thing, vibration processes, which are unavoidable when an amplifier is switched on again, for example, due to small voltage differences, are not misinterpreted as physiological events. For another thing, refractory periods can be introduced this way, similar to cellular behavior, where an input amplifier is switched to become insensitive. The advantages of such a refractory period are explained in more detail in Sect. 38.3 with the introduction of various pacemaker modes.

38.2.1 The Stimulation Function

The behavior of a stimulation system is determined by the actual impulse generator, the electrodes required for coupling, and the tissue through which the excitation current flows. A very detailed description of this system can be found in [38.5].

The Pulse Generator

Nearly all pulse generators are based on the principle of capacitor discharge, i. e., a so-called reservoir capacitor C_{res} is charged to a certain voltage via the switch S_1 during the passive phase and discharges itself into the tissue to be excited in the active phase via switch S_2 and an additional coupling capacitor C_c (Fig. 38.7). If the required stimulation voltage lies above the battery voltage U_{bat} , a charge-pumping circuit downstream multiplies the voltage by the factor n .

Fig. 38.7 Equivalent circuit of a stimulation system, consisting of a pulse generator, electrodes, and tissue

This setup prevents the battery from being directly coupled with the myocardium in the event of a single component defect (e.g., defective switch), which would lead to electrolysis and thus to damage to the surrounding tissue. This principle increases the safety of the stimulators and is referred to as *single failure safety*. The output voltage and current are thus in no way constant with respect to time, but drop nearly exponentially, depending on the impedance of the external components.

Since capacitive components (C_c as well as the limiting phase capacitances of the electrodes) are charged by the stimulation pulse, effective discharging between the individual stimuli must be ensured. This is done using a so-called autoshorting switch S_3 , which is closed during the passive phase.

The Electrodes

From an electrical engineering point of view, pacemaker electrodes are solid-state electrolyte interfaces. A detailed description of such systems can be found in [38.2]. They therefore have capacitive properties due to the Helmholtz layer and possibly oxidized top layers. C_H describes the specific Helmholtz capacitance in what follows, which only delivers the capacitance that is interesting for the circuit after multiplying with the geometrical electrode surface A . This way, surface modifications, which lead to a roughening and thus to a larger electrochemical contact surface, can be easily considered in the model. R_F correspondingly describes the Faraday resistance and R_L stands for the lead resistance.

The Tissue

The excitation of at least one heart muscle cell (myocyte) is required for electrically stimulating the heart, i. e., a depolarization of its cell membrane. In its resting state, the transmembrane potential is about -90 mV. If this value is increased by a depolarization voltage U_{dep} of about 30 mV, automatic depolarization, and thus the contraction, is initiated.

For stimulation using extracellular electrodes, a displacement current is therefore necessary beyond the cell membrane. The first approximation of the electrical equivalent circuit for the target organ consequently consists of a specific cell membrane capacitance C_m and a parallel ohmic resistance R_{extra} , which takes the extracellular space into account. There are three other approximately ohmic contributions in addition to this. $R_{fibrotic}$ represents the resistance of the thin layer of fibrotic tissue, which develops after implantation between the electrode and the place of stimulation. R_{tissue} describes the resistance of the tissue between the place of stimulation and the counterelectrode. R_{shunt} stands for a leakage current, which is not coupled into the target organ via the blood or other tissues, but flows directly into the counterelectrode.

All named elements are at least known in terms of their order of magnitude, so that quantitative estimations are also possible (Table 38.1). Using the Laplace transformation and simplifications

$$C_1 = \left(\frac{1}{C_{res}} + \frac{1}{C_c} + \frac{1}{C_H^{diff} A} + \frac{1}{C_H^{indiff} A_{in}} \right), \quad (38.1)$$

Table 38.1 Summary of the used parameters and their number values (after [38.7–10])

Parameter	Range	Average	Source
Reservoir capacitance C_{res}	5–20 μ F	10 μ F	10
Coupling capacitance C_c	5–20 μ F	10 μ F	10
Spec. Helmholtz capacity C_H	Polished surface Fractal surface	0.1–0.4 μ F/mm ² 10–500 μ F/mm ²	11 12
Lead resistance R_L	10–100 Ω	50 Ω	10
Geom. electrode surface A	1–20 mm ²	10 mm ²	10
Surface of the indifferent electrode A_{in}	Unipolar Bipolar	5–15 cm ² 20–100 mm ²	10 10
Pulse duration T	0.1–2 ms	0.5 ms	10
Membrane capacitance C_m		0.01 μ F/mm ²	13
Tissue resistance R	30–70 k Ω	40 k Ω	14
Shunt resistance R_{shunt}	0.1–2 k Ω	600 Ω	10
Depolarization voltage U_{dep}		30 mV	15

$$C_2 = \frac{C_m A}{2}, \quad (38.2)$$

$$R = R_{\text{fibrotic}} + R_{\text{tissue}}, \quad (38.3)$$

$$R_1 = R_F^{\text{diff}} + R_F^{\text{indiff}}, \quad (38.4)$$

$$R_2 = R_{\text{shunt}}, \quad (38.5)$$

$$a = (R_1 R_2 + R_1 R + R_2 R) C_1 C_2, \quad (38.6)$$

$$b = (R_2 + R) C_2 + (R_1 + R_2) C_1, \quad (38.7)$$

and the two poles p_1 and p_2

$$p_1 = -\frac{b - \sqrt{b^2 - 4a}}{2a}, \quad (38.8)$$

$$p_2 = -\frac{b + \sqrt{b^2 - 4a}}{2a}, \quad (38.9)$$

yield the minimum pulse voltage, referred to as the stimulation threshold, required for a successful stimulation

$$U_{\text{thr}} = \frac{2U_{\text{dep}}}{C_1 R_2} \frac{\sqrt{b^2 - 4a}}{\exp(p_1 T) - \exp(p_2 T)}. \quad (38.10)$$

Similarly, one also gets a relationship for the charge (important for calculating the service life), which must be taken from the battery for every stimulus [38.5]. The specific Helmholtz capacitance has special meaning for the development of new systems. With increasing C_H , both the stimulation threshold and the charge threshold decrease. Clinically, this means that electrodes with fractal surfaces have the lowest energy consumption, and thus guarantee the longest implant service life. In order to maximize the ohmic parts of the tissue at the same time, the electrode head should be as small as possible. This design – a geometrically small head with a high specific interface capacitance – has become a standard

38.3 Stimulation Modes

From a physiological standpoint, the two atria/two ventricles are always excited together. For this reason, a maximum of two stimulation sites – one in the atrial or one in the ventricular plane – and, correspondingly, a maximum of only two detection sites

Fig. 38.8 The stimulation threshold as a function of pulse duration. An effective stimulation can be achieved for amplitude values lying above the curve

under the term *highly ohmic electrodes* in the last 5 years.

Figure 38.8 shows the dependence of the stimulation threshold on the pulse duration. From the output voltage perspective, it is recommended to choose a large pulse duration in order to avoid switching on a charging pump, which involves high conversion losses. At the same time, however, it has become evident that longer pulse durations increase the charge consumption nearly linearly. From a clinical aspect, then, it makes sense to select the shortest pulse duration that is still possible without using a charging pump. To be able to specify a simple rule of thumb for optimizing the pulse parameters, the two terms *chronaxy* and *rheobase* have been empirically introduced, which can be determined from the stimulation threshold curve. The *rheobase* is a theoretical value and describes the minimum voltage that triggers an electric cardiac response for an infinite pulse duration. The *chronaxy* is the pulse duration at the stimulation threshold for a voltage twice the strength of the *rheobase*. Based on experience, the energetic optimum lies near the *chronaxy* [38.1].

are required. Based on this, the generally recognized NBG code was developed for defining stimulation modes.

The multifocal modes, which were recently introduced for special heart disorders (interatrial conductive

disturbance, cardiac insufficiency), allow biatrial/biventricular stimulation, but are not yet included in the NBG code.

38.3.1 International (NBG) Pacemaker Code

NBG code (NASPE/BPEG Generic Pacemaker Code), which has been applied since 1988, describes the global function of a pacemaker with the specification of a maximum of five letters, of which the first three are always used, and the fourth and fifth optionally [38.3].

The first letter refers to the stimulation site:

- V: Ventricle: Stimulation in the ventricle only
- A: Atrium: Stimulation in the atrium only
- D: Dual: Stimulation in both the atrium and the ventricle
- S: Single: Single-chamber stimulation in the atrium or ventricle
- 0: No stimulation

The second letter stands for the place of perception:

- V: Ventricle: Detection in the ventricle only
- A: Atrium: Detection in the atrium only
- D: Dual: Detection in both the atrium and the ventricle
- S: Single: Single-chamber perception in the atrium or ventricle
- 0: No perception

The third letter defines the operating mode, i. e., the pacemaker function, which is triggered by a perceived signal:

- I: Inhibited: The pacemaker stimulation is suppressed
- T: Triggered: A perceived signal leads to the pacemaker delivering the pulse
- D: Dual: Inhibition and triggering
- 0: No inhibition and no triggering

The fourth letter describes the programmability, telemetry, and frequency adaptation:

- 0: Not programmable
- P: Programmable: Up to two functions are programmable
- M: Multi programmable: More than two functions are programmable
- C: Communication: Data telemetry possible
- R: Rate modulation: Adaptation of the pacemaker frequency to a load-induced signal

The fifth letter refers to the antitachyarrhythmia function:

- 0: No antitachyarrhythmia function
- P: Pacing: Antitachyarrhythmia stimulation
- S: Shock
- D: Dual: Pacing and shock

A variety of possible pacemaker modes result from combining different detection/stimulation channels together with different operating modes. A detailed explanation can be found in [38.2]. In what follows, the two most common modes, the VVI and the DDD modes, will be described in more detail.

38.3.2 VVI Pacemaker

The VVI pacemaker is a single-chamber pacemaker, where one single electrode is anchored in the right ventricle. It detects the ventricular activity in addition to the fixed-rate ventricular stimulation of the V00 and inhibits its output when an intrinsic ventricular event occurs. Thus, a VVI system only stimulates when required, i. e., when the natural excitement fails, which is why it belongs to the group of so-called *demand pacemakers*. A schematic diagram is shown in Fig. 38.9.

The flow diagram in Fig. 38.10 shows the principal mode of operation. The basic interval and the refractory period of the ventricular detection channel are started at the same time. If an intrinsic event is detected within the refractory period, it is interpreted as interference and is discarded. If it is detected outside of the refractory period, the basic interval and refractory period counters are reset. If no R-wave is detected, the VVI pacemaker behaves like a V00 and stimulates after the basic interval is over.

In the functional diagram in Fig. 38.11, the ventricular stimuli are marked with “V”. As compared to the V00 principle, R-events are added now, which indicate

Fig. 38.9 Schematic diagram of the VVI pacemaker. The ventricular electrode (V) leads to a control and logistics circuit via an input amplifier (1) and a monoflop for checking the ventricular refractory period (2), which also evaluates the output of the basic interval counter (6). The stimulation channel is equivalent to that in the V00 pacemaker

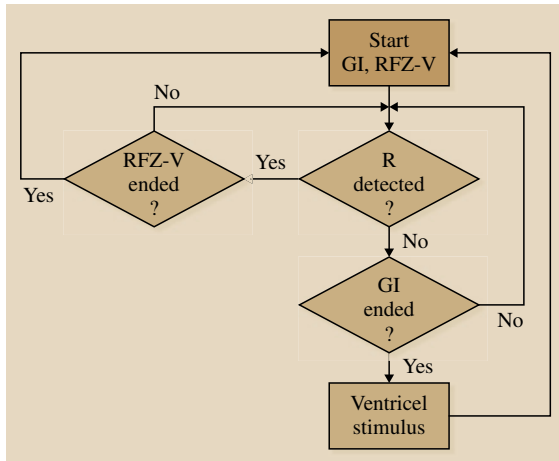

Fig. 38.10 Flow diagram of a VVI pacemaker

the detection of an R-wave. A third marking, plotted below the counter display, indicates the end of the artificial refractory period (RFZ-V) of the ventricular detection channel.

In the ECG, the first two stimulated events (V) are shown, which were triggered by the end of the basic interval. A natural event (R) follows this, which was detected outside of the refractory period and resets the counter. The pacemaker doesn't deliver a stimulation pulse, i. e., it is in inhibiting mode. Afterwards, there is an escape interval, since no intrinsic event is detected. This is followed by another normal basic interval. The ventricular extrasystoles (VES) that follow the stimulated event (V) are detected as an intrinsic cardiac excitement since they are outside of the refractory period, which causes the counter to be reset. Afterward, another escape and a basic interval follow with the associated ventricular stimuli.

Fig. 38.11 Functional diagram of a VVI pacemaker

Clinical Assessment of the VVI Pacemaker

The VVI pacemaker has an energy-saving mode. It only becomes active when there is no intrinsic cardiac activity (demand pacemaker). It also does not lead to parasystoles and avoids stimulation in the vulnerable phase. Like the VOO pacemaker, however, it is not able to adapt the heart rate to physical exertion. The main problem, however, is the loss of atrioventricular synchrony, which can trigger pacemaker syndrome.

VVI Pacemaker Application

Bradycardias can be generally treated with a VVI pacemaker. Extensive studies have proven in the last few years, however, that the mortality of patients with a VVI pacemaker are considerably higher than that of synchronously stimulated patients. Therefore, the use of VVI pacemakers only makes sense for patients with atrial flutter or fibrillation in connection with an AV block, as well as atrial paralysis (atrium which is not able to contract).

38.3.3 Two-Chamber Pacemaker

In the case of the two-chamber cardiac pacemakers, electrodes are applied to both the atrium and the ventricle to ensure synchronous stimulation. Two principal function options result from this – atrium- and ventricle-based actions. In the case of the atrium-controlled sequence, the basic interval counter and the newly added AV counter (which simulates the natural PR interval) always start at the same time. The ventricle-based sequence, on the other hand, uses a series connection of the two counters, whereby the AV counter must first run down before the timer can be started, and vice versa. The different approach can be especially well explained using the example of a DDD pacemaker.

Fig. 38.12 Atrium-controlled DDD pacemaker. Both the atrium and the ventricle have a detection and stimulation channel. The basic interval counter **6** is connected to the atrium control unit, which influences the ventricular control unit via the AV counter

The Atrium-Controlled DDD Pacemaker

The disadvantages of the DVI pacemaker, especially the danger of stimulation of an intrinsic atrial event in the vulnerable phase, are remedied with the DDD pacemaker (Fig. 38.12), which, from the rhythmology point of view, is a kind of *all-rounder* among pacemakers. It combines the AAI, VAT, and VVI functional modes.

Of all the pacemakers, the DDD pacemaker comes closest to simulating the physiological function of the

heart. DDD means that stimulation and detection are both possible in the ventricle and the atrium. The pacemaker also masters the trigger and inhibition mode.

The AV interval is started after every atrial excitation (natural or after the basic interval has been artificially induced). If no ventricular heart activity is detected, the ventricle is stimulated at the end of the AV interval. Ventricular extrasystoles (VES) reset the basic interval counter without starting an AV interval. This

Fig. 38.13 Flow diagram of an atrium-controlled DDD pacemaker

automatically leads to a compensation pause. The basic interval counter is reset as a consequence when one of the following three events happens

- An atrial stimulus is delivered,
- A natural atrial excitation has been detected,
- A natural spontaneous ventricular excitation occurs outside of the AV interval (i. e., a ventricular extrasystole).

In addition, after each event, the respective refractory periods are started. As a special feature, an atrial refractory period should be mentioned here, which begins after ventricular events, in addition to those already described. The task of this so-called postventricular atrial refractory period (PVARP) is to detect ventricular stimuli or to suppress their retrograde feedback to the atrium. Without these protective measures, this could easily lead to one's own output signal being self-detected, and thus to pacemaker-induced tachycardia. Details are shown in Fig. 38.13.

Detection and stimulation in the atrium (P, A) and ventricle (R, V) are shown in the first line of the functional diagram (Fig. 38.14). The small upward dashes indicate the end points of the refractory periods of the atrium, and the downward ones those of the ventricle. The second line of the functional diagram contains the basic interval counter with the refractory periods of the ventricles and the atria.

The bottom line is the AV counter, which has so-called AV hysteresis. The AV interval can be prolonged by means of a second trigger level as soon as the pre-

ceding atrial event has been stimulated and was not of a physiological nature. This way, the transit-time differences are compensated, which ensures constant good AV synchronization.

The third line in the functional diagram (Fig. 38.14) contains the surface ECG. The ECG first indicates an atrial pacemaker stimulation (A) with a subsequent artificial P wave. After the AV interval is over, the ventricle is stimulated and the PVARP is begun. After the timer has expired, the above-described cycle repeats itself.

Now a detected natural atrial excitation (P) follows. The basic interval counter is reset and an AV interval is started. Since this is a natural P wave, no AV hysteresis is used. During the AV interval, no ventricular excitation is detected, and therefore, after it is over, a ventricular pacemaker stimulus is delivered (V) and the PVARP timer is started.

Then the basic interval timer runs out, after which a pacemaker pulse is generated in the atrium (A). Even before the AV interval is over, the R wave of the intrinsic ventricular event is detected. The intended ventricular stimulus is inhibited and the PVARP timer is not started. The ventricular extrasystole that now follows is detected by the pacemaker, which then resets the basic interval timer and starts the refractory period.

After the compensation pause, another atrial (P) and a ventricular pacemaker stimulus (V) follow. The P wave of the subsequent natural ECG is detected by the pacemaker (P) and the atrial stimulus is inhibited. The detected R wave prevents a ventricular stimulation since it occurs before the AV interval is over.

Fig. 38.14 Functional diagram of an atrium-controlled DDD pacemaker

Fig. 38.15 Flow diagram of a ventricle-controlled DDD pacemaker

DDD Pacemaker (Ventricle-Controlled)

The decisive advantage of the DDD system – the complete synchronicity of both chambers – can also be achieved with time control on the ventricular level, of course. In the case of ventricular-based timing, the two counters, AV and the basic interval (here also referred to as the atrial escape interval), are in series and are never active at the same time (Fig. 38.15).

First, measurements are made in the atrium. If an intrinsic atrial event occurs, the AV counter is started and an attempt is made to detect signals in the chamber. If no atrial excitation occurs, an artificial atrial stimulation is delivered at the end of an atrial escape interval, and then measurement continues in the chamber. If a natural excitation occurs in the chamber, measurements are taken in the atrium and the associated timer is started. If this is not the case, another ventricular stimulus is delivered after an AV interval, the counter is reset, and measurements are taken from the atrium. For reasons of simplicity, refractory periods were omitted here.

Clinical Assessment of the DDD Pacemaker. This pacemaker comes closest to simulating the physiological function of the heart. With this pacemaker, no pacemaker syndrome is possible. It has an energy-saving mode of operation. Only in the case of chronotropic insufficiency is the system unable to adapt to the physical stress.

Detecting the atrial electric action is dangerous when the atria have tachycardiac arrhythmia. To prevent ventricular tachycardia from occurring here, the 1:1 atrium/ventricle conduction frequency is limited. If the atrial frequency exceeds this limit, referred to as the maximum synchronization frequency, then there is only partial conduction to the ventricle. For example, the AV delay increases from beat to beat until a beat is no longer conducted and finally the cycle starts over (Wenckebach mode). Another possibility is to just conduct every second atrial action to the ventricle.

A retriggerable atrial refractory period was introduced under the term *dual demand*, which leads to a variable prolongment when tachyarrhythmias occur, and is therefore also considered to be a protective function. Most of these methods, however, have the disadvantage that they abruptly change the ventricle frequency when an atrial tachyarrhythmia occurs, which patients find unpleasant.

For this reason, more complex methods for reacting to tachycardiac atrial arrhythmia were introduced recently under the term *mode switching*. The precondition for this is an algorithm for automatically detecting atrial tachyarrhythmias. The state of the art nowadays is the so-called “*x* out of *y*” algorithm, where a programmable minimum number *x* of PP intervals out of a total number *y* of consecutive intervals must lie under a certain limit. In this way, even irregular atrial tachycardias are reliably detected. When such an arrhythmia sets in, the pacemaker switches over to a ventricular stimulation independent of the atrial action (e.g., VVI). After the end of the atrial tachyarrhythmia, there is another stimulation in DDD mode.

Application of the DDD Pacemaker. DDD pacemakers are suitable for:

- Patients with normal sinus node function and AV block,
- Rare atrial arrhythmia,
- Congenital long QT syndrome and torsade des pointes (special type of ventricular tachycardia).

A special indication for using two-chamber stimulation is hypertrophic obstructive cardiomyopathy. Due to the formation of muscle contractures in the outflow tract of the left ventricle, blood is prevented from flowing out. By choosing a very short AV delay and sometimes also a stimulation in the outflow tract, the muscular excitement can be modified such that the outflow tract obstruction is considerably reduced [38.1]. This pacemaker should not be used for supraventricular

ular tachyarrhythmias. In this case, a VVI system is indicated.

38.3.4 Frequency-Adaptive Pacemakers

Frequency-adaptive pacemakers allow the heart rate to be increased in stressful situations, even in patients with sinus node dysfunction. They are therefore indicated for physically fit patients who have an insufficient heart rate increase under stress (chronotropic insufficiency). The frequency adaptation is achieved via sensors, which determine the stress-related parameters and relate these to the stimulation frequency (so-called *interference coupling*). Up to now, a multitude of different parameters have been tested [38.3], e.g.:

- Physical activity (vibration or acceleration sensors)
- Respiratory minute volume
- Blood temperature
- Blood oxygen content

Other parameters were tested at the same time, but only the physical activity measurement found practical application. Thanks to miniaturized acceleration sensors, it is technically easy to execute and responds immediately. The disadvantage is the nonphysiological sensor information. Furthermore, passive movements (e.g., driving over cobblestones) is misinterpreted. The state-of-the-art technology is therefore made of so-called *dual-sensor systems*, where the movement information is linked with a respiratory sensor signal based on the transthoracic impedance. This way, the reaction times are adapted and nonphysiological effects can be avoided

by comparing both signals. Emotional stress or fever, which can also cause the heart rate to increase, are also not detected by this, however.

The currently most promising solution approach is the development of regulating pacemaker systems. The healthy body has several control elements for stabilizing circulation. In addition to an affected sinus node when there is chronotropic insufficiency, the AV node, the myocardium, and the vascular system also act regulatively. Regulatory systems are based on the basic assumption that the control variables of intact control elements can be used to determine the physiologically correct heart rate. For example, an increased inotropism indicates that a greater cardiac output is required, which is used to increase the stimulation frequency. Figure 38.16 makes these relationships clear. The following are currently being tested as input variables:

- AV delay (dromotropism)
- QT interval of the intracardial ECG signal
- Contractility of the myocardium (dp/dt)
- Motion dynamics of the myocardium (acceleration, impedance)

The dromotropic pacemaker is impressive with its elegance, but it can only be used with limitations, since some people with chronotropic insufficiency also have A-V dysfunction. The QT interval for detecting myocardial contractility has already proven itself clinically but under certain boundary conditions can exhibit positive feedback since other parameters also influence the chamber action potential. The two latter approaches seem to be especially promising now and are already be-

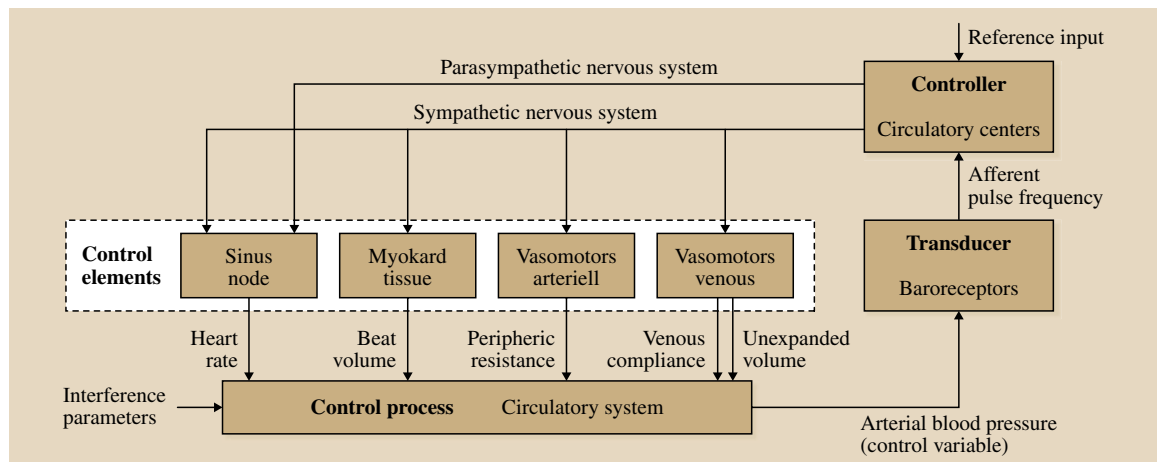

Fig. 38.16 Simplified control diagram of the baroreflex (after [38.7])

ing clinically tested in prototype implants. Their further clinical acceptance will depend on the degree to which they are able to guarantee long-term stability. Due to the sensors growing into the tissue, myocardial restructuring, or just simply aging, these systems are subject to drift, which requires recalibration.

38.3.5 Antitachyarrhythmia Pacemakers

One can attempt to end tachycardia both via a certain sequence of stimulation pulses as well as via electric shock. Since atrial tachycardia is being increasingly successfully treated with catheter-supported ablation methods, pacemaker treatment only plays a subordinate role here. The main indication for electric rhythmization treatment are dangerous tachycardiac ventricular

arrhythmias. The corresponding systems are usually offered in connection with a defibrillation option (so-called ICDs).

38.3.6 Batrial Stimulation Systems

It recently became clear that a pathological prolongment in the interatrial transition period can lead to atrial reentry tachycardia. For this reason, special pacemaker systems have been developed that allow several consecutive stimulations at short intervals in both atria. These so-called *batrial stimulation systems* have meanwhile proven themselves in patients with prolonged P waves. Technically, they are like a DDD system, whereby, however, the second electrode comes to rest in the left atrium. The challenge here is the development of

Fig. 38.17 Semischematic diagram of biventricular stimulation. Stimulation electrodes are located in the right atrium, right ventricle, and in a cardiac vein (V. cordis), which runs laterally over the left ventricle (LA left atrium, RA right atrium, LV left ventricle, RV right ventricle, V. cordis)

suitable electrode systems. The state of the art for stimulating the left atrium is access via the sinus coronarius. This way, the implant remains in the low-pressure system. This puts high demands on the flexibility of the electrodes and the skills of the implant surgeon, however.

38.3.7 Biventricular Stimulation Systems

The objective of biventricular stimulation is the treatment of serious myogenic cardiac insufficiency, independent of the cause that led to damage of the heart muscle. Although optimizing the heart rate and atrioventricular synchronization have already had favorable effects on patients with cardiac insufficiency these methods are often unsuccessful in achieving sufficient hemodynamic improvements. This is especially the case for patients with a pronounced left bundle-branch block, which leads to a desynchronization of the contraction of the right and left ventricles [38.11].

The technical basis of biventricular stimulation is an atrium-controlled ventricular pacemaker (DDD system), which has an additional second ventricular output for detection in the left ventricle. Here, the left ventricular electrode is placed in a cardiac vein in the left ventricle. The access path is the same as with biatrial stimulation, via the sinus coronarius (Fig. 38.17).

This method, which is still very new, has already been introduced in clinical practice. Its long-term success, however, can only be verified in broader studies [38.12]. Improvements in the hemodynamic situation are to be proven with this special stimulation method. In further development, improvement in the electrode technology is necessary, and suitable param-

Fig. 38.18 Selecting a suitable pacemaker system (after 38.4)

eters for patient selection and for optimally programming the pacemaker system are to be selected. The combination with an implantable cardioverter/defibrillator is possible.

38.3.8 Selection Criteria

The correct selection of a suitable pacemaker system still requires expert knowledge today, despite all the automatic functions of the pacemaker, since an exact diagnosis is often determined by essential details. Figure 38.18 attempts, however, to formalize the selection, to at least provide a rough starting point.

39. Introduction to Neuroprosthetics

Klaus-Peter Hoffmann, Silvestro Micera

Neuroprosthetics is a comparatively young, dynamically developing subject with double-digit sales growth rates. Due to the preconditions on implantability, biocompatibility, and miniaturization, it is strongly linked to the development of microsystems technology, nanotechnology, information technology, biotechnology, and the application of new materials. The fields of application of neuroprostheses are diseases associated with impairments of myogenic or neurogenic functions. These can lead to the loss of the whole function. Neuroprostheses use electric stimuli to stimulate neural structures, muscles or receptors, in order to support, augment or partly restore the respective disordered or lost function. Functional disorders include paralysis after stroke, reduced hearing, tremor as an example of movement disorders, or the loss of an extremity. Often, the use of a neural prosthesis can improve the quality of life of the person concerned. The objective is to help the patient to participate in everyday life. Thus, cosmetic, ethical, and social aspects always have to be considered.

39.1 Neuroprostheses

Neural prostheses are applied with the objective of compensating an existing motor or sensory neural dysfunction. They electrically stimulate myogenic areas and neural structures in the peripheral, spinal, and central nervous system to supplement, replace, or restore neurological function [39.1]. However, neural prostheses can also be used to acquire and analyze bioelectrical activity from the mentioned neural structures to control technical systems (Fig. 39.1).

Two information transfers can be distinguished. Inward information transfer can be accomplished by activating any of the intact senses by appropriate stimuli (cochlear or retinal implant) or by direct

electrical stimulation of neural tissue (brainstem implant). Outward information transfer can be done after recording bioelectrical signals associated with neural or muscular activation. These signals can be used for electrical stimulation of muscles (cardiac pacemaker) or neural tissue (bladder stimulator) or to control the movement of technical devices (hand prostheses) [39.2]. In some cases information transfer is not needed, for example in basic electrical stimulation of muscular or neural tissue (neuromodulation).

Figure 39.2 shows an overview of common neural prostheses. Cardiac pacemakers, cochlear implants,

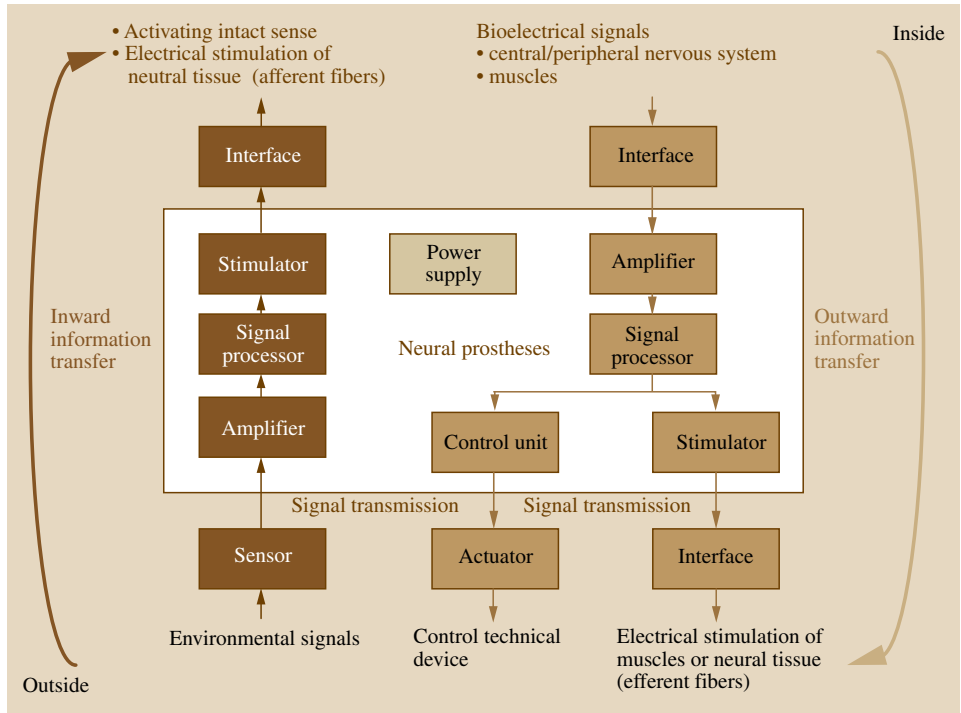

Fig. 39.1 Schematic of a neural prosthesis

Fig. 39.2 Examples of the application of neural prostheses

and implants for deep brain stimulation have been established for years in clinical practice. Stroke patients, paraplegics, and drop-foot patients can often be helped by functional electrical stimulation. Implantable electri-

cal stimulators are increasingly applied for the therapy of chronic pain or incontinence using neuromodulation. Other applications, for instance the retinal implant, are in clinical trials. The research field of neuroprostheses is strongly characterized by preclinical experimental work.

39.2 Application of Neural Prostheses

39.2.1 Cardiac Pacemaker

So far, the most frequently used neural prosthesis is the cardiac pacemaker. Electrical stimulation of the heart is applied to compensate for pathological changes of the generation and transmission of stimuli, including cardiac arrhythmia. With appropriate stimulation, the respective symptoms and thus the effects on the patient can be positively influenced.

Classical cardiac pacemakers have been applied for many years. They are designed as a single-chamber system for stimulation in the right atrium or the right ventricle, or as a dual-chamber system. The latter enables the correction of disorders in atrioventricular transmission. As frequency-adaptive systems, they adapt their stimulation frequency to the respective physical strain of the patient.

The therapeutic concept also includes regular aftercare of implant patients. In the future, this can be supplemented by the use of telemedical systems for remote monitoring. Event-related data can be transmitted to a medical center by mobile radio and internet technologies. If necessary, this can be supplemented by automated alerting of the physician. Moreover, future developments for cardiac pacemakers include stimulation of the left chambers. Also, vagally controlled cardiac pacemakers are undergoing preclinical testing.

39.2.2 Cochlear Implant

In many cases, cochlear implants enable the restoration of auditory impressions and speech comprehension. Thus, deaf children can often be introduced to hearing and speaking. For the application of a cochlear implant, the auditory nerve has to be intact and healthy. A cochlear implant substitutes lost functions of the inner ear. It is placed in the cranial bone behind the ear. The stimulating electrode is positioned in the cochlea. The number of separate channels including the corresponding electrodes determines the informa-

Cardiac pacemakers, cochlear implants, and deep brain stimulation represent about 95% of the currently implanted neural prostheses [39.1]. The state of the art is characterized by progressing miniaturization and the application of new biocompatible materials and manufacturing technologies.

tion bandwidth that can be achieved. An external speech signal processor with microphone and coil receives the acoustic signals and transmits them to the implanted receiver. The required energy is telemetrically transmitted together with the converted acoustic signals.

Although the speech processor has to be set individually for each patient, the comprehension of acoustic signals and thus hearing and understanding has to be relearned. For many patients, lip-reading is significantly facilitated after the operation, and their ability to follow conversations is improved. It is recommended to supply the patient with cochlear implants on both sides, to improve spatial hearing.

If both auditory nerves have lost their function, the application of a cochlear implant is not reasonable. Here, acoustic sensations can be achieved by stimulating the higher tracts, e.g., in the nucleus cochlearis (in the brain stem), to enable rudimentary hearing. Stimulation of the auditory center is also conceivable.

39.2.3 Deep Brain Stimulation

Severe movement disorders can be treated by electrical stimulation deep inside the brain. Especially for patients with Parkinson's disease, this yields a therapeutic approach. Charge-compensated short rectangular electrical stimuli, for instance in the nucleus subthalamicus, inhibit the pathologically overactive regions. Similar to the cardiac pacemaker, the neurostimulator is implanted between the skin and the pectoral muscle.

Previous applications of deep brain stimulation have often been associated with an improved psychic situation. First results of stimulation of the nucleus accumbens in obsessive-compulsive disorder patients indicated improvements with respect to speech, mood, and motor behavior.

A promising approach is the electrical suppression of epileptic seizures. Several studies indicate that electrical high-frequency stimulation can inhibit a spurious synchronization of neurons. However, this method is

only applied in patients whose seizure disorders cannot be treated by pharmaceuticals or surgery.

39.2.4 Bladder Stimulation

Besides impaired mobility, paraplegic patients can suffer from reduced control of internal body functions, for instance control of urinary flow. Accompanying surgical means can restore the storage function of the urinary bladder of paraplegics. Electrical stimulation of the sacral roots enables controlled bladder voiding without catheter. Besides the positive social aspects, the bladder stimulator also yields a reduced risk of infection.

39.2.5 Human–Computer Interfaces

Patients with locked-in syndrome, amyotrophic lateral sclerosis or paraplegia often have difficulties in communicating with their environment. With human–computer interfaces, technical systems can be controlled by recorded biosignals of the peripheral or central nervous system. Thus, lost communication channels can be restored, and the patients become able to interact with the environment. Often, recording, amplification, analysis, and the generation of the control or communication signals is computer-aided, including integrated microprocessors (embedded systems).

One branch is the brain–computer interface controlled by cerebral activity changes. Here, systems

recording the signals with surface electrodes (EEG-controlled), plate electrodes placed on the cortex (ECoG-controlled) or implanted multielectrodes (electrode arrays) can be distinguished. The objective of all mentioned systems is the control of special output devices (for instance the cursor on a computer monitor) or the control of technical systems or actuators (e.g., technical grapplers or prostheses).

39.2.6 Extremity Prostheses

Hand prostheses belong to the group of prostheses of the upper extremities. The realization of the various grasping movements of the hand, e.g., cylindrical grasp, pincer grasp, lateral grasp, spherical grasp, is a technical challenge. Myoelectrically controlled hand prostheses are the state of the art. They use muscle action potentials from the remaining muscles of the forearm. The envelope of the recorded activity is proportional to the number of activated muscle fibers and thus to the muscle force. Therefore, it can be used as a control signal for prostheses. The precondition for a coordinated movement is the ability of the prosthesis wearer to selectively and independently tense various muscle groups.

The introduction of microcontroller systems integrated in the prostheses enables controlled movements with regulated grip velocity and grip force proportional to the muscle signal. The proportional control makes high demands on the quality of the recorded surface EMG signal.

39.3 Specific Technological Features

39.3.1 Biocompatibility

One of the main preconditions for the application of neural prostheses is their biocompatibility. This means the execution of a desired function in a specified application with an appropriate host reaction. Often, the provocation of biological functions and reactions is desired and the aim of the use of neural prostheses. This desired compatibility between a technical system and the biological tissue in the sense of an adaptation of the structure and surface of the implant to the receiving tissue is denoted as biocompatibility. Surface compatibility includes the adaptation of the chemical, physical, biological, and morphological surface properties of the implant. The adaptation of the implant structure to the mechanical behavior

of the receiving tissue yields structure compatibility.

The verification of the biocompatibility for the complete system is done in three stages:

- In vitro tests with isolated cells, cell cultures, and organ structures with the objective to collect possible changes of the implant surface, to observe a possible dissolution of material components, e.g., ion release from metals, to determine corrosion and so on. Short-term as well as long-term exposure is observed.
- In vivo tests with animal models (mice, rats, dogs, rabbits) as long-term tests with the objective to observe the occurrence of toxic effects, the change of the tissue morphology, and the carcinogenic poten-

tial of the material. Histological examinations are used for the evaluation.

- Clinical studies are performed to monitor allergenic and inflammatory reactions.

Implantation site, implantation time, applied materials and their function determine the application of a neural prosthesis. In any case, the production process can influence the material biocompatibility. Plasma activation is one example of changing the biocompatibility of surfaces.

39.3.2 Encapsulation

Neural prostheses have to be encapsulated for two reasons: first to protect the implant against influences of body fluids, and second to protect the organism in the sense of biocompatibility. Moreover, electronic circuits have to be shielded from corrosion and possible occurrence of short circuits. Another function is the mechanical protection of the implant against forces produced by the body. It is essential that the encapsulation must not influence the function of the implant. Also, the sterilizability of the encapsulated implant has to be ensured.

For cardiac pacemakers, titanium housings have been applied for many years. Here, the metal housing can often be simultaneously used as counter electrode. Other materials include ceramics, (e.g., for cochlear implant) or glass (e.g., BIONsTH). For flexible microimplants, silicone, parylene, polyimide or other polymers are used as encapsulation materials.

39.3.3 Energy Supply

Lithium iodide batteries are the classical form of energy supply for implantable neural prostheses. For a sufficiently small design, they provide energy for a duration of 5–10 years. These batteries are for instance applied to cardiac pacemakers and deep brain stimulators. For other applications, e.g., retinal implant or cochlear implant, alternative energy sources have to be found. Often, the required energy is transmitted telemetrically. Future concepts are based on energy generation from the immediate environment of the implant. This can for instance be achieved using biochemical, piezoelectric, thermoelectric, electromagnetic, capacitive, or thermomechanical generators. These concepts require the design of an adaptation of the electrical properties of transducer, storage, and consumer. The specific parameters depend on the transduction mechanism from high

voltage capability for piezoelectric to ultralow voltage for thermoelectrical transducers.

39.3.4 Electronics

The application of neural prostheses makes high demands on the respective electronics. They have to ensure the function of the implant over a very long period. Thus, they have to be self-verifying and have to transmit the respective operating state as well as potential errors to the outside. The design of the electronics has to be space-saving. An interaction with other diagnostic or therapeutic methods, for instance MRI, HF surgery or defibrillator, should have only little influence on the function. In recent years, the fast-paced development in microelectronics has led to smaller and smaller volumes. In order to minimize galvanic processes at the electrode, an additional circuit component is necessary for decoupling of DC components. Examples are monolithic circuits and low-voltage applications. It has to be mentioned that especially in the field of neuroprosthetics, low-voltage and low-power integrated circuits (IC) are of great benefit for recording of nerve and muscle signals. For stimulators, ICs with high-voltage technology or discrete components, which can be used as an end stage to provide the necessary current, have to be generated. In order to avoid corrosion of electrodes, very low input bias currents are necessary. Moreover, the general demands on a medical product and the electromagnetic biocompatibility have to be met.

Fig. 39.3a,b Sieve electrode with multiplexer. (a) Electrode structure; (b) embedded multiplexer (after [39.3])

Microfabrication processes enable the design of novel kinds of electrodes including active electronics. The preprocessing of recorded signals is possible very close to the recording electrode. This can minimize the influence of superimposed artifacts and increase signal quality. Integrated electronic circuits can reduce the number of connection lines to the electrode. An example of such an electronic integration is the sieve electrode with a multiplexer [39.3, 4] (Fig. 39.3).

39.3.5 Signal Processing

On the one hand, neural prostheses stimulate myogenic or neurogenic tissue; on the other hand, they record bioelectric signals. Here the biosignal or the stimulus has to be adjusted to the technical system or the biological tissue, respectively. For instance, the cochlear implant receives external acoustic signals, analyzes them and, after an appropriate interpretation, converts them into a stimulation signal. This requires an immediate signal processing at the implantation site. Integrated digital real-time signal processors (DSP) allow the implementation of sophisticated analysis routines and algorithms. This includes filtering, detection of certain signal fea-

tures (e.g., spikes), and their classification based on Fourier transformation, wavelet analysis, neural networks etc. First, analog signals are converted into digital series and thus become computer-usable. These data are further processed in microprocessors, by the use of suitable algorithms.

In the example of the cochlear implant, the acoustic signal is decomposed into individual frequency bands, and after signal adaptation, each frequency band is assigned to one stimulation electrode. Thus, tonotopic stimulation of the cochlea is enabled.

39.3.6 Signal Transmission

The transfer of data from and to the implant is often realized by inductive interfaces. This enables a concurrent energy supply of the implant. The field of an external transmitting coil is coupled to the receiving coil of the implant. For data transmission, the carrier wave of the transmitter is modulated. Taking the cochlear implant as an example, a power of 30 mW can be transmitted, with a simultaneous data rate of 400 kBit/s. The communication of the implant to the outside can generally be achieved by the same means.

39.4 Biological–Technical Interface

39.4.1 Electrodes

For technical interactions with the neural system, interfaces are needed. Implantable microelectrodes represent the direct interface between biological tissue and technical systems. They transform the ion current of the biological system into a current of electrons [39.5]. Electrodes are used for both stimulation and recording of biological potentials. Although their surface is generally small, low contact impedance between electrode and tissue is required. This can be achieved by electrolytic treatment of the metal electrodes, surface structuring, coating with polymer structures, integration of nanoparticles etc. Traditional electrode materials include silver, silver/silver chloride, platinum, platinum black, gold, iridium, and iridium oxide.

Two different kinds of electrodes can be distinguished: flexible and stiff electrodes. One example of stiff electrodes is the Utah electrode array [39.6]. This array of 10×10 silicon-based needle-shaped electrodes is used for measuring of the extracellular potentials of neurons and single-neuron action potentials. The

length of the electrodes is currently limited to 1.5 mm. By using μ -wire electrical discharge machining from a pure tungsten block the length can be increased to 5 mm [39.7].

The advantage of flexible electrodes is that they are able to move with the tissue in which they are implanted. Compared with silicon electrodes the Young's modulus is much lower. The materials used most for flexible electrodes are polyimide and polysiloxane (silicone). Polyimide is light (1.42 g/cm^3) and can be fabricated as very thin films (10–15 μm). The water absorption is smaller than 0.5%. Using photolithography arbitrary geometric structures can be realized.

The design depends on the application (Fig. 39.4). The cuff electrode is a circumneural electrode. It is placed around the peripheral nerve like a tube. Thereby the electrodes are positioned inside the cuff to get in close contact with the nerve.

The concept of the shaft electrode is to insert it into the neural tissue. It has a needle shape with multiple electrode sites. This results in a closer contact between the electrode site and the nerve fibers.

Fig. 39.4 Examples of flexible implantable microelectrodes made of polyimide

The sieve electrode is placed between two cut ends of a nerve trunk. As a guidance and fixation for the nerve, silicone tubes are placed at both sides of the sieve. The nerve fibers regenerate through the holes of the sieve electrode. The sieve area is circular in shape with a diameter of 1.8 mm. The 571 holes of the sieve are 40 μm in diameter and hexagonally arranged. Ring-

shaped electrodes encircle 27 of the holes [39.3]. The advantage of the sieve electrode is the possibility to selectively contact sensory and motor nerve fibers. Thus it is possible to record signals from afferent fibers as well as to stimulate efferent fibers.

A kind of intrafascicular electrode is the thin-film longitudinal intrafascicular electrode (tf-LIFE). It com-

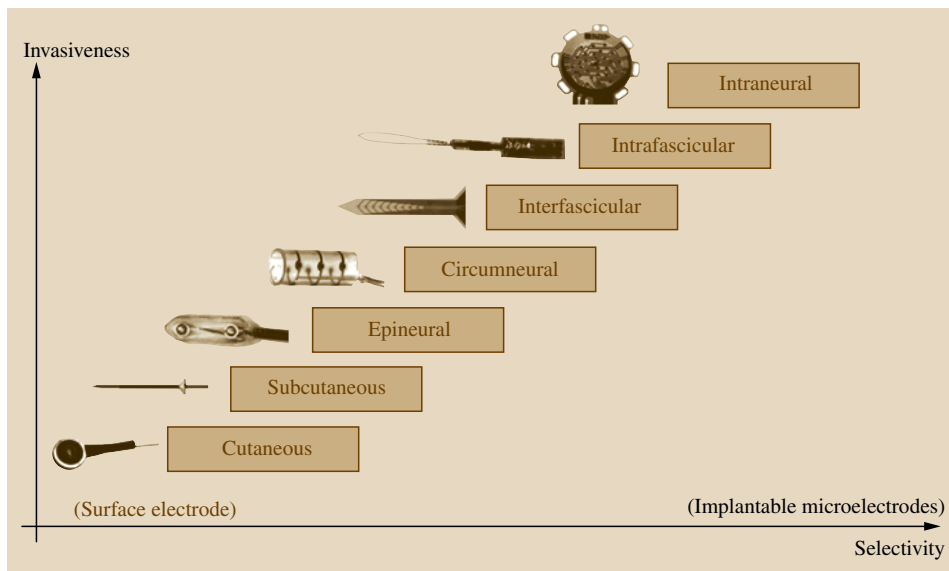

Fig. 39.5 Selectivity versus invasiveness of electrodes

bins a loop of a thin polyimide multisite electrode with Kevlar fibers including a thin needle. This needle can be used as guidance to implant the thin-film electrode longitudinally into the nerve. Additional electrodes are placed directly on vestibularis, retina, cortex or epimysium. So they can be used to stimulate electrically or to record neural or muscular signals [39.8].

The selectivity of the electrode increases with its invasiveness [39.9]. Surface electrodes are placed on the intact body surface and are thus noninvasive. They exhibit a very restricted selectivity. In addition, the biological tissue, which is situated between the electrode and the source of bioelectrical activity or the structure to be stimulated, changes the form of the signal. Electrodes introduced intimately in the biological tissue are considerable more selective. However, they have the disadvantage of invasiveness with all its side effects. Also, the design and the implantation method can influence the selectivity. Anyway, there is a strong correlation of selectivity and invasiveness (Fig. 39.5)

39.4.2 Interfaces for a Bionic Hand Prosthesis

The natural hand is a very complex system. With a weight of only 400 g, a volume of 50 cm³, and the possibility of 22 degrees of freedom, humans can generate a grip force of more than 500 N. Force, velocity, and precision can be controlled according to the type of grasp. Approximately 17 000 different sensors are used for this regulation. So the loss of an extremity has always been a dramatic event for the person

concerned. For compensation of a lost hand, both cosmetic and functional aspects have to be taken into account.

Bionic hand prostheses use neuronal signals to control hand movement and give information to peripheral nerves as sensory feedback. Therefore bidirectional interfaces and sensors are necessary. Proprioceptive sensors detect hand position and movement. Exteroceptive sensors acquire the nature of the environment and the quality of the grasp. As biological–technical interface, implantable microelectrodes like cuff electrodes, sieve electrodes, and thin-film longitudinal intrafascicular electrodes (tf-LIFEs) are used. These electrodes allow a bidirectional interface for recording neural activities and for stimulating afferent nerve fibers [39.10]. The concept of bidirectional bionic hand prosthesis is shown in Fig. 39.6. Motor control of the hand prosthesis can be established by placing electrodes inside the motor cortex [39.6, 11], the peripheral nerve [39.12] or directly epimysially [39.13]. Sensory feedback requires electrodes placed on afferent fibers or skin areas.

In this system, implanted microelectrodes record the innervation rate transmitted by the motor cortex to the peripheral nerve. The signals are amplified, A/D converted, and telemetrically transmitted to the actual hand prosthesis. Here, a control signal corresponding to the innervation rate is used to generate the desired movement. The hand prosthesis is equipped with sensors to record, e.g., temperature, holding pressure, and surface morphology of the held object. These measurement values can be transmitted to a stimula-

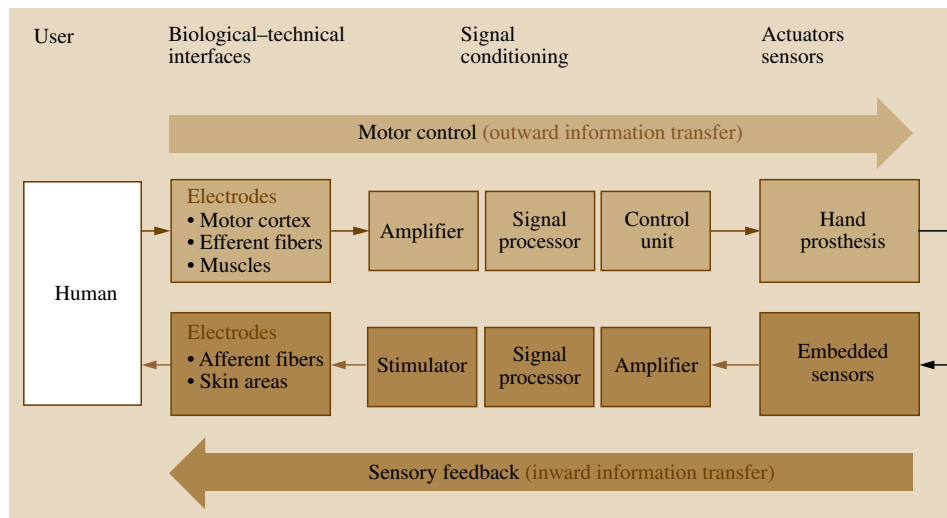

Fig. 39.6 Schematic of a bidirectional bionic hand prosthesis

tor electrically stimulating the afferent fibers via the implanted electrodes. In the sensory cortical projection areas, the corresponding sensation is generated. Thus, it can become possible to provide a feedback on the grasp and hold function of the hand prosthesis, including the properties of objects, to the patient.

39.4.3 Thin-Film Longitudinal Intrafascicular Electrode (tf-LIFE)

Design

The microelectrode system is based on a double-sided longitudinal flexible multielectrode, the so-called tf-LIFE (thin-film longitudinal intrafascicular electrode), which was basically designed by *Yoshida* [39.14]. This electrode combines a loop of a thin-film electrode with a filament loop including a thin needle. This needle can be used as guidance to implant the thin-film electrode longitudinally into the nerve. It is intended as a selective electrode system for recording and stimulation applications in the nerve fascicle. To this end, the system is penetrated through a nerve with the aid of a sharp tung-

sten needle and an additional supporting wire such that it can be fixed around the application area. The needle and the supporting wire are directly removed after the implantation procedure. Only the thin-film electrode is placed into the nerve. Depending on the implantation of the electrode a high selectivity can be achieved [39.9].

The active part of the electrode is made of flexible polyimide thin films. The polyimide acts as substrate and as insulator on which platinum tracks are sputtered and the active sites are realized. The mechanical properties of the polyimide give great flexibility to the active part of the electrode, decreasing relative drifts between the tissue and the electrode associated with fibrous encapsulations. The basic requirement for all components that directly interact with the biological tissue is biocompatibility of the used materials. Especially for electrodes, biocompatibility has to be investigated under stimulation as well as recording conditions. Electrode materials with stable electrochemical properties like electrochemical impedance and corrosion stability are needed [39.8].

The tf-LIFE microstructure consists of a polyimide substrate with an overall thickness of 10 μm and an

Fig. 39.7 Electrode assignment and dimensions of the tf-LIFE. GND are the ground electrodes, L0 and R0 are the counter electrodes, and L1–L4 and R1–R4 are the working electrodes for each side of the loop, respectively

overall length of over 5 cm (Fig. 39.7). On both ends of the structure there are bonding pads to contact the flexible part with an adaptor (made of Al_2O_3 ceramic via a screen printing process) for applying additional wires. These bonding areas are attached opposite to each other on each side of the adaptor (mirrored), which results in a looped structure of the thin-film electrode. The working electrodes (four electrodes on each side) and the proximal electrodes (counter and ground electrodes on each side) are on the outer part of the loop. The ground electrode has a width of $200\ \mu\text{m}$ and a length of $2500\ \mu\text{m}$, and the counter and working electrodes have a rectangular shape of $100\ \mu\text{m} \times 40\ \mu\text{m}$ with a semicircle of $40\ \mu\text{m}$ diameter attached on each side. The connection lines and electrodes are made of a 300-nm-thick platinum layer.

The additional guiding wire is also made of polyimide with a width of $200\ \mu\text{m}$, an overall thickness of $20\ \mu\text{m}$, and a total length of 4 cm (2 cm as a loop). This guiding wire is pulled around the assembled flexible electrode loop on the adaptor and then glued on a tungsten needle with medical-grade instant adhesive. Several investigations have shown the reliability of the polyimide guiding wire regarding its mechanical strength as well as the sufficient bonding strength of the glued wire/tungsten connection.

Micromanufacturing

Microelectrode processing consists of different process and development steps and needs well-defined design parameters [39.8].

Four main steps can be distinguished:

1. Design phase
2. Processing of thin-film microelectrodes
3. Assembling of the flexible microelectrodes to wires and/or plugs
4. Encapsulation of the assembled system regarding the needs of the application.

Designing of microelectrodes starts with CAD development of photolithographic masks, which defines the implant shape and the electrode design. Important points are the connection lines and electrode sides, depending on application, location, and implantation method. For effective system integration to combine the microscopic with the macroscopic world the adaptors should be carefully designed.

Based on a micromachining process polyimide (PI 2611, Du Pont) is used as carrier layer for connection lines and pads as well as the electrode material. After applying a $5\text{-}\mu\text{m}$ -thick substrate layer of polyimide on a silicon wafer, a single metallization layer of plat-

Fig. 39.8 General process sequence for the micromachining development of flexible thin-film microelectrodes based on polyimide substrate material (after [39.8])

inum is sputtered. After a lift-off process the polyimide top layer of 5 μm thickness is applied and then coated with aluminum as etching mask for the subsequent dry etching process to open the electrode area and the connection pads. After the removal of the etching mask, the wafer is cleaned and the single structures (thin-film electrodes) are removed from it. The process flow is shown in Fig. 39.8.

After removing the single structure from the silicon carrier wafer the thin-film electrode is bonded on a ceramic-based adaptor, which is made via screen printing. On the other side of the bonded adaptor 12 cooner wires (AS631) are soldered on the connection pads of the ceramics (six wires on each side). The wire bundle is covered with a medical-grade silicone tube with a diameter of 2 mm and an overall length of 50 cm. On the other side of the wires an Omnetics plug (Type NPD-12-WD-12.0-CSMT) is assembled which is also connected and encapsulated to the silicone tube.

The micro flex interconnection technique (MFI) is used for bonding of connection lines on flexible foils to a substrate (Al_2O_3 , FR4 or glass) to build up a strong and reliable connection between a flexible foil and the adaptor [39.4]. By this, easy soldering or welding of wires and plugs on the adaptor system is possible. For

more complex approaches electronics have to be placed directly at the electrode. Integrated circuits (ICs) should be used to reduce the size of the system. A special bonding technique was developed to connect electronics to a flexible thin-film structure. Gold bonds can be placed through a hole of the thin film on the contact pad of the IC. On the side of the gold ball, the thin-film electrode needs a ring contact around the hole. By this method a mechanical as well as an electrical contact between electrode and IC can be achieved. Additional components like capacitors or resistors can be placed in a similar way or can be glued by conductive epoxy or soldered to pads of the flexible substrate.

For protection of the electrode and to ensure biocompatibility of the electrode system, coating of the structure with Parylene C and silicone is necessary. Parylene C is a biocompatible polymer that is deposited directly on the substrate from the vapor phase in microscale gaps. So it can be cured to a wide range of geometrics [39.15]. The sterilization method is gas sterilization with ethylene oxide.

Characterization and Optimization

Electrode characterization is used to determine the behavior in a physiological environment and to optimize mechanical and electrical parameters. It is an important

Fig. 39.9a,b
Microstructured platinum. **(a)** Scanning electron microscopy picture of a microrough platinum electrode surface. **(b)** tf-LIFE during the coating process. The same setup is used for impedance spectroscopy

step in the fabrication process of implantable microelectrodes. The methods used are valuable tools for quality management to evaluate the different process steps and parameters.

To increase the effective area of a microelectrode the electrode contacts can be coated with microrough platinum (Fig. 39.9). This leads to lower impedance as well as a higher charge injection capacity [39.16].

For electrical stimulation with microelectrodes, charge injection capacity has to be considered. This means the maximum amount of charge per area that can be reversibly injected with the respective electrode. If this value is exceeded, irreversible Faradaic reactions occur with corrosion of the electrode, shift of the local pH value, air bubbles at the electrode surface, and finally damage of the surroundings. For an electrode made of platinum a maximum charge of approximately $64 \mu\text{C}/\text{cm}^2$, and after coating with microrough platinum of approximately $524 \mu\text{C}/\text{cm}^2$, can be injected [39.17].

For recording of biosignals the impedance of the electrode in comparison with the amplifier input impedance is important for the signal quality. After the electroplating process to coat platinum electrodes with microrough platinum, the electrodes' impedance is significantly reduced by a factor of approximately 100, depending on the signal frequency (Fig. 39.10).

Electrical impedance spectroscopy is a useful method to determine the specific impedance by in vitro investigation in 0.9% NaCl solution. This test specifies the quality of the electrode and its functionality. Using a three-electrode setup a current in a frequency range of 10–100 000 Hz is applied between the working and the counter electrode, mostly a platinum electrode. The resulting electrical potential is measured between the working electrode and the reference electrode, usually a Ag/AgCl electrode. The relation between input signal (current) and output signal (voltage) is used to calculate impedance and phase. Figure 39.10 shows a typical impedance investigation of a tf-LIFE structure with electroplated platinum electrodes.

An additional electrochemical characterization method is cyclic voltammetry. A triangular voltage is applied and the current through the electrode is recorded. If the measured current is plotted versus the potential, the reversible potential limits can be identified. The charge storage capacity of the electrode can be estimated by calculating the area inside the resulting hysteresis loop. Furthermore, pulse tests, corrosion tests, and leakage current tests are very helpful to estimate the long-term behavior of the electrodes.

Typical methods for optical characterization are light microscopy, and Fourier transform infrared (FTIR) spectroscopy. With laser profilometry the surface of the

Table 39.1 Tests to be performed according to ISO 10993

Raw material tests (e.g., electrode material, Kevlar fiber)	
Cytotoxicity	ISO 10993-5
Acute toxicity test	ISO 10993-11
Intracutaneous reactivity	ISO 10993-10
Final product investigation (electrode implant with adaptor system, wires, and equipment)	
Cytotoxicity	ISO 10993-5
Genotoxicity	ISO 10993-3
Implantation	ISO 10993-6
Ethylene oxide residuals	ISO 10993-7
Irritation test	ISO 10993-10
Sensitization test	ISO 10993-10
Systemic (acute) toxicity	ISO 10993-11
Bioburden test	ISO 11737

electrode is scanned with a laser beam to obtain its profile. Scanning electron microscopy (SEM) is used to analyze the microrough structures of the electrode.

Mechanical characterizations are mainly focused on the structural parts of the electrodes like the stability of the substrate.

Biological Characterization and Tests in Animals

Before an electrode structure can be implanted in humans or animals, biological characterization including the assessment of biocompatibility has to be done. According to the ISO 10993 European standard, the following tests have to be performed to ensure that the

electrode system is suitable for implantation (Table 39.1).

The tf-LIFE was implanted in the sciatic nerve of rats and rabbits. They can be inserted longitudinally or transversally into the peripheral nerve tissue (Fig. 39.11b). Thus the electrodes are placed inside and parallel to the nerve fibers or perpendicularly to them. Histological studies after 3 months of chronic application in rat peripheral nerve have shown that the tf-LIFE caused only minimal damage to the nerve [39.18]. The electrodes can selectively collect nerve signals and provide a good interface to analyze sensory information from peripheral nerve fascicles [39.19].

Different kinds of algorithms are approached for processing of signals recorded with tf-LIFEs. Especially, the wavelet is a very efficient tool. Various sensory stimuli were applied to the hind leg of the animal and the elicited signals were recorded. After wavelet denoising and spike sorting, vector machines were successfully trained to use the spike waveforms of the signals to achieve decoding information regarding various sensory stimuli [39.20].

Using tf-LIFEs, it was shown that specific information is provided on the possibility of extracting and appropriately interpreting the neural code for motor commands and of delivering sensory feedback by stimulating afferent fibers [39.19]. The result showed that both the extraction of motor information and the restoration of sensory function are possible.

Four tf-LIFEs (Fig. 39.11) were implanted in the median and ulnar nerves of an amputee. Thirty-two

Fig. 39.11a–d Thin-film longitudinal intrafascicular electrode (tf-LIFE)

channel signals were recorded with Grass amplifiers in a frequency range of 100–10 000 Hz. To stimulate the afferent fibers the Grass stimulator delivered trains with square pulses. Rectangular cathodal pulses of duration 10–300 μ s and current intensity 10–100 μ A were employed [39.12]. Because the maximal current density for platinum electrodes is 1.5 mA/cm² the stimulation current for each working electrode of the tf-LIFE structure was limited to approximately 80 μ A. The optimal active sites for sensory feedback were characterized starting with stimuli of 10 μ A amplitude and 10 μ s duration. Electrical characterization of the electrodes has been performed showing impedance values in the range of 5500–7500 Ω for active and 400–500 Ω for ground electrodes at 1000 Hz [39.21].

The bionic hand is a stand-alone version of the CyberHand prototype with five fingers actuated by six

motors. Proprioceptive and exteroceptive sensors are embedded [39.22].

Activity classes were identified using denoising and spike-sorting algorithms. Up to 85% of individual movements were correctly classified. Discrete tactile sensation was elicited from different stimulation sites in the median as well as the ulnar nerve. The sensation magnitude was modulated by pulse frequency. The results showed that tf-LIFEs implanted in peripheral nerves can be used for tactile feedback and to control independent types of handgrip of a bionic hand prosthesis. Tf-LIFEs can be implanted and used in humans for several weeks with a high success rate, picking up signals with a good signal-to-noise ratio. Multiple electrodes in different nerves with numerous contacts guarantee a reliable flow of signals [39.12, 21].

39.5 Future Developments

Future developments within the field of neuroprosthetics are characterized by proceeding miniaturization, the application of new materials and technologies, as well as the integration of cognitive technical systems. Also, misunderstood basic issues related to the coupling of neurons with technical materials have to be clarified. Bioactive substances released after implantation can enhance biocompatibility. Thus, research in the field of

neuroprosthetics is still characterized by experimental and preclinical work.

Current fields of application include:

- Central paralysis, e.g., paralysis due to stroke
- Paralysis due to lesions of the spinal canal
- Hypoventilation of central origin, sleep apnea
- Deafness, blindness

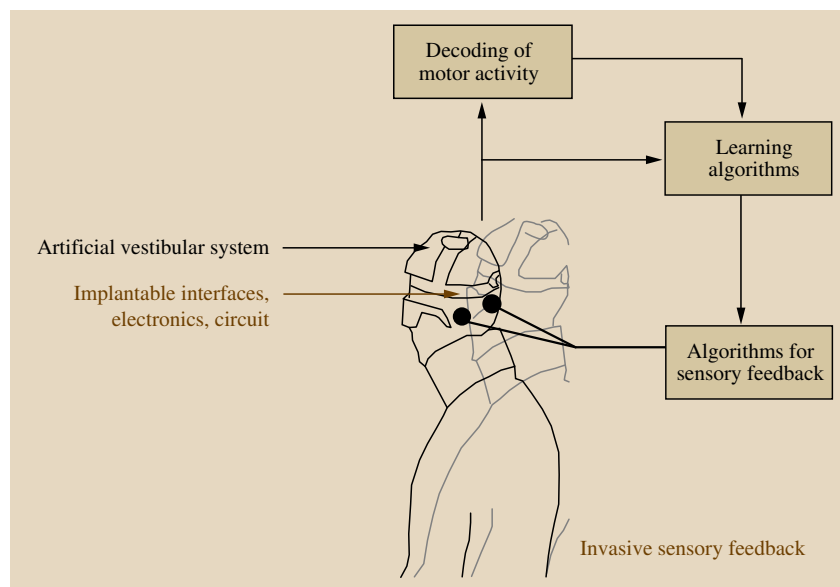

Fig. 39.12 Closed-loop neural prostheses for vestibular disorders: CLONS Project (after [39.23])

- Multiple sclerosis, seizure disorders, depression, Parkinson's disease
- Pain, cluster headache
- Weakness of the bladder, incontinence, impotence
- Vocal cord paralysis.

Autonomous active implants working as closed-loop systems could be developed for different therapeutic applications or rehabilitation using cognitive technical systems. The association of an implanted smart stimulator to stimulate the vagus nerve with an interacting and smart monitoring system can be used for control of the cardiovascular system [39.24].

Another new research area is the 3-D vestibular neural prosthesis [39.23]. An innovative closed-loop sensory neural prosthesis is able to restore vestibular information by stimulating the semicircular canals electrically. Inertial sensors embedded in a device attached to the head and donned by the user provide the information for stimulation. Innovative learning algorithms process concurrent sensory and motor data (Fig. 39.12).

Future neural prostheses will be smaller and more intelligent. New biocompatible materials will establish additional chances. Microactuated electrodes on the basis of shape memory will allow movable interfaces. In this way, the optimal position of electrical contacts can be searched inside the nerve and a loss of connection with neural cells can be counteracted [39.25]. Bioactive implants with embedded neurochemical stimulation will allow a more inartificial way to stimulate neural tissue. These new stimulators could be based on microfluidic or solid-state drug delivery systems. Owing to new materials, undesired side effects will occur more rarely or with lower intensity. The combination of technical systems with biological components will increase

the long-term stability of biological connections to the nervous system.

Implantable

40. Implantable Microsystems

Prashant Tathireddy, Florian Solzbacher, Robert Hitchcock, Klaus-Peter Hoffmann

A microsystem is a collection of electromechanical and electronic elements that have been reduced in size using advanced lithographic and machining techniques. Many types of medical devices rely on microsystem architecture to improve the health and well-being of millions of people. These systems are found in devices which are used for short and long periods of time, in diagnostic and therapeutic applications, and in devices which have limited contact with the patient and devices that are permanently implantable. Many types of implantable devices rely on microelectromechanical systems (MEMS) to achieve their functionality. Integrated circuit technology has extended beyond the fabrication of electronic elements to millimeter-scale mechanical structures with subelements in the nanometer to micrometer range. These MEMS devices often possess a high level of integration and provide numerous functions in one monolithic package. In addition, these devices allow

the creation of sensors and actuators with enhanced stability and low power consumption. However the MEMS device on its own is not able to function in the body without the requisite power source, physiologic interface, and packaging that allow it to perform its intended function over the intended lifetime. This chapter describes different implantable microsystems and their use in clinical application.

40.1 Market, Applications, and Common Requirements

Microsystems integrate two broad classes of structures, electromechanical and electronic, into a single assembly with the appropriate size, biocompatibility, and safety to be used in implantable medical devices and provide diagnostic or therapeutic assistance to a patient. MEMS devices such as pressure sensors and accelerometers are now relatively inexpensive components that medical device designers can specify into designs to enable direct physiologic sensing or to provide on-device diagnostics. An example of direct measurement is seen with pressure transducers that are permanently implanted in an aortic aneurysm sac to measure intrasac pressure and detect leakage after aortic aneurysm repair. In other applications, implantable drug pumps, for example, pressure sensors can be used to detect outlet occlusion. Ac-

celerometers that are integrated into pacemakers can sense the activity level of the patient and adjust the rate of the pacemaker accordingly. This capability has catalyzed an entire new generation of cardiac rhythm management devices. As new sensor technology matures and component costs are reduced, these miniature electromechanical structures will also catalyze next-generation medical devices and provide future revenue growth for device companies.

Implantable microsystems for medical applications rely on the integration of MEMS components with electronic components in a package or packages to perform their intended function. Active electronic components, MEMS components, and passive components are used in combination with application-specific integrated

circuits (ASICs) to provide complete system-level performance. Predefined electronic components such as batteries, capacitors, voltage regulators, transistors, memory, microprocessors, transceivers, and oscillators are commonly specified off-the-shelf by microsystem designers. In order to reduce implant size, many designers opt for miniaturization through component size reduction or integration rather than custom ASIC design. Component size reduction is often considered a less expensive and more flexible design approach than integration, and thus we see the continued miniaturization of many passive electronic devices. These components are routinely available in ultrasmall package sizes such as the submillimeter 0201 (0603 metric) rectangular, two-lead package.

The length of time the implant is resident in the body is a key requirement in the design and testing of implantable microsystems. All devices must be developed with thorough consideration of application, outcome, and duration. ISO 10993-1:2009 describes the general principles regarding the biological evaluation of medical devices and categorizes the devices based on the nature and duration of their contact with body tissues. The ISO standard describes the implant duration as limited (less than 24 h), prolonged (24 h to 30 days), and permanent (greater than 30 days). Understanding each application is critical not only to fulfill the regulatory requirements but also to design a safe and effective device. Implantable microsystems can fall into any of these three categories. Consider a MEMS-based sensor that is attached to the fetal scalp during birth to continuously monitor infant pH. This device would have a duration of less than 24 h, whereas an intracranial pressure sensor would have a prolonged duration of between 1 and 30 days. A pacemaker is considered a permanent implant with a duration lasting much longer than 30 days. Duration is therefore a key requirement when developing any type of implantable medical device. Although on the surface there appears to be little difference in regulatory scrutiny between an implant whose duration is 1 month and an implant whose duration is many years, this is not an accurate assessment. Regulatory compliance is often dictated by data on safety and effectiveness, scrutinizing the design, manufacturing, and testing processes. Testing must be conducted not only to verify performance but also to validate safety and effectiveness over the life of the implant. For implantable microsystems this often involves lengthy and sophisticated testing.

Implantable microsystems cover a broad range of medical devices that provide very different functions

over different time points and come into contact with various tissue types. These devices range in terms of integration from low-component-count systems such as neuroelectrode arrays to high-component-count systems including pacemakers, deep brain stimulators, and implantable cardioverter-defibrillators (ICD). These devices can provide physical sensing as seen with the Cardiomeems pressure sensor [40.1] or they can provide continuous core temperature as can be monitored with the ingestible Cortemp body temperature device [40.2]. Other devices provide chemical sensing as demonstrated by the Integra PO₂ intracranial probe [40.3]. In addition to physical and chemical sensing, other devices function by stimulating various tissues. Pacemakers electrically stimulate cardiac tissue to promote normal heart rhythm. Implantable cardioverter-defibrillators continuously monitor electrical impulses in the heart and respond to ventricular tachycardia or ventricular fibrillation by delivering an electrical shock to restore normal heart rhythm. Another family of implantable microsystems that provide stimulation is cochlear implants which stimulate the inside of the cochlea and trigger the auditory cortical functions in deaf persons. Other implantable tissue stimulation systems include bone growth stimulators, phrenic nerve stimulators, and deep brain stimulators.

Because of the variety of applications for implantable microsystems, these systems also come into contact with a number of different tissue types. Subcutaneous glucose sensors come into contact with the skin, neuroelectrodes interface with neural tissue, ingestible pH and temperature sensors are in contact with the gastrointestinal mucosa, and endoluminal pressure sensors reside in proximity to the vascular system.

Despite the variety of applications, durations, and tissue types seen by these implantable microsystems, they have many common characteristics. The devices must all function in a complex and oftentimes nonpermissive environment. Virtually all implantable devices are exposed to acute inflammation, which often extends to chronically persistent inflammation. This can lead to the formation of a fibrotic capsule of scar tissue that compromises the intended function of the device. Proteins are often deposited on the surface of the device, and this accumulation of proteins can also cause unwanted drift in sensors or build an incompatible interface between the device and host tissue. Many devices are surgically implanted and have to be compatible with the surgical procedure, incision site, and postsurgical healing process. In addition, permanently implanted devices must function for extended periods of time.

Premature failure of these devices implies costly and sometimes risky revision surgery.

No matter the intended use, duration or type of tissue in contact, the devices must be designed with patient safety at the forefront. All implantable devices must be sterilized prior to placement, and the mode of sterilization brings up another challenge for the designer. Electronic systems used in medical devices may not withstand radiation sterilization nor the high temperatures associated with autoclaving. A frequent choice is ethylene oxide or hydrogen peroxide plasma sterilization, and these must be considered during the design and development process. Devices must also be designed to integrate with the host tissue and minimize inflammation. Judicious selection of materials, surface finishes, and geometry can minimize the host inflammatory response and reduce the possibility that the implant will harm the patient. An additional consideration for any permanent implant is magnetic resonance imaging (MRI) compatibility. MRI and other imaging modalities provide an important diagnostic function in current medical practice, and many new-generation implants are designed to be compatible with diagnostic imaging systems.

Implantable microsystems must be integrated into a type of package that is tolerated by the host, protects the electronics from the ionic milieu of the physiologic environment, and minimizes leakage currents from the device to the host. These packages can be as simple as a conformal coat such as is provided with neuroelectrode arrays or as complex as a pacemaker pulse generator that encases the electronics within a hermetically sealed titanium enclosure with ceramic feedthroughs for the pacing leads. In addition to host compatibility, implantable medical electronics must be compatible with electromagnetic (EM) environments. This includes the EM emission from the device and the ability of the device to withstand EM environments such as electrostatic discharge (ESD), radiated emissions, electrical fast transients (EFTs), and surges.

Several types of fully implantable transducers based on MEMS technology have been developed for biosensor applications. These systems utilize telemetry to communicate information from within the body to an externally located receiver. Commercial systems are available from several manufacturers for both research and clinical applications. Wireless systems, in which both nodes (i.e., the implanted sensor and the receiver) have internal power, provide high data bandwidth and ranges of 0.2–10 m. These systems require batteries which must be charged or replaced and necessitate larger packages. Smaller implantable systems based

on active telemetry have been developed where the primary node powers the secondary node via electromagnetic coupling [40.4]. These systems do not require batteries and therefore have a longer lifetime and smaller size. Other systems based on passive telemetry systems use coupled inductors where the secondary node passively loads the primary node. The primary node oscillation changes as a function of pressure and alters the frequency spectrum of the transmitted signal [40.5]. Passive telemetry systems for biomedical pressure measurement have been approved by the Food and Drug Administration (FDA) for endovascular monitoring [40.1].

Medical microsystems oftentimes are required to communicate information from the body to external monitors or data collection systems. This communication can typically be handled in one of three modes: onboard storage, wired or wireless communication. Onboard storage consists of semiconductor memory storage that is part of the microsystem assembly. The memory records data or patient events, the medical device is retrieved, and the data from the onboard electronics are downloaded to a local host computer. Onboard storage is used in nonimplantable microsystems such as cardiac monitors, activity monitors, and gait/load monitoring systems. Implantable microsystems typically use wired or wireless communication. Wired systems are typically seen with catheter-type implants such as intracranial pressure and pO₂ monitors. Wireless communication is becoming increasingly used as the components become more available and the cost of integration decreases. In 1999 the US Federal Communications Commission (FCC) allocated the 402–405 MHz band for the Medical Implant Communication Service (MICS). Although it is a relatively new standard, it is being designed into many new generations of cardiac devices such as pacemakers and ICDs as well as implantable drug delivery systems, hearing aids, and neurostimulators. Key characteristics of MICS transceivers are 402–405 MHz, 25 μ W maximum effective isotropically radiated power (EIRP), specific base station/implant negotiation, and frequency agility. MICS transceivers can achieve up to 250 kbit/s at a range of approximately 6 feet [40.6].

According to market researchers at the Freedonia Group, the current US market for all implantable medical devices is US \$33 B, and this is expected to increase by 8.3% annually through 2014. Within the overall implantable market are implantable microsystems, which comprise approximately one-half of this market. The largest market segment of implantable microsystems

corresponds to the cardiac rhythm management devices: pacemakers and ICDs. Globaldata estimates that the global market for pacemakers could be valued at US \$4.2 billion in 2008. The market is expected to reach US \$6.1 billion in 2015 with an annual growth rate of 5.4%. According to Reuters, the global ICD market was approximately US \$6 B in 2008 with 7% growth. Bone growth stimulators is a smaller market, and implantable stimulators account for only a fraction of the total bone growth stimulator market. In 2006 this was a US \$400 M market, although this number includes implantable, semi-implantable, and external stimulators. According to reports by Neurotech, a market research firm, the cochlear implant market will grow from US \$725 M in 2008 to US \$1.59 B in 2012. The same firm reports that the deep brain stimulator market will grow from US \$461 M in 2008 to US \$1.36 B in 2012 and the cochlear implant market will grow from US \$289 M in 2008 to US \$914 M in 2012. The worldwide infusion pump market is expected to grow from US \$3.3 B in 2010 to US \$4.5 B in 2015 (6.2% compound annual growth rate, CAGR) according to the *Infusion Pumps Worldwide Market April 2009* report published by Marketstrat, Inc. Although this number includes all infusion pumps, the implantable infusion pump market is expected to achieve a compound annual growth rate of around 15% and is recognized as a potentially high-volume, high-growth segment.

Various microsystems technologies have been touted as game changers in the medical device area, and the last three decades have seen a tremendous number of devices conceived, tested, and even used to motivate new companies. Only a small percentage of these inventions are truly driving market acceptance and market share today. One of the largest disappointments has been in implantable glucose monitoring systems. Whether permanently implantable or implanted for only a few days, few of the myriad proposed systems are accurate enough to provide reliable measurements over the range needed for those with significant swings in blood glucose [40.7].

MEMS-based microsystems were heralded in the 1970s as an enabling technology for implantable systems. Many technology forecasters looked into the not too distant future and predicted that multifunction sensors, microrobotic surgery, and neural interface devices would usher in a new frontier of medicine. Although the technology was not adopted at the pace that the forecasters predicted, microsystems have slowly proven to drive both improved patient outcomes and increased company revenues. Adoption of the technology has been

slower than forecasted due in part to the conservative and regulatory nature of medical device development. In addition, physiologic environments are a hard place for MEMS devices to function due to an immune response that is robust to virtually all implanted materials.

Market forces that will drive new microsystems into the implantable device market include emerging technologies, new indications for use, increased regulatory scrutiny, and customer demand. Emerging technologies require time to prove reliability and cost-effectiveness. This has been shown historically, and because of safety and regulatory requirements, this technology latency will continue to be a characteristic of technology-driven medical device innovation. New indications for use will continue to be an attractive growth strategy for medical device companies. This approach can open new markets through an established device platform. For example, cochlear implants will continue to be prescribed for the profoundly deaf but will also be used in people who have severe hearing impairment and no longer respond to hearing aids. Deep brain stimulators which were developed and used for Parkinson's disease will see future applications in treating psychiatric disorders, brain injury, epilepsy, and stroke. The regulatory pathway for new indications is oftentimes significantly less arduous than for a brand new technology; however, regulatory agencies will continue to increase the levels of testing and quality for all medical devices. This requires additional company resources to respond and additional time as regulatory pathways are lengthened.

An aging and educated patient population will create demand for new technologies on both the diagnostic and therapeutic sides of healthcare delivery. As our population ages, there will be increased demand, particularly in the cardiac, neural, orthopedic, and diabetes markets, for implantable microsystems that can lead to earlier disease diagnosis and improved patient outcomes. Patient education through readily accessible information is creating a consumer-like demand for medical technology. Websites, blogs, advertisements, and word of mouth provide information that often drives patients towards specific device technologies, manufacturers, and healthcare providers.

There are large unmet needs in the medical device sector, and implantable microsystems can address many of these needs. Patients want better outcomes in virtually all areas of medicine, and patient outcomes will drive new technology into the marketplace. Implantable microsystems technology can improve patient outcome and reduce healthcare costs. These changes, however, will take place slowly and deliberately. Proving patient

safety, improved outcomes, and reduced cost requires extensive bench and clinical testing for validation. These data are not only required by regulatory agencies but also by insurance companies in order to provide cost reimbursement, a critical necessity for virtually all med-

ical devices. Combined with body area networks and telemedicine, implantable microsystems devices with features such as onboard sensing, drug delivery, tissue stimulation, microcontrollers, and wireless telemetry will be significant drivers in improving healthcare.

40.2 Sensors

Key drivers for implantable sensors can be found in personalized medicine needs for monitoring of biological markers in patients. These include neurological, metabolic, cardiovascular, and pulmonary disorders and pathologies. Measurement of, e.g., pH, pCO₂, and glucose can allow home treatment and continuous monitoring and reduce laboratory costs. The number of diabetes patients alone will increase to over 360 million patients worldwide by 2030 according to the World Health Organization. Implantable sensors will in most cases have to allow wireless transmission of data and/or power, requiring the integration of electronics, telemetry, and power modules into a small implantable device. They all have in common that they need to comprise biocompatible materials and be hermetically sealed so as to protect the device from the biological environment and vice versa without losing function of the device.

40.2.1 Pressure Sensors

Starting with their integration into microcatheters, implantable pressure sensors were amongst the first microsensor devices to become implantable. Driving applications include cardiovascular applications such as cardiac pressure, pulmonary pressure, intracranial pressure, abdominal pressure, and intraocular pressure in acute (e.g., pre- or postsurgery monitoring) or chronic use. Continuous implantable pressure sensors can be divided into wired and wireless sensors. An example of a wireless sensor could be a wireless continuous glucose monitoring system shown in Figs. 40.1 and 40.2.

Piezoresistive and capacitive effects constitute the two predominant sensing mechanisms for this type of sensor. The majority of devices in this realm are presently in research.

Pressure-sensing contact lenses are currently able to detect changes in the radius of curvature of enucleated porcine eyes of approximately 3 $\mu\text{m}/\text{mmHg}$ of pressure using a temperature-compensated strain gage embedded in the circumference of a silicone contact lens. The contact lens makes use of wireless power and communication. Its weaknesses are still:

- Movement of the eye with respect to the pressure sensor causes noise in measurement
- It works better with contact lenses custom-modeled to the eye.

A current clinical intraocular pressure (IOP) sensing technique is tonometry, which is not continuous but rather an in situ sensing method. A lot of researchers have developed small-size, accurate IOP sensors, some of which are also implantable and suitable for pressure monitoring.

Although there are piezoresistive sensors and strain gage sensors, the most popular sensing mechanism is still capacitor based. Capacitive sensors have the advantages of high accuracy, good stability, and low power consumption.

Some other problems encountered with current IOP sensing designs are:

- The device implant process is not entirely reversible. Original tissues may be removed forever to offer more space for implantation
- Current IOP sensor designs are less practical because of the spatial constraints in the eye and surgical complexity.

40.2.2 Voltage Sensors

Measurement of electrical signals (primarily voltages/potentials) inside the human body is typically associated with electrophysiological measurements, which originated in external recordings through electroencephalogram (EEG) and electromyogram (EMG) recordings. One of the key driving forces for these measurements inside the body was the emergence of neuroprosthetics in the late 1980s in which electrical signals from the central or peripheral nervous system or selected muscles are used to allow patients with neurological disorders, injuries or amputations to regain motor function through biological or prosthetic limbs. Conventional EEG and EMG signals are still far from providing sufficient information about,

Fig. 40.2 Microchip sensor array with four independent pressure sensors (1.5 × 1.5 mm each)

search efforts, originating in the USA and Europe, to develop acutely and chronically implantable devices that can reliably record signals from locations as diverse as areas of the brain, peripheral nerves, and muscles. These devices exhibit much higher temporal and spatial resolution of neural/electrophysiological signals. The emergence of these devices and technologies has also provided a novel and advanced tool for basic neuroscience research, including the development of new pharmaceuticals targeting the nervous system.

Today, the successful providers of this technology are offering a system-level solution that includes implantable electrodes and electrode arrays, insertion and manipulation tools (pneumatic inserters, microdrives, etc.), external electronics for control, data recording, signal processing and storage, software, and surgical and user training protocols, all of which contribute to

e.g., motor intent, nor do they allow high-resolution sensory feedback. Bridging of broken nerve connections is not possible without tapping into the neural tissue directly. This has led to a multitude of re-

Fig. 40.3a,b Examples of penetrating (courtesy of Microsystems laboratory, University of Utah and Microprobes for Life Science, Inc.) and surface electrodes: implantable signal processor chips (courtesy of Reid Harrison, Intan technologies LLC.) and coils (a) for use in integrated implantable neural interfaces (b) (courtesy of Microsystems laboratory, University of Utah)

Fig. 40.4 (a) Wired 100-channel silicon-based penetrating electrode array on the cortex of a human epileptic patient next to a conventional 8x8 electrocortical grid array (ECoG) and micro ECoG. the overall performance and long-term stability of the recorded signals (Figs. 40.3, 40.4).

The continued improvement in our understanding of nervous system function, and its dysfunction due to disease and trauma, has motivated an expectation that this understanding should allow us to develop new therapeutic solutions to a variety of nervous system disorders. The emerging discipline of neuroprosthetics is one new direction that has proven to be effective in mitigating some nervous system disorders. Cochlear prosthesis [40.8], deep brain stimulation for disorders of the motor system [40.9, 10], and vagal nerve stimulation for epilepsy [40.11] and chronic depression [40.12] are specific examples of how electrical stimulation of the nervous system can allow severely disabled individuals to return to relatively normal activities of daily living. As we learn more about the normal and pathological function of the nervous system, we can expect new therapies to be developed based on neuroprosthetic techniques. Neuroprosthetic interventions in the central nervous system (CNS) are expected to restore to a limited, but functional, degree lost sensory functions (sight, hearing, and vestibular-mediated balance),

and to correct dysfunctional motor functions such as Parkinson's disease, essential tremor, dyskinesia, and cognitive behaviors such as depression, schizophrenia, and bipolar disorder, and to acquire signals related to desired volitional control of the skeletal musculature. Neuroprosthetic devices applied in the peripheral nervous system (PNS) may provide new therapeutic interventions such as bladder and bowel control, the production of graceful stance and gait in subjects with stroke and spinal cord injury, volitional control of prosthetic devices (arms, hands, and legs), as well as pacing functions of the heart and diaphragm. Although only a few of these applications have begun to reach the clinical stage [40.13], many are currently being investigated in animal models, and some have passed proof-of-concept testing of the proposed therapy.

Even the simplest skeletal movement requires the coordinated activation of thousands of sensory and motor neurons in the CNS and PNS. Sophisticated movements associated with grasp and targeted movements are likely associated with complex spatiotemporal firing patterns of hundreds of thousands of neurons. In spite of this architectural complexity, four electrodes implanted

in the cochlea of profoundly deaf subjects can restore functional hearing, even though normal hearing results from selective stimulation of subsets of the 30 000 auditory nerve fibers. Researchers at Case Western Reserve University have demonstrated functionally useful, walker-assisted stance in spinal-cord-injured subjects with as few as eight epimysial electrodes positioned over appropriate extensor muscles of the legs [40.14]. Continued progress in the development of such neuroprosthetic interventions will be related to improved ways to communicate directly with neurons of the central nervous system and with the afferent and efferent nerve fibers of the PNS. The concept and value of selective neuronal communication has been appreciated for decades, but only two major research programs have pursued the development of complex and integrated electrode array architectures that can begin to provide such highly selective neural communication: at the University of Utah and the University of Michigan [40.15, 16]. Both of these programs have understood that highly selective neural communication can only be achieved with electrode arrays that penetrate into the nervous tissues, and both these programs have produced arrays containing on the order of 100 electrodes (Fig. 40.5).

State of the Art

Over the past two decades, the fields of neuroscience and neuroprosthetics have gained tremendous momentum through the development of novel architectures for neural interfaces. Some of these devices have great advantages over conventional neural electrodes: surface areas and dimensions are on the same order of magnitude as the biological structures they interface with (columnar structure in the cortex, neuron cell size, etc.). This enables greatly improved recording and stimulation selectivity compared with conventional neural electrodes. Key drivers in this field are the Michigan electrode array and the Utah electrode array (UEA). The commercialized version of the UEA, fabricated by Cyberkinetics Neurotechnology, Inc., was granted the first FDA investigational device exemption (IDE) for human trials [40.13, 17]. While there is little debate on the potential of this new generation of microelectrode arrays to restore lost sensory or motor function, this potential has yet to be realized in a clinical application.

Key Requirements and Challenges

Whilst detailed requirements depend on the specific application and location of implantation, a few common requirements can be listed.

A number of core issues have so far prevented a breakthrough of these devices in clinical application:

1. The long-term biocompatibility and stability of these systems remains an unsolved problem. The materials used in novel microelectrode arrays and interfaces generally tend to be fairly bio-inert and provoke only a minimal response. Long-term data are, however, characterized by a vast distribution ranging from only days to years, rather than reliably lasting as chronic implants.
2. The signals recorded from the electrodes need to be amplified and potentially processed. Conventionally, the electronic systems needed for this purpose are bulky and power consuming, which is why processing is carried out outside the human body. The necessary skin-penetrating connectors and cables not only pose a constant risk for infection but also provide a number of mechanical and physiological

failure modes due to the large number of mechanical and electrical interfaces, wires, and connectors that are exposed to the tissue. Tethering forces can displace the electrodes, changing the recording characteristics and provoking further immune system responses.

The delicate mechanical/electrical interconnects and wires can fail because of mechanical stress and exposure to a wet ionic environment. Cosmetic aspects of the experimental system used previously as proof-of-concept [40.13] would be in most cases unacceptable for real-world clinical use.

Technologies and Solutions

Implantable devices for this category can be separated into categories of penetrating and nonpenetrating (surface) electrodes, and single and array electrodes. Nonpenetrating electrodes are mostly polymer-based

Fig. 40.6 Drawings showing different components of the Utah wireless neural interface device (a,b) and picture of a completely integrated wireless cortical neural recording system (c,d) (SMD – surface mount device) (courtesy of Microsystems laboratory, University of Utah)

(polyimide, parylene C, liquid-crystal polymer) flexible devices with Au, Pt or recently IrO_x thin-film electrodes, which come in planar or cuff form. Most of these devices are passive electrodes that are connected via a microribbon cable, bond wires or other solutions to a skin-penetrating connector. Some effort has been made to couple these devices with active electronics for amplification, data processing, and wireless telemetry (Figs. 40.6, 40.7). Alternatively, pill-shaped active devices with wireless data transmission have been developed and demonstrated. Penetrating electrodes come in three basic configurations: as single-wire electrode (Pt or IrO_x wires), tetrode (four wires bundled to one four-channel device), and arrays. For the generation of larger arrays, electrode wires are tethered together, e.g., by a ceramic platform, and manually assembled. Alternatively, silicon-based devices have been developed by various groups.

Chronically implantable neural interfaces can only be realized if the devices have a high channel count, can be made independent of wired connections, and provide long-term stable and functional neural interconnections inside the human body. Wireless technology will be necessary in enabling chronic implantation and clinical use. Since the first demonstration of a wireless system for acquisition, processing, and telemetry of biomedical data by *Song* in 1997 [40.18], about a dozen groups worldwide (Table 40.1) have developed individual components or systems for recording and wireless transmission of neural data from the central or peripheral nervous system [40.19–40]. With the exception of recent efforts at the University of Michigan and the University of Utah, none of these devices was ever designed for chronic implantation and use of high-channel-count electrodes and their potential later clinical use. The specification and subsequent technical and physiological characterization of the devices presented in literature are far from complete. Often only specific parts (electrode, amplifiers, telem-

try units, etc.) were demonstrated. Table 40.1 gives an overview of the core radiofrequency (RF) wireless neural recording or stimulation activities presented in literature worldwide [40.19–21, 41–46].

40.2.3 Biochemical Measurement Sensors

The measurement of biochemical species *in vivo* is important in a number of application areas. Monitoring of metabolic and cardiovascular markers *in vivo* has been driven largely by diabetes and other metabolic disorders and the need to measure, e.g., glucose levels continuously for therapeutic and research purposes. Recently, other relevant markers, including pO_2 , pCO_2 , pH, and others, have been subject to intensive research and development activities. Two core technologies are being pursued today: electrochemical (amperometric) sensors and hydrogel-based sensors.

The incidence of the metabolic syndrome that links obesity, heart disease, and diabetes is increasing at an alarming rate [40.47]. Popular approaches to weight control such as exercise plans or low-carbohydrate diets have failed to halt the obesity epidemic. Obesity occurs when there is a persistent long-term excess in energy intake over expenditure, and fats and carbohydrates are the body's two major sources of fuel. An area of intense research is the rate of carbohydrate utilization as a function of age, diet, exercise intensity, and fitness level [40.47–49]. A recent study that involved blood sampling showed remarkable differences among healthy young males in the dynamics of the blood glucose response after glucose ingestion [40.49]. Hence, new tools are needed for tracking metabolism that give real-time results and that are either noninvasive or minimally invasive. Diabetes mellitus is a leading cause of heart attacks, strokes, kidney failure, blindness, and amputations. For both type 1 and 2 diabetes, tight control of blood glucose concentrations can prevent and/or delay the onset of these complications [40.50–53]. Many

aspects of the disease can only be understood in the context of an intact organism. Progress in research on the disease is therefore highly dependent upon animal models.

Electrochemical Sensors

For human use, the FDA has approved four continuous short-term glucose sensors [40.54, 55]. All four are subcutaneous amperometric sensors such as the continuous glucose monitoring system (CGMS) from MiniMed [40.56–58]. All four and the only commercial mouse glucose sensor (Bluebox Sensors, Inc.) use an enzymatic reaction based on glucose oxidase (GOx) that continuously consumes glucose within the surrounding interstitial fluid (ISF). The electrons exchanged in this reaction are transferred to an anode and read as a current. Even though this type of sensor has been intensely researched for over 20 years, it is still not suitable for chronic implantation (> 14 days), and hence insurance companies are reluctant to pay for it. According to pioneers in electrochemical glucose sensors, all four FDA-approved sensors still exhibit instability over the approved period (3–7 days), and the calibration is good for only 12 h [40.55]. Many of the electrochemical sensors exhibit a run-in period in which the sensitivity drops by 10–30% immediately after implantation [40.55, 59, 60], followed by a period of stability of 1–7 days. There are many possible explanations for the

Fig. 40.9 Response of hydrogel based glucose sensor to changes in glucose concentration (0–20 mM); pH = 7.4 (hydrogel thickness $\approx 400 \mu\text{m}$) in bovine serum

instability of electrochemical sensors. The consumption of glucose may cause problems if the supply of glucose is reduced near the implant area due to its consumption by inflammatory cells [40.61, 62]. All four electrochemical sensors employ an enzyme (GOx) that exhibits activity loss after 14 days in vivo [40.55]. All four are transport sensors, hence sensor calibration varies with the glucose diffusion coefficient [40.63]. All four employ nanoporous membranes to block endogenous redox species (e.g., ascorbate) from oxidizing at the anode. Some of the electrochemical sensors also employ nanoporous glucose-restrictive membranes [40.64] to avoid the oxygen-deficit problem, which arises because the molar concentration of glucose in ISF greatly exceeds that of oxygen [40.57, 65]. If either of these nanoporous membranes becomes blocked with protein fragments, glucose diffusivity will drop, changing the sensor calibration constant [40.63].

Hydrogel-Based Sensors

A smart hydrogel is a crosslinked polymer network that reversibly swells or changes electrical or optical properties in response to changes in the environment, such as pH, temperature or concentration of an analyte [40.66]. Several research groups worldwide have become interested in this topic [40.67–79]. The science is now reasonably well understood but has not yet been translated into commercial products. For the

Table 40.2 Summary of leading candidate implantable glucose sensors

	Implantable sensor	
	Electrochemical	Hydrogel array
Requires nanoporous membrane for diffusion restriction?	Yes	No
Calibration constant varies with changes in glucose diffusivity?	Yes	No
Contains enzymes that may deactivate after 14 days?	Yes	No
Continuously consumes the analyte (glucose)?	Yes	No
Easy to implant using catheter?	Yes	No
Exhibits run-in period with drop in sensitivity?	Yes	Probably no
Response time	< 1 min	7–20 min for 400 μm -thick gels. < 5 min possible
Simultaneous measurement of glucose, pH, pCO_2 ?	No	Yes

measurement of electrical properties, the gel is placed on an (interdigitated) electrode structure and exposed to changes in pH or concentration of analyte. Significant progress has also been made with fluorescent glucose-sensitive hydrogels, which are boronic acid based. Binding the sugar to a receptor increases the fluorescence of the dye embedded in the hydrogel. For the measurement of swelling, a smart hydrogel is confined between a porous membrane and the diaphragm of a piezoresistive pressure transducer. An increase in the analyte concentration, sensed through the pores of the membrane, is detected by a change in the swell pressure of the hydrogel. Thinner hydrogels lead to faster sensor response. Microfabrication of highly sensitive piezoresistive pressure sensors is a mature technology. The selectivity of the sensor arises from the binding specificity of the hydrogel, not from the porous membrane. Hence the pore size can be used to optimize the lifetime of the sensor in vivo.

A hydrogel is also an ideal biocompatible material for detecting changes in fluid osmolality, because the equilibrium swelling degree is determined as a trade-off between osmotic forces that favor swelling and

the polymer chain-stretching entropic penalty that opposes swelling [40.73, 81]. Thus, almost all hydrogels swell, all other factors being held constant, when the osmolality of the surrounding environment decreases. A glucose-responsive hydrogel also swells or deswells in response to changes in glucose concentration. The signal must therefore be corrected for fluctuations in environmental osmolality. In sensor array developed at UofU (Fig. 40.2), this correction is performed by comparing the signal of the glucose-responsive hydrogel to that of a reference hydrogel that is unaffected by changes in glucose concentration and pH. For glucose sensing (Table 40.2) a polyampholytic hydrogel containing phenylboronic acid which is reversibly crosslinked by the pair of diols present in glucose results in hydrogel shrinkage due to increase in the entropic chain-stretching penalty [40.78]. The polyampholytic gel does not use enzymes, does not require oxygen, and is relatively insensitive to pH and ionic strength because it is polyampholytic. Endogenous diols such as in fructose and glycerol cannot crosslink the gel. Thus, glucose sensors that employ this gel are unaffected by physiological levels of fructose [40.78, 82].

40.3 In vitro and in vivo Testing

Microsystems can be designed, manufactured, and rigorously evaluated in laboratory environments yet fail prematurely after implantation due to environmental conditions such as moisture, ionic contamination, protein deposition, and blood clotting, all of which are compounded by the host inflammatory response. A complex set of physiologic responses to implanted materials leads to both short- and long-term changes to the local tissue environment that can have a pro-

found and oftentimes deleterious effect on the implant. In virtually all implants a cascading series of events occurs in vivo, starting with the adsorption of blood proteins which coat the implant material surface with serum proteins leading to the formation of a protein matrix overlying the implanted material. This matrix subsequently becomes the site of attachment for migrating immune-responsive cells that attempt to integrate, eliminate or isolate the foreign implant. This tempo-

rally diverse inflammatory response leads to local tissue changes that include chemistry, cell type, and mechanical and electrical properties [40.83]. The dynamic physiologic response is one of the unique challenges of implanted microsystem oxygen sensors.

In vitro testing of implantable microsystems generally involves biocompatibility tests, environmental tests or performance tests. Because of the cost and complexity of in vivo tests, it is much more practical for implant developers to use in vitro methods to gain an understanding of device function in vitro before engaging in animal or human evaluation or for providing a chemical milieu that mimics a small portion of the physiologic environment to test basic performance parameters of a device. Biocompatibility tests are a regulatory requirement and typically follow ISO 10993. This international standard includes guidelines for duration of implant and type of tissue contacted, and outlines in vitro tests such as cytotoxicity, genotoxicity, hemolysis, and pyrogenicity (ISO 10993-1:2009). In vitro testing that attempts to mimic the physiologic environment has been performed with electrochemical sensors and neuroprosthetic electrodes where serum proteins and reactive scar-forming cells are placed in culture media and allowed to interact with the sensing interface [40.84, 85]. Other in vitro tests include long-term environmental conditioning in isotonic saline solutions.

In vivo testing of implanted microsystems can generally be considered from three perspectives: host compatibility, device compatibility, and device function. Host compatibility is determined through a series of tests that indicate that the device is tolerated or safe and will not cause adverse biologic effects on the host. Device compatibility tests evaluate device performance to determine the effects of protein deposition, cell adhesion, tissue encapsulation, and other unique tissue environmental and biologic factors. Device function tests consider the functional requirements of the implanted system and how it meets those requirements after short-term (< 30 days) or long-term (> 30 days) implantation. Host compatibility test design is guided by ISO 10993 but is always considered in light of the characteristics and end-use application of the device under consideration. In vivo biocompatibility testing considers requirements such as sensitization, irritation, intradermal reactivity, systemic toxicity, chronic toxicity, carcinogenicity, hemocompatibility, reproductive toxicity, biodegradation, and immune responses. The device must function in the host tissue environment and therein lies one of the greatest challenges of implanted microsystems. The Achilles' heel of most implanted

microsystems is the interface between the implanted device and the host tissue. The lack of long-term reliability at the biotic–abiotic interface leads to the lack of reliability in oxygen sensors [40.86], recording and stimulating electrodes [40.87], glucose sensors [40.88], and pH sensors [40.89]. In vivo evaluation not only looks at the critical performance interface between the physiologic environment and device but also environmental conditions unique to the implanted environment. This unique environment is often hostile to, or at the very least marginally permissive of, implantable devices. Biological processes can lead to mechanical changes in the surrounding environment, material fatigue due to constant motion, bioerosion due to fluid flow or tissue friction, corrosion due to the various ions in solution, encapsulation due to immune response, local chemical changes due to inflammation or other changes directly caused by the unique physiochemical environment of the body. In vivo tests are expensive and time consuming, and present unique challenges. Implanted devices are typically evaluated for performance during the implant period. During the implant period, devices can also be evaluated for host integration using imaging techniques such as x-ray, computerized axial tomography (CAT) scan, MRI, and ultrasound. These evaluations are often limited by the compatibility of the imaging modality with the medical device. Histological evaluation of tissue adjacent to implanted materials has been the most routine measure of assessing host compatibility. The implanted device is removed along with the surrounding tissue, and the tissue, the interface between the device and the tissue, and the device are analyzed for cell type, cell density, vascularity, and fibrous encapsulation. More in-depth histology can be used to look for specific biomarkers. In vivo animal testing is required for prehuman validation of new designs or design changes.

One of the many challenges is the long-term care that is required to maintain the host in a healthy state over extended periods of time. Unlike many types of physical and environmental testing, in vivo testing cannot currently be accelerated. Although in vivo testing cannot currently be accelerated, this type of testing is often performed on the bench. As in the electronics industry, accelerated aging is conducted according to the Arrhenius formula. These types of tests validate both performance and shelf-life parameters; however, the maximum temperatures must be carefully considered because of the use of thermoplastic polymers in many medical devices.

Visual Prosth

41. Visual Prostheses

Eduardo Fernandez, Klaus-Peter Hoffmann

Visual impairment is one of the ten most prevalent causes of disability that afflicts millions of people worldwide. This chapter provides an overview of some of the progress that has been achieved in the field of visual prosthesis. While the full restoration of vision seems to be impossible, it is expected that an implanted microelectronic device can create truly meaningful visual percepts that can be translated into functional gains such as the recognition, localization and grasping of objects or skillful navigation in familiar and unfamiliar environments resulting in a substantial improvement in the standard of living of blind and visually impaired persons. However we should be aware that the scientific and engineering problems are much more complex than originally believed and that there are still many unresolved issues than could cause a delay in its development.

Living with acquired blindness not only lowers the quality of life of these individuals, but also strains society's limited resources for assistance, care, and rehabilitation. For decades, the possibility of restoring sight to blind individuals has been a subject of intense scientific research. Drug development and genetic engineering have had only marginal success in this context, but new hope has been generated by recent advances in microfabrication technologies, neurosciences, biomaterials, neuromorphic engineering, and information technologies leading to the development of highly sophisticated neural prosthetic devices designed to interact with the nervous system. Such assistive devices have already allowed thousands of deaf patients to hear sounds and acquire language abilities, and the same hope exists in the field of visual neurorehabilitation.

Loss of vision affects millions of people worldwide and poses extraordinary challenges to individuals in our society that relies heavily on sight. Although in recent years the techniques of molecular genetics have led to a rapid identification of a great number of genes

involved in visual diseases [41.1], once damaged the nervous system is capable of little functional regeneration, and currently there is no effective treatment for many patients who are visually handicapped as a result of degeneration or damage to:

1. the retina,
2. the optic nerve, and/or
3. the brain.

While pharmacological interventions provide therapeutic solutions to many physiological problems, a pharmacological approach to the mechanisms of blindness has not been discovered. Furthermore, there remains the pervasive question as to how these molecular approaches will actually restore functional vision after it is completely lost in a given individual. Therefore, there are compelling reasons to pursue the development of sophisticated microelectronic prostheses as viable rehabilitative and therapeutic options to substitute, and ultimately, restore sight.

41.1 The Case for Artificial Vision

The possibility to restore visual perceptions in blind individuals has a long history in biomedical engineering. A German neurosurgeon, Forester, was the first to expose the human occipital pole under local anesthesia and to electrically stimulate it. In 1929 he noted that electrical stimulation induced the perception of points of light, called phosphenes and usually described as *stars in the sky*, *clouds*, and *pinwheels*, which were dependent on where the stimulation probe was placed. These findings, together with the earlier studies of *Penfield* and co-workers during the course of neurosurgical interventions for the treatment of epilepsy [41.3] settled the physiological basis for present efforts to develop a visual prosthesis for the blind.

Subsequent experiments by different research groups [41.4, 5] showed that stimulation of multiple electrodes simultaneously allowed blind volunteers to recognize simple patterns, including letters and Braille characters (Fig. 41.1). The results of these studies supported the premise that patterned electrical stimulation of the visual cortex can evoke patterned percepts. However, these early efforts did not culminate in the restoration of a useful visual sense. Problems with this

early work were associated mainly with the large surface electrodes that were used to evoke phosphenes. Thus, relatively high electrical currents were required to evoke phosphenes, and when multiple electrodes were stimulated, these large currents could interact in a nonlinear fashion, evoking phosphenes with unpredictable spatial properties. Furthermore, they also found that a visual prosthesis based on relatively large surface electrodes implanted subdurally would have limited usefulness because of occasional elicitation of pain due to meningeal or scalp stimulation, and the risk of inducing epileptic seizures. This body of work suggests that relatively large surface electrodes may not be a tenable approach to stimulation of the visual cortex, and led a number of investigators to develop a visual prosthesis that could be implanted directly into the retina, the brain, or other parts of the visual pathways. One of the pioneers in this field was *Tas-sicker*, an Australian researcher who in 1956 was the first to patent a method of implanting a light-sensitive selenium cell in a blind person's retina to transiently restore the patient's ability to perceive the sensation of light [41.6, 7].

Fig. 41.1a,b Examples of patterned phosphenes. (a) Possible perception generated by simultaneously stimulating three electrodes arranged as a triangle. (b) The neural plasticity of the visual system can contribute to ever-improving correlation between the physical world and evoked phosphenes. Immediately after implantation the evoked phosphenes are likely to induce a poor perception of an object (the letter E in this example). However, appropriate learning and rehabilitation strategies will contribute to provide concordant perceptions (after [41.2])

41.2 Visual Pathways: From Real Vision to Visual Neuroprostheses

The concept of artificially producing a visual sense in blind individuals is founded on our present understand-

ing of the structure of the mammalian visual system, its processing elements, and the relationship between elec-

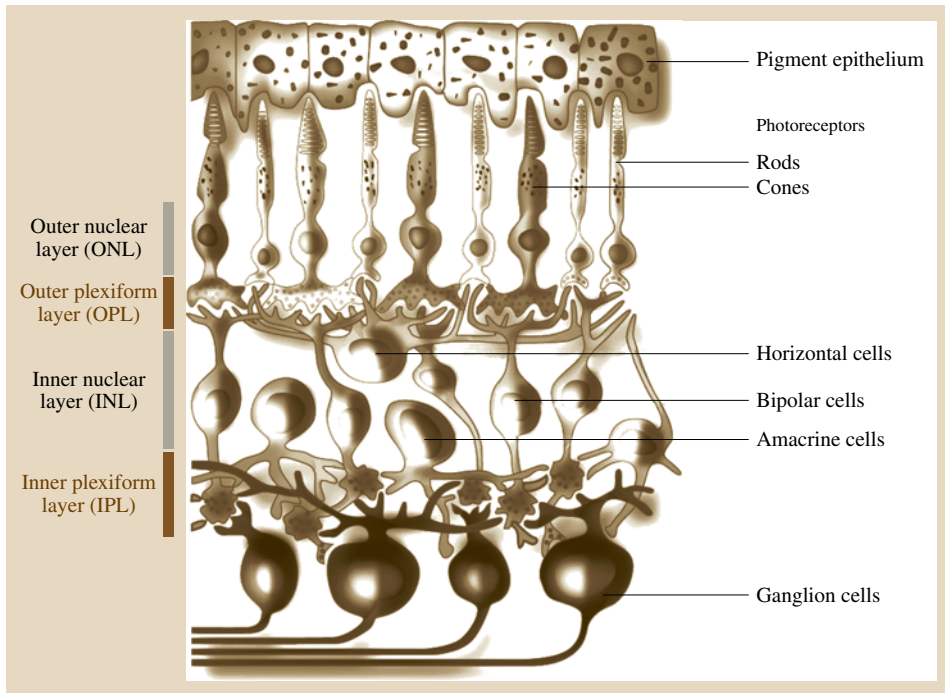

Fig. 41.2 Crosssection of the retina. Light must travel through the thickness of the retina before striking and activating the rods and cones. Subsequently, the absorption of photons by the visual pigment of the photoreceptors is translated into an electrical message that can stimulate all the succeeding neurons of the retina. The retinal message concerning the photonic input and some preliminary organization of the visual image are transmitted to the brain from the spiking discharge pattern of the ganglion cells (image courtesy of Dr. Markus Bongard)

trical or mechanical stimulation of any part of the visual pathways and the resulting visual sensations [41.8].

Our entire experience of the external visual world derives from the concerted activity of a restricted number of retinal ganglion cells (Fig. 41.2), which have to send their action potentials through the *bottleneck* optic nerve to the brain (Fig. 41.3). The retina is essentially a piece of brain tissue that gets direct stimulation from the outside world's lights and images. Visual input to the retina consists of a stream of photons, which can be unequivocally quantified in space and time. The retina performs spatial, temporal, and chromatic processing on visual information and converts it into a compact *digital* format composed of neural impulses [41.9]. In addition, starting at the retinal level, vision is an active process and eye movements are essential for information processing [41.10]. Thus our entire experience of the external visual world derived from the concerted activity of a restricted number of retinal ganglion cells, which have to send their information, via the optic nerve, to higher visual centers. This representation has to be unequivocal and fast, in order to ensure object recognition for any single stimulus presentation within a few hundreds of milliseconds [41.11]. Therefore, the question of how the information about the external world is compressed in the retina, and how this compressed representation is

encoded in spike trains is an important challenge for the success of any visual prosthesis.

The next processing center is the lateral geniculate nucleus (LGN), which begins to integrate information from both eyes into a binocular representation of visual space. Once retinal signals arrive within the LGN, they are in a position to be influenced by a wide variety of other inputs, as well as the complex feed forward and feedback circuits. These inputs include not only visual information, but also nonvisual information that comes from cortical areas, superior colliculus, pretectum, parabrachial nucleus, reticular nucleus, and other brain stem pathways [41.12]. The number of synapses provided by these nonretinal inputs greatly outnumbers the number of parallel pathways coming from the retina, but their function is not fully understood.

The LGN neurons mainly project to the primary visual cortex (also known as the striate cortex or V1), which was the first cortical area clearly identified in the human brain by *Gennari* in 1782 [41.13]. Area V1 is located at the back of the head, in the occipital lobe, and from here the information is distributed to a number of higher cortical centers for further processing [41.14]. The main point, as stated by *Hubel* and *Wiesel*, is that the primary visual cortex is in no sense the end of the visual path [41.15]. It is just one stage, probably an

Fig. 41.3a,b Human visual pathways. **(a)** The optic nerve transmits the information from the retinal ganglion cells to the lateral geniculate nucleus (LGN), which relays information to the primary visual cortex (image courtesy of Webvision, <http://webvision.umh.es>). **(b)** Functional segregation of the visual system, presenting the projection of large retinal ganglion cells to the magnocellular layers of the LGN and further to layer 4Ca of the primary visual cortex. early one in terms of the degree of abstraction of visual information processing.

As blindness results from an interruption in the normal flow of signals along the visual pathways, a visual

prosthesis has to excite the neurons of the pathway at some point after the damage site [41.2]. The only requirement is that the device should have contact with still functioning neural elements.

41.3 Current Approaches to Visual Prostheses

Figure 41.4 shows the main approaches for the design of a visual neuroprosthesis. Since retinal diseases frequently reduce visual acuity and result in noncurable blindness, several groups worldwide are working on the development of different prosthesis designed to interact with the remaining healthy retina [41.6, 16–19], optic nerve [41.20, 21], and LGN [41.22, 23]. However, the output neurons of the eye, the ganglion cells, often degenerate in many retinal blindness cases [41.24, 25], and therefore a retinal, optic nerve, or LGN prosthesis would not always be helpful. This extensive degeneration usually spares the neurons in the higher visual regions of the brain, which suggests the enormous potential of a cortical prosthesis designed to stimulate cortical neurons [41.2, 26]. Due to the complexity of the interconnectivity and the receptive field characteristics, visual areas beyond V1 have not been proposed as sites for vision prostheses.

In general, all the approaches share a common set of components: a bioinspired retina-like encoder able to transform the visual scene into patterns of electrical

stimulation, a second stage that processes the information and transmits it through a radio-frequency link to the implanted device, and an electrode array implanted at some level in the visual pathways and located near the target neurons.

41.3.1 Retinal Stimulation

Retinal prostheses are being developed to apply electrical stimulation to the retina in order to restore vision in patients with age-related macular degeneration and retinitis pigmentosa, and more than five groups are already pursuing human clinical trials of diverse retinal prosthesis [41.27, 28]. There are significant advantages to the retinal approach as it is less invasive and the implants are lower in the visual pathways, which means that they are closer to the photoreceptors and have more opportunities for natural processing of the visual information. However, there are also some problems related with the encapsulation, fixation of the implants, power dissipation, and the production of sufficient

Fig. 4.1.4a-d Summary diagram of different approaches to restore vision. The *inset figures* illustrate the approaches in detail. **(a)** Schematic diagram of a retina crosssection showing two methods of stimulating ganglion cells. The epiretinal device is attached to the inner surface of the retina and stimulates the inner retinal layer. In the subretinal approach, photodiodes are implanted underneath the retina and used to generate currents that stimulate directly the retina. **(b)** Stimulation of the optic nerve by implanting a cuff electrode around the nerve. **(c)** LGN microstimulation. **(d)** Cortical approach

currents [41.29, 30]. Furthermore, for a retinal visual prosthesis to work, there must be some functional retinal ganglion cells, and therefore these systems are not capable of treating conditions such as glaucoma and diabetic retinopathy [41.28, 31].

Currently, there are mainly two kinds of retinal implants under development: subretinal and epiretinal. Furthermore, some groups are studying the efficacy of the suprachoroidal-transretinal stimulation to generate focal excitation in retinal ganglion cells [41.32, 33]. In addition, a novel photostimulation approach has been proposed, which involves re-engineering retinal ganglion cells or bipolar cells to become light sensitive by incorporation of artificial opsins [41.34].

Subretinal Implants

As some of the neural retina, with the exception of the photoreceptors layer, is preserved for both age-related macular degeneration and retinitis pigmentosa, a reasonable approach to the restoration of vision under these

pathologies is the replication of the function of the photoreceptors [41.6, 35, 36]. One of the main advantages of this location is that the remaining retinal cells in the outer plexiform layer (vertically running bipolar cells and horizontally oriented horizontal cells) may be utilized to stimulate the amacrine and ganglion cells directly.

In a general sense all research groups focusing on the subretinal approach have proposed similar methods. Thousands of light-sensitive microphotodiodes equipped with microelectrodes are assembled on a very thin plate and placed in the subretinal space. The subretinal device or microphotodiode array (MPDA) is implanted between the pigment epithelial layer and the outer layer of the retina, which contains the photoreceptors. Then light falling on the retina generates graded currents that stimulate the dendrites of the bipolar cells in the outer plexiform layer to induce a visual sensation.

The schema is tantalizingly simple, requiring no external power or control signal. Furthermore the pho-

todiodes can be tailored to provide either positive or negative current in response to illumination, with the intention of mimicking the function of ON and OFF bipolar cells. However, the success of this approach depends upon three assumptions. First, the bipolar cells of the dysfunctional retina should persist and function in a somewhat physiologically normal manner. Second, the photodiodes must generate enough current under normal illumination levels. Third, the electrodes can be placed in close enough proximity to the bipolar cells. Encouraging progress has been reported in each of these areas.

Epiretinal Implants

As an alternative approach to stimulate the retina, other research groups have proposed placing the stimulating electrodes in close proximity to the retinal ganglion cells. This approach attempts to stimulate the remaining retinal neurons of patients who are blind from end-stage photoreceptor diseases. In this context, several reports indicate that significant portions of the retinal ganglion cells survive even in end-stage of pathologies such as age-related macular degeneration and retinitis pigmentosa [41.37, 38].

The epiretinal approach implies the use of implanted multielectrode arrays (MEAs) and transcutaneous telemetry to transfer data and power to the implanted MEAs. To date, a number of experiments performed in sighted and blind human subjects demonstrate the potential for epiretinal electrical stimulation to provide patterned visual perception [41.39–42]. There are, however, issues relevant to the epiretinal approach that should be solved. Thus, the epiretinal devices need to be firmly affixed in place in order to efficiently stimulate the retina and provide a consistent visual perception. Another issues of concern are power dissipation, cross-talk between electrodes, and the viability of the tissues under the implant. Nevertheless, epiretinal implants appear to be a potentially viable approach for restoring functional vision in some blind individuals.

41.3.2 Optic Nerve Stimulation

The next visual prosthetic approach is to stimulate the optic nerve fibers. The optic nerve, composed of retinal ganglion cell axons, can be reached surgically and may be a suitable location for implanting a stimulation electrode providing that the retina cannot safely support a prosthesis, for example in long-standing retinal detachments.

The rationale for using a nerve cuff electrode is completely distinct from all the retinal approaches

where an increased number of electrode contacts may theoretically increase the resolution [41.43–45]. In contrast, in this approach a few contacts are expected to be capable of generating a large number of potential field shapes within the nerve that can activate different parts of the nerve and thereby allow a large number of distinctly located phosphenes to be generated. However, the selective and simultaneous stimulation of multiple subsets of axons requires cuffs with a prohibitively large number of contacts. Furthermore, the present cuff electrodes do not allow selective stimulation of individual fibers, so that this approach is unlikely to be able to recreate a high-resolution visual scene.

41.3.3 LGN Stimulation

The lateral geniculate nucleus (LGN) is the primary processing center for visual information, meaning that the neural signals encoding visual information have not yet been extensively processed. The LGN receives information directly from the retinal ganglion cells and projects mainly to the primary visual cortex. The LGN holds promise as a target of electrical stimulation for artificial visual percepts since it has been demonstrated that LGN microstimulation produces predictable visual percepts [41.22, 23]. Therefore, a visual prosthesis based on LGN stimulation may be helpful to restore sight to those who have become blind because of trauma of the eye or diseases such as glaucoma, macular degeneration, and retinitis pigmentosa.

A possible disadvantage of this approach is the limited number of electrodes that can be inserted in the LGN and, hence, the limited visual resolution. Moreover the neurons in the LGN are too close together to be stimulated individually, which would be important when trying to reproduce natural vision. Furthermore, most of the projections to the LGN are from the primary visual cortex making it difficult to create complex visual percepts.

41.3.4 Intracortical Stimulation

If the primary visual cortex can be stimulated with visual information in a format somewhat similar to the way it was stimulated before the onset of blindness, a blind individual may be able to use this stimulation to extract information about the physical world around him/her [41.2, 46]. Although a cortical prosthesis based on relatively large subdural electrodes has a limited usefulness, a promising approach, which can activate populations of neurons with greater spatial

specificity and lower levels of stimulation than is possible with larger electrodes on the surface of the brain, is the use of intracortical microelectrodes. In this context, *Schmidt et al.* [41.26] described the implantation of 38 floating microelectrodes within the right visual cortex of a 42 year old woman who had been blind over 22 years. 34 of the microelectrodes were able to elicit phosphenes for a period of 4 months, and most of the microelectrodes had stimulation thresholds below 25 mA. Unfortunately, these microelectrodes were not well suited for a long-term application. Thus, due to the breakage of lead wires early in the experiment, only limited tests could be done to evaluate pattern recognition. Nevertheless, taken as a whole, the previous results suggest that passing electrical currents through an array of electrodes inserted into an appropriate location in the visual pathway, is able to produce the perception

of phosphenes, and that these phosphenes may be appropriate for restoring some limited but useful sense of vision to the profoundly blind. This cortical approach requires intracortical penetrating electrodes with exposed tips located in layer 4 and with sizes of the same order of magnitude as the neurons that are intended to be stimulated.

This approach is the only treatment available for blindness caused by glaucoma, optic atrophy, or diseases of the central visual pathways, such as brain injuries or stroke.

The main problem of a cortical implant is the lack of preliminary processing by the brain, particularly in the retina where much of the information reduction takes place [41.31]. Furthermore, it is unclear what kind of percepts will be evoked by simultaneous stimulation of a large number of microelectrodes.

41.4 Engineering Visual Neuroprostheses

Regardless of the differences in the approaches, all vision prostheses (with the exception of subretinal prostheses and the photostimulation approach) share a common set of components [41.8], which are illustrated in Fig. 41.5. One or two cameras provide image acquisition, which is then processed by a bioinspired retina-like encoder in order to transform the visual world in front of a blind individual into electrical signals. This first stage performs a multichannel spatio-temporal filtering, to extract and enhance the most relevant features of the scene and also re-encodes this information into a neuromorphic stream of electrode addresses [41.47]. The second stage serializes the information and transmits it through a radiofrequency link to the implanted device. This telemetric transmission provides a wireless transfer of power and data to the internal system (Fig. 41.6). The implanted electronics package must decode the signals, identify the target electrodes, and generate the stimulation signals applied using multiple microelectrodes.

These transformations must take into account many issues that are normally performed by the retina. For example, sampling across the retina is not uniform and, therefore, retinotopic gradients and magnification factors must be introduced to match image representation. On the other hand, it is clear that several streams of information are processed in parallel from any retinal point by several dozens of interneuronal subtypes before contrast, brightness, orientation move-

ment, and color are finally coded as modulation of ganglion cell action potential series [41.48]. While chromatic information is not of utmost priority, a differential characterization will nevertheless be required when designing *achromatic* processing modules for basic representation of image components. The goal of developing such a bioinspired retinal encoder is not simply to record a high resolution image, but to transmit visual information in a meaningful way to the appropriate site(s) in the retina, optic nerve, LGN, or brain.

Although it is not the purpose of this chapter to present a detailed study of the problem of coding/decoding of retinal images by ensembles of retinal ganglion cells, increasing evidence suggests that the retina and the brain utilize distributed codes that can only be analyzed by simultaneous recording of the activity of multiple neurons [41.49–52]. Far from a simple transducer of light into electrical neural impulses, the retina performs a locally-computed spatio-temporal contrast enhancement function and a very efficient compression of visual information. These tasks are essential to provide a high adaptation capability to very different lighting conditions, high noise immunity, and to efficiently communicate the visual information by means of a limited number of optic nerve fibers. Thus, our entire experience of the external visual world derives from the concerted activity of a limited number of ganglion cells in the retinal output layer that have to represent all the features of objects in the visual world, namely

Fig. 41.5a–c Schematic organization of a bioinspired retinal model. **(a)** The input images are captured by a photosensor array and processed by a combination of several spatial and temporal filters that enhance specific features of the captured information. **(b)** Performance of the encoder/stimulator in transforming an image of a hand into an electrode stimulus pattern. **(c)** Leaky integrate-and-fire spiking neuron model showing the response to a stimulus for a given component of the activity matrix

their color, intensity, shape, movement, and the change of these features in time. This representation must be unequivocal and fast in order to ensure object recognition for any single stimulus presentation within a few hundreds of milliseconds.

The development of a bioinspired visual encoder, therefore, poses an information processing challenge without parallel in neuroscience, computer science, or communication technologies. Consequently, several researchers are developing complex retina encoders for visual implants [41.53, 54].

Figure 41.5 summarizes the basic architecture of a typical bioinspired retinal model. It is based on information about the photoreceptor distribution within the human/primate retina and on electrophysiological recordings from populations of retinal ganglion cells. Through a set of parametrized filters and functions, that

simulate the complex operations of the neural retina, a portable model is obtained that can be easily translated into a hardware description for automatic synthesis using the appropriate tools. The input images are captured by a photosensor array (preferably a logarithmic response camera that has a similar response to the human visual system and can reduce saturation in high contrast visual scenes) and are processed by a set of separate spatial and temporal filters that enhance specific features of the visual information captured. The model can take into account the irregular distribution of photoreceptors within the human retina: a high density of pixels and smaller receptive field sizes in central areas and lower density and bigger receptive fields in peripheral areas. A gain factor can be specified for every individual channel as well as a global gain. The next stage reduces the information to the resolution of the electrode

Fig. 41.6 Functional blocks of a visual neuroprosthesis. This includes a bioinspired visual information block (artificial retina) to extract and enhance the most relevant features of the visual scene. A coding block that translates the retina-like output into pulses modulated with different cadences and temporal lags and whose projection onto the electrode matrix must be fully configurable. An RF block providing a wireless transfer of power of data and the implanted electronics package that must decode the signals, identify the target electrodes, and conform the voltage shape (D/A converter) of the final waveforms to be applied to the electrodes located near the target neurons (after [41.46])

matrix, with the option of defining specific receptive field shapes and sizes. Finally, a mapping and neuromorphic coding (into output charge-balanced pulses that can be sent to each electrode) is carried out and feeds the radiofrequency link that goes to the microelectrode array. Thus, the continuously varying input video stream is converted into neuromorphic pulse-coded signals through a circuit that emulates the function of retinal neurons [41.46,55].

The implementation of the model in digital hardware provides a flexible design, achieving a high performance with response times several orders of magnitude lower than those of biological systems. The present version of the whole system is able to work properly up to 40 MHz [41.29, 46, 47]. This means that 40 000 electrodes may be stimulated with an inter-spike temporal resolution equal to or lower than 1 ms. The use of reconfigurable circuitry (FPGA) permits one to adjust or even change the spiking model easily [41.47,54]. Furthermore, this technology can be also used for psychophysical experimentation in order to determine the best image processing strategy, and to obtain insights into the optimal number of electrodes, gray levels, and grid size [41.56,57].

Finally the output of the bioinspired retina must be transmitted to a remote stimulating device that electrically connects with the implanted microelectrode array (Fig. 41.6). Ideally, this should be done telemetrically (i.e. without the need for attached wires) to reduce the risk of infections and an opto-coupling stage should be incorporated to protect the patient against electrical risks. Furthermore, for a durable system material must be biocompatible and electrical-charge displacements must be in margins of capacitive work, never in an irreversible-faradaic working zone [41.58].

Several factors should be taken into account, especially safety, size, and power consumptions. Thus, this stimulating device should be able to operate in real-time for a high number of electrodes, have low power requirements and be flexible enough to generate different waveforms and adapt to different stimuli and image processing conditions. Basically, it should be able to solve the problem of transmitting data and power to multiple microelectrodes, while simultaneously having the possibility of remote control and sensing of microelectrode status. This implies a compromise between the power level requirements of the stimulation circuits and the signal bandwidth requirements [41.47, 59].

41.5 Safe and Effective Stimulation of Visual Pathways Through Multiple Microelectrodes

Any visual neuroprosthetic system must be implanted into the retina, optic nerve, LGN, or visual cortex and remain fully functional for periods that will eventually extend to many decades. Therefore, these devices must be highly biocompatible and be able to resist the at-

tack of biological fluids, proteases, macrophages or any substances of the metabolism. Furthermore, it is necessary to take into account the possible damage of neural tissues by permanent charge injection and the most effective means of stimulating the visual pathways. On the

other hand, although there are no major safety concerns stemming from the pilot studies carried out to date, the risks of the surgical procedures involved are not negligible. All these considerations place unique constraints on the architecture, material, and surgical techniques used in the implementation of visual prosthesis interfaces [41.29, 42, 46, 60, 61].

Important problems reported with all available microelectrodes to date are long-term viability, biocompatibility, and biostability. Recent studies of the response of neural tissue to stab wounds have shown that there are acute and chronic inflammatory reactions that affect

both the neural tissue and the surface of the microelectrodes [41.62]. These reactions often result in damage to neurons and microelectrodes and lead to the proliferation of a glial scar around the implanted probes, which prevents recording or stimulation of neurons [41.63, 64]. The reasons for the inflammatory response lie in molecular and cellular reactions at foreign surfaces [41.65]. These responses can be controlled, and one of the big challenges in this field is to create new, more biocompatible surfaces. The solution may involve coating the electrodes with bioactive molecules that are slowly released into the surrounding neural tissue [41.60].

41.6 Selection of Suitable Subjects for a Visual Prosthesis

The selection of a specific person for a visual implant is not straightforward. There are no strict standardized criteria for accepting or rejecting a candidate or for the best rehabilitation procedure for every type of blindness. Generally, a choice may be made between different approaches and/or rehabilitation procedures depending on availability, efficacy or rejection of invasive methods [41.28, 66, 67], but a presurgical protocol and improved methods for predicting success with a visual neuroprosthesis need to be developed [41.46, 56, 68].

In general, it is considered crucial, at least in these preliminary stages, that the subject have no residual vision and has not had any significant benefit from a conventional visual aid. However, these seemingly straightforward criteria have not always worked well in practice, and there are different definitions of residual vision and significant benefit from a visual aid. Needs and wishes of individual subjects are also significant variables for implant candidacy. This issue is further complicated because it is not possible to predict success with a visual implant in a specific person. Clearly, our knowledge regarding visual system anatomy and function may allow for crude bioinspired models and strategies of stimulation. However, what has not been discussed is how the type, onset, duration, and temporal profile of an individual visual loss may have repercussions on the success of the device. To decide what time is the most suitable in that matter is a difficult double-faced ethical decision [41.66].

Recognizing these limitations, it is generally acknowledged that previous visual experience is necessary for the patient to interpret and recognize the visual patterns that are generated. In this context, it has been presumed that if blindness occurs after the age of ten

years of age (i. e. with respect to the critical period), visual pathways should develop normally and thus remain excitable [41.28, 66].

Improved networking among research groups would clearly help in developing a common body of standardized test and standardized selection criteria [41.56]. Among them, possible criteria to specify the characteristics of adults who are potential users of a visual neuroprosthesis [41.68] are listed here.

- Visual function criteria and pre and postimplantation testing. Indications in favour of a cortical visual implant may include profound and bilateral visual loss, but more objective and quantitative criteria should be developed. These studies need to incorporate a more quantifiable means of estimating risk and benefit for a given candidate.
- Electrophysiological criteria. Registration and analysis of electroretinogram (ERG) as well as visual evoked potentials (VEP) should be a basic component in candidate selection. Improved methods for predicting success with a visual implant need to be developed. These methods may include test using data from transcranial magnetic stimulation (TMS) of visual pathways and new imaging techniques such as functional magnetic resonance imaging (fMRI).
- Medical, anatomical, and surgical criteria. The usual candidate should be a healthy adult. The medical history should include the onset and evolution of the blindness, physical examination, and laboratory tests to include or exclude candidates and to assist the implant team in planning a total program, including postimplant training.

- Evaluation of the risks and limitations associated with the surgery and every specific approach. These are usually small for persons in good general health but increase with age and other pathological conditions.
- Quantitative evaluation of the subjects' needs and performance using standardized psychophysical and behavioral methods.
- Psychological testing to discard psychiatric disorders and other possible mental status that may affect the success of the visual prosthesis.

There are other important issues that should be taken into account and case studies of surgical sight restoration following long-term visual deprivation [41.69, 70] provide a relevant insight. For example, following ocular surgical procedures aimed at regaining some degree of functional vision, patients blinded for many years experience profound difficulty in various visual tasks, particularly those requiring the identification and recog-

ognition of objects. Interestingly, if patients are allowed to explore the same object through touch, they can recognize it immediately and register their newly acquired visual percepts with their existing senses. These findings demonstrate that even when vision reaches the brain physiologically, visual perception nonetheless remains impaired. Thus, the simple restoration of a lost sensory input may not itself suffice in reconstituting the sense it normally provides, and active visual rehabilitation may be necessary to maximize the adaptation and get the most from these devices. Moreover, some form of spatial remapping between the bioinspired encoder and the stimulation pattern delivered to the array of electrodes implanted in the visual cortex is highly recommendable [41.46, 50, 53, 59]. As a result, the right learning, remapping, and rehabilitation strategies may potentially help to modulate the plasticity of the brain and contribute to ever-improving performance and more concordant perceptions.

41.7 Challenges and Future Perspectives

Visual prosthesis is a rapidly emerging field that requires extraordinary diverse, lengthy, and intimate collaborations among basic scientists, engineers, and clinicians. Significant challenges to the development of a successful visual prosthesis include limitations to the number of electrodes, biocompatibility, encapsulation, electrode degradation, power interference, signal and imaging processing, interference with residual vision, functional evaluation, and training [41.31, 46, 68]. Despite all these issues several research groups are developing sophisticated microelectronic devices designed to stimulate viable neuronal tissue in the hopes of generating functional vision artificially.

To date, at least 23 different devices are under development and 5 groups are pursuing human clinical trials either with acute or chronic implantation of neurostimulating devices, and increasing numbers are expected within the next years [41.27, 28]. However, even the most advanced of these experimental devices has only been able to provide evidence that such an approach may indeed be feasible. What remains to be conclusively demonstrated is whether or not the visual percepts produced by implanted microelectronic devices can create meaningful visual perceptions that can be translated into functional gains such as the recognition, localization and grasping of objects, or skilful

navigation in an unfamiliar environment, thus, ultimately, having the potential to improve the quality of life of a patient.

The greater impediments to future progress in implementing a visual neuroprosthesis approach are not only the technical, engineering, and surgical issues that remain to be solved, but also the development and implementation of strategies designed to interface with the visually deprived brain specifically tailored for an individual patient's own needs. This would particularly involve an improved patient selection and a custom-tailoring of visual prosthetic devices. A key issue in this context that has often been utterly underrated is the role of neural plasticity. Thus, these strategies should take into consideration not only standardized methods and employ current clinical and technological expertise, but also consider newly emerging developmental and neurophysiological evidence. For example, there is considerable evidence that adaptive and compensatory changes occur within the brain following the loss of sight [41.46, 71–73]. These studies suggest that in some patients the occipital parts of the brain that sighted subjects utilize to process visual information are transformed and utilized to process tactile and auditory stimuli. This plastic change in the brain probably allows blind subjects to extract greater information from

touch and hearing, thus improving living standard and enhancing the integration of the blind in the social and working environment of a sighted society. The modulation and understanding of these neuroplastic processes is crucial for the success of any visual neuroprosthesis and can, therefore, provide the neuroscientific foundation for improved rehabilitation and teaching strategies for the blind.

It is hoped that the advances in medicine, ophthalmology, and genetics will be able to devise new ways of preventing diseases of the retina and visual pathways or in transplanting neurons that have been lost.

However, genetic science and treatment will not help in injuries due to accidents and probably will not eliminate all the visual impairments that are due to aging. Therefore, progress in vision prosthesis technologies is regarded as a necessity for the future. We hope that the progress in medical technologies, material science, and bioengineering, together with the increase of intelligence in these visual neuroprosthetic devices will foster the improvements in the quality of life of people that are affected by visual impairments, and result in the development of new custom-tailored neuroelectronic systems for restoring functional sight in the blind.

42. Rehabilitation and Therapeutic Robotics

Rehabilitatio

Loredana Zollo, Dino Accoto, Silvia Sterzi, Eugenio Guglielmelli

The successful introduction of robotic technologies in the rehabilitation arena critically depends on the possibility to design machines able to operate in symbiosis with patients, i. e., adapting the level of assistance to their residual abilities. Safety, easiness of use, and flexibility are key factors for these systems, which typically operate in continuous physical contact with the human body.

Rehabilitation robotics aims at enabling new and effective therapeutic approaches. Highly repetitive, intensive, structured motor exercises carried out while the patient is actively interacting with an assistive robot can have a direct, positive impact on the restoration of motor functions. Active involvement of the patient in planning and execution of motor exercises is expected to empower cortical reorganization, e.g., after stroke. Rehabilitation robotic systems can also provide quantitative, accurate measurements about the patient's motor performance.

This chapter has a twofold aim: (1) to introduce human-centered design criteria for rehabilitation robotic systems by analyzing a specific case study; (2) to present an example of robot-based assessment of patients' sensorimotor abilities.

42.1 Background

Rehabilitation robotics aims at developing novel solutions for assisted therapy and objective functional assessment of patients with reduced motor and/or cognitive abilities [42.1,2]. These solutions augment existing therapeutic systems to improve patients achievable functional recovery. They are intended as therapeutic tools for temporary use (i. e. to be employed only for the duration of the therapy at home or at the clinic center) and are designed to maximize the objective clinical effectiveness of the therapy and the efficiency of the entire clinical process.

Recent neuroscientific achievements (mainly regarding the mechanisms of neurogenesis [42.3,4] stimulated by voluntary movements during motor training, and cerebral plasticity underlying the motor learning and the functional recovery after cerebral injury [42.5,

6]) point out the potential of robotic technologies to create a real discontinuity in the clinical procedures of the (neuro)rehabilitative treatment. Clinical evidence in physical medicine and rehabilitation clearly demonstrates that there is an important and increasing demand for innovative therapeutic solutions to address a wide variety of pathological conditions; for instance, patients experiencing severe stroke events have a high probability, in most cases higher than 50%, of retaining severe disabilities for the rest of their lives. The positive correlation of the prevalence of many neuromotor diseases with age can give an idea of the social relevance of this research area. Novel, cost-effective solutions able to significantly improve the outcome of the rehabilitation process or to assist the patient in coping with residual abilities after the rehabilitation process are needed

urgently in the several industrialized countries facing the challenges posed by their *ageing society*. Such societies predict that soon 20–35% of their population will be over the age of 65 and in need of rehabilitation support.

But how can robots be actually useful to support the functional recovery process? What is the rationale for their introduction in the rehabilitation arena?

To answer these basic questions, at least four main fundamental issues have to be considered:

1. *The technological evolution of machines for physical exercise and cognitive training.* Modern fitness and rehabilitation gyms are more and more being populated with machines equipped with a variety of proprioceptive and exteroceptive sensors for recording multimodal data on the performance of the user as well as on her/his psychophysiological conditions. In some cases, these machines also have one or more actuators and simple feedback control systems, as in the case of automatic treadmills or continuous passive motion systems. At the same time, the concept of *brain training* by means of interactive exercise/games is gaining rapid popularity. No doubt this trend is paving the way for a massive introduction of real robotics technology also in this area of rehabilitation medicine, just like what has already happened in diagnostics and surgery.
2. *Evidence-based rehabilitation.* Modern medicine is based on objective evaluation and quantitative comparative analysis of the impact of different therapeutic approaches. Robotics technology provides accurate, precise, and very sensitive tools for assessing and modeling human behavior, well beyond the capability of a human observer. This is of paramount importance for enabling appropriate initial diagnosis and early adoption of corrective clinical strategies, and for identifying verifiable milestones as well as prognostic indicators of the recovery process.
3. *Rehabilitation therapy is a time-consuming and intensive activity for health-care operators.* Typically, one or more therapists should operate at the same time to administer rehabilitation therapy to a single patient. In some cases the role of the therapist is physically very demanding, involving physical activities that can lead to professional disorders such as low back pain and strain. This is particularly true in the case of severely disabled patients who need direct physical assistance even to perform very simple exercises. Proper introduction of robotics

and automation technologies in this scenario can produce a dramatic reorganization of the working procedures within the rehabilitation process. Machines can take over most of the unpleasant and physically demanding tasks, leaving to the health-care operators the possibility to mainly concentrate on the quality of the therapy that is administered. The existence of these robots creates relief and opportunity. On one hand, the problem of the shortage of specialized personnel is mitigated by the possibility that a single operator can effectively supervise multiple patients, locally or even remotely (i. e., in telerehabilitation). On the other hand, patients' access to rehabilitation is improved by the opportunity to increase the duration and the frequency of their therapy experience, with limitations depending on clinical considerations and not other organizational or economic limitations imposed by the health-care system.

4. *Empowerment of the patient.* Recent findings on neural reorganization phenomena (neuroplasticity) related to functional recovery clearly demonstrate that patients suffering from neuromotor diseases can greatly benefit from activity-dependent rehabilitation therapies, which typically require the execution of goal-directed, repetitive exercises dominated by temporal and spatial constraints [42.7, 8]. During the exercise, the patient is supposed to play an active role, so that the whole sensorimotor coordination system is solicited and trained, including high-level brain functionality, such as imagination, planning, and anticipation of motor actions. In this perspective, rehabilitation robots can represent an ideal solution to implement training environments where this technology is able to continuously provide the patient with the minimal level of physical and/or cognitive support needed to repetitively initiate, execute, and complete a given exercise, while accurately complying with predefined spatial and temporal constraints.

On the basis of this analysis, the main functional requirements that rehabilitation robots should meet to properly address the targeted application domain can be derived. In detail:

- Rehabilitation robots are among the very few robotic systems that are typically devised to operate in continuous physical interaction with the human body. The main challenge is to harmonize their behavior in constrained motion with the patient's

residual abilities, which are unpredictable in nature and dynamically varying, even within the same single therapeutic session.

- In many cases, the robot should implement assist-as-needed strategies, so that the whole set of sensorimotor control functionalities underlying the execution of the motor task is adequately stimulated and trained. Typical working conditions often require the robot to challenge the patient by using haptic interaction (e.g., spatially varying force fields) for opposing or favoring motion in predefined directions. In other situations, e.g., during evaluation sessions, the robot could be required to become fully *transparent* to the patient, so as to assess human motion parameters without introducing any perturbations on the physiological system.

These requirements, and especially the key issue of enabling an active role of the patient to reach a real physical and/or cognitive symbiosis with the machine, pose major technical challenges for designing dependable, flexible, and effective robotic platforms. Typical main technical requirements include high back-driveability, easy adaptation of the mechanical structure to different anthropometric parameters, adaptive schemes for physical human–robot interaction control, and friendly human–machine interfaces for involving and motivating the patient, and for allowing customization of the robot performance, especially in terms of the level of assistance and feedback provided to the patient during the exercise.

This chapter will try to provide some direct insights into robot-aided rehabilitation by focusing on two main

issues strictly related to each other to achieve the challenging objective of creating a real symbiosis between the patient and the machine by increasing the level of machine adaptability to the patient’s actual status.

In Sect. 42.2, the problem of *human-centered rehabilitation robot design* will be tackled. We propose adopting a truly biomechatronic approach, by harmoniously merging mechanics, electronics, and adaptive interaction control techniques to properly address technical and functional requirements coming from the required operative condition of a tight human–machine physical interaction. The proposed design approach is outlined by presenting a specific case study, the CBM-motus, which is a novel planar rehabilitation robot recently developed at the Laboratory of Biomedical Robotics and Biomicrosystems of the Università Campus Bio-Medico, Rome, Italy.

Then, in Sect. 42.3, the possibility of exploiting the typical capabilities of a robotic system to carry out *objective, rigorous measurements* of the patient’s sensorimotor abilities is analyzed. This is a crucial issue, because early detection of the positive or negative impact of a given therapeutic protocol when applied to a patient will allow the physician to change/modify/customize the therapy as appropriate to achieve the best possible clinical outcome. The potentiality of current robotic machines to provide a quantitative evaluation of patient’s performance is explored by means of the definition and pilot application of a core set of kinematic and dynamic indicators. Also, the prospective use of such information to modify robot behavior in accordance with specific patient characteristics is envisaged for future developments.

42.2 Human-Centered Approach to Rehabilitation Robot Design

The design of a robotic machine for robot-aided neurorehabilitation develops in a highly collaborative research scenario where roboticists, neuroscientists, and physicians contribute to define system specifications. The main reason is that the human subject (i. e., the patient exposed to the rehabilitation therapy) plays a key role in the design in view of the tight and continuous physical human–robot coupling [42.9–13]. The robot helps the subject to carry out part of the task that she/he is no longer able to perform autonomously, with a level of assistance that can be adapted to her/his residual abilities [42.14, 15]. Requirements such as accuracy, repeatability, preprogrammed movements, and

task specificity (typical of industrial or service robotics scenarios [42.16, 17]) yield to priorities imposed by the close physical contact with the user, such as safety, reliability, robustness, adaptability, and back-driveability (i. e., low mechanical impedance).

All these features depend on the robot mechanical and control design [42.18–20] and can be addressed by searching for the optimal combination of mechanics and control in order to answer requirements coming from the specific application context.

More specifically, the design of a rehabilitation machine is based on a typical human-centered, biomechatronic design approach, which is a top-down process

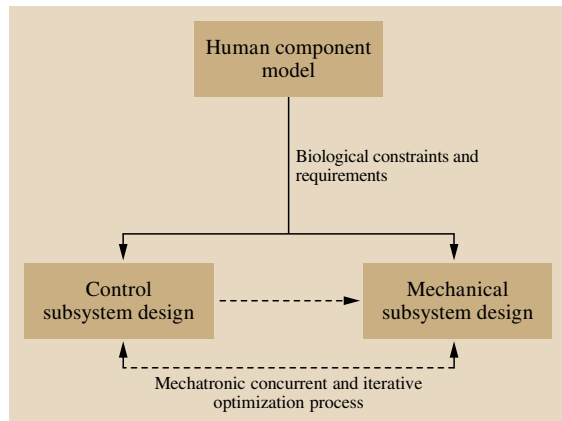

Fig. 42.1 The general scheme of the top-down biomechatronic design approach

consisting of two main steps, as depicted in Fig. 42.1 and briefly discussed in the rest of this section.

The first step includes an accurate characterization and modeling of the biological system, i. e., the human body and the human sensorimotor control system, by using the best knowledge available from different disciplines, such as biomechanics, neuroscience, and behavioral and motor sciences, and the full set of analytical, computational, and experimental methods and tools made available in bioengineering. Developing a model of the biological system that directly interacts with the machine offers the possibility to:

- Model and study the coupled dynamics between the biological system and the machine
- Evaluate robot performance in the interaction with the biological system
- Model and evaluate pathological abnormalities or alterations in the behaviors of the biological system
- Assess and optimize the behavior of the machine, by introducing and simulating modifications to the mechanical and control design hypotheses and evaluating the effects of these changes on the interaction with the biological system.

By exploiting the human (patient) component model, one can identify the initial set of constraints and requirements deriving from the biological domain that will represent the starting point of the subsequent design phases.

Obviously, developing the model of a biological system that could be, at the same time, *detailed and simple* enough to comply with the resource constraints of

a machine design process, implies a series of simplifications with a level of approximation that depends on the specific application. For instance, when the goal is to investigate issues related to the interaction between the robotic machine and the patient from the mechanical and control point of view, it is typically conceivable to consider only the basic mechanisms (originated in the central nervous system) of generation of muscular forces and joint torques needed to move the limb, thus dramatically reducing the complexity of the description of the biological phenomena underlying human voluntary motor actions.

The second step is the mechatronic design of the machine, in which the functional and technical specifications are detailed and all the components of the system (interfaces, mechanical structure, actuators, sensors, and control unit) are concurrently defined and designed via an iterative process.

Although rehabilitation robotic machines are a wonderful paradigm of biomechatronic systems, quite surprisingly the harmonious merging of mechanics and control is often not achieved, mainly because highly nonlinear phenomena able to strongly degrade robot performance, such as friction and stiction, are typically not accounted for in their design.

Several examples of robotic machines for rehabilitation can be found in the literature [42.21–33]. From the perspective of robot design approaches, they can be classified into two main groups.

The first group consists of systems derived from adapting or reconfiguring industrial robots for use in rehabilitation [42.22–24]. This approach has the consequent critical drawback that low impedance, comparable to the human arm, cannot be practically be obtained, because machines are intrinsically position-controlled. Despite the use of active force feedback to enhance robot responsiveness, back-driveability required to move smoothly and rapidly in compliance with patients' actions [42.34] is not achieved. High inertia, anisotropy of dynamic properties, and low acceleration capabilities are often the main factors responsible for that [42.35, 36].

The second group consists of robots specifically conceived for tight human–machine interaction and includes two main classes of systems [42.23]:

1. Class I machines. They resort to mechanical solutions able to intrinsically enhance system back-driveability, with the main purpose of making the user perceive a very low mass, as for haptic interfaces [42.37]. They have low mechanical inertia and

- friction, fine-tuning of viscoelastic properties, and high cost [42.31, 33, 38, 39].
- Class II machines. They have a simple mechanical structure, no back-driveability, non-negligible inertia, possible presence of friction, and low cost. Although having some limitations, class II machines are very interesting for their applicability to remote rehabilitation (i. e., telerehabilitation) [42.40], justified by the low cost and the simplicity of the functioning mode.

For both class I and class II systems, control design typically resorts to traditional approaches, e.g., stiff proportional–integral–derivative (PID) voltage control (i. e., a proportional–integral–derivative action), compliance control (i. e., a proportional–derivative action plus gravity compensation) [42.41, 42], or sometimes impedance control (i. e., inverse dynamics interaction control). They can ensure the two important properties of system robustness and ease of implementation, especially in the case of PID and compliance control (which do not require an estimation of robot dynamics); however, friction and stiction are generally disregarded even though they can notably affect system performance in the interaction with the patient and degrade back-driveability.

In this section, the CBM-motus rehabilitation robot design is presented as a case study of biomechatronic system design: mechanics and control are concurrently designed and integrated to address the specific requirements coming from the rehabilitation application domain; it combines the advantages of class II machines (coming from simplicity in the mechanical structure and low cost) with the potentialities of inverse dynamics interaction control to compensate for mechanical drawbacks, such as high friction and reduced capability of viscoelastic regulation. The resulting machine is described in detail in the following.

42.2.1 CBM-motus Mechanical Design

The design criteria of the CBM-motus were inspired by the need of achieving:

- Low and isotropic apparent inertia when back-driven; the goal was pursued by designing a robot having inertia ellipses with small radius and unitary eccentricity, which are independent of the robot configuration in the workspace [42.43, 44].
- A large workspace to allow the administration of several rehabilitative treatments (target: $0.5 \text{ m} \times$

0.5 m); workspace dimensions were determined in collaboration with therapists in order to allow a typical session of robot-aided rehabilitation therapy to be carried out.

- Interaction forces up to 50 N; the value was extracted from the analysis of the maximum force applicable by the patient at the robot end effector.

In addition, the robot was conceived for applications of telerehabilitation [42.45], thus aiming to be highly dependable, low cost, and portable in order for it to be moved to and mounted at the patient's site with no or little need for specialized skills.

The CBM-motus has a Cartesian kinematic structure consisting of two modules, each corresponding to an actuated axis. As shown in Fig. 42.2, each module includes six pulleys with the same radius ($R = 0.025 \text{ m}$) and two timing belts (9.4 mm wide, reinforced with a glass fiber cord). Two couples of pulleys (on the left in Fig. 42.2) are mounted on the same shaft, and one pulley per module is directly driven by the motor, with no reduction gearing being used. Two belts for each module are mounted in such a way that the points along segments AB and CD move vertically with the same speed. A ground stainless steel bar is fixed to a couple of such points, e.g., P and P' in Fig. 42.2. The second module is connected to the robot frame with a rotation of $\pm 90^\circ$ with respect to the first module. The end effector of the robot, i. e., the handle grasped by the patient, is connected to both bars, at their minimum-distance points,

Fig. 42.2 A single kinematic module comprising six pulleys and two belts. P and P' move vertically with the same speed

Fig. 42.3a,b Overview of the kinematic scheme (a) and of two assembled kinematic modules (b). The rigid bars slide in a double prismatic joint and are connected to the driving belts

Fig. 42.4 Overview of the complete robot

through a couple of orthogonal prismatic joints, rigidly linked together to make a single compound joint, in the following referred to as a *double prismatic joint*. Friction at each prismatic joint (still remaining non-negligible because of the sliding motion) is reduced by means of linear ball bushings.

Both ends of each bar are connected to driving belts. The outer prismatic joints (P_1, \dots, P_4) correspond to the segments of the belts to which the two bars (1 and 2) are connected. The two bars slide through the compound prismatic joint ($A + B$), to which the end effector (E) is connected. The bars and the double prismatic joint are depicted in Fig. 42.3.

This patented kinematic architecture [42.46] has the main feature of ensuring good rigidity of the robot with relatively small moving masses, because the double prismatic joint ensures that only tensile forces are transmitted to the belts. In order to balance vertical loads and axial forces caused by friction at prismatic joints, both ends of the bars are supported by a ball-bearing-supported wheel running in a rail. The stiffness

of the system and the low moving mass ensure a high resonance frequency, which helps avoid spurious mechanical stimuli, which may perturb haptic rendering. Anyhow, the resonance frequency can be tuned by regulating screw-based belt tensioners. The two modules are actuated by DC servomotors (Aerotech BM 250) with a rated torque of 2 N m and a peak torque of 5 N m. The radius of the pulleys being 0.025 m, the maximum force which the robot is able to exert is 80 N for each axis. For safety reasons, it was limited via software to 50 N. The overall dimensions of the robot frame are $0.83 \times 0.82 \times 0.11 \text{ m}^3$. The total mass (frame and motors included) is less than 30 kg. An overview of the system is shown in Fig. 42.4.

CBM-motus inertia is independent on the robot configuration and is isotropic. Thus, the mass perceived at the end effector has the same value everywhere in the workspace and is 2.59 kg.

As expected, friction is not negligible. The static friction is around 4–5% of the maximum force that the robot can generate (50 N); it requires 0.25 A along the x -axis and 0.30 A along the y -axis to be overcome, that is, about 60% of average current values in normal operating conditions (the mean value of the current is 0.42 A along the x -axis and 0.47 A along the y -axis). On the other hand, viscous friction reaches 2.1 and 2.7% of the maximum force along the x -axis and the y -axis, respectively, in normal operating conditions of 0.3 m/s.

4.2.2.2 CBM-motus Control System Design

The control system of a rehabilitation robotic machine has the twofold objective of (1) assisting the patient when she/he is able to move autonomously, by mak-

ing the patient perceive a very low impedance (close to zero), and (2) helping or forcing the patient's limb toward the target in accordance with her/his residual motion capabilities when she/he is not able to move or complete the motor task. To pursue these objectives the control system is required to ensure a high level of adaptability to the different motor capabilities of the patients, different for each patient, and to devote maximum priority to safety in the interaction, also at the expense of accuracy in the execution of the motor task.

Viscoelastic regulation and adaptable impedance are keywords of human–robot interaction during a rehabilitation session. To achieve them, two main issues need to be addressed: the first one is CBM-motus friction compensation, friction being an undesirable phenomenon that terribly degrades back-driveability; the second one is robot impedance adaptation to specific patient requirements.

An interaction control able to cope with these two issues is proposed in the following. Key points of the control system (named *current-based impedance control*) are:

- Compensating for friction and tuning robot compliance by means of an interaction control law based on inverse dynamics.
- Closing the control loop on electric currents, in lieu of traditionally used force sensors, in addition to position feedback. Current monitoring plays a fundamental role in fine-tuning of robot impedance during interaction by providing an indirect force feedback in the control loop. It does not require force sensors mounted at the robot end effector and solves problems related to the increase of the apparent inertia perceived by a human user (due to force sensor mass), wiring issues, and the costs of the sensors.

The choice of impedance control in lieu of compliance control (as typically done in the literature) is motivated by the need to compensate for static and dynamic friction, which are nonnegligible from the identification procedure of the CBM-motus dynamic parameters. Hence, the core of the control law is the robot dynamics compensation, which allows us to significantly reduce the effects of robot friction and inertia during interaction and properly achieve impedance regulation.

Consider the robot dynamic model as

$$\begin{aligned} B(q)\ddot{q} + c(q, \dot{q}) + F_v\dot{q} + f_s(q, \dot{q}) + g(q) \\ = \tau - J^T(q)h, \end{aligned}$$

where $B(q)$ is the inertia matrix, $c(q, \dot{q})$ is the vector of centrifugal and Coriolis torques, $F_v\dot{q}$ is the viscous friction, $f_s(q, \dot{q})$ is the static friction, $g(q)$ is the vector of gravitational torques, and $J^T(q)h$ is the torque contribution due to interaction force h exerted by the patient on the robot, $J(q)$ being the robot Jacobian matrix.

The control law can be written as

$$\begin{aligned} \tau = B(q)y + c(q, \dot{q}) + F_v\dot{q} + f_s(q, \dot{q}) \\ + g(q) + J^T(q)h(I), \end{aligned} \quad (42.1)$$

where $h(I)$ is the interaction force extracted from sensed current I . The addition of $J^T(q)h(I)$ allows decoupling and linearizing the robot dynamics, thus yielding

$$\ddot{q} = y.$$

Choosing for acceleration y the following expression

$$\begin{aligned} y = J^{-1}(q)M_d^{-1}(M_d\ddot{x}_d + K_D\dot{\tilde{x}}_d \\ - M_d\dot{J}(q, \dot{q})\dot{q} - h(I)), \end{aligned} \quad (42.2)$$

where $\tilde{x} = x_d - x$ and $\dot{\tilde{x}} = \dot{x}_d - \dot{x}$ are position and velocity errors, respectively, between the planned trajectory x_d and the actual trajectory x , yields

$$M_d\ddot{\tilde{x}} + K_D\dot{\tilde{x}} + K_P\tilde{x} = h(I).$$

The robot behaves as a mass–damper–spring mechanical system through mass matrix M_d , stiffness matrix K_P , and damping matrix K_D , thus allowing modeling of patient–robot interaction as the parallel of two mechanical impedances (one for the human, the other for the robot). Robot impedance can be varied by means of control gains M_d , K_P , and K_D and, at the equilibrium, the robot elastic term directly balances the force exerted by the patient.

42.2.3 Experimental Validation

The idea behind current-based impedance control is to measure interaction force by means of current monitoring instead of direct force monitoring. This entails the need to identify a relation between electric current and interaction force in the whole robot workspace, by distinguishing current values during free motion (i. e., without interaction) from current values in constrained motion (i. e., during interaction).

To this purpose, the robot was programmed to perform 500 point-to-point movements along different directions of the workspace, in conditions of free motion and constrained motion. Synchronized acquisitions

Fig. 42.5 Experimental setup for force and current recordings

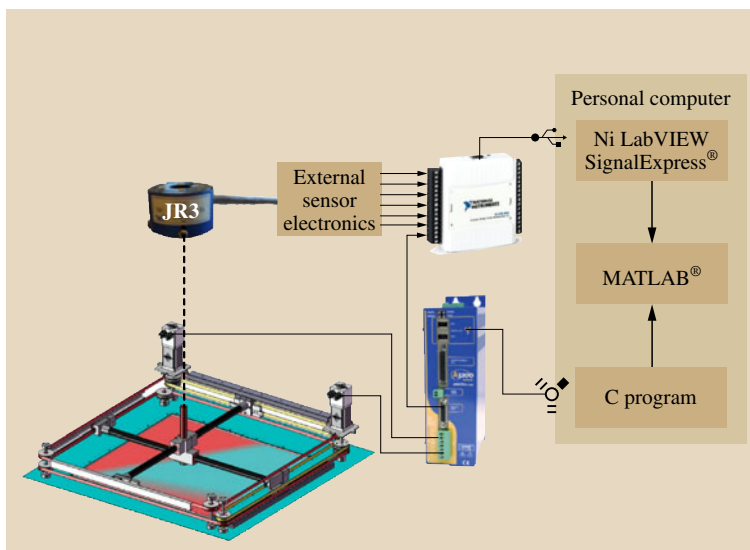

Fig. 42.6a–d Experimental results for the current-based impedance control during a constrained task with 1 kg applied at the end effector: desired and actual end-effector trajectories (a), position error norm (b), recorded electric currents (c), and force values extracted from currents (d). Control gains are $K_P = \text{diag}(40, 40)$ and $K_D = \text{diag}(4, 4)$

of force and currents were carried out (Fig. 42.5). In the case of constrained motion, the robot was required to perform a point-to-point motion with a known mass applied to the end effector by means of a pulley–string system. Four different experimental conditions were analyzed, corresponding to four different values of applied mass, (0.2, 0.4, 1.0, and 2.0 kg), in addition to the case of zero mass.

Because of the anisotropic friction distribution in the robot workspace, four separate linear regression analyses were required for directions toward positive and negative x -axes and y -axes (i. e., x^+ , y^+ , x^- , y^-).

The analytical expressions for the four linear regression functions are

$$\begin{aligned} F_{x^+} &= -9.84I_{x^+} + 3.73, \\ F_{x^-} &= -10.42I_{x^-} - 4.73, \\ F_{y^+} &= -10.94I_{y^+} + 4.58, \\ F_{y^-} &= -9.97I_{y^-} - 5.29, \end{aligned} \quad (42.3)$$

where forces are expressed in newtons and currents in amperes. It is worth noting that they are valid when motion occurs along axes. Solving (42.3) with respect to current in the absence of interaction force provides

Fig. 42.7a–d Experimental results for the current-based impedance control during a constrained task with 1 kg applied at the end effector: desired and actual end-effector trajectories (a), position error norm (b), recorded electric currents (c), and force values extracted from currents (d). Control gains are $K_P = \text{diag}(100, 100)$ and $K_D = \text{diag}(10, 10)$

Fig. 42.8a–d Experimental results for motion in the free space: desired and actual end-effector trajectories (a), position error norm (b), recorded electric currents (c), and force values extracted from currents (d). Control gains are $K_P = \text{diag}(100, 100)$ and $K_D = \text{diag}(10, 10)$

mean values of the current in the free space for each direction. On the other hand, when one axis is commanded to move while the other one is commanded to maintain its position, the force–current relation for the axis that is not moved changes as

$$F_{x\pm} = -10.13I_{x\pm},$$

$$F_{y\pm} = -10.46I_{y\pm}.$$

For the moved axis, relations (42.3) are still valid.

Force–current relations in (42.3) were used to implement and test current-based impedance control in (42.1) and (42.2). Experimental tests of free motion

and interaction with an external environment were performed with the control law. They were representative of control capability to adapt to external forces. In the case of free motion, the robot was commanded to track a minimum-jerk trajectory, i.e., a quintic polynomial function, from (0; 0) to (0.0; 0.10) m; for constrained tasks, the same trajectory was planned while a weight was applied at the end effector. Different mass values were tested by varying control gains and measuring the corresponding end-effector position and motor currents.

Figures 42.6 and 42.7 report desired and actual end-effector trajectories, position error norm, and recorded electric currents when a weight of 1 kg is applied and

two different sets of control gains are chosen (i. e., $K_P = \text{diag}(40, 40)$, $K_D = \text{diag}(4, 4)$, and $K_P = \text{diag}(100, 100)$, $K_D = \text{diag}(10, 10)$). Control gains were empirically chosen in order to set two different levels of robot compliance within system stability limits. Also, force values extracted from the electric currents are shown in Figs. 42.6d and 42.7d. It can be observed in Fig. 42.7 that the computed force value is constant as long as the robot end effector holds the position imposed by the applied weight. A threshold check is made on the electric current, so that when during interaction it drops below 0.57 A for the x -axis and below 0.62 A for the y -axis (as an effect of the torque command), interaction force is maintained constant with the position. When the current is beyond the threshold, the force

values vary according to relations (42.3). The threshold value corresponds to the maximum current values for each axis in free space motion.

It is worth noting that, thanks to current feedback providing information about the applied force, the same set of control gains, $K_P = \text{diag}(100, 100)$ and $K_D = \text{diag}(10, 10)$, can be successfully used in free space as well as in constrained space (Figs. 42.7 and 42.8); this set can ensure a high level of adaptability to the external constraint ($h = 21.41$ N) and, contemporarily, a good level of accuracy in free motion (0.0093 m is the maximum value) for the application addressed. This achievement can be especially fruitful in managing situations of shared control between the patient and the machine without requiring one to change control gains.

42.3 Robot-Based Measure of Patient's Performance

In order to enhance the active role of the patient, by enabling even severely impaired patients to actively intervene in the decision regarding the execution of a motor task, it is desirable that the robot plans its motion on the basis of the patient's motion intentions and assists the patient to carry out that part of the task that she/he is no longer able to perform autonomously, with a level of assistance that can be adapted to her/his residual abilities. In this perspective, the robot sensory system (possibly in addition to other sources of information) plays a fundamental role. Data from the patient (such as kinematic, dynamic, and physiological data) could be processed for continuous analysis of her/his motion intentions and physiological state. This information could be used to:

1. Update robot control online during the execution of a motor exercise in order to guide, help, or force the patient's limb toward the target in accordance with her/his residual motion capabilities
2. Apply corrective actions in case of incorrect motion
3. Provide therapists with objective, accurate measurements of the subject's body functions, thus enabling therapists to track the subject's progress in therapy, evaluate the efficacy of various interventions, and customize the machine for each particular user.

In spite of the number of works on design and development of robotic devices, and a few clinical studies, differing in design and methods, on the effect of robotic devices on stroke rehabilitation in a clinical

setting [42.7, 30, 47, 48], body function and structure assessment was typically carried out by means of traditional clinical impairment scales [42.49], which can suffer from being subjective, operator-dependent, and qualitative. In recent years, studies on movement smoothness [42.50] and decomposition of complex movements in submovements [42.27] used kinematic data recorded by the robot to analyze motion characteristics of unimpaired patients. Recently, the first examples of evaluation metrics were provided [42.51, 52] for quantifying motor recovery of stroke patients undergoing robot-aided rehabilitation. However, they were both limited to a characterization of patient kinematics during unperturbed point-to-point motion, where no active force regulation was required.

In this section a complete set of kinematic and dynamic indices is provided for an objective measure of the effect of robot-aided therapy [42.53]. They are used to characterize human performance during unperturbed motion [42.51, 52] as well as in resistive motion, when active force regulation is required to successfully achieve the motor task by resorting to adaptation mechanisms to external force fields, as studied in [42.54]. A robot-aided motor therapy of the upper limb was administered to 15 chronic poststroke patients. Two robotic machines were used to administer therapy: InMotion2 (also known as MIT-Manus [42.38]) and InMotion3 (i. e., MIT wrist robot [42.39]). Patients were evaluated by means of the performance indices extracted from kinematic and dynamic data measured by the MIT-Manus planar machine.

42.3.1 Kinematic and Dynamic Performance Indicators

Kinematic indices aim at characterizing the following temporal and spatial features of subject motion:

- *Duration*. This is measured by means of the *execution time*, defined as the time for performing a point-to-point movement, elapsed from movement onset (i. e., time instant where velocity exceeded a threshold of 10% of peak velocity [42.55, 56]) and movement termination (i. e., time instant where velocity went below a threshold of 10% of peak velocity). Movement duration is expected to reduce with recovery.
- *Accuracy*. This is assessed by means of the *area index*, defined as the area between the desired straight line and the curve actually performed by the patient in the *XY* plane during a point-to-point movement. Accuracy increases when the area tends to zero.
- *Direction*. This is measured through the *aiming angle*, defined as the angular difference between the target direction and the direction of travel from the starting point to peak speed point [42.55, 56]. The angular displacement is expected to reduce with the therapy.
- *Path length*. A normalized measure of path length is used, named the *length ratio*, and is formally defined as the length ratio between the actual patient curve and the desired straight line. An improvement of patient motion capabilities makes the actual path tend to the straight line and consequently makes the length ratio tend to 1. The length ratio provides a measure of the ability of the patient to reach the target, by means of a threshold value of 0.5; index values under the threshold indicate patient inabilities to reach the final point.
- *Velocity*. This is analyzed by means of
 - *Mean velocity error*. This is defined as the mean value of the distance vector between the ideal velocity profile for point-to-point motion, based on the minimum-jerk hypothesis [42.57], and patient velocity. A reduction of mean velocity error with training is expected.
 - *Peak speed*. This is the peak value of patient velocity. In the unperturbed motion the patient is stimulated to improve motion smoothness; thus, globally, a reduction of peak speed is expected.
- *Smoothness*. The following two measurements of smoothness are summarized from [42.50]:

- *Jerk index*. This is calculated by dividing the mean jerk magnitude by the trajectory length and is expressed on a logarithmic scale; using a logarithmic scale has the advantage of reducing the range of variation of the index and facilitating its use in clinical practice. Note that increases in the jerk index correspond to decreases in smoothness. A decrease of this index following robot training is expected.
- *Speed index*. The speed index is defined as the normalized mean speed (i. e., the mean value of the speed divided by the peak speed). As subjects recover, it is expected that the normalized mean speed will be significantly higher because of a reduction of the series of peaks with deep valleys in between in the subject's speed profile.

Force applied and work expended during motion are important features of recovery that clinical studies on robot therapy have often disregarded. They are especially meaningful in resistive tasks. In the following, a set of dynamic performance indicators based on force measurements are proposed.

Force exerted during motion. A basic distinction is provided between total force and useful force exerted by the patient during motion because they can exhibit different evolutions with training. Although an increase of force can be measured, the direction of force application could be wrong. Hence, with *useful force* the amount of total force directed toward the target is intended. This distinction led to the definition of four different force indices:

1. *Mean force*. This is the mean value of the force exerted by the patient during motion. Because of the rigidity of the limb on admission, patient mean force will be quite high at the beginning. In free motion it is expected to reduce with training; otherwise it should increase in resistive motion.
2. *Peak force*. This is the peak value of the force exerted by the patient during motion. It will behave similarly to mean force, but with larger variations.
3. *Useful force*. This index measures the amount of mean force directed toward the target. The useful force is calculated by weighting the mean force value with the aiming angle index normalized with respect to its maximum (i. e., 90° in our case). It ranges between zero, when the aiming angle is more than 90° , and the mean force value, when the aiming angle is 0° . An increase with recovery is expected.

4. *Useful peak force.* This measures the amount of peak force directed toward the target, and is calculated similarly to useful mean force. It varies between zero and the peak force value.

Work expended during motion. By analogy with force, a basic distinction is provided between total work and useful work expended by the patient during motion. Work is measured in addition to force because it provides a measure of the energy expended in the execution of the task by combining motion and force information in a unique parameter:

1. *Total work.* This index is calculated as the line integral of the force along the path described by the patient. In free motion it is expected to reduce with training. In resistive motion total work should increase as a consequence of force increase.
2. *Useful work.* This index measures the amount of total work directed toward the target and is extracted from the total work value by means of the aiming angle. It will vary between zero and the value for total work. An increase with recovery is foreseen, in free motion as well as in resistive motion.

42.3.2 Case Study

Experimental Protocol

Fifteen community-dwelling persons with chronic stroke (ten men, five women) met inclusion criteria and volunteered to participate in this study. Six weeks of shoulder-elbow therapy was administered to all subjects with the InMotion2 robotic machine and 6 weeks of wrist therapy was administered to all subjects with the InMotion3 machine, for a total of 12 weeks of robot-aided therapy (Fig. 42.9). The subjects received approximately 1 h of robotic therapy three times a week.

Training consisted of three games of 320 assisted-as-needed point-to-point movements from the center to eight outbound targets distributed along a circle at a distance of 0.14 m. Patients were required to move with a self-paced speed in a maximum time slot of 3 s. The assistance was tuned on the basis of the patient's performance [42.14]. In wrist training, the first two assisted games trained wrist flexion/extension, abduction/adduction, and a combination of these movements. The last assisted game exercised exclusively pronation and supination [42.39].

Evaluation was carried out on admission to and discharge from the robotic treatment for a period of 12 weeks. It consisted in performing unperturbed and resistive motion exercises with the InMotion2 robotic machine. The robot was completely passive while position and force sensors recorded the subject's kinematic and force data. Each subject was asked to perform five blocks of unassisted 16 point-to-point movements in free space (in the following briefly named as unperturbed motion) and, subsequently, one block of 16 point-to-point movements in the presence of a force field generated by the robot (in the following briefly referred to as resistive motion). The force field can be modeled as a viscoelastic force field applied against patient motion. It is generated by means of a proportional-and-derivative control (with constant gains) pushing the robot end effector to the central position of the workspace.

Results of Unperturbed Motion

Figure 42.10 reports motion trajectories of a representative patient during a point-to-point evaluation task in pretreatment and in posttreatment phases. One can see the improvement toward more and more linear trajectories over the 80 trials and, mainly, the improved capability of extending the arm toward the more distal targets (at the top of the plot).

Fig. 42.9a,b InMotion2 (a) and InMotion3 (b) robotic machines

SD standard deviation

^aA negative t value indicates that discharge scores were higher than the admission scores.

^bThe strength, or magnitude, of our findings was determined by calculating the effect size r [42.58]:

for a small treatment effect $r = 0.1$ – 0.23 , for a medium treatment effect $r = 0.24$ – 0.36 , for a large effect $r \geq 0.37$

Tables 42.1 and 42.2 report the results of robot-based evaluation during unperturbed motion. Patients globally improved kinematic performance and all kinematic indices varied in the expected direction with statistically significant changes, except for *peak speed* ($t_{14} = 1.398$, $p = 0.092$, $r = 0.412$). As regards dynamic performance, it can be observed that, with train-

ing, mean force ($t_{14} = 0.768$, $p = 0.227$, $r = 0.174$), peak force ($t_{14} = 1.431$, $p = 0.0871$, $r = 0.404$), and total work ($t_{14} = 0.613$, $p = 0.275$, $r = 0.182$) did not significantly decrease; on the other hand, the amount of total force (namely, the useful work $t_{14} = -2.065$, $p = 0.0290$, $r = 0.410$) and total work (namely, the useful work, $t_{14} = -2.04$, $p = 0.030$, $r = 0.407$) directed

Dynamic index	Admission (mean \pm SD)	Discharge (mean \pm SD)	t_{14}	P	r
Force exerted during motion					
Mean force (N)	1.952 \pm 0.688	1.848 \pm 0.545	0.768	0.227	0.174
Peak force (N)	4.408 \pm 1.993	3.781 \pm 1.092	1.431	0.0871	0.404
Useful force (N)	1.317 \pm 0.531	1.513 \pm 0.454	-2.065	0.0290	0.410
Useful peak force (N)	3.046 \pm 0.998	3.125 \pm 0.807	-0.425	0.338	0.091
Work expended during motion					
Total work (J)	0.217 \pm 0.156	0.195 \pm 0.062884	0.613	0.275	0.182
Useful work (J)	0.141 \pm 0.0672	0.165 \pm 0.0525	-2.04	0.030	0.407

toward the target significantly increased as a consequence of the improvement of motion direction.

Results of Resistive Motion

Figure 42.11 reports motion trajectories of a representative patient during the resistive evaluation task in the pretreatment and in the posttreatment phases. After the robot therapy, the patient exhibited improved capability of opposing the external force field and extending the arm toward the more distal targets.

Kinematic and dynamic robot-based evaluations for resistive motion are reported in Tables 42.3 and 42.4. As for unperturbed motion, patients globally improved kinematic performance in a statistically significant manner. However, in accordance with [42.55, 56], indices related to motion velocity and smoothness were not reported, being meaningless for perturbed movements. On the other hand, the dynamic analysis showed that in re-

sistive motion force and work did exhibit a different trend with therapy with respect to unperturbed motion. All force indices increased after the robotic treatment, even if not significantly, whereas they decreased in the unperturbed motion. Only changes of *useful force* ($t_{14} = -1.599$, $p = 0.066$, $r = 0.394$) and *useful peak force* ($t_{14} = -1.728$, $p = 0.0529$, $r = 0.345$) tended to approximate the threshold value $p = 0.05$ of statistical significance. Furthermore, work expended during motion significantly increased with respect to that on admission.

Discussion

The results of this study reinforced earlier findings that short-term, goal-directed robotic therapy could significantly improve functions and structures of the exercised limb segments in persons with chronic stroke [42.30, 47, 48], and provided a measure of their improved mo-

Table 42.4 Dynamic indices for the resistive motion task

Dynamic index	Admission (mean ± SD)	Discharge (mean ± SD)	t_{14}	P	r
Force exerted during motion					
Mean force (N)	9.967 ± 4.123	10.945 ± 3.674	-0.967	0.193	0.260
Peak force (N)	19.306 ± 7.333	20.922 ± 6.488	-0.987	0.170	0.241
Useful force (N)	7.848 ± 4.229	9.424 ± 4.054	-1.599	0.066	0.394
Useful peak force (N)	15.502 ± 7.805	18.060 ± 7.519	-1.728	0.0529	0.345
Work expended during motion					
Total work (J)	0.965 ± 0.6804	1.171 ± 0.7396	-1.957	0.0353	0.300
Useful work (J)	0.784 ± 0.6094	1.044 ± 0.7415	-2.834	0.0066	0.398

tion capabilities. Kinematic changes were measured by means of eight indices describing temporal and spatial features of subject motion. Dynamic changes were measured through six indices describing the ability to modulate forces and energy and properly direct them.

The analysis of motion kinematics (Tables 42.1 and 42.3) showed that all the performance indicators changed in the expected direction. This can be regarded as a result of the relearning process which improved subject capabilities of moving and coordinating all the degrees of freedom of the upper limb, with the main effect on extension degrees of freedom (Figs. 42.10 and 42.11). Moreover, the combination of different indices, for example, smoothness, with the other spatial indices (aiming angle, area, path length) also assessed the progress of the patient's spatial and temporal efficiency, thus providing new insights into the association of motion ideation and execution (i.e., ideomotor apraxia) and envisaging the possibility of extracting prognostic indices of pathological disorders related to altered motion perception [42.59].

The analysis of motion dynamics (Tables 42.2 and 42.4) proved that whereas useful force and work (both including the dependence on a kinematic variable, i.e., the aiming angle) exhibit significant changes, mean force and total work applied during motion did not undergo a striking variation from admission to dis-

charge, especially in unperturbed motion tasks. The main reason is supposed to be found in the type of robotic training consisting of assisted kinematic-goal-directed exercises, which stimulate the improvement of motion kinematics more than force control. When the patient was required to reach only a kinematic target, she/he applied compensatory strategies which avoided her/his controlling other independent elements [42.60–62], such as force.

Improvements of motion dynamics (i.e., force and work), mainly obtained in resistive motion, can be regarded as an indirect effect. It is worth noting that a significant change of force was not obtained, but an improvement of energy (i.e., the combination of force and position) was measured. When the patient was asked to oppose a force field, she/he was stimulated to control a major number of independent elements (i.e., motion and forces). As a consequence, owing to the contemporary improvement of position and force control, *total work* and *useful work* underwent a significant change.

The use of performance indicators can therefore provide fruitful indications of the appropriateness of the therapy and new insights into the corrective actions to apply. Furthermore, the online extraction of performance indicators from robot data is envisaged for future developments. This would enable, on one hand, patient quantitative assessment as performed in this study and,

on the other hand, online change of robot impedance during therapy in order to address specific patient requirements. The immediate expected results would be an

increase of patient–machine interactiveness, a really customized machine able to fit the therapy for each specific patient, and a disruptive increase of patient motivation.

42.4 Conclusions and Further Readings

Design of rehabilitation robotic machines, exposed to tight and continuous physical interaction with humans, continues being a very challenging and attractive area of robotics research. Moreover, the use of robotic systems in rehabilitation for therapy administration and sensory-motor assessment is an interesting possibility to discover and fruitfully exploit.

This chapter provided an overview of current evidence of the effect of robot-aided rehabilitation on patient recovery and pointed out the main functional and technical requirements coming from the application of robotic machines to motor therapy. Two important issues were faced in detail in this chapter, the *rehabilitation robot design approach* and the *objective measure of patient performance*, both focused on the central role of the patient and her/his active involvement in the therapy. The case study of the CBM-motus robotic system was reported as a paradigm of a design approach fully merging mechanics and control. On the other hand, an example of an objective measure of patient performance for motor and body function assessment was presented. It relies on the extraction of a core set of quantitative indicators from sensory information directly recorded by the robotic machine and their use in the kinematic and dynamic analysis of patient motor recovery.

An important challenge in the design of a robotic system for neurorehabilitation is to carefully adapt the behavior of the machine to patients' specific motor capabilities, intentions, and performance. To this purpose, it is desirable that an additional module (which was not dealt with in this chapter), i.e., the patient–machine interface, is carefully conceived. It should be able to provide the patient with an attractive graphical interface for promoting her/his active involvement in the therapy, acquire and process information on the current status of the patient, from the motion analysis to recordings of physiological signals and the cerebral activity, and provide inputs to the machine regarding the actual patient motion, her/his motion intention, and her/his responsiveness to the therapy. The ability of the machine to modulate its own viscoelastic characteristics as well as to generate force fields associated with a given workspace during the rehabilitative exercise is a fundamental feature for controlling

the interaction between the patient and the machine during therapy. Future rehabilitation robotic systems are evolving toward multimodal robotic platforms that, harmoniously integrating mechanics, control, and a multimodal human–machine interface, allow one to:

- Record signals from different sources and reconstruct patient global status (i.e., physiological, neurological in addition to kinematic and dynamic).
- Extract performance indices, to be used for updating the control system (and correspondingly modify the therapy), as well as for evaluating the effects of the therapy.
- Increase the level of customization and adaptability to each specific patient of current rehabilitation machines. The multimodal analysis will allow:
 - a) The online update of robot control during the execution of an assisted task in order to guide, help, or force the patient limb toward the target in accordance with her/his residual motion capabilities.
 - b) Application of corrective actions in the case of incorrect motion.
 - c) Change of the motor exercise and the graphical interface in order to increase patient active involvement and maximize her/his motivation.
- Investigate basic research issues related to the recovery process, such as:
 - a) Neuroplasticity phenomena, defined as the recruitment of areas usually not involved in the task, and changes in the intensity, temporal sequence, and functional hierarchy of neuronal excitability.
 - b) Efficiency of the sensorimotor feedback circuits, e.g. through the acquisition of indices measurable via hand sensory stimulation [42.63] and movement during functional MRI (fMRI) recording, as well as recording EEG or MEG signals during isometric contraction in both a relaxed condition and sensory stimulation [42.64].

Finally, it is worth mentioning that the use of robotic systems in conjunction with instrumentation for data acquisition and measurement of neurophysiological sig-

nals (EMG, EEG, MEG, or fMRI) is opening another important area for rehabilitation robotics research, i. e., the development of fMRI-compatible systems [42.65, 66] or, more generally, of brain-imaging-compatible robotic systems (i. e., brain-imaging-compatible systems that can be used in conjunction not only with fMRI but also with MEG, transcranial magnetic stimulation (TMS), repetitive TMS, near-IR spectroscopy, and other brain imaging tools). Whereas using EMG and EEG does not involve the issue of disturbance and interference with the functioning mode of the electrical actuated devices, the joint use of tools such as MEG and fMRI with robotic or mechatronic devices necessarily requires one to handle problems of electromagnetic compatibility and interaction. For several years there has been intensive research on MRI-compatible sys-

tems in surgical robotics [42.67–69] to exploit the great potential of MRI for guiding insertion of tools and monitoring and controlling therapy. Only recently the issue is being addressed in rehabilitation robotics, thus giving rise to preliminary studies on fMRI-compatible rehabilitation robots [42.70–72]. This is an important research pathway because brain-imaging-compatible machines can ultimately lead to *closing the loop* between the rehabilitation process and motor recovery: physicians and bioengineers could have a direct picture of the specific effects of the application of a rehabilitation protocol in terms of brain-induced modifications/adaptations, thus opening novel avenues for the identification of patient-specific, highly effective therapies based on these new platforms integrating robotic and brain imaging technologies.

Cardiac Devices

43. Cardiac Devices and Testing

Michael Bateman, Stephen A. Howard, Christopher Rolfes, Timothy G. Laske, Paul A. Iaizzo

From the earliest reported cardiac surgeries in the late 19th century, exponential improvements in surgical techniques and operating times have opened the door for the development of novel cardiac devices. The design and development of cardiac devices in the 21st century is driven by the innovation and resources of an industry forecast to be worth \$266 billion by 2012. This market growth is demonstrated by the many patent applications submitted each year to create novel devices or embellish existing products.

This chapter seeks to provide a brief description of the history of cardiac surgery, the evolution of cardiac devices, and a glimpse into the future of the industry as a background to the design process. The fundamental principles involved with the design and development of cardiac devices are discussed, from an explanation of the many stages involved with device design and the biological factors and material properties that engineers must consider when prototyping and testing devices to the steps taken by a medical device company to successfully deliver a product to market. Additionally, the chapter includes examples of market available cardiac devices and illustrates the novel devices and therapies currently in development.

Driven by the fields of surgery and cardiology, the rapidly expanding cardiac device industry continues to produce innovative and revolutionary devices and therapies. Although many devices are conceived from a distinct need within the operating room or cardiac catheterization laboratory, their design and

development often lead to novel procedures and techniques that continue to improve treatment of cardiac pathologies. There is little doubt that these innovative improvements will extend and enhance the overall quality of the life for patients worldwide.

43.1 Background

The roots of cardiac device design and development are found in fairly recent history (in the past 60 years), and are associated with the expanding fields of interventional cardiology and cardiac surgery. Innovative surgeons and interventionists in the 1950s and 1960s pioneered and revolutionized treatments for cardiac trauma and/or defects. These early procedures may seem tentative and cautious by today's standards, however the operations performed by these individuals were revolutionary. These brazen clinicians pushed the limit beyond what was considered acceptable and thus often were not well respected by their peers.

The earliest reported heart surgeries were conducted out of necessity to repair potentially fatal cardiac wounds. From *Rehn's* repair of a stab wound in a Frankfurt hospital in 1896 (considered to be the first successful human heart surgery) [43.1] to the treatment of field wounds during the two world wars, the increasing success of cardiac repairs finally opened the door to a whole new field of cardiac surgery.

Throughout the 20th and 21st centuries there have been rapid advancements in heart surgery, thanks to concurrent progress in cardiac medical technology. The use of hypothermia, heart-lung bypass machines, and cardioplegia solutions has provided surgeons with a motionless and bloodless operating field. These advances greatly increased the possible operating time from minutes to hours. Whereas previously heart surgeries were limited to simple procedures, such as the repair of minor congenital defects, these advances then enabled the development of novel surgical techniques and technologies. More recently, this has been accompanied by the necessary testing and approval requirements. The modern day process of product development, from the initial steps of brainstorming and idea generation to bench top and clinical testing, continues to be refined. Throughout this process, the innovation and resources of an industry forecast to be worth \$266 billion by 2012 [43.2] continue to drive the development of novel technologies in the field of cardiac devices.

43.2 Selected Landmark Events in Cardiac Devices and Surgery

Cessation of the heart for 4 min or more is known to cause permanent brain damage, thus requiring the earliest cardiac surgeries to be performed on a beating and blood-filled heart. The first step to increase this surgical window was conceived by the Canadian surgeon *Bigelow* when, in a 1950 paper, he described the use of hypothermia on dogs [43.3]. This idea was first clinically used in 1952 at the University of Minnesota, when *Lewis*, *Varco*, and *Lillehei* used hypothermia to successfully repair an atrial septal defect in a five-year-old girl [43.4]. Though hypothermia extended the window during which blood flow could be stopped, physicians considered that cardiac surgery still had to be completed in less than six minutes, thus not allowing enough time for surgeons to attempt more complicated operations.

John *Gibbon* originally came up with the idea for a heart-lung machine in 1930. When charged with monitoring a patient slowly dying from a massive pulmonary embolus, he realized that her condition could be improved if he could provide some assistance to help oxygenate and pump the blood [43.5]. He worked for over 20 years on his machine before attempting the first use in humans, which unfortunately failed. Sub-

sequently, due to limited success, *Gibbon* halted work on his bypass machine after only a few attempts. Yet, from this groundwork, similar concepts were attempted by others around the world. One notable approach was the biological heart-lung procedure employed by *Lillehei* and colleagues in 1954–1955, in which they used a second person, typically a relative of the patient, as the life support system [43.6]. This procedure, known as cross-circulation, though ground-breaking was short lived primarily due to criticisms that it carried a risk of 200% mortality.

It was during these procedures that the consequence of surgically induced heart block also was identified. The solution to this problem was to electrically pace the heart using an external stimulator. It was *Johnson* at the University of Minnesota who suggested this approach to his clinical colleagues, including *Gott* and *Lillehei* [43.7]. Once this was found to be an effective solution for keeping such patients alive, the need for a battery powered system was also identified; this became a more immediate need when a patient being supported by an in-house power source died during a power outage in the operating room at the University of Minnesota. At that time, *Earl*

Bakken, cofounder of Medtronic, Inc., was repairing equipment in the hospital operating rooms, and was recruited to build the first wearable, battery powered pacemaker that was then used on a patient in 1958. During this period, further developments and refinements of mechanical means of circulation occurred, including the Dodrill-GMR, created by *Dodrill* at Harper Hospital in Michigan [43.8], a heart-lung machine developed by *Kirklin* at the Mayo Clinic [43.9], and the bubble oxygenator developed by *DeWall* and *Lillehei* at the University of Minnesota [43.10]; these developments offered greater advantages compared to the cross-circulation procedure. Importantly, these mechanical heart-lung machines, along with the development of the membrane oxygenator and the pacemaker in the 1960s, allowed cardiac surgeons hours in which to operate in a motionless and bloodless heart and provide pacing therapy as needed.

As the allowable surgical time for cardiac surgery increased, so did the complexity of the procedures that could be attempted. Subsequently, innovations flourished as the rapidly changing field of cardiac medicine stimulated the formation of hundreds of medical device companies. Some companies were founded to commercialize newly invented devices, such as St. Jude Medical, a business formed around development of the bileaflet mechanical heart valve. Other companies, like

Boston Scientific, were started to create new markets for less invasive medicine [43.11], designing catheters that facilitated minimally invasive procedures. In modern medicine, these companies have developed a multitude of devices that are used to correct a wide variety of cardiac pathologies, and many additional innovations are submitted to the United States Patent and Trademark Office every year. For example, a search of their website [43.12] produced the following numbers of published patent applications based on specific key words:

- CARDIAC (18920 as of July 2004; 54 155 as of May 2009; 72 690 as of April 2011),
- CARDIOLOGY (1480 as of July 2004, 4557 as of May 2009, 5988 as of April 2011),
- CARDIAC REPAIR (32 as of July 2004, 149 as of May 2009, 244 as of April 2011).

It should be noted that this list does not include many international patents, but demonstrates the exponential acceleration of device innovations in regards to the assessment of cardiac health and treatment of cardiac pathologies [43.13]. The number of patent applications submitted each year is indicative of the conception of ideas that ultimately create novel devices or embellish existing products.

43.3 Market Released Cardiac Devices

Table 43.1 displays a list of some of the most common cardiac devices available on the market today. This list exemplifies the vast number of products

designed and produced for the treatment of cardiac pathologies and illustrates the diverse nature of these devices.

43.4 Device Development

The invention of a cardiac device is the same as many other well known and widely used products; both must come from an idea and/or recognized unmet clinical need. In many cases, a device can have a beginning as humble as a rough sketch on the back of a napkin, thus beginning the iterative process of device development, which may even allow such an idea to evolve into a marketable product.

Today, it is generally considered that most new medical devices are not created by large organizations, but by small startup companies. These companies are funded by either a venture capital firm or an angel investor (investment from a single person), and are

typically focused on developing one primary product. Larger organizations, on the other hand, will generally focus on improving devices currently available rather than developing new devices, although they do partake in their own device development from start to finish. Academic institutions also foster device design using grants or federal funding, yet very few are able to develop a device beyond the concept (or an early prototype) stage due to the lack of resources and general capabilities of the institution. However, the intellectual property (IP) of an institution can be licensed to an external company to further develop the concept and perform animal and clinical testing [43.14]. Generally,

Table 43.1 Examples of market released cardiac devices used to treat cardiac pathologies

- Pacemakers
 - Atrial pacing systems
 - Ventricular pacing systems
 - Biventricular pacing systems
 - 3 chamber system (e.g., right atrial and each ventricle separately)
 - Activity sensing for rate control
- Implantable cardioverter defibrillators (ICD), with pacing capabilities
- Pacemaker and ICD leads
 - Active fixation
 - Passive fixation
- Ventricular assist devices
- Prosthetic valves
 - Mechanical valves
 - Tissue valves
 - * Surgically implanted
 - * Transcatheter delivered
- Prosthetic coronary arteries
 - Bypass graft anastomosis devices
 - Engineered grafts
- Valve annuloplasty rings
- Septal defect closure devices
- Stents
 - Coronary artery stents
 - Endovascular and extravascular stent grafts
- Angioplasty balloons
- Valvuloplasty balloons
- Ablation catheters
 - Cryoablation catheters
 - Radio-frequency ablation catheters
- Heart rate monitors
 - External
 - Implantable
- Drug delivery pumps and catheters
- Vascular aspiration devices
- Artificial hearts
- Positioners and stabilizers

academic institutions are not focused on device development, and thus are not fully equipped to address all of the issues involved with creating, testing, and/or marketing a cardiac device.

43.4.1 The Six Phases of Device Development

Device development can begin anywhere, but there is a general sequence for how a device is developed. There are a number of different systems to categorize the steps taken for development and testing of any cardiac device and one in particular involves breaking the process up into six phases of development. These phases are shown in Fig. 43.1.

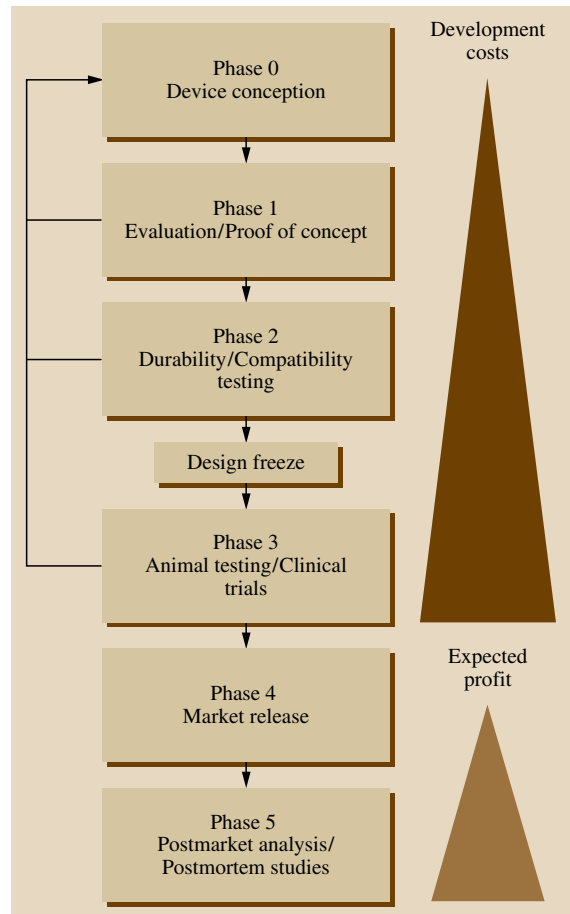

Fig. 43.1 Flow chart of device development process. The six phases of device design are shown, as well as the expected cost and profit with marketing a medical device

Phase 0 is thought of as the planning phase. During this phase much of the groundwork is completed – creating a product platform, assessing market opportunity (determining if the product will be worth pursuing financially), and determining product constraints associated with IP.

Phase 1 is considered the concept development phase. This is when the development process as well as bench top testing of the device begins. For example, feasibility studies are performed to determine whether it is technically possible to manufacture the product and/or if there is a potential market of adequate size for it to be profitable. It should be noted that in the field of cardiac devices there remains a need for pediatric-sized devices, but often it is considered not profitable to pursue these opportunities.

Phase 2 occurs after the device meets the previous criteria from phase 1. This is where further bench top tests are performed for both accelerated failures and required function of the devices. In vitro work or acute animal studies can also be initiated to assess potential biocompatibility. The end of phase 2 generally involves a design freeze, where nothing can be changed on the device without going back to phase 1 or 0.

Phase 3, which occurs after the design freeze, assures that testing will provide an accurate assessment of device function in a living organism. Testing often includes chronic implantation in appropriate animal models, which is then followed by regulatory approvals before the onset of clinical trials in humans. Subsequent to a successful clinical trial, final approval for market release of the product is sought.

Phase 4 is initiated when the product is market released; usually this is the first phase of the overall process during which the company expects to see return on investment. Yet, profitability assumes that all clinical trials were successful, that the regulatory body of the country has approved the device for market release, that the company can begin to commercialize and market the device, and that they can receive payment (reimbursement) for sales.

Phase 5 is considered to be the postmarket assessment. Even though a product is fully marketed and approved by a regulatory agency, the company is still required to perform follow-up studies on their products to ensure that they are not causing any unforeseen issues with patients over time. This also gives the company more information for future improvement of their device. Types of studies that can be performed in this phase include postmortem studies, where the company may receive the explanted

device and then analyze its postimplant status or condition.

Importantly, throughout all of these phases, a number of different elements need to be checked and rechecked to achieve successful device production. For example, during *voice of customer* (VOC) research, feedback on device design is obtained from consumers of the product, including professionals who implant the device, patients, and their caregivers; this information will help ensure that the concept or device fulfills the needs of all those considered as customers. Business feasibility and marketability will also drive the device design, i. e., to be as cost efficient as possible. The initial stages of research and design are generally the cheapest portion of designing a device. When animal studies need to be undertaken, especially chronic implant studies, the costs dramatically increase. Subsequent human clinical trials can cost many millions of dollars.

43.4.2 Intellectual Property

At the outset of any device development project, it is critical to review published literature and issued patents for similar products or ideas that may be currently protected. Thus, a major part of the product design process is to maintain IP related to the technologies being developed. A continually changing design can be determined to be novel, non-obvious, and useful and may therefore warrant a new patent application. It is considered that there are a number of ways that developers can keep their IP safe from others infringing on their idea and using it as their own. For example, a *trademark* is a name or symbol that is associated with a product or brand, which means the company and only the company has full rights to use that name or symbol. This prevents others from using the name and associated marketing as a means of promoting their products or services. Similarly, a *copyright* may be given for any written and graphical material to an individual or group of individuals to protect their work and to reduce the risk of it subsequently being plagiarized [43.15]. Another suggested way to protect an idea or product is to keep it a trade secret, simply by not divulging any information regarding how a product is made, or how it operates or performs (e.g., the device runs on proprietary software or novel circuitry). One downfall to this type of IP protection is that if anyone successfully duplicates the product or procedure (even without knowing the trade secret), there are no legal consequences [43.15].

The most noteworthy way of protecting one's IP in the medical device industry is to file and obtain a *patent* with broad claims. A patent is a legal document that explicitly explains how a device works or how a procedure is done, with enough information that anyone within the field would be able to duplicate the device or process. Most medical devices are physical entities that can generally be taken apart. Thus, a competing company could theoretically, but not ethically, obtain a marketed device, disassemble the device into its core components, and rebuild it (reverse-engineering). By doing this they may improve upon the design, create a better product, and take away market revenue from the inventors. Hence, as early as possible in the device development process, a patent should be drawn up to protect the device design. Most patents provide legal protection for 20 years (e.g., US patents), thus guaranteeing exclusive marketing rights for that period. However, upon expiration, the device can be copied without legal recourse [43.15]. With cardiac medical devices this is often of little concern, since the product life of the original design is often less than 5 years, and thus is typically updated with new patent protection. Nevertheless, with all new product development, it is important to avoid infringement of all protected patents (and subsequent infringement lawsuits). Thus, for any product developer it is vital to know and understand how to read patents. Typically, patents are classified according to their device type and use and will first provide the filing numbers, inventor(s), and the date filed. Next a description of the device or process is presented, generally involving sketches and other images of IP. The most pertinent information is contained within the claims section, which specifically lays out what part of the IP is novel, and hence what is officially patented and protected by the patent. The claims section is generally the portion that legal teams will address when reviewing a patent case, as it gives the specifications of the patent and what is fully covered by the patent.

In many cases, finding and utilizing patent information can benefit medical device designers. According to the European Patent Office, there are a number of reasons and ways to use patents to your benefit, i. e., “find out what currently exists and build on it . . . keep track of who's doing what . . . [and] avoid infringing on other people's patent rights” [43.16]. To find patents relative to the cardiac devices you hope to develop, there are many online databases that can search for patents with specific information. A few examples of such databases include the European publication server [43.17], free patents online [43.18], and Google [43.19].

43.4.3 Device Prototyping

In the early stages of creating a medical device, it is best to fully investigate all potential options of the device design. Brainstorming and ideation are key aspects of product design. Using the philosophy that any idea is a good idea, anything from very quick drawings to off the wall ideas can be used to generate novel concepts. It is generally accepted that promoting idea generation is important because, even if a particular idea may not be possible or useful, it may spark ideas from someone else, and provide another angle or approach to solving the problem at hand. Typically once ideas are abundant, a team can begin to create a list of best concepts for the device.

Additionally, a very important part of phase 0 in the development process is the creation of quick mock ups of prototype devices. The goal is to generate many tangible ideas to help fully visualize and understand the product or concept. In other words, a sketch can give one the ability to depict the idea from one particular view point, but it requires a 3-D physical rendering (e.g., a moveable and/or moldable prototype to portray the workings of the device and the human factor interactions) to fully appreciate the idea and understand the nature in which it will interact with its environment. Additional purposes of phase 0 are to develop a proof of concept and to confirm that the ideas put forth can be constructed and eventually manufactured to perform as intended.

After a proof of concept has been attained and market potential assessed, the design team should select a handful of devices that will be fully prototyped and shown to customers for feedback. This is considered to be part of phase 1 during which feedback is obtained by collecting the *voice of customer* from a large sample size of potential users with varied backgrounds and clinical experiences; this can be obtained through direct questioning, observing, and/or discussing the product with the customer. Customers may consist of many groups of people, including those who use the device, benefit from the device, pay for the device (reimbursement, insurance companies), and those who may potentially profit from the device. These groups of individuals will offer assistance in the design process and likely improve the overall design of the product, however, it can be difficult to fully meet the expectations of all primary customers. For instance, a user may want the device to be easy and intuitive to use, in contrast to payers who may want the device to be inexpensive and beneficial to the patient in reducing costs (e.g., a reduc-

tion in the number of required future procedures). Those who expect to profit from the product (e.g., a company's chief financial officer) may demand that the costs of product development be minimized. Hence, all of these concerns must be proactively considered and addressed by the design team to create a product that satisfies the majority of their potential customers.

In addition to brainstorming, it follows that one needs to track all potential device defects and failures. Note that early on in such a process, one needs to consider the risks and benefits of employing any new procedure that utilizes a newly developed device (Fig. 43.2).

In order to complete the risk analysis on an entire device, one typically employs *failure modes and effects analysis*. These activities are generally defined as procedures in product development and operations management for identifying potential failure modes within a system, i.e., classification by the severity and likelihood of failures. Any successful analysis activity helps the research and development team identify potential failure modes based on past experience with similar products or processes, enabling the team to design those failures out of the system with a minimum of effort and resource expenditure; in turn, this helps to reduce both development times and costs. Figure 43.3 depicts an example data sheet of such an activity. Complete failure modes and effects analysis on a new cardiac device, such as a prosthetic valve, typically creates a 150-page spreadsheet of potential problems, including everything from leaflet material breakdown to misalignment of the prosthesis within the heart. Each of these failure modes must be assessed as to how likely it will happen and

how severe the impact on the patient could potentially be. If one particular failure mode may feasibly occur 1 out of every 100 000 patients and, as a result, have minimal impact on the patient's health, typically this failure mode will not create a drastic design change. However, if within the same occurrence rate, a given patient may experience serious health problems from the complications, this would be a failure mode that would need to be addressed.

43.4.4 Device Testing

When a device design moves from phase 0 into phases 1 and 2 of the design process, basic testing of a cardiac device begins. During this process, it is important to consider the standards set forth by various international governing organizations with respect to testing and manufacturing medical devices. The most notable organization is the International Organization for Standardization (ISO); others include the medical device directive (MDD) and the International Electrotechnical Commission (IEC). Each of these regulatory standards are readily available to the design team to ensure that the medical product being developed will "remove or minimize as far as is possible the risk of injury, in connection with their physical features" [43.20]. Many regulatory bodies require that a company abides by these sets of standards for creating a medical device; statements such as ISO certified mean that the company, for instance, is in ISO compliance with the policies and regulations in regards to all phases of testing, manufacturing, and developing their medical devices.

Fig. 43.3 Example of a failure modes and effects analysis (FMEA) data matrix used to study a new rigid bileaflet heart valve design

Apart from biological and mechanical properties, there are other aspects of the device development process that must be taken into consideration. Obviously financial feasibility is a critical consideration, but there are other additional factors as well. For example, if a specific patient requires a pacemaker and s/he is likely to need an implantable defibrillator/pacing system in 5 years, there is no need for the battery in the pacemaker to last 20 years; in fact, many pacemakers are built with a battery lifespan between 6–8 years, depending upon the output settings of the system. This requirement allows physicians to change out the device with newer devices with better, more advanced technologies (e.g., new algorithms that may be customized for the patient's needs) [43.21]. This, in turn, is associated with the recommended longevity of the product. Most importantly, if the device is labeled as having a particular lifespan, then assessments on the product will only need to be tested for that period of time as noted by ISO regulations (ISO5840:2005(E)).

When testing the properties of a medical device, it is important that one isolates each of the components that require testing. More specifically, cardiac devices

can be very complex in nature and have multiple associated parts fabricated from different composite materials. Even something as simple as a bare metal stent has multiple components. Such products may be required to hold an exact shape at physiological temperatures, the surfaces should be biocompatible, and the materials should not fracture or fail after being subjected to external pressures [43.15]. It is also important to test the performance of the developed device for all the intended situations, e.g., a device may be required to function in a variety of anatomies and maintain an accepted performance level for all manufactured sizes. This is emphasized by the ISO standards for development of a cardiac prosthesis. The standardized regulations state that a rigid heart valve, such as a tilting disc valve, must undergo durability testing over no less than 400 million cycles on at least three of each of the largest, medium, and smallest size valves (ISO 5840:2005(E)). To ensure that the device achieves this goal, tests are often designed around the critical conditions to which the device may be exposed. Shown in Fig. 43.4 is a typical flow chart one would employ to perform such a testing process.

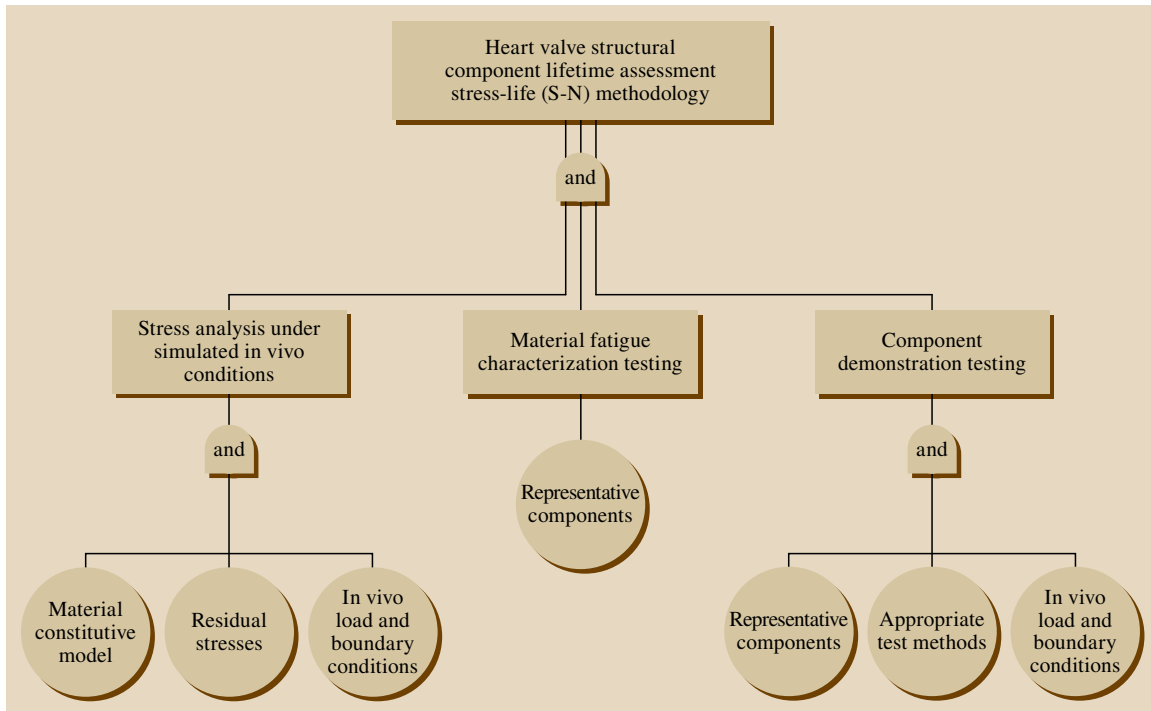

Fig. 43.4 Typical flow chart of a preclinical structural evaluation process that a valve research and development team might utilize to ensure proper durability of design. Note that typically these criterion can be evaluated in series

In many cases, the properties of cardiac devices can be tested without the use of native biological tissues. For instance, silicone, nylon, sponge, or foam can be used to create a mock testing environment for the device [43.15]. For example, if one wishes to investigate whether or not a pacing lead tip (active fixation helix) will properly engage with the endocardial surface, the properties of lead fixation into a silicone simulated tissue may be assessed, i.e., active fixation into a mock biological substrate followed by assessment of relative damage to the simulated myocardium (silicone). This is not only a more repeatable procedure due to a decrease in substrate variability, but it is also generally cheaper than obtaining live tissue or animals to perform initial basic testing.

Performing device testing with animal models or living biological tissues is not only expensive, but it also requires much effort and expertise. As such, to address questions during the early design stages of the device, alternate methods can be devised to ascertain device performance. Sometimes the testing approaches can be as simple as employing fresh meat obtained from a local grocer or meat packing plant; this can provide useful

insight during initial device testing. For example, one could test an ablation catheter using fresh meat and then readily assess visual changes in the meat's appearance to determine the relative region of ablation [43.15]. Additionally, it is often possible to purchase animal organs such as hearts from meat packing plants and directly test a device in a more relevant cardiac anatomy.

Biocompatibility is a primary issue when developing a device which will be implanted within a human body. More specifically, in the case of cardiac devices, most of the current therapies and monitoring tools need to be inserted into the body and thus be exposed to the biological environment. In some cases, this is for only a short period (ablation catheters), while some devices will be implanted for a few years (invasive heart rate monitors), and yet others for the rest of the patient's life (mechanical heart valves). Nevertheless, in each of these scenarios the device is required to display an appropriate level of biocompatibility. In general, the potential for device rejection can be assessed with *in vitro* immunological responses to the device; a strong immunological response would be indicative of a possible problem with biocompatibility and possible device

rejection. However, today most cardiac devices are constructed from well studied materials with known levels of biocompatibility; as such, adverse reaction testing is predominantly assessed during chronic animal studies.

Another important factor that one must consider when designing a cardiac device is the combined effect that temperature and pressure may have on a given device. There are many polymers or compounds that change elasticity properties when exposed to temperatures at or near normal body temperature. On the other hand, this can be advantageous depending upon how the device is designed. The informed engineer may choose to design the device, a catheter for example, to be stiff when entering into the vein/artery, thus allowing for easier placement. Subsequently, the device might become more malleable inside the body, as the temperature increases, so as not to cause internal damage to the vessels or myocardium.

43.4.5 The Visible Heart

Before embarking upon the expensive animal testing protocols that are required to prove the efficacy of a potential cardiac device, there is exceptional value in testing the device in a reanimated beating heart model. For example, the Visible Heart apparatus was developed by our laboratory at the University of Minnesota to reanimate large mammalian hearts that replicate the working physiological conditions of the heart in vivo. Reanimated hearts are perfused and then actively pump a clear crystalloid perfusate rather than blood, thus allowing the opportunity to uniquely and visually document the tissue device interactions of a large variety of cardiac devices [43.22]. Additionally, this approach has allowed researchers to employ an isolated, living heart as a model to visualize what occurs inside the heart during a device deployment procedure and how the device interacts with the organ throughout all the phases of the cardiac cycle.

In addition to the reanimation of swine hearts for early prototype testing using visible heart methodologies, our laboratory has been privileged to study the deployment of cardiac devices within reanimated human hearts. This reanimation of donor hearts, deemed not viable for transplant, enables the visualization of the specific device interaction with the varied endocardial anatomy of human hearts, both relatively healthy and those eliciting heart failure. With an increasing interest in the use of transcatheter delivered therapies, the ability to visualize the deployment and function of these devices using comparative imaging modalities has proved

exceptionally beneficial to the engineers and physicians involved with evaluating novel concepts and designs.

43.4.6 Animal Testing

Once all in vitro testing techniques have been properly utilized and the device design has been locked, the development process moves into phase 3, whereupon the device must then be proven safe in appropriate pre-clinical testing; usually this requires extensive testing on animal models (acute and/or chronic) before it can be moved into a human clinical trial. In order to ensure proper care and use of the animals during such experimentation, a detailed prestudy protocol is developed to address proper animal welfare in accordance with one's Institutional Review Board and ISO standards (ISO 10993-2). Typically, such protocols must be reviewed and approved by the appropriate governing body, such as an Institutional Animal Care and Use Committee. In general, preclinical in vivo testing is designed to critically assess the performance of the cardiac device when implanted in a beating heart. These analyses include assessments of the device's effect on the hemodynamic performance of the heart, the biocompatibility and mechanical durability of the device, and the efficacy and ease of the implantation procedure. It is essential that any preclinical in vivo testing be designed to replicate the environmental factors that the device will experience when implanted in humans.

In general, animal testing essentially falls into two distinct categories – acute and chronic. Acute animal testing usually focuses on the immediate function of the device. Since the animal is sacrificed shortly after device implant, it is typical to perform multiple methods of invasive monitoring. This may include measuring right-sided and left-sided pressures, intracardiac electrical monitoring, the use of ultrasonic crystals to create pressure–volume loops, or blood flow and metabolic measurements. This instrumentation can help to determine if the device is working properly and assess its influence on physiological parameters, such as the effect of an artificial valve on ventricular pressures.

The protocol for a typical chronic animal experiment is designed to test the long-term biocompatibility, function, and durability of a cardiac device. In such studies, cardiac devices are implanted in the same manner as the intended human procedure, and the animals are monitored postoperatively until a predetermined endpoint. If the animal does not reach the experimental endpoint, a postmortem investigation will be conducted to determine whether the implanted device directly

caused the mortality. Commonly in surviving animals, upon reaching the planned experimental endpoint, the device function is often retested both before and after the animal is sacrificed. Typically, the primary parameters assessed include the location and function of the device (i. e., did the implanted device move?), the immune response of the host and the overall health of the animal (i. e., was the systemic health of the animal compromised by the device?).

When developing a research protocol, it is important to use the appropriate species for the specific testing. Great strides have been made into the investigation of the pathophysiological mechanisms of cardiac disease with the use of transgenic mice and mice with gene deletions. However, while mice and rats can work well for specific tissue and metabolic work, most cardiac device testing of devices to be implanted in humans takes place on large animal models due to obvious technical limitations. It should be noted that within most of these large animals, the natural occurrence of cardiac disease is rare and often associated with comorbidities that preclude breeding efforts. Nonetheless, it is possible to surgically or otherwise induce various disease states (e.g., heart failure) or anatomical abnormality (e.g., an incompetent valve) within animal models. For example, to thoroughly test a device that treats heart failure induced by coronary disease, it is possible to induce a myocardial infarction in the animal prior to treatment by ligation or occlusion (e.g., the partial deployment of a covered stent) of a coronary artery [43.23].

For years, the use of canines for such experimentation has provided an excellent model for animal work since dogs typically have good temperament and can be trained to sit still during postoperative examinations. Yet, it should be recognized that canine hearts have an unusually large amount of collateral coronary circulation, which is only similar to humans who present with a slowly progressing end-stage chronic heart failure. Furthermore, this collateral circulation in the canine model can also lead to inconsistent or minimal ischemic regions that cannot be reproducibly induced [43.23].

Our laboratory and many others consider that swine are excellent models for acute cardiac device testing. For instance, swine have very similar cardiac anatomy to humans with respect to the conduction system, coronary arteries, and great vessels. Additionally, pig valves are very similar to human valves and are commonly used as tissue valve material. Yet, swine are not often used for long-term chronic studies due to frequent postoperative complications such as arrhythmias and sudden death. Additionally, it should be noted that

mongrel swine grow at a fast rate, making chronic implantation difficult and often inconsistent from animal to animal [43.23]. In contrast, the use of mini pigs for chronic studies is possible, yet availability and cost can be prohibitive.

Sheep are commonly employed for chronic valve implantation studies since there is little growth in the adult sheep. These animals have been used as the historic model for such work and have valve orifice size and function very similar to a human, in addition to relatively large atria allowing for straightforward surgical approaches to the atrioventricular valves. The ovine model is also characterized by a higher immune response than other animals. This means that, in many cases, a thrombolytic event will be observed in sheep more prominently than in swine or dogs, and therefore may provide investigators with a better idea of what the failure will look like in humans [43.23]. There is vast literature available on the use of the ovine model for chronic valve implantation studies.

Today, primates are rarely used in cardiac device research due to prohibitively high cost and animal care. Thus, little cardiac work has been done and the lack of historical data provides little motivation to begin work with this model [43.23].

In summary, a well written preclinical testing protocol defines that in order to predict the safety and performance of clinical use, a sufficient number of animals of the same species, and preferably the same gender and age, should have experimental and control devices implanted. This number may be best determined based upon the risk analyses of the device and the statistical significance of the experimental design. The duration of the experiment is typically specified in accordance with the parameter under investigation, and each animal must undergo a macroscopic and microscopic postmortem examination.

Common goals of a preclinical study are to report:

- Any detectable pathological consequences around the device implant or in the major organs of the body.
- Any macroscopically or microscopically detectable structural alterations in the device itself.
- Histological assessment of any thromboembolic material, inflammatory reactions, or degenerative process.

Once the preclinical animal testing is completed using *good laboratory practices*, a third party observer (outside auditor) of the laboratory tests will produce a report

to summarize all data collected and a recommendation of the clinical safety and performance of the device.

43.4.7 Clinical Testing and Regulatory Approval

Once a device has been proven safe and efficacious during rigorous animal testing, developers will embark upon clinical trials of the device before it can be properly market released. It should be noted that current regulatory processes in the United States and the European Union differ significantly in the requirements and guidelines laid out for clinical testing and market approval. However, both regulatory committees share the same fundamental principles and apply frameworks designed to ensure the safe and effective release of medical devices into the market. This section will briefly highlight current features of both approval processes.

From a legal standpoint, in the United States human clinical testing of an unapproved cardiac device cannot be initiated without pre-approval from the Food and Drug Administration (FDA) in the form of an *investigational device exemption* (IDE). The IDE is designed to provide the FDA with all the relevant data on device design and preclinical testing, as well as the intended study protocol. A device company must also apply for an IDE if they wish to expand the indication of an existing device. These clinical investigations may begin at an approved site 30 days after the FDA receives the IDE application, assuming that in-house institutional review board approval has already been obtained and the FDA has not notified the sponsor that the investigation may not begin [43.14].

To date, FDA approval is contingent on many factors. One of the most important factors determining the ease of starting a clinical trial is the device classification (Class I, II, or III), which is briefly defined as:

1. *Class I devices* pose the lowest risk to the patient and include noninvasive devices such as surgical bandages and tongue depressors. These devices are placed under the general rules applied to all medical devices and nothing more. The controls include prohibition of adulteration and misbranding, requirements on establishing registration and device listing, adverse event reporting, and *good manufacturing practices* [43.24].
2. *Class II devices*, such as cardiac catheters, are deemed to pose a high enough risk that regulation through the general controls alone is not sufficient. The majority of Class II devices require a premarket notification in the form of a 510(k) to provide data demonstrating that the described device is of *substantial equivalence* to an existing product with regard to its safety and effectiveness. Although a 510(k) can be substantiated through preclinical testing, approximately 10% of applications include clinical data [43.14].
3. *Class III devices*, such as implanted cardiac devices, are used to support and sustain human life, and also present a high risk of injury or fatality if the device fails. Almost all Class III devices require *premarket approval* by the FDA before being legally marketed, thus requiring clinical data demonstrating that the device is safe and effective in the target population [43.14]. Recently, the development of the *humanitarian device exemption* has created a pathway for accelerated market release of Class III devices; this exemption is intended for devices that address diseases or conditions that affect fewer than 4000 patients/year in the United States. Nevertheless, approval of a humanitarian device exemption requires the sponsor to prove that the device is safe and effective, and that all possible associated risks are outweighed by foreseen benefits. Typically, such approval requires smaller clinical trials in fewer institutions, allowing smaller companies to develop Class III devices beyond preclinical investigations.

Commonly, full scale clinical trials of Class III devices are preceded by a series of pilot trials typically limited to 100 patients spread over a few institutions, in order to establish the initial safety of the device and help in the design of the pivotal phase of clinical trials. The pivotal phase will be a large multicenter trial designed to generate the appropriate data required to define the patient populations in which the device functions safely and effectively. Many devices for which developers are seeking market approval are similar to current market released products and consequently can be measured against the standards set by these products. However, when entirely novel devices are introduced into clinical trials, the FDA requires randomized control studies to be completed. Yet, depending on the primary and secondary endpoints defined by the FDA, pivotal trials can require the enrollment of up to 1000 or more patients at 30–50 sites over a period of 1–2 years, with postoperative evaluations up to a year after implant. As such, these trials represent the largest commercial risk to a device developer, due to the recruitment and coordination of multiple test centers, core laboratories (for impartial data analysis), and a data safety monitoring board

(to determine if continuation of the study is appropriate scientifically and ethically) [43.14].

Within the European Union, there are three major differences in the regulatory process which include 1) use of *notified bodies*; 2) general criteria for product approval, and 3) local site regulations. Notified bodies are independent commercial organizations established to regulate the process of device market approval in the European Union. The responsibilities of these organizations include:

1. Device classification
2. Continuing assessment of the trials to ensure conformity and quality
3. Approval of design dossiers for high risk devices
4. Postmarket regulatory control [43.24].

To receive market approval for a high risk device in the European Union, the manufacturer must prove that the device is safe and functions to the guidelines laid out by the manufacturer. The difference in the criteria required to gain market approval for a high risk device in the United States and the European Union is best demonstrated by the following example.

The GuardWire temporary occlusion and aspiration system (Medtronic, Inc., Minneapolis, MN), a device designed to recover liberated plaque during angioplasty or stent placement, underwent clinical trials in the United States and the European Union before market

release. The device was classified as a Class II medical device by the FDA and, therefore, required 510(k) clearance. To satisfy this clearance, an 800-patient multicenter randomized trial comparing the device against a control was performed to prove a statistically significant reduction in major adverse cardiac events [43.25]. A trial of such magnitude can cost up to \$ 12 million and may take up to 2 years [43.14]. To gain market approval within the European Union, the manufacturer had to demonstrate the device's safety and effectiveness. This was achieved by running a 22-patient single site study requiring significantly less investment than the clinical trial requested by the FDA [43.26].

To summarize, gaining market approval in either the United States or the European Union can be a lengthy, expensive, and time consuming endeavor. Before embarking on the development of a cardiac device, it is critical that the designer develop an understanding of these pathways and the intricacies of each regulatory body, in order to complete the process in the most timely and cost effective manner possible. To date, the differences between the United States and the European Union regulatory bodies help explain why a large portion of pilot clinical trials and early device testing occurs outside of the United States. These differences also help to explain why a typical cardiac device is introduced into general clinical practice in the United States 1–3 years after market release in the European Union [43.14].

43.5 The Anatomy of a Device

Recently, much has changed in the field of cardiac devices with the improvement of established therapies, the development of novel devices, and the increase of associated regulatory issues. In order for any device to be considered acceptable for clinical use, it must display a number of essential characteristics that illustrate the anatomy of a cardiac device. This section will outline the key criteria that need to be fulfilled when developing a cardiac device and, in the interest of brevity, will focus on implantable devices.

43.5.1 Functionality

Although it may be obvious, it is vital that any product performs to the standards set by the manufacturer's claims. Many medical devices are born from the desire to satisfy a previously unmet clinical need. So to

be successful, a new product will have to complete this functionality above and beyond the currently available solutions and techniques. The functionality of a cardiac device also encompasses its ability to perform the desired task without compromising any other biological process. For example, a right-sided apically placed pacemaker lead should not compromise the function of the tricuspid valve. These specifications are often outlined by regulatory committees such as the International Organization for Standardization as seen in Table 43.2, which describes the operational specifications for cardiac valve prostheses.

For implantable cardiac devices, the question of functionality typically includes the way in which the device is delivered. Surgically implanted devices require a suitable method of fixation to the heart, such as the sewing ring of a prosthetic heart valve. How-

Table 43.2 Specifications for a prosthetic cardiac valve

Define that the device has reproducible function

- Allowing forward flow with acceptably small mean pressure difference
- Preventing retrograde flow with acceptably small regurgitation
- Remaining fixed once placed
- Having an acceptable noise level
- Maintaining its functionality for a reasonable lifetime, consistent with its generic class
- Maintaining its functionality and sterility for a reasonable shelf life prior to implantation

Define that the device is biocompatible

- Resisting embolization
- Resisting hemolysis
- Resisting thrombus formation

Define that the device is compatible with in vivo diagnostic techniques

Define that the device is deliverable and implantable in the target population

ISO 5840:2005(E)

ever, these matters can be greatly complicated when one chooses to deliver such devices through minimally invasive techniques, e.g., either through the wall of the heart or through the vasculature without placing the patient on cardiopulmonary bypass. Hence, not only must the delivery system be able to place the device in its intended position, but additionally it must not induce any adverse effects on the patient. Examples of such devices include stents, septal occluders, valves, and pacing/defibrillation leads. These devices can all be delivered in the cardiac catheterization lab rather than a surgical suite, and thus greatly broaden the patient populations that can receive such therapies.

Another, more recent example involves the development of transcatheter delivered heart valves to treat patients with highly stenotic or regurgitant aortic valves. Importantly, once implanted correctly, any prosthetic aortic valve must allow blood to exit the left ventricle during ventricular contraction (systole), and close to inhibit the return blood to the heart during ventricular relaxation (diastole). Still today, the majority of prosthetic aortic valve replacements are implanted via open heart surgery. Further, such valves can be placed

into two main categories that describe the materials that act as the valve leaflets – mechanical or tissue. Both designs have advantages and disadvantages, and there has been much debate over which performs better in various patient populations. However, the high surgical risk associated with patients with severe aortic valve disease due to multiple comorbidities, often considered as too sick to undergo an open heart surgical repair, has recently driven the need for transcatheter delivered, minimally invasive aortic devices [43.27, 28]. This transcatheter approach to aortic valve repair offers clear advantages because the prostheses can be implanted without open heart surgery or cardioplegia to stop the heart. To date, due to fairly complex delivery techniques, the valve leaflets have been primarily constructed from pericardial tissues; due to the nature of this approach, which requires seating either a balloon expandable or self expanding Nitinol frame in the aortic annulus on top of the native valve leaflets, questions have surfaced regarding how the implanted valve will function. It is currently considered that the options available to a cardiac surgeon while working on the heart during an open heart procedure – the ability to remove the native leaflets, size the aortic annulus directly and suture in the appropriate prosthesis – greatly decrease the likelihood of improper implantation. Consequently, there is an ongoing debate as to whether the performance of transcatheter delivered aortic valves can be considered comparable to continually improving surgically implanted valve procedures, and whether the advantages of minimally invasive implantation outweigh possible limitations in the functionality of the prosthesis [43.29, 30].

To date, companies developing these new transcatheter delivered technologies have been very specific in describing the patient populations for which the valves are designed and the conditions under which the valves should be implanted. By doing so, they have ensured that the devices are used only in situations that correspond to the conditions under which the device was designed to function.

43.5.2 Biocompatibility

Biocompatibility related to medical devices is generally defined as the ability of a material to perform with an appropriate host response in a specific application [43.31].

In 1987, Williams described how the biocompatibility of a material can be qualitatively evaluated to

assess its performance when implanted. The succinctness of this term is often misleading when applying the principles of biocompatibility to cardiac devices due to the number of different materials that are commonly used during manufacture. For example, tilting disc valve prostheses such as the St. Jude Medical Masters series (St. Jude Medical, St. Paul, MN) are manufactured from a variety of materials including pyrolytic carbon for the discs and Dacron for the sewing cuff (Fig. 43.5). All of these materials elicit different responses from the host body, and need to be individually assessed and quantified before the device is implanted. Examples of such tissue responses can be seen in Table 43.3.

The mechanism of how the host responds to the different components of a cardiac device must be extensively evaluated to ensure that the correct materials are selected for the final device design. This evaluation can be complicated by the fact that it is hard to replicate the human immune response *in vitro*. Consequently, all cardiac devices also undergo rigorous animal testing, yet it is important to note that this too can sometimes furnish misleading results as to bioreactivity. An example of this can be seen in the design and development of the Braunwald–Cutter heart valve ball and cage prostheses (Fig. 43.6), whereby cloth-covered cage struts were designed to encourage endothelialization and hence decrease any chance of thrombolytic

Table 43.3 Potential patient–device interactions causing clinical complications (after [43.32])

Adverse local tissue interactions

- Inflammation
- Toxicity
- Carcinogenic response
- Calcification
- Embolization or lymphatic spread of material fragments

Induced device migrations: encapsulation or a foreign body response

Inappropriate or altered healing responses

Associated infections

Thrombosis

- Thrombotic occlusion
- Thromboembolism

events [43.33]. Extensive testing in the mitral position of pigs, sheep, and calves showed promising results, thus the device was subsequently approved for human clinical trials. However, the device did not elicit the same host response when implanted in humans, in-

Fig. 43.5 St. Jude Medical bileaflet valve

Fig. 43.6 Braunwald–Cutter valve

stead resulting in aggravated wear on the cloth cage struts and more critical debris embolization. It should also be emphasized that host responses are not limited to immune reactions; for example, implanted tissue heart valves remain susceptible to accelerated prostheses leaflet calcification. More specifically, this type of calcification is initiated by reactions between the extracellular fluid and the leaflet membranes, creating calcium phosphate mineral deposits [43.34]. As a result, much research is currently underway to enhance leaflet materials to include calcification inhibitors, thereby limiting mineral deposition on the implanted materials.

In addition to the possibility of inducing mineral deposition or endothelialization, material selection has a critical impact on the overall biocompatibility of a particular device, due to the wide variety of mechanisms by which the host body can affect the implanted device. For example, initially there were several reports concerning insulation fracture of the Medtronic 6792 pacing lead (Medtronic, Inc.) [43.35, 36]. Initially, these leads were manufactured using Pellethane 2363-80A [43.37], which has since been proven to be particularly susceptible to calcification, environmental stress cracking, and/or chain scission when implanted in humans [43.38]. Newer versions of the polyurethane coating, such as Pellethane 2363-55D, have displayed much improved biocompatibility when used to coat pacing leads [43.39]. Although material selection itself may not be the sole reason for a particular mechanism failure, how a given material is applied in the device design may also play a critical role.

A device's material can also result in unexpected interactions with the host, as evidenced by the earliest versions of the Starr-Edwards caged-ball mechanical heart valve. The valve design used a silicone ball that was found to absorb lipids from the blood and swell [43.40]. In addition to poor valve function, this resulted in the silicone balls becoming brittle and increased the possibility of ball fracture and consequent embolization of small fragments into the arteries downstream of the valve position.

Many modern implanted devices incorporate specific coatings to assist in reducing biological responses. A prime example of this is the drug-eluting stent, designed to minimize cell growth and scar formation, thus decreasing the likelihood of restenosis. To date, in treating coronary artery disease, the use of these drug-eluting stents is considered to have shown great improvement over angioplasty alone [43.41]. In a second example, steroid-eluting pacing leads

have helped to manage the acute inflammation associated with lead implantation and, therefore, reduce the energy required to pace the heart [43.13]. In summary, it can be assured that the combination of pharmaceuticals with implantable devices will continue to expand as novel biologically engineered coatings are identified and consequently continue to improve biocompatibility.

43.5.3 Durability

As well as exhibiting the appropriate level of biocompatibility, any device implanted into a human heart must also display sufficient durability and longevity. It should be noted that this poses a unique problem in the field of cardiac devices due to the extremely large number of cycles that such prostheses are expected to endure; of course, there are potentially life-threatening implications due to device failures as well. Furthermore, the heart is itself a dynamic organ which can elicit threefold to fourfold increased cardiac outputs (internal pressures during exercises), hence the mechanical stresses on an implanted device can increase fourfold to sixfold.

The case studies of pacing leads offer important insights into the sheer magnitude of this problem. A lead will move approximately 100 000 times a day, or 37 000 000 times annually, in multiple locations along its length, usually in more than one degree of freedom [43.13]. This continuous movement exerts forces on the lead body that, in turn, can accentuate the mechanical breakdown of the device. The underlying mechanisms can include material creep or erosion due to contact with other components. Coronary placed stents represent another important example; standard dynamic mechanical stresses due to bending, axial loading, and torsion can be induced during contraction of the heart. Additionally, stents are influenced by the dynamic changes in the coronary arteries during exercise such as circumferential forces due to changes in the lumen diameter.

The durability of any cardiac device is further challenged when the device directly interacts with the turbulent and pulsatile flow of blood, as is the case for prosthetic cardiac valves. More specifically, the flow of blood through mechanical prostheses, particularly tilting disc valves, can lead to a particular type of erosion called cavitation, whereby gaseous bubbles form and violently collapse on the surface of the valve discs due to the sudden temporary decrease in pressure during closure. This phenomenon can lead to the fracture of the

valve disc and was originally observed in the 1980s in association with the failure of the Edwards-Duromedics valve (Edwards CVS, Irvine, CA) [43.42]. Subsequent tilting disc valves, such as the St. Jude bileaflet valve (St. Jude Medical), have been designed specifically to reduce this particular material erosion by reducing the area of the tilting disc.

As with other cardiac devices, prosthetic valves are expected to endure a large number of cycles in their lifetime. For example, in order to minimize the possibility of failure when embarking upon a human clinical trial, the ISO has set up a series of strict guidelines for the performance of prosthetic heart valves. The current ISO guidelines require rigid devices, such as tilting disc mechanical valves, to remain functional for 400 million cycles (approximately 10 years in vivo) and flexible devices, such as tissue valves, to remain functional for 200 million cycles (approximately 5 years in vivo). This testing must be done under the following minimum performance conditions: beat rate is 70 cycles/min, simulated cardiac output is 5.0 l/min, mean aortic pressure is 100 mmHg, and systolic duration is 35% (ISO 5840: 2005(E)). No valve can be approved for clinical trial before demonstrating this level of durability over a suitable sample size. Even today, due to the relative infancy of the field of prosthetic valves, there is little long-term clinical data regarding durability. Yet, a recent study by Mykén et al. regarding the durability of surgically implanted tissue valves such as the St. Jude Epic stented tissue valve (St. Jude

Medical) has shown promising data 20 years post implantation, hence demonstrating the durability of these prostheses [43.43].

43.5.4 Design for Manufacture

During the cardiac device design process, it should be specifically noted that the design team must not neglect the fact that the device will eventually need to be manufactured in an efficient and cost effective manner. Such methodology is known as *design for manufacture* (DFM) and emphasizes the fact that an economically successful design should also ensure a high quality product while minimizing manufacturing cost. By utilizing manufacturing cost estimates, this process proactively helps to guide and prioritize cost reduction efforts involved with device design, and thus should have significant effects on product lead times, development costs, and ultimate product quality. As such, design for manufacture methods require input from a multidisciplinary team in addition to the core design team, thus drawing upon the expertise of manufacturing engineers, cost accountants, and production personnel [43.44]. Yet, when applying this principle to cardiac devices, it is critical to understand that the quality of care impacted by the device must not be compromised by the need for a more cost effective manufacturing process, but rather production costs can be controlled by using existing technologies and established manufacturing techniques.

43.6 Emerging Cardiac Device Technology

Rapid innovations in medical technology continue to build and advance with many new and emerging technologies that are being developed and improved constantly. For example, while specific diseases such as atrial fibrillation and heart failure have been known to exist for a long time, new therapies and devices are continuously being tested and developed on a daily basis.

43.6.1 Atrial Fibrillation

Atrial fibrillation is the most common type of cardiac arrhythmia in humans worldwide. While drug therapies and ablation procedures (radio- and cryoablation) are highly effective in treating this arrhythmia, there are associated side effects. The clotting risk within the

patient's left atrial appendage is usually treated with the anticoagulant warfarin, which is effective in preventing strokes [43.45], yet another suggested approach for preventing such clots is to seal off the appendage. While surgical options and specialized tools for sealing the appendage can be used, another suggestion recently promoted by Atritech Inc. (Plymouth, MN) is to implant a tiny filter in the appendage to prevent blood clots from ever leaving the heart.

Additionally, other types of implanted devices can provide ongoing treatment for atrial fibrillation. For example, pacing implants have continuously improved algorithms that can now help with treatment and prevention. Alternatively, for patients who have a difficult time managing drug treatment either because of non-compliance or harmful side effects, implantable drug

pumps may be able to deliver treatment directly into the pericardial space. Our laboratory has employed animal models to show that this type of targeted drug delivery can dramatically reduce side effects of the drug by minimizing the amount of the drug in the bloodstream while providing well-controlled doses directly to the heart (i. e., drugs can often be administered in greater concentrations than those recommended to be delivered intravenously).

43.6.2 Heart Failure

In general, congestive heart failure and dilated cardiomyopathy are associated with increased morbidity and mortality [43.46]. First line treatments typically involve therapeutic methods, including lifestyle changes (cessation of smoking, increasing exercise regimens, etc.) and medications (ACE inhibitors, beta blockers, etc.). When therapeutic methods are not enough, surgical repair or implanted devices may be required with the specific course of action being determined by the cause of heart failure (e.g., the use of an assist device; see following section).

43.6.3 Left Ventricular Assist Devices and Artificial Hearts

The concept of a completely artificial heart has been discussed since the early days of cardiac surgery. In its most basic form and function, the heart is simply two pumps that work in series. However, over the last 50 years, there have been many attempts to create an artificial heart with only limited success. In the United States, certain left ventricular assist devices are approved as a *bridge to transplant* therapy as well as for compassionate use. Currently, clinical trials are underway in the United States for the EXCOR pediatric ventricular assist device (Berlin Heart, Berlin, Germany) which can be used for medium- to long-term pediatric support. While left ventricular assist devices are typically implanted in patients with the intent to *bridge to transplant*, some patients, particularly pediatric patients, have been observed to recover intrinsic cardiac function to the extent that they can be completely weaned off the device [43.47,48].

43.6.4 Heart Transplant

When heart disease in a given patient has advanced beyond the point where pharmaceuticals or surgery

can help, a complete heart transplant may be indicated. While the procedure has changed little in the last 30 years, one area that has received focus for improvement is myocardial preservation. While organs like the kidney and liver can be safely transplanted up to 24 h after explantation from the donor, the heart is only viable for up to 6 h. Hence, new devices are being tested to increase this time, like the organ care system (Transmedics, Andover, MA), which keeps the heart beating at normothermic temperatures. This system has been reported to greatly improve heart health at 12 h of storage [43.49]. It is considered that devices and approaches like this will allow for improved transport of donor hearts and consequently increase the number of hearts available to potential recipients. Other methods to preserve heart function are also being explored. For example, our laboratory is investigating targeted delivery (pretreatment) with cardioprotective anesthetics, hibernation induction trigger, and omega-3 fatty acids using perfusion pumps, which we have observed to help improve transplanted heart function.

43.6.5 Valves

Damaged or defective functioning of valves is a well known cause of heart failure. In such cases, valve repair or replacement is often recognized as the most effective treatment. While replacement valves have been around since the 1950s, new valves and delivery systems are constantly being developed, such as the transcatheter Melody valve (Medtronic, Inc.; Fig. 43.7). While the Melody valve is designed to work when surgery is not an option (e.g., when the patient has already had numerous open heart procedures to correct congenital defects), today a surgically implanted valve is the gold standard among replacement valves. Hence, research will continue to make surgically implanted valve replacements better, with the ultimate

Fig. 43.7 Melody valve (Medtronic, Inc.)

goal of an artificial valve that will not require life-long anticoagulation or replacement in 10–20 years, problems typically encountered with current mechanical and tissue valves. Such a valve would drastically reduce the prospect of reoperation and improve patient quality of life by not requiring concurrent anticoagulant therapy.

In addition to valve replacement, there is continued research into the development of annuloplasty devices designed to correct regurgitation by reducing the annular size of the atrioventricular valves. For example, two companies, MiCardia Corporation (Irvine, CA) and MitralSolutions, Inc. (Fort Lauderdale, FL) are developing surgically implanted annuloplasty rings that can be adjusted postoperatively to optimize their therapeutic effects. Conversely, Cardiac Dimensions, Inc. (Kirkland, WA), Edwards LifeSciences (Irvine, CA), and Viacor, Inc. (Wilmington, MA) are developing transcatheter annuloplasty devices deployed within the coronary sinus which lie adjacent to the mitral annulus to minimize dilations [43.50].

43.6.6 Vascular Disease

Today, the primary interventional treatments for atherosclerosis in coronary arteries include angioplasty and stenting. Early studies with drug-eluting stents showed them to be more effective at preventing restenosis [43.51], yet a more recent study indicated that late thrombosis rates were higher than with bare metal stents [43.52]. Hence work continues relative to developing the ideal stenting solution, including optimization of drug coatings. Alternatively, recent focus in the device developmental phase has been on biodegradable stents and coatings. For example, these stents, like the Igaki–Tamai stent (Igaki Medical Planning Co, Ltd, Kyoto, Japan) provided the short-term support required to prevent early restenosis, however did not provide adequate long-term support; yet, there was a considered lack of or limited long-term risk after stent degradation. Alternatively, biodegradable coatings, such as those used in the BioMatrix stent (Biosensors International Group, Singapore), provided short-term protection from restenosis, with the degradation of the coating leaving a bare metal stent, which may be further validated to display lower rates of late thrombosis.

For patients who are not good candidates for stenting, or if restenosis has occurred, *coronary artery bypass grafting* (CABG) is most often recommended. Since the first CABG procedure 50 years ago, it has

become one of the most frequently performed cardiac surgeries. Importantly, new tools and technologies allow cardiac surgeons to perform the procedure in a less invasive manner. Equipment like the daVinci robotic surgical system (Intuitive Surgical, Inc., Sunnyvale, CA) has allowed surgeons to use smaller incisions and novel techniques to perform a wide array of cardiac procedures. Similarly, the development of heart stabilizing devices has allowed surgeons to perform cardiac surgery on the beating heart without cardiopulmonary bypass. It is envisioned that the continuing advancements of surgical techniques and tools and the development of both anastomosis devices and prosthetic coronary arteries will continue to improve patient outcomes and reduce overall hospital costs for CABG procedures.

43.6.7 Hybrid Operating Rooms

With many procedures blurring the line between cardiac surgery and cardiology, the development of hybrid operating rooms has led to increased equipment needs for both fields. This new type of operating room is built with the fluoroscopic imaging capabilities of a catheterization lab. This provides advantages as simple as a post-CABG angiogram, but also allows for multi-tiered treatments, such as stenting and valve replacement, all in the same room. This will be the ideal setting for procedures like transcatheter valve replacement, which is a surgical-like procedure requiring fluoroscopic guidance. As these centers of excellence develop, with a team of surgeons working side-by-side with cardiologists, one must consider that new devices and technologies may require design features that meet the requirements of each specialty.

43.6.8 Novel Devices

Around the world, thousands of innovators are busily developing the next generation of novel cardiac devices. For example, one potential treatment for heart failure, under clinical trials in the United States, is the Acorn CorCap Cardiac Support Device (Acorn Medical, St. Paul, MN). This device is implanted around the ventricles and provides support to the weakened heart walls and reduces ventricular wall stress. The use of this device is also expected to improve the heart's ability to pump blood, provide relief from heart failure symptoms, and potentially allow the heart muscle to heal. If this proves to be effective, it may be used in conjunction with other treatments.

43.7 Conclusions

It was the general aim of this chapter to lay out the fundamental principles involved with the design and development of cardiac devices, from an explanation of what design features engineers should integrate into their devices to the steps taken by a medical device

company to successfully deliver a product to market. Additionally, the chapter provided a brief description of the history of cardiac surgery, the evolution of cardiac devices, and a glimpse into the future of the industry as a background to the design process.

44. Functional Electrical Stimulation in Rehabilitation and Neurorehabilitation

Kei Masani, Milos R. Popovic

Individuals with spinal cord injury and stroke may be unable to voluntarily move different body parts and perform functional movements. However, as long as the nerves innervating the muscles and the joints are intact, electrical stimulation can be used to generate joint movements by contracting muscles that actuate the joint. The electrical stimulation used for this purpose is called neuromuscular electrical stimulation (NMES). An organized and patterned NMES that aims to generate coordinated limb or body movements instead of isolated muscle contractions is called functional electrical stimulation (FES). The FES technology is not only used as a prosthetic device, as a permanently used assistive technology, but has also recently been used as a therapeutic tool. This chapter summarizes the basics of electrical stimulation, discusses various prosthetic applications including walking, standing, reaching/grasping, bladder voiding, respiration and hearing, and describes therapeutic applications. The dramatic progress made taking advantages of recent technologies such as miniaturization of electronic components, new sensory systems, new delivery methods for electrical stimulation is introduced.

Individuals with spinal cord injury (SCI) and stroke have injuries that prevent the central nervous system from generating the desired motor command and/or from transmitting the desired motor command to the parts of the peripheral nervous system that innervate muscles. As a result, these individuals are frequently unable to voluntarily move different body parts and perform functions such as sitting, standing, reaching, grasping, and bladder voiding. However, as long as the nerves innervating the muscles, the muscles themselves, and the joints and soft tissues supporting the muscle-joint structures are intact, electrical stimulation can be

used to generate joint movements by contracting muscles that actuate the joint. The electrical stimulation used for this purpose is called neuromuscular electrical stimulation (NMES). An organized and patterned NMES that aims to generate coordinated limb or body movements instead of isolated muscle contractions is called functional electrical stimulation (FES). One possible application of FES technology is to artificially generate body movements such as grasping and walking. In such a context, the FES technology is used as a prosthetic device; in the literature, this use of FES technology is referred to as neuroprosthesis.

Up to now, two prevalent modes of applying FES technology have emerged. In one application, FES is used to develop neuroprostheses that are used to permanently substitute the impaired function [44.1–4], i. e., a consumer that needs the neuroprosthesis would use the device each time he/she wants to generate a desired function. Good examples of such devices are neuroprostheses for hearing (i. e., cochlear implants) [44.5–7], grasping [44.8–10], bladder voiding [44.11–13], and walking [44.14–16]. In the second application, the FES technology is used as a therapy to retrain motor functions such as the FES cycle ergometer [44.17–22], which is used to improve and/or maintain muscle volume and the cardiovascular system, grasping [44.23–29], reaching [44.23,25,26,28,29], and walking [44.30–

32]. In other words, FES therapy is used as a short-term intervention to help the central nervous system of the consumer to relearn how to execute these functions voluntarily instead of making the consumer dependent on neuroprostheses for the rest of his/her life.

These are two very different applications of the FES technology, which are not mutually exclusive. On contrary, one should first use the FES technology as a short-term therapy to restore as much voluntary function as possible, and only if an adequate return of function is not accomplished with FES therapy should clinicians resort to permanent FES systems (i. e., neuroprostheses) that the consumer would use as a permanent assistive device.

44.1 The Basis of Electrical Stimulation

44.1.1 History – The Use of Electrical Stimulation in Medicine

In 46 AD, Scribonius Largus described what may be considered the first neuroprosthesis: the torpedo ray, which was capable of generating an electric potential of 25–30 V [44.34]. For centuries, torpedoes were prescribed for all sorts of ailments, including headaches, hemorrhoids, and even mental illness.

Following the invention of the electrostatic generator in the late 17th century, electrical discharges were

found to excite animal muscles. Stronger discharges, and hence stronger biological responses, were made possible when the first capacitor was invented in 1745. Physicians began treating a wide range of diseases by applying electrical discharges to their patients. Benjamin Franklin pioneered some of these techniques.

In 1791, Luigi Galvani published his discovery that dissected frog legs could be stimulated by touching a bimetallic rod to nerve and muscle. Michael Faraday built the first electric generator in 1831. It introduced the possibility of applying a series of high-frequency electrical pulses to nerves, which is the basis for all modern electrical stimulation. G.B. Duchenne utilized Faradism extensively in the latter part of the 19th century to treat various neurological disorders. Duchenne developed electrodes for localizing currents, and he produced a set of maps of the body indicating locations called motor points, where electrodes can be positioned to excite specific muscles.

44.1.2 Physiology

In nerve cells, information is coded and transmitted as a series of electrical impulses called action potentials, which represent a brief change in the cell electric potential of approximately 80–90 mV. Nerve signals are frequency modulated; that is, the number of action potentials that occur in a unit of time is proportional to the intensity of the transmitted signal. Typical action potential frequency is between 4 and 12 Hz. An electrical stimulation can artificially elicit this action potential

Fig. 44.1 A concept of FES using surface electrodes. The FES system causes a muscle contraction by electrically stimulating the motor axons that are connected to the muscles. The electrical stimulation generates action potentials in the motor neurons, which propagate along the motor neurons toward the muscle. When the action potentials reach the muscle, they cause the muscle to contract (after [44.33])

by changing the electric potential of a nerve cell or a nerve axon by inducing electrical charge into the cell (Fig. 44.1).

The stimulated nerve bundle includes motor nerves (efferent nerves, descending nerves from the central nervous system to muscles) and sensory nerves (afferent nerves, ascending nerves from sensory organs to the central nervous system). In some applications, FES can be used to directly stimulate muscles, where peripheral nerves have been severed or damaged (i. e., denervated muscles) [44.35]. However, the majority of FES systems used today stimulate the nerves or the points where the junction between the nerve and the muscle occurs. The main reason for this is the fact that direct muscle stimulation requires considerably more energy to generate contractions (at least three orders of magnitude more [44.36]), which makes these systems more challenging to implement at home and in clinical settings. An electrical charge can stimulate both motor and sensory nerves. In some applications, the nerves are stimulated to generate localized muscle activity, i. e., the stimulation is aimed at generating direct muscle contraction. In some other applications, stimulation is used to activate simple or more complex reflexes. In other words, the afferent nerves that evoke a reflex are stimulated, which is typically expressed as a coordinated contraction of one or more muscles in response to the sensory nerve stimulation.

When a nerve is stimulated, i. e., when sufficient electrical charge is provided to a nerve cell, a localized depolarization of the cell wall occurs, resulting in an action potential that propagates toward both ends of the axon. Typically one *wave* of action potentials will propagate along the axon towards the muscle (orthodromic propagation) and concurrently the other *wave* of action potentials will propagate towards the cell body in the central nervous system (antidromic propagation). Note that while the direction of propagation in the case of the antidromic stimulation and the sensory nerve stimulation is the same, i. e., towards the central nervous system, their end effects are very different. The antidromic stimulus has been considered an irrelevant side effect of FES, although in recent years a hypothesis has been presented that suggests a potential role of the antidromic stimulation in neurorehabilitation [44.37]. Typically, FES is concerned with orthodromic stimulation and uses it to generate coordinated muscle contractions.

In the case when sensory nerves are stimulated, the reflex arcs are triggered by the stimulation on sensory nerve axons at specific peripheral sites. One example

of such a reflex is the flexor withdrawal reflex. The flexor withdrawal reflex occurs naturally when a sudden, painful sensation is applied to the sole of the foot. It results in flexion of the hip, knee, and ankle of the affected leg, and extension of the contralateral leg in order to get the foot away from the painful stimulus as quickly as possible. The sensory nerve stimulation can be used to generate desired motor tasks, such as evoking flexor withdrawal reflex to facilitate walking in individuals following stroke, or they can be used to alter reflexes or the function of the central nervous system. In the later case, electrical stimulation is commonly described by the term *neuromodulation*.

44.1.3 Technology

Nerves can be stimulated using current or voltage regulated pulses. Although both types of stimulation pulses are effective, current regulated pulses have a few advantages over voltage regulated stimulation pulses. One advantage is that changes in the tissue resistance (which occur all the time, in particular with surface stimulation systems) do not affect the amount of charge that is delivered to the nerves. In other words, the current regulated pulses always deliver the same amount of charge to the targeted tissue. This in turn reduces the need for persistent stimulation amplitude adjustments, which is a common problem with voltage regulated stimulators. Another major advantage is that in current regulated stimulation pulses one can accurately control how much charge is delivered to the tissue and how much of the delivered charge is extracted back from the tissue. This is an important feature because accumulation of charge may cause galvanic processes that can damage the tissue. Current regulated stimulation pulses, if applied so that they are balanced and biphasic, will ensure that the delivered charge is extracted out of the targeted tissue at the end of every single stimulation pulse.

The stimulation pulses can be either monophasic or biphasic. When the pulses are monophasic, they essentially deliver the charge to the tissue, without an attempt to remove the charge from the tissue. When the pulses are biphasic, the charge is delivered to the tissue but is also removed from it. If the biphasic pulses are balanced, the amount of charge delivered to the tissue is removed from it during the same pulse. If the biphasic pulse is unbalanced, residual charge is left in a tissue. The balanced biphasic pulses can be symmetric or asymmetric. Present day sophisticated FES systems apply asymmetric balanced biphasic pulses to ensure that muscle contractions occur only in the mus-

Fig. 44.2 Portable FES system with surface electrodes. This FES system is programmable using the memory chip cards and can make flexible stimulation patterns with four channels (after [44.38])

cles over which the anode electrode is placed. If the pulses are symmetrical balanced biphasic, both muscles under cathode and anode may be contracted.

Nerves can be stimulated using either surface (transcutaneous) or subcutaneous (percutaneous or implanted electrodes). Surface electrodes are placed on the skin surface above the nerve or muscle that needs to be *activated* (Fig. 44.2). They are noninvasive, easy to apply, and generally inexpensive. Due to the electrode–

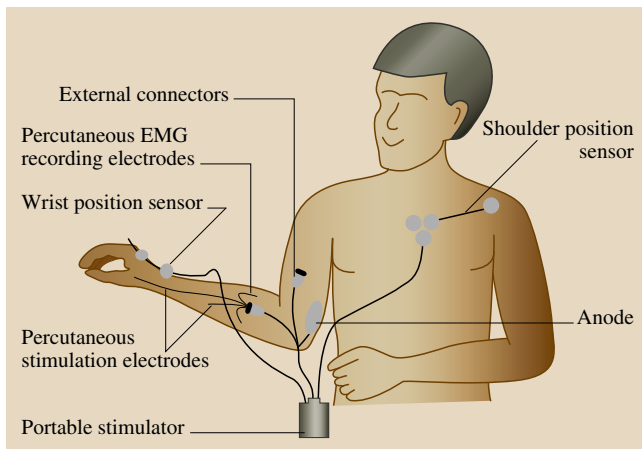

Fig. 44.3 Scheme of a percutaneous hand neuroprosthesis (after [44.39])

skin contact impedance, skin and tissue impedance, and current dispersion during stimulation, much higher intensity pulses are required to stimulate nerves using surface stimulation electrodes as compared to the subcutaneous electrodes. A major limitation of the transcutaneous electrical stimulation is that some nerves, for example, those innervating the hip flexors, are too profound to be stimulated using surface electrodes.

Subcutaneous electrodes can be divided into percutaneous and implanted electrodes. The percutaneous electrodes consist of thin wires inserted through the skin and into muscular tissue close to the targeted nerve. These electrodes remain in place for a short period of time and are only considered for short-term FES interventions (Fig. 44.3). One of the drawbacks of using percutaneous electrodes is they are prone to cause infection and special care must be taken to prevent such events.

The other class of subcutaneous electrodes is implanted electrodes. These are permanently implanted in the consumer's body and remain in the body for the remainder of the consumer's life (Fig. 44.4). Compared to surface stimulation electrodes, implanted and percutaneous electrodes potentially have higher stimulation selectivity with much less electrical charge applied, both of which are desired characteristics of FES systems. To achieve higher selectivity while applying lower stimulation amplitudes, it is recommended that both cathode and anode be in the vicinity of the nerve that is stimulated. The drawbacks of implanted electrodes are they require an invasive surgical procedure to install, and, as is the case with all surgical intervention, there exists a possibility of infection following implantation. The implanted electrodes come in different shapes and sizes. The most notable implanted electrodes are:

1. Intramuscular electrodes [44.40]
2. Nerve cuff electrodes [44.41, 42]
3. Epimysial electrodes [44.1, 2]
4. A miniature electrode-stimulator system called BION, which is implanted using a hypodermic needle [44.8, 43] (Fig. 44.5).

FES systems come in many different shapes and sizes and serve many different purposes. The common components in all FES systems are:

1. A stimulator that consists of a power source, some type of microcontroller, and a stimulator output stage that produces electrical pulses
2. A user interface
3. Electrodes.

Most modern FES systems use batteries, disposable or rechargeable, as the power source. Implantable FES systems are as big as a pacemaker and surface FES systems are typically not bigger than a hand-held voltmeter. Various user interfaces have been applied to control FES systems. The simplest are push buttons [44.38,44], joysticks [44.45], force sensitive resistors, potentiometers [44.46], accelerometers, inclinometers [44.30], and proximity sensors [44.1]. The next level in complexity are the FES systems that are controlled using electromyography (EMG) signals. EMG-based user interfaces can be proportional (i.e., as the EMG signal intensity increases the FES stimulus increases proportionally) [44.33] or EMG triggered (i.e., as the EMG signal exceeds a particular threshold the FES stimulus is delivered) [44.33]. Some sophisticated EMG triggered user interfaces use complex EMG patterns to activate the FES systems [44.38], but these are seldom used in clinical practice. The main challenge with using the EMG controlled FES systems is the fact that the electrical stimulation induces voltage noise in the body, which is often significantly larger in magnitude than the EMG signal itself [44.33]. Hence, recording an EMG signal from a muscle at the same time that the same or neighboring muscle is stimulated is not a trivial task. Finally, voice control (our unpublished results), brain machine interfaces [44.45,47], sophisticated gate phase detection sensors [44.48], and reaching motion detection sensors [44.49] have been used to control FES systems.

As discussed earlier in this article, FES can be used for neuroprosthetic and therapeutic purposes. If FES is used as a neuroprosthesis, the purpose of this device is to generate a body function that the consumer is unable to perform him/herself, such as walking, biking, bladder voiding, grasping, etc. In this application the FES system needs to be worn/used each and every time the consumer needs to perform the desired function. In essence, the consumer uses the FES device as a permanent orthotic system. Some of these neuroprosthetic systems are also used for cardiovascular conditioning and muscle strengthening. Although the ultimate goal of this type of application is therapeutic, this is not FES therapy (FES therapy is discussed later in this chapter). Good examples of these FES systems are neuroprostheses for rowing and biking. Each time the consumer would like to row or bike he/she needs to use the neuroprosthetic system, without which he/she would not be able to perform this task at all.

When FES technology is used to deliver FES therapy, the purpose of that intervention is to restore a voluntary function. In other words, FES is used only

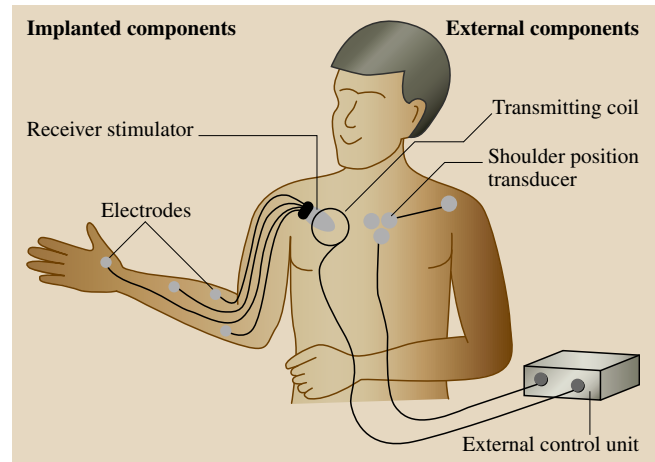

Fig. 44.4 Scheme of an implant electrode (after [44.39])

Fig. 44.5 BION implant electrodes (after [44.43])

temporarily as a short-term intervention with the objective to help the neuromuscular system relearn to execute a function that has been impaired due to neurological injury or disorder. In this application, the ultimate goal of the FES intervention is to recover voluntary functions of the consumer as much as possible, so that the consumer does not need to use the FES system for the rest of his/her life. In this application, the central nervous system essentially relearns how to control the impaired muscles and how to contract them in a temporarily appropriate manner to generate desired body function. To date, FES therapies have been used to restore walking functions [44.30,31,50–52] and voluntary reaching/grasping [44.23, 25, 26, 28, 29, 32, 53, 54].

Implanted FES systems are primarily used as permanent neuroprostheses, and some attempts have been

made to use BION for FES therapy. On the other hand, surface FES systems have been used equally successfully as neuroprostheses and platforms to deliver FES therapy. In the past, the main focus of the FES field was on developing neuroprosthetic systems, in particular those that patients had to use daily. In recent years, the advances made in the field of FES therapy and the use of neuroprostheses for muscle strengthening and cardiovascular exercises have shifted the focus of the FES field, at least partially, towards the use of surface FES systems. As a result, a number of commercially available surface FES systems have been developed in last decade.

44.1.4 Muscle Fatigue

While FES has succeeded in assisting individuals with neuromuscular disorders, there is one major limitation of FES: stimulated muscles tend to fatigue rapidly, thus limiting the benefits of FES [44.55]. The problem of muscle fatigue is further compounded by the fact that paralyzed muscles show greater fatigability than healthy ones [44.56–61]. Two basic mechanisms of muscle fatigue are known: central and peripheral [44.62]. Central fatigue results from the failure of motor neuron excitation, whereas peripheral fatigue results from failure of transmission of neural signals or of the muscle to respond to neural excitation [44.63, 64]. Two major sources of peripheral fatigue are:

1. Electromechanical coupling related to propagation of action potentials within the muscle membrane and conduction of the sarcoplasmic reticulum to Ca^{2+} ions
2. Phosphometabolite concentration affecting actin-myosin cross-bridge creation and Ca^{2+} -troponin kinetics [44.65].

In the case of individuals with neuromuscular disorders, especially with SCI and stroke, the central component of fatigue is minor or absent. In this population, fatigue results mostly from within the motor unit, such as depletion of substances, accumulation of catabolites, or problems in excitation–contraction coupling [44.55]. Rapid fatigue in electrically stimulated muscle can be attributed to two major factors: mode of activation, and reverse recruitment order.

Mode of Activation

In electrically induced contractions, the same nerve fibers are usually stimulated all the time, and all the motor units are fired synchronously. This is contrary

to what occurs in normal muscle movement, where the work during contraction is shared between different motor units of the same muscle [44.66]. Thus, in stimulated muscles, a synchronized and massive fiber contraction replaces the normal physiological mechanism of motor unit recruitment and firing rate regulation [44.67].

Reverse Recruitment

Normal muscles are usually recruited in an *orderly pattern*, known as the *size principle* of motor neurons, i. e., small alpha-motor neurons (small diameter axons) innervating slow motor units are recruited at a lower excitation level than larger alpha-motor neurons (large diameter axons) innervating fast units [44.68, 69]. Thus, in a normal skeletal muscle containing a mixture of muscle fiber types, low force tasks requiring fatigue resistance, such as force generation to maintain posture, are accomplished by recruiting the small motor units. The rapidly fatiguing fast motor units are recruited only at higher and more dynamic force levels. FES is characterized by a *reverse recruitment*, whereby large axons that innervate the more easily fatigable fibers are recruited at low stimulus magnitudes, and the smaller axons follow with increased stimulation levels [44.2, 39]. Due to these two factors, the large motor units are fired synchronously and at stimulation frequencies above the usual physiological values in normal consumers, which results in a rapid reduction of the muscle force, i. e., rapid fatigue [44.6, 49, 55, 64, 70–73].

Prevention of Fatigue in FES

To date, different methods have been proposed to mediate the muscle fatigue induced by FES such as modulation of stimulation parameters [44.74–76], variable frequency trains [44.70, 77–82], random stimulation trains [44.73], and sequential stimulation [44.83, 84]. Research done in the field of *stimulation parameters modulation* suggests that using lower frequency stimulations with longer pulse durations is one possible approach to reduce the FES induced muscle fatigue [44.75]. Also, the variation of the stimulation parameters over the time course of stimulation, in both an open-loop [44.85–89] and a closed-loop manner [44.90, 91], has also been found to be helpful. Some researchers have proposed the use of *variable frequency trains*, i. e., the interpulse intervals are not kept constant, as a means of remedying the muscle fatigue problem, but up to now, both positive and negative outcomes have been reported. Some time ago, it was suggested to use *random stimulation trains* (randomize pulse duration or pulse frequency or pulse amplitude) to reduce muscle

fatigue. However, a recent systematic trial has demonstrated that this method is not effective [44.51, 73]. The last method that was investigated as a means to address FES induced muscle fatigue is *sequential stimulation*. In this particular method, different muscle compartments are stimulated in asynchronous manner, i. e., each muscle compartment is activated at another stimula-

tion interval and these compartments are contracted with the frequency rate much lower than if continuous FES were applied. This stimulation method mimics, in a way, the natural muscle contraction patterns observed in healthy individuals. Our recent experiments with sequential stimulation (yet unpublished results) suggest that this approach has great potential.

44.2 Neuroprosthetic Use of FES

44.2.1 Neuroprosthesis for Drop Foot

Liberson and colleagues developed a simple neuroprosthesis to correct drop foot [44.92]. The drop foot is a common symptom in hemiplegia, characterized by a lack of dorsiflexion during the swing phase of gait, resulting in short, shuffling strides. Liberson's device, which has the distinction of being the first neuroprosthesis to receive a patent, consisted of a power supply worn on a belt, two surface electrodes positioned for stimulation of the common peroneal nerve, and a heel switch. The stimulation was activated whenever the heel lost contact with the ground, and was deactivated when the heel regained contact with the ground. Stimulation of the common peroneal nerve causes contraction of the muscles responsible for dorsiflexion (i. e., tibialis anterior and extensor hallucis longus, among others). Following Liberson's invention and Vodovnik's revisions, a number of drop foot stimulators were developed. The first commercially available implanted drop foot stimulator was developed by Rancho Los Amigos Medical Center and Medtronic Inc. [44.93]. The surgically implanted components were a radio-frequency receiver, a pulse train generator, and one bipolar electrode implanted adjacent to the peroneal nerve. An external unit worn on the belt delivered power via the RF coil and received input commands from a wireless foot switch. Despite some problems with electrode migration and infections, the device was considered a success.

The Odstock Dropped Foot Stimulator [44.31], the WalkAide [44.30] and the NESS L300 (formally known as NESS Drop Foot System) [44.94] are new generations of drop foot stimulators that use surface FES technology; they are commercially available and have been FDA (USA Food and Drug Administration) approved. The ActiGait [44.15] and the STIMuSTEP [44.95] are implantable drop foot stimulators that are also commercially available and have the CE mark in Europe (Fig. 44.6).

Most modern drop foot stimulators continue to use a heel switch for active input. *Burridge* et al. tried using the foot switch on the unaffected leg, but found that it was not preferable as the patient was unable to reliably achieve heel contact on the affected leg [44.50]. Other alternatives to the heel switch include a heel/toe switch [44.3], an array of four single-axis accelerometers positioned on the shank [44.96], a tilt sensor positioned on the shank [44.97], and the Gait Phase Detection System [44.48] (a derivative of this system is presently used to detect gait phases in the above knee powered orthosis Power Knee from Ossur hf – personal communication). Drop foot stimulators are one of most successful neuroprosthesis to date. Overall, consumer perception of drop foot stimulators is they are superior to the ankle-foot orthosis [44.98].

44.2.2 Neuroprosthesis for Walking

As early as 1960, *Kantrowitz* demonstrated paraplegic standing by applying continuous electrical stimulation

Fig. 44.6 Scheme of STIMuSTEP implant drop foot stimulator. The FES system allows stimulation of the common peroneal nerve (after [44.39])

Fig. 44.7 The Parastep electrical stimulation system (after [44.101])

to the quadriceps and gluteus maximus muscles of a patient with complete spinal cord injury, using surface FES technology [44.99]. This earliest neuroprosthesis for paraplegic gait provided continuous stimulation to the quadriceps to produce a mode of gait similar to long leg-brace walking, by inducing stiffened legs. Later systems used alternating bilateral quad/glut stimulation (during the stance phase) out of phase with peroneal nerve stimulation to induce the flexor withdrawal reflex (during swing phase) [44.3]. Later, *Kralj* and colleagues described a technique for paraplegic gait using surface stimulation, which remains the most popular method in use today [44.100]. Electrodes are placed over the quadriceps muscles and peroneal nerves bilaterally. The user controls the neuroprosthesis with two push buttons attached to the left and right handles of a walking frame, or on canes or crutches. When the neuroprosthesis is turned on, both quadriceps muscles are stimulated to provide a standing posture. The left button initiates a swing phase in the left leg by briefly stopping stimulation of the left quadriceps and stimulating the peroneal nerve. This stimulation is applied suddenly, so as to trigger the flexor withdrawal reflex, resulting in simultaneous hip and knee flexion, as well as dorsiflexion. After a fixed period of time, peroneal nerve stimulation is stopped and quadriceps

stimulation is initiated while the reflex is still active to complete the stride. Similarly, the right button initiates a swing phase in the right leg. Many current FES systems for walking have employed this technique as the basic concept.

As microprocessor technology developed, neuroprostheses became more portable and flexible. Examples of this type of neuroprosthesis are Parastep [44.44, 102], HAS [44.9], RGO [44.103], Praxis [44.104], and the Compex Motion neuroprosthesis for walking [44.32, 38]. The Parastep system is one of most popular products and uses *Kralj*'s technique [44.44, 102] (Fig. 44.7), which was the first neuroprosthesis for walking to receive approval from FDA. The HAS and the RGO walking neuroprostheses are devices that also apply active and passive braces, respectively. The braces were introduced to provide additional stability during standing and walking. The Praxis system is an implantable system, which was developed to provide better stimulation selectivity and a more natural walking pattern. This system was also designed to provide a bladder-voiding function as well. Compex Motion neuroprosthesis for walking is an 8 to 16 channel surface FES system used to restore walking in stroke and SCI individuals. The system uses push button control strategy, similar to that one used in the Parastep system and a gate phase detection sensor [44.48] to trigger the FES sequences.

A major limitation of neuroprostheses for walking that are based on surface stimulation is that the gait is slow, awkward, and unnatural looking, e.g., poor stance phase posture due to hip flexion induced by rectus femoris activity when the quadriceps are stimulated. Further, the flexor withdraw reflex is subject to rapid habituation and is highly variable. Perhaps a major reason for this is that the hip flexors cannot be stimulated directly. Therefore, hip flexion during walking must come from voluntary effort, which is often absent in paraplegia, or from the flexor withdrawal reflex. Implanted systems have the advantage of being able to stimulate the hip flexors, and therefore, to provide better muscle selectivity and more natural gait patterns. Hybrid systems with exoskeleton devices have also been proposed to solve this problem [44.105]. These technologies have been found to be successful and promising, but at the present time these FES systems are mostly used for exercise purposes and seldom as an alternative to wheelchair mobility. The main reason for this is the high metabolic cost of FES assisted walking as compared to wheelchair mobility [44.39].

44.2.3 Neuroprostheses for Standing

While neuroprostheses for walking assists in keeping a standing posture in individuals with SCI, several FES systems and studies especially focused on maintaining the standing posture because standing itself is advantageous for those patients. The Case Western Reserve University/Department of Veterans Affairs (CWRUVA) standing neuroprosthesis uses an implanted stimulator with 8–16 channels to bilaterally activate muscles of the trunk, hips, and thighs making the body stiff in an upright posture. With external orthoses, such as walkers, which are used to stabilize the body, CWRUVA can offer more than 10 min of uninterrupted upright stance [44.4, 106, 107]. However, this system does not provide balance control, and the consumer has to rely on a walker or a similar device to maintain balance. In addition, this device uses an open-loop control scheme, which tends to result in quicker fatigue. The second generation of this system is presently under development [44.108].

Despite numerous attempts to develop a neuroprosthesis for unsupported, arm-free standing, a device that is actually capable of performing this task does not yet exist. To realize this technology, a closed-loop multiple joint control system is required. So far, most of the FES systems for unsupported standing that have been applied to individuals with neurological disorders were focused on stimulating ankle joints. *Hunt et al.* [44.109], *Holderbaum et al.* [44.71], and *Gollee et al.* [44.110] developed and evaluated a series of closed-loop nested feedback control systems that used FES to actuate the ankle torque of a paraplegic subject with a complete lesion at T7/8. During the experiments, the subject was standing in an apparatus that acted as a full body cast, allowing only the ankle joints to move in the anterior–posterior direction. *Abbas and Chizeck* [44.111] compared the performance of a closed-loop feedback system with an open-loop stimulation strategy for two paraplegic subjects (T7 and T9) during standing; both systems regulated the movement of the hip joints in the coronal plane. *Vette et al.* [44.112, 113] applied a liner feedback controller mimicking a physiological controller and succeeded in better stabilizing a patient's standing balance. *Kim et al.* [44.114, 115] recently performed a series of dynamic kinematics and stability analyses suggesting that FES assisted unsupported stance is feasible, as long as 6 degrees of freedom in the leg joints (out of 12) are controlled with the FES system. This work still needs to be properly validated in experiments with individuals with complete SCI.

44.2.4 Neuroprostheses for Reaching and Grasping

The neuroprostheses for grasping and reaching are FES systems designed to restore or improve function in stroke and tetraplegic individuals. Some notable grasping and/or reaching neuroprostheses are the Freehand system [44.116], the NESS H200 (formally known as NESS Handmaster) [44.117], the Bionic Glove [44.46], the ETHZ-ParaCare neuroprosthesis for grasping [44.33, 38], the systems developed by *Rebersek and Vodovnik* [44.118], the Belgrade Grasping-Reaching System [44.49], and *Compex Motion neuroprosthesis* for reaching and grasping [44.38]. The Freehand system is an implantable system; all the other devices use surface FES technology.

The key element for achieving the synergistic activity of muscles that results in reaching and/or grasping is the appropriate sequencing of the stimulation pulses. The available neuroprostheses for grasping can restore the two most frequently used grasping styles: the palmar and the lateral grasp. The palmar grasp is used to hold bigger and heavier objects such as cans and bottles, and the lateral grasp is used to hold smaller and thinner objects such as keys, paper, and compact discs. The lateral grasp is generated by first flexing the fingers to provide opposition, followed by the thumb flexion. The palmar grasp is generated by first forming opposition between the thumb and the palm, followed by simultaneous flexion of both the thumb and the fingers.

The neuroprosthesis developed by *Rebersek and Vodovnik* was one of the first neuroprosthesis for grasping [44.118]. This neuroprosthesis has three stimulation channels, which are used to generate grasping by stimulating the finger flexors and extensors and the thumb flexors. Although this device was developed almost three decades ago, it is one of the rare systems that allows a subject to control the stimulator via different sensory interfaces such as an EMG sensor, a sliding resistor, or a pressure sensor. This option is important because it allows the neuroprosthesis to be tailored to the subject. The main disadvantages of this neuroprosthesis are that donning and doffing times are long and selectivity of stimulation is quite limited. *Merelitti et al.* modified this system and used it for stroke subjects [44.119]. They applied two channels to augment the elbow and fingers/wrist extension. They concluded that the neuroprosthesis contributed greatly to recovery of hand and elbow movements in five stroke subjects, but in the remaining three the improvement was significant only at the elbow joint.

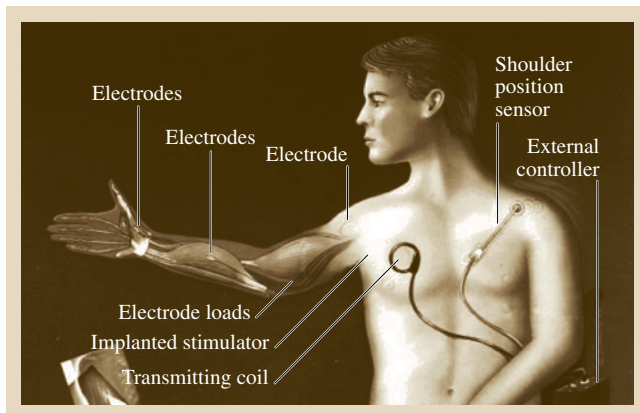

Fig. 44.8 The Freehand system (after [44.101])

Fig. 44.9 The NESS Handmaster system (after [44.10])

The Freehand system [44.116], consists of eight implanted epimysial stimulation electrodes that stimulate flexion and extension of the fingers and the thumb in order to provide lateral and palmar grasp (Fig. 44.8). Commands are given by an external position sensor placed on the shoulder of the subject's opposite arm. An additional external switch allows the user to choose between palmar and lateral grasp. This sequence is then sent, via a radio frequency coil, to the implanted unit, which generates the stimulation sequences for each channel. The electrode leads are tunneled subcutaneously to the implanted stimulator located in the pectoral region. Surgical procedures to enhance both voluntary and stimulated hand functions are often performed in conjunction with the stimulator implantation.

The Freehand system is the first neuroprosthesis for grasping approved by the FDA. The main advantage of the Freehand system is that it is implanted, and the time needed to don and doff the system is shorter compared to most of the surface FES systems.

The NESS H200 consists of an orthosis that has built-in flexibility to enhance and control freedom of movement within the forearm and hand, while supporting the wrist joint at a functional angle of extension [44.117] (Fig. 44.9). The NESS H200 multiplexes a single channel of stimulation through a selected combination of surface electrodes on the inner surface of the orthosis; this effectively transforms the device into a three-channel neuroprosthesis. One stimulation channel is used to stimulate the extensor pollicis brevis. The second channel stimulates the flexor digitorum superficialis. The third channel stimulates the flexor pollicis longus and thenar muscle group. The setup position of the electrodes depends on the device user's specific needs. The NESS H200 is controlled with an array of push buttons allowing the subject to select the operating mode and to trigger programmed movement sequences. Using the buttons, the subject can also control stimulation intensity and thumb posture, thereby adjusting the grasp to the size and the shape of the target object. One of the major advantages of the NESS H200 is that it is easy to don and doff. It is exceptionally well designed and one of the best neuroprostheses for grasping presently available on the market.

The Bionic Glove is a neuroprosthesis designed to enhance the tenodesis grasp (by extending their wrist, users can cause passive finger flexion due to the limited length of the finger flexors) in subjects who have good voluntary control over wrist flexion and extension [44.46]. The Bionic Glove stimulates finger flexors and extensors, significantly enhancing the strength of the tenodesis grasp. Four self-adhesive surface stimulation electrodes provide stimulation, and the stimulator and a wrist position sensor are located on the forearm of the glove. An easy-to-use interface, with three push buttons on the stimulator, is used to set the stimulation parameters, and the optional audio feedback facilitates faster learning.

The Belgrade Grasping-Reaching System proposed by *Popovic* et al. is a neuroprosthesis for grasping that also provides a reaching function [44.49]. It consists of four stimulation channels, three of which are used to generate the grasping function. The fourth channel is used to stimulate the triceps brachii muscle augmenting elbow extension. Reaching is achieved by measuring the

subject's shoulder velocity with a goniometer and by generating a synergistic elbow motion by stimulating the triceps brachii muscle. This neuroprosthesis, similar to the system proposed by Rebersek and Vodovnik, requires more time to don than the Handmaster.

The Compex Motion neuroprosthesis is a very flexible device designed to improve reaching, grasping, and walking functions in individuals with SCI and stroke [44.33, 38]. This multichannel surface stimulation system is programmable and can be interfaced with any sensor system. As a four-channel neuroprosthesis for grasping, it provides both palmar and lateral grasps. It can be controlled with proportional EMG, discrete EMG, push buttons, sliding resistor and brain machine interface control strategies [44.120]. By combining two Compex Motion stimulators, an eight-channel neuroprosthesis for reaching and grasping was developed [44.29]. One of the main disadvantages of this system is that it requires about 8 min to put on or take off.

It is already well established that the neuroprostheses for reaching and grasping have been successful in restoring arm and hand functions in individuals with stroke and SCI. It is the authors' opinion that this technology has much potential and in the near future, one may expect the emergence of multiple commercially available surface FES systems besides the NESS H200, as well as a revival of the Freehand system.

44.2.5 Neuroprostheses for Bladder Function

Neuroprostheses have been very successful in treating lower urinary tract dysfunctions commonly associated with SCI, such as urge incontinence and urinary retention. The first attempts to electrically stimulate the bladder were made in the 1950s, when researchers sought ways to induce bladder emptying. At that time, a bladder wall stimulator was developed and implanted in three individuals [44.121], and animal studies of pelvic nerve stimulation were carried out [44.122]. Later, it was found that electrical stimulation of the sacral anterior roots produces excellent bladder voiding, and this led to the development of the Finetech–Brindley stimulator, which is the most widely used neuroprosthesis for bladder management today [44.16].

Attempts to manage incontinence using electrical stimulation began in the 1960s [44.123]. It was found that urethral resistance could be increased by stimulating the muscles of the pelvic floor, vagina, and rectum using external electrodes [44.124]. Eventually,

fully implanted systems were developed to suppress the detrusor muscle, thus preventing reflex incontinence and increasing bladder volume [44.11]. Most SCIs result in reflex incontinence. Typically, detrusor-sphincter dyssynergia develops, in which the detrusor and urethral sphincter contract simultaneously rather than reciprocally. The detrusor also becomes hyperreflexic, and the bladder becomes overactive. The standard treatments are anticholinergic medication, which blocks the neuromuscular junctions, and sensory rhizotomy (surgical transection of the posterior sacral roots). Neuroprostheses for bladder management serve as a practical alternative to these treatments. They can also augment sensory rhizotomy.

The Finetech–Brindley stimulator has been implanted in a large number of consumers, usually individuals having had a rhizotomy [44.12]. The electrodes are positioned on the second, third, and fourth sacral roots, bilaterally and extradurally. If a rhizotomy has not been performed, the electrodes must be implanted inside the dura to prevent crossover stimulation of the sensor neurons, which will trigger the detrusor reflex. A portable external controller transmits power to the implant via radio frequency coil, and the user initiates bladder voiding by pushing buttons on the external unit. Micturition is usually achieved with residual volumes of less than 50 mL, contributing to a dramatic reduction in urinary tract infections [44.125]. The Finetech–Brindley stimulator has proven to be extremely robust [44.126].

The Medtronic Interstim stimulator is a sacral root implant for incontinence, using neuromodulation to correct inappropriate reflex behavior [44.127]. It consists of fine wire electrodes inserted into the sacral foramina. When active, these electrodes inhibit the detrusor, but the mechanism of this inhibition is not yet properly understood. Thorough testing must be done using a temporary implant before permanent implantation can be recommended. The clinical success rate of this device is about 50%. Bladder emptying has to be achieved either voluntarily or by means of intermittent catheterization.

44.2.6 Neuroprostheses for Respiration

Phrenic nerve pacing is a clinically accepted technique to provide artificial ventilatory support in patients with trauma and with respiratory failure secondary to cervical SCI [44.39]. The stimulating electrodes are implanted on each phrenic nerve. Bilateral phrenic nerve stimulation results in the descent of each diaphragm and a decrease in intrathoracic pressure resulting in in-

spiration. Cessation of stimulation results in diaphragm relaxation, an increase in intrathoracic pressure, and exhalation.

Phrenic nerve pacing is an effective means of providing ventilatory support with an advantage over mechanical ventilation [44.128, 129], suggesting that phrenic pacing provides important health and lifestyle benefits compared to mechanical ventilation. Presently, new approaches for delivering phrenic nerve pacing are being developed and tested in a clinical setting [44.130].

44.2.7 Neuroprostheses for Hearing

Cochlear implants are neuroprostheses for the hearing impaired who have severe (70–90 dB) or profound (> 90 dB) hearing loss. A long wire electrode is implanted directly into the cochlear duct, and electrical stimulation is applied to the residual spiral ganglion cells of the cochlear nerve. Note that this neuroprosthesis primarily stimulates the auditory sensory system, and as such, does not strictly belong to the FES class of neuroprostheses. The cochlear implants were first developed in France in 1957. Since then, cochlear implants have been refined and miniaturized, and now they have received widespread acceptance, more so than any other class of neuroprostheses. More than 75 000 patients have received cochlear implants worldwide. Originally, few hearing impaired people were eligible for cochlear implantation, but as the technology has improved, the selection criteria have expanded greatly to include a wide range of hearing impairments [44.7].

Due to the success and popularity of cochlear implants, there are many different brands on the market. Most brands, however, are essentially similar. Differences between the currently available cochlear implants mainly involve the number of electrode channels (12–22), speech coding strategies, and the mode of electrode stimulation [44.5]. A recent study carried out at the University of Toronto concluded that the Clarion CI (Advanced Bionics, USA) and the Nucleus 22 (Cochlear Corp., Australia) cochlear implants were totally comparable in function and performance, although their modes of operation are not identical [44.6]. Both devices succeeded in reducing tinnitus, thereby increasing word and sentence recognition, but there was no significant reduction in vestibular function. Among the implantees, 76% reported that they were satisfied with their implants, and 96% reported an overall positive impact on quality of life. Some other brands of cochlear implant are the COMBO 40+ system (MED-EL, Austria), Digisonic (MXM, France), and the SOUNDTEC

direct system (SOUNDTEC, USA), most of which are FDA approved.

Cochlear implants generally consist of:

1. An external earpiece
2. A speech processor
3. An internally implanted unit.

The earpiece, usually very small and lightweight, is worn comfortably behind the ear, much like a hearing aid. It contains an ear-level or in-ear microphone and a radio frequency coil to transmit signals to the implanted components. The speech processor can be in the form of a small box worn somewhere on the body or, in some models, it is contained in the external unit worn behind the ear. The internally implanted unit consists of a receiver coil located underneath soft tissue in a cavity drilled in the temporal squama and a 20–24 mm insulated wire ending in a multichannel electrode array, which is inserted into the cochlear duct. Sound waves are received by the external microphone and converted into electrical signals that are input into the external speech processor. There, the signals are digitally encoded and transmitted to the internal unit via radio frequency coil. The internal unit decodes the radio signals back into elementary electrical signals to stimulate each channel of the electrode array. Therefore, the multichannel device provides a complex sound analysis similar to the physiological analysis of sound in healthy individuals.

44.2.8 Therapeutic FES Besides FES Therapy

Patients with motor disabilities, such as SCI, tend to experience considerable deterioration of their physical condition and fitness. This often precipitates development of various secondary complications that ultimately result in a shorter life span. A good example of a secondary complication that results from loss of muscle tone in individuals with SCI is pressure ulcers. One possible application of FES is to help maintain or improve muscle tone in these individuals and by doing so prevent occurrence of secondary complications such as pressure ulcers or cardiovascular deconditioning. In these applications, neuroprostheses are used as a means of providing regular exercise and cardiovascular system conditioning. This, in turn, results in enhanced muscle strength, retarded muscle atrophy, and reduced spasticity. Good examples of neuroprostheses that are used in these applications are arm and/or leg crank ergometry assisted with FES [44.17–22] and FES systems

for walking [44.131–133]. To date, it has been shown that these systems have positive effects on cardiovascular fitness and muscle tone. However, consumers must use these devices continuously to maintain their muscle strength and cardiovascular fitness. As soon as the consumer stops using such a device, his/her muscle strength and cardiovascular fitness tend to deteriorate again.

NEMS systems have also been used to maintain and enhance muscle strength and muscle performance [44.24, 29, 90, 117, 134]. This modality of electrical stimulation-based interventions have been used not only with individuals with neuromuscular disorders, but also with consumers who have diabetes [44.135, 136], knee arthroplasty [44.137, 138], amyotrophic lateral sclerosis [44.134], and able-bodied athletes recovering from injuries [44.72] or trying to enhance their performance [44.139, 140].

44.3 FES Therapy

Since the 1970s, some FES researchers and practitioners have observed that following an FES intervention some patients using the neuroprostheses for grasping or walking experienced recovery of voluntary function. Most of these reports were anecdotal in nature. One of the first papers where this phenomenon was specifically discussed was by *Merletti et al.* in 1975 [44.119]. It took almost two decades before this phenomenon started being examined seriously.

First, it was examined in FES systems for drop foot, where scientists explored the ability of the system to restore voluntary walking function in individuals with stroke and incomplete SCI [44.30, 31, 50–52]. These studies were then followed by studies that examined use of neuroprosthesis for grasping and later neuroprostheses for reaching and grasping for restoring voluntary arm and hand functions in individuals with stroke and SCI [44.23, 25, 26, 28, 29, 32, 53, 54]. Finally, the neuroprosthesis for walking was used to investigate restoration of voluntary walking function in individuals with incomplete SCI [44.32]. Among these studies, few were registered randomized control trials that clearly demonstrated the utility of the FES interventions as a means of restoring voluntary upper and lower limb functions. It is worth mentioning that the study published by *Thrasher et al.* [44.29] showed that both reaching and grasping functions can be restored, even in severe stroke individuals who were unable to reach and grasp prior to joining the study; since they had upper extremity Chedoke–McMaster stages of motor recov-

Some of the FES systems discussed above, such as FES systems for walking and FES systems for leg ergometry, have been suggested as having positive effects on bone health. For example, individuals with SCI tend to experience massive bone loss in their legs, pelvis, and parts of the spine that are immobile due to SCI. It has been reported that individuals with SCI may lose up to 1/3 of the bone structure when compared to age-matched healthy individuals. Several studies reported bone mineral density increase in individuals with SCI following FES cycle ergometry training [44.141, 142] and FES walking [44.143]. It has been also suggested that larger effects have been observed in females as compared to males [44.144]. Although these preliminary findings are encouraging, a proper evaluation of the FES interventions with respect to bone mineral density improvement need to be carried out.

ery scores 1 and 2 they were not expected to improve these functions at all. The improvements published in that study have not yet been matched by any other therapeutic interventions, including rehabilitation robotics therapies and constraint induced movement therapy. The use of neuroprostheses as a means of providing short-term therapeutic intervention for improving and restoring voluntary function has been termed FES therapy (FET).

Although at present, the exact mechanisms to explain the observed carryover effect are not known, there are ongoing, or recently published, studies that may provide an insight into the mechanisms behind FET. First, we know that FET is able to completely restore voluntary control over paretic muscles, regardless of whether they were spastic or flaccid before the FET was administered to the patient [44.145]. This effect has been observed even in individuals with chronic stroke [44.145] and SCI [44.47]. It is important to stress that if FET is administered to individuals with stroke, the strength of the muscles in previously impaired limbs following FET does not reach the same levels as in able-bodied individuals or in less impaired limbs [44.145]. Second, we know that a temporal order of muscle activations in complex tasks such as grasping [44.145] and walking are restored to a large extent. Third, the tone and spasticity in the impaired limbs drops considerably, sometimes to less than 50% of the original tone and spasticity observed prior to FET [44.145]. In addition to these initial findings, it has also been sug-

gested that through forced repetitive movements, FET may activate sensory nerves and through sensory nerve stimulation it may promote the neuroplasticity in the central nervous system [44.27, 29, 32, 37, 146]. It has been also suggested that the antidromic firing of stimulated motor nerves may enhance the cortico-muscular connectivity via Hebb's law [44.37, 146]. In any event, the carryover effect is probably multifactorial and needs to be fully examined. However, what is certain is that

the FET is an effective method of restoring voluntary upper limb function in individuals following stroke and SCI, and is able to remedy the drop foot problem in hemiparetic stroke and SCI individuals by improving voluntary control of the muscles of the impaired leg. It is our impression that the FET is a very promising intervention that is only now being seriously examined and has the potential to revolutionize the way we rehabilitate individuals with diverse neuromuscular disorders.

44.4 Other Uses of Electrical Stimulation

44.4.1 Pressure Ulcers

It is a well known fact that persons with SCI are at high risk of developing pressure ulcers. Up to 95% of individuals with SCI will experience a pressure ulcer at least once in their lifetime and 31–79% may experience pressure ulcers multiple times. NMES has been shown to facilitate healing of stages II, III, and IV pressure ulcers [44.147, 148]. FES also shows positive effects in preventing pressure ulcers due to the fact it induces postural movement and increases blood flow [44.149, 150].

44.4.2 Diabetes

Physical activity, especially aerobic endurance exercise, can reduce the incidence and prevalence of diabetes. Thus, physical exercise induced by FES has the potential to reduce the risk of diabetes and potentially provide a treatment for diabetes. It has been reported that muscle training using NMES on thighs reduced blood glucose, suggesting a positive effect on patients with diabetes [44.135]. It has been also shown that the FES cycle ergometry training reduces blood glucose levels and improves glucose utilization [44.136].

44.5 Concluding Remarks

This chapter summarizes the basics of electrical stimulation, explains the difference between NMES and FES, discusses various neuroprosthetic systems, and talks about recent developments in the field of FES therapy (FET). Taking advantages of recent technology such as miniaturization of electronic components, new sensory systems, new delivery methods for electrical stimulation, and improved diagnostics techniques, this field has shown dramatic progress in recent years. Many neuroprosthetic systems are already commercialized and many more are in the process

of being developed and/or commercialized. This is a booming field that is slowly, but surely, creating new technologies and interventions; many academic and commercial entities, who are championing this technology, have already emerged. We feel strongly that this field has enormous potential. We anticipate that this field, as well as rehabilitation robotics, prosthetic robotics, and brain-machine interfaces are slowly converging towards creating a combined force that will change the way we treat individuals with disabilities.

45. Treatment Planning and Patient Treatment

Golam Abu Zakaria, Wilhelm Schütte, Stephan Garbe

Treatment planning and patient treatment are essential parts in the medical technology of external radiotherapy. For patients undergoing such a radio-therapeutic treatment, the prescribed and absorbed dose to the target volume and the organs at risk need to be determined and notified. Furthermore, in radio-therapeutic treatments, registrants and licenses shall ensure, within the ranges achievable by good clinical practice and optimized functioning of equipment, that the prescribed absorbed dose with the respective beam quality is delivered to the planning target volume as well as doses to other tissues and organs is minimized. Therefore in this chapter modern and standard equipment, treatment procedures, basics of treatment planning and quality control in radiation therapy will be presented.

45.1 Principles of Radiotherapy and Treatment Planning

Radiation therapy is a medical field that deals with the use of ionizing radiation to humans and on animals by treating benign and malignant diseases. According to the disease and its stage, radiotherapy has either a curative or palliative intention.

45.1.1 Principles of Radiotherapy

Curative radiotherapy is carried out with the aim of healing; a palliative radiotherapy treats symptoms such as pain, occlusions, and bleeding and prevents the progression of disease.

Today high-energy, ionizing rays are commonly applied in modern radiation therapy like gamma radiation, x-ray radiation and electron radiation. In large therapy centers with appropriate radiotherapy equipment, proton therapy and heavy ions (e.g., carbon ions) are increasingly being used.

With radiotherapy, benign as well as malignant diseases can be treated. Before a radiotherapy treatment is performed, treatment planning occurs. Sometimes, one distinguishes, on the one hand, simple planning with programs without graphic representation of the patient and target volume that calculates the monitor prefix in water merely for a given field size and tumor depth from, on the other hand, extensive radiotherapy planning using 3-D planning systems. While the simple programs are programmed by the medical physicist in radiotherapy, it is within the 3-D radiotherapy planning system, it is within the 3-D radiotherapy planning system that commercial software is used that calculates the dose distribution in the CT slice and offers numerous possibilities for the graphic representation of the result.

In many cases, radiotherapy is performed on tumors in combination with chemotherapy (known as radiochemotherapy, RCTX). Chemotherapy could lead to radiosensitization of the cancer cells with subsequent strengthening of the radiation effect to the tumor. Hence a combination of radiotherapy and chemotherapy for the treatment of malignant tumors is more effective than radio- or chemotherapy alone. Combined RCTX can appear as curative, adjuvant or palliative radiotherapy. One distinguishes between the following kinds of combined RCTX:

- Simultaneous RCTX: both treatments occurring in parallel
- Sequential RCTX: chemotherapy before or after radiotherapy

- Definite RCTX: treatment of tumor exclusively by RCTX
- Adjuvant RCTX: aftercare of tumor or tumor bed after its complete or partial removal
- Neoadjuvant RCTX: reduction of tumor by RCTX with subsequent surgical removal of tumor

Other treatments, for example hyperthermia, can cause a strengthening of the radiotherapy effect. Tumors with low blood supply or low in oxygen are mostly resistant to radiation damage. Conversely, one can observe that such tissue is especially sensitive compared with therapeutic hyperthermia. Also, special substances can raise the resistance of normal tissue. An example is Amifostine, which is still used today, though only experimentally [45.1, 2].

Another area of application of radiotherapy treating benign diseases is so-called stimulative radiotherapy. It is applied on chronic-inflammatory and degenerative diseases like heel spur, tennis elbow, shoulder pains and arthrosis of different joints. Nevertheless, the main area of application of radiotherapy is the treatment of malignant tumors. Here the different radio sensitivities of tumor tissue and surrounding normal tissue are utilized. In contrast to cancer cells, normal tissue cells recover after radiotherapy relatively fast. While the fraction doses of benign diseases are about 0.5 Gy and the total dose varies from 3 to 8 Gy, the fraction doses required for the treatment of malignant tumors are about 2 Gy and the total dose varies from 30 to 80 Gy according to the kind of tumor [45.3, 4].

Radiotherapy is divided into two kinds of usage: teletherapy, where the radiation penetrates the patient's body from outside by a distant radiation source, and brachytherapy, where the radiation source is placed in cavities of the patient's body, in the tissue or directly on the external body shell.

The energy used in brachytherapy is about 1 MeV maximum, while in teletherapy using conventional medical linear accelerators the energy of the electron beams and x-ray bremsstrahlung goes up to 25 MeV. In Fig. 45.1 four depth dose curves for different kinds of radiation and different energies in water are shown.

The mechanism of interaction of radiation with cells can be explained by energy transfer to the penetrated tissue using scatter processes. The direct penetration of biomolecules does not have a larger impact on cell growth than the ionization of water molecules. The ionization of water delivers free high-toxic radicals. For

Fig. 45.1a-d Depth dose curve in water for radiation beams of various types and energies. (a) Photons, (b) neutrons, (c) electrons, (d) heavy charged particles (after [45.5])

an anticancer (tumor) effect, damage occurs to the heritable information of the DNS in the cells, especially damage to the double helix. Damage exceeding the repair capabilities of the tumor cells prevents cell proliferation and leads directly to apoptosis.

45.1.2 Principles of Treatment Planning and Treatment

In this section, the principles of treatment planning of malignant tumors with teletherapy will be described.

For the application of a radiotherapy treatment a justifiable indication must be given according to radioprotection regulation. Therefore, the tumor and extension will be localized by image-guided modalities like ultrasound, x-ray fluoroscopy, computed tomography (CT), magnetic resonance tomography and positron emission tomography (PET). The diagnosis will be substantiated by laboratory and histological investigation.

Commonly, the patient's case is presented at the tumor conference by the respective medical staff. Meanwhile there are tumor centers in many medical clinics like breast cancer, cervical cancer, intestinal cancer and prostate gland cancer centers. In these centers, tumor conferences are held that include all physicians in their respective disciplines who determine the guidelines for the corresponding therapy. Depending on the kind of tumor, extension and staging, surgery, chemotherapy, radiotherapy or a combination of the three treatment modalities are applied. If radiotherapy or a combined RCTX is indicated, the following procedure will be carried out.

Depending on the region of treatment, immobilization support aid of the patient will be needed. This will be utilized for an optimized fixed position of the patient during radiotherapy. This is necessary especially for irradiations near organs at risk in order to protect them, e.g., patients with tumors in the head and neck region. A precise positioning is extremely important in order to

protect the surrounding spinal cord. If irradiation from all angles is required, a treatment couch with almost no dose absorption, i. e., made of carbon, is indicated. For treatment of the breast and chest, a so-called combi board could be applied. It allows for variation in the angle between chest and couch and can be adjusted to the patient's size. The patient's arms need to be elevated behind the head and can repose on an armrest. This prevents the arms from being irradiated. For irradiations in the head and neck region, individualized thermoplastic head or head-shoulder masks are available. These masks are then fastened to head and shoulder mounting plates. With tumors in the abdomen and the pelvis, i. e., prostate and rectum cancer, exposure of the intestines needs to be minimized. This could be achieved by a prone position on a belly board. The belly board

places most of the abdomen, by gravity, out of the lateral treatment beam. Further support aids for stabilization of the patient are the combifix for knee and feet, as well as head and wedge cushions. In conclusion, one may summarize the patient positioning as follows.

The well-directed treatment of a tumor, the so-called target volume, requires maximum precision in the tumor and patient setup. This will be achieved by:

- Immobilization (no motion during treatment)
- Reproducibility of the patient setup (typically the patient receives 30 dose fractions 5 times a week over 6 weeks)
- Skin markers to identify the position of the target volume in relation to treatment beams.

3-D treatment planning systems calculate the dose distribution mainly on a kV-CT slice. The kV-CT is generated in a common spiral computer scanner utilizing support aid dedicated to the patient. The CT study is then exported to the 3-D treatment planning system mainly via DICOM. On the CT study the physician will contour the gross tumor volume (GTV), clinical target volume (CTV) and planning target volume (PTV). Depending on the institution, many other structures like the patient outline (external), organ at risk (OAR) and margins are defined either by physicians or technical assistants (TAs). The external contour on each CT slice determines the region as a discrete matrix for which the calculation can be performed. If the target cannot be determined in the kV-CT study, an MRI or PET/CT study will be imported to delineate the target (volume). In those studies, target volumes will be transferred via case matching by bone structures, landmarks, external markers, etc.. MRI is used in cases of brain tumors. PET/CT is often used in cases of lung tumors to obtain information about the extension of the tumor and its vital parts. The treatment planning cannot be performed directly on an MRI or PET scan. A CT scan is necessary due to the need for a correct representation of the electron density in the grayscale in the image.

After the last structures have been contoured, treatment planning can start. Therefore, in the case of forward planning (a major part of treatment planning system (TPS) until now), the treatment beams will be built conformal to the target volume. The direction of the beams depends strictly on the OAR close to the target volume. By optimizing the weighting factors of each beam, the dose distribution can be modified with the use of compensation beams, wedges, MLC, lead blocks, mechanical compensators, etc..

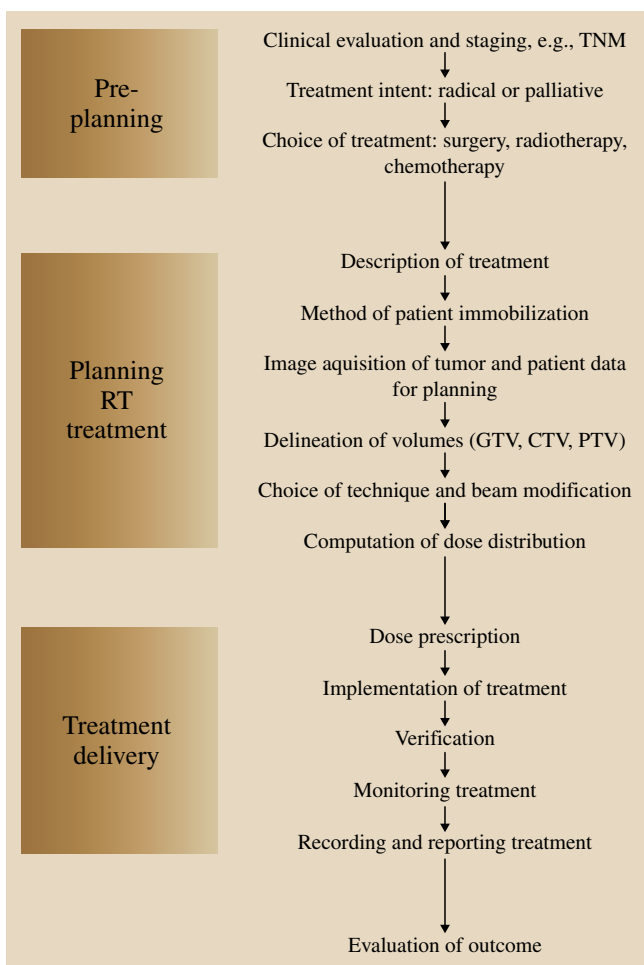

Fig. 45.2 Planning process in radiotherapy (after [45.6])

According to ICRU 50 [45.7], the target volume should receive between 95 and 107% of the prescribed dose. High-energy photon irradiation ($E > 1$ MeV) does not have a dose maximum at the surface but at a certain depth depending on the energy (Fig. 45.1a). For 6 MeV photons the maximum is at about 16 mm, for 18 MeV photons at about 32 mm in water. As results of this the surface dose is significantly lower than recommended by [45.7]. For tumors close to the surface, the dose can be enhanced by using a tissue equivalent bolus with a sufficient thickness.

Before the application of the treatment plan, the treatment planning needs to be verified. The verification of all treatment beams is performed at a therapy simulator. During the verification process, all treatment parameters are transferred to the patient as there are two different kinds of therapy simulator used. One is used exclusively for verification and localization and is equipped with a kV x-ray generator for imaging and a rotating gantry. The other is a modified CT scanner with positioning room lasers (virtual simulation). During simulation all reference points

and field shapes are usually marked on the skin. All beams are verified by making x-ray images that is sent via DICOM to the treatment planning system and the linear accelerator in order to compare the patient's setup with the original treatment plan and to find any deviations in the setup that must be corrected.

After simulation, the patient is transferred for treatment. The patient will be placed on the treatment couch and the skin markers adjusted to the positioning room lasers. To verify the correct patient setup, an x-ray-sensitive film is exposed, an electronic portal image is made or an MV-CT cone beam is performed. The images made are then compared to the x-ray images of the simulation and the digitally reconstructed radiographs (DRR) of the treatment plan. After correction of misalignments, the first fraction will be delivered to the patient. At least those setup verifications are repeated weekly. If the last fraction is delivered, the patient will be released to follow-up care. In Fig. 45.2 a schematic overview of a radiotherapy treatment process including treatment planning is shown.

45.2 Imaging in Treatment Planning

The definition and delineation of the target volume has been based primarily on the experience of radiotherapists, whose knowledge about anatomy, lymphatic drainage, and frequency and placement of recurrences and side effects determines the individual effectiveness and balance between volume definition and dosage for each patient.

The basic principle in treatment planning is the chosen radiation type and the intensity in its direction to the target volume. The target volume definition and the dose calculation are based on a specific 3-D representation of the properties of human tissue. The radiotherapist defines the target volume and tolerance doses for all delineated contours. The contouring of the organs and target volumes is essentially performed directly on the CT images. For more diagnostic information one can turn to the MRI and PET studies, although the dose calculation can only be performed in CT images. By putting the image studies on top of each other the target volume can be delineated on the PET or MRI study and then transferred to the CT study. MRI and CT are the standard imaging techniques for the representation of anatomical relations in the human body.

Meanwhile special MRI imaging techniques like functional MRI, diffusion, perfusion and special PET

imaging methods are focusing more on radiotherapy. Those imaging techniques contain information about the biological structure and extension of tumors and the circumventing tissue.

In the following sections different diagnostic imaging techniques and their application in radiotherapy planning will be described in more detail.

45.2.1 Computed Tomography

CT plays an important role in imaging, as only CT images represent the electron densities of tissue in the grayscale (Hounsfield units) necessary for dose calculation. The relationship between electron densities and Hounsfield units requires periodic calibration. This calibration is usually performed using a CT scan of a phantom consisting of material with well-known densities. All other imaging methods only have diagnostic information and can not be used for dose calculations.

In the present status of CT scanner technology, the scanner is equipped using a detector array of up to 256 lines. CT has been used routinely for radiotherapy treatment planning since the early 1980s. Because of the widespread availability of modern third- or fourth-generation CT scanners, they are commonly used

for contouring target volumes and OARs. CT studies display nearly perfect inhomogeneities, especially in humans. Geometrical distortions do not have a major influence on the application of CT studies, unlike artifacts caused by metal implant or prosthesis, which could reduce the CT's applicability. To overcome those problems, adaptive filtering of the CT raw data could improve CT images.

The definition of the target volume could be complicated by the low soft tissue contrast and inter- and intrafractional organ motion, although internal or external markers have been introduced. This problem of the uncertainty in location is overcome by introducing safety margins according to ICRU 50 [45.7].

Organ motion could be minimized by introducing respiratory triggering and abdominal pressing.

Using contrast agents, morphological differentiation between infiltrated and normal tissue could be improved. While measuring the temporal contrast agent enrichment, the capacity for perfusion and diffusion of tissue could be determined.

45.2.2 Magnetic Resonance Imaging

The principle of nuclear magnetic resonance is described in the pertinent literature. Recently, one can observe differences in magnetic properties between normal and cancerous tissue. Magnetic resonance imaging (MRI) has assumed a position of growing importance in medical imaging. Today, MRI and angiography, along with functional imaging, hold great promise for revealing characteristics of the human body. Improved soft tissue contrast has made MRI indispensable for visualizing and contouring several tumor entities. Today

1.5 Tesla MRI is a clinical standard. Spatial resolution is improved by increasing the magnetic field, and the scan time is decreased. This enables the visualization of (neuro)functional processes. Due to inhomogeneities of the magnetic field, distortions of several millimeters could occur. These distortions need to be determined and corrected before introducing MRI into radiotherapy treatment planning. This could be accounted for using phantom measurements.

Several studies have investigated the differences in target definitions due to contoured volumes by CT and MRI. It was found that in more than 40% of the investigated cases, the target volume could be shrunk down. These investigations were performed in cases of prostate and brain cancer.

45.2.3 Positron Emission Tomography

The basic principles of PET are described in the pertinent literature. PET imaging with ¹⁸F-FDG is very useful in radiation oncology for assessing the spread of the primary cancer, detecting metastases and monitoring the patient during and after treatment.

Particularly useful for this purpose are scanners that combine PET and CT in the same unit so the PET images can be overlaid on x-ray CT images. PET imaging is rapidly becoming recognized as an essential imaging tool for radiation oncology.

A good example of the application of PET in radiation oncology is lung non-small-cell carcinoma. For those tumors, PET distinguishes between atelectasis and tumor, and the involved mediastinal lymph nodes can be detected with a higher accuracy. As a consequence one can spare the treatment of uninvolved lymph nodes and escalate the dose to the primary tumor.

45.3 Basic Techniques in External Beam Therapy

Depending on the region to be irradiated, the tumor type, and the different radiotherapy technologies being used, the most important technologies are as follows [45.8–10]:

- Basic treatment planning
- Conformal treatment planning
- Intensity modulated radiotherapy (IMRT)
- Tomotherapy
- Image guided radiotherapy (IGRT)
- Respiratory guided radiotherapy (RGRT)
- Intraoperative radiotherapy
- Stereotactic irradiation

- Total body irradiation (TBI) with photons
- Total skin irradiation with electrons

45.3.1 Simple Treatment Planning

Basic one-dimensional treatment planning is used in cases of treatment, where only one simple beam or two opposed beams are used. Typical applications are stimulation irradiation (single beam) or bilateral whole brain irradiation in the case of brain metastasis (opposed beams).

For such one-dimensional treatment, the calculation becomes very simple. Assuming a quadratic field, the

applied monitor units (proportional to the dose after calibration) could be calculated as

$$\text{MON}(\text{FS}, d) = [\text{Ref.MON}/\text{FSR}(\text{FS})\text{TMR}(\text{FS}, d)] \times [\text{FIA}/(\text{FIA} + d_{\max})]^2,$$

where $\text{Ref.MON} = \text{Ref.Mon.}$ for a 10×10 cm beam, d_{\max} is the depth at dose maximum, FIA the focus isocenter distance, FS the field size, d the depth, FSR the field size ratio and TMR the tissue maximum ratio.

For calculations of applied monitor units of rectangular fields, the equation must be reformatted in equivalent-quadratic fields whereby the side length must be recalculated and a and b are the side length of the rectangular field.

The side of an equivalent square field is $2ab/(a + b)$ [45.11, 12].

45.3.2 Three-Dimensional Conformal Treatment Planning (3-D CRT)

Conformal irradiation is routinely used as a standard method in external beam therapy. Treatment planning is commonly performed in three dimensions. In order to achieve conformal treatment for the target volume, a multileaf collimator (MLC) will be shaped as the target volume appears in the beam eye view for any beam direction and sometimes a margin will be applied (forward planning).

Due to the narrow containment of the target volume, exposure to surrounding tissue can be drastically minimized. The rate of the resulting side effects at the OAR adjacent to the target volume is reduced. An escalation of the dose to the target volume is accompanied by a narrowing of the margin to the target volume and a lower dose to the surrounding OAR, resulting in a lower rate of side effects.

Image-guided contouring using CT, MRI and PET of the target volume plays a major role in treatment. Only this combination of imaging guarantees a precise delineation of a tumor in relation to surrounding tissue and OAR.

The optimization and quality control of a treatment plan is based on several criteria; one is the ICRU 50 conformity of the dose to the target volume $D_{\text{PTV}}(95\% < D_{\text{PTV}} < 107\%)$. Furthermore, the dose constraints for D_{\max} , D_{\min} , D_{mean} and D_{50} and the accepted tolerance doses to the OAR are adjusted utilizing a dose volume histogram (DVH) to preserve the OAR by minimizing the resulting side effects caused by overdose. Accepted values for tolerance doses are taken

from the literature. In addition to dose constraints like D_{\max} , there are side effects depending on the partial volume dose. The tolerance then depends on the volume receiving a certain dose and the organ's function; either the organs act in a serial-like manner, such as the spinal cord, or in a parallel manner, such as the liver, lungs or kidney. Unfortunately, most tumors have a parallel functioning structure so that a perceptible damage is only caused after a certain threshold dose.

Serially acting organs have a different threshold dose; if their function is significantly affected, the organs suffer irreversible damage. In Fig. 45.3 conformal treatment of bronchial cancer is shown.

Most treatment plans are coplanar plans; all beams are in the same plane. Noncoplanar planning is mainly used in stereotactic treatment (Sect. 45.3.10).

45.3.3 Inverse Planning

Radiation therapy inverse planning involves the development of a treatment plan whereby the planning computer is given a set of objectives and beam parameters to adjust in iterative fashion to arrive at a satisfactory dose distribution. For example, the treatment planning computer could iteratively adjust the weights of the beams to provide more uniform dose to the target.

45.3.4 Intensity Modulated Radiation Therapy

Aside from 3-D CRT treatment, IMRT has become more and more acceptable as routine radiation therapy [45.13, 14]. In IMRT the adjustment of the dose distribution to the target volume and limitation at the same time with the dose to normal tissue is performed not only by modulating the beam shapes, but also by modulating the dose dividing the beams into small beamlets (e.g., 2×2 mm). The weight of each beamlet can then be adjusted. This timely intensity modulation could be realized in two different kinds of delivery using the movable multileaf blades either in a *sliding window* technique or in a *step and shoot* technique. The MLC conversion refers to the process of transferring the ideal fluence map to deliverable MLC beamlets [45.15, 16].

This IMRT technique allows one to treat complex target volume scenarios where the PTV is very close to an OAR, i.e., head and neck case, and spare the spinal cord. In order to meet all treatment objectives (constraints) set by the physician, the inverse planning calculation becomes time consuming. The delivery of the plan (monitor units used) takes longer and the qual-

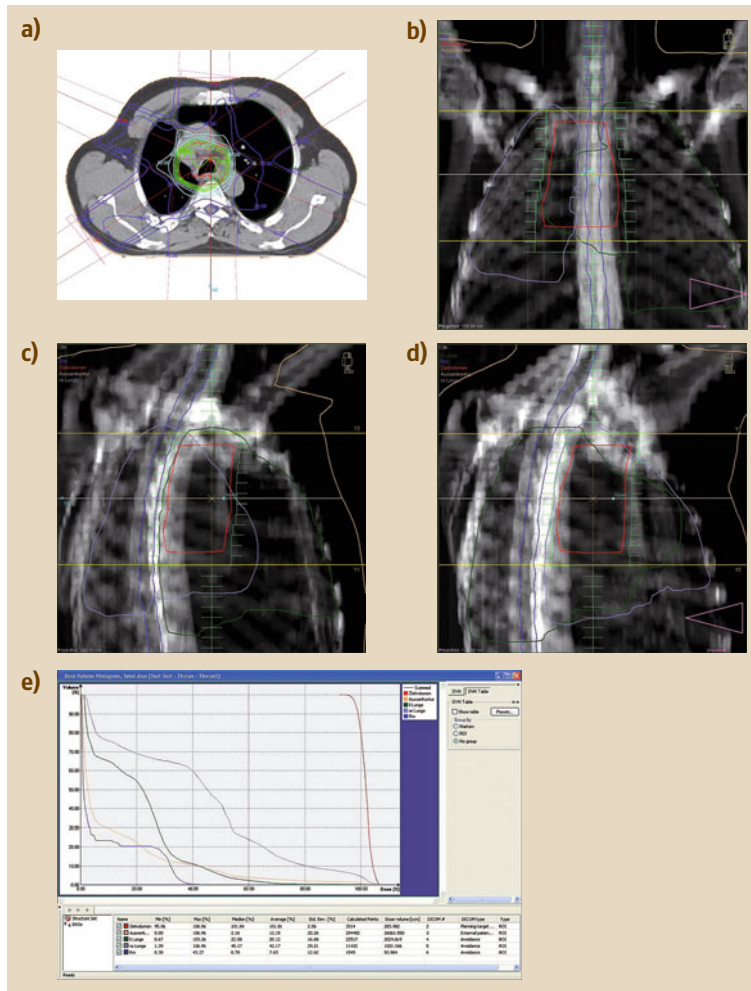

Fig. 45.3 (a) Dose distribution of three-isocentrical-beams technique (b)–(d). Pictures showing eye beam views from different beam directions (e). DVH showing relative dose for PTV and organs at risk (i. e., spinal cord and lungs) (after [45.17])

ity assurance is more tedious than in 3-D CRT. As a consequence before the first treatment of the patient, the treatment plan must be verified. Figure 45.4 shows a medical linear accelerator with an MLC.

45.3.5 Dynamic Delivery Techniques

The *sliding window approach* to treatment delivery involves moving the MLC leaves while the x-ray beam is on. This approach is more complex than step and shoot for the following reasons: (a) the window is often very narrow, resulting in narrow beam geometry, and (b) the MLC quality assurance protocol for dynamic delivery is more stringent, requiring leaf speed characterization. With the sliding window method very complex distributions can be achieved.

Allowing the gantry to arc while the leaves are moving is a technique known as intensity modulated arc therapy (IMAT) or dynamic arc therapy (RapidArc and VMAT). This approach may require a few arc passes to completely deliver the treatment because a given gantry angle can have only one MLC shape per arc. This method allows for very complex dose distributions but is challenging to plan and verify.

45.3.6 Tomotherapy

Serial Tomotherapy

Serial tomotherapy, literally meaning *slice therapy*, has been in clinical use since 1994. The commercial system, Peacock, combines a narrow MLC attachment to the linear accelerator (MIMiC collimator)

Fig. 45.4 (a) Linear accelerator, (b) multileaf collimator (after [45.18], Cinac 2100C, HD-MLC2)

with precise couch increments to deliver a slice-by-slice treatment. The MLC operates in binary mode, with the leaves either fully open or fully closed. Thousands of patients have been treated with this system, most of whom are patients with brain or head and neck cancers. The Peacock system has paved the way for other planning and delivery systems that are now available because it provided much of the early clinical data demonstrating the benefits of IMRT.

Helical Tomotherapy

In the same manner that CT scanners have moved from axial to helical delivery, Tomotherapy Inc. has adopted a helical delivery system [45.20]. The treatment unit looks much like a CT scanner, with a compact 6 MV linear accelerator replacing the x-ray tube (Fig. 45.5). With this design, many of the components in a standard linear accelerator are not needed. For example, (a) the compact size eliminates the long cantilevered gantry

Fig. 45.5 Tomotherapy HI-Art II system (after [45.19])

and the bending magnet; (b) there are no electron energies and the target is fixed, so there is no carousel; and (c) since the beam is modulated by the MLC, there is no need for a flattening filter. The absence of a flattening filter provides a higher beam output compared with a conventional linear accelerator. A binary MLC is used, similar to the MIMiC collimator previously mentioned. A primary advantage of the tomotherapy system is that it fully integrates real-time patient imaging with the delivery of radiation treatments. The clinical success of conformal (and conformal avoidance) radiotherapy relies upon the ability to accurately localize the beam on a day-to-day basis. Onboard axial image information is obtained using a megavoltage beam and a bank of CT detectors. So-called megavoltage CT (MVCT) provides surprisingly good image quality and is not subject to artifact generation in high-density objects (e.g., dental fillings) [45.21]. Also, an electron density conversion is not required because the imaging beam and treatment beam are one and the same. The imaging capabilities of this device offer a distinct advantage for comparison with virtual simulation. In helical tomotherapy, the exit fluence at the detectors is used to reconstruct the dose delivered during the actual treatment. This information is fed back to the TPS to monitor the dose delivered over the patient course of therapy. This method of providing information from the actual treatment back to the planning computer is called adaptive planning. Changes to the treatment to achieve the intended constraints can be made as treatment progresses.

45.3.7 Image Guided Radiotherapy (IGRT)

IGRT is the process of frequent two- and three-dimensional imaging, during a course of radiation treatment, used to direct radiation therapy utilizing the imaging coordinates of the actual radiation treatment plan. The patient is localized in the treatment room in the same position as planned from the reference imaging data set. An example of 3-D IGRT would include localization of a cone-beam computed tomography (CBCT) dataset with the planning CT dataset from planning (Fig. 45.6). Similarly 2-D IGRT would include matching planar kV radiograph fluoroscopy or MV images with DRRs from the planning CT scan.

This process is distinct from the use of imaging to delineate targets and organs in the planning process of radiation therapy. However, there is clearly a connection between the imaging processes as IGRT relies directly on the imaging modalities from planning as the reference coordinates for localizing the patient. The variety of image-gathering hardware used in planning includes CT, MRI and PET, among others. Through advancements in imaging technology, combined with a further understanding of human biology at the molecular level, the impact of IGRT on radiotherapy treatment continues to evolve.

45.3.8 Respiratory Guided Radiotherapy

The use of four-dimensional CT (4-D CT) in lung cancer radiotherapy reduces geographical miss and reduces normal tissue toxicity by individualizing the margin from the clinical target volume. The main steps in the target definition for 4-D CT are as follows. First, a composite of the gross tumor in all phases of the respiration

cycle is created, then a margin for microscopic disease is added to create the clinical internal target volume; finally, a margin for setup error is added to create the planned target volume (4-D PTV). This 4-D PTV is designed to ensure satisfactory irradiation of the tumor in all positions throughout the respiration cycle. With the introduction of 4-DCT, there has been a great deal of interest regarding the possibility of using the 4-D CT to plan and deliver respiratory guided radiotherapy (RGRT). The patient's respiration cycle, for example, is monitored continuously by an external surrogate, an infrared marker box placed on the sternum. The movement of the marker box is picked up by a camera and a respiratory trace is seen in the control room. This trace enables the selection of a respiratory phase or *gate* for treatment delivery and the treatment beam is switched on only during this interval. RGRT has been shown to reduce the size of the PTV when compared to the standard 4-D PTV [45.23].

45.3.9 Intraoperative Electron Radiation Therapy

Intraoperative electron radiation therapy (IOERT) is the application of electron radiation directly to the residual tumor or tumor bed during cancer surgery. IOERT has also been called precision radiotherapy, as the physician has direct visualization of the tumor, can exclude normal tissue from the field and can also protect critical structures within the field by narrowing the irradiated volume. IOERT is a method that provides dose escalation as a precision component of radiotherapy. IOERT can also be combined with radiation sensitizers to better treat hypoxic cells and can be given at the time of surgery when microscopic residual tumor cells are most vulnerable to destruction. IOERT has been used in combination with curative external beam therapy as it results in lower integral doses and shorter treatment times in boost dose concept (20–30% of the dose is dedicated to the IOERT). It has been proved that local tumor control and the 10 year survival rate could be improved for rectum cancer, soft tissue sarcoma, stomach cancer, pancreatic cancer, kidney cell cancer and gynecological tumors without an increase in side effects.

In principle IOERT is applied as a primary radiation therapy or directly after a presurgery external radiation therapy. If the tumors are inoperable, then IOERT is used as a palliative treatment, especially for pancreatic tumors (Fig. 45.7). The prescribed dosage varies between 10 and 30 Gy. The biological effectiveness of this

Fig. 45.6 Linear accelerator with IGRT (after [45.22])

Fig. 45.7 IOERT using an electron tube during surgery directly mounted on medical linear accelerator (after [45.24])

single treatment is increased by two or three times the conventional fractionation of 2 Gy per day. A significant dose escalation in the target volume can be achieved by combining IOERT and conventional external beam therapy. In parallel, the late side effect rate in normal tissue will be reduced and local tumor control will be improved.

45.3.10 Stereotactic Irradiation

Stereotactic irradiation is a specialized type of external beam therapy. It uses focused small radiation beams targeting a well-defined tumor using extremely detailed imaging scans. In using this technique one can deposit a very high dose to the tumor and spare the normal tissue. Radiation oncologists perform stereotactic treatments, often with the help of a neurosurgeon for tumors in the brain or spine. There are two types of stereotactic radiation. Stereotactic radiosurgery (SRS) is when doctors use a single or several stereotactic radiation treatments of the brain or spine. Stereotactic body radiation therapy (SBRT) refers to one or several stereotactic radiation treatments with the body, such as the lungs.

Some physicians say that an advantage of stereotactic treatments is that they deliver the right amount of dose (12–18 Gy per fraction or single dose) to the target volume in a shorter amount of time than conventional radiation therapy, which can often take 6 to 11 weeks. In addition, treatments are given with extreme accuracy, which should limit the effect of the radiation on healthy tissues. One problem with stereotactic treatments is that they are only suitable for certain small tumors.

Fig. 45.8 (a) CyberKnife (after [45.25]), (b) Gamma Knife (after [45.26])

Stereotactic treatments can be confusing because many hospitals call the treatments by the name of the manufacturer rather than calling it SRS or SBRT. Brand names for these treatments include Axesse, remote-controlled radiosurgery system Cyberknife (Fig. 45.8a), Co⁶⁰-source Gamma Knife (Fig. 45.8b), Novalis, Primatom, and others. While the gamma knife is used on brain tumors, a medical linear accelerator with stereotactic properties can perform extracranial stereotactic treatments, and the Cyberknife could be applied for extracranial stereotactic treatments.

45.3.11 Total Body Irradiation with Photons

Total body irradiation (TBI) is primarily used as part of the preparative regimen for hematopoietic stem cell (or bone marrow) transplantation. As the name implies, TBI involves irradiation of the entire body, though in modern practice the lungs are often partially shielded to lower the risk of radiation-inducing lung injury. TBI

Fig. 45.9a,b Two arrangements for total body irradiation using a medical linear accelerator, parallel-opposing-beams technique (a) and translational technique (b) (after [45.8])

in a context of bone marrow transplantation serves to destroy or suppress the recipient's immune system, preventing immunologic rejection of transplanted donor bone marrow or blood stem cells. Additionally, high doses of TBI can eradicate residual cancer cells in the transplant recipient, increasing the likelihood that the transplant will be successful.

Doses of TBI used in bone marrow transplantation typically range from 10 to 12 Gy. For reference, a dose of 4.5 Gy is fatal in 50% of exposed individuals without aggressive medical care. At these doses, TBI both destroys the patient's bone marrow (allowing donor marrow to engraft) and kills residual cancer cells. Nonmyeloablative bone marrow transplantation uses lower doses of TBI, typically about 2 Gy, which do not destroy the host bone marrow but do suppress the host immune system sufficiently to promote donor engraftment [45.27].

In modern practice, TBI is typically fractionated. That is, the radiation is delivered in multiple small doses rather than one large dose. Early research in bone marrow transplantation demonstrated that this process of splitting TBI into multiple smaller doses resulted in lower toxicity and better outcomes than a single, large dose.

Indications for TBI are different kinds of leukemia in pediatrics and for adults:

- Acute lymphatic leukemia (ALL)
- Acute myeloic leukaemia (AML)
- Chronical myeloic leukemia (CML)
- Myelodysplastic syndrome (MDS)

Several techniques for delivery of TBI have been developed. One of the most common techniques is the translational technique (Fig. 45.9b), which utilizes a conventional medical linear accelerator. Therefore, large beams are needed. An extension of the focus-skin distance to about 2 m enables the width body to be captured by the beam. For the longitudinal direction the patient is moved onto a motorized couch through the beam. As an alternative, the focus-skin distance can be extended to ca. 3.5 m, so that the beam covers the entire body. Then either the patient is placed in two positions, a prone and supine setup, or two accelerators are used (Fig. 45.9a).

45.3.12 Total Skin Electron Beam Therapy

Total skin electron beam therapy (TSEBT) is a radiation treatment method to irradiate the skin in case of melanoma using fast electrons. Typical electron energies are between 6 and 12 MeV, and the total dose is in a range of 30–40 Gy.

Typical treatment techniques are as follows:

- Several field arrangement: the patient stands hands up facing the medical linear accelerator. After the first irradiation the patient must turn by a certain angle in order to irradiate the other part of the skin (Fig. 45.10).
- Continuous rotation: the patient stands hands up facing the medical linear accelerator on a continuous rotating platform and performs a full 360° rotation.

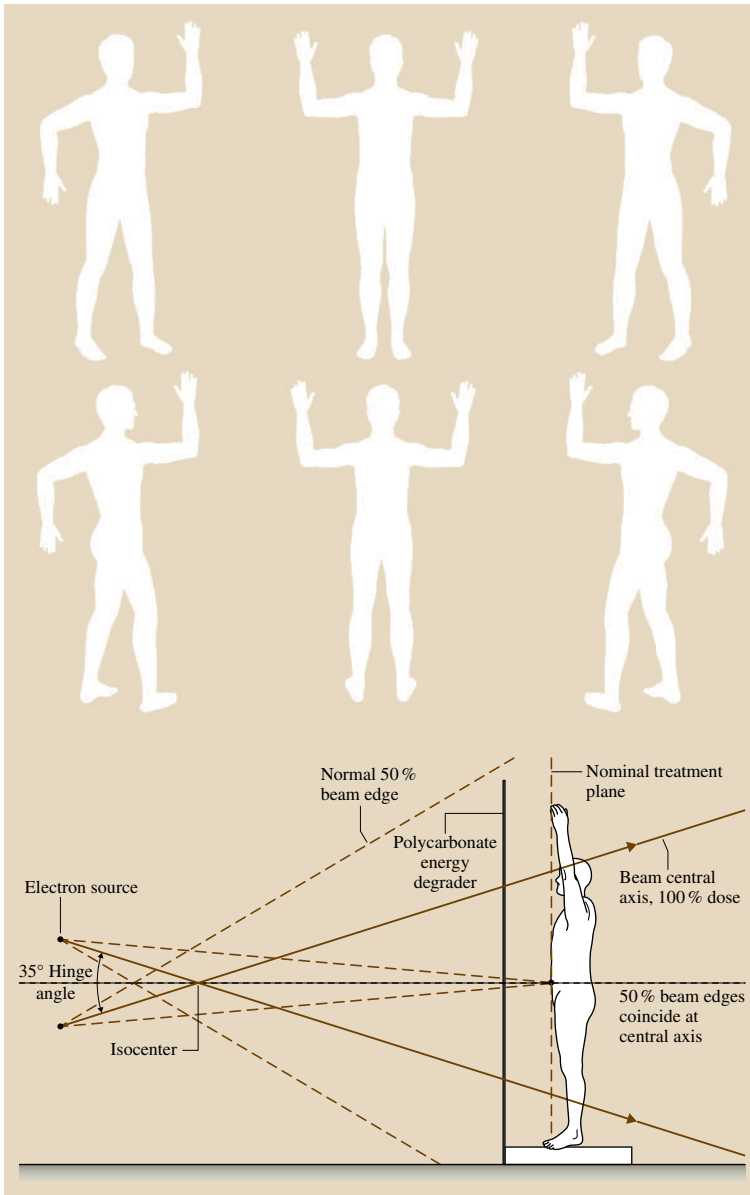

Fig. 45.10 Total skin irradiation with electrons (after [45.28, p. 83], courtesy of Dr. P. Rudd)

45.4 Target Volumes and Organ at Risk

In the ICRU 50 and the ICRU 62 as supplement, the target volume definitions are described in detail (Fig. 45.11). A target volume defines the region to be treated or to be irradiated. The following target volumes are differentiated.

- **Tumor volume:** The tumor volume is described as a macroscopic palpable region or as a tumor visible in the imaging. According to ICRU 50, the tumor volume corresponds to the gross tumor volume (GTV).

Fig. 45.11 (a) GTV – gross tumor volume; CTV – clinical target volume; PTV – planning target volume; TrV – treated volume; IrV – irradiated volume (after [45.28]). (b) Schematic example of a GTV (demonstrable tumor = striated area) and also for CTVs to care for suspected, subclinical extensions surrounding GTV (CTV I, here also including the GTV) and the regional lymph nodes (CTV II, = open area) (after [45.29])

- *Clinical target volume:* The clinical target volume contains, in addition to the clinically detectable tumor, the area where tumor cells could exist or could not be verified. The area is called the tumor propagation area. ICRU 50 defines the volume as the clinical target volume (CTV).
- *Planning target volume:* The planning target volume contains the CTV including a safety margin. The safety margin describes the uncertainty of the determination of the CTV. The safety margin contains uncertainties due to organ motion caused by breathing, an interfractional change of the organ fillings, i. e., bladder or intestine, and limited precision of the patient setup. These uncertainties of the patient setup vary depending on the positioning. Support equipment such as a thermo-plastic mask, vacuum matrices or a belly board is used. The planning target volume is named in the ICRU planning target volume (PTV). The volume receive neither more than 107% of the prescribed dose nor less than 95% of the prescribed dose.
- *Treated volume:* This defines the area where the dose is sufficient to reach the therapeutical goal.
- *Irradiated volume:* This defines the area where a direct, not exclusively scatter, dose is delivered.

45.5 Modern Treatment Planning Systems

Modern conventional 3-D treatment planning systems for IMRT and 3-D CRT of patients receiving external beam therapy consist of different modules. The fundamental modules of these treatment planning systems are, on the one hand, the beam data entry for photons and electrons and, on the other hand, the different calculation algorithms for photons and electrons. All treatment planning systems require the entry of data that describe the radiation beam. The amount of data

required depends on the computational algorithm, varying from almost none to thousands of measurements that completely map the radiation beam for a variety of field sizes. Systems that require the entry of almost no measured beam data rely upon a detailed description of the design of the accelerator head, collimator and accessories. The dependence of a system on a large amount of measurements is thought by some to be a disadvantage because substantial effort is required to accumulate

Fig. 45.12 Two 3-D treatment planning systems; (front) Helax-TMS, (back) Oncentra-MasterPlan (after [45.33])

the large amount of data. The accuracy of any treatment planning system is ultimately determined by comparison with measured data. Complete validation of a treatment planning system requires a comparison between calculations and measurements over a wide variety of treatment conditions, necessitating a large amount of measured data. For photon beam calculation, pencil beam algorithms such as precalculation and collapsed cone algorithms for final calculations are recommended for forward planning. For electron calculations the Monte Carlo method is widely used. An explanation of the differences and precision of those algorithms can be found in the literature [45.9, 30–32]. For inverse planning, where iterative algorithms find an optimal solution for the objective function, the AAA superposition algorithm is commonly used [45.10]. In Fig. 45.12 two different 3-D treatment planning systems are shown.

45.5.1 Basic Components of a Treatment Planning System

A treatment planning system is a combination of hardware and software components that allow the user to produce and display the calculated dose distribution for the physician who prescribes a patient's radiation treatment. The basic components of treatment planning system are as follows [45.3, 34]:

- Software
 - Utility software for entering, printing and accessing an external beam treatment unit and measured absorbed dose data (physics module);
 - Utility software for transferring patient CT, MRI, PET and other imaging modalities and converting the CT data into electron densities.

- Software for creating and organizing patient data (import module);
- Contouring software for entering the external contour of the patient, internal contours, target volumes and landmarks pertinent to the treatment (contouring module);
- Dose calculation initializing software for establishing a calculation grid and method of calculation (beam modelling module);
- Dose calculation software (dose calculation module);
- Isodose display software including normalization, DVH and beam weighting (analyzing and optimizing module);
- Printer and plotter for (scaled) documentation on paper (DIN 6827-1) or as a PDF file [45.35];
- DICOM export of the dose plan to record and verify system;
- Archiving system to guarantee for 30 years;
- Backup.

- Hardware

- Central processing unit, sufficient (virtual) memory to accommodate and operate the application software and host the database;
- High-resolution graphics capability including high-resolution monitors;
- (External) mass storage (hard disk) capacity sufficient to easily retain all current patients in treatment for backup, archiving, removable storage, CD, DVD, tape and network drives;
- Digitizer and scanner to enter patient contours and phantom manual;
- Uninterruptible power supplies (UPS) in order to prevent data loss due to electrical shut down;
- Ethernet card (connection) for import and export of DICOM data from external modalities like CT, simulator or PACS system, and remote access. In order to overcome the large amount of data transferred, the minimum recommended transfer rate today is 100 MB/s.

45.5.2 Physics Module

All treatment planning calculation algorithms require input beam data of some form. For conventional treatment planning systems, beam data need to be measured for each beam quality available at the site. The accuracy and quality of the input data are dependent on the measured or calculated data that are produced by the user. For practical reasons, the data are generally determined over a limited range of conditions, e.g., limited depths

and field sizes. Whenever calculations extend beyond the range of measured data, the output results should be scrutinized since the algorithms can perform inaccurate extrapolations. In addition, the measured data have their own inherent uncertainties or inconsistencies that depend on the care taken by the individual person generating the data, the types and sizes of the detectors that are used, as well as on the stability of the linear accelerator producing the radiation beam (e.g., variations in flatness, PPD and symmetry with gantry angle or with time). Generally both relative data and absolute data need to be determined – relative data in the form of dose ratios and absolute data in terms of the linear accelerator output calibration. The latter is a requirement of the treatment planning system if it is used for monitor unit or time calculations. Before use, the data need to be approved and locked from unauthorized use.

45.5.3 Import Module

There are at least three major sources of input data. The first includes measured beam data from a 3-D water phantom system. The second includes image data, usually from a CT scanner, MRI, ultrasound or PET. The third source includes data from keyboard and mouse and involves details of the plan input such as field size, gantry angle, collimator rotation, beam energy, etc.. The latter is standard practice for any treatment planning system. The first two usually require network connections or magnetic media such as discs or tape and must have file formats that are compatible with the treatment planning system. As part of the commissioning process, it is important to check for hardware compatibility, especially when the data sources are from different manufacturers. For image data DICOM version 3 or DICOM RT (for radiation therapy) formats must be used. While file compatibility should be defined in the specifications, compatibility of file formats can only be assessed by going through a file transfer process. It is important that the data from the water phantom system and the patient image sources be checked for accuracy and that they have been properly transferred to the radiation therapy planning system. This can be simply done by performing analysis of the input data for well-known configurations, i. e., that the geometries are correct with no magnification errors and no spatial coordinate errors.

The conversion to electron density and scattering power is often performed with a user-defined lookup table. The data within the table are then used with a linear interpolation to determine the relative electron density for any CT number. Usually such tables are generated

using a water equivalent circular phantom with a number of different materials inserted into the phantom of known electron densities representative of normal tissues within the patient, especially lung- and bone-equivalent materials. The import module should also be able to read the DICOM RT format from previous irradiations of the patients.

45.5.4 Target Definition or Contouring Module

The contouring module is used for the delineation of the target volume, OAR and external contours. In most treatment planning systems, the dose calculation is limited to external contours drawn. The delineation of the target volume is the responsibility of the attending physician. The organ at risk and other contours are drawn by a medical physicist depending on the regulations of each institution. Furthermore, the reference point (isocenter) should be marked. If margins, help contours or boluses (including its density) are needed, they must be contoured in the module. The definition of margins differ from institution to institution depending on known setup errors, respiration organ fillings and uncertainties in the imaging of the tumor. The following organs are typically at risk depending on the body region:

- Head and neck: parotids, brain stem and spinal cord;
- Chest: heart, lungs and spinal cord;
- Abdomen: intestine and kidney.

The risk of side effects caused by radiation therapy was investigated by *Emami* et al. [45.36] and the tolerances found were categorized for different OARs for the appearance of side effects of 5 and 50% in 5 years (called TD5/5 resp. TD50/5).

Not only are the structures of the target volume and OAR the treatment aim and region of risk but also, after successful dose calculation, dose information about D_{\max} , D_{\min} and D_{mean} could be derived by accessing the so-called dose volume histogram (DVH). It is recommended to delineate all OARs and critical structures within and outside the treatment area.

In the target definition module, the reference point is defined as being related to retraceable anatomic structures and defines a displacement vector to the isocenter of the medical linear accelerator. This isocenter is defined by a stationary laser coordinate system and coincide with the laser systems at the simulator, CT-scanner and medical linear accelerator. The alignment of the patient for the isocenter or the reference point is marked or tattooed on the patient. These markers al-

low a precise realignment of the patient relative to the isocenter at a known displacement vector.

45.5.5 Beam Modeling Module

In the beam modeling module (in forward planning), the beam configuration is selected for a target-volume-conforming arrangement by sparing the OAR. The beam quality and beam energy depend mainly on the tumor depth. For a surface near tumor one would select either electrons or photons with a tissue-equivalent bolus. For tumors deeper in the body ($d > 1$ cm) photons are the selection of choice. The beam size is shaped either by MLC or lead blocks to be conformal to the target volume. As beam modifier, it acts as either a fixed or dynamic wedge filter or a combination of them. A typical beam arrangement is a combination of several beams of different directions and different energies, and perhaps different beam qualities as well. Many TPSs are capable of calculating treatment plans for brachytherapy and have the ability to overlay or add plans from brachytherapy and external beam therapy.

The determination of the calculation grid defines the precision and resolution of the calculation, but a coarse calculation grid resulting in short calculations allows a quick overview of the dose distribution according to the prescribed dose and the dose to the OAR. If the overview is satisfactory, then the calculation grid becomes finer and the resolution could be dropped by a fraction of a millimeter. It is handled different among the TPS to which contour a voxel belongs in case of an overlapping between the planning target volume (PTV) and the OAR. The voxel is taken into account among the TPSs is different; either the voxel belongs to the volume set with higher priority or it belongs to both volumes. In the case of a DVH comparison, the qualities of different plans made in different TPSs must be taken into account.

Treatment planning using electrons can be directly added to photon planning in terms of the biological effectiveness of the beam, but on the other hand electrons mostly come with an electron applicator of a certain size, and a shaped beam needs to be constructed using lead inlays for applicators. The other difference is the shape of the percentage depth dose (PDD) of electrons in tissue. The electron beams do have a flatter D_{\max} than photon beams but a higher D_{surface} and a very shape decline of a certain distance, where 97% of the dose vanishes and just bremsstrahlung remains.

In inverse planning the beam modeling module is completely different from that in forward planning.

Here the constraints to the PTV and the OAR need to be defined. The dose prescription must become more precise in terms of the permission for D_{\max} , D_{\min} , D_{mean} , D_{50} etc.. One could restrict the number of gantry angles and the minimum opening size of the MLC. Problems occur when the constraints cannot be fulfilled simultaneously. Then the constraints must be reset and relaxed.

45.5.6 Dose Calculation Module

In the dose calculation module, the actual calculation of the dose distribution takes place. The calculation algorithm and its precision are chosen, i. e., pencil beam, collapse cone or Monte Carlo method, which is becoming more and more fashionable, while the CPU is improved [45.37]. The patient contour can be extended, (i. e., if the beam enters the end of the CT-scan but does not leave the patient contour before. Due to the calculation time, the inhomogeneity correction can be set off, so that with large density differences like between bone and lung tissue the calculation becomes incorrect by several percentage points.

45.5.7 Evaluation and Optimization Module

In the evaluation and optimization module, the final point of normalization is defined. The isodose setup is placed in relation to that point. According to ICRU 50, the normalization level is set to 100% (deviations need to be denoted). The prescribed dose is then set to 100% (deviations need to be denoted). In order to calculate the monitor units for a treatment fraction, the fraction dose must be configured. In the case of an integrated boost, the fraction dose for target volumes needs to be determined, although certain thresholds should neither be exceeded (2.5 Gy) nor undershot (1.7 Gy). One target volume is defined as the leading target volume, which determines whether the monitor unit is irradiated. The DVH reveals D_{\max} , D_{\min} , D_{mean} and other important dose values like D_{10} , D_{20} and D_{50} . Figure 45.13 shows the influence of different beam arrangements on the dose distribution.

If ICRU 50 for the PTV in forward planning is not fulfilled, the beam weights, gantry angle or wedge must be varied; otherwise beams for saturation or vertex beams must be added. In the case of inverse planning, constraints for PTV and OAR must be relaxed or the modulation factor [MLC openings (time or size)] changed. If this approach does not have the desired success, then one must consider loosening the ICRU 50 demand, and then a change in the constraints or, in very

Fig. 45.13 (a) Anterior beam, (b) two opposing beams, (c) three-beam plan (one beam without a wedge and two beams with wedges), (d) four-beam box (after [45.17])

difficult cases, the contouring must be reconsidered. This is a task for the medical physicists and physicians. There will always be a tradeoff between increasing the risk of side effects and the loss of control over the (local) tumor. The general condition of the patient and the treatment goal are important boundary conditions.

If the reconsideration leads to a successful treatment plan and the ICRU 50 [45.7] could be fulfilled, the plan must be approved by medical physicist and the documentation (i. e., according to DIN 6827-1 [45.35]) must start with a printout of the plan report, requested isodose distributions (i. e., slice showing D_{\max} , isocenter, reference point, normalization point, etc.), DVH and DRR.

45.5.8 Plan Analysis Module

In the analysis module, an evaluation of the treatment is performed. Here treatment plans can be added, subtracted, or overlaid. Of particular interest will be the target volume and the ICRU conformality as well as the dose at the OAR and the fulfilled constraints. If the patients had been preirradiated, then the addition of the previous irradiation is needed to see the total dose. By adding plans from different TPSs the calculation grid plays an important role because if the resolution be-

tween two plans is not identical, this might cause problems, especially with preirradiated patients, even though areas of over- and underdosage in the OAR or target volume can be visualized. Furthermore, the presentation of the isodoses, i. e., color wash, lines, the dose levels must be shown etc.. In Fig. 45.14 the radiation therapy of a head and neck case with DVH is shown.

45.5.9 Export Module

The export module becomes increasingly important when different TPSs are involved in treatment planning, where treatment plan data need to be archived or transferred to portable discs, i. e., dose verification in the case of IMRT. The export consists of either a DICOM format or some standardized data format, i. e., export to a record and verification system like MOSAIQ or Varis. These formats contain the planning CT, the structure set (PTV, external, OAR, etc.) as well as DRR or the plan report as a PDF file. Typical addresses are:

- Archive systems,
- PACS system,
- Simulator (conventional or virtual),
- Record and verification systems of the medical linear accelerator,

Fig. 45.14 (a) Dose distribution shown on a CT slice of a patient with a pharyngeal tumor. The technique is based on a complex combination of 19 fields (7 main fields and 12 subfields in this special case) in order to achieve an optimal dose in the target volume taking into consideration all organs at risk (spinal cord, eyes, lens, etc.). The tolerance must be considerably high. **(b)** Dose volume histogram showing minimum and maximum dose % inside the target volume and in the organ at risk. The ICRU requirements are not maintained in this type of case due to the positions of the organs at risk. In such cases higher or lower doses can be accepted depending on the tumor localization inside the target volume. It is up to the doctor to accept a plan or not (after [45.17])

- Portable discs for dose verification or other health institutions,
- Other treatment planning systems (for comparison, addition or further processing).

45.6 Simulation of the Patient and the First Treatment

During conventional simulation the treatment plans are directly transferred to the patient either with an x-ray equipped machine or a linac (using a MVCT) where the plans can either be corrected or approved.

This data transfer is an approval for the correctness of the patient beam data transferred by the record and verification system [i. e., MOSAIQ (IMPAC, Elekta), VARiS (Varian), LANTIS (Siemens)]. The created im-

Fig. 45.15a–c From image acquisition to dose delivery, (a) computer tomography, (b) simulation, (c) linear accelerator (after [45.38]) ►

ages for each beam is then compared to the DRRs from the treatment plan. The detector is either an image intensifier (conventional simulation) or a solid-state detector (in linear-accelerator-based plan verification). The modern method of performing a simulation using a CT scanner (virtual simulation) is explained in Sect. 45.6.2.

45.6.1 Conventional Simulation

After localization of the isocenter the beam shapes are transferred to the patient's body. The transfer of the beam data is supported by a room-based laser system that has the same isocenter as that of the medical linear accelerator and the CT scanner.

The marks on the patient's body using the laser system enable a precise setup for the first treatment at the medical linear accelerator because the laser system there will be a clone of the simulation laser system. The achieved precision of the patient's setup can be less than 3 mm. The precision of the setup will be determined during external radiation therapy at least every week using an EPID or a solid-state detector. The verification images are overlaid with the verification of the first treatment day or the simulation and corrected for. Some medical linear accelerators like Tomotherapy can perform linac-based CT in order to assure the correct position of the PTV and OAR (Sect. 45.3.7).

45.6.2 Virtual Simulation

Virtual simulation is the process by which a detailed 3-D model of a patient is built from a sequence of closely spaced transverse CT (or MRI) images. Since the grayscale of the CT images is directly related to tissue density, the computer model can be used to calculate the image that would be produced on a piece of film by a conventional diagnostic x-ray machine or a DRR. The advantage of the DRR is that it can be calculated almost instantly for any angular projection through the body. Use of a mechanical x-ray machine and films requires several minutes of setup and film development for each projection. When planning high-energy radiation treatments for cancer patients, it is a distinct advantage for the physicians and physicists to be able to rapidly evalu-

ate many potential projections in order to find those that minimize the exposure of healthy organs to the radiation beams. Linear accelerators equipped with MLCs can be then programmed to selectively irradiate the tumor from many different projection angles.

45.7 Quality Control in Radiation Therapy

External radiation therapy comprises a chain of different modules starting from diagnostics, setup of the patient, treatment unit and dose and geometry verification methods. Several aspects in the quality assurance in radiation therapy are important such as, on the one hand, the education of the people carrying out the external radiation therapy and, on the other hand, the machine used for radiation therapy.

45.7.1 Personnel

Depending on the country, the education of the staff performing the external radiation therapy differs in terms of duration and content of qualifications, but the dangerous properties of ionization radiation require a special qualification of the staff by law. In Germany the law for using and handling ionization radiation concerns the medical physicist. The radiotherapist, medical physicist and the MTRA are requested to attend special courses on radiation protection and other related subjects to achieve technical qualification. This qualification has to be renewed every five years. To become a radiotherapist is regulated by legislation comprising a credit system. To become medical physicist radiation protection legislation regulates the minimum requirements.

Guidelines set up by DEGRO and ESTRO for the treatment of different malignant diseases enable the radiotherapist to remain current in modern treatment methods.

45.7.2 Planning system

For calculations treatment planning systems use beam data taken at each medical linear accelerator.

These beam data are gathered during commissioning of the linac, and then transferred, converted and implemented into the treatment planning system. This procedure is followed directly by an intense check of the planning system whereby the calculations are compared to measurements in a water tank for each medical linear accelerator.

Firstly, standard plans in the water tank or solid-state phantom are calculated and verified. These phantoms must have installations for hosting ionization chambers for absolute dosimetry or films for dose distributions. Nowadays dose distributions are verified by electronic devices like detector arrays (diodes or ionization chamber).

After the initial check of the beam data, periodical tests of these treatment plans and typical dose distributions need to be performed. This is required by legislation. The treatment planning system itself must undergo periodic checks of the intrinsic beam data. This is requested in order to identify uncertainties or changes in the beam data in an early state, especially after software updates. The frequency of those periodic checks is either monthly or after changes to hardware or software [45.39].

The requested properties in the treatment planning system to be regularly checked are as follows:

- Calculation of different treatment plans on different phantoms (PMMA, water, Alderson)
- Check of coincidence of the report and the treatment plan by checkpoints
- Transfer of treatment plans to external machines (simulator, record and verify system) and verify the data consistency with original treatment plan:
 - Collimator/gantry position
 - Shape of MLC
 - Dose values and monitor units
 - Hounsfield conversion to grayscale

45.7.3 Medical Linear Accelerator and Simulator

The treatment plans calculated by the treatment planning system during commissioning are defined as the gold standard. Therefore, changes by time of the relevant properties of the treatment plan are not permitted. As the planning site undergoes periodic check, the medical linear accelerator must undergo regular checks on its properties. Those checks can be performed daily, before patient treatment, weekly, monthly, quarterly, semiannually and annually.

The properties that need to be surveyed are as follows:

- Safety interlocks due to operating failures and malfunctions;
- Dosimetry (dose-monitor calibration, dose profiles, PDD, ...) compared with the gold standard;
- Transfer of treatment plans to the linac and check on whether the values coincide with the original plan.

Figure 45.16 shows a water tank to gather the beam data and examples of absolute dosimetry as well as an electrometer and an exposed film for checking the isocenter

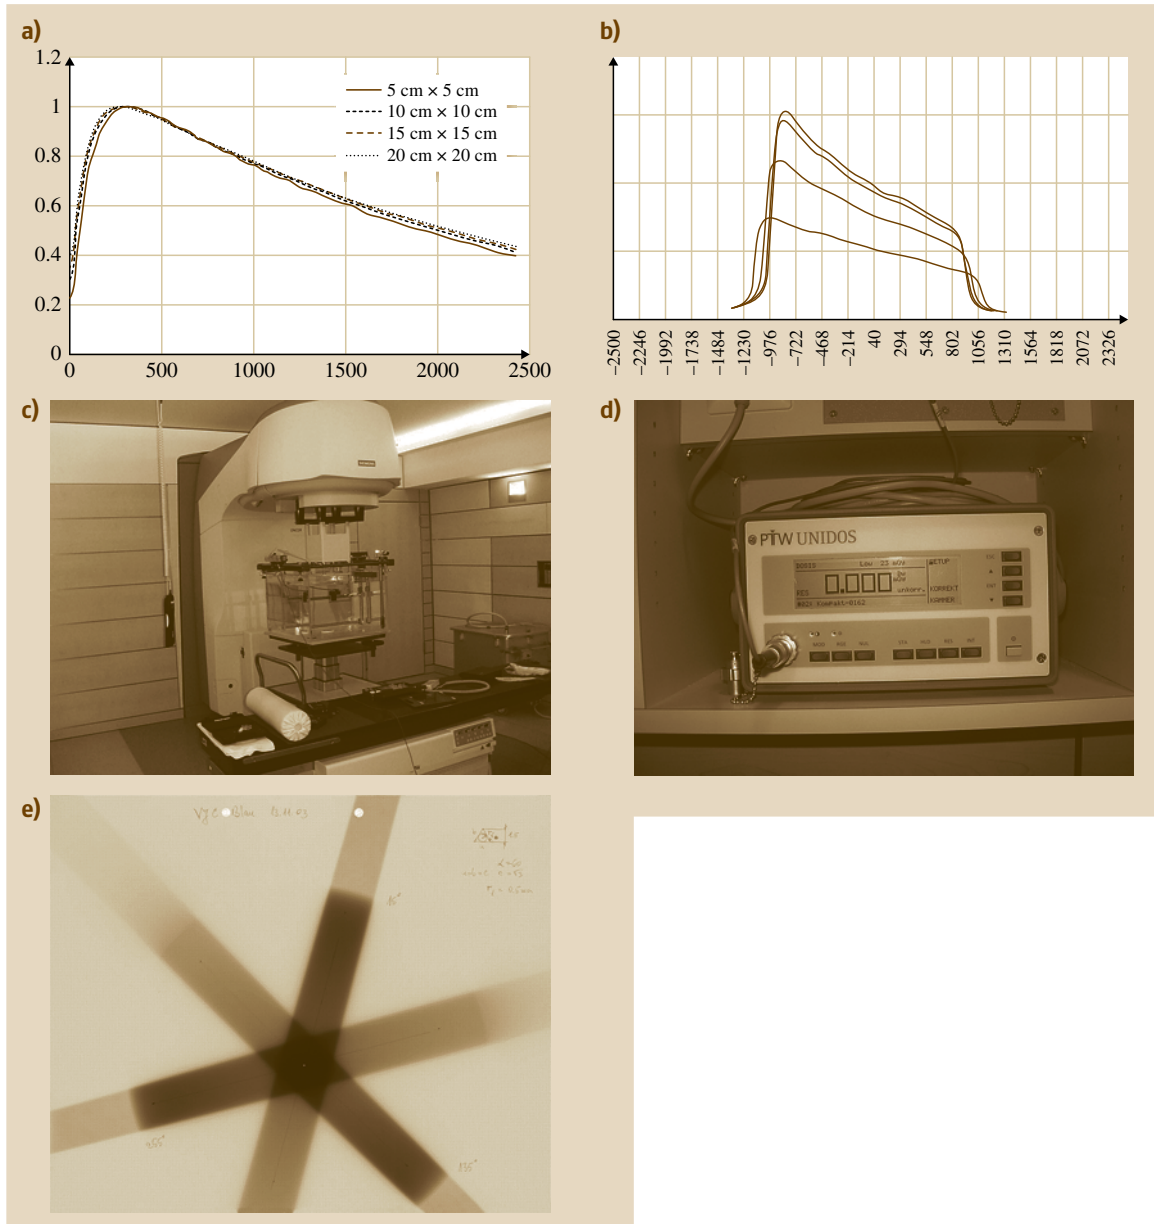

Fig. 45.16 (a,b) Relative dose distribution, (c) water phantom, (d) absolute dosimeter, (e) star shot at different gantry angles on a film after irradiation (after [45.38])

using five beams in different gantry positions of a medical linear accelerator [45.40, 41].

A conventional simulator requires periodic checks of the geometry and the isocenter like at the linac because the setup must be the same.

The data in Fig. 45.16a,b needed for the beam data include the relative dose distribution (depending on the TPS vendor) and the absolute dosimetry under reference conditions, i. e. according to DIN 6800-2 [45.42].

46. Recording and Processing of Biosignals

Klaus-Peter Hoffmann, Florian Solzbacher

Measuring is the experimental determination of a measured value by quantitative comparison of the measurand with a comparison value. The measured value obtained by this procedure is given as a product of a numeric value and a dimensional unit. It can be recorded continuously as a temporal variation of a physical value or discontinuously at particular moments. The deviation of the measured value from the measurand is the measurement error. It depends on the measurement procedure, the measurement device, and environmental effects. Systematic and random errors are distinguished.

The measurement can be done directly or indirectly, depending on the chosen measurement procedure. For instance, the concentration of substances is determined by the measurable value extinction, ion activity, dielectric permittivity, or magnetic susceptibility. Here, the measurand is transformed into one or several intermediate values in order to further process the signal. The result of a measurement is the measured value itself or a combination of several measured values.

This chapter covers the acquisition of different biosignals and the specifics of the measurement process in medical use.

46.1 Measuring in Medicine

The aim of measuring in medicine is the objective description of the state of a patient who might possibly not be able to cooperate. It should help the physician to define the respective therapy and to evaluate the therapy process. Moreover, the prognosis of the course of disease can often be estimated. The long-term monitoring of physiological parameters is combined with an alarm function if preset limiting values are exceeded or undershot. Further developments include closed-loop systems which directly intervene in the patient's state after analysis of the measured values, for instance by raising or

reducing the infusion rate in infusion therapy. But also the examination of patients who are not able to cooperate often becomes only feasible by the determination of objective parameters (Fig. 46.1).

Often, various procedures are combined in medicine, e.g. the combination of functional, metabolic and morphologic methods for functional brain imaging in brain diagnosis. Here, the combined analysis of EEG, CT, MRI, PET and MEG can yield new information, for instance in presurgical diagnosis of epileptic seizure diseases and epileptic focus localization.

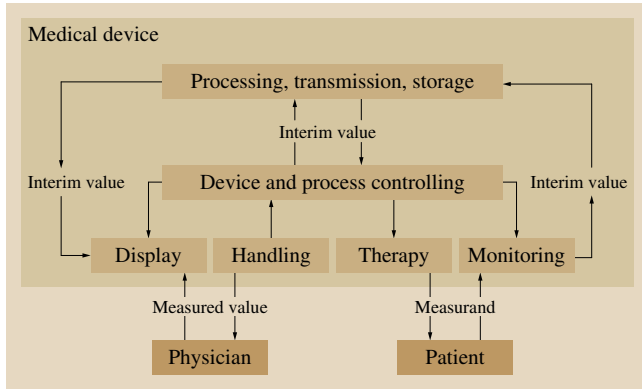

Fig. 46.1 Measuring in medicine

For measuring in medicine, the following five objectives can be distinguished:

1. Metrological acquisition, conversion, processing and telemetric transmission of biological signals.
2. Measuring the reaction or the behavior of the biological object to an external stimulus.
3. Measurements during the application of extra- or intracorporal assist systems to support organ functions or as organ compensation, as well as manipulators for therapeutic means.
4. Application of substances, irradiation or waves and measurement of reflection, absorption, scattering, distribution or fluorescence to display structures and functions in the organism.
5. Extraction of body fluids, substances and tissues, as well as tests and analysis in clinical and chemical laboratories.

In contrast to technical measurements, interindividual and intraindividual deviations occur for biological measurements, owing to biological variability. This means, that the obtained measured values vary from patient to patient. But also for one and the same patient, deviating measured values (e.g. blood pressure) occur in the course of the day.

The extent of inconvenience for the patient and the measurement procedure directly influences the reliability of the measured values. Moreover, biological sources of interference (biological artifacts with physiological origin) superimposing the measurand have to be considered. The measurement duration and the reproducibility of an examination are limited for most methods. In addition, the wide variability of the examined persons has to be taken into account, ranging from fetus, infants and trained athletes to aged people.

Opposed to the objective methods are the subjective methods, requiring cooperation of the patient. Those include audiometry, vibration tests and temperature sensation.

46.1.1 Biosignals

In the biological measuring chain, the biosignal is the actual measurand that should be metrologically determined for diagnostic purposes. Biosignals can be defined as phenomena to describe functional states and their variations in a living organism. They provide information about metabolic, morphological and functional changes, describe physiological and pathophysiological states as well as process dynamics. To analyze them, the generation locus and thus the spatial and temporal correlation is significant. Biosignals are acquired from living organisms, organs and organ parts down to single cells.

Biosignals can be distinguished with respect to their properties. On the one hand, there are structural parameters, for instance length, area, amount, volume, elasticity or viscosity. On the other hand, functional parameters can be found, among them temperature, pressure, flow, electric potentials and acoustic sounds. Biosignals are described by their frequency, amplitude, shape and the time of occurrence. They can be displayed in the time domain and the frequency domain, but also as two- or three-dimensional pictures. Their occurrence can be stochastic, stationary, periodic or discrete. Figure 46.2 shows some examples for biosignals.

With respect to the physical properties, biosignals can be divided into:

1. Bioacoustic signals (heart sound, lung sounds, speech)
2. Biochemical signals (substance compositions, concentrations)
3. Bioelectric and biomagnetic signals (electric potentials, ion currents)
4. Biomechanical signals (size, shape, movements, acceleration, flow)
5. Biooptical signals (color, luminescence)
6. Biothermal signals (body temperature).

46.1.2 Biological Measuring Chain

The biological measuring chain is used for the metrological acquisition of biosignals. It includes the registration (sensor, transducer), the processing (amplification, filtering, linearizing, transmission), the analysis (bio-

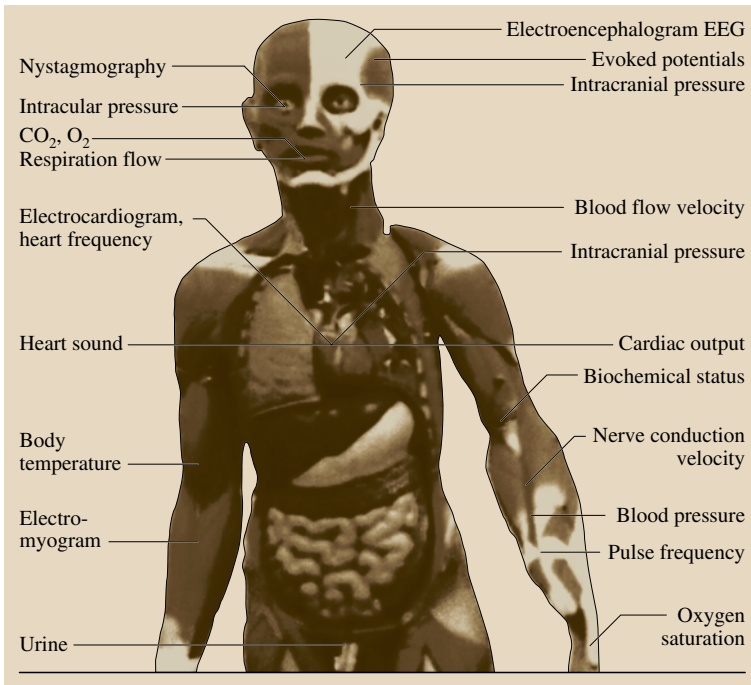

Fig. 46.2 Examples of biosignals that can be obtained by measurements

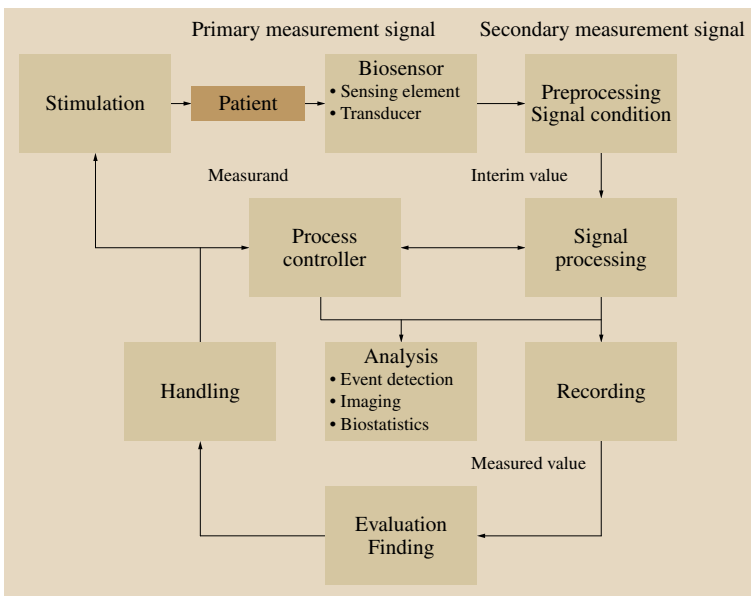

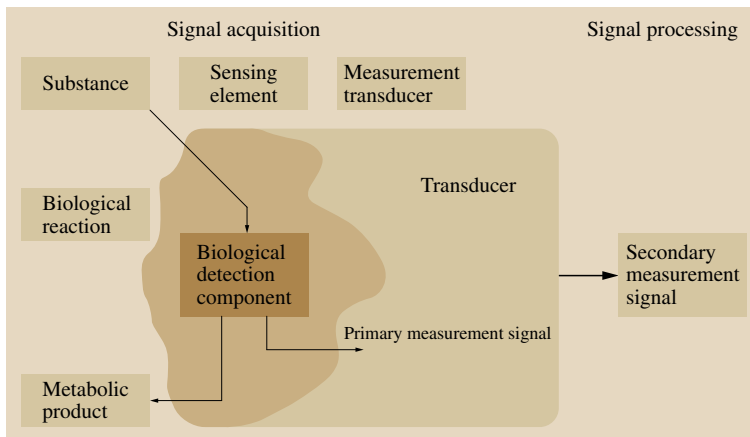

Fig. 46.3 Structure of the biological measuring chain

statistics, biosignal analysis, image processing) and the display of the biological signals. The objective is to provide assistance to the physician for diagnostics. Figure 46.3 shows the structure of a biological measuring chain in principle.

Sensors

A biosensor is a probe to register biological events and morphological structures. Often, it is directly connected to a transducer, or it transduces the primary measurement signal into a secondary signal itself (e.g.

Fig. 46.4 Schematic of a biosensor

Fig. 46.5 Design and principle of a p_{CO_2} electrode

electrode). It can be distinguished between sensing and transfer elements. In e.g. a piezoresistive pressure transducer the membrane would be a transfer element, transferring pressure into mechanical stress. The piezoresistor would be the sensing element that turns the mechanical stress into an electrical signal. The secondary measurement signal is mostly an electric signal, which can be easily processed electronically. Examples for signals which can be registered are blood pressure, body temperature, heart rate, bioelectric potentials (EEG, ECG, EMG, EOG), metabolic parameters (glucose, pH-value) and the size and locus of space-occupying lesions.

Biosensors in the narrower sense include a biological detection component, which acts as a probe directly connected to the transducer. Its function is to specifically and sensitively react with the substance to be analyzed. In doing so, heat, electrons, protons, light, ions, gases, fluorescence and mass deviations can be generated. The biological component as the actual signal generator can consist of enzymes, microorganisms, organelles, cell

compounds or antibodies. It is immobilized at the transducer. Figure 46.4 shows the schematic of a biosensor.

The main requirement for a biosensor is a feedback-free registration of the signals. It has to provide reproducible measurement results. The transmission behavior has to remain constant for a long time, to enable long-term recordings and monitoring. Narrow production tolerances, a high biocompatibility, low stress to the patient, low mass and low volume are other requirements. The application should be simple and manageable. This is especially related to possibilities of cleaning, disinfection and possibly sterilization.

Development objectives for sensors are reliability enhancement including the reduction of artifacts, the increase of the amount of channels (multi-transducer technology) and complexity enhancement (closed-loop systems). On the one hand, this becomes possible by miniaturization including the reduction of mass, volume and power input, by new biomaterials and by the improvement of incorporation possibilities. On the other hand, new non-contact measurement procedures have

to be developed to enable a completely feedback-free registration.

Transducers

Chemoelectric Transducers. Chemoelectric transducers are used for the measurement of individual chemical components in the blood, in body tissues, in the exhaled air or on the skin. Distinctions are drawn between:

- Potentiometric sensors, based on the measurement of cell potential
- Amperometric sensors, based on cell current
- Conductometric sensors, based on admittance.

Potentiometric transducers generally consist of a metal electrode surrounded by a selectively permeable membrane, which is dipped into the electrolytes to be examined. The ions or molecules reaching the electrode change the electrochemical potential difference between this measuring electrode and a reference electrode dipped into a defined reference solution. The corresponding potential change is proportional to the logarithm of the ion concentration. As an example, Fig. 46.5 demonstrates the principle of a p_{CO_2} electrode.

Ion-selective field effect transistors have a gate which is surrounded by a membrane. Diffusion of ions or molecules through the membrane causes a change in the drain current, which can be registered as measurement signal.

Electric and Magnetic Transducers. Electric transducers are recording electrodes, which transduce an electric signal (ion current) into an electric signal (electron current). They are selected based on the properties of

Fig. 46.6 Needle electrodes for electromyographic examinations. *Top to bottom:* concentric needle electrode, bipolar needle electrode, single-fiber electrode, monopole needle electrode (*top indifferent, bottom different*)

the corresponding biosignal, its locus of generation, the dimensions of the bioelectric generator and environmental influences. The electrodes are distinguished into two groups: microelectrodes (glass capillary electrodes, metal microelectrodes) and macroelectrodes (surface electrodes, subcutaneous needle electrodes and depth electrodes).

In Figure 46.6, schematics of various types of needle electrodes are shown. For pure metal electrodes or polarizable electrodes, positively charged metal ions move into the electrolyte solution, thus creating the Helmholtz double layer at a molecular distance. This is the reason for the high electrode impedances especially in the low-frequency range. Thus, the field of application for such electrodes is the recording of high-frequency signals, such as evoked potentials.

For unpolarizable electrodes, the anion in the electrolyte solution is part of the metal electrode (e.g. Ag/AgCl electrode, electrolyte NaCl, anion Cl^-). This leads to a reduction and stabilization of the Galvani potential and thus to lower interface impedances in the whole frequency range. Figure 46.7 shows the equivalent circuit diagram of an electrode including the polarization voltage.

Biomagnetic examinations can be done with a superconductive quantum interferometer. Such a device contains one or two Josephson elements, which enable a current flow without a potential drop. They are built up as gradiometers, to inhibit the homogeneous sensor-remote magnetic fields, especially the terrestrial magnetic field (Fig. 46.8).

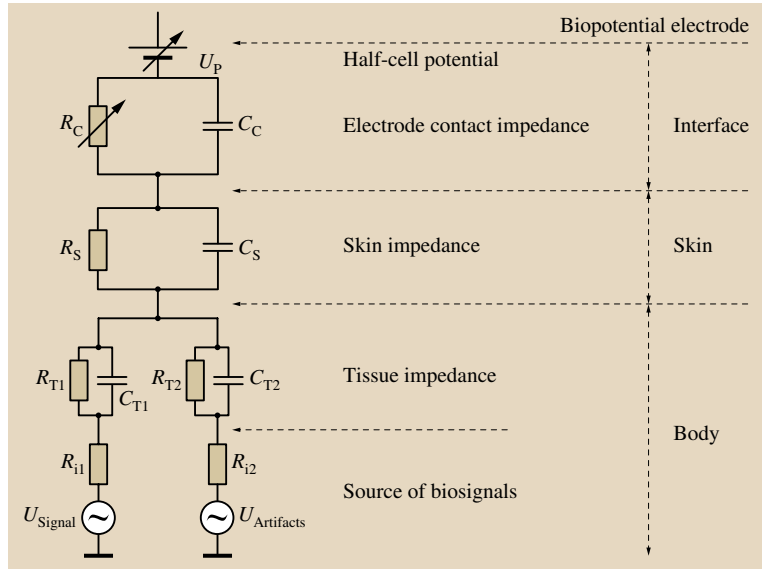

Mechanoelectric Transducers. To measure length changes, strains, pressure changes in tissue, body fluids and organs as well as for the measurement of sounds, microvibrations and blood flow, mechanoelectric transducers are used. Resistive, inductive and capacitive transducers have a membrane receiving the force change. This causes the membrane to deflect, which can be detected by a deformation of strain gauges or semiconductor resistances, by a shift of small iron or ferrite cores in a coil, or by a change in the distance of the two plates of a capacitor.

For a strain gauge, the resistance can be calculated from the geometry.

$$R = \rho \frac{l}{A}, \quad (46.1)$$

with R the Ohmic resistance, ρ the specific resistance, l the length, and A the cross-section of the conduc-

Fig. 46.7 Equivalent circuit diagram for the recording of biopotentials with surface electrodes (U voltage source for signal and artifacts, R_i internal resistance, $R_T C_T$ tissue impedance, $R_S C_S$ skin impedance, $R_C C_C$ electrode contact impedance, U_P polarization voltage)

tor. Alternatively, using piezoresistive elements as strain gauge in a Wheatstone bridge configuration, changes in resistivity can be observed that are up to one hundred times larger than the geometric effect yielding a more sensitive strain gauge and subsequently more sensitive pressure or force sensor.

If a force is applied to a capacitor yielding a change in the distance between its two plates, its capacity also changes

$$C_X = \epsilon_0 \epsilon_\gamma \frac{A}{x}, \tag{46.2}$$

with C the capacity, A the area, x the plate distance, and ϵ the dielectric permittivity. The measured value is determined using suitable measuring bridges.

Piezoelectric transducers consist of piezoelectric contacts. Mechanical stress in the direction of a polar electric axis causes the generation of electric charges due to a shift of the atoms, at very small deformations. The induced surface charge is the product of the piezoelectric constant and the external force

$$\Delta q = k \Delta F, \tag{46.3}$$

where Δq is the induced surface charge, ΔF the force change, and k the piezoelectric constant.

Hence, the potential change can be calculated to be

$$\Delta U = \frac{\Delta q}{\Delta C} = \frac{k \Delta F}{\epsilon_0 \epsilon_\gamma A} x, \tag{46.4}$$

with ΔU the potential change, ΔC the capacity change, A the area, x the plate distance, and ϵ the dielectric permittivity.

Fig. 46.8a,b Schematic design of a first- (a) and second-order (b) gradiometer for the registration of biomagnetic fields in nonshielded environments

The change of the surface charge can be measured. Figure 46.9 shows the schematic setup of a piezoceramics.

Hall sensors are used to measure magnetic fields and thus to register all parameters generating or influencing magnetic fields. The Hall voltage results from the

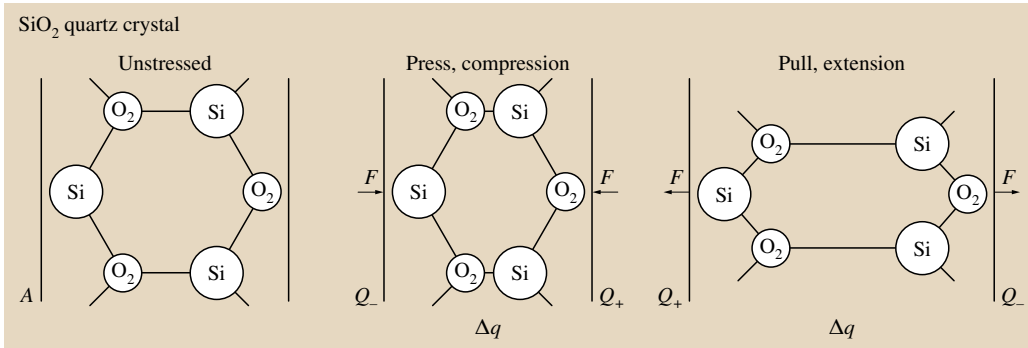

Fig. 46.9 Basic principle of the piezoelectric effect using a SiO_2 quartz crystal as an example. Owing to the positive Si ions and negative O_2 ions, a surface potential is generated in the deformed state (A surface, F force, Q_+ and Q_- electric charges)

Fig. 46.10a,b Schematic setup of a Hall sensor (a) and its corresponding characteristic curve (b) (U Hall voltage, B magnetic flux density, d depth of plate, I current across plate length, b breadth)

Lorentz force and is proportional to a control current longitudinally to a small plate subjected to a magnetic field and its magnetic flux density. It decreases with increasing electron concentration, and increases with increasing electron velocity and electron mobility. Figure 46.10 shows the setup and the characteristic curve of a Hall sensor.

Photoelectric Transducers. Photoelectric transducers include photoresistors, photodiodes, photoelements and phototransistors. Depending on the incident light intensity, the current flowing through the device is changing. Thus, light absorptions and light reflections of body tissue and biological substances can be detected, to measure blood circulation and oxygen saturation.

Thermoelectric Transducers. Using a thermocouple consisting of 2 different metal wires, a thermoelectric voltage (Seebeck effect) can be measured between the

contacts for a temperature difference

$$U_T = \alpha_T \cdot (T_2 - T_1) , \quad (46.5)$$

with U_T the thermoelectric voltage, T the temperature, and α_T the Seebeck coefficient.

The thermoelectric voltage depends on the temperature and the selected metals (Fig. 46.11).

Thermistors (NTC resistors or high-temperature conductors) are sintered elements based on oxide composites. Their Ohmic resistance depends on the temperature (NTC, negative temperature coefficient). By connecting a resistor in parallel, it is possible to linearize the exponential run of the characteristic curve. Thermistors are used for the routine measurement of the respiration flow and the body temperature (Fig. 46.27).

Infrared-sensitive semiconductor materials, such as HgCdTe , InSb and PtSi , enable the conversion of the infrared radiation emitted by a patient into an electrically analyzable signal. Thus, temperature distributions can

Fig. 46.11 Picture of a thermocouple consisting of metals A, B, and C. The thermoelectric voltage is proportional to the sum of the three individual voltages at the metal interfaces

be measured. The materials have to be cooled, which can be done using liquid nitrogen, a Stirling cooler or a Peltier element.

Other Transducers. For the indirect measurement of biosignals, also methods are applied which do not immediately register the biosignal itself, but measure the influence of irradiance and waves as well as the distribution of radioactive substances etc. These include particularly imaging techniques using radioactive isotopes (PET, SPECT), magnetic fields (MRI) and x-rays (CT, angiography). If isotopes are used, a scintillation camera acts as the transducer. It consists of a NaJ monocystal transducing gamma radiation into a light

signal. If the light quanta are incident on a photocathode, electrons are released, which can be amplified using a secondary electron multiplier. For x-rays, luminescent screens with an adjacent photocathode and an image amplifier are used.

For biochemical examinations in a clinical chemical laboratory, a variety of transducers and methods are used. For instance, chemical and biological reactions are applied with antibodies and enzymes, cell cultures are grown in culture media, substances are separated into their components, and interactions with light, magnetic fields or flames are registered. Transducers have to be able to count particles, cells and blood cells, and to register the temporal and spatial fractionation of substances. This also includes changes in the chemical composition of material mixtures, changes in color or temperature, absorption and emission of radiance, and the registration of nuclear magnetic resonance and electron spin resonance.

Transducers can for instance be microphones of a photoacoustic spectrometer, photodiodes used to count flowing blood cells which temporarily intercept or attenuate a laser beam, coils for magnetic resonance spectroscopy or semiconductors for infrared spectroscopy.

Amplifiers

Figure 46.12 shows the basic equivalent circuit diagram of a biosignal amplifier consisting of two input impedance transformers and a differential amplifier. The amplifier is characterized by a high input imped-

Fig. 46.12a,b Amplification of biosignals. (a) Setup of a differential amplifier; (b) control of the frequency response (amplitude and phase) with high-pass or low-pass filter

Fig. 46.13a,b Dynamic properties of a sensor. (a) Input and output relation for nonlinear transfer function; (b) sensor with time delay (dead time) and oscillating behavior

ance and a low output impedance. It is set up as differential amplifier with a high common mode rejection, so that the output voltage (U_3) is a multiple of the difference between the two input voltages (U_1 and U_2). Other properties of the amplifier are sensitivity or amplification, linearity between the input and the output signal, frequency response, phase response and noise. Depending on the properties of the biosignal, the amplification and the frequency response have to be selected. The latter is controlled with a high-pass or a low-pass filter.

Signal Processing

The ideal transmission behavior of a measuring chain is linear, i. e. a change in the measurand is directly and unambiguously related to the corresponding measured value. In reality, the relation is not linear, owing to the selected measurement process, the nonlinearity of the transducers, the influence of noise causing measurement errors, and the indirect registration of the measurand (Fig. 46.13).

Influence quantities are changes due to temperature deviations, pressure deviations and transducer deterioration. An example for a nonlinear transmission behavior of a measurement system is the invasive measurement of the arterial blood pressure with an external transducer. The system consists of the arterial catheter, the reusable valve, the pressure-sensitive transducer and the rinsing system. This coupling path is filled with physiological saline. Owing to the compliance of the tubes and the transducer membrane, to the flow resistance and the volume, it is an oscillatory system. To minimize the influence on the amplitude and the phase of the wanted signal, the catheters and the connecting tubes should be as rigid, short and large-volume as possible, air bubbles should be avoided, the transducer

membrane should be rigid and the coupling path should be fixated.

The objective of signal processing is the correction of the nonlinear transmission behavior of the measuring chain. By a generally multistage signal processing, the signal is transformed into a mainly electric output signal. Digitalization enables a variety of complex algorithms and control modes. Besides measurand conversion, signal transduction, filtering and amplification, these methods particularly include linearization. This is achieved to a large extent by stabilizing the zero point and the sensitivity as well as avoiding the drift of signals. By tracing the characteristic curve, it is possible to control the transmission behavior of the measuring chain. Further approaches include models of the measuring chain and the identification of coefficients as well as the determination of the parameters for adaptive control.

In order to do so, the signal has to be A/D-converted, i. e. the continuous signal is temporarily sampled and its amplitude is quantified. The Shannon sampling theorem states that the sampling rate has to be at least twice the highest frequency contained in the signal (Nyquist frequency). In order to optimally convert the curve shape, the sampling rate should be even higher (5 or 10 times the maximum signal frequency).

A violation of the sampling theorem causes a falsification of the signal in the time domain and the occurrence of reflections in the frequency domain (*aliasing*), with the latter being displayed as apparent amplitudes in the frequency spectrum.

Storage and Registry

Direct Writing. Direct writing enables direct and immediate signal output on a graph paper. This can be

Fig. 46.14 Setup of a thermal comb

achieved with a write pointer or a writing lever, whose deflection can be controlled by a measuring instrument, often a rotary magnet in a coil field. The write pointer can be heated and thus writes a graph on thermosensitive paper. But it can also be an ink jet nozzle with a piezoelectric element activated by voltage pulses or a heating element generating a steam bubble by current pulses. In both cases, the resulting pressure causes ink to be sprayed on the graph paper.

In pigment printing, carbon paper and graph paper move in opposite direction over a writing edge. The write pointer is pressed against this edge. Thus, its movements create an orthogonal output.

Other techniques are laser printers and thermal comb writers (Fig. 46.14). The latter include thermal elements on a substrate, which can be controlled digitally. They write a graph on thermosensitive paper. Besides curves, also alphanumeric and graphic outputs are possible.

Indirect Writing. Indirect writing techniques include photo writers and UV writers. Here, a moving light spot is projected onto special photo paper by a mirror. The result is only available after developing the photo paper.

Monitor. Measurement results can also be shown on a monitor or on digital or analog displays. As the data is easily readable, especially the latter are of great importance for medical diagnostics and for the monitoring of intensively treated patients.

Storage. Biological signals can be stored on conventional data storage media, such as hard disk, DVD,

CD-ROM, MOD, ZIP disks and magnetic tape. Here, it must be guaranteed that the storage media keep their data for a period of 10 years in good condition. Different database management systems help to operate the databases, provide storage, access, security, backup etc. For the exchange, management and integration of electronic healthcare information standards like the Health Level Seven (HL7) should be used.

Transmission (Telemetry)

For medical objectives, signals are increasingly transmitted telemetrically. This may concern signals generated directly in the body of the patient, which provide information about the patient's state or the functional state of an implanted device. For evaluation, both signals have to be displayed outside the body (e.g. for cardiac pacemaker patients the intracardial ECG and the charge of the pacemaker battery). This is done with magnetic transmission coils. In addition, it is possible to program a pacemaker via this path. Figure 46.15 shows a programmable cardiac pacemaker as an example for telemetry. Here, the read-out data can also be transmitted to a diagnostic station via internet.

Another application of telemetry is the examination of patients moving freely in the meantime. Here, the examination results have to be transmitted to an evaluation station or a diagnostic center. Such applications are particularly important for long-term monitoring of EEG, ECG, blood pressure and labor pains as well as for sports medicine and occupational medicine. For telemetric transmission, a transmitter and appropriate modulation of the signal are required. For amplitude modulation, the low-frequency signal is converted

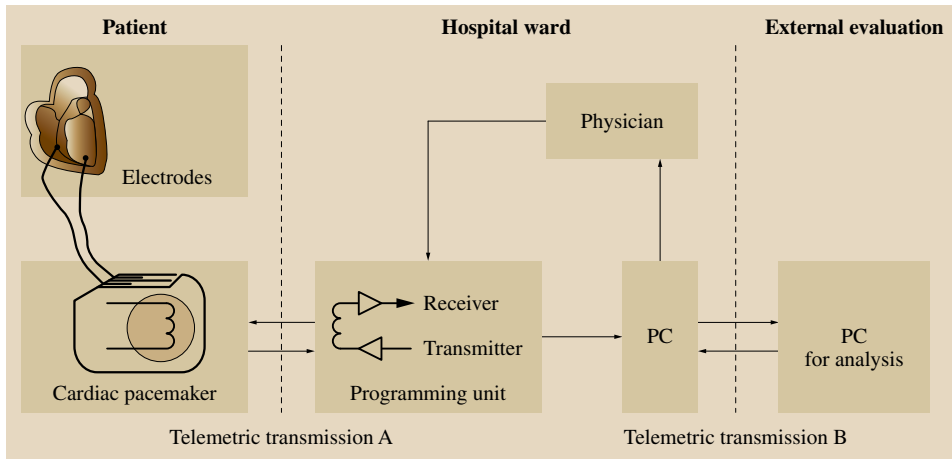

Fig. 46.15 Telemetric transmission paths for a programmable cardiac pacemaker (A via transmitting and receiving coils, B via Internet to a diagnostic computer)

into a high-frequency signal with constant frequency, but varying amplitude. For frequency modulation, the amplitude change of the biosignal is coded by the frequency change, for pulse-width modulation by the duration of square-wave pulses, and for pulse-position modulation by the temporal position of two impulses to each other. For evaluation and display, demodulation is required on the receiving side.

Transmission via telephone and cell phone is also possible. Digital transmission of biosignals has opened up new possibilities of signal transmission, also via internet. Parallel and serial data transmission are the two main possibilities. Standardized interfaces have been created requiring data transmission protocols.

Via telemetric transmission, it is possible to directly influence the patient. One example is the application of surgery robots in sparsely populated regions of the earth. Here, telemedicine offers new opportunities.

Application of Stimuli, Substances,

For medical objectives, it is often important to observe the reaction of the patient towards stimuli with respect to diagnostics. These stimuli can be mechanical, for instance to provoke reflexes, electrical or magnetic to determine the nerve conduction velocity, acoustic, optical or electrical for the stimulation to record evoked potentials and to test sensory performance. By using substances, which may also be radioactively labeled, their participation in metabolism can be examined, and thus their transport velocity, their accumulation site or their expulsion dynamics. The application can be systemic or localized.

The reflection of ultrasound waves enables the display of moving interfaces to view anatomical structures,

but also work movements, for instance of heart valves, and to measure the blood flow velocity. By absorption measurement of x-rays, anatomical structures can be measured. Physical stress is used for cardiac stress tests, and for physiological examinations to measure e.g. the sympathetic skin response or the heart rate.

Process Control

The temporal correlation within the measuring chain is controlled by the process control. This includes signal processing with the setting of the sampling rate for the A/D converter, the synchronization of the averager and the stimulator, and the choice of the corresponding time-frame. Process control also includes the setting of parameters for amplification, signal analysis, storage and registry.

46.1.3 Artifacts

The registered biosignals are often superimposed by interferences, so-called artifacts. Those are registered together with the wanted signal and impede or preclude its evaluation. With respect to their point of origin, artifacts can be divided into biological and technical artifacts. They are caused by metrology, the applied method and by the patient. In the following, electroencephalography is used as an example to briefly explain artifacts:

1. *Physiological artifacts* are biological signals superimposed to the EEG, but with non-cerebral origin. Examples include various forms of electromyographical signals (EMGs) such as eye movements (EOG), tense neck (muscle artifacts), ECG, as well as pulse waves if an electrode is placed directly on

Fig. 46.16 Biological artifacts in EEG. *Top to bottom:* eye movements, sweating, muscle contractions, pulse, and ECG

a pulsating vessel, heavy sweating and spontaneous movements of the patient. Figure 46.16 shows examples of biological artifacts.

2. *Technical artifacts* are errors in the recording and registration technique. They can also be found at contact sites (electrode–skin, cable–electrode, cable–connector, connector–socket), if different electrode types and materials are used simultane-

ously, or for cable defects, cable movements and in the absence of grounding.

3. *Externally caused technical artifacts* are galvanically coupled interferences via direct, and high-resistance circuits, capacitively coupled currents due to alternating electrostatic fields, alternating magnetic fields and high-frequency alternating electromagnetic fields.

46.2 Registration of Biological Signals

Many biological processes are related to acoustic phenomena (Table 46.1).

46.2.1 Bioacoustic Signals

This includes sounds of the upper respiratory tracts (snoring, speech), lung sounds and heart sound. The latter evolves from the opening and closing of the heart valves and is registered phonocardiographically. For the bloodless blood pressure measurement, oscillations of the vessel walls are registered as signal. They occur due to the squeezing and reach a maximum at a cuff pressure between the systolic and the diastolic value. Bioacous-

tic signals can be registered with a microphone and a stethoscope.

46.2.2 Biochemical Signals

Biochemical signals can be determined both *in vivo*, i. e. inside the body of a patient, an *in vitro* in a laboratory. They are the result of metabolic processes and can be described by identifying their structure, composition, concentration of their constituents and partial pressure. They can be registered directly or by reaction with enzymes, antibodies or cells.

The methods for examination of tissue or body fluids range from electrophoresis, gas chromatography, flame absorption spectroscopy, mass spectroscopy and infrared spectroscopy to scanning electron microscopy. The applied chemical transducers are used to determine the structure, the composition and the respective concentrations. This also includes cell counting and blood cell counting.

Table 46.1 Bioacoustic signals

Signal	Specification	Frequency (Hz)
Heart sound	Adults	15–1000
	Fetus	15–150
Lung		0.2–10

One example for the detection of biochemical signals is glucose identification. The reaction

catalyzed by glucose oxidase can be amperometrically detected by the O_2 consumption or the hydrogen peroxide formation. The schematic of an amperometric glucose electrode is shown in Fig. 46.17.

Infrared spectrometers measure the intensity attenuation of infrared radiation after passing a measuring cuvette and compare it with a reference

$$I_a = I_0 e^{-kcl} \quad (46.7)$$

with I_a the output intensity, I_0 the input intensity, c the concentration, l the layer thickness, and k a constant of proportionality.

Fig. 46.17 Schematic setup of an amperometric glucose electrode

Fig. 46.18 Setup of an infrared spectrometer (I_0 input intensity, I_a output intensity, I_b reference intensity)

Owing to the chopper, the detector is alternately irradiated with both intensities. Before reaching the detector, the polychromatic light is filtered to the measurement wavelength. The schematic setup is depicted in Fig. 46.18.

46.2.3 Bioelectric and Biomagnetic Signals

Bioelectric signals (Table 46.2) are potential differences originating from processes at the membranes of nerves and muscle cells, leading to rest and action potentials. Excitations are routed as action potential and, in the case of a motor unit, cause muscle contractions. Depending on the source, EEG, EMG, EOG, ERG, ECG etc. can be distinguished.

Bioelectric potentials can be recorded with electrodes. Registering the potential difference between two electrodes on electrically active sites is denoted as bipolar recording. If one of the electrodes is placed on a site which is considered to be rather electrically inactive, for instance at the earlobe for EEG recordings, the recording is called unipolar.

One example is the ECG with the bipolar recording from limb leads (Fig. 46.19). For the latter, the reference is the neutral point of the interconnection of several electrodes via equal resistances, in order to create an

Table 46.2 Bioelectric signals

Signal	Frequency (Hz)	Amplitude (mV)
ECG (heart)	0.2–200	0.1–10
EEG (brain)	0.5–100	2–1000 μV
EMG (muscle)	10–10 000	0.05–1
EGG (stomach)	0.02–0.2	0.2–1
EUG (uterus)	0–200	0.1–8
ERG (retina)	0.2–200	0.005–10
EOG (eye)	0–100	0.01–5
FAEP (brain stem)	100–3000	0.5–10 μV
SEP (somatosensory system)	2–3000	0.5–10 μV
VEP (visual system)	1–300	1–20 μV

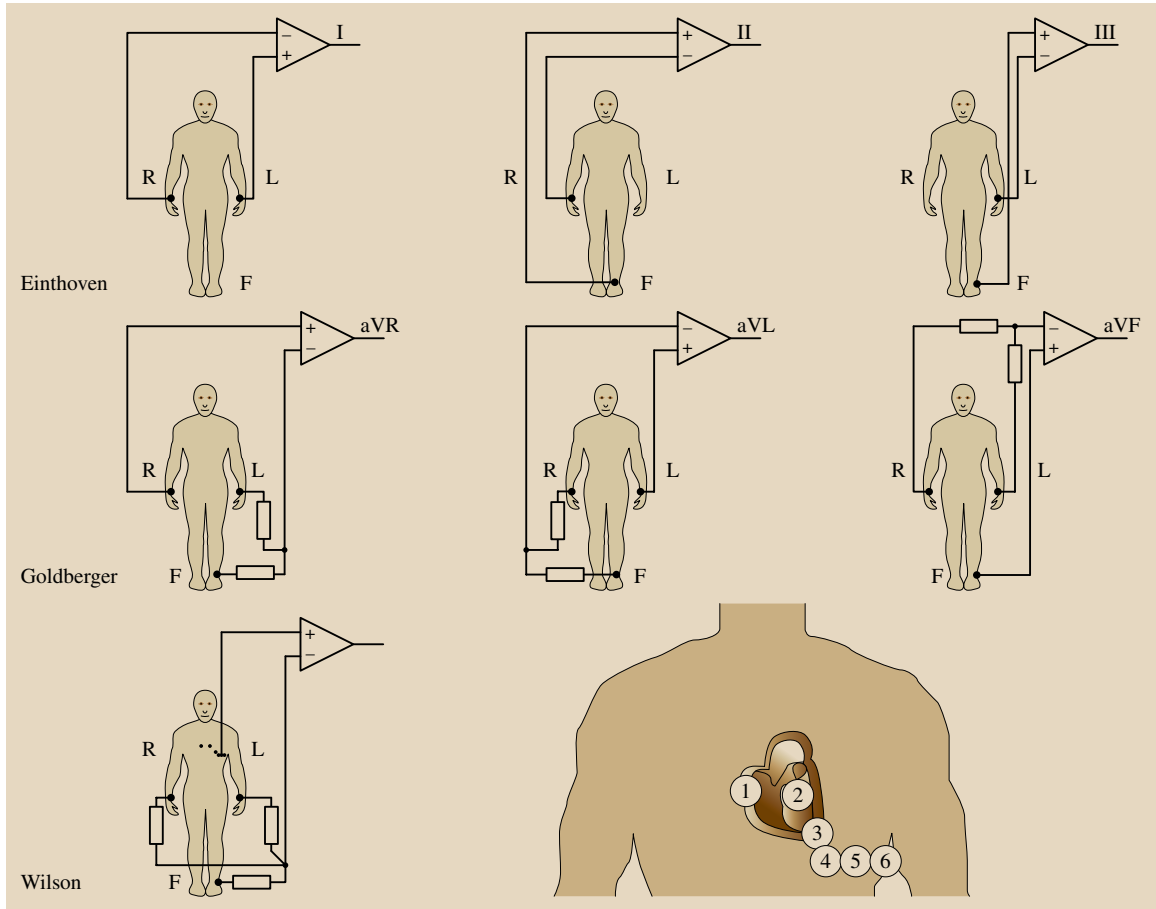

Fig. 46.19 Possibilities of ECG recording with surface electrodes (standard recordings)

Table 46.3 Biomechanical signals

Signal	Spezification	Amplitude	Conversion
Pulse (rate)		720–200 min ⁻¹	
Breathing (rate)		5–60 min ⁻¹	
Blood pressure (arterial)	Systole	8–33 kPa	60–250 mmHg
	Diastole	5–20 kPa	40–150 mmHg
Blood pressure (venous)		0–4 kPa	0–30 mmHg
Intraocular pressure		0–7 kPa	0–50 mmHg
Blood flow		0.05–5 l/min	
Blood flow velocity		0.05–40 cm/s	
Respiratory flow velocity		20–120 cm/s	
Cardiac output		3–8 l/min	
Respiratory volume		200–2000 ml/gasp	
Muscle work		10–500 W	
Blood volume	Adults	7000 ml	
Amount of urine	Adults	1500 ml/d	
Nerve conduction velocity	Median nerve	50–60 m/s	

Fig. 46.20 Simultaneous registration of a somatosensorily evoked potential and the somatosensorily evoked magnetic field after stimulation of the median nerve of the right hand

average reference with the average potential of those electrodes. Recordings from the limbs and from the chest wall are perpendicular to each other. Thus, the spatial potential distribution can be calculated.

As electric phenomena are always accompanied by a magnetic field, they can also be detected by registering the magnetic field. With superconductive quantum interference devices (SQUID), these magnetic fields can be detected. The sources can be exactly located, which makes this method advantageous. As an example, Fig. 46.20 shows the simultaneous registration of a somatosensorily evoked potential and its corresponding magnetic field after electrical stimulation of the median nerve. For the magnetic registration, five second-order gradiometers were used. Thus, measurements in unshielded environment are possible.

46.2.4 Biomechanical Signals

Biomechanical signals represent the mechanical functions of the biological system. Some examples are mentioned in Table 46.3.

Movement

The measurement of movements is important for diagnostics, but also for the optimization of motion sequences. Thus, the motion sequence during walking is registered for both the fitting of lower extremity prostheses and post-fracture physical therapy. The extremities can be marked with optical markers, and the motion sequence can be recorded with a video camera. Subsequently, image processing techniques can be used to determine the position of the light spots to each other and to calculate the movement.

For tracking examinations of the upper extremities, a goniometer is fixed, e.g., at the elbow joint to

measure the angle between the upper arm and the forearm. Quantitative measurements of tremor, for instance in Parkinson's patients, and of spontaneous periodic leg movements during sleep, is also diagnostically important. Eye movements can be measured electrooculographically, photoelectrically and videooculographically. From the registered movements, the velocity and acceleration of the motion can be calculated.

Pressure

Various forms of pressure measured for clinical purposes are blood pressure, cerebral pressure, intraocular pressure, pressure during labor pains etc. Blood pressure can e.g. be measured invasively by a catheter with an attached pressure transducer consisting of a resilient membrane connected to strain gauges. In a different setup, the transducer is directly positioned inside the blood vessel. Figure 46.21 shows two pressure transducers.

Blood pressure can also be measured indirectly from the cuff pressure squeezing an artery. At the point when the blood begins to flow again, measurable sound occurs, which disappears for unobstructed blood flow. Thus, systolic and diastolic blood pressure can be measured.

Flow

The detection of respiratory flow is important for the monitoring of risk patients. It can be detected by placing a thermistor below the nose measuring the temperature difference between the exhaled and the inhaled air. Respiration flow can be quantitatively measured with a pneumotachograph. With this method, it is also possible to calculate the respiratory volume by integrating the flow (Fig. 46.22)

$$\dot{V} = \frac{\pi r^4 \Delta p}{8l\eta}, \quad (46.8)$$

with \dot{V} flow volume, r radius, l length, η viscosity, and Δp the pressure difference, where

$$V = \int_0^t \dot{V} dt, \quad (46.9)$$

where V is the volume.

Blood flow can be determined by measuring the magnetic-inductive flow and with the ultrasound Doppler method (Fig. 46.23). The measurement signal is the frequency shift between transmitted and received signal due to the movement of blood cells

$$\Delta f = f_1 - f_2 = f_1 \frac{2v \cos \varphi}{c}, \quad (46.10)$$

Fig. 46.21a,b Sensors and transducers for invasive measurement of blood pressure. (a) External transducer, (b) internal transducer

Fig. 46.22 Functional principle of a pneumotachograph. The respiratory volume can be calculated by integrating the respiratory flow over time

where Δf is the frequency shift, f_1 the transmitted ultrasound frequency, ϕ the angle of incidence, v the particle velocity, and c the speed of sound in tissue.

Measurement of volume in form of volume flow is very important. For instance, the amount of urine within a certain time is measured as well as the forced expiratory volume in 1 s (FEV1) and the cardiac output. To determine the cardiac output, indicator dilution methods are applied. Commonly used indicators include dyes, radioactive substances and cooled NaCl/dextrose solution. Impulse-type injection of the indicator is preferred, to obtain a homogeneous mixture with the flowing blood. Downstream, an indicator dilution curve

Fig. 46.23 Measurement of the blood flow velocity using the Doppler effect

is registered reflecting the velocity distribution in the considered segment of the flow path and corresponding to the transfer function (Fig. 46.24).

The cardiac output can be determined using the relation

$$CO = \frac{m_0}{\int_{t_0}^{\infty} c(t) dt}, \quad (46.11)$$

where CO is the cardiac output, m_0 the amount of injected substance, and c the indicator concentration.

Velocity

Velocities have already been discussed for the registration of movements and the measurement of volume flow. Measurement of nerve conduction velocity ex-

Fig. 46.24 Indicator dilution curve to detect the cardiac output (t_0 time of injection, t_1 beginning of concentration increase, t_2 maximum concentration, t_3 beginning of recirculation)

Fig. 46.25 Functional principle of a quartz microbalance

hibits a few special features. It is determined electrophysiologically after stimulation of a nerve at two sites and registration of the corresponding motor response for motor nerves. From the difference of the latency periods and the distance between the stimulation sites, the nerve conduction velocity can be calculated as

$$\text{NCV} = \frac{\Delta s}{\Delta t}, \quad (46.12)$$

with NCV the nerve conduction velocity, Δs the distance between the stimulation electrodes, and Δt the difference of the latency periods of the motor response potentials.

For sensory nerves, orthodromic and antidromic nerve conduction velocity are distinguished.

Size, Shape, Volume, Mass

Size and body weight are of great importance to evaluate the development of a human. This concerns also individual organs. Tape-measures and scales are used for the measurement. But also for standardization of laboratory values, e.g. for the determination of creati-

Fig. 46.26 Absorption spectrum of deoxyhemoglobin and oxyhemoglobin. The various absorptions are used to measure the oxygen saturation with a pulse oximeter

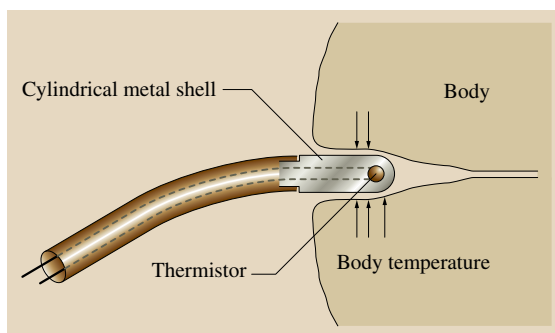

Fig. 46.27 Measurement of the body temperature using a thermistor

nine clearance, weight and size have to be known. They can be used to determine the body surface area, corresponding to the size of the glomerular membrane.

The localization, size and dimension of space-occupying lesions as well as changes in these parameters are also important. Those may be determined using imaging procedures, also including the evaluation and measurement of fractures and the size and location of organs.

Small masses with a detection limit of 10^{-12} g can be registered with a quartz microbalance (Fig. 46.25). The measurement is based on the resonance frequency shift of an oscillating crystal due to deposition of substances on the crystal surface

$$\Delta f = \frac{2.3 \times 10^6 f_0^2 \Delta m}{A}, \quad (46.13)$$

with Δf the frequency shift, f_0 the resonance frequency of the quartz without deposit, A the area with deposit, and Δm the mass change.

Fig. 46.28a,b Thermographic measurement of the surface temperature of the back of the hand of a 20 year old female test person before (a) and 2 min after smoking a cigarette (b). The temperature reduction due to a reduced blood circulation can clearly be seen

The surface can also be (bio-)chemically active, enabling the adsorption of substances to increase the mass.

The electrical properties of biological tissue can be described by the dielectric permittivity and the specific resistance. They vary depending on the blood circulation. Using impedance plethysmography, volume changes and pulsations are registered by the associated

impedance change. Thus, it can be used to determine the heart stroke volume.

Force

Force can be measured using mechanical dynamometers indicating an elastic deformation due to the contraction of a muscle or a muscle group. The simplest method is a force measurement from the elongation of a spring. Other applied devices include hydraulic dynamometers indicating the pressure created by a piston in a liquid, and quartz dynamometers with a piezoelectric crystal.

46.2.5 Biooptical Signals

The evaluation of color, for instance of the skin of newborns or shock patients, is an important criterion for the estimation of the current vital situation. Using fluorescent dyes, optical measurement of pH value, CO_2 and O_2 with so-called optodes becomes feasible. For this method, reagents sensitive to the respective target are necessary. Another field of application is the evaluation of O_2 saturation based on the different absorption characteristics of oxygenated and deoxygenated hemoglobin (Fig. 46.26). Changes in the fluorescence of tissue during the application of laser enables the intraoperative discrimination between healthy tissue and tumor tissue.

46.2.6 Biothermal Signals

The most important biothermal signal is the body temperature measured with a thermometer, thermistor or an infrared thermometer (Fig. 46.27). Using thermography, the temperature distribution on a skin area can be determined. Changes occur due to superficial space-occupying lesions as a consequence of increased blood circulation or circulatory disorders. Figure 46.28 demonstrates the influence of nicotine on blood circulation and thus a simulated circulatory disorder.

46.3 Measurement and Signal Analysis from a Metrological Point of View

The statistical evaluation of measurement data includes on the one hand the description of results which can be directly extracted from samples, on the other hand an analytical comparison of the results of the concrete sample of the population. Here, estimation procedures provide approximations of the characteristic values of

the population. For instance, the t test can be used to test if two average values belong to the same population. Other test methods include the χ^2 test, the F test and the U test. Further information can be gained from plotting the measured values as frequency distributions, diagrams or time series.

46.3.1 Biostatistical Methods

Univariate Statistical methods

Table 46.4 summarizes the formulas used to calculate the average value, the standard deviation, the test statistics for the *t* test, the correlation coefficient and the coefficients for a linear regression function. In the *t* test, the null hypothesis, claiming that both average values belong to the same population with a predefined probability value, is rejected if the test statistic is greater than the quantile of the *t* distribution.

Multivariate Statistical Methods

In contrast to the univariate methods, multivariate methods simultaneously include several measured values or parameters in the analysis. Important methods are cluster analysis, discriminant analysis and factor analysis.

Cluster Analysis. Cluster analysis aggregates the sample cases in several clusters. This is done based on the rule that the cases within only cluster should be as homogeneous as possible, while each cluster should be significantly different from the others. Similarity is the criterion for the aggregation of cases to clusters. Different methods have been developed for this procedure. The cluster membership provides information to the physician with respect to the allocation of a patient to a patient group.

Discriminant Analysis. Discriminant analysis is done to predict the assignment of new observations to a group. The simplest case is the assignment to a positive or negative test result, i. e. pathological or healthy. The dependent variables represent the membership to two or more groups.

Discriminant analysis consists of two steps:

1. The estimation of a discriminant function
2. The classification of the cases with respect to this function.

Often, the discriminant function is a linear combination of criteria essential for the separation

$$D = b_0 + \sum_{i=1}^n b_i x_i, \tag{46.14}$$

where *D* is the discrimination value, *b* the coefficients, and *x* the measured values.

The discriminant function is derived in a multistage process, and is optimized each time based on the indispensability and the separation measure. Figure 46.29 shows the result of a reclassification.

Table 46.4 Parameters of univariate statistics

Parameter	Formula
Average value	$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$
Standard deviation	$s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2}$
Test statistic for student test (<i>t</i> test)	$t = \frac{\bar{x}_1 - \bar{x}_2}{S_G} \sqrt{\frac{n_1 n_2}{n_1 + n_2}}$ $S_G = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}$
Degree of freedom	$f = n_1 + n_2 - 2$
Regression line	$y = a + bx$
Slope of the regression line calculated from the minimum square deviation of the measured values y_i from the line	$b_{yx} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2}$ $a_{yx} = \bar{y} - b_{yx}\bar{x}$
Linear correlation coefficient	$r_{xy} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}$

46.3.2 Biosignal Analysis

The fast development in computer technology has opened up many possibilities for measurement analysis in time domain, frequency domain and complex variable domain. Often, results of the methods are combined and plotted together. The connection to hospital information systems and the direct access to patient data is a very important backing. This concerns also the already mentioned biostatistical methods.

Time Domain. Biosignal analysis in the time domain improves the processability of the measured biosignals and extracts features and parameters from the signal.

Fig. 46.29 Reclassification of cases based on the calculation of the values of the discriminant function. The frequency distribution is depicted. The healthy and the patient groups can be easily separated

Fig. 46.30 Calculation of the autocorrelation function from the ECG. The varying distance between the R peaks due to breathing is reflected in the periodic component of the function (HF heart rate, AKF autocorrelation function)

The main fields of application are time variate signals describing the functional state or its change in functional diagnostics. Examples are heart-rate change and the occurrence of epileptic activity in the EEG.

The first stage of signal analysis is the detection and elimination of biological and technical artifacts and high-frequency noise. The latter can be easily minimized using moving averaging or smoothing algorithms such as

$$y_n = \frac{y_{n-2} + 2y_{n-1} + 3y_n + 2y_{n+1} + y_{n+2}}{9}, \quad (46.15)$$

where y is the amplitude.

The influence of biological artifacts can be minimized by additionally recording the respective biological signal. In consideration of the amplitude ratio and possible changes in shape, the artifact (e.g. EOG or pulse in EEG) can be subtracted from the wanted signal.

Averaging is often applied to improve the signal-to-noise ratio. It can be used if the wanted signal is

temporally correlated with an event, e.g. a stimulus. Using continuous averaging, the signal-to-noise ratio increases proportionally to the square root of the number of averaging steps. Averaging is indispensable for the recording of evoked potentials superimposed by the EEG.

Other methods include the detection of patterns and events and their measurement with respect to temporal occurrence, duration, amplitude, frequency, shape and individual components. Examples are the measurement of waves and peaks in the ECG, the determination of the heart-rate from the distance of the R peaks, and the latency of individual waves in an evoked potential. Often, the detection of features and parameters is connected with a classification.

To determine the similarity of two signals, the cross-correlation function can be calculated. If the signal is correlated to itself, the autocorrelation function is obtained. It can be used to gain information about a periodic component in the signal, and about the stochastic component using the exponential decay. Figure 46.30

Fig. 46.31 Mapping of the cortical bioelectric potentials during a movement of the field of vision to the right. The dynamics of the potential distribution is displayed in steps of 1 ms for the period of 5–9 ms after saccade initiation

shows an example of the periodic variation of the R peak distance due to breathing, which can be determined from the rest ECG using autocorrelation.

In order to plot two-dimensional potential distributions on a body region, the potential values between the electrodes are interpolated. Subsequently, points with equal potential are connected (isopotential lines) or color-coded. The thus obtained maps can be used to get a general idea of the activity distribution and the localization of events. As an example, Fig. 46.31 shows the map of the cortical potential distribution during a saccadic eye movement. Mapping is also applied in the frequency domain.

Mathematical models can be used to perform calculations to locate bioelectric sources, and to solve the inverse problem. This means that the measured magnetic field distribution is compared to a field distribution calculated based on an assumed dipole, thus optimizing the dipole location.

Frequency Domain. Signal analysis in the frequency domain is done to gain information about the frequencies contained in the signal. The biosignal, whose amplitude is a function of time, is transformed into a signal, whose amplitude is a function of frequency. Often, Fourier transformation or fast Fourier transformation (FFT) is used. Amplitude spectra and power spectra can be calculated.

The latter provide information about the power of a certain frequency in the signal. If the frequency spectrum of an interference is known and outside the spectrum of the wanted signal, it can be subtracted from the signal. After back transformation into the time domain, an almost noise-free signal can be obtained. This procedure is called optimal filtering. But also high-pass filters and low-pass filters can be achieved using this method.

Other transformations include the z transformation, Walsh transformation and wavelet transformation. The latter does not consider the signal as a combination

of sine and cosine functions, but as a combination of square functions or wavelet functions.

Image Processing. Images are two-dimensional representations which can be obtained using imaging techniques (CT, MRI, PET, thermography) or mapping of biopotentials. During their generation and processing, they are represented as matrices of gray scale values. One of the primary objectives of image analysis is to detect and locate space-occupying lesions and other processes which can be displayed, and to measure geometric structures. Images are created based on various physical methods.

In image processing, the stages:

- Image editing
- Image improvement
- Detection
- Segmentation

can be distinguished.

Linear methods of image improvement are related to contrast, focus and noise suppression. Various methods of convolution, filtering, rotation and transformation are used. But also the subtraction of images, for instance in digital subtraction angiography, is part of image processing. Here, a mask is subtracted from an image, to increase the contrast of important image components, which can hardly be distinguished from surrounding structures, and thus to highlight the desired structure. By determining the time-dependent behavior and the concentration of contrast agents in a part of the vascular system, dynamic information can be gained.

46.4 Test Planning and Clinical Studies

In order to conduct clinical studies, the required measurements have to be planned systematically. Here, data can be collected retrospectively, prospectively or experimentally. It is necessary to estimate the amount of samples and to ensure that samples are collected stochastically. This includes the consideration of the independence of the elements of a sample, each having the same chance to be included in the sample.

To avoid influence by the patient on the examination result (placebo effect), blind tests are run to ensure that the patient has no information about the influencing factors. In medication studies, this means that he does not know if he receives a placebo or the active drug. If this is also concealed to the examiner, the experiment is denoted as double blind method.

Knowledge-Based Systems

To support the physician in decision making, methods of artificial intelligence are often applied. Thus, expert systems based on knowledge are established, and the examiner can use these to find a solution by creating links. Often, rules are executed to simulate the special knowledge and the approach of experts. The explanation component pointing out the solution path is vital. Neural networks can be used for pattern recognition after a learning stage. A drawback of this method is the fact that they do not provide an explanation component. Thus, the interpretation of the results is sometimes problematic.

Biological Models and Simulation. The modeling of biological systems and the identification of the model parameters is useful to gain new insights (system research), to understand the system and to apply technical knowledge (system control). The developed models can be used for PC simulation. By experiments and the measurement of target values, the model can be compared to the biological system, validated and improved on this basis.

But also the measurement of the transmission behavior of biological systems and the identification of its order yields new models. Of particular importance is the description of control loops, for instance the regulation of blood pressure, body temperature, heart activity, the pupils, eye movements and reflexes. Knowledge of blood sugar regulation and its simulation is one of the preconditions for the development and the application of implantable insulin pumps.

Observation units, which are largely homogeneous with respect to interference, can be combined to blocks. Thus, connected or paired samples can be obtained. Pharmacokinetics and the biological and

Table 46.5 Contingency table for evaluation of diagnostic methods

	Patient diseased K	Patient healthy \bar{K}	Sum
Test positive T	True positive TK	False positive $T\bar{K}$	$TK + T\bar{K}$
Test negative \bar{T}	False negative $\bar{T}K$	True negative $\bar{T}\bar{K}$	$\bar{T}K + \bar{T}\bar{K}$
Sum	$TK + \bar{T}K$	$T\bar{K} + \bar{T}\bar{K}$	

Table 46.6 Parameters for evaluation of a diagnostic method

Parameter	Description	Formula
Sensitivity	Correctly recognized patients	$p\left(\frac{T}{K}\right) = \frac{TK}{TK+TK}$
Specificity	Correctly recognized healthy subjects	$p\left(\frac{\bar{T}}{\bar{K}}\right) = \frac{TK}{TK+TK}$
Efficiency	Correct test result	$p\left(\frac{T}{K}, \frac{\bar{T}}{\bar{K}}\right) = \frac{TK+TK}{TK+TK+TK+TK}$
Relevance	Probability of disease for positive test	$p\left(\frac{K}{T}\right) = \frac{TK}{TK+TK}$
Negative predictive value	Probability of absence of disease for negative test	$p\left(\frac{\bar{K}}{\bar{T}}\right) = \frac{TK}{TK+TK}$

physical half-life period have to be considered in particular. The latter is especially important for the application of radioactive markers participating in metabolism.

For drug testing, 4 stages can be distinguished:

- *Stage I*: Clarification of pharmacokinetic issues and dose for healthy probands.
- *Stage II*: Testing of the basic efficacy against various diseases.
- *Stage III*: Exact comparison of the efficacy among competing therapies and registration of adverse effects from a large patient collective.
- *Stage IV*: Testing of rare adverse effects and exact discrimination of the field of application with approved drugs.

For long-term examinations, the drop-out of several probands and patients, the so-called *drop-out rate*, has to be taken into consideration. This can lead to systematic distortions. The quality of a diagnostic method can be derived from the contingency table (Table 46.5). For this, sensitivity, specificity and efficiency of the method can be determined (Table 46.6). Of particular importance is the location of the cut-off point determining the ratio of sensitivity and specificity (Fig. 46.29).

Monitoring Systems

47. Monitoring Systems

Ulrich Hieronymi, Rüdiger Kramme

The term patient monitoring describes the measurement of vital signs and organ functions of the patient by a dedicated device with automatic detection and alarming of abnormal or life-threatening conditions (e.g., violation of the selected parameter limits and arrhythmia events). The physiological parameters are acquired continuously, at automatic intervals or else in individual measurements, analyzed, displayed as waveforms and/or numerical values, stored in trends, and, if required, printed out or, for example, forwarded to patient data management systems. After an introduction to the fields of use for patient monitoring systems (Sect. 47.1), the types of monitors and displays are described (Sects. 47.2, 47.3), followed by sections on handling aspects such as controls, user guidance, and operating philosophy (Sect. 47.4). Section 47.5 covers the important features of handling alarms and events, followed by a discussion of trend display and automated calculations (Sects. 47.6, 47.7). The chapter concludes with an overview on monitor networks (Sect. 47.8).

Traditionally, the monitoring function which is primarily used at the bedside or in the operating theater is carried out over a relatively short period of time (short-term monitoring, e.g., during an operation) or a relatively long period of time (long-term monitoring, e.g., in intensive care units), and is intended to reliably

draw the medical staff's attention to physiologically unstable conditions as early as possible. This requires reliable and reproducible detection and display of measurements and includes both self-monitoring of the unit and monitoring of the effectiveness of life-supporting systems to which the patient is connected.

Table 47.1 Classification of patient monitoring systems

Features			
Type of monitoring	Basic monitoring with non-invasive parameters	Basic and advanced monitoring with non-invasive and invasive parameters	Advanced and highly specialized monitoring with non-invasive, invasive, and special parameters
Parameters measured	1–5 with trend	3–7 with trend and calculations	>8 with trend, calculations, and communication with other systems
Graphs displayed simultaneously	1–4, (color) LCD	3–8, if required also 12 lead ECG, color LCD/TFT	6–32, color LCD/TFT
Communication	Stand-alone or networkable	Networkable (hard-wired or wireless), devices connected to the workstation	Networked, optionally with web browser and advanced communication and various connections
Field of use	Induction and postanesthetic rooms, recovery rooms, A&E units, outpatient clinics, step-down units, transport	Induction and postanesthetic rooms, OT, recovery rooms, A&E units, intensive care units, intermediate care, transport	General and special intensive care units, special OT units, research areas

The conventional electronic measuring and monitoring unit or monitor has become a multifunctional, software-controlled system with extensive data collection and storage capabilities which is used for diagnosis and, in combination with other clinical observations and assessments, both for therapeutic decision-making and for monitoring the effects of the therapy. In standards the general term used for such systems is programmable electrical medical system (PEMS).

For users the ease of operation of both monitor and its accessories is top priority, including their versatile use and the reliability of all measurements and alarms. There should be as few false alarms as possible, and above all, a life-threatening situation should never remain undetected.

Modern monitors are expected to be scalable, which is to say that they can be adapted to the respective requirements at any time by simply adding or removing extra modules or software options. By means of updates and upgrades, they must be forward-looking, keeping pace with new developments, and must be capable of being extended, for example, with new measuring techniques.

Modern monitors feature a highly intuitive operating philosophy and communicate with each other and with central monitoring stations via network connections. Communication with other units and with networks in the hospital is one of their advanced system properties. Table 47.1 lists some basic classifications of patient monitors and systems.

47.1 Fields of Use for Patient Monitoring Systems

Patient monitoring systems are mainly used in general and specialized operating theaters (OT) (especially cardiac, vascular, and neurosurgical):

- Induction and postanesthetic rooms, recovery rooms, and observation wards
- General and special intensive care units (ICU), including neonatal (NICU) and coronary (CCU)

care units as well as stroke units, accident and emergency (A&E) units, procedure rooms, and outpatient clinics, emergency services and patient transport.

Furthermore, monitors are regularly used in wards and units which take patients from intensive care units at a very early stage (step-down units).

47.2 Types of Monitors

47.2.1 Stand-Alone Monitors

A stand-alone monitor does not communicate with other monitors or with a central station and is often used only for selective measurement or short-term monitoring of a few patient parameters.

47.2.2 Transport Monitors

This type of monitor is portable and a device as light as possible with an integrated display, which can be fastened to the bed or to the transport bed and that is used in battery operation to monitor the patient during transport (Fig. 47.1c).

47.2.3 Telemetry Devices

These are portable transmitters (often without a display) for wireless monitoring of patients in a defined coverage area of an antenna system installed in the clinical environment. Unlike the transport monitor, such devices are carried by the ambulant patient himself and are used for monitoring the electrocardiogram (ECG) and, if necessary, the oxygen saturation and (non-invasively) blood pressure at a central station. Modern telemetry devices no longer use the usual ultrahigh-frequency (UHF) and very high-frequency (VHF) bands which require proprietary antenna and receiver systems, but instead use a Wi-Fi radio network called WLAN (wireless local area network) using certified generally available components complying with industry standards.

47.2.4 Preconfigured or Compact Monitors

Such devices have an integrated display and a fixed and limited number of measurement parameters. Semimodular (compact) monitors can furthermore be expanded by a module for additional measurements. A recorder can be integrated. Integration in networks is usually

possible nowadays. When equipped with accumulators, there is no strict distinction from use as a transport monitor. When integrated in a WLAN, the monitor can work in the same radio network as a WLAN telemetry unit. If

Fig. 47.1a–c Components in a modern monitoring system. (a) Widescreen information monitor (*foreground*) with integrated transport monitor (in the background on the docking station). (b) Central station for 16 patients. (c) Monitor is securely locked on a bed mount for transport (© Dräger Medical, Lübeck, Germany) ►

the monitor is further miniaturized, it will without doubt no longer be possible to draw such strict boundaries between a telemetry device and monitor in the future.

47.2.5 Modular Monitors

The performance of these monitors is freely scalable by exchanging or adding modules (plug-in units or external extensions) for detection of further parameters and also by means of software options (e.g., for advanced arrhythmia monitoring) and can be adapted in each case to the specific requirements. These monitors, which have an integrated or separate screen, can often only be used in a stationary position at the patient's bedside or in the operating theater (OT) and as a rule are combined with monitor systems in a network.

47.2.6 Information Monitors with Integrated Transport

A modular monitor which is suitable for transport throughout the hospital, combined with a logically associated medical-grade panel personal computer (PC) (Fig. 47.1a). The monitor is docked at the bedside on a so-called docking station which provides secure mechanical mounting and contains all the connections to the power supply, network, and, if required, to external devices and other display units. Simply by turning a lever, the mechanical connection and all electrical connections are disconnected and the monitor is used as a transport monitor, without any interruption in monitoring (pick-and-go principle). On return from transport, the monitor is simply put on the docking station, the lever is returned into its locking position, thereby re-establishing all of the connections which were previously disconnected. There is no need for any cables and/or modules between the bed monitor and transport monitor to be reconnected, and absolutely seamless monitoring of the patient is ensured, without any restrictions on the parameters. The dedicated bedside panel PC is firstly used for advanced monitoring, to present the abundance of monitor information clearly, intelligibly, and in a large size in various screen layouts. Secondly, it acts as an information technology (IT) portal for doctors and nurses and provides access to all electronically available information in the hospital

Fig. 47.2a,b Monitor components of the Infinity Acute Care System. **(a)** Medical cockpit with docked transport monitor. **(b)** hand-held transport monitor M540 (© Dräger Medical, Lübeck, Germany) ►

about their patients [images, e.g., x-ray, magnetic resonance tomography (MRT) and ultrasound, test results,

medical histories, and pre-existing conditions] and to databases (red list, care guidelines). Thereby essential information for decision-making on further therapy is available where it is needed – at the bedside, the *point of care* – without a time-consuming search. Thirdly, the PC can simultaneously be used for paperless documentation by running a patient data management system.

47.2.7 Integrated Acute Medical System

This system represents a further development of the information monitor mentioned above and of the pick-and-go principle (Fig. 47.2a). A convenient and light but very powerful monitor with a touchscreen (Fig. 47.2b) records all the vital signs and stays with the patient at all times (including during transport). At the bedside it can be inserted into the automatically locking docking station with one hand and thereby connected to the

information monitor which is used for comprehensive operation. The information monitor acts at the same time as an IT portal for all of the possible web-based applications or Citrix applications in the hospital. The standardized hardware provides a user interface which has basically the same design, not only for monitoring but also, for example, for respiratory therapy and anesthetic equipment. The aim is to always provide the user with the same operating philosophy in an integrated system, and as a result of this standardization to minimize both the cost of training and the sources of operator errors throughout all the wards and departments, from accident and emergency (A&E) units to the OT, and from the recovery room to intensive care units. The system is scalable according to the various requirements in the different wards and departments, facilitates intelligent data transfer, and ensures effective transport without any loss of time.

47.3 Monitor Screen Content

47.3.1 Display

Apart from very simple blood pressure and temperature measuring units, which only display numerical values, virtually all monitors have a screen for displaying waveforms of the continuously monitored parameters (usually ECG, pulse curve, respiration, and invasive blood pressure) with their associated labels, measured values, and alarm limits, as well as for displaying trends and other information.

Color flat-screen monitors based on liquid-crystal display (LCD) and thin-film transistor (TFT) technology with screen sizes between 6 inches (15 cm) and 17 inches (43 cm) and above, with resolutions of 640×480 to 1024×768 pixels, have generally become widespread. The trend is towards a wide screen of 20 inches (51 cm) and 1680×1050 pixels. Monochrome LCD or electroluminescent (EL) screens today may only be found in small stand-alone monitors and transport monitors. Good screens are flicker free, high contrast, and antiglare and have a sufficiently large viewing angle (>160°), such that they can easily be read, even if there is excessive ambient light and when viewed from a awkward perspective.

47.3.2 Channels

In addition to the size and quality of the screen, the number of possible monitor channels also describes

the performance and capability of a monitor. This is the maximum of waveforms that can be selected for monitoring and their associated parameters which are displayed in parameter windows or boxes. Transport monitors and compact monitors usually have three or four channels. Modular monitors traditionally have five, six or eight channels. Modern monitors with 17 inch or 20 inch screens offer as many as 32 channels.

47.3.3 Waveform Representation

Either the waveforms constantly move from the right to the left of the screen (source mode or paper mode) or they are drawn and redrawn anew from left to right on the screen, with an erase bar deleting the waveform of the previous sweep (erase bar mode). The sweep speed can be selected, at least in modular monitors. Conventional speeds are 25 or 50 mm/s for ECG and blood pressure waveforms and 12.5 or 6.25 mm/s for respiratory ones. Many monitors have a freeze function, which enables the image on the screen to be frozen to be viewed more accurately. Waveforms showing physical measurements (ECG and blood pressure) have a scale.

47.3.4 Screen Configuration

The arrangement of the waveforms and parameters on the screen (positioning, layout) as a rule can be set by

the user. At least one such configuration can be stored and is used as a standard when the monitor is switched

on. In modular monitors, 5 or 10 layouts can usually be stored.

47.4 Handling

47.4.1 Controls

The controls on the monitor can be fixed buttons, a rotary knob, and touchscreen, which can be found single or in every possible combination. Some monitors additionally allow for wired or infrared remote control. Monitors with an integrated web browser may have a keyboard and mouse.

47.4.2 User Guidance and Operating Philosophy

Simple, logical, and highly intuitive usability is required to ensure good acceptance by users and to avoid faulty

operation. It is user-friendly to have direct access to important function keys (all alarms off, standby, main screen, and preferably highlighted in color the most important key: alarm audio pause) and a logical, easily understandable menu design with no more than two or three levels. Some monitors provide auxiliary functions and built-in simulation programs for learning how to operate them.

47.5 Alarms and Events

An important function of the monitor is to provide audible and visual alarms with at least three different levels. The highest priority is given to alarms for life-threatening situations (such as cardiac arrest or ventricular fibrillation), to which attention must urgently and clearly be drawn acoustically and visually in the form of a red alarm. Serious warnings, e.g., when a limit value is violated, are displayed in yellow. Technical and/or advisory alarms appear in white. Audible alarms are intended to attract attention. The alarm levels must sound distinctly different and be capable of being differentiated by staff from the alarms of other medical equipment. Visual alarms are used to quickly recognize: (1) which monitor is sounding an alarm (alarm light on the monitor), and (2) what is causing the alarm (parameter value flashing colored).

An alarm can be printed automatically on a (laser) printer or a special alarm strip recorder and stored in the monitor and/or in a central station as an *event*. Storing alarms allows subsequent evaluation and, if necessary,

selective documentation. This can save printing out all events.

A monitoring system can be configured in a way that the alarm from one patient bed is also displayed on all other monitors and the medical staff can immediately identify the nature and location of the alarm. In the simplest case, this is a brief indication of the bed and the parameters causing the alarm in a message bar displayed on the other monitors (simple bed-to-bed communication). Optionally, even the display content of the monitor which is emitting the alarm can appear automatically on the other monitors (full bed-to-bed communication). Either way, an alarm will sound from and be displayed on a connected central station. Particularly in wards which have been built in a manner which gives staff a very poor view of the whole ward, it may be necessary to transmit important alarms to an existing nurse call system and to display them on information displays in corridors which are visible from a long distance.

47.6 Trend Display

All values measured are stored by the monitor in the trend memory. Mean minute values (or median values) from the last 24 h or more of continuously measured pa-

rameters are usually stored (96 h is quite normal). The trend is displayed as a table or as a graph, and the user can select a period from 24 h up to a few minutes (zoom).

47.7 Automatic Calculations

Physiological calculations of variables which are derived from the continuously and discontinuously measured parameters are customary for hemodynamics, res-

piratory values, and oxygen supply. These results are then also available as a trend. Many monitors also permit dose calculations for various medications and infusions.

47.8 Advanced System Properties

47.8.1 Data Integration at the Workstation

By integrating data from external devices (e.g., specialized monitors from other manufacturers) and/or ventilators or anesthesia systems, it is possible to display additional waveforms and parameters together with the data from the monitor, and a common database (trend memory) is created. The data are transmitted, for example, via a medical information bus (MIB) or serially.

47.8.2 Monitor Network

Networking (local area network, LAN) is the step from an individual monitor to a monitoring system. Using industry standards for hard-wired LAN or wireless LAN (WLAN), the monitors communicate with each other from bed to bed and with central monitoring stations and also, for example, with commonly shared printers.

Data (e.g., demographic data from the hospital information system or test results) can be imported and exported (e.g., to a patient data management system) from the monitoring system via the network and special gateway computers. Using the medical grade computer of the information monitors mentioned before, it is possible, for example, that all patient-related information that is electronically available throughout the hospital can be displayed at the bedside and integrated into the monitoring process using a web browser or a dedicated

application. Thus, less time is wasted searching for information, and no data are lost for documentation.

Screen contents and trend information from monitors can be accessed web-based via the hospital intranet and a gateway server so that authorized doctors can get this information from any PC in the hospital network using a standard web browser. Consultations can therefore take place and diagnoses be made anywhere in the hospital. It is also possible to trigger pager systems, in order to also provide doctors or nursing staff, for example, with alarm information outside a ward and independently of hard-wired monitors and central stations.

Since vitally important alarms must not be delayed in a monitoring network and gaps in transmitted waveforms are not acceptable, a strict physical separation between the hospital network and the monitor network has always been required in the past. Modern technology for ensuring the priority of time-critical data now also allows a monitor network to be operated as part of the network installation of a hospital as a result of logical separation of the network segments by means of virtual LANs (VLAN), with corresponding system stability and the guarantee of a minimum bandwidth for the prioritized application as quality of service (QoS). Only as a result of this, it is now possible for monitors and, for example, computers used on ward rounds to separately communicate via WLAN using the same access points without interfering with each other.

47.9 Central Monitoring and Documentation

Via network, monitoring central stations provide all alarms visually and acoustically at central workplaces and also provide an overview of the state of the connected patients using one or more screens. Limit values on the bed monitor and, if applicable, telemetry units can be changed from the central station. Central stations also have to be scalable and must be capable of being adapted, in terms of their performance, to requirements by means of hardware and/or software

options, e.g., in terms of the number of patients to be monitored and displayed (usually between 4 and 32) with or without telemetry, the number of waveforms per patient, long-term storage for waveforms (e.g., 1–3 days full disclosure of 4–16 curves) and events (e.g., 1000 per patient as event disclosure), and other functions, e.g., view of beds from other wards or of waveforms stored in other central stations, as well as exporting the full disclosure waveforms and

events to the intranet to be viewed on doctors' PCs when needed for diagnosis. Another important function is that of documentation, i.e., the option of printing out trends, events, and reports in adjustable formats and time periods. A laser printer with standard paper format is the standard today. Network printers can also be used without central stations directly from the monitors.

Cardiovascular

48. Cardiovascular Monitoring

Ulrich Hieronymi, Rüdiger Kramme

The generic term *cardiovascular monitoring* covers the monitoring of heart and circulatory functions. Cardiovascular monitoring is vital and of crucial importance in the case of cardiological diseases, unstable circulatory states, and shock as well as for pre, intra, and postoperative monitoring of the cardiovascular system. Firstly, it must be possible to commence interventions quickly in the event of any impairment, and in addition the measurements are used to assess the condition of the patient, reach a diagnosis, decide on the therapy, and monitor the therapy. It covers cardiac function (Sect. 48.1) in the form of an electrical phenomenon (ECG) and its mechanical effect, i. e. the pressure build-up and the volume delivery, which is dependent on heart rate, contractility, preload, and afterload. In particular, when the patient is in a state of shock, it is important to maintain or restore the main function of the circulatory system (Sect. 48.2), which is to supply sufficient oxygen to the body. In addition to artificial respiration and volume management, doctors have a wide variety of means available to them for this purpose, which act differently on the cardiovascular system and are only used

selectively with meaningful measurements and can be checked for their effectiveness.

48.1 Monitoring the Cardiac Function

48.1.1 Electrocardiogram (ECG) and Heart Rate (HR)

In emergency and intensive care medicine, in surgical fields, and in the emergency services, continuous ECG monitoring is part of basic monitoring. The ECG provides information about the heart rate and rhythm, the excitation, conduction, and repolarization and disturbances in these functions, but does not provide any direct information about the pumping

capacity of the heart (i. e. the mechanical cardiac function).

The ECG is a record of sum potentials of the electrical cardiac activity and can be measured very easily directly from the surface of the body using electrodes (Fig. 48.1). It is customary to use 3, 5, 6, or (e.g. for monitoring in cardiology) 10 electrodes. Only one ECG lead can be displayed when three lead wires are used. 7, 8, and 12 ECG leads can be obtained from 5, 6, and 10 electrodes, from which generally up to three leads can

Fig. 48.1 Standard electrode positions for ECG monitoring with three, five, and six electrodes. Color code and labels according to IEC2 (AHA/US): RA: white, LA: black, LL: red, RL: green, V: brown, V+: gray/brown; in parenthesis according to IEC1 (Europe): R: red, L: yellow, F: green, N: black, V: white, V+: gray/white

be selected on conventional 5 to 8 channel monitors for constant display on the screen channels.

Three lead wires are sufficient to determine the heart rate (HR) and are often used for basic monitoring, e.g. in the normal operating theater (OT). Three particularly small neonatal electrodes are found exclusively in neonatology. Simultaneous monitoring of multiple leads is recommended for better artifact suppression, for reliable recording of cardiac arrhythmias, and for pacemaker detection. Special ECG interval measurements can also be performed. The automatic analysis and monitoring of the ST segments in the ECG is of particular importance in the case of myocardial ischaemia and infarction. In these cases, it is important to view the heart as far as possible from all sides, i.e. to utilize up to 12 leads so that local ischaemias are not overlooked. For this purpose, methods have also been developed that make highly reliable ST monitoring possible from eight true and four computed leads (TruST algorithm) using just six electrodes (reduced lead set) which are placed entirely as normal. Using 10 lead wires, modern monitors can display, and if necessary automatically evaluate, a 12-channel resting ECG of diagnostic quality. It is vital to keep in mind here that correct application of the electrodes is the basis for achieving a diagnostic quality for the ECG. The placing of electrodes on the thorax, which is performed in the monitoring process, cannot completely replace the true limb leads, which are necessary for diagnosis. It can simulate apparent pathological deviations of the cardiac axis, which are not present at all when electrodes are placed correctly on the limbs.

The heart rate (typical measuring range of 15–300 beats/min) is determined as a moving average over a specific time (e.g. 10 s), or a specified number of QRS complexes, and displayed numerically. As an

alternative to the ECG, the heart rate can be obtained (automatically switched over by the monitor when there are interferences in the ECG, e.g. during cauterization in the OT) in the form of the pulse rate from the arterial blood pressure or the pulse curve from the SpO₂ signal. The basis of heart rate measurement is safe detection of the QRS complexes in the ECG and assessment of the intervals between them (RR intervals) using digital filters and detection techniques. This way, it is possible for impulse noise or movement artifacts to be eliminated and not be included when determining the heart rate. Pulses from pacemakers are already detected prior to the actual QRS detection on the basis of their special characteristics (very short and very steep) and can be added to the ECG as a marker. An alarm can be activated when adjustable limit values are violated, and these events can be stored as a brief ECG episode in an event memory in the monitor or in a central station.

Numerous factors can interfere with ECG monitoring: Patient-related interferences are primarily due to ECG electrodes and lead wires falling off, insufficient electrode contact with the skin (poor preparation of the skin, dried out electrode gel), sweaty or greasy skin, and also muscle tremors and movement artifacts in the patients. In the case of highly elevated movement artifacts, it is also necessary to consider the possibility of there being too low a contact force at the electrode connections. Technical problems that interfere with the ECG can, in particular, be caused by radio frequency (e.g. RF surgical equipment and, in particular, also the low-frequency modulated emissions from RF surgical equipment), by coupled AC voltage or by impulses from transcutaneous electrical nerve stimulation (TENS). In operating theaters, the use of special lead wires and/or filters to reduce interference is recommended or prescribed by the manufacturer.

48.1.2 Arrhythmia Monitoring

Continuous arrhythmia monitoring is used to detect cardiac arrhythmias and their precursors and symptoms in real time. A detected arrhythmia can trigger an alarm, be stored as an ECG strip in the event memory, and/or be printed out automatically. Life-threatening conditions such as asystole, ventricular fibrillation, or ventricular tachycardia must be reliably detected and an unambiguous acoustic and optical alarm (red alarm) must be triggered. These three forms of arrhythmia are basic or lethal arrhythmias, which every modern monitor should fundamentally detect and respond to by generating an alarm. The asystole alarm is triggered if no QRS complex is identified within a certain period of time (generally 4 s). If the reason for no QRS complex being identified is that electrodes have fallen off, a corresponding technical note is generated and the asystole alarm is not triggered. In neonatology, bradycardia (excessively low heart rate) is a lethal alarm and should fundamentally be recognized by every monitor in neonatal operating mode as life-threatening.

The monitored ECG leads form the basis for analysis of arrhythmias. Cardiac arrhythmias are frequently linked to heart conditions and can also occur sporadically in patients without heart problems. The nature and number of events are of particular clinical interest. Monitor systems often provide the option of continuously storing and analyzing the ECGs of multiple patients over several days.

Arrhythmia monitoring begins with a learning period in order to ascertain the normal QRS complex that is currently typical for the patient, and this normal QRS complex is learnt as an individual normal beat and is stored as a template or reference com-

plex. All incoming QRS complexes are subsequently compared with the template (template matching). This involves an online decision as to whether it is a normal beat, a ventricular beat, or an artifact. Various features and detection criteria of the ECG cycle are used for this (feature extraction), e.g. polarity, width and shape (morphology) of the QRS complex, slope and area of the ST segment, as well as the time interval (RR interval) of the complexes. The distinction between normal and ventricular is no longer made according to a set of rules of fixed measurement criteria (rule-based system); the monitors instead imitate human approaches to template matching, e.g. using probability criteria or fuzzy logic. Frequency analysis (detection of flutter and fibrillation) and artifact analysis (movement, muscle tremors, etc.) is performed in parallel. After the classification of the individual QRS complexes, the distinction is made, using rhythm logic, as to whether the event concerned is an isolated ventricular extrasystole (VES) or whether it concerns linked events (pairs, runs, ventricular tachycardia, bigeminy, etc.). If a pacemaker pulse has been detected, the only important thing is to judge whether or not there is a physiological response from the heart. Because pacemaker pulses can give rise to transient electrical phenomena in the heart, which can be very similar to a natural heart action, this judgment is by no means trivial. Pacemaker patients should, therefore, always be given additional monitoring of the circulatory function, e.g. the pulse rate from SpO₂ monitoring or continuously measured arterial blood pressure.

The analytical quality of the monitors is determined, among other methods, by testing using reference ECG recordings from international societies (American Heart Association, AHA) or recognized institutions.

48.2 Monitoring the Circulatory Function (Hemodynamic Monitoring)

Hemodynamics is the study of the flow of blood in the circulatory system. This flow is driven by the pressure generated by the heart. Since the pressure in the vascular system is highly dependent on activity and the position of the body (hydrostatic pressure), blood pressure measurements are always taken at rest and are based on the height of the heart (right atrium).

The vascular system is functionally divided into a low-pressure system (small, pulmonary circuit) and a high-pressure system (large, systemic circuit), which are connected to one another by the central driving element, the heart. The heart generates pressure in its

contraction phase (systole), by means of which the stroke volume (SV) is expelled from the ventricle and into the arterial vascular system. Every stroke volume conveyed generates a pulse wave. The peak pressure during the expulsion of the stroke volume from the ventricle is the systolic blood pressure (highest point of the pressure curve). The pressure at the end of the relaxation phase (diastole) is referred to as diastolic blood pressure (lowest point of the pressure curve). The difference between the systolic and diastolic pressure is the blood pressure amplitude. The pressure that maintains the blood flow in the vascular system, that is to

Fig. 48.2 Overview of circulation monitoring

say the driving force of perfusion, is the mean pressure (in the systemic circuit the mean arterial pressure APm (also MAP), and in the pulmonary circuit the mean pulmonary artery pressure PAPm).

The stroke volume is dependent on the preload, the contractility of the myocardium and the afterload. The preload is the stretching of the myocardium, which is brought about by passive filling of the ventricle at the end of diastole and is best described by the end-diastolic volume. The afterload is the force exerted by the cardiac muscles to overcome the resistance in the outflow tract of the left ventricle and of the peripheral circuit. The mean arterial pressure and the vascular resistance are used as measures of the afterload.

In addition to the pressure-volume work of the heart, factors that also determine the blood pressure behavior are the elasticity of the vascular system, the circulating blood volume and, in particular, the peripheral vascular resistance, which is influenced by the wall tension of the vessels (vessel tone) controlled by the sympathetic nervous system.

The delivery volume of blood per minute is known as the cardiac output (CO) and is the product of the stroke volume and heart rate.

Control mechanisms in the body regulate circulation with the aim of adjusting the cardiac output to the circulation that is required to supply oxygen to the organism and eliminate CO₂, keeping the blood pressure largely constant and adjusting the circulation in the individual organs and tissues to the functional state in each case. Because doctors have means available to them for specifically treating the individual determinants of the cardiac output (chronotropic medications for heart rate, inotropic medications for contractility, vasodilators and vasoconstrictors for vessel tone, and diuretics or fluid administration for preload), it is therefore important to maintain this information, as reliably as possible, as the basis for decision-making and therapy monitoring in the monitoring process.

Monitoring of the circulatory function involves non-invasive and invasive measurements of vital signs using indirect and direct methods, which are used in high-pressure or low-pressure systems (Fig. 48.2).

48.2.1 Pulse

Pulse monitoring is performed either invasively from the arterial pressure curve or noninvasively from the

plethysmogram of pulse oximetry (Chap. 49). Pulse monitoring has particular importance as a safety measure when monitoring pacemaker patients (see above).

48.2.2 Discontinuous Noninvasive Blood Pressure (NIBP)

Noninvasive blood pressure measurements are part of the minimum requirements for pre, peri, and postoperative patient monitoring, but are also used in the field of intensive care medicine. Patient monitors have a measuring module or include the measuring parameter NIBP (synonymous abbreviation NBP) in the basic configuration. Monitors and stand-alone units work discontinuously (after being started manually or automatically at selectable intervals) according to the oscillometric measuring principle.

The auscultatory method is today performed almost exclusively *by hand* and is only an indirect part of the monitoring process. However, due to its wide distribution and historical significance it should be briefly explained here.

Sphygmomanometer

In 1896, the Italian doctor Riva Rocci developed a sphygmomanometer that was easy to handle (a device for measuring blood pressure; an inflatable cuff with an attached mercury manometer) for noninvasive measurement of the blood pressure in the upper arm. The cuff pressure was increased considerably beyond the point at which a pulse was no longer detectable at the wrist (palpatory method). When the first pulse became perceptible as the air was slowly released from the cuff, the manometer pressure read off was taken as the systolic blood pressure.

It was only after a further discovery that it also became possible to measure the diastolic blood pressure noninvasively. In 1905, the Russian doctor Korotkoff discovered characteristic turbulence noises that could be auscultated (listened to using a stethoscope) when releasing the pressure from a compressed artery. The description of the blood pressure values measured in this way as RR (after Riva Rocci), which is still customary today is historically false, because no diastolic value could be measured according to Riva Rocci, nor was a stethoscope used.

Functional Principle of the Auscultatory Method

The cuff must be placed on the exposed upper arm at the level of the heart such that the middle of the rubber blad-

der is positioned over the brachial artery. After palpating the brachial artery, the cuff is inflated to ≈ 30 mmHg above the pressure at which the pulse can no longer be detected. The stethoscope is placed against the brachial artery and the cuff pressure is slowly released. The pulsation that then begins causes knocking noises (Korotkoff sounds phase 1). At this point, the systolic blood pressure is read off from the manometer. In the other phases, the sounds change (see list below) until a sound can no longer be heard. This is the fifth phase and is approximately equal to the diastolic pressure.

Korotkoff sounds [48.1]:

- Phase 1: A clear knocking sound begins, the intensity of which increases during the course of the phase.
- Phase 2: The knocking sound from phase 1 is accompanied by an additional murmuring sound.
- Phase 3: A knocking sound can be heard on its own again, which is now especially loud and clear.
- Phase 4: Sudden change: the sounds appear muffled and quieter and they now lack the typical knocking quality.
- Phase 5: The noises disappear completely.

Oscillometric Method

In 1909, the French doctor Pachon discovered the oscillometric measurement method. He recognized that, when the cuff pressure is released once the systolic pressure has been reached, the vessel walls begin to oscillate and maintain this behavior until the vessel is no longer occluded. These oscillations are transmitted to the air in the cuff and are read on the manometer. Today, these oscillations are measured electronically using pressure sensors.

The Functional Principle of the Oscillometric Method

In the oscillometric method, the cuff is inflated at the beginning of the measurement to ≈ 25 – 30 mmHg above the point at which virtually no oscillations are measured any longer (very low oscillations can come from the part of the artery lying proximal to the cuff). The pressure in the cuff is automatically released at 2–3 mmHg/s [48.2]. When the cuff pressure drops below the value of the systolic blood pressure, the artery begins to open and the oscillations become stronger. They reach their peak when the cuff pressure corresponds to the mean arterial pressure. This is the actual measured value of the oscillometric method. As the cuff pressure drops further, the oscillation amplitudes decrease once more and finally remain constant

Fig. 48.3 The principle of the oscillometric method

when the cuff pressure has reached the diastolic value (Fig. 48.3). The values for the diastole and systole are determined from the progression of envelope curves around the oscillations detected and are thus calculated values.

Single-Tube and Double-Tube Systems

Cuffs with single-tube or double-tube systems are normal. In order to avoid the release of pressure influencing the measurement results, a pressure tube may be com-

posed of two lumina. One leads directly from the cuff to the pressure sensor, and the other is only designed for inflation and pressure release. Single-tube systems are more flexible on account of their lower total cross section and can, therefore, be better handled in practice.

Plausibility Checking

Artifact detection is the most important requirement for reliable oscillometric measurement. Mechanical in-

fluences on the cuff or blood pressure tube during measurement must not be recorded by the device as relevant oscillations, as incorrect blood pressure values could otherwise be displayed. Modern equipment eliminates such artifacts by releasing the pressure in stages. Only when at least two successive pulses of the same amplitude are detected at each stage is the pressure released to the next level. If artifacts occur, then the device remains at a pressure level until two identical pulses are identified. As a result, even the smallest artifacts can be detected, e.g. in neonates. Although methods that in contrast operate with a continuous and linear release of pressure provide a result more quickly, they often give incorrect values when there is interference.

When there is insufficient plausibility, a reliable device will tell the user that it has not been possible to take an exact reading. In the case of shock patients with extremely low pressure values in peripheral vessels, the systolic and diastolic value can only be ascertained with a large degree of uncertainty as a result of the flat progression of the oscillation curves. The oscillation peak is still detected, however, and the mean arterial pressure can, therefore, be measured and displayed. The systole and diastole would be displayed as not measurable (e.g. as a dash).

Methodological Notes

Cuff Size. One of the most common sources of faults when measuring blood pressure is the incorrect choice of cuff size. The cuff width should be $\approx 40\%$ of the circumference of the limb, and the rubber bladder should surround $\approx 80\%$ of the circumference [48.3]. If the correct width is not used, this causes considerable measuring errors. If the cuff is too narrow the measurements are too high, and if the cuff is too wide the measurements are too low. It is therefore absolutely essential, particularly in obese patients, children and neonates, to use the correct cuff size in each case.

Taking into Account Hydrostatic Pressure. Blood pressure measurement is always based at the level of the heart. Measurement on the upper arm is, therefore, not a problem either in the case of seated patients or in patients in the dorsal position. Measurements can be taken from the thigh or lower leg if the upper arm is not available as a measuring site, and if the patient is lying flat. If the measuring site is not at the level of the heart, due to the hydrostatic pressure difference a lower measurement is given for the blood pressure above the level of the heart, and a higher measurement is given below the level of the heart. Measuring errors of approx-

imately 7.5 mmHg occur for every 10 cm difference in height.

Other sources of errors in noninvasive blood pressure measurement are user errors, such as too loose application of the cuff, touching the cuff during measurement, movement of the tube (also, for example, as a result of directly touching the respiratory tubes). Technical errors are usually leaks in the tube or cuff system. Movement artifacts occur because of patient movements and must be mainly taken into consideration as a source of error in the case of children or in postoperative monitoring.

Limits to NIBP Measurement. During the measuring procedure, the tissue lying below the cuff on the limb being measured is compressed. There is a risk of neural pressure lesions forming, particularly in cachectic patients, premature neonates, and patients with neuromuscular diseases, because the muscle tissue and adipose tissue protecting the nerves are reduced. With these patients, noninvasive pressure measurements should, therefore, be performed with the largest possible time intervals between measurements. In all other cases it is recommended that the time intervals between noninvasive blood pressure measurements be selected to be no less than 5–10 min, in order to avoid pressure damage in the region of the cuff and also in the supply area of the artery [48.4].

48.2.3 Continuous Noninvasive Arterial Blood Pressure Measurement (CNAP)

Blood pressure is not always constant but can change within a matter of seconds. In particular, during anaesthesia and its induction, variations in blood pressure can arise and require immediate medical attention. However, such episodes can be detected only unsatisfactorily or not at all using the normal NIBP measurement [48.5].

The noninvasive technique of the relaxed arterial wall (*vascular unloading technique* or *volume clamp method*), which has become known as the Penaz method [48.6], uses an optical sensor in a small cuff around the finger to measure the volume pulses that occur with each heart beat. The pressure in the cuff is regulated by means of feedback such that the optical measuring path always remains constant. When a pulse occurs, the cuff pressure is, therefore, increased accordingly, and when the pulse subsides the cuff pressure is reduced. The cuff pressure, therefore, reflects the pressure occurring in the enclosed finger artery with a high degree of accuracy. Following various techni-

Fig. 48.4a,b CNAP Pod (a) with controller, (b) applied sensor cuff and controller fixed to the lower arm (© Dräger Medical AG, Lübeck, Germany)

cal developments in this field (Finapres, Amsterdam), CNAP then emerged (continuous noninvasive arterial pressure from CNSystems, Graz), and it is the first system of this type to be integrated as a module into a patient monitoring system (CNAP Pod from Dräger Medical, Lübeck; Fig. 48.4). CNAP uses pairs of sensor cuffs, which are placed on adjacent fingers. Care must be taken to ensure the correct size is used. Only one cuff is ever used for measurement at any one time, and after no longer than half an hour the continuous measurement is automatically switched. The venous stasis that naturally occurs during measurement on the finger very quickly decreases once more after the switch. The great advantage of this method is the calibration of the continuous measurement with the normal NIBP measurement, so that correct values are displayed even when the fingers are not level with the heart. This technique, therefore, bridges the gap between discontinuous

NIBP measurement, which involves the risk of overlooking rapid drops in blood pressure, and continuous invasive measurement, the use of which is not indicated for every preferred event and requires an arterial catheter that may only be inserted by a doctor. CNAP satisfies the demand for correct, continuously measured blood pressure values including a pressure curve, instantaneously shows any occurring changes in pressure, can be applied by any instructed member of nursing staff, and involves virtually no risk of lesions for the patient. CNAP is, therefore, suitable for increasing patient safety – above all in the case of interventions that require sedation [48.7].

48.2.4 Invasive Pressure Measurement in the High-Pressure and the Low-Pressure Systems

Invasive blood pressure measurement is a direct method for determining the pressure conditions in the high-pressure and low-pressure systems. The fundamental advantage over conventional noninvasive blood pressure measurement is the continuous availability of the measurement signal (pressure curve) and the pressure values. This provides the possibility of triggering an alarm if predefined limit values violated and of further signal processing of the measurement data obtained.

The High-Pressure System

A connection is set up by means of an intra-arterial catheter between the intravascular blood column and a liquid-coupled pressure transducer, which converts the mechanical variable of pressure into an electrical signal. The arterial pressure is dependent on the stroke volume of the left ventricle and on the vascular resistance.

Links in the pressure-measuring chain (Fig. 48.5) are essentially:

- Cannula or arterial catheter
- Liquid-filled tube system with a three-way stopcock
- Pressure transducer (reusable: with pressure dome, with or without terminal membrane, and with separate or integrated flushing system; disposable transducer always including flushing system) with monitor cable
- Monitor.

Pressure Sensors and Pressure Transfer

Reusable pressure sensors (Fig. 48.6) consist of a mechano-electrical pressure transducer and a remov-

able, liquid-filled cavity (pressure dome). The pressure dome (single use per patient) is directly coupled to the measuring surface (transducer membrane) mechanically via an integrated thin plastic membrane. The arterial compression wave is transmitted to the pressure dome via the liquid medium (sodium chloride solution) in the pressure-measuring line and the catheter and causes a corresponding deflection in the pressure transducer membrane. The mechanical membrane deflection is converted, in the case of reusable and disposable pressure transducers, by means of pressure-sensitive chips whose electrical properties change in proportion with the pressure. An applied voltage causes an electrical signal linearly proportional to the pressure, which is conveyed to the monitor and is displayed there on the screen following amplification.

The greater the distance between the tip of the catheter and the heart, the higher the pressure amplitudes that are recorded. A time delay in the recording is determined by the transit time. The systolic, diastolic, and mean values are calculated electronically from the respective pressure curves and displayed.

Connectors

The pressure dome usually has two Luer-lock connectors, each of which has a three-way stopcock fitted to it. They are used to lead in the pressure, remove air from the system during filling, and flush the pressure-measuring line. The pressure transducers are generally fit into mounting plates that are used for fastening, for example, to an IV stand at the correct height relative to the heart. The inlet tubes and/or the slots on the mounting plates are often color-coded for the various invasive pressure measurements as:

Red: arterial pressure measurement
 Blue: venous pressure measurement
 Yellow: pulmonary artery pressure measurement
 White: other pressure measurement (e.g. intracranial pressure measurement).

48.2.5 The Ideal Pressure Measurement System – Requirements

An idealized invasive pressure measurement system has the following characteristics, which comply with modern clinical requirements:

- Simple and fast setup of the system
- Easy to fill, with simple and secure removal of air as well as visual inspection for air bubbles

Fig. 48.5 Measuring chain for invasive pressure measurement

- Integrated system for constant flushing with *one-handed operation*, reliable flushing rate, even in the case of rapid flush
- Closed overpressure safety valve
- High reliability of all the individual components in the pressure-measuring chain
- Good resonance frequency
- High long-term stability
- Possibilities for negative calibration
- Mounting on the arm and on a bracket
- Low input resistance (impedance).

Metrological Requirements

Invasive blood pressure measurement is technically a measurement of the differential pressure between the blood vessel and the ambient pressure (atmospheric pressure). The pressure transducer must, therefore, be adjusted before each measurement (zero compensation, with the transducer adjusted to the level of the heart in order to avoid measuring errors as a result of hydrostatic pressures from the tube system). Pressure transducers are temperature-dependent, which is to say that the zero point of its actual value can vary when the temperature changes (zero drift).

The weakest link in the measuring chain is the mechanical pressure transfer. The pressure can only be determined exactly if all of the components in the system meet specific requirements, such as high static and dynamic accuracy of the measuring system (transmission behavior, natural frequency, damping, etc.). The transmission properties are dependent on the length and

Fig. 48.6 (a) Reusable pressure transducer, (b) diagram of a disposable pressure transducer, (c) Wheatstone bridge (courtesy of Becton Dickinson, Heidelberg)

elasticity (compliance) and also on the internal diameter of the pressure tube. It is imperative to use tube connections that are as short and pressure-resistant as possible, without any additional connectors.

The functionality of all of the components should be checked prior to each measurement (bubble-free measuring system, secure connection of the individual system components, no leaks). When using reusable

pressure transducers, calibration is recommended to check the functionality before each measurement.

The pressure system contains a section that is capable of oscillating (hydraulic system: from the tip of the cannula to the membrane of the pressure transducer) and can be induced to natural oscillations that alter the pressure signal. The metrological aim is to represent the pressure curve unaltered at frequencies of up to 12 Hz. Below 20 Hz – here the pressure signal has frequency components – the natural and resonance frequency of the measuring system becomes particularly noticeable, which is to say that undesirable interferences and deformations of the actual pressure signal occur. As a result of air bubbles in the measuring system, clots at the tip of the catheter or in the tube system, a disconnected or loose pressure dome of the pressure transducer, movement artifacts caused by the patient, or a change in the catheter position, the pressure curve is damped or changed and the measurement information impaired.

Pressure Measurements in the Low-Pressure System

The aim of pressure measurements in the low-pressure system is to obtain information about the right ventricular function, the pulmonary circuit, and the filling of the vascular system on the basis of the measurement results obtained.

Central Venous Pressure (CVP)

Measurement of the central venous pressure is by means of a liquid manometer or a pressure sensor, using a central venous catheter (CVC), which is placed in the superior vena cava at the entrance to the right atrium of the heart. Unlike water column manometry, pressure transducers have the advantage that the measurement information is available continuously and certain signal characteristics of the CVP curve are additionally available. Because of the small pressure values, it is particularly important that the pressure measurement system is situated level with the heart (correct zero point positioning) in order to avoid falsification of the measurement reading by hydrostatic pressure differences. The progression of the CVP curve shows the atrial contraction (a-wave), the beginning of the ventricular contraction (c-wave), and the relaxation phase (v-wave). The CVP is only shown as a mean value (CVP waveform and other pressures, Fig. 48.7) and is fundamentally influenced by the capacity of the vascular system, the cardiac output, the blood volume, the compliance of the myocardium, and also the afterload of the right ventricle.

Fig. 48.7 Different pressure waveforms and mini-trends in the monitor image

Pulmonary Artery Pressure (PAP) and Pulmonary Capillary Wedge Pressure (PCWP)

In order to monitor and measure the hemodynamics of the right ventricle, a balloon catheter is pushed through the venous system into the right atrium, the right ventricle, and from there through the pulmonary valve into the arteria pulmonalis. The path of the catheter can be followed on the basis of the different typical pressure curves (Fig. 48.8).

The correct catheter position has been reached once the so-called wedge position (Fig. 48.9) has been taken, which is to say once the inflated balloon of the catheter blocks off the pulmonary artery branch. If the tip of the catheter rests against the wall of the pulmonary artery (in a so-called pseudo-wedge position), this causes damping of the pressure curves when the balloon is filled and there is a continuous rise in pressure. Although the catheter is in the right ventricle, in the wedge position the pressure in the left atrium can be inferred

via the distal lumen: the PCWP value corresponds in the first approximation to the left atrial pressure (LAP) and thus to the end-diastolic filling pressure in the left ventricle, since the left atrium, pulmonary capillaries, and pulmonary artery under normal conditions form a common pressure connection during diastole.

Balloon Catheters

Using different balloon catheters (so-called flow-directed catheters, pulmonary artery catheters, or Swan–Ganz catheters), which differ in terms of their length and thickness, number of lumina, position of the lumen exit sites, and other characteristics, the CVP, PAP, and core body temperature can be measured simultaneously, and the PCWP and CO can be measured intermittently.

In addition, specialized balloon catheters provide additional possibilities such as intracardiac ECG measurement (e.g. His bundle ECG), supraventricu-

Fig. 48.8 Measuring sites and typical pressure curves in various heart and vessel sections

lar and ventricular stimulation, measurement of the mixed venous oxygen saturation S_vO_2 as a result of integration of fibre optics, introduction of a transluminal stimulation probe, or additional infusion lumina.

Balloon catheters that are newly inserted or have already been in place intravasally for hours or days are not free of risks and can cause complications, which partly depend on the catheter access site such as:

- Supraventricular and ventricular arrhythmias
- Ventricular tachycardias or ventricular fibrillation (rarely)
- Venous thromboses (particularly with a low CO)

- Sepsis (the risk rises as the duration of catheterization increases)
- Pulmonary infarction (as a result of catheter occlusion of a peripheral pulmonary artery)
- Pulmonary artery rupture (by balloon inflation or the catheter tip).

48.2.6 Determining the Cardiac Output (CO)

The cardiac output, the volume of blood conveyed per minute, is given in l/min. The classical way of determining the CO is by a method according to Fick (Fick's principle), whose calculation is based quite simply on the law of conservation of mass: CO is the quotient

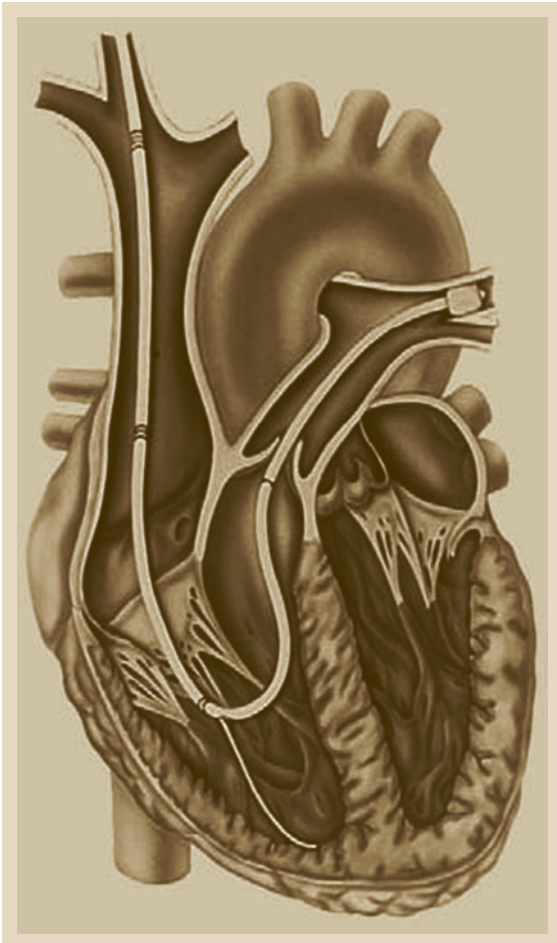

Fig. 48.9 Pulmonary artery catheter in the wedge position

from oxygen consumption (VO_2) in the body and difference in oxygen content ($avDO_2$) between arterial blood flowing to the body and mixed venous blood returning from the body: $CO = VO_2/avDO_2$. However, under routine conditions oxygen consumption cannot be measured with sufficient accuracy in the clinical environment.

Dilution Methods

The 1920s saw the development of the fundamental work of Stewart and Hamilton to determine the CO by means of dye dilution. With the introduction of the thermistor catheter by Swan and Ganz in the 1970s, of all the known indicator dilution methods (dye dilution, cold, ions, radioisotopes), thermodilution by means of a pulmonary artery catheter had established itself as

Fig. 48.10 Monitor window for the CO measurement. Erroneous measurements are deleted from a series of measurements and a mean value is formed

very practicable in the clinical environment. A defined amount of physiological sodium chloride solution (at a temperature of 0–25 °C; the lower the temperature, the more accurate the measurement) is injected into the right atrium via the proximal port of the multilumen pulmonary artery catheter. Because the injected fluid is mixed with the warm flowing blood (37 °C) and is, therefore, diluted, the change in temperature in the blood stream can be measured by the thermistor, which is situated close to the tip of the catheter. The shape and the area of the dilution curve change with the cardiac output. With a known temperature of the injected fluid and blood as well as a known volume of injected fluid, the measuring system determines the cardiac output from the area of the thermodilution curve (Fig. 48.10). The disadvantages of this method are the discontinuity and the need for the pulmonary artery catheter, the indication of which is viewed particularly critically since the study by *Connors* [48.8], if not before. The disadvantage of discontinuity was overcome by emitting heat pulses to the blood using a special pulmonary artery catheter and by evaluating their dilution curve. Since heat pulses can be applied at very short intervals (30–60 s), this virtually provides continuous measurement.

PiCCO Technology

Thermodilution can, in principle, also be performed transpulmonarily, i. e. the cold bolus passes through the lungs and a thermistor in the arterial system records the dilution curve [48.9]. The cold bolus is injected into the right atrium in the same way as in normal thermodilution except with a normal central venous catheter that is customary in intensive care patients, but the temperature profile is measured (preferably) in the arteria femoralis. The advantage of this method is that it is less invasive (omission of the pulmonary artery

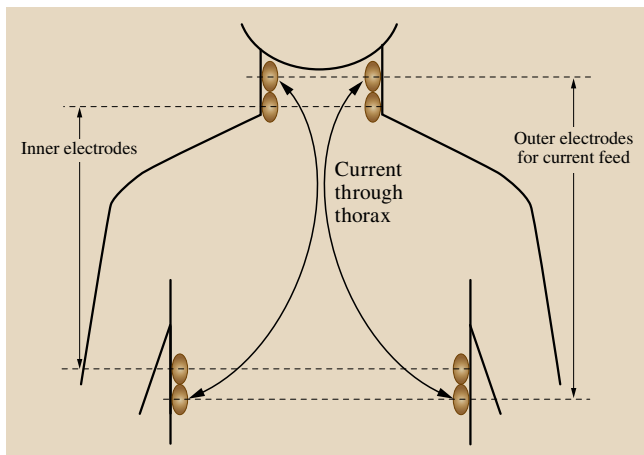

Fig. 48.11 Two double electrodes are applied to each side of the throat and thorax. The impedance is determined from the voltage drop between the inner measuring electrodes

catheter and, therefore, of the dangers mentioned above) and that respiratory influences on the measurement are reduced. PiCCO technology (introduced into the market in 1997 by Pulsion Medical Systems, Munich; PCCO, pulse contour cardiac output) is a combination of transpulmonary thermodilution (in the form of CO measurement) and pulse contour analysis (in the form of continuous determination of the changes in the CO). The CO is inferred beat-for-beat from the invasively measured arterial pressure curve. Calibration must be performed in advance by means of thermodilution, and this should be repeated at least every 8 h. The great value of the PiCCO method lies not only in the less invasive and continuous CO measurement but in the extraordinarily valuable parameters for assessment of the circulation and the volume situation of the patient, which can be read from the monitor without any further effort at all. These parameters are, in particular, the preload indicators global end-diastolic volume (GEDV) and intrathoracic blood volume (ITBV), which are significantly more sensitive and more specific than the filling pressures CVP and wedge pressure, the contractility measures dP/dt_{\max} (maximum pressure increase) and GEF (global ejection fraction), the systemic vascular resistance SVR as a measure of afterload, the parameter EVLW as a measure of the extravascular lung water, and (in the case of patients without arrhythmia requiring artificial respiration) the stroke volume variation SVV. The last parameters are used for optimum fluid management, in particular in shock patients where it is important to stabilize the circulation and thus the oxy-

gen consumption and to avoid and quickly recognize pulmonary oedemas.

Other invasive procedures use the pulse contour method or pulse wave analysis in isolation (Vigileo, from Edwards Lifesciences, Irvine) or in combination with lithium ion dilution (LiDCO, from LiDCO, Cambridge). Furthermore, continuous measurement of the mixed venous saturation SvO₂ by means of fibre optics in a pulmonary artery catheter is used to estimate changes in the CO.

Impedance Cardiography

It has long been known that the blood volume expelled with each heart beat (stroke volume) leads to measurable variations in the thoracic impedance. There have also been attempts to determine the stroke volume and CO from the variations in the thoracic electrical bioimpedance (TEB), which are detected using four electrode arrangements [48.10]. A weak high-frequency constant current (e.g. 2.5 mA, 70 kHz) is passed through the thorax by means of the external ring electrodes (or special double electrodes, Fig. 48.11) arranged on the neck and thorax. The current seeks the path of least resistance, which is essentially the blood-conducting aorta. The voltage drop is measured currentlessly by means of the inner measuring electrodes, such that the thoracic impedance can be substantially ascertained independently of the contact resistance.

The basic impedance Z_0 is about 35 Ω . Fluctuations that originate from the breathing and from the pulsating blood flow in the aorta are superimposed on it. The respiratory signals are not of interest here and are filtered out. The higher-frequency impedance fluctuations $\Delta Z(t)$ (amplitude approximately 0.15 Ω) are represented by the impedance cardiogram (ICG), from which the stroke volume and the CO can be determined by means of certain model assumptions and refined methods [48.11].

In the 1990s, the impedance cardiograph BioZ.com from the Californian company CardioDynamics, Bothel, USA, was developed. Its measuring accuracy and reproducibility have been proven in clinical studies [48.12]. To date this is the only impedance cardiograph to have been incorporated in a patient monitoring system as a special module (Solar from GE Medical Systems).

Impedance cardiography has the advantages of:

- Being completely noninvasive
- No risk to the patient
- Continuous beat-to-beat measurement
- Being easy to apply.

The method is not indicated in patients with septic shock, in patients with aortic valve defects with regurgitation, in patients <1.20 m in height, in patients <30 kg or >155 kg in weight, when an aortic balloon pump is used, or during operations on the open thorax.

Despite all of the advantages of ICG, its nonavailability – for example in the case of septic shock when accurate observation of the hemodynamic and volumetric parameters is of real importance – is probably particularly responsible for that fact that it still has not established itself in the field of patient monitoring to this day. PiCCO-technology is clearly the more advantageous.

48.2.7 Calculation of Hemodynamic Variables

The vascular resistances can be calculated from the measurements of the pressure and flow. The total peripheral resistance (TPR), also called the systemic vascular resistance (SVR), is the resistance of the systemic circuit and mathematically it is simply the quotient of the propulsive pressure difference (mean arterial pressure APm minus central venous pressure CVP) and the flow (CO)

$$SVR = (APm - CVP) / CO .$$

The pressure difference in the small circuit is the mean pulmonary pressure minus the wedge pressure PCWP (as a measure of the left atrial pressure). The pulmonary vascular resistance is, therefore,

$$PVR = (PAPm - PCWP) / CO .$$

The international unit of measurement has remained dyn/s/cm⁵ in this case (resulting from the old unit of pressure dyn/cm² divided by the volume flow cm³/s).

Monitors generally provide calculation programs that can also be used to calculate other circulatory parameters (e.g. cardiac work) and also – if blood gases and respiratory gases are additionally measured – to calculate the oxygen supply (DO₂) and oxygen consumption (VO₂).

49. Respiratory Monitoring and Pulse Oximetry

Ullrich Hieronymi, Rüdiger Kramme, Harald Kronberg

Respiratory monitoring includes the measurement, evaluation, and monitoring of parameters of the respiratory system, which are grouped firstly into parameters of respiratory mechanics (Sect. 49.1) and of the mechanics of machine-assisted artificial respiration (e.g., respiration rate, tidal volume, and airway pressure as part of the settings at the ventilator), and secondly into parameters of gas exchange (Sect. 49.2). Special consideration is given to pulse oximetry (Sect. 49.2.2) – a basic non-invasive monitoring procedure of great importance – and its recent further development to pulse CO-oximetry, to transcutaneous blood gas monitoring (Sect. 49.2.3) which has its focus in neonatal monitoring, and to capnography (Sect. 49.2.5) which is a standard monitoring to

be performed during anaesthesia in the induction and the OT.

In the case of machine-assisted artificial respiration in the OT or in intensive care units, the monitoring is focussed on ventilation and oxygenation (Chaps. 27 and 30). Monitoring of the artificial respiration parameters and of the inspiratory oxygen concentration

usually is part of the ventilator. Cardiovascular parameters, blood gases, and also, if necessary, anaesthetic gases (when not measured by the anaesthesia device itself) are generally monitored by means of a separate patient monitor.

49.1 Respiratory Mechanics

In monitoring, the respiratory mechanics is primarily the description of the mechanical processes of the thorax that are necessary for ventilation, in the form of pressure/volume relationships. In the case of patients who are given artificial respiration, the airway pressure and tidal volume are of particular interest, and the variables and behavior of these parameters are dependent, in particular, on the compliance (elasticity) of the lungs and on airway resistance. The aspects of pulmonary function testing (Chap. 8) are not central to monitoring but are closely related.

49.1.1 Monitoring of the Respiration Rate

The respiration rate (RR) is a vital parameter that plays a large role in neonatal monitoring, in particular in the case of spontaneously breathing patients (Chap. 54). It is preferably determined from:

- Impedance pneumography (indirect method)
- Capnography (indirect method).

The so-called *acoustic respiration rate* is measured using an entirely new method and sensor (Masimo 2010);

it is not yet possible to estimate the significance of this here.

The Principle of Impedance Pneumography

An increase and decrease in the thoracic volume is linked to inspiration and expiration. As a result of the increase in volume during the inspiration phase, the impedance of the thorax increases, whereas a decrease in the volume means a reduction in the thoracic impedance. In order to detect this, a very low, high-frequency constant current (e.g., 10 μA at approximately 40 kHz) is conducted through two thoracic electrodes. ECG electrodes are used for this, generally those of lead II or optionally, if appropriate, those of lead I. When the current is constant, a change in the impedance causes a synchronous change in the voltage drop. These fluctuations are displayed on the monitor in the form of an impedance pneumogram (or respiration waveform) and this is used to ascertain the respiration rate. The signal is highly vulnerable to movement artifacts, as every movement of the body influences the thoracic impedance.

Determining the Rate

A running average of the breaths counted per minute is displayed. With some monitors, the respiration waveform must only exceed a single adjustable trigger threshold, and this is already classed as a valid breath. Even small artifacts can, therefore, easily lead to a miscount. The combination of an upper and a lower threshold, the interval between which can be adjusted, is better and safer than simply counting the positive passages of the impedance curve through the single trigger threshold. The upper and lower thresholds span a minimum amplitude which must be exceeded by the impedance signal in order to intersect both. Thus, the depth of the respiratory action and not merely its single trigger passage decides whether it is classed as a valid breath and is included into the determination of the respiration rate.

Apnoea Monitoring

Counting the respiratory actions also makes it possible to monitor any pause in breathing or apnoea that occurs. If no breath is detected within the time frame defined by the adjustable monitoring limit *apnoea time*, then an apnoea alarm is triggered.

It is important to take into account that every heart beat causes a measurable change in impedance in the thorax, which may be visible in the impedance pneumogram. If the trigger threshold or the minimum amplitude is set such too low such in cases, then it is not the respi-

ration rate that is counted but the heart rate (cardifact). Cases of apnoea can then be overlooked. Particularly in the neonatal monitoring mode, monitors are capable of determining whether the respiration rate and heart rate closely resemble one another or are identical and of triggering an alert in the event of such cardifacts. (For the significance of respiratory monitoring please also refer to Chap. 54.)

49.1.2 Pressure and Flow

Tidal volume, airway pressure, and the temporal profile thereof (slopes and respiration rate) are specified in the case of patients given artificial respiration by adjusting settings on the respirator or anaesthetic equipment. For those cases where the equipment displays do not provide sufficient diagnostic information, the monitoring includes modules for supervision of the respiratory mechanics. A special flow sensor measures the inspiratory and expiratory gas flows and volumes in the mainstream and also the airway pressure. Both the waveforms of flow, pressure and volume, and also the flow-volume and pressure-volume loops (F-V and P-V loops) can be displayed on the monitor. Parameters that can be displayed and provided in trends, for example, inspiratory and expiratory tidal volumes, minute volumes, maximum flows and airway resistance, maximum and average airway pressure, PEEP (positive end-expiratory pressure), respiration rate and inspiration/expiration ratio (I/E), as well as the lung compliance.

If these measurements are combined with the capnography, the CO_2 production, the alveolar ventilation as well as anatomical and physiological dead space ratios can also be ascertained. All these parameters are used for diagnosis and therapy monitoring in the case of patients given artificial respiration.

Flow Sensor with a Fixed Orifice

When measurements are to be taken close to the patient directly in the mainstream between the endotracheal tube and the Y-piece of the ventilation hoses, it is important to have a robust sensor with small dead space and low flow resistance that can be easily applied and provides reliable measurements without having to undergo calibration procedures, despite the constantly moist gases. The pneumotachograph usually used for measuring flow in functional diagnostics (Chap. 8) is not suitable for this purpose as it would quickly become blocked.

A special sensor has proved successful for use in long-term artificial respiration, which measures the gas

flows in both directions by measuring the differential pressure at a flow resistance point in the form of a fixed orifice. This system is affected less quickly by the negative effects of condensate and can be constructed with such a small amount of dead space that it can even be used for neonates. The nonlinear relationship between the pressure difference and flow is compensated by using a microprocessor.

Different Measurements from the Module and Ventilator

Ventilators generally measure the pressure and volume in the equipment remote from the patient, whereas the respiratory mechanics module takes measurements close to the patient. In addition to the compliance of the ventilation hoses, the measuring temperature also plays a particularly important role for the volumes displayed. Measurements taken directly from the patient are effectively taken at body temperature ($\approx 37^\circ\text{C}$). These gas conditions are described as BTPS (body temperature and pressure, saturated). The condition ATPS

(ambient temperature and pressure, saturated) is present in the equipment for expiration, and strictly speaking ATPD (ambient temperature and pressure, dry) for inspiration, because dry gases are present, which are only humidified on the way to the patient. There is, therefore, a considerable difference in temperature between the two measurement points, which leads to noticeable differences in volume. The gas laws give the following equation for an ambient temperature of 22°C

$$\begin{aligned} V(\text{BTPS}) &= V(\text{ATPS}) \times \frac{273.15 + 37}{273.15 + 22} \\ &= 1.05 \times V(\text{ATPS}). \end{aligned}$$

Volume measurement at body temperature is thus approximately 5% higher than at an ambient temperature of 22°C .

The condition STPD (standard temperature and pressure, dry) should in addition be mentioned, which was determined as being at standard temperature 0°C , standard pressure 760 mmHg and dry (water vapor partial pressure = 0 mmHg).

49.2 Gas Exchange

Measurement methods and measurement parameters for respiratory gases, blood gases, and anaesthetic gases can be summarized as so-called gas monitoring under the generic term gas exchange.

49.2.1 Gas Monitoring: Preliminary Remarks

There are very differing conditions under which the respiratory gases and blood gases of a patient must be monitored: spontaneous respiration or artificial respiration with or without oxygen enrichment. In the case of anaesthetic ventilation, nitrous oxide N_2O or volatile anaesthetics are added.

In the pulmonary alveoli, the respiratory gases are in contact with the blood over a short diffusion path through the alveolar and capillary walls. Oxygen (O_2) first dissolves in the blood plasma and then diffuses further into the red blood cells (erythrocytes), which contain the red blood pigment hemoglobin (Hb) as an oxygen-transporting agent. Oxygen is not directly bound to Hb, but is only attached to the iron atom of each of the four haem groups. A molecule of Hb can, therefore, transport up to four oxygen molecules and easily release them again when it has reached surrounding tissue structures, which have a lower oxygen

partial pressure via the bloodstream. Hb is, therefore, not oxidized, but rather oxygenated and in turn deoxygenated.

Carbon dioxide (CO_2) is constantly produced in the body as a product of metabolism and is likewise partly dissolved in the blood plasma, but is for the most part transported back to the alveoli as a bicarbonate chemically bound by attachment to an NH_2 group of the hemoglobin.

Whereas blood gas analysis (BGA) only ever measures the gases oxygen and carbon dioxide, the concentration of nitrous oxide and volatile anaesthetics in the respiratory gases must, if necessary, also be monitored. The respiratory gases are often measured as a concentration in percent by volume (vol.%), whereas the blood gases are measured as partial pressures in mmHg (= torr) or kPa. Both measurements can be converted from one to the other. In principle it would be physiologically meaningful to present partial pressures under BTPS conditions only. But – historically introduced by the gas-mixing technology – especially the inspired gases are given as volume concentration of a dry gas mixture under standard conditions STPD.

In a mixture of ideal gases with the concentrations c_i (measured in vol.%), the partial pressure p_i of one com-

Table 49.1 Composition of the air

Constituent	Abbreviation	Fraction (vol.%)
Oxygen	O ₂	about 21
Nitrogen	N ₂	about 78
Argon	Ar	about 1
Carbon dioxide	CO ₂	about 0.03

ponent is the fraction of the total pressure (here always the atmospheric pressure p_{baro}) which is proportional to its concentration:

$$p_i = c_i \times p_{\text{baro}} .$$

The total pressure is accordingly the sum of the partial pressures of each of the individual gas components

$$\begin{aligned} p_1 + p_2 + \dots + p_n \\ = c_1 \times p_{\text{baro}} + c_2 \times p_{\text{baro}} + \dots + c_n \times p_{\text{baro}} = p_{\text{baro}} . \end{aligned}$$

Normal respiratory air with the familiar composition (Table 49.1) is heated to 37 °C during inhalation and is mixed with a newly added gas as a result of humidification in the airways: water vapor. At full water vapor saturation, the water vapor partial pressure $p_{\text{H}_2\text{O}}$ is entirely dependent on the temperature and is 47 mmHg at 37 °C. This is 6.2 vol. % ($= (47/760) \times 100$ vol. %) at standard atmospheric pressure $p_{\text{baro}} = 760$ mmHg. In its otherwise unchanged composition, the respiratory air now takes up only 93.8% of the volume, and in this wet gas oxygen, therefore, only has a concentration of 19.7% ($= 0.938 \times 21\%$) or a partial pressure of $19.7\% \times 760$ mmHg = 150 mmHg.

The remaining expiration gas in the alveoli mixes with this fresh gas, such that a noticeably lower alveolar O₂ partial pressure p_{AO_2} results, with a standard value of ≈ 100 mmHg ($= 13.33$ kPa) (conversion: 1 kPa = 1 kN/m²; 100 kPa = 750 mmHg; 1 mmHg = 0.133 kPa). The difference between the partial pressures of a gas is the driving force behind diffusion. Venous blood arriving in the lungs has the comparatively low venous oxygen partial pressure p_{vO_2} , which in the capillaries, in ideal ventilation, becomes equal to the alveolar partial pressure as a result of gas exchange. Because not all blood is involved in gas exchange, in practice there is an alveolar-arterial oxygen difference AaDO_2 of 10–20 mmHg in healthy individuals.

Venous blood transports CO₂ to the lungs and the inhaled air contains virtually no CO₂. The gas exchange leads to a normal alveolar CO₂ partial pressure p_{ACO_2} of ≈ 40 mmHg ($= 5.3$ kPa).

Spontaneous respiration primarily aims to stabilize the CO₂ partial pressure and $p\text{H}$ of the blood, whereas

large fluctuations in the O₂ partial pressure are tolerated. It also worthwhile to measure the carbon dioxide in the respiratory gas as a partial pressure and not as a volume concentration, because the latter is dependent on air pressure.

As mentioned above, the oxygen is essentially transported by the erythrocytes. Hemoglobin binds approximately 70 times more O₂ than the blood plasma is capable of dissolving. The amount of oxygen in the blood is called the oxygen content and is measured in ml O₂ per dl blood. Together with the cardiac output, it decisively determines the transport of oxygen in the blood stream. How much hemoglobin is loaded with oxygen is dependent on the O₂ partial pressure in the blood and is given as the oxygen saturation, the percentage ratio of oxygenated hemoglobin to the total amount of hemoglobin. One gram of hemoglobin (Hb) can transport ≈ 1.34 ml of oxygen; the solubility factor for 1 ml of oxygen in 1 dl of blood is about 0.003 per mmHg. The arterial and venous oxygen content can accordingly be given by

$$ca_{\text{O}_2} = 1.34 \times \text{Hb} \times \frac{Sa_{\text{O}_2}}{100} + pa_{\text{O}_2} \times 0.003$$

and, correspondingly,

$$cv_{\text{O}_2} = 1.34 \times \text{Hb} \times \frac{Sv_{\text{O}_2}}{100} + pv_{\text{O}_2} \times 0.003 ,$$

where Sa_{O_2} is the arterial and Sv_{O_2} the venous oxygen saturation as a percentage, Hb is the hemoglobin content of the blood in g/dl, and pa_{O_2} and pv_{O_2} are, respectively, the arterial and venous oxygen partial pressure in mmHg. The arteriovenous oxygen difference $av\text{DO}_2$, unlike the AaDO_2 , is, therefore, not a partial pressure difference but a content difference that provides evidence about the oxygen consumption of the organism. Table 49.2 shows a summary of terms and units of measurement for oxygen transport.

In addition to the functional hemoglobin Hb (deoxyhemoglobin), which is available for oxygen uptake, and O₂Hb (oxyhemoglobin), which is already saturated with oxygen, there is also a series of dysfunctional Hb derivatives; the most frequent representatives of these, COHb (carboxy-Hb, Hb poisoned with carbon monoxide) and MetHb (methemoglobin), are mostly present in the blood in fractions of less than 5 and 1%, respectively. Whereas the amount of oxygen physically dissolved in the blood is simply proportional to the oxygen partial pressure (second summand in the content calculation above), the significantly more complex relationship between the p_{O_2} and the degree of hemoglobin oxygenation, i. e. the oxygen saturation, is represented by

Arteriovenous oxygen difference	$avDO_2 = caO_2 - cvO_2$	ml/dl
Oxygen availability	$DO_2 = CO \times caO_2 \times 10$	ml/min (CO = cardiac output in l/min)
Oxygen consumption	$VO_2 = CO \times avDO_2 \times 10$	ml/min

the oxygen–hemoglobin dissociation curve (synonyms: oxygen dissociation curve, oxyhemoglobin dissociation curve) of the hemoglobin (Fig. 49.1).

The position and shape of the oxygen–hemoglobin dissociation curve are dependent on various factors in the blood, such as:

- pH and pCO_2
- Temperature
- Hemoglobin type (foetal or adult)
- Proportion of dysfunctional Hb derivatives (COHb, MetHb)
- Enzyme content (2,3-DPG).

Some deviations from the normal value lead to an improved O_2 supply. With a fever or an increased pCO_2 , for example, the dissociation curve is displaced to the right, such that oxygen is released to the cells more easily. Mountain dwellers have an increased 2,3-DPG content, which also results in the dissociation curve being displaced to the right. Carbon monoxide poisoning with the formation of high concentrations of COHb is, in contrast, accompanied by displacement of the dissociation curve to the left, such that the remaining functional hemoglobin, which is already depleted, also releases the oxygen with greater difficulty.

Dangers resulting from decreased supply of oxygen can be detected in good time in the arterial blood by monitoring both the arterial oxygen partial pressure

p_aO_2 and the oxygen saturation SAO_2 . Whereas arterial blood samples could previously only be examined for this purpose in the laboratory analyzer at relatively long time intervals, noninvasive continuous monitoring procedures are now available for both measurement parameters: pulse oximetry (Sect. 49.2.2) for determining the SpO_2 as a measure of the arterial O_2 saturation, and

Fig. 49.1 Oxygen–hemoglobin dissociation curve of the hemoglobin under normal conditions (temperature 37 °C, pH 7.4)

transcutaneous blood gas measurement (Sect. 49.2.3) of *ptc* O₂ (and *ptc* CO₂) as correlates of the arterial gas partial pressures *pa*O₂ (and *pa*CO₂).

Important terms relating to physiological states of oxygen deficiency are:

Hypoxia	low oxygen partial pressure (<i>pa</i> O ₂)
Hypoxxygenation	low oxygen saturation of the hemoglobin (<i>Sa</i> O ₂)
Hypoxaemia	low oxygen content in the blood (<i>ca</i> O ₂)
Anaemia	low hemoglobin content in the blood (Hb).

It can be seen from the oxygen-hemoglobin dissociation curve in Fig. 49.1 that, in the case of oxygen deficiency, even small changes in the *pa*O₂ signify large changes in the *Sa*O₂, and O₂ saturation is, therefore, a variable that reacts very sensitively in the case of oxygen deficiency, which means that pulse oximetry is particularly suitable for monitoring oxygen deficiency. On the other hand, even with a normal *pa*O₂ of approximately 90–95 mmHg virtually all of the hemoglobin is oxygenated. Monitoring of an upper limit by means of pulse oximetry is no longer conclusive, particularly if the patient is being given oxygen, and transcutaneous blood gas measurement is considered preferable. Transcutaneous blood gas monitoring is, therefore, most commonly used to avoid hyperoxia in premature infants; relatively long-term hyperoxia in their case leads to irreversible blindness.

49.2.2 Pulse Oximetry

Pulse oximetry is a noninvasive method for continuously measuring the oxygen saturation in the arterial blood. The parameter is not called *Sa*O₂ but *Sp*O₂, to signify that the oxygen saturation is determined by means of pulse oximetry and to point towards the principal difference.

Functional and Fractional Saturation

The value *Sp*O₂ from pulse oximetry is always what is known as the *functional* saturation: the oxyhemoglobin as a percentage of the *total functional* hemoglobin, which can transport oxygen:

$$SpO_2 = \frac{O_2Hb}{O_2Hb + Hb} \times 100\% .$$

Fractional saturation is determined using laboratory CO-oximeters, however: the hemoglobin as a percent-

age of the *total measured* hemoglobin, including the dysfunctional hemoglobin derivatives, e.g. carboxyhemoglobin or methemoglobin:

$$SaO_2 = \frac{O_2Hb}{(O_2Hb + Hb + COHb + MetHb)} \times 100\% .$$

When significant amounts of MetHb are present (in the case of methemoglobinaemia), this fundamental difference between *Sp*O₂ from pulse oximetry and *Sa*O₂ from the laboratory CO-oximeter naturally leads to differing results, the cause of which is not known to every user. The situation is worse when COHb is present (e.g. in the case of smoke poisoning): pulse oximetry is not capable of distinguishing between O₂Hb and COHb and in this case provides erroneously high *Sp*O₂ values.

Conventional Pulse Oximetry

Conventional pulse oximetry was developed in 1974 by Aoyagi and has been commercially available since 1981. Pulse oximetry monitoring has since become an indispensable monitoring standard.

Using an easily applied sensor (finger sensor for adults and children or, for newborn infants, an adhesive sensor on the hand or foot, for example), the oxygen saturation *Sp*O₂ and the pulse rate are determined and a plethysmographic curve is displayed on the monitor. Pulse oximetry uses the different absorption properties of oxyhemoglobin (O₂Hb) and deoxyhemoglobin (Hb) at different wavelengths of light (Fig. 49.2). Two LEDs transmit red and infrared light through the measurement point. A detector registers the intensities *I*_{RD} and

Fig. 49.2 Absorption spectra of the functional Hb forms Hb (deoxyhemoglobin) and O₂Hb (oxyhemoglobin) and also of the dysfunctional Hb derivatives COHb and MetHb, which are not capable of binding oxygen

Fig. 49.3 Conventional pulse oximetry. Two LEDs transmit red (RD) and infrared (IR) light through the measurement point, and this light undergoes pulsatile absorption (AC) through arterial blood and constant absorption through tissue (DC1), venous blood (DC2) and non-pulsatile arterial blood (DC3). The detector measures the intensities I_{RD} and I_{IR} of the transmitted light as a function of time (transmission photometry)

I_{IR} of the penetrating red (RD) and infrared (IR) light (Fig. 49.3).

Conventional pulse oximetry is based on the assumption that only arterial blood has a pulsatile AC component of the light absorption, whereas tissue, venous blood and nonpulsatile arterial blood always constitute a constant DC component of the light absorption at the measurement point (Fig. 49.3). The intensities I_{RD} and I_{IR} registered by the detector thus include an AC and a DC component in each case. These are then compared with one another, and from the quotient

$$r = \frac{I_{RD} AC / I_{RD} DC}{I_{IR} AC / I_{IR} DC}$$

of these two relationships the percentage value of the oxygen saturation SpO_2 is empirically determined. This quotient from two quotients has the advantage that no calibration procedure is necessary for the pulse oximetry measurement and the process is, therefore, particularly user-friendly.

Movement in the Case of Conventional Pulse Oximetry

If the patient moves, then the venous blood at the measurement point also moves. This inevitably results in considerable interference components in the signal being investigated, because pulsatile elements no longer

originate from arterial blood alone. The AC components are distorted and an imprecise saturation value emerges. Even with normal patient movements or low perfusion, the interference components in the detected signals can be far higher than the desired signals. In these cases, the quotients are primarily determined by the interference components and r has a value close to 1. Many systems then show a saturation value of approximately 85%.

As a countermeasure, in conventional pulse oximetry systems, for example, the time for determining the average is increased or the display is *frozen* if movement is detected. This does not provide clinicians with continuous information, however, and can in the worst case scenario lead to misinterpretations.

Masimo SET Pulse Oximetry

In 1989 *Diab* and *Kiani* [49.1–3], founders of Masimo Corporation, developed signal extraction pulse oximetry, which made it possible for the first time to differentiate the arterial signal from nonarterial interferences. This pioneering technology has been used in clinical practice since 1998.

Masimo signal extraction technology (SET) rejects the conventional assumption that pulsatile signal components originate from arterial blood alone. By means of adaptive noise suppression, the venous component can be separated. The principles of this are explained in more detail in [49.2].

Important features and advantages of Masimo SET pulse oximetry are:

- The saturation algorithm is independent on the pulse rate algorithm (whereas, in conventional pulse oximetry systems, an accurate pulse must be detected in order to calculate the exact arterial oxygen saturation).
- Using Masimo SET, arterial oxygen saturation and the pulse rate can even be monitored when movement has already begun before the pulse oximeter has been switched on (whereas conventional technology relies on *clean* data at the beginning of monitoring).
- As an aid for optimum sensor placement, an additional parameter is supplied: the perfusion index (PI). Displaying the signal IQ serves as signal quality control.

Perfusion Index

The infrared signal, which is influenced less by the oxygen saturation, is used to calculate the PI. The in-

dex is determined from the pulsatile ($I_{IR AC}$) and the nonpulsatile IR signal ($I_{IR DC}$) and is given as a percentage

$$PI = \frac{I_{IR AC}}{I_{IR DC}} \times 100\% .$$

The value of the PI relates to the respective measurement point on the patient. According to the physiological conditions, it differs from one measurement point to the next and from patient to patient. The PI is suitable for assessing the suitability of the measurement point. A large PI means optimum measurement for pulse oximetry. The PI display covers values from 0.02 to 20%. A PI above 1% is desirable.

SpO₂ Signal Quality Control – Signal IQ

Masimo pulse oximetry provides a visual display for the quality of the plethysmographic signal. It is referred to as signal IQ (signal identification and quality indicator). Using signal IQ it is possible to identify the occurrence of a pulse as well as the associated signal quality of the measurement. When the patient moves, the plethysmographic pulse curve is frequently distorted by artifacts. The signal IQ, which is represented as a vertical line (pulse bar), reliably shows the time of the arterial pulsation, and its height indicates the quality of the signal measured. When a sharp reduction in the signal quality can have a negative influence on the accuracy of the SpO₂ measurement, a warning message (signal IQ low) is shown on the display.

Sensitivity Modes

Masimo pulse oximetry enables the measurement sensitivity to be set at three levels.

Normal: recommended mode for typical monitoring, such as in intensive care units, for example.

Adaptive probe off detection (APOD): recommended mode when, because of staffing levels, it is not possible to detect immediately if a sensor has become detached. This mode offers better protection against erroneous measurements being displayed, even though the sensor has become detached from the measurement point (e.g. as a result of the patient moving).

Maximum: this mode is used to obtain and display data even when the signal is very weak due to impaired perfusion (can be used, for example, during treatment or examination, i. e. when someone is with the patient). If the sensor becomes detached from the patient, this mode makes virtually no provision for measurements that are displayed erroneously.

Pulse CO-Oximetry

Masimo Rainbow SET Pulse CO-Oximetry, a further development of the two-wavelength pulse oximetry, was first introduced in 2005 and is based on Masimo Signal Extraction Technology. It is a continuous, noninvasive method that, in addition to oxygen saturation, pulse rate and perfusion index, enables the following parameters to be measured, which are of great interest clinically:

- The total hemoglobin (SpHb)
- The oxygen content (SpOC)
- The carboxyhemoglobin content (SpCO)
- The methemoglobin content (SpMet)
- The pleth variability index (PVI).

Masimo pulse CO-oximetry uses multiwavelength sensors that transmit more than seven different wavelengths of visible light and infrared light from LEDs through the measurement point and correspondingly detect the respective absorption.

Arterial Oxygen Content SpOC

With typical paO_2 values of around 100 mmHg, the oxygen content dissolved in the plasma is only approximately 0.3 ml/dl and can in practice be assumed to be a constant. For normal concentrations of carboxyhemoglobin and methemoglobin, the functional saturation determined using a pulse oximeter is about 2% higher than the fractional saturation: $SpO_2 = 1.02 \times SaO_2$.

For the arterial O₂ content, this approximation gives a simplified calculation for SpOC from SpHb and SpO₂:

$$SpOC = 1.31 \times \left(SpHb \times \frac{SpO_2}{100} \right) + 0.3 .$$

The measurements from the pulse CO-oximetry can be compared with laboratory measurements from blood samples. Interpreting comparisons of this type requires a great amount of care, as the values ascertained from the blood gas sample may under some circumstances differ from the SpO₂, SpCO and SpMet measurements. For SpO₂, differences from the arterial blood gas sample occur when the effect of the influencing variables on the oxygen-hemoglobin dissociation curve have not been corrected. In the case of SpCO and SpMet, in addition to temperature and pH abnormal values for the oxygen saturation ($SaO_2 < 90\%$) and/or for the concentration of methemoglobin ($MetHb > 2\%$) in the blood gas sample can also influence the results.

Pleth Variability Index (PVI)

The heart and lungs interact physiologically in different ways. Intrathoracic pressure changes as a result of res-

piration have a direct influence on the filling of the heart with blood and on its pumping capacity. These pressure changes are visible as a cyclical change in the arterial blood pressure. A reliable, continuously and noninvasively measurable indicator of such cyclical changes would be of great clinical value.

Masimo has developed the pleth variability index, which shows the cyclical changes in the pulse curve as a result of changes in the physiological conditions. The perfusion index (PI), which has already been mentioned, is used for this purpose. The pleth variability index (PVI) is a measure of the dynamic changes in the PI during the respiratory cycle and is calculated as a percentage value from the PI changes during the respiratory cycle or multiple complete respiratory cycles:

$$\text{PVI} = \frac{\text{PI}_{\text{max}} - \text{PI}_{\text{min}}}{\text{PI}_{\text{max}}} \times 100\%$$

The lower the PVI, the lower the PI variability in the course of a respiratory cycle. The PVI can provide potentially useful information about the balance between the intrathoracic airway pressure and the intravascular fluid volume. Its trend can be helpful in estimating the hydration status. An increase can indicate hypovolaemia [49.1].

Overall, the parameters from pulse CO-oximetry introduced in recent years have significantly broadened the possibilities for noninvasive monitoring of patients and are attracting increasing interest among their users.

Mixed Venous Oxygen Saturation SvO₂ and Central Venous Oxygen Saturation ScvO₂

In pulse oximetry, the measurement point is transilluminated. This is not possible in large vessels, e.g. in the pulmonary artery, where the venous blood from all the organs arrives thoroughly mixed together. A catheter with fiber optics placed here can detect the mixed venous oxygen saturation SvO₂ by means of reflection photometry, however. If a pulmonary artery catheter is to be avoided, the central venous saturation ScvO₂ can in the first approximation be measured using a central venous catheter, situated a little upstream of the right atrium, and fiber optics. The two values may differ, but react to the same extent to changes in the haemodynamics [49.4]. Both parameters may, therefore, be used in monitoring as immediate indicators for haemodynamic changes.

By taking account of the arterial oxygen saturation SaO₂ and the cardiac output, important information can be obtained about the oxygen utilization of the organism.

49.2.3 Transcutaneous Blood Gas Measurement

Miniaturized electrochemical sensors of the Clark type, known in principle from blood gas analyzers, are placed directly on the skin. A measuring membrane encloses a very small volume of electrolyte, into which the oxygen and/or carbon dioxide can diffuse from the cutaneous capillary bed. Since only arterial values are of interest, the capillary bed is heated to 42–45 °C by means of a heating element in the sensor and thus arterialized: the high temperature reduces the vascular tone, the arterioles become slack, and arterial blood penetrates into the capillary bed.

The transcutaneous oxygen partial pressure *ptcO₂* is measured according to the polarographic method (Fig. 49.4). Microelectrodes made from platinum or gold are situated in the electrolyte and are biased towards a silver anode with a fixed plateau potential (typically 0.8 V). A small *ptcO₂*-proportional measurement current,

$$I \propto p_{\text{tcO}_2},$$

then flows, which is generated as a result of the reduction of O₂ molecules at the microelectrodes

At the same time, silver at the anode is converted to silver chloride

The response time (T₉₀, based on partial pressure peaks of 10–90%) is approximately 8 s and is, therefore, not

Fig. 49.4 Polarogram of an electrochemical O₂ converter

Fig. 49.5 Sectional drawing through a transcapnode

slower-acting than pulse oximetry, which uses similar averaging times to stabilize measurements.

The transcutaneous carbon dioxide partial pressure $ptcCO_2$ is measured according to the potentiometric method using a pH electrode. By way of illustration, Fig. 49.5 shows a diagram of a transcapnode with an iridium/iridium oxide pH electrode.

This type of electrode is considerably more stable mechanically and has a significantly lower and more noise-free output impedance than the previously customary glass electrodes. The CO_2 , which diffuses into the measuring cell, shifts the pH value by forming carbonic acid:

When the partial reactions are at equilibrium, there is a logarithmic relationship between the CO_2 partial pressure and the pH, such that the potential present at the pH electrode is likewise logarithmically dependent on the $ptcCO_2$,

$$U \sim \log(ptcCO_2).$$

The response time (T_{90}) for the $ptcCO_2$ measurement has been considerably shortened over the years and is now typically 40 s.

Transcutaneous oxygen monitoring requires a minimum heating temperature of $43^\circ C$; for CO_2 monitoring, a temperature of $42^\circ C$ is sufficient. A temperature of $43.5^\circ C$ provides a good compromise between the desired high correlation with arterial measurements and the risk of local burns to the skin. A temperature of $45^\circ C$ must not be exceeded and at this temperature the sensor must be repositioned approximately every hour; infants have been found to withstand a heating temperature of $42^\circ C$ even over a period of 24 h without burning.

Measuring Accuracy and the Influence of Errors in Transcutaneous Blood Gas Measurement

Transcutaneous blood gas sensors are intended to react as quickly as possible to changes in partial pressure and, therefore, contain only a very thin electrolyte layer. Heating the sensors leads to the drying out and sweating of the patient, and to thinning of the electrolyte, resulting in unstable measurements. Such sensors must, therefore, be calibrated at least once daily to air ($pO_2 = 0.21 \times p_{baro}$) and if necessary to at least one defined CO_2 mixture (5 or 10% CO_2). From experience, the electrolyte and measuring membrane must also be replaced at least once a week.

In a similar way to ECG electrodes, the sensors are attached to the skin using adhesive rings. A drop of aqueous contact agent is applied to the application site. This provides better diffusion and prevents inclusion of any of the surrounding atmosphere which, despite the low volume, would impede fast adjustment to real transcutaneous measurements.

In principle, transcutaneous and arterial blood gas values do not correspond with each other, but a good measuring system guarantees a high correlation ($r > 0.8$) of the $ptcO_2$ and $ptcCO_2$ values with the paO_2 and $paCO_2$ values, respectively. Heating of the capillary blood leads to significant temperature-dependent increases both in the O_2 and CO_2 partial pressure (capillary arterial reference values: $pcapO_2 + 6\%/^\circ C$, $pcapCO_2 + 4.8\%/^\circ C$). This is because an increase in temperature shifts both the oxygen-hemoglobin dissociation curve of the hemoglobin and the chemical equilibrium between dissolved carbon dioxide and bound CO_2 (bicarbonate or bound to hemoglobin).

During diffusion of the blood gases through the epidermis, due to the increased cellular metabolism oxygen is consumed and carbon dioxide is also released. In newborns, the compensatory oxygen effect, therefore, gives $ptcO_2$ values that differ slightly from the paO_2 (and which in older patients are always below the paO_2), whereas the $ptcCO_2$ values are elevated by about 50%. The $ptcCO_2$ values are, therefore, mostly given as corrected values, because the individual effect on the skin is relatively small here compared with the systematic temperature effect. Some manufacturers also allow in vivo correction, which is used to adapt the transcutaneous measurements to the results of blood gas analysis. In the case of stable peripheral perfusion ratios, there is then no longer any difference between the displayed transcutaneous and central arterial measurements.

In the case of low perfusion – e.g. as a result of the onset of peripheral hypoperfusion – transcutaneous O_2

measurement gives misleadingly low values. It can then be dangerous to ventilate the newborn with an increased O_2 concentration in order to compensate. However, the transcutaneous measurement method itself provides an excellent key to explaining this situation, which unfortunately is repeatedly forgotten: a sudden drop in the electrical heat output indicates hypoperfusion. This is because the sensor is heated to a predetermined stable temperature, which is always above the temperature of the blood that is flowing in (e.g. $43.5^\circ C$). In the case of strong perfusion, the sensor is, therefore, cooled more substantially by the blood than in the case of low perfusion. In order to maintain the temperature, a higher heat output is, therefore, necessary in the case of strong perfusion. The trend in the heat output, therefore, runs parallel to the trend in perfusion. If the $ptcO_2$ trend and the trend in the heat output therefore drop simultaneously, this indicates that the $ptcO_2$ drop can be attributed to a decrease in perfusion due to the method of measurement.

Transcutaneous blood gas measurement is also possible in special cases in adults, when it is important to detect changes. It has not proved to be suitable for monitoring trends because the skin perfusion probably plays an even greater role. Known applications are monitoring in cases of hyperbaric oxygen therapy and measurements in angiology, particularly in the case of peripheral occlusive disease and when monitoring the effectiveness of measures to eliminate angiostenoses in the limbs.

49.2.4 Measuring the Respiratory Gases

In addition to oxygen and carbon dioxide, respiratory gases here should also be understood to mean nitrous oxide and volatile anaesthetics (halothane, enflurane, isoflurane, desflurane, and sevoflurane). They are either measured in the respiratory flow of the intubated patient (mainstream method) or in the sidestream method, in which the mixture of respiratory gases is drawn off from the patient's ventilation hose by means of a sampling tube at a gas flow rate of between 50 ml/min and 250 ml/min and, if necessary, is fed to the measuring cell in the monitor via a water trap and drying stage (Nafion tube).

The mainstream method is becoming increasingly widely used for isolated monitoring of carbon dioxide (Sect. 49.2.5), in which the sensor is seated directly on a special airway adapter. The advantage of the mainstream method is its faster reaction to changes in the composition of the respiratory gas, whereas the advantage of the sidestream method is its more robust

construction and the lower amount of additional dead space in the ventilation hose.

Measuring Cells

Oxygen is measured either using inexpensive but slow-acting fuel cells (e.g. in the inspiratory respiratory gas in the case of artificial respiration) or in synchrony with breathing using paramagnetic measuring cells. As an example, Fig. 49.6 shows a paramagnetic measuring cell with a dumbbell-shaped design in a shock-proof construction. Two thin-walled glass balls filled with nitrogen are suspended in the strongly inhomogeneous magnetic field of a permanent magnet. Oxygen in the atmosphere surrounding the magnet gap displaces the glass balls. The resultant torsional moment is compensated with a regulating current through coils on the glass balls and the dumbbell is held in a fixed position. The oscillatory system is, therefore, on the one hand strongly damped, and on the other hand the regulating current is proportional to the O_2 partial pressure in the respiratory gas,

$$O_2 \text{ concentration: } \%O_2 = \frac{pO_2}{p_{\text{baro}}}.$$

Unlike oxygen, carbon dioxide, nitrous oxide (N_2O), and anaesthetic gases have polar molecules, which can be excited to mechanical oscillations by infrared radiation in the wavelength range of between 2.5 and 15 μm and which in the process absorb radiation of characteristic wavelengths. Figure 49.7 shows the absorption bands of the respiratory gases of interest, including water vapor.

Fig. 49.6 Paramagnetic O_2 measuring cell

Fig. 49.7 Absorption spectra of the respiratory gases (simplified, without details of the fine structure)

These very specific absorption bands are utilized for measurement. A radiation source emits an entire spectrum of infrared light. In nondispersive infrared measurement or spectroscopy (NDIR), originally a detector was used that was sensitive only to specific wavelengths absorbed by the gas being investigated. Today, by means of filtering usually only those wavelengths are selected at which there is the greatest absorption of the gas to be measured. In the dispersive infrared measuring technique, a measuring wavelength that is suitable for the gas being sought is generated by dispersion of the light (e.g. by refraction in a prism).

According to the basic law of photometry after Lambert–Beer, the absorption A is proportional to the amount c (frequently inaccurately referred to as the concentration) of molecules capable of reaction in the beam path

$$A = \log \left(\frac{I_0}{I} \right) = \epsilon l c .$$

Here, I_0 and I are, respectively, the irradiated and measured beam intensity, ϵ is the molar extinction coefficient, and l is the length of the reacting beam path.

The higher the partial pressure of the gas components measured in the mixture, the more frequently photons impinge on such molecules. Using infrared photometry, the absolute partial pressures of the gas components are, therefore, initially determined, and the percentage gas concentrations are then determined by reference to the effective total pressure.

If the gas mixture sucked in were not dried, there would be a broad water vapor band (2.7–3.6 μm) di-

Fig. 49.8 Single-beam infrared measuring cell with chopper wheel

rectly above the anaesthetic gas bands (A-gases), which would then disappear. The absorption bands of the anaesthetic gases also overlap such that, when using relatively simple analyzers, it must be entered which gas is used. Measuring devices with automatic identification therefore use other spectral ranges with wavelengths that are above those shown.

The absorption bands of CO_2 (4.26 μm) and N_2O (4.55 μm) lie in a gap in the water vapor spectrum and can be reliably separated using appropriate filters in the filter plate of the measuring apparatus. The filter plate contains a filter in an additional position, which transmits radiation in a gap in the total absorption spectrum through the flow-through cell. This is used as a reference measurement to stabilize the measurements and, therefore, prevents a drift in the measurements when there is gradual contamination of the measuring cell or a change in the radiation source.

Figure 49.8 shows the structure of an infrared measuring cell with a chopper wheel, which is used to alternately move filters for the measurement wavelength and reference filters into the beam path. Today, particularly in monitoring, solid-state sensors without moving parts are used.

Measuring Accuracy

Relatively large anaesthetic gas measurement errors occur in sidestream measuring systems when sampling tubes made from the wrong material are used. So, for example, as a result of surface absorption of halothane, a polyethylene sampling tube can completely distort the erratic concentration changes that are in synchrony with breathing and can give false inspiratory and expiratory

measurements. It is, therefore, imperative to ensure that only those sampling tubes that are recommended or endorsed by the manufacturer of the measuring system are used.

Similar effects arise in relation to measurement of the other gases, too, if a sampling tube is repeatedly disinfected for reasons of thrift. The inner surfaces are very rough and there is no longer any laminar flow in the sampling tube, with the result that concentration levels are distorted on the way to the analyzer.

In routine clinical practice, questions are repeatedly raised about the measuring accuracy of the end-expiratory CO₂ measurements (etCO₂). Deviations in the respiratory gas measuring results from the blood gas values are the reason for this: the *pet*CO₂ is generally lower than the *pa*CO₂ by 2–13 mmHg. Differences in the measurements of equipment from different manufacturers are also unsettling. There are technical and physiological explanations for this.

There is cross-sensitivity between the CO₂ measurement and the other gases, partly due to spectral overlapping (with N₂O) and partly because of an indirect influence of O₂ on the CO₂ absorption band (collision broadening effect). If a capnograph does not also measure the other gases simultaneously, for correction purposes it must be specified whether the gas mixture contains O₂ and/or N₂O in relatively large concentrations. Failure to observe this can lead to errors of about 2 mmHg.

Specific NDIR measuring cells are very sensitive to the CO₂ fine structure spectrum and do not require any correction. There are also infrared analyzers whose CO₂ measurements are automatically corrected with the anaesthetic gas concentrations. If the anaesthetic gas is not detected automatically, indication of an incorrect anaesthetic gas then leads to relatively big errors, not only in the anaesthetic gas but also in the *p*CO₂. Example: If isoflurane is stated but halothane is used, the *p*CO₂ is up to 7 mmHg too low.

These days there is a requirement to state the CO₂ partial pressure as a lung value in accordance with the BTPS standard, since only CO₂ lung values can be compared with blood gas values. Because the infrared measuring cells measure in dry gas, however, the CO₂ lung value must be reduced again by around 2.5 mmHg

$$p\text{CO}_2 (\text{lungs}) \approx p\text{CO}_2 (\text{IR cell}) \times \frac{p_{\text{baro}} - 47}{p_{\text{baro}}}.$$

(In actual fact, this correction is just a little too severe, as the gas in the IR cell is not completely dry.)

The influence of dead space ventilation as a result of a ventilation–perfusion disproportion is frequently underestimated, and feeds directly into the discrepancy between *pet*CO₂ and *pa*CO₂. Alveolar shunts also contribute to the fact that end-expiratory values can be lower than arterial values. Where there are sudden changes in the *pet*CO₂, blood gas analysis must therefore be used to investigate whether the *pa*CO₂ has also changed to the same degree or whether a change in the ventilation–perfusion ratio is (also) responsible for this.

It is not always known that in major operations, the patient's blood is noticeably hypothermic, but blood gas analysis is always carried out at 37 °C. The blood gas analysis values are thus elevated by approximately 4.8% per °C compared with the lung values! Therefore, if the patient were to be cooled down to 34 °C, for example, the uncorrected blood gas analysis value would be about 4.3 mmHg above the actual partial pressure in the patient's blood.

49.2.5 Capnography

Capnography is to be understood as the measurement and graphic representation of the CO₂ in the respiratory gas. Spontaneous respiration is primarily aimed at stabilizing the arterial CO₂ partial pressure to values around about 40 mmHg (Sect. 49.2) and represents the fundamental respiratory drive. Relatively large deviations in the *pa*CO₂ have considerable physiological consequences, such as vasodilatation in the case of hypercapnia, with the possible consequence of an increase in the intracranial pressure. Hypocapnia leads, in contrast, to vasoconstriction with the risk of organ hypoperfusion, which primarily puts the brain at risk.

This means that, as a noninvasive and continuous monitoring process for ventilation, capnography is of high importance for the safety of the patient while under general anaesthetic and in intensive care medicine. The capnogram plots the CO₂ partial pressure over time. The end-expiratory CO₂ (*pet*CO₂) is the maximum at the end of the alveolar plateau, which correlates with the *pa*CO₂.

Due to different recording speeds, CO₂ curves can be displayed in high resolution (12.5 mm/s) or as a trend (25 mm/min) (Fig. 49.9). In monitoring, 6.25 mm/s is customary and trends are as a rule displayed as a course of values (1 value per minute).

In the mainstream method, the measuring sensor is situated close to the patient on an airway adapter between the tube and ventilation hose. It is preferred in the

case of intubated patients because of the very accurate results and lack of temporal latency.

Fig. 49.9 Normal capnogram. F Beginning of exhalation (expiratory phase). Gas is exhaled from the anatomical dead space. F-G Steep rise in the CO₂ concentration, predominantly from the lower airways. G-H Alveolar plateau, consisting of the CO₂ concentration and CO₂ partial pressure of the alveolar gas. H End-expiratory or end-tidal PCO₂ (PetCO₂). H-I Downward curve; the inspiratory phase exhibits a rapid decrease in the CO₂ concentration as a result of the fresh gas taken in

In the sidestream method, the respiratory gas is sampled by means of a fine tube line at a sampling rate of between 50 ml/min and 250 ml/min. The measurement chamber is situated in the patient monitor. This leads to a delay in the display of the capnogram.

However, the sidestream method also allows monitoring of nonintubated patients wearing a respiratory mask, which is constructed from fine tubes and draws off respiratory gas from the nasal openings.

Using microstream technology, a sidestream method that also operates with a high level of accuracy has established itself. The method uses a laser light source at the precise wavelength, which is absorbed most by CO₂. As a result, there is no interference due to other gases with adjacent absorption bands. The special design of the measuring tubes has made the method very reliable in its handling to counter ingress of moisture or secretions into the measuring chamber. Due to its low

Fig. 49.10 The capnograms show influences of the anaesthesia and of the patient, which are reflected in the respective capnograms (courtesy of Hewlett Packard and Agilent Technologies)

sampling rate (50 ml/min) it can also be used for newborn infants.

Indications for capnography are:

- Monitoring of the ventilation during machine-assisted artificial respiration in anaesthesia and intensive care treatment
- Monitoring during cardiopulmonary resuscitation.

Benefits of capnography are:

- Early detection of an intraoperative air embolism, malignant hyperthermia, disconnection of the tube system and stenosis
- Detection of an obstruction, dead space ventilation, rebreathing, malfunction in the absorber or valve system, tube dislocation during narcosis, and haemodynamic changes (e.g. drop in blood pressure, cardiac arrest)
- Indirect information about the muscle relaxation.

The limitations and sources of errors in capnography are essentially:

- Faults in the respiratory physiology: ventilation-perfusion disproportion, dead space ventilation, shunt augmentation

- Faults of a technical nature: calibration errors, condensate or secretions in the sampling tube, stenosis or bending of the sampling tube
- Methodological limitations: high respiration rate, mixed gas analysis, interference of foreign gases (e.g. nitrous oxide, water vapor)
- Errors on the part of the user: interpretation errors.

Figure 49.10 shows how influences on anaesthesia and on the patient are reflected in the respective capnograms.

Temperature

50. Temperature Monitoring

Rüdiger Kramme, Ullrich Hieronymi

Temperature measurements are indispensable as a form of standard monitoring in intensive care medicine, emergency medicine, and anesthesia. This chapter covers various aspects of hyperthermia and hypothermia and discusses the measuring sites for temperature measurement as well as temperature sensors and probes.

50.1 Hyperthermia and Hypothermia.....	987
50.2 Measuring Sites for Temperature Measurement.....	987
50.3 Temperature Sensors and Probes	987
50.4 Methodological Notes	989

Body temperature is a vital sign and is closely related to metabolism. Monitoring of the body temperature is of particular importance in intensive care medicine, because fever elevation of the core temperature above 38 °C is an early sign of sepsis, one of the most common causes of death in intensive care units. The types of fever are important for monitoring of intensive care patients are:

- Continued fever (fluctuations in temperature >1 °C)
- Remittent fever (fluctuations in temperature >2 °C)
- Intermittent fever (fluctuations in temperature >2 °C over the course of a day, with possible drops below normal temperature)
- Undulant fever (constantly changing body temperature which does not follow a trend).

50.1 Hyperthermia and Hypothermia

If the heat input exceeds the heat loss of the body (e.g. in the case of heat stroke, alcohol or drug withdrawal, hyperthyreosis, malignant neuroleptic syndrome or malignant hyperthermia), this state is described as hyperthermia. As a result of an increase in heat loss, a core

temperature below 35.5 °C is described as hypothermia (e.g. following surgical interventions, in the case of extracorporeal circulation and haemodialysis procedures and at the onset of sepsis).

50.2 Measuring Sites for Temperature Measurement

The measuring site is crucial for the assessment of body temperature (Table 50.1), because there may be a temperature difference of up to 5 °C between the different

areas of the body. There can also be a temperature gradient between the core body temperature and the temperature at the periphery (e.g. shock).

50.3 Temperature Sensors and Probes

Various temperature sensors and probes are available for determining the temperature as a thermic measure-

ment parameter (typical measurement range 24–42 °C, optimum measurement range 10–45 °C, in order also

Table 50.1 Overview of temperature sensors/probes and measuring sites for determining body temperature (Figs. 50.1–50.4)

Localization	Comments
1. Surface body temperature sensors	
Axilla	Roughly 1 °C lower than in the rectum; less suitable for temperature measurements in intensive care units (ICU) and in the operating theater (OT)
Skin	Applied to various parts of the body (e.g., forehead and soles of the feet, among others); temperature values are dependent on the perfusion quality of the skin (Fig. 50.1)
2. Temperature sensors and probes for body orifices	
Sublingual	Less suitable for temperature measurements in intensive care units and in the OT
Rectum	The simplest approximation to the core temperature but not representative, because the temperature is dependent on the perfusion of the intestinal mucosa and on spatial temperature gradients, additionally feces can be taken into account as a temperature isolator (Fig. 50.2)
Nasopharynx	Application: mucosa of the nasopharyngeal space; good conditions for temperature measurement due to the spatial proximity to the internal carotid artery
External auditory canal	Application close to the tympanic membrane; measurement result comparable to esophageal temperature (Fig. 50.4)
3. Intracorporeal temperature probes	
Esophagus	Application in the lower third by means of an esophageal stethoscope with an integrated temperature probe; temperature conditions comparable to those of the brain (corresponds approximately to the core temperature)
Pulmonary artery	Online measurement of the temperature by means of a Swan–Ganz catheter; infusion of cold solutions may interfere with the measurement
Bladder	By means of a Foley catheter; temperature conditions correspond approximately to the core temperature (Fig. 50.3)

to be able to measure extremes of body temperature, such as hypothermia or hyperthermia), which present virtually no problems technically (Table 50.1).

Thermistors (also known as negative temperature coefficient (NTC) resistors) are thermosensitive semiconductor elements whose electrical resistance decreases as the temperature increases. If the resistance changes – even very small temperature changes cause changes on account of the high responsiveness of the sensor – then the voltage in the bridge circuit changes in proportion with the temperature change.

This voltage is amplified and displayed via a calibrated (°C) electrical temperature measuring device. Thermistors are the most used temperature sensors in practice.

Thermoelements are composed of two metals which are connected to one another. One connection point is maintained at a constant temperature, while the second forms the actual temperature sensor. When heated,

a difference in temperature arises between the metal connections, and this temperature difference is proportional to the electrical voltage.

Thermal measuring tapes are impregnated with cholesterol crystals whose molecular structure changes as a function of the temperature. Other sensors and probes for determining temperature are:

- Thermal radiation sensors
- Needle thermometers
- Deep-body temperature sensors.

In clinical practice it is widely customary to monitor the temperature difference between the core temperature and a peripheral temperature (surface temperature). Temperature difference is an essential criterion for early detection of the beginning of states of shock, since the temperature at the body peripheries drops more quickly than the core temperature.

50.4 Methodological Notes

Reusable temperature sensors and probes must not be autoclaved or subjected to hot-air sterilization. Gas (ethylene oxide) or plasma sterilization is possible, however.

Temperature sensors and probes must bear the CE marking. In accordance with the German Medical

Devices Operator Ordinance, they are subject to the requirement for metrological checks every two years (for infrared radiation thermometers, the period is one year).

Cerebral Monitoring

51. Cerebral Monitoring

Barbara Schultz, Arthur Schultz, Harald Kronberg

In this chapter, two kinds of cerebral monitoring are presented: electroencephalography (EEG) monitoring and intracranial pressure (ICP) monitoring. EEG monitoring is used in the operating room to assess the depth of hypnosis during anesthesia and to detect effects of hypoxia and of induced hypothermia. In intensive care unit patients, EEG monitoring can be used for the control of sedation, for therapy control, e.g. in status epilepticus, for the assessment of the patient's current clinical status and trends thereof, and as an exploratory diagnostic tool with respect to epileptiform activity and focal brain disorders. Hypnotic drug effects are accompanied in a dose related manner by a slowing of the EEG. These EEG changes can be classified automatically. Especially through the automatic interpretation, EEG monitoring can be carried out as a routine method for patient monitoring with little effort. The aim of detecting and treating elevated ICP is to avoid secondary damage to the brain. The most common indication for ICP monitoring is trauma to the head. Methods for ICP measurement with higher invasiveness include

intraventricular, intraparenchymal, or subdural catheter localisations. A less invasive method is epidural cerebral pressure measurement.

51.1 EEG Monitoring

The electroencephalogram (EEG), a record of the electrical activity of the brain, can be used for patient monitoring in the operating room and in the intensive care unit. Indications for the use of EEG monitoring in the operating room are the assessment of hypnotic drug effects, the early detection of the effects of hypoxia, and the documentation of the cerebral effects of induced hypothermia. In the intensive care unit, EEG monitoring can be used for the control of sedation, for therapy control, e.g., in status epilepticus, for the assessment of a patient's current clinical status and trends thereof, and as an exploratory diagnostic tool with respect to epileptiform activity and focal brain disorders.

51.1.1 Kinds of EEG Activity

Attenuation of brain function is mostly accompanied by a slowing of the EEG. The frequency composition of the EEG can therefore be used to support the assessment of the severity of alterations or impairments of brain function. Furthermore, EEG potentials with a specific shape, e.g., epileptiform potentials, are of interest in EEG monitoring.

In principle, generalized and focal EEG alterations have to be distinguished. Generalized EEG alterations have a similar representation over different areas of the head. Typical examples are hypnotic drug effects, and

alterations of the EEG caused by hypothermia, hypoglycemia or global hypoxia. Focal EEG changes are restricted to a circumscribed area of the head; they can be caused, e.g., by tumors, bleeding or localized hypoxia.

Interpretation of conventional multichannel EEG recordings takes considerable practical effort. Nevertheless, generalized EEG changes can be assessed on the basis of a single EEG channel with high reliability. This is an important precondition for the use of the EEG as a monitoring method.

51.1.2 Spectral Analysis

The conventional visual assessment of the EEG requires expert knowledge and experience. Therefore, it is a considerable simplification for the user in the operating room and in the intensive care unit if the EEG is analyzed automatically by means of computer-based methods and if support for interpretation is given.

Spectral analysis is a method for signal evaluation. The signal is subdivided into segments, which are analyzed with regard to their frequency components.

The result is a power spectrum, which can be displayed graphically and can be used as a basis for further evaluations. Single spectral parameters can be extracted, e.g., the 50% and the 90% (or 95%) quantile of the spectrum, which are also called the median and the spectral edge frequency. Other commonly used spectral parameters are the total power and the power in the different frequency bands. The following frequency bands are distinguished: delta (δ : 0.5–3.5 Hz), theta (θ : 3.5–7.5 Hz), alpha (α : 7.5–12.5 Hz), and beta (β : > 12.5 Hz). Such monoparameters are often able to show general trends within the EEG, but the complex information contained in an EEG cannot be described comprehensively or adequately by monoparameters.

51.1.3 Other Parameters

For the purpose of EEG monitoring in the operating room and in the intensive care unit, also other mathematical and statistical parameters are used.

An example is the bispectrum, which includes information from spectral analysis as well as information about phase coupling. Bispectral analysis is a component of the functions that are used by monitors which were developed by Aspect Medical Systems (Natick, MA, USA) [51.1, 2].

Entropy is a measure of the order or disorder, thus randomness or predictability, of a system. Spectral entropy is the basis of the algorithm which is implemented

in monitoring units of GE Healthcare (Helsinki, Finland) [51.3–5].

Autoregressive parameters can be used to describe the course of a raw EEG. In a regression model, a given value on a time axis is calculated as the weighted sum of one or more past values and a random term. Autoregressive and other parameters are used by Narcotrend (MT MonitorTechnik, Bad Bramstedt) [51.6, 7].

A review of different methods for EEG analysis and of different monitors is given by *Jameson and Sloan* [51.8].

51.1.4 EEG Stages of Anesthesia and Sedation

Hypnotic drug effects are accompanied in a dose-related manner by a progressive slowing of the EEG. Criteria to classify these EEG changes visually into the stages A (awake) to F (very deep anesthesia/sedation) (Fig. 51.1) were proposed by *Kugler* [51.9].

A scale from A to F which was modified for the purpose of EEG monitoring served as the basis for the development of an automatic EEG classification. It was realized by means of a multivariate approach using special pattern recognition algorithms and is a component of the EEG monitor Narcotrend, which was developed for use in the operating room and in the intensive care unit. For the assessment of the hypnotic component of anesthesia and sedation with this device, one EEG channel is used as a standard. For this, three electrodes have to be attached to the patient's forehead. Depending on the kind of surgery performed or if injuries to the head exist, other electrode types (e.g., needle electrodes) or electrode positions can be used. Two-channel recordings are also possible.

The Narcotrend analyzes the EEG in real time; the assessments are updated every second. The central part of the main screen of the Narcotrend is depicted in Fig. 51.2.

51.1.5 Course of EEG Stages During Anesthesia

As an example for the use of automatic EEG classification, Fig. 51.3 shows a course of EEG stages recorded during anesthesia with the hypnotic propofol and the opioid remifentanyl. Due to their short half-lives, the dosing of both drugs can be adapted easily and quickly. Both were given in an intravenous and continuous manner using perfusers. After the induction from stage A to stage E/F, anesthesia was maintained in the deep

Fig. 51.1 Typical examples for EEG stages A–F

stages D/E. At approximately 10:00, a sudden shift to B stages was noticed. This was caused by a short interruption of the drug supply due to technical reasons. When anesthesia is maintained in such light stages the possibility of acoustic perceptions is increased. Subsequently, anesthesia was maintained in stage E. At about 11:30, emergence from anesthesia began, indicated by continuous lightening of the EEG stages from stage E to the awakening in stage A/B. Postoperatively the patient did not remember any intraoperative events.

The dosage of the hypnotic for maintenance of anesthesia was titrated individually according to the EEG in this patient, therefore it was possible to avoid longer periods of over- and underdosage. With the help of the EEG, the short, unwanted lightening of anesthesia could be quickly recognized and immediately corrected.

Parameters for patient monitoring during anesthesia customarily used in daily clinical practice are, among others, blood pressure and heart rate. Especially during

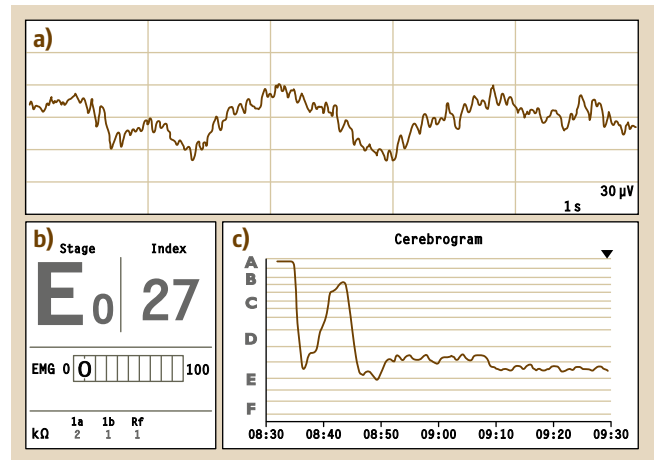

Fig. 51.2a–c A part of the main screen of the Narcotrend. (a) Raw EEG, (b) current stage (E_0) and index (27) value, EMG index (0), and electrode impedances. (c) Course of the EEG stages (cerebrogram). After the hypnotic (propofol) for induction of anesthesia was given to the patient, there was a quick transition from the awake state (stage A) to a deep hypnotic stage (stage E/D, \approx 8.35 h), the muscle relaxant was given, and the patient was intubated. Due to the short half-time of the hypnotic, within a few minutes stage B was reached again (\approx 8.40 h). A propofol bolus (\approx 8.43 h) caused a deepening to level D/E, which was maintained during the steady state. The opioid used for induction and maintenance of anesthesia was remifentanyl

Fig. 51.3 Cerebrogram showing a course of anesthesia with a short unexpected awakening caused by a technically determined interruption of the drug supply (\approx 10.00 h)

intravenous anesthesia, cardiovascular parameters are not a reliable basis for the assessment of the hypnotic

component of anesthesia. The EEG detects hypnotic drug effects directly at the target organ, the brain, and therefore is a valuable help in titrating the dosage.

When the EEG is used and interpreted in clinical practice, the whole clinical situation of the patient has to be taken into account, because other factors, such as hypoxia, hypoglycemia, and hypothermia, can influence the EEG in a manner similar to anesthetics/sedatives.

Visually classified EEG epochs are a stable and clear basis for the development of classification algorithms and support easy validation. Using a visual EEG classification as a basis provides methodological transparency for the user, because a clear relationship exists between the characteristics of the raw EEG and the automatic classification. This can be regarded as an important advantage of the Narcotrend compared with other concepts for automatic EEG classification which do not comprise a defined relationship between the raw EEG and mathematical/statistical parameters, e.g., indexes.

51.1.6 Technical Requirements

In practical use, the following technical details of the monitors have proved to be important: The quality of the EEG signal and, as a consequence, the validity of the subsequent automatic analyses depend on a constantly good electrode–skin impedance. Therefore, it is necessary to carry out impedance checks frequently.

The EEG signal can easily be disturbed, therefore automatic artifact detection is an indispensable prerequisite for further processing of the signal.

Visual analysis has been the standard method for EEG assessment for decades, and it is still indispensable in clinical practice (e.g., assessment with regard to artifacts, identification of special potentials, e.g., epileptiform potentials). Therefore, it is necessary to show the raw EEG in a very clear way with different scaling options.

Age-related changes of the EEG have to be considered when the EEG is automatically classified and when it is displayed.

Different operating fields, patient positions, and kinds of injuries require variable electrode positions and the possibility to use different kinds of electrodes.

For an exploratory examination for the purpose of comparing EEG signals from both hemispheres, at least two channels should be available.

For documentation purposes it should be possible to make printouts of raw EEGs and of courses of spectral parameters as well as of classifications.

51.1.7 Benefit of EEG Monitoring in the Operating Room

In clinical studies it was demonstrated that EEG monitoring leads to improved quality of anesthesia, e.g., with regard to individualized dosing of drugs, avoiding awareness situations, and to fast postoperative recovery. This shall be illustrated by some examples.

The high interindividual variability with regard to dosing requirements of drugs with hypnotic action was demonstrated in a multicenter study comprising 4,630 patients [51.10]. Additionally, it was shown that EEG monitoring supports age-adjusted dosing [51.11]. In a subgroup in this study, the EEG was recorded in a blinded manner, i. e., the classification results were not displayed to the attending anesthetist. During the steady state of anesthesia, only 68.8% of the patients of this subgroup had an EEG corresponding to the medium to deep Narcotrend stages D/E. The remaining courses of anesthesia were either very light, very deep or unstable. Postoperatively, 2 out of 603 patients with blinded EEG registrations reported intraoperative awareness [51.12]. On the contrary, there was no intra- or postoperative indication of awareness in the group with maintenance of anesthesia in stages D/E.

When data from 32 study sites were analyzed it was shown that EEG monitoring caused changes of the propofol doses from -28.4 to $+86.2\%$ in the different centers [51.13].

In studies with EEG-controlled propofol/remifentanyl anesthesia it was demonstrated that EEG monitoring supports gender-adapted dosing. Women had higher propofol requirements but, nevertheless, awake more quickly from anesthesia [51.13, 14].

EEG monitoring supports dosing by means of target-controlled infusion (TCI). TCI pumps incorporate dosing algorithms which are based on pharmacokinetic models. Deviations between calculated drug target levels and measured drug levels were described [51.15]. By means of the EEG, the propofol dosage can be adjusted to individual requirements, taking into account the opioid dosage as well [51.16].

In another study, neurosurgical patients undergoing brain tumor operations were monitored intraoperatively with the Narcotrend. These patients, with Narcotrend stages D/E during the steady state of anesthesia, received only half of the propofol dose which was given to patients without EEG monitoring. Most of the patients with EEG monitoring could already be extubated in the operating room. This facilitated neurological assessment immediately after the operation [51.17]. The

patient care requirements in the intensive care unit were reduced.

By means of EEG, very short recovery times were achieved in patients after thoracic surgery. This resulted in more effective use of the resources in the operating room [51.18].

In a study of *Rundshagen* [51.19], patients with EEG monitoring during anesthesia showed faster postoperative recovery of their psychomotor functions than patients without EEG monitoring. According to the authors' interpretation, EEG monitoring improves the adequate control of the intraoperative depth of anesthesia, causing a reduction of the signs of drug accumulation and improved psychomotor function in the early postoperative period.

In studies of *Weber* [51.20, 21] it was demonstrated that anesthetics can be dosed individually by means of EEG.

In children undergoing cochlear implant surgery the EEG helped to maintain reliably very light EEG stages during a short period in which the implant was tested. The modification of brain function, and consequently of acoustic processing, by drugs with hypnotic action should be as small as possible during this period to enable the use of the measurement results as a basis for postoperative individual fitting of the speech processor [51.22].

51.1.8 Benefit of EEG Monitoring in the Intensive Care Unit

Including the EEG as a method for patient monitoring enables, not only in the operating room but also in the intensive care unit, more differentiated assessment

of the patient in situations with limited possibilities for clinical examination and assessment. This applies to patients having received muscle relaxants and to persons in deep stages of sedation or coma with weak remaining reactions to external stimuli.

A 2 year comparison with regard to the length of stay of ventilated patients in an anesthesiological and surgical intensive care unit demonstrated that, in a year with EEG examinations carried out at regular intervals, the length of stay was 24.4% shorter than in a year without EEG examinations [51.23].

Experience shows that especially geriatric patients, who often suffer from preexisting illnesses and have limited compensation potential, benefit from EEG monitoring during sedation. The risk of secondary infections due to unnecessarily long ventilation times is reduced.

Control of sedation is an important indication for EEG monitoring in patients in the intensive care unit. Besides this, there are numerous other applications supporting diagnosis and therapy, e.g., during the therapy of increased intracranial pressure, in the diagnosis and therapy of epileptic disorders, in the assessment of the current state and the course of the disease of comatose patients, and in the exploratory examination of focal brain disorders [51.12, 24–27].

In summary, it can be concluded that, due to its modern technical implementation and especially through automatic interpretation, EEG monitoring can be carried out as a routine method for patient monitoring with little effort. It is a valuable addition to the monitoring methods used to date. The use of EEG monitoring results in considerable improvement of the quality of anesthesia and intensive care.

51.2 Intracranial Pressure

Space-occupying processes in the brain can lead to dangerous increases in intracranial pressure (ICP) if the compensation capacity of the homeostatic regulatory mechanisms concerned is exhausted. Elevated intracranial pressure causes cerebral hypoxia as a result of inadequate blood perfusion, because the drop in pressure between the systemic arterial pressure (SAP) and the ICP (CPP; cerebral perfusion pressure) is reduced. Ultimately, these underlying space-occupying processes carry the risk of life-threatening brain stem herniation with respiratory paralysis.

Space-occupying processes can proceed slowly (tumor), develop over the course of hours or days (cerebral

edema) or can also appear suddenly (massive hemorrhage). There are also wave-like pathological ICP increases which are probably connected to fluctuations in the cerebral blood volume.

The most common indication for ICP monitoring is trauma to the head. This is because the usual emergency treatment of the patient with artificial respiration, sedation, and relaxation conceals the clinical symptoms of ICP increases. There is no prophylactic therapy for elevated intracranial pressure without long-term side-effects. Treatment of these patients must therefore be carried out under constant monitoring of the intracranial pressure, usually for a period of 3–6 days.

Various methods have been introduced for ICP measurement, and these can essentially be divided into two groups of different invasiveness. Invasive methods, which have an increased risk of infection when longer-term monitoring is necessary, are direct catheter measurement of the intraventricular pressure (gold standard), the intraparenchymal pressure or the subdural pressure; a less invasive method, whose risk of infection can be well controlled but which suffers from frequent measurement artifacts, is epidural cerebral pressure measurement. Lumbar pressure measurement with the possibility of drawing off fluids, a method which sometimes used to be preferred, is now no longer recommended owing to the risk of brain stem herniation. The fact that the significance of and indication for cerebral pressure measurement are barely controversial any longer is evident from the large number of publications in the last 35 years. Although measurement of cerebral pressure has been practiced for around 100 years, with the introduction of the lumbar puncture by Quinke in clinical research, ICP monitoring was finally first established in the clinical routine of cerebral monitoring with the classic study by *Lundberg* [51.28] and the definition of intracranial pressure waves which he introduced. The article by *Allen* [51.29] is recommended for an overview of the physiology and measurement technique, a comprehensive account including examples of measurements can be found in *Gaab* and *Heissler* [51.30], while *Steinbereithner* [51.31] gives a brief overview of treatment for head injuries with an evaluation of intracranial pressure measurement. *Betsch* [51.32] deals specifically in his dissertation with the technical problems of epidural ICP measurement, which is preferred in routine clinical practice in Germany. The cited works include comprehensive information on further reading, and no quotations are therefore given below.

51.2.1 The Physiology of Intracranial Pressure

The central nervous system (CNS) is suspended in the cerebrospinal fluid (CSF) and is enclosed by the dura mater. After closure of the fontanelles, the cranium forms a solid shell around the brain, while the lumbar sac, which protects the spinal cord, has a limited degree of elasticity. The adult brain contains approximately 1500 ml of parenchyma and 120 ml each of blood and CSF. The interstitial fluid makes up 10–15% of the weight of the brain. CSF is constantly formed in the ventricles as a blood filtrate (≈ 500 ml/day) and

flows into the subarachnoid space, a layer between the CNS and dura mater, which is a few millimeters thick. The CSF is finally resorbed by the venous circulatory system by means of pressure-sensitive valve-like villi (Pacchioni's granulations). The result of production and resorption is a normal intracranial pressure of 5–15 mmHg. Since the production of the CSF is for the most part independent of the ICP, the venous pressure essentially determines the average intracranial pressure.

Space-occupying processes in one of the brain's components, e.g., in the case of edema, require a reciprocal change in volume with at least one of the other components if the intracranial pressure is to remain constant. Up to an ICP of around 15 mmHg, homeostatic regulatory mechanisms in these cases prevent hypoperfusion of the brain. CSF can first be forced into the extensible lumbar sac, and if further space is needed more CSF is also resorbed into the venous system. Finally, the venous system can also be compressed and the volume of blood in the brain thus reduced. Once these compensation steps are exhausted, with an ICP which increases quickly there is the threat of herniation of the cerebral tissue in the tentorial notch. Figure 51.4 shows a schematic representation of this pressure–volume relationship.

If the homeostatic regulation is exhausted (ICP > 15 mmHg) or defective, then the cerebral blood perfusion and thus the supply of oxygen to the brain follow the pressure difference between arterial inflow and venous drainage. This pressure difference largely corresponds to the cerebral perfusion pressure $CPP = SAP -$

Fig. 51.4 Intracranial pressure–volume characteristic (schematic)

Table 51.1 Intracranial pressure ranges in adults

Status	Pressure (mmHg)
Normal	5–15
Slightly elevated	15–20
Requiring treatment	20–40
Very serious elevation	> 40

Table 51.2 Perfusion pressure (CPP) ranges

Status	Pressure (mmHg)
Normal	50–150, typical 80
Hypoperfusion	< 50

ICP as the average difference between the systemic arterial pressure and the intracranial pressure.

Therapeutic measures to lower the intracranial pressure must not lower the CPP to below 50 mmHg, and the CPP must therefore always be monitored in addition to the ICP. The normal intracranial pressure is not static but is affected by dynamic components which stem from arterial blood pressure waves and from fluctuations in the respiratory pressure which are conveyed by the venous system. The ICP drops during spontaneous inspiration and increases again during expiration (Fig. 51.5).

In the case of normal intracranial pressure, the pressure curve of individual ICP pulses still exhibits a marked fine structure which changes and gradually disappears as the ICP increases (Fig. 51.6). A review of the clinical relevance of this phenomenon is still the subject of research, however.

Pathological values for the intracranial pressure frequently appear as waves. Plateau or A-waves are ICP increases to a level of 50–100 mmHg for a period of 5–20 min. A-waves are obviously linked to phases of

Fig. 51.5 Dynamic components of the intracranial pressure of an infant with hydrocephalus

cerebral vasodilation and therefore to hyperemia. B-waves are sudden ICP leaps from normal values to values in the range 30–60 mmHg with a frequency of approximately one leap per minute. The waves are frequently observed in head trauma patients and are caused by problems with CSF circulation and likewise by fluctuations in the cerebral blood volume. C-waves are pressure waves with a low amplitude of up to 20 mmHg and frequencies of about 6 per minute. They correlate with Traube–Hering–Mayer waves in the arterial blood pressure.

Intracranial space occupation easily leads to circulation problems or even tissue herniation in the region of the septal foramina, particularly in the case of faster processes. Pressure gradients then appear between the craniospinal compartments, which can be an indication for ICP monitoring at numerous locations, and the ICP should likewise be monitored in the region of the lesion.

51.2.2 Intracranial Pressure Measurement to Monitor Treatment

The aim of treating elevated intracranial pressure is to avoid secondary damage to the CNS. It is vital to

Fig. 51.6 Fine structure of the ICP pulse curve, dependent on pressure

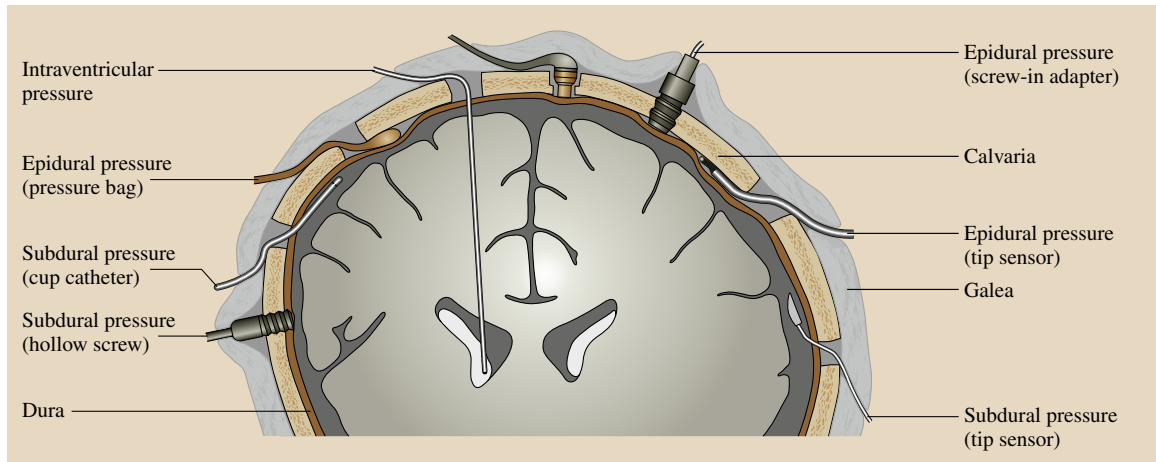

Fig. 51.7 Technical options for clinical measurement of intracranial pressure

take into account the position of the head and neck, as this can have a significant influence on the cerebral venous blood volume and thus on the ICP. A slightly elevated head position reduces the cerebral venous pressure and ICP. Hyperventilation leads, by means of the hypocapnia which accompanies it, to vasoconstriction with a reduction in the intracranial blood volume. In the event of longer hyperventilation, however, the reduced blood perfusion carries the risk of hypoxia, which can result in cerebral edema, increasing the ICP. Dehydrating and diuretic medications for osmotherapy are only suitable for acute lowering of an elevated ICP, but are not suitable for treatment of cerebral edema due to undesirable side-effects. Treatment with barbiturates with a decrease in the cerebral metabolism reduces cellular oxygen consumption and provides protection from long-term consequences of hypoxia. High doses of barbiturates over the longer term reduce the arterial blood pressure, however, with the risk of a perfusion pressure CPP which is too low. There is therefore no long-term prophylactic treatment for elevated intracranial pressure. The various forms of treatment should always be carried out while monitoring intracranial pressure. In the case of head trauma, the first 48 h following injury are particularly critical, and in most cases the ICP need not be monitored for longer than 1 week. Various studies have shown that the introduction of intracranial pressure monitoring has lowered mortality rates by around 40%, without increasing morbidity. The modern state-of-the-art methods for intracranial pressure measurement are still invasive but differ in terms of their risk of infection (Fig. 51.7):

1. Measurement of the intraventricular, intraparenchymal or subdural pressure via a catheter
2. Measurement of the epidural pressure using miniature pressure transducers or by means of pneumatic sensors.

Unusually high requirements must be placed on the zero-point stability of the sensors (drift ≤ 2 mmHg/day) since the ICP itself is a low-pressure signal. However, many sensors are less stable following application, particularly because of humidity drift, and therefore require regular zero-point adjustment. If the fine structure of the pulse waves is of interest, the measurement system must have a bandwidth of around 20 Hz (40 Hz in infants), but a bandwidth of around 3 Hz is sufficient in order to record the ICP pulse amplitude with adequate dynamics.

All methods require trepanation for the application of sensors. In order to perform intraventricular ICP measurement, a catheter is passed through the hole in the meninges and the parenchyma and into the lateral ventricles, and the pressure is usually recorded externally as in the case of blood pressure measurement. The external pressure sensor must be at the precise level of the lateral ventricles in order to avoid hydrostatic errors ($1 \text{ mmHg} = 13 \text{ mm fluid column}$). This method is the gold standard and has the advantage that acute increases in intracranial pressure can often be treated by draining off CSF. Problems include the fact that, in the case of advanced space occupation and thus a narrow ventricle, application of the catheter is difficult to impossible and that a well-applied catheter

Fig. 51.8a–c The principle of applanation tonometry. **(a)** Free dural balloon, which envelops a positive pressure volume. Membrane in equilibrium between the force pushing out $F(\text{ICP})$ and the resulting counteracting force from the dural tension $F(\text{Dura})$. **(b)** Rigid sensor-measurement membrane applanates the dura, and the dural tension forces offset each other [$F(\text{Dura}) = 0$], so that only the force $F(\text{ICP})$ which corresponds to the ICP remains effective for the measurement. **(c)** Dural inhomogeneities, bone fragments or blood clots introduce a dural tension component $F(\text{Dura})$ which overlaps with the intracranial pressure force $F(\text{ICP})$ with the effect of increasing the measurement value

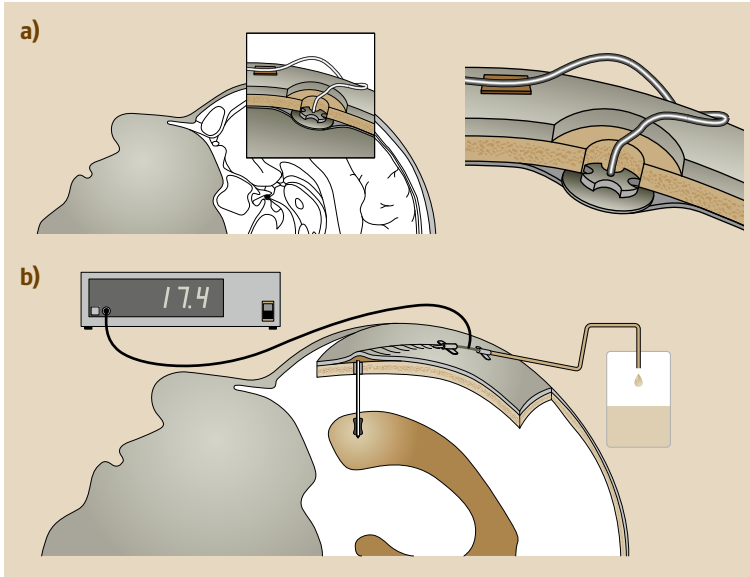

Fig. 51.9 **(a)** Epidural application of a pneumatic single-use sensor, **(b)** intraventricular pressure measurement

can become blocked; above all, the risk of infection in the immunocompromised intracerebral space increases considerably after about 2 days. Infections creep in via the oscillating fluid column in the catheter (pulse wave and respiratory wave), in which bacteria migrate against the irrigating flow and against the force of gravity at approximately 1.5 m/24 h. Epidural measurement of intracranial pressure (2) on the closed dura mater has therefore become largely prevalent in routine clinical practice as opposed to methods (1). If infections nevertheless occur (rarely), they are usually easy to control. Although this procedure also requires a burr hole in the calvaria, it is therefore considered to be a comparatively low-invasive method. The problem with this method is that epidural application of sensors requires increased surgical attention in order to avoid dural artifacts. This is often neglected in routine practice, resulting in erroneously elevated epidural ICP values. Pressure measurement on the closed dura is based on the principle of applanation tonometry, which also makes ophthalmotonometry possible. The pressure sensor itself flattens the dura at the application site, so that the

dural tension can no longer have any influence on the result of the measurement.

Figure 51.8 provides a schematic representation of the principle, including the effects of measuring errors as a result of bone fragments or blood clots on the dura, which have the effect of increasing the measurement value in a William Tell effect by superimposing components of the dural tension with the pure pressure signal. Prerequisites for correct epidural ICP measurement are therefore: to apply the burr hole on the side of the lesion; to detach the dura with a blunt hook in the region of ≈ 10 mm from the internal lamina of the skull so that it can rest against the measurement membrane without any tension on the edges; and careful hemostasis in the area of the application site (bone wax, etc.) and rinsing of the dura. It is therefore an advantage if the operating surgeon can view the application site directly (as opposed to application of the sensor between the dura and the internal lamina of the skull). By way of example, Fig. 51.9a shows the technique of epidural intracranial pressure measurement using a pneumatic system. The sensors are single-use sensors which pneu-

matically transmit the pressure in the sensor head via a tube which is similar to a catheter. There are three types of sensors for this intracranial pressure measurement system: for application concentrically in the burr

hole, for insertion between the internal lamina of the skull and the detached dura, and for intraventricular ICP measurement (Fig. 51.9b), with the option of draining CSF via a second lumen.

Brain Computer Interface

Günter Edlinger, Cristiano Rizzo, Christoph Guger

This chapter introduces the current state of the art of brain–computer interface (BCI) technology based on noninvasive surface electroencephalogram (EEG) recordings. The basic idea of a BCI is to enable a new communication channel that bypasses the standard neural pathways and output channels in order to control an external device. The ultimate goal of BCI technology is to enable lost body or communication functions in handicapped persons. Persons suffering from, e.g., amyotrophic lateral sclerosis (ALS), stroke or spinal cord injuries might lose the ability to fully control (peripheral) muscle activity. Depending on the disease either the neural pathway might be affected or the muscle itself. In a first attempt one can substitute the neural pathways or the affected muscles with still functional pathways or muscles. This approach might be very beneficial to the subjects, though the approach might also have limitations. Subjects can use, e.g., eye movements for communication or control. In the BCI approach body functions are restored by detecting the proper neural or muscle

activity above the level of injury. These signals can serve as input to the BCI, which properly encodes the patterns and converts the activity into control commands. After a certain time of training the BCI can predict the user's intentions and the user can operate, e.g., the closing/opening of a robotic hand or control a wheelchair.

52.1 Introduction to BCI

Since the early 1990s the brain–computer interface (BCI) research field started growing constantly driven by relatively high performance and low cost computer power as well as electroencephalogram (EEG) instrumentation capable of being used in real-time and closed-loop data processing. However, a first systematic discussion of possible brain–computer communications [52.1] based on EEGs can be found in *Vidal* [52.2] in the early 1970s; *Farwell* and *Donchin* described in another pioneering work the usage of evoked potentials for communication [52.3]. Figure 52.1 displays the principle of a BCI system.

Since then, the performance and usability of BCI systems have advanced dramatically over the last

Fig. 52.1 Principle of a BCI system. EEG/ECoG/neural spike signals are measured from a subject. The BCI converts these signals into control signals utilized to construct various applications, e.g., a spelling program for BCI communication. A feedback loop provides information about, e.g., the selected character or word in the speller application so the user can change or correct the output

several years. Only about 10 years ago, one of the pioneering laboratories in BCI research in Europe published the first BCI that could provide communication for disabled users in their homes. However, the system was only validated with two users, required months of training, and was still slow and inaccurate [52.4]. Thereafter research laboratories in the USA and Europe were among the first to describe BCIs that could provide real benefit to handicapped people without extensive training [52.5–8]. Still the BCI users needed a training of several weeks to operate the system with acceptable accuracy [52.6,9]. Recently the training time of BCI systems dropped down to only minutes and some BCI systems do not even need any training [52.10, 11]. However, BCIs require the user to engage in some conscious, intentional activity to convey information. Work has shown that immersive feedback, which may include virtual reality, can reduce training time and improve accuracy [52.12, 13].

The confluence of ICT techniques (brain/neuronal–computer interfaces, affective computing, virtual real-

ity, ambient intelligence) and neuropsychology allows their integration into an advanced platform which will improve the quality of life of people not only by providing means for communication, but also by performing advanced and user-orientated analysis of deficits and providing individual training scenarios. Still, the principal focus of many BCI research teams is to provide user/patient groups with very special needs with a new skill for communication and control. Recently there has been remarkable attention to facilitate BCI control to new user groups, such as healthy subjects as well as to less disabled people. Furthermore, BCIs have been recently evaluated to serve as an advanced neurofeedback tool in stroke rehabilitation, ADHD (attention-deficit/hyperactivity disorder) or other diseases [52.1, 14]. However, the focus and the ambitious goal of BCI research has been since the very beginning to support and help locked-in patients to facilitate communication with their environment again, thus enabling social interaction. Therefore the most popular BCI application is for spelling purposes [52.4, 7, 11, 15–18].

52.2 Measuring Brain Activity

The basic principle of any BCI is to detect specific voluntarily modulated changes in brain activity in order to control a device. Different sensors and imaging modalities are available to detect in principle such changes. Measurements of the electrical activity of the brain – though the scale changes from the microscopic level to the macroscopic level – can be performed in different ways.

52.2.1 Invasive BCIs

Recording electrodes are implanted directly into the gray matter in order to better detect signals from the neurons, like single-cell action potentials or local field potentials (LFP). In this case electrodes commonly come in the form of a microelectrode array, tetrodes or microwires with different shape and size, as shown in Fig. 52.2a. Problems may arise for this approach as the body may react to the implanted electrodes in the brain, thus reducing the possibility to properly collect signals. This approach requires neurosurgery procedures for the implantation of the electrodes and thus the practical application is limited. However, the spatial resolution of invasive measurements is rather high and is in the order of several micrometers. Examples of the electrodes used are shown in Fig. 52.2a.

52.2.2 Partially Invasive BCIs

Recording electrodes are located inside the skull but do not penetrate the gray matter, they are simply applied on the surface of the cortex. This recording technique is referred to as electrocorticography (ECoG) and gives a spatial resolution of several millimeters. This resolution is better by far than the resolution of any noninvasive technique, but is still poor if compared to invasive techniques. Still, ECoG requires neurosurgery procedures for the positioning of the electrodes. BCI research has taken place in this way by simply taking advantage of patients who had such kinds of recording electrodes because of other disease (i. e., epilepsy). Examples of the electrodes used are shown in Fig. 52.2b.

52.2.3 Noninvasive BCIs

Recording electrodes are located on the scalp and the collected signal is the EEG of the subject. This technique provides lower spatial resolution signals, in the range of several centimeters, as the skull as well as other compartments (like cerebrospinal fluid) or tissue act as a sort of damping filter for lots of signals that could be collected with invasive and partially invasive techniques. On the contrary, the lack of invasiveness

Fig. 52.2a–c BCI recording electrodes. **(a)** Microelectrode arrays (Blackrock, Salt Lake City) in three different sizes/shapes and the recording electrodes with their wire and connector. **(b)** EEG amplifier (g.USBamp – g.tec, Graz) connected to an eight-channel ECoG electrode grid and a 64-channel ECoG electrode grid. **(c)** EEG recording cap (g.tec, Graz)

has made this technique easily accessible and widely used. EEG signals are recorded typically from electrode positions mounted according to the so-called international (extended) 10/20 system. An example of an EEG cap with prefixed electrodes at the standard positions as defined by the international 10/20 system is shown in Fig. 52.2c.

52.2.4 Other Functional Imaging BCIs

Various approaches, such as PET (positron emission tomography), fMRI (functional magnetic resonance imaging), functional NIRS (near-infrared spectroscopy), and MEG (magnetoencephalography), have been evaluated as possible brain activity data sources for BCI. However, PET, fMRI, and MEG are techni-

cally demanding and bulky devices that are typically available at very special laboratories and hospitals only. Additionally, PET, fMRI, and NIRS depend on metabolic changes in the cerebral blood flow. These changes have intrinsically longer time constants compared to the electrical changes in the brain. Therefore a high data transfer rate – which is one important criterion for usability in BCI – might not be accomplished using these methods.

EEG, ECoG, and single-cell recordings are therefore still the only methods that are relatively easily accessible and have the desired temporal resolution for setting up BCI systems. Most of the BCIs used in laboratories around the world rely on the EEG and ECoG, which measures electrical brain activity from the intact human scalp or from the surface of the brain.

52.3 BCI System Structure

A subject interacts with the BCI system in a closed-loop setup. It is important to note that for a successful BCI operation the BCI system must be adaptive, i. e., it

adapts itself to the subjects' specific brain activity patterns. On the other hand, the subjects learn over time to operate the BCI system. Hence an appropriate and

real-time feedback is important for optimal BCI control performance and for learning the new skill. A BCI consists in principle of four major parts:

1. *Signal acquisition and signal conditioning.* This component of the BCI system is basically an amplifier including an analog to digital converter that aims to measure EEG/ECoG or neural spike signals

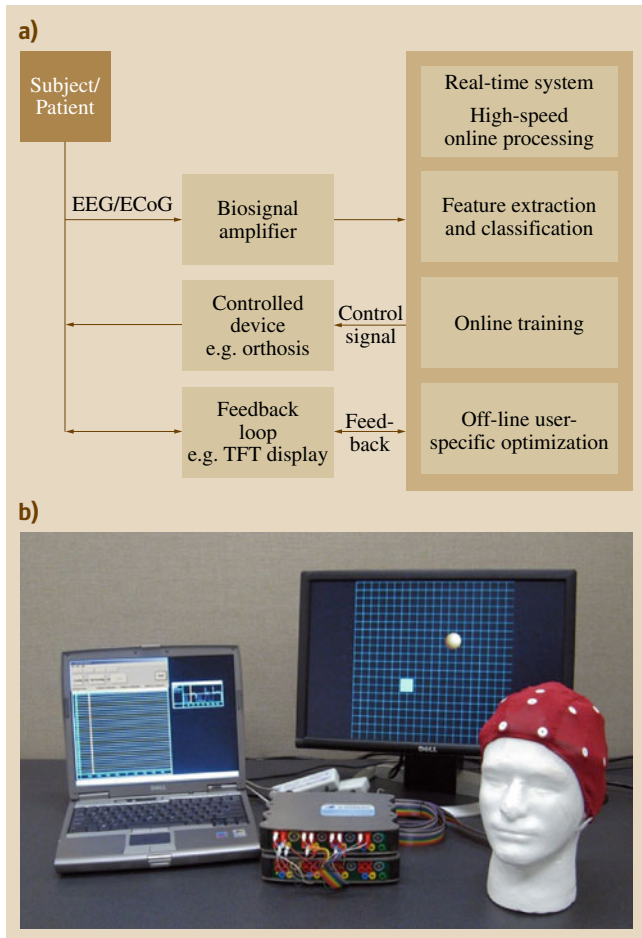

Fig. 52.3 (a) Components of a BCI system. Here the biosignal amplifier system g.USBamp (g.tec medical engineering, Graz) is connected to the BCI processing part running under MATLAB/Simulink on a laptop. In this case the high-speed online processing of the Simulink toolbox was used for the signal processing and paradigm presentation in real time. (b) BCI setup using a 32-channel g.USBamp system for data acquisition and the BCI2000 platform for real-time processing on a laptop (after [52.19]). The TFT screen displays the actual application as a 2-D cursor control task

with a high signal to noise ratio. From one channel up to 512 channels can be recorded depending on the kind of BCI experiment to be performed (see previous paragraph). Figure 52.3b displays a typical BCI system setup for 32 channels for scalp EEG recordings with an EEG cap (g.USBamp, g.tec medical engineering GmbH, Graz, Austria). Signals are also properly conditioned in order to be better analyzed by the successive block of the process.

2. *Feature extraction and classification.* This component of the BCI system is generally a signal-feature to control-signal converter which extracts distinct and stable features from the recorded signals in real time and translates them into corresponding control signals. Depending on the BCI technology, features in both the frequency domain and/or time domain can be extracted. Spatiotemporal pre-processing algorithms like common spatial patterns can be used to improve the signal to noise ratio and to maximize the difference between the signal patterns. Using supervised learning strategies nonlinear classifiers (e.g., neural network based) or linear classifiers (e.g., linear discriminant analyzer) are trained with the individual user's EEG features during a learning phase. User-specific features evaluation and optimization steps are usually investigated off-line based on training data. Thereafter most reactive parameters can be identified and used for the real-time application of the BCI. Figure 52.3a displays the different components of the BCI data processing part.
3. *Controlled device and application.* After successful training an external device like an orthosis is operated by the BCI which acts on the converted control signals.
4. *Feedback loop.* Results of the application are sent from the external device back to the user in the feedback loop. This information can be simply the position of a cursor on a screen but can also be a tactile or electrical signal fed back to the user. The results of the BCI as well as the feedback can be sent remotely via a network UDP connection to remotely located caregivers or BCI specialists.

52.3.1 Noninvasive (EEG) BCI Systems

Since this chapter aims at providing an overview of the widely used BCI technologies that are easy to use and could possibly become home monitoring device systems, EEG-based BCIs are discussed more thoroughly.

BCI systems have been successfully realized based on different EEG phenomena whereby two major groups of BCI can be distinguished.

Endogenous BCIs

In this type of BCI subjects learn and train to perform specific mental tasks to change willingly brain activity. This type of BCI includes slow cortical potentials (SCP) and sensorimotor rhythmic (SMR) or event-related desynchronization/synchronization (ERD/ERS) based BCIs:

1. *SCP based BCIs.* Very early approaches of BCIs included the use of SCP [52.4]. This approach required months of training. Today the SCP approach is not widely used anymore for BCI control.
2. *SMR- and ERD/ERS-based BCIs.* BCI systems based on the oscillatory brain electrical activity use motor imagery strategies that generate ERD and ERS in the alpha and beta frequency ranges of the EEG. In ECoG also gamma band activities have been used to construct BCI control [52.20]. More specifically, changes in sensorimotor rhythms associated with imagined hand or feet movements are mostly used to realize this type of BCI. However, even less specific movement imagery developed via training can be used [52.1, 10, 21]. Applications of this so-called SMR BCI are found for cursor control on computer screens, for navigation of wheelchairs or controlling virtual environments.

Exogenous BCIs

In this type of BCI the presentation of external stimuli evokes a specific change in the brain activity. Typical evoked potentials that are found in the ongoing EEG, depending on focused or selective attention to an external stimulus, are the P300 response and steady-state visually evoked potentials (SSVEP).

1. *P300-based BCIs.* The P300 BCI approach requires the user to focus on a visual or tactile stimulus, whereby the brainwaves differ for stimuli that the user attends versus ignores. Such a system uses the effect that an unlike event induces a P300 component in the EEG, i.e., a positive deflection in the EEG signal occurring around 300 ms after the event [52.3, 22]. In spelling applications typically several letters are displayed on a computer screen in a row-column format. All the letters are flashed transiently. The user selects and attends the letter she/he wants to select by simply counting the number of times it is flashed. Then the BCI system

can determine which of several visual targets the user attends. In a similar way, recently P300 BCIs have been realized on tactile stimulation. Several factors are mounted to different parts of the body and transiently switched on. The BCI system can determine which of several tactile targets contains the desired information. Applications here are supposed to aid in situations where tactile stimulations are more suitable than, e.g., visual cues [52.23].

2. *SSVEP-based BCIs.* SSVEP approaches use the fact that flickering light sources with flickering frequencies in the range of 5–20 Hz induce brain oscillations of the same flickering frequency. Similarly to the P300 BCI, here the brainwaves differ again for stimuli that the user attends versus ignores. Applications so far comprise, e.g., robot control or mobile phone control [52.24, 25].

52.3.2 SMR-based BCIs

Event-related synchronization and desynchronization of oscillatory components in the EEG are well-known phenomena of the electrical brain activity [52.26–29]. If, for example, the EEG is measured over the visual cortex in a relaxed person with eyes closed, then typically a very prominent rhythmic activity around 10 Hz with amplitudes of up to 100 μ V can be observed. This activity is a so-called alpha rhythmic activity. If the person suddenly opens their eyes, then the amplitude of the alpha wave drops down. Compared to the relaxed state an event-related desynchronization, i.e., an amplitude decrease with respect to the relaxed phase, can be observed. Similarly, desynchronization and synchronization phenomena, i.e., a decrease and increase in amplitudes, can be observed over the corresponding motor representation areas for tongue, hand, or foot movement execution and similarly also for the movement imagery. Figure 52.4a displays a typical EEG amplitude decrease by evaluation of the power spectra for a right hand motor imagery in comparison to a resting condition measured from electrode position C3.

An imagination of the left hand is typically accompanied by an amplitude decrease over the contra lateral (right) hemisphere around electrode position C4. An imagination of the right hand is accompanied by a corresponding amplitude decrease over the left hemisphere (near electrode position C3). Figure 52.4b and c give an example of a typical ERD pattern measured during motor imagery of a left and right hand motor movement. Two distinct areas of maximal ERD over the left and right hand representation areas can

Fig. 52.4a-c Spectra and overlay display of event-related desynchronization patterns. **(a)** Display of the power spectral density during rest condition (*solid line*) and during motor imagery of the right hand (*dashed line*) recorded over electrode position C3. The *top line* indicates significant differences (95% level indicated by the *dashed brownish line*) between the two spectra around 17–18 Hz as well as at the first harmonic band around 34–36 Hz. During motor imagery the amplitudes in the specific frequency bands drop down. **(b)** and **(c)** Event-related desynchronization patterns computed from a dense 64-electrode array (positions are indicated by *small black disks*) and individual MR-based reconstructed cortical surfaces. The nose of the subject points to the top of the page. *Dark red color-coded areas* indicate largest desynchronization. *Light yellow areas* indicate smallest values of desynchronization. *Black solid lines* indicate the *Sulcus centralis*. **(b)** represents results for right hand motor imagery; **(c)** represents results for left hand motor imagery (after [52.35])

be seen. A foot movement imagery would induce an amplitude decrease in EEG measured over the vertex position. Hence these distinct and specific spatiotemporal changes in the rhythmic brain activity can be used as input to a motor imagery based BCI system. In

practice amplitude changes in different frequency bands (alpha and beta bands for EEG) are utilized to train the BCI system. However, the changes in amplitudes related to motor imagery do not contain additional information about the type of the imagined movement, the

velocity or the direction of the movement. Such information could be found only in more invasive recordings in ECoG [52.20, 30–33] or by observing changes in firing rates of action potential in *motor cortex in monkeys* [52.34].

It is well described in the literature that BCIs based on brain oscillatory activities might need a long training time. Hence people are trained in several sessions in order to operate a BCI with a high accuracy. Therefore it is of interest in general to investigate in how many

people a BCI could work within only a short period of training.

In a study done in 99 untrained naïve subjects recruited at a local public fair in Graz, Austria, *Guger et al.* [52.36] described a simple ERD/ERS-based BCI experiment.

Subjects imagined either moving their right hand or left hand to cues provided on a monitor. Figure 52.5a,b display the corresponding experimental paradigm for the training and application phase. Figure 52.5c and d dis-

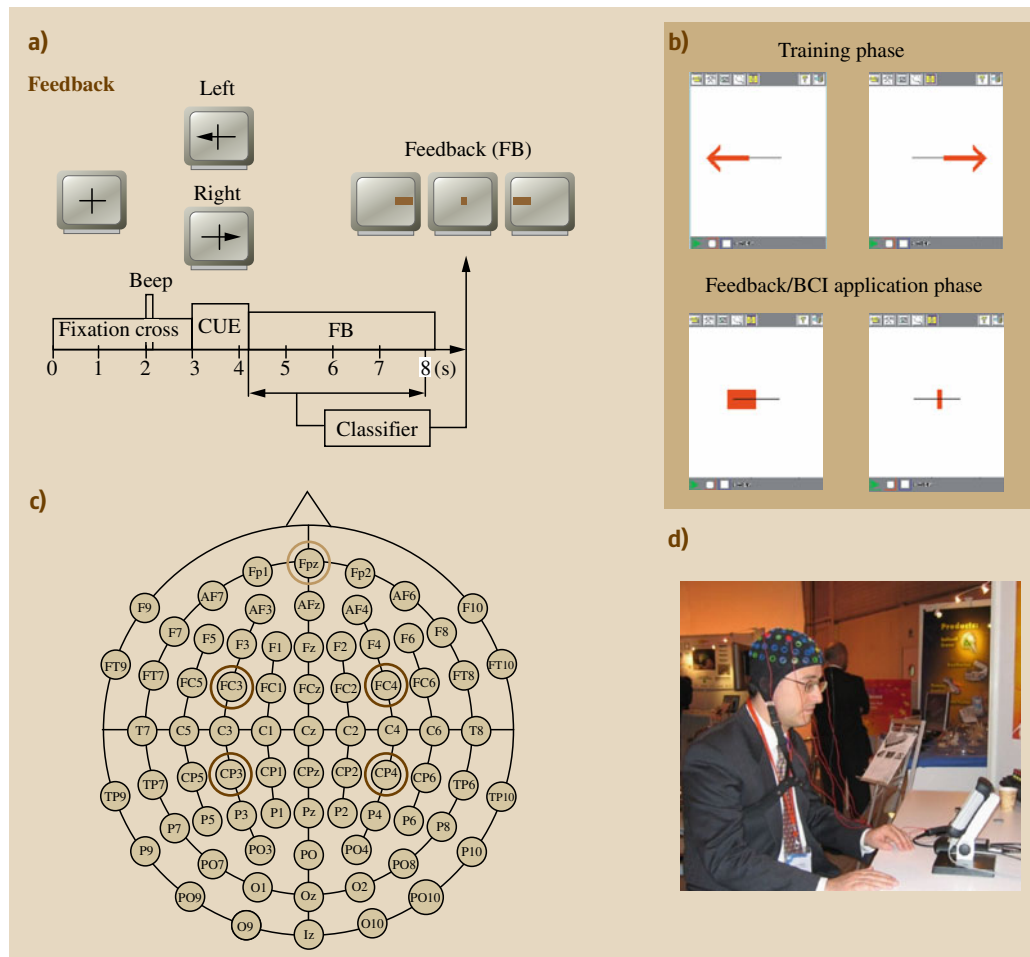

Fig. 52.5a–d Typical BCI application session. **(a)** and **(b)** yield the experimental paradigm as a function of the time. At the beginning of each trial a fixation cross is shown on the screen. At second 3 a cue, i. e., an arrow pointing to the left or right side, is displayed and the subjects perform a corresponding motor imagery of the left or right hand. The accuracy of the BCI is fed back as a bar extending to the left or right side depending on the classification accuracy. **(c)** displays the electrode positions used for the motor imagery task (after [52.36]). Two bipolar EEG channels (*brownish circles*) measured over the left and right hand representation area are sent to the BCI system. The *light brown circle* at Fpz indicates the position of the ground electrode. **(d)** shows a subject at the local fair operating the BCI

Fig. 52.6 P300 evoked brain signal response for target versus nontarget stimuli. A clear positive deflection in the EEG averaged 15 times for the target character (*brown line*) can be observed around 300 ms after stimulus onset (indicated by the *vertical brown line*). In all nontarget characters such a positive deflection cannot be observed (*gray line*)

play the bipolar electrode montage used and an example of a practical usage of the BCI. The BCI system was trained on the EEG data recorded from electrode positions C3 and C4. The training time was approximately 6 min and band-power features in the alpha band between 8 and 12 Hz and beta band between 20 and 24 Hz or parameters of an adaptive autoregressive model were estimated. For classification a linear discriminant analyzer (LDA) was used. After the training the participants had to control a computer cursor on the screen and move it to the left or right side. In this simple 1-D center out cursor task about 6% of the participating subjects could operate the BCI immediately. In about a further 20% of the subjects the performance was acceptable, but in more than half of the subjects the performance was not acceptable (see Table 52.1 for details of the accuracy).

Changes in EEG amplitudes of mu rhythmic activity and beta activity have been utilized to control cursor movement in 2-D and 3-D cursor task scenarios [52.37, 38], controlling orthotic devices [52.6, 39] or wheelchairs [52.40]. Such BCI approaches have been used rather in a *process control* way, i. e., controlling

Table 52.1 Percentage of sessions which were classified with a certain accuracy for motor imagery classified with the RLS algorithm or band power (BP) estimation. N specifies the number of subjects

Classification accuracy in %	RLS + BP percentage of sessions ($N = 99$)
90–100	6.2
80–89	13.0
70–79	32.1
60–69	42.0
50–59	6.7

a cursor directly in the x , y , or z directions or similarly moving a robotic arm. Another maybe more natural approach is the implementation of *goal-oriented control*. In a goal-oriented BCI approach it is then not necessary, e.g., to control the exact trajectory of a robotic hand in order to reach a glass of water, but in a more natural way humans can initiate a control command like “I want to grasp the glass of water”. A P300 BCI is one example introducing such a goal-oriented control. A subject can select one target command out of many possible commands.

52.3.3 P300-based BCI

The underlying phenomenon of a P300 speller is the P300 component of the EEG, which is induced if an unlikely event occurs. In the classical Donchin speller setup subjects are presented 6×6 characters and numbers on a computer screen arranged in six columns and six rows, respectively. In an oddball-like paradigm subjects are instructed to concentrate on only one TARGET character out of all 36 characters. All characters are flashed on and off for a certain time in a random manner. When the target character flashes on, a P300 evoked response is induced and the maximum amplitude found in the EEG is reached typically around 300 ms after the flash onset (Fig. 52.6). Several repetitions are needed to perform EEG data averaging to increase the signal to noise ratio and accuracy of the system.

However, the layout of the character matrix, the color of the flashing and nonflashing characters, and the number of targets influence the accuracy of the speller [52.18, 22, 41, 42]. The P300 signal response is more pronounced, e.g., in the single-character (SC)

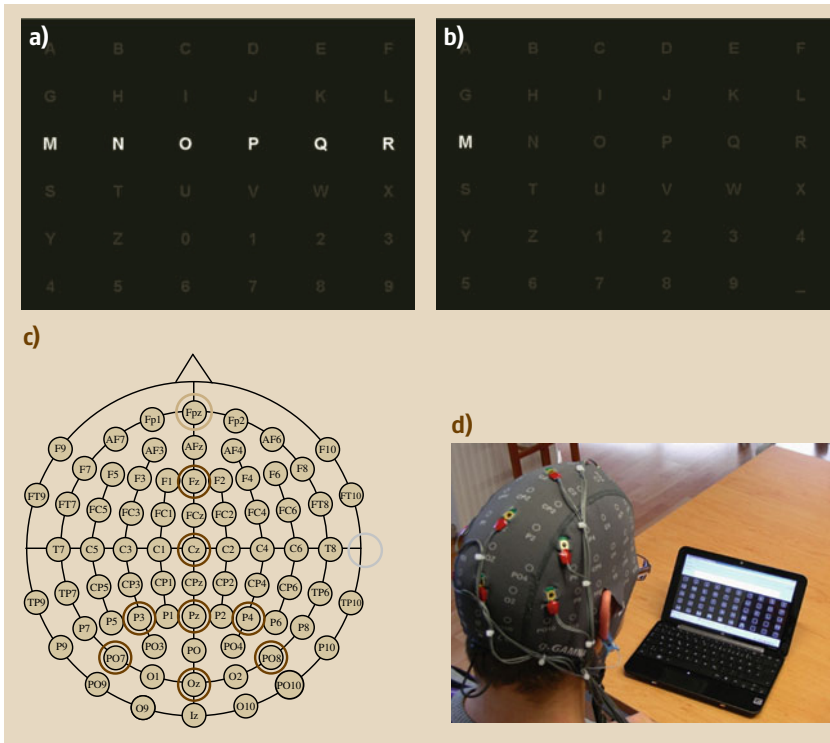

Fig. 52.7a–d P300 speller application. (a) and (b) display the screen layout of the 36-character speller. Either all characters of one row or column are highlighted at the same time in the row/column speller or only one single character is highlighted for a certain time in the single-character speller. (c) displays the electrode layout (after [52.22]). A total of eight electrode positions distributed mostly over occipital and parietal regions are used. *Brownish circles* indicate the electrode positions Fz, Cz, P3, Pz, P4, PO7, Oz, and PO8. The *brownish ring* indicates the ground electrode mounted on the forehead at Fpz and the *gray ring* indicates the reference electrode attached to the right ear lobe. (d) displays the home system setup intendiX with the portable wireless EEG device g.MOBILab+, an active electrode system g.GAMMAsys, and the standalone P300 speller application intendiX (courtesy of g.tec medical engineering GmbH, Austria)

speller than in the row/column (RC) speller and is therefore easier to detect [52.22, 43]. Figure 52.7 shows an example of a P300 speller setup.

Spelling with a P300 BCI

An interesting question in general is how many people could learn the new skill of operating a P300 BCI. As discussed above ERD/ERS-based BCIs need typically a longer time of training and some subjects cannot use such a BCI. However, it is described in the litera-

ture that a P300-based BCI needs less training. A recent study explored the P300 BCI across 100 subjects. In addition, 35 subjects received questionnaires to explore demographic issues [52.43].

In the experiment a P300 spelling device based on a 6×6 matrix of different characters was displayed on a computer screen. Subjects had to perform predefined evaluation steps of a RC speller or of a SC speller. This yields of course different communication rates; with a 6×6 matrix, the row/column approach increases

Table 52.2 Percentage of sessions which were classified with certain accuracy. N specifies the number of subjects participating

Classification accuracy in %	Row–column speller: Percentage of sessions ($N = 81$)	Single-character speller: Percentage of sessions ($N = 38$)
100	72.8	55.3
80–100	88.9	76.3
60–79	6.2	10.6
40–59	3.7	7.9
20–39	0.0	2.6
0–19	1.2	2.6
Average accuracy of all subjects	91.0	82.0
Mean of subjects who participated in RC and SC ($N = 19$)	85.3	77.9

speed by a factor of 6. For training, EEG data are acquired from the subject while the subject focuses on the appearance of specific letters in the copy spelling mode. In this mode, an arbitrary word like LUCAS is presented on the monitor. First, the subject counts whenever the L flashes. Each row, column, or character flashes for, e.g., 100 ms per flash. Then the subject counts the U until it flashes 15 times, and so on. Then, EEG data elicited by each flashing event are extracted within a specific interval length of 800 ms and divided into sub-segments. The EEG data of each segment are

averaged and sent to a stepwise LDA. The LDA is trained to separate the target characters, i.e., the characters the subject was concentrating on (15 flashes \times 5 characters), from all other events (15 \times 36 – 15 \times 5). It is very interesting for this approach that the LDA is trained only on five characters representing five classes and not on all 36 classes. This is in contrast to the motor imagery approach where each class must also be used as a training class. The P300 approach allows minimization of the time necessary for EEG recording for the setup of the LDA. However, the accuracy of

Fig. 52.8 CAVE setup. *Left:* CAVE system at University College London. *Right:* Smart home VR realization from Chris Groenegrass and Mel Slater from Universitat Politècnica de Catalunya, Barcelona

Fig. 52.9 Components of a VR setup

the spelling system also increases with the number of training characters.

In this experiment a total of 72.8% ($N = 81$) of the subjects were able to spell with 100% accuracy in the RC paradigm and 55.3% ($N = 38$) spelled with 100% accuracy in the SC paradigm. Less than 3% of the subjects did not spell any character correctly. People who slept less than 8 h performed significantly better than other subjects. Age, sex, education, working duration, and cigarette and coffee consumption were not statistically related to differences in accuracy. The disturbance of the flashing characters was rated as 1.5 on a scale from 1 to 5 (1 – not disturbing, 5 – highly disturbing). See Table 52.2 for the details of the evaluation.

Virtual Reality Smart Home Control with the P300 BCI

BCI systems were also combined with virtual reality (VR) systems both for SMR BCI and P300-based BCIs [52.13, 44]. VR systems use either head-mounted displays (HMDs) or highly immersive back-projection systems (CAVE-like systems) as shown in Fig. 52.8. Such a CAVE has three back-projectors for the walls and one projector on top of the CAVE for the floor. The system projects two images which are separated by shutter glasses to achieve 3-D effects.

There are several issues that must be solved to use a BCI system in such an environment: the biosignal amplifiers must be able to work in such a noisy environment, the recordings should ideally be done with

Fig. 52.10a–d Smart home interface masks and VR representation. **(a)** displays the main interface mask consisting of 41 different icons arranged in a rectangular grid. Similarly to the P300 speller matrix the individual icons are flashed on and off in a random manner. **(b)** displays a 3-D view of the living room including some of the devices that can be controlled via the BCI like the TV set, room light or telephone. **(c)** and **(d)** display a bird's eye view of the apartment. Here 21 characters represent all user-selectable positions. In the *top left corner* of the living room can be found, the *top right corner* represents the kitchen, the *bottom left corner* represents the sleeping room, and on the *bottom right corner* the bathroom is located as well as the entrance door of the apartment

data sent via a radio to avoid collisions and irritations within the environment, the BCI system must be coupled with the VR system for real-time experiments, and a special BCI communication interface must be developed to have enough degrees of freedom available to control the VR system.

Figure 52.9 illustrates the components in detail. A 3-D projector is located next to a projection wall for back projections. The subject stands in front the projection wall to avoid shadows and is equipped with a position tracker to capture movements, shutter glasses for 3-D effects, and a biosignal amplifier including electrodes for EEG recordings. The XVR (eXtreme VR, VRmedia, Pisa) PC controls the projector, the position tracker controller, and the shutter glass controller. The biosignal amplifier transmits the EEG data to the BCI system that is connected to the XVR PC to exchange control commands.

In order to show that such a combination is possible, a virtual version of a smart home was implemented in XVR. The smart home consists of different rooms whereby each room is equipped with several different devices that can be controlled: TV, MP3 player, telephone, lights, doors, etc. Therefore, all the different

commands were summarized in seven control masks: a light mask, a music mask, a phone mask, a temperature mask, a TV mask, a move mask, and a go to mask. Figure 52.10 shows the TV mask and as an example the corresponding XVR image of the living room. The subject can, e.g., switch on the TV by selecting the TV symbol. Then, the TV station and the volume can be regulated. The bottom row of Fig. 52.10 shows the go to mask with an underlying plan of the smart home enabling the subject to move to a spot in the room where he wants to go. After the decision of the BCI system, the VR program moves to a bird's eye view of the apartment and zooms to the spot that was selected by the user. This is a goal-oriented BCI control approach, in contrast to a navigation task, where each small navigational step is controlled individually [52.44].

The control masks contained 13–50 commands. In such an application, precise timing between the appearance of the symbol on the screen and the signal processing unit is very important. Therefore, the flashing sequence was implemented under Simulink where the real-time BCI processing was also running. A UDP interface was also programmed that sent the data to the XVR system to control the smart home, as shown in Fig. 52.9.

52.4 Conclusions

BCI enabled control and communication is a new skill a subject has to learn. In an initial adaptation phase the BCI system is trained to the specific subject's brain activity. In addition the subjects have to get used and adapt to the BCI system as well. The time needed for a subject to adapt to the system is shorter by far in exogenous BCIs like P300 and SSVEP approaches. Such BCI systems yield higher accuracies in a higher number of subjects and therefore give for control purposes more reliable results. However, subjects have to look at flashing or flickering light sources or pay attention to tactile stimulations. Hence external stimulations might interfere with daily life situations and may distract subjects from other ongoing activities.

ERD/ERS-based BCIs rely on intrinsic changes of alpha and beta power activities. In principle no external stimuli or cues are necessary to operate the BCI. However, it has been shown that this type of BCI needs adaptation and training from the subjects' side over many hours [52.45]. The accuracy and speed of an ERD/ERS-based BCI is below that of a P300 BCI.

However, one of the most consistent observations in the BCI literature is the fact that a certain percentage of the population cannot operate a specific type of BCI for various reasons. Inter-subject as well as intra-subject variability often leads to a so-called BCI illiteracy [52.5, 13, 25, 46]. Across the different BCI approaches (ERD/ERS, P300, SSVEP) around 20–25% of subjects are unable to control one type of BCI in a satisfactory way. Therefore, the usage of *hybrid* BCIs has been introduced using the output of an SMR BCI as well as P300- or SSVEP-based BCIs [52.44, 47], enabling subjects to choose between these different approaches for optimal BCI control. Recently it has been shown that progress in BCI research terms of usability and robustness made it possible to move the technology to the patients' homes. *Nijboer* et al. [52.48] showed that severely handicapped people can use a P300 speller. Signals were stable over months as well as the ability to operate a 6×6 spelling application with stable accuracy. However, in order to operate a BCI system on a daily basis, well-trained staff members supported the partici-

pants. One of the participants quit the study as result of the experimental setup and discomfort of the procedure.

Therefore attempts have been made to enable a more easy usage of BCI systems at home. The system *intendiX* (www.intendix.com) is designed to be installed and operated by caregivers or the patient's family at home. It consists of active EEG electrodes to avoid abrasion of the skin, a portable biosignal amplifier, and a laptop or netbook running the software under Windows. Electrodes are prefixed into the cap to allow a fast and easy montage. The *intendiX* software allows viewing of the raw EEG to inspect data quality, but indicates

automatically to the inexperienced user if the data quality on a specific channel is good or bad. If the system is started up for the first time, 5–10 training characters are entered and the user has to copy spell the characters. Then the software switches automatically into the spelling mode and the user can spell as many characters as wanted. The number of flashes for each classification can be selected by the user or the user can also use a statistical approach that detects automatically if the user is working with the BCI system. The latter one has the advantage that no characters are selected if the user is not looking at the matrix or does not want to use the speller.

Fetal Monitoring

Birgit Wacker, Martin Maier

Cardiotocography (CTG) is the process of monitoring the fetal heart rate and uterine activity, and is used both prior to (antepartum, prenatal) and during (intrapartum) childbirth in the delivery room. The equipment is operated by midwives and nurses, who also analyze the graphs along with the attending physicians. This chapter covers cardiotocography (Sect. 53.1) and obstetric monitoring systems (Sect. 53.2).

53.1 Cardiotocography (CTG)

53.1.1 Areas of Application

Cardiotocographs are primarily used to monitor the fetal heart rate and uterine activity via external and internal measurements taken by what are referred to as transducers (Fig. 53.1). Some devices also measure the maternal heart rate, as well as the blood pressure and oxygen saturation of the parturient. Table 53.1 compares the various measuring procedures.

53.1.2 Measuring Procedures

Ultrasound

This procedure uses quartz crystals fitted in the transducer to transmit high-frequency acoustic signals. These sound waves are reflected by body tissue at various intensities and then received and amplified by the

transducer. The shift in frequency among the reflected acoustic signals (Doppler effect) is used to detect movement. By optimizing the movement pattern of the fetal heart and using additional signal processing procedures (autocorrelation), it is possible to gain an extremely accurate reading of the fetal heartbeat. Extra procedures such as precision signal track and hold (according to the time the ultrasound waves spend in the tissue) can be used to filter out interference signals from movements unrelated to the fetal heart.

Fetal Movement Profile

The ultrasound procedure described above can also be used to determine the child's movement within the womb. The signals that are filtered out when determining the fetal heart rate can be analyzed separately to provide a valuable insight into the fetal movement pat-

Fig. 53.1 Sample CTG with transducer and accessories. *Left to right:* Patient module with adapter cable for the scalp electrode and leg electrode, an ultrasound transducer, a toco transducer with connected cable for the maternal ECG, a patient module with adapter cable for the IUP catheter, a sensor to measure the mother's oxygen saturation and pulse. *Foreground:* IUP catheter and a scalp electrode. *Background (right):* CTG paper with a preprinted scale, belt to attach the transducer to the mother's abdomen, and a blood pressure cuff

Table 53.1 External and internal cardiotocograph measuring procedures

Patient	Parameter	External measuring procedure			Internal measuring procedure		
		Transducer type	Area of application	Unit	Transducer type	Area of application	Unit
Fetus	Heart rate	Ultrasound sensor	Antepartum, intrapartum	rpm	Scalp electrode	Intrapartum, high-risk pregnancy	rpm
	Fetal movement profile	Ultrasound sensor	Antepartum, intrapartum	%			
Mother	Heart rate/pulse	Skin electrode, also indirect via blood pressure cuff or light sensor	Antepartum, intrapartum	rpm			
	Uterine activity	Pressure sensor (toco transducer)	Antepartum, intrapartum	Relative pressure	Catheter with pressure sensor	Intrapartum, high-risk pregnancy	mmHg or kPa
	Blood pressure	Blood pressure cuff	Under anesthesia	mmHg			
	Oxygen saturation	Light sensor	Under anesthesia	%			

tern, namely information on movement of the body and limbs of the fetus. As well as purely marking out periods of activity, the equipment can also generate a percentage value to provide information on fetal vitality without the need to calculate the movement pattern manually.

53.1.3 Direct ECG

This procedure uses a scalp electrode, which is fixed to the child's head and measures the fetal ECG to determine the heart rate (Fig. 53.2). This is what is known as an internal measurement, which can only take place during childbirth, and only then once the amniotic membranes have broken and the cervix is dilated by at least 2–3 cm. It is primarily used when the more typically used ultrasound transducers experience a loss of signal and cannot give a reliable reading of the heart rate trace. This can become necessary, particularly during

the later expulsion stage (e.g., if the patient is moving a lot). A direct fetal ECG measurement also provides a qualitative analysis of the fetal ECG, the ST segment of which ST waveform analysis (STAN) can be of particular significance.

53.1.4 Toco Procedure

This procedure is used to record uterine activity by means of pressure-sensitive sensors that detect the hardening (tensioning) of the uterine muscle. The value measured is only relative and depends on many factors, such as the position of the transducer. For this reason, the display must first be calibrated with a base value once the transducer is in place. As this procedure cannot produce an absolute value, another procedure must be used where this is required. This procedure is described in more detail in the next section.

Fig. 53.2 Direct ECG

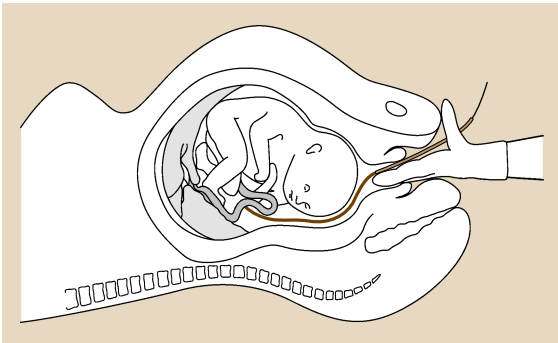

Fig. 53.3 Intrauterine pressure measurement

Fig. 53.4 Cordless transducer system

53.1.5 Intrauterine Pressure Measurement

This procedure involves inserting a catheter into the uterus via the vagina. The catheter is filled with a neutral solution and connected to a pressure sensor. This method produces an absolute pressure value, but is quite

Fig. 53.5 Underwater monitoring using a cordless transducer system

complex and its usage is in decline. Today's increasingly widespread transducers have a pressure sensor at the end of the air column or directly on the tip of a flexible probe, which is also inserted into the uterus via the vagina (Fig. 53.3). The laborious and training-intensive catheter procedure is no longer required.

53.1.6 Additional Functions and Options

Equipment manufacturers offer a range of other functions and options for the above procedures to facilitate day-to-day work and enhance quality. These extras include:

- Automatic cross-channel heart rate monitoring. The CTG constantly checks to make sure the maternal heart rate or that of the other fetus (in the case of multiple pregnancies) is not accidentally being monitored on the fetal channel (known as cross-channel verification or coincidence detection). New developments have seen the function for measuring the mother's pulse integrated into the toco transducer to simplify use.
- Battery-operated, watertight transducers also enable use in the bathtub to ensure that continuous monitoring is maintained, be it while having a relaxing bath or during an underwater birth.
- Option to connect to a telemetry system or a cordless transducer (Fig. 53.4) for monitoring outpatients and for use in underwater monitoring (Fig. 53.5).
- Integrated maternal measurements (fetal/maternal monitor).
- Options to connect to obstetric monitoring systems for a central overview of several beds with an intelli-

gent alarm system and automatic long-term storage of monitoring logs and patient records.

- Storage of graphs with remote transmission option. This can be used for home deliveries or for consultations at smaller affiliated hospitals.
- Integrated battery within a CTG with a printer for supporting scenarios involving transport; this is intended for use in the increasing range of applications for home visits, and for bridging power failures.

53.1.7 CTG Selection Criteria

CTGs should meet the following requirements.

1. Antepartum requirements:

- One to three ultrasound channels (two/three channels if monitoring of twins/triplets is required)
- One toco channel
- Fetal movement profile
- Recorder with adjustable paper speed (1, 2, 3 cm/min)
- Digital display for heart rates and toco
- Volume adjustment for heart sounds
- Low level of energy for ultrasound signal
- Autocorrelation of ultrasound signal
- Cross-channel signal comparison (of all fetal and maternal heart and pulse rates available)
- Method to reduce artifacts (e.g. precision signal track and hold)

- Means to fix to the cart or wall
- Option to extend to system interface for system connection
- Option to connect a telemetry system
- Coded connectors or automatic recognition of the connected transducers
- Latex-free transducers and accessories
- Watertight transducers for cleaning purposes
- Option to integrate measurement of the mother's heart rate and blood pressure
- Simple operation (e.g. via touchscreen)
- Automated CTG assessment.

2. Intrapartum requirements: The features listed in this section either differ from or are in addition to the features listed in 1.

- One to three ultrasound channels (two/three channels if monitoring of twins/triplets is required)
- Direct ECG measurement
- Channel for intrauterine pressure measurement
- Channel for maternal ECG (MECG)
- Option to integrate the mother's vital signs (blood pressure, SpO₂, MECG)

3. Optional functions:

- Alarm systems for tachycardia and bradycardia as well as for the presence of any maternal vital signs
- System interface
- Additional input options (barcode scanner, mouse, keyboard, etc.).

53.2 Obstetric Monitoring Systems

53.2.1 Areas of Application

Obstetric monitoring systems are used in the antepartum, intrapartum and postpartum sections of hospitals dealing with 500 plus births per year. Depending on individual requirements, one or more of the listed functions are required:

- Central CTG monitoring with a bed overview
- Automatic alarm system
- Patient data management functions, e.g. creating and managing electronic patient records
- Long-term storage media for data archiving and retrieval
- Computer communication within the obstetrics department

- Computer communication with other hospital systems and access to their data.

53.2.2 System Setup

This section is not intended to give a detailed description of an individual system; the commercial system referenced here is used solely to illustrate certain system features. It is essential for the user to have a workstation, which these days is usually a personal computer (PC) connected to a networked system. This PC will serve different functions and may require different configurations depending on where it is used and by whom; for example, a midwife needs to be able to input patient test results in situ, whereas the physician may like to access all data from his office. Here

Fig. 53.6 Working area for obstetric monitoring

are some examples of where the PC may be used (Fig. 53.6):

- Central station
- Delivery room
- Ambulance
- Doctor's room
- Nurses' lounge
- Midwife's room
- Postpartum area
- Newborn nursery.

A PC will serve one or more tasks depending on which of the above areas it is used in as well as individual requirements and configurations. These tasks include:

- Collection and processing of data from the connected CTGs
- Assessment of the CTG data and raising the alarm
- Presentation of the CTG data
- Patient data management, enabling electronic patient records to be created, managed and output, and supporting the workflow within the care unit
- Archiving and retrieval of all data via long-term storage media

- Computer communication within obstetrics
- Computer communication with other hospital systems and access to their data.

No matter what the function of the obstetric monitoring system, the protection of patient data is the top priority. This is assured by:

- Restricting access rights within a role model
- Logging all access and transactions, especially changes to patient data and configuration
- Encrypting patient identification and patient data in the database
- Encrypting communication via VPN
- Preventing physical access to central system components (database server, web/terminal service server, network components such as switches and routers)

The following sections outline these individual functions in more detail.

53.2.3 Collection and Processing of Data from the Connected CTGs

One of the most important aspects of obstetric monitoring systems is the central monitoring of the CTG

Fig. 53.7 Example of notes input on the CTG

data of pregnant women, which is why the CTGs are connected to the system. Virtually all CTGs available today feature interfaces to enable data to be transferred to a monitoring system.

There are two connection methods:

1. Digital connection with
 - Serial data transfer logs (standardized RS232, RS422, RS485 interfaces with proprietary data formats)
 - Local area network (LAN) (standardized network logs with proprietary data formats)
2. Analog connection with
 - Signal transfer over several lines corresponding to the parameters supported
 - Proprietary signal levels

The digital method is superior to the analog method in the following ways.

1. More comprehensive data
2. Greater protection against transmission interference
3. Adaptable to changes in CTG functionality
4. Reduced equipment, installation and maintenance costs

Nowadays, the analog connection is only used with older CTG equipment. When selecting the CTG connection system, the parameters to be transferred are of paramount importance.

- The following must be transferred as a minimum:
 - Fetal heart rate
 - Second fetal heart rate (for monitoring twins)
 - Maternal heart rate
 - TOCO

- Automatic time synchronization of the CTG with the system
- CTG changes, e.g. change in transducer
- Recorder status
- The following are desirable:
 - Third fetal heart rate (for monitoring triplets)
 - Additional maternal parameters (e.g. SpO₂, noninvasive blood pressure, heart rate)
 - Fetal oxygen saturation
 - Notes input on the CTG (Fig. 53.7) (e.g. vaginal examinations)
 - Fetal movement profile
 - Result of the cross-channel signal comparison to avoid mix-ups (mother–fetus, fetus–fetus)
 - ST segment analysis of maternal ECG (STAN)
 - Measurement of the forces present during ven-touse extraction
 - Automatic transmission of cervical dilation value and fetal station
 - CTG errors/interference

53.2.4 Assessment of the CTG Data and Raising the Alarm

One key function of obstetric monitoring systems is the assessment of CTG data so that the user can be made aware, when necessary, of any problems the patient is experiencing. The simplest method is an alarm system that is triggered whenever a threshold is breached; in other words, the system alerts the user if the fetal heart rate rises above or falls below a certain threshold for a given period. One weakness of this method is that the user is alerted more frequently than is required, for example due to false alarms or signal loss. However, there are better methods available these days; *intelli-*

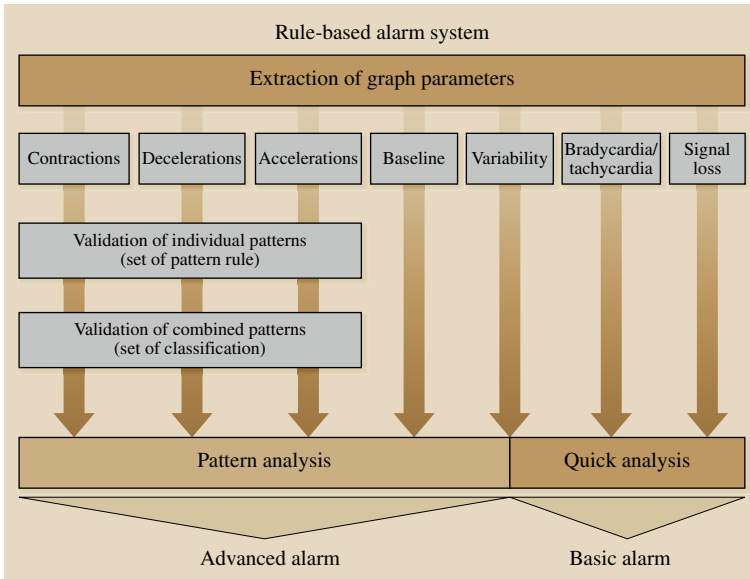

Fig. 53.8 Schematic representation of an alarm system using a rule-based algorithm as an example

gent alarms are able to monitor the profile of the heart rate signal, examine it for certain suspect, dangerous or even pathological patterns, and then alert the user. They can even take into account dependencies between different parameters, such as the profile of the fetal heart rate in relation to uterine activity. Figure 53.8 illustrates the two alarm system principles, and Fig. 53.9 shows an example of an intelligent alarm.

The following list contains the minimum requirements for the different methods.

1. Threshold breach alarm system:
 - Tachycardia alarm system (adjustable threshold values and time delay)
 - Bradycardia alarm system (adjustable threshold values and time delay)
 - Signal lost for a given time period (to be defined)
2. Intelligent alarm system:
 - Detection of accelerations and decelerations and their types (e.g. early deceleration, late deceleration, etc.)
 - Detection of contractions
 - Determination of baseline
 - Detection of variability

The operating concept and type of alarm are also key components of the alarm system. In principle, an alarm can be visual or acoustic in nature. A visual alarm system usually involves part of the screen flashing conspicuously, e.g. an alarm bell; an acoustic alarm system outputs an audible signal, which should have an ad-

justable volume. Many systems also offer the option of connecting the alarm to the central call system. Any alarm being issued should (unless configured otherwise) always alert the user, regardless of which workstation he or she is currently logged onto or which screen he is currently viewing. The type of alarm system should depend on the user’s responsibility and be configurable, e.g. visual alarm only or acoustic alarm only.

Alarms should always be confirmed. The confirmation should be automatically documented and there should potentially be an option to add a comment.

Fig. 53.9 Example of an intelligent alarm

53.2.5 Presentation of the CTG Data

As stated previously, the central monitoring of pregnant women is one of the most important tasks performed by the system. As such, the system should offer a range of ways to display the CTG graphs, such as an overview using various configurations (overview of 2, 4, 6, 9, 12 or 16 beds), a single-bed display, and a compressed single-bed display (Fig. 53.10). It should be possible to configure each PC separately to ensure maximum flexibility. The single-bed display at the very least should be able to offer a quick review of the graphs (quick scroll).

The following must be taken into account when selecting the system:

- The timeline-to-heart rate ratio must be maintained (1:1 mapping of the CTG recording) and adjusted to the respective screen resolution. This applies both to the on-screen display and print-outs.
- The overview screens should be configurable such that they offer different display formats (e.g., an overview of 2, 4, 6, 9, 12 or 16 beds) while maintaining the aspect ratio (CTG recording).
- The normal and compressed single-bed displays should, at the very least, have a scrolling function. It should be noted that it is possible to scroll back to the start (back to the first CTG graph after admission), and not just to the CTG graphs for the last 12 or 24 h.
- The normal single-bed display at the very least should provide an option to add notes directly.

53.2.6 Patient Data Management

The requirements of modern patient data management are extremely far-reaching, beginning with the patient's

first visit and then spanning the entire pregnancy, labor and labor outcome, ending for the mother in the postpartum follow-up area and for the newborn in the nursery. Access to previous pregnancies and births is of course also available (Figs. 53.11, 53.12).

Patient data management in obstetrics is characterized by the fact that we are dealing with multiple *patients* (Fig. 53.13): the mother, the fetus and then the neonate(s). Administration for the fetus is typically tied in with that of the mother, with the neonate(s) then acquiring their own patient records/identity.

The tasks required in patient data management are generally divided into three categories: organization, documentation and quality assurance.

All patient data that is input or automatically recorded is stored, providing a seamless way to manage patient records. Patient management is improved as a result because all past and current data on a patient is available at all times. The entire department should of course be able to access the data both quickly and easily. Seamless management of patient records also enables statistical assessments to be performed and reports to be generated for administration, research and quality assurance purposes. It should be possible to adapt the data input to meet the requirements of the patient in question without any problems, and also to generate a flowsheet-based patient record. This record should generally contain the following information:

- Data collection/input
 - Predefined/configurable input screens that cover everything required from the necessary patient records
 - Labor progress chart (Fig. 53.14)
 - Plausibility checks during input

Fig. 53.10 Example of an overview display

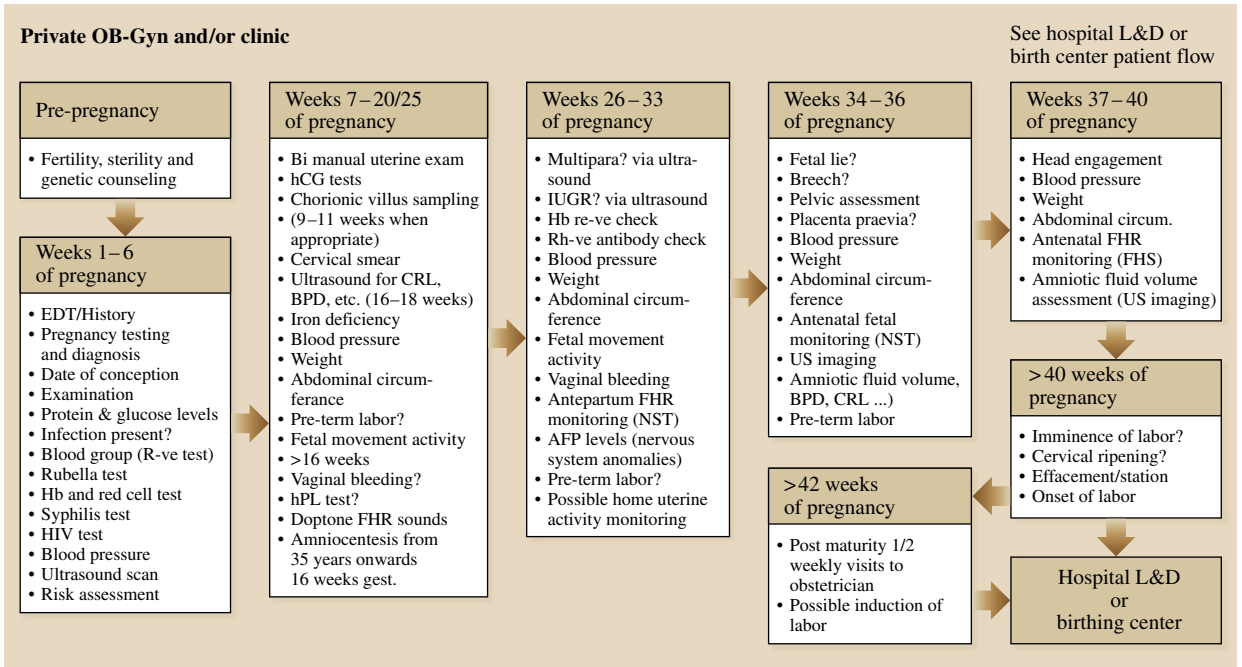

Fig. 53.11 Continuum of care – pregnancy

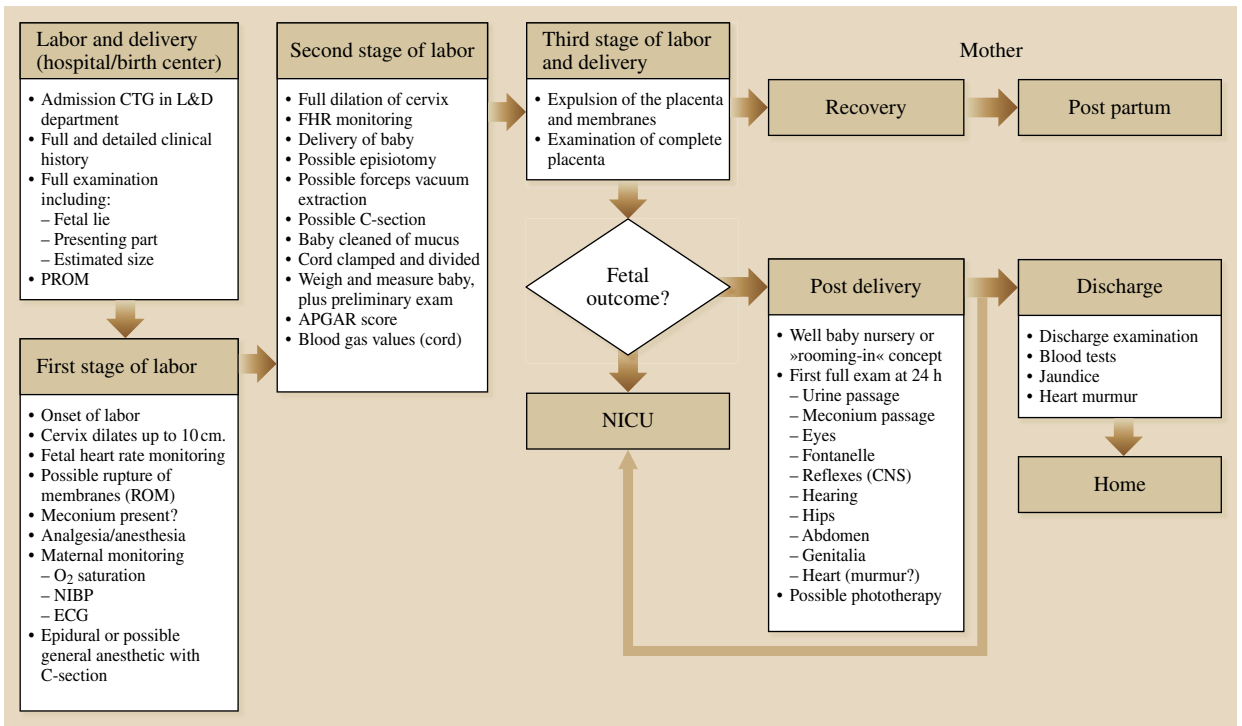

Fig. 53.12 Continuum of care – birth process, postpartum care and newborn nursery

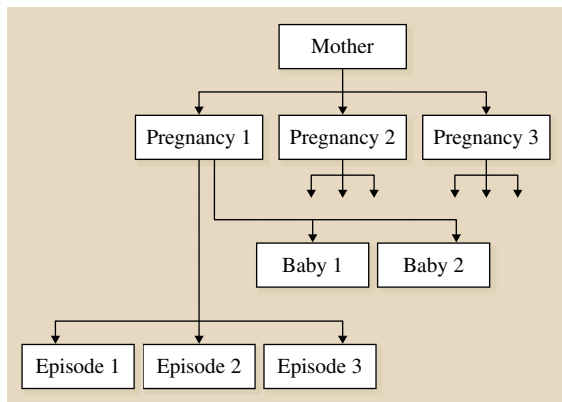

Fig. 53.13 The three patients (mother, fetus, neonate)

- Patient administration
 - Admission, transfer and discharge
 - Activity input
 - Consent to cesarean section
 - Handover of child to parents.
- Production of report
 - Generation of doctor's letter with predefined/configurable screens and text
 - Transport service request
 - Transfer report
 - Birth report
 - Mother's discharge note to hospital administration
 - Neonate's discharge report to hospital administration
 - Mother/child's discharge report to private practice doctor
 - Registration of birth at civil register office.

Fig. 53.14 Example of documentation for a flowsheet-based patient report (labor progress chart)

- Routine documentation
 - Tag creation
 - Pregnancy record
 - Birth register
 - Print-out of full patient records.
- Statistics, trending and reports
 - Ad hoc database queries
 - Weekly, monthly or annual birth statistics
 - Special statistics: e.g. cesarean sections for each doctor, average length of patient stay, anomalous incidents
 - Special QA statistics

53.2.7 Archiving and Retrieving Data via Long-Term Storage Media

Electronic data archiving and retrieval have grown in importance at many hospitals in the last few years, mainly due to the increased number of lawsuits filed by parents of injured children, but also because of the medical interest in the subsequent analysis of births. Modern archiving is usually achieved via access-restricted network drives managed by the hospital's IT department, for example through storage on NAS devices (network attached storage) or a SAN (storage area network). The IT department manages the access rights to ensure that no unauthorized users can access the archive or even delete it entirely. Long-term storage such as this enables patient records to be archived in full (for both inpatients and outpatients), and minimizes the risk of not being able to trace patient records or CTG records. Hard copies of records can be lost, and thermal printed CTGs can become illegible after a number of years – both of which have already led to court cases being lost because the exonerating documentation could not be submitted. Straightforward access to the information stored should be ensured for review and research purposes or to call up a closed case. A good security concept is essential for the archiving system, but is less vital for a system merely intended for monitoring CTG graphs.

However, the following must be satisfied under all circumstances:

1. Safeguarding of the power supply by means of an uninterruptible power supply (UPS) that is connected to the server and the network components.
2. Safeguarding the data on the server by one of the following two methods:
 - a) *High-availability concept.* A second server operates in parallel to the first. In the event of

a defect, the fault-free server takes over all tasks until the other is functional again.

- b) *RAID technology*. This is a group of hard drives that save the data redundantly and independently. Should one of the hard drives fail, it can be exchanged during operation and the system automatically ensures that the repaired drive is updated to reflect the current status.
3. Creation of a security concept to protect the long-term archive. Regular backups ensure that the archive can be restored in the event of a disaster. These backups can also be stored at different locations for extra protection, against fire for instance.

53.2.8 Computer Communication Within Obstetrics

This section covers communication between obstetrics departments in different hospitals within a town, communication with smaller outpatient clinics that work in conjunction with a hospital, the midwife recording CTGs on site, and the doctor who needs to assess patient data either at home, on the move or from his practice (Fig. 53.15).

Obstetric monitoring systems should not only enable patients to be transferred from bed to bed within the same hospital, but also to other hospitals to ensure direct access to patient records. This particularly occurs if the woman was unsatisfied with her previous delivery or the level of urgency means that the delivery location can no longer be accessed (blockage). Web access to patient records plays a key role when communicating with the doctor at home or in his practice; the hospital must have the necessary infrastructure to ensure that the communication is secure. If the doctor is out and about and his interpretation of the CTG is required as a matter of urgency, the relevant sections of the CTG can be sent to mobile telecommunication devices such as an iPhone for his consultation (Fig. 53.16).

53.2.9 Computer Communication with Other Hospitals

The obstetric monitoring system is just one of many systems within a hospital, and it is extremely important for it to be integrated within the overall network, with the result that standalone solutions are receding into the background. Normally, an HL-7-based interface is used to connect to other computer systems, with integration occurring via direct data transfer or via access at the workplace to other systems (Fig. 53.17).

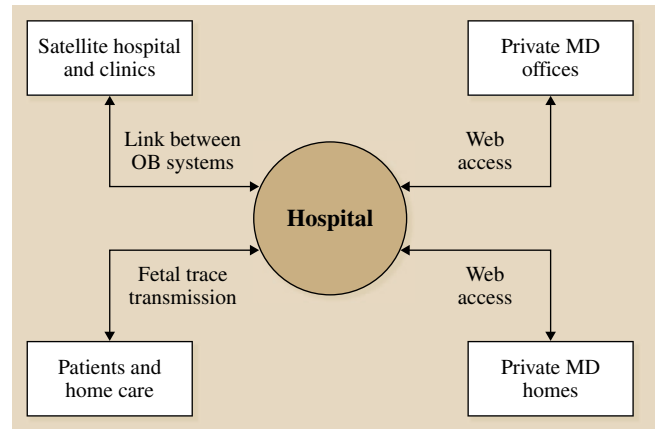

Fig. 53.15 Obstetrics outside the hospital

53.2.10 Communication with the Hospital Administration Computer

The bidirectional connection in this area enables a straightforward patient admissions procedure through the automated importation of personal data, and notifies the hospital administration computer of discharges and transfers.

53.2.11 Exporting Patient Data to Other Hospital Systems

Because data are exported to a data archive, this means that they are also available for other applications, such as for hospital-wide patient records.

Fig. 53.16 CTG can be sent to mobile telecommunication devices such as an iPhone for consultation

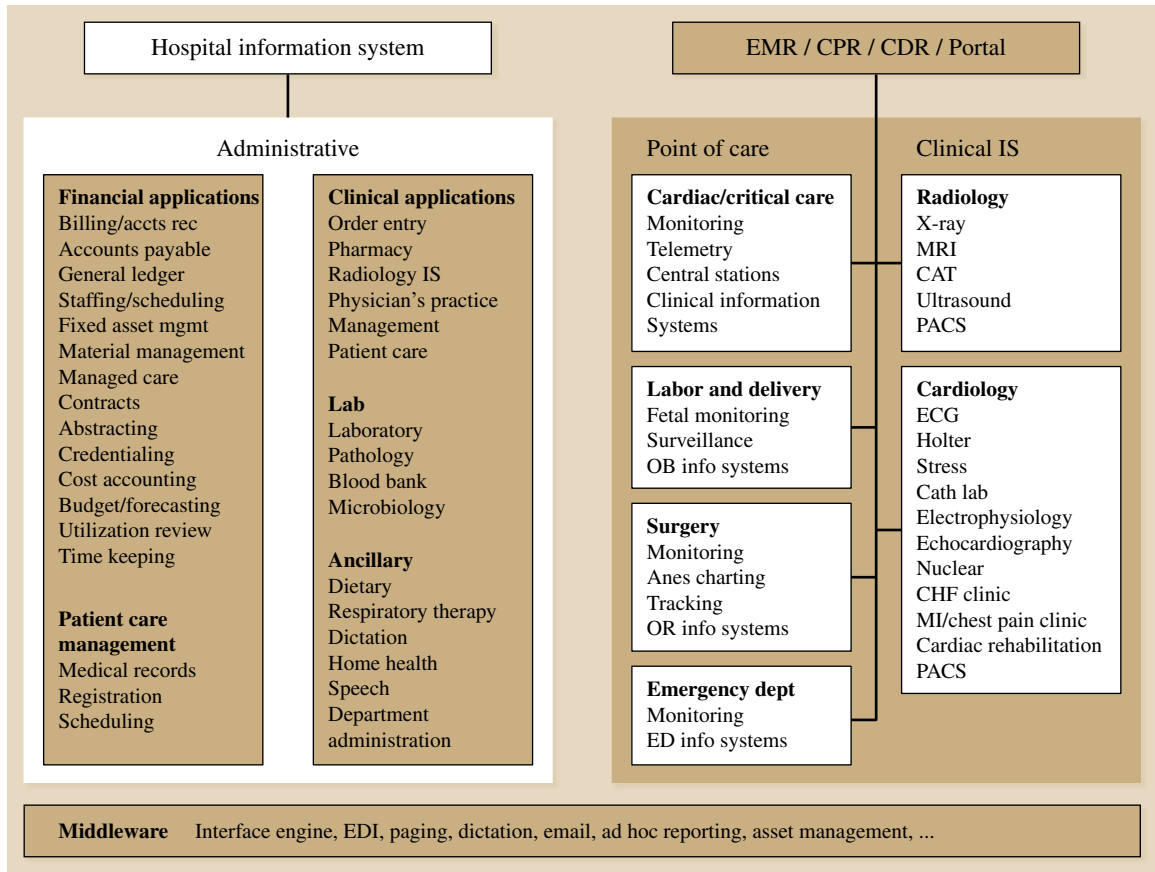

Fig. 53.17 Obstetrics and the hospital

53.2.12 Connection to Lab Computer

Lab results can be documented automatically in the patient's records by importing the data from a lab computer.

53.2.13 Access to Internal Hospital Computer Systems

Various methods have been developed in this regard:

- Direct access via a client application installed on the obstetrics workstation
- Direct access via Internet Explorer using a web-based application
- Indirect access via web-based hospital portals

A visual integration of obstetrics and other applications is possible, as long as the applications are able to exchange their context (user context and/or patient context). If a user switches from one patient to another within the program, the other system will detect this and also switch to the relevant patient.

Neonatal Monitoring

54. Neonatal Monitoring

Roland Hentschel

Because they are naturally helpless compared to adults, sick newborns are reliant on careful observation and, due to their characteristically pathophysiological qualities, the monitoring performed is sometimes quite different from that done for adult patients. In order to understand this, it is necessary to consider some of the characteristic peculiarities of neonatology.

The most important diagnoses of neonatal patients are premature birth, disturbance of adaptation (Sects. 54.1, 54.2) in the respiratory and the circulatory system, sepsis, and congenital malformations, in particular of the cardiovascular system (Sect. 54.3). All newborns have instability in the respiratory and cardiovascular systems in common. The more immature the premature infant, the more likely it will be that it needs artificial respiration or respiratory assistance due to having underdeveloped lungs (respiratory distress) or marked central respiratory regulation disorders. Respiratory pauses (central apnoeas), obstruction of the upper airways (obstructive apnoeas), or the typical respiratory pattern of the premature

54.9	Setting Alert Limits and Limit Values	1040
	References	1041

infant (periodic breathing) result in a drop in the O₂ saturation, with subsequent bradycardia (Sects. 54.4–54.8).

Unlike with adults, undersaturation of the blood sets in extremely quickly because the oxygen stores (as measured against the oxygen demand) are very low. On the other hand, bradycardia can occur spontaneously as a result of the activation of vagus reflexes in the pharyngeal region (accumulation of secretions). Central, obstructive or mixed apnoeas are a key problem in the monitoring of premature infants.

Newborns have two particular characteristics in terms of their respiration: they are obligate nasal breathers and, in contrast to adults, they breathe predominantly with the diaphragm. Because a newborn infant's thorax is mechanically very unstable, see-saw breathing frequently occurs: the lung volume which is gained because the diaphragm descends during

inspiration is for the most part lost again as a result of inward movements of the sternum and upper thorax.

Various pathophysiological disorders, such as:

- Cerebral immaturity
- Cerebral haemorrhages
- Respiratory distress
- Infections
- Congenital metabolic disorders
- Electrolyte imbalances
- Convulsions
- Hypo- or hyperthermia
- Hypoglycaemias, or
- Anaemia

manifest themselves in cardiorespiratory disorders in premature and newborn infants. It is possible to gather from this that the following parameters are central to neonatal monitoring:

- Single-channel ECG
- Respiration
- O₂ saturation
- Transcutaneous blood gas values
- Blood pressure.

Furthermore, on account of the particular thermal instability of premature and newborn infants, temperature monitoring also plays a large role. Premature infants are therefore cared for in incubators. In contrast to adults, premature infants are at particular risk in terms of their oxygen status. As with adults, a toxic (excessively high) inspiratory oxygen concentration can trigger a sterile inflammatory response in the lungs, leading to chronic lung damage. In addition, the feared retinopathy of the retina (vascular proliferation which can lead to blindness) can also be triggered in premature infants as a result of an excessively high inspiratory oxygen concentration with subsequent hyperoxia; this

risk is present up until the point at which a premature infant reaches its previously expected delivery date. Continuous monitoring of the oxygen status is therefore imperative.

In patients who are given artificial respiration, the inspiratory oxygen concentration is adjusted using the ventilator and also monitored. Also, premature infants who are capable of spontaneous breathing or those connected to a CPAP machine must always be connected to an oxygen monitoring unit. If a nasal cannula is used to administer a specific gas flow at a specific oxygen concentration, the knowledge of these variables does not allow the inspiratory oxygen concentration to be estimated, as the child can breathe additional air. It is better to set a certain oxygen concentration in the *microclimate* of the incubator and to use a suitable measuring and alert system for monitoring. As with adults, in neonatology, modular universal monitors are mostly used which record different parameters using a dedicated measurement module for each, and display these parameters on a multichromatic multichannel monitor. Alert systems for monitoring the oxygen concentration are usually integrated ex factory into ventilators and CPAP machines and also into incubators.

54.1 Electrocardiogram

The electrocardiogram (ECG) records the electrical activity of the heart in terms of its changing amplitude and the changing direction of the electrical principal axis. As with adults, the single-channel ECG is conventionally recorded by means of ECG electrodes at the typical positions on the chest. It is occasionally recommended that all of the electrodes are placed on the lateral thorax so that the lungs are covered as minimally as possible in x-ray images (which must be taken regularly), meaning that the electrodes do not have to be removed in order to perform an x-ray. For this purpose, electrodes can be attached to the upper arms and abdomen. Because the single-channel ECG is not usually used for cardiological diagnosis, standard electrode placements are unnecessary, and the red and yellow electrodes are otherwise arranged in the electrical axis of the heart. The electrodes for newborn infants are smaller than those for adults, and they are usually coated on the back with an adhesive which simultaneously acts like a contact gel in order to reduce the contact resistance. For premature infants, it is necessary to consider the skin tolerance of the material used and the x-ray transparency. In fully de-

veloped newborn infants, problems occur shortly after birth, in particular if they have a lot of vernix caseosa; it is often possible to obtain an ECG recording only after degreasing measures and by using electrodes which adhere well.

Violent (respiratory) movements frequently cause *shaking* of the ECG; this is not a critical issue when recording the heart rate, but it is for the recording of arrhythmias, which is occasionally necessary. By interconnecting the three chest electrodes, it is possible to obtain three different leads, provided that all the electrodes adhere well. The amplification selected should always result in the amplitude of the complete ECG signal occupying the entire bandwidth of the monitor channel; it is only in this way that interference with normal depolarisation and repolarisation (e.g. in the case of hypokalaemia) can be reliably detected.

However, the only diagnoses which can reliably be made from the single-channel ECG are: bradycardia, tachycardia, asystole, supraventricular and ventricular extrasystoles, ectopic rhythm, and atrial and ventricular flutter or fibrillation. Automatic evaluations such as

the diagnosis of arrhythmias, measurements of the ECG portion and the like are not customary in neonatology. As already mentioned, the positioning of the electrodes is usually not critical when recording an ECG, but it is crucial when recording the thoracic impedance curve, and must therefore be selected with great care in this respect (see below). The single-channel ECG is primarily used to detect tachycardias and (more commonly) bradycardias. To this end, the alert limits for the heart rate must be set such that they correspond with the standard values for the age group (Table 54.1).

The majority of monitors these days provide memory recording of the heart rate and other parameters over a period of at least 24 h. The duration of a heart rate anomaly can then be accurately traced retrospectively over a time axis which must span a different length of time. In addition, event recording is desirable in which between five and six cardiac cycles are automatically recorded when an alert based on the heart rate is triggered, with the result that later analysis of the event

Table 54.1 Standard values for the heart rate (average and simple standard deviation (SD)) (after [54.1])

Age	Average + 1 SD (beats/min)	
0–24 h	133	22
2nd–4th week	163	20
1st–3rd month	154	19
3rd–6th month	140	21
6th–12th month	140	19
1st–3rd year	126	20
3rd–5th year	98	18
5th–8th year	96	16
8th–12th year	79	15
12th–16th year	75	13

is possible using a graph which is true to the original. Unfortunately, most monitors only display these events with a compressed time axis, making accurate analysis of the rhythm impossible. It should be possible to store at least 20 events.

54.2 Impedance Pneumography

This method detects changes in the electrical impedance occurring between two electrodes during a respiratory cycle, probably as a result of changes in the vascular filling. Due to the susceptibility of premature and newborn infants to respiratory disorders, this part of the monitoring assumes great significance in neonatology. The method can show the respiration rate, respiratory pattern, amplitude and respiratory pauses via the existing ECG electrodes.

In the case of unstable respiration in premature infants, a recording speed that is as slow as possible should be selected (e.g. 6 mm/s), as this is most likely to give information about the respiratory pattern (e.g. periodic breathing). The electrodes should be positioned in the area of the greatest change in size during a respiratory cycle. This area is between two electrodes on the anterior right and left axillary lines in the region of the costal arch.

The large degree of variability in the respiratory patterns of premature and newborn infants is problematic. Since the respiratory regulation is immature at various levels, respiration is not as autonomic (*machine-like*) as in adults. The result of this is not only pronounced respiratory pauses but also variations in the amplitude and the respiratory starting position. The recording and processing of the thoracic impedance curve therefore

places considerable demands on the software of the monitor.

The respiration rate (Table 54.2), the frequency of apnoeas and occasionally also the durations of the individual apnoeas are monitored using limits which can be adjusted according to the age of the patient. Sub-threshold respiratory pauses that do not reach the selected duration of a defined apnoea can be added together on dedicated monitors to give *respiratory deficits* via adjustable limit values in order to facilitate the detection of periodic breathing.

According to its definition, an apnoea exists when there is respiratory arrest for a period of at least 20 s.

Table 54.2 Standard values for the respiration rate (average and simple standard deviation (SD)) (after [54.1])

Age	Average + 1 SD (beats/min)	
Premature infant	50	10
Newborn infant	40	10
Infant	31	8
1st–4th year	24	4
5th–9th year	20	2
10th–14th year	19	3
14th–16th year	17	3

It should be possible, however, to freely select other intervals for monitoring too.

Due to the greatly oversized volume of the heart (in comparison with the thoracic volume) compared with adults, fluctuations in the size of the heart during a normal cardiac cycle, with a corresponding amplification in the impedance pneumography, occasionally appear as normal respiratory cycles. This is particularly true of the cardiac hyperactivity which is very frequently observed in the context of cardiac problems (e.g. ductus arteriosus). In this situation, the monitor can under some circumstances incorrectly interpret the heartbeat – which continues for a while even when breathing has completely stopped – as continuing respiratory activity. By activating a detection mode which compares the recorded heart rate with the incorrectly recorded *respiration rate*, this signal problem can be detected so that an alert is triggered.

In order to interpret causal relationships, it is necessary to obtain a retrospective evaluation with respect to current measures such as nutritional probing, care times or administration of medication. Only then is it possible to make any statements about the possible aetiology of a respiratory disorder. The recording of a complete respiratory cycle requires a curve profile, in opposite directions in each case (inspiration and expiration), where a defined minimum amplitude, based on a minimum or maximum value, has always been reached. The amplitude can either be input permanently or adapted to the changing depth of respiration in accordance with a (usually very complicated) algorithm.

Displacement of the normal respiration is usually not a problem when detecting a breath. However, an apnoea is occasionally recorded erroneously. Modern monitors are capable of varying or automatically adapting the size of the amplitude shown and the zero point

within certain limits, such that a diagram of the respiratory pattern which is to some degree realistic can be achieved, and thus a visual recording of apnoeas is possible. After every change in the position of the electrodes, but also after the patient has been moved, the monitor setting for the impedance pneumography must be readjusted (the settings for the depth of respiration and the amplitude size or the selection of the automatic setting function). In the case of infants, for undisturbed monitoring of respiration, the electrodes are usually attached at a markedly lateral and low position (based on the entire projection field thorax–abdomen). An undisturbed recording of the single-channel ECG should also be possible in this position.

It is desirable to have the option to record the thoracic and the abdominal impedance pneumography in two channels superimposed on one another on the time axis. Ideally, the amplitude maxima will lie exactly above each other, with the leads orientated in the same direction. Each phase shift between two leads signifies a reduction in respiratory economy, and in extreme cases where there is an opposing deflection there is paradoxical respiration with entirely ineffective respiratory work (*thoracoabdominal asynchrony*).

This sometimes cyclically occurring phenomenon is found in certain chronic lung conditions of premature infants (*bronchopulmonary dysplasia*). Because it can improve under some circumstances as a result of various measures (medication, inhalations, inflation manoeuvres, CPAP), this diagnostic possibility is of great significance. Unfortunately, such a diagnosis is not yet possible using standard monitors, but there are special devices which, in addition to displaying the phenomenon, can also precisely calculate the angle of the phase shift.

54.3 Combined Cardiorespiratory Analysis

In order to recognise the aetiology of a cardiorespiratory disorder in premature infants, it is important to be able to retrospectively analyse the precise chronological sequence of respiration (respiratory pattern), heart rate and saturation curve. Only then is it possible to differentiate whether a primary O₂ undersaturation has led to apnoea and then to bradycardia, whether a primary reflex bradycardia has led to undersaturation with consequent apnoea, or whether a primary apnoea has triggered undersaturation with subsequent bradycardia

(Fig. 54.1). It would also be desirable to see the graph displayed in addition to the retrospective analysis of the O₂ saturation. Unfortunately, the memory capacities of standard monitors are usually insufficient for a data set of this size.

Cardiorespiratory monitoring or analysis is important, particularly in the field of home monitoring of infants which are at risk of sudden infant death syndrome (SIDS). These are, in particular, siblings of infants who have suffered from sudden infant death syn-

Fig. 54.1 Impedance pneumotachography. Nasal flow, abdominal movement, heart rate, oxygen saturation (from top to bottom). Pronounced, prolonged, obstructive apnoea with an absence of nasal flow and with good autorespiration. Note the artefact-related decreases in saturation

drome, children with severe neurological disorders, and infants who have constant respiratory disorders.

Exclusive monitoring of the respiration is carried out, for example, using a mechanical applanation sensor (Graseby capsule). This sensor records pressure changes within a closed, air-filled system when a convexly curved balloon that is stuck to the skin in the abdominal region is slightly compressed as a result of a respiratory movement. Because it is not capable of distinguishing unsuccessful respiratory movements or a final gasp with the accompanying bradycardia from effective respiration, exclusive monitoring of the infant using this method is no longer standard these days.

54.4 Pulse Oximetry

Pulse oximetry has developed as a continuous, non-invasive, indirect method of measurement to become the standard method of monitoring the oxygen status. It is a method which uses transmission photometry to measure the concentration of oxygenated and deoxygenated haemoglobin according to the Beer–Lambert law. These two forms of haemoglobin have different spectral properties. Two light-emitting diodes conduct light – in the range of the absorption maxima of the two substances (visible range approximately 660 nm and infrared range approximately 940 nm) – through a peripheral body part, and a photodiode is located at the exit point opposite. The percentage of saturated

Most SIDS monitors have the option of recording alert sequences and trend curves of the monitored parameters and analysing them offline using special analysis software.

According to the most recent recommendations, the monitoring of apnoeas should preferably be done using a pulse oximetry device (see below) which also records the pulse rate; additional monitoring of the respiration is then not necessary. Note: *Devices which are freely available on the market for monitoring SIDS are based on different measurement principles; they should generally be rejected on account of their high susceptibility to faults or unproven effectiveness.*

haemoglobin is calculated from the attenuations of the two light beams.

What is crucial here is that the measuring system records a pulse wave and thus only evaluates the pulsatile fraction of the measurement signal. The pulsatile fraction is detected via the increase in the distances covered by the light beams in the arterial filling phase in the tissue. If no pulse wave can be detected, the device does not display any reliable values; the recording of the pulse curve (plethysmogram) is therefore a fundamental part of any pulse oximetry system, and preference should be given to displaying an authentic pulse curve on a time axis (x -axis) as opposed to a simple LED dis-

Fig. 54.2 Pulse oximetry in a premature infant

play with rising and falling *level values*. The pulse curve is generally also used to calculate a pulse rate.

The pulse curve is also suitable for use as a diagnostic tool in order to show the quality of the peripheral pulse wave, e.g. in the event of resuscitation. In neonatology, adhesive sensors or soft plastic sensors are used exclusively instead of clip sensors, and these are placed loosely around the preferred recording sites and fixed with a small piece of hook-and-loop tape (Fig. 54.2). Preferred positions are the wrist, forefoot, arm and leg.

If the patient has poor peripheral microcirculation (e.g. also in the context of catecholamine administration), application of the sensor is difficult; often no pulse wave is recorded, since the light pressure of the sensor on the skin and on the underlying tissue is sufficient to stop the perfusion in this measurement area. This can be detected by a nonphysiological plethysmography curve or by a discrepancy between the pulse rate measured and the heart rate based on the ECG recording.

Reliable measurement is also often not possible in oedematous tissue. In order to avoid pressure necroses in very small premature infants, in some circumstances the recording sites must even be changed at intervals of 3–4 h. The sensors can cause burns on the skin, namely when the surface is damaged or when sensor and device are not optimally tuned to one another.

In the event of scattered light falling on the sensors, excessively low saturation values are usually erroneously simulated. In some circumstances, however, a normal saturation value can be displayed even when there is complete loss of skin contact, although, a pulse curve is not recorded then. If the two diodes are not in exact contact with the skin, this can likewise lead to incorrect high or low saturation values. When the blood pressure falls below 30 mmHg, some devices no longer

function reliably. Unfortunately, most pulse oximetry devices show measurement values on the display despite a detectable error in the recording as a result of movement artefacts or the like.

It is imperative that all pulse oximetry values which do not originate from an artefact-free recording are eliminated by the device, and at the very least are not displayed as a numerical value. All devices calculate average values from a specific – sometimes selectable – number of cardiac beats, or they calculate the averages over a specific time frame. The longer the duration of the averaging, the slower the device is to react to acute changes, but the lower the rate of (false) alerts, too. There are improvements in the software which allow movement artefacts to be better detected and excluded from the computer analysis. These devices filter the venous pulse waves which result from movement artefacts out of the analysis.

If the pulse oximeter does not display a pulse curve, or if the values are unreliable, it is first necessary to rule out the possibility of scattered light (especially from heat lamps) falling on the sensor. The next step should be to try to loosen the fixing. If this does not solve the problem either, then another recording site should be selected where less tissue is transilluminated.

Considering the sources of errors identified, pulse oximetry values must also be counter-checked regularly with arterial or hyperaemised capillary blood gases. The sites used to take blood samples and record the pulse oximetry should be identical with respect to the positional relationship to the ductus arteriosus.

The characteristic curve of this measuring technique is not linear: in the region below 75% the sensor displays unreliable values, and in the upper region the validity of the measured values is restricted by the physiologically flat profile. The devices mostly take into account general average values of haemoglobin molecules which do not serve as oxygen carriers (COHb and MetHb), but which taken together usually comprise less than 3%. This percentage can be calculated exactly by cooximetry analysis in modern blood gas analysis systems. Elevated COHb and MetHb values can lead to incorrect pulse oximetry measurements. The MetHb value can rise when nitric oxide gas is used.

Due to the asymptotic relationship between the oxygen partial pressure and the associated Hb saturation, pulse oximetry is only suitable for monitoring premature infants up to a point: hyperoxia cannot be reliably detected, whereas a decrease in oxygen can be recorded very well. Since hyperoxia must be avoided at all costs in premature infants, pulse oximetry is not a suit-

able method for monitoring premature infants requiring oxygen. In the case of premature infants without an additional oxygen requirement (room air), pulse oximetry is a good method for recording decreases in saturation and, to be exact, the upper limit value in this situation can be set at 100%, because hyperoxia can be virtually ruled out in room air (although it cannot be completely prevented in any case).

Pulse oximetry offers a good compromise as a simple monitoring device insofar as both the heart rate and the saturation can be recorded as central cardiorespiratory variables using a single cable and the associated sensor, meaning that there is no need to attach ECG cables. This is an advantage in particular for a very immature premature infant with very sensitive skin that does not tolerate the application of adhesive ECG electrodes. However, the recording of the pulse is not very reliable because of its susceptibility to movement artefacts.

Pulse oximetry is also of essential importance in the detection of pathophysiological perfusion disorders, in which the upper and lower halves of the body receive blood which is saturated to different degrees. In rare, complex heart defects, the lower half of the body can be better oxygenated than the upper half, but the opposite situation is more common: in persistent foetal circulation (*PFC syndrome*), unoxygenated blood is conducted – as a result of high pressure in the pulmonary circuit – from the pulmonary artery via the ductus arteriosus into the lower half of the body, thus leading to undersaturation in this region, whereas the upper half of the body is

Table 54.3 Recommended limit values for monitoring the oxygen status in neonatology

Parameter	Recommended limit values
Pulse oximetry	
Premature infants	83–93%
Sick newborn infants	92–98%
Transoxodes	
Premature infants	45–65 mmHg
Sick newborn infants	65–90 mmHg

supplied with oxygen-rich blood via the section of the aorta before the junction with the ductus arteriosus.

This pathophysiological situation, which can often vary widely, is of great significance and is therefore monitored with the aid of pulse oximetry sensors on both the right hand and one of the feet. Unfortunately, most universal monitors do not provide the option to record two pulse oximetry values.

It is very difficult to standardise pulse oximetry devices; they vary from one manufacturer to the next, and from one device to the next. Even the reconstruction algorithms vary between different manufacturers depending on whether the fractional or the functional oxygen saturation is quoted. For the most common devices, however, there is now good data in the scientific literature for the correlation between oxygen saturation and oxygen partial pressure. Recommended alert limits for the monitoring of premature and newborn infants are reproduced in Table 54.3.

54.5 Transcutaneous Measurement of the Partial Pressure

This method of transcutaneous partial pressure measurement for carbon dioxide ($P_{tc}CO_2$) and oxygen ($P_{tc}O_2$) is peculiar to paediatrics, as the greater skin thickness in adults usually prevents accurate measurement. The local hyperthermia at the location of the measuring sensor causes arterialisation at the measurement site. The blood gases, which under these conditions are in equilibrium with the partial pressure values in the peripheral tissue, can thus be monitored noninvasively. However, the values must be regularly calibrated with (preferably arterial) blood samples. Both gases ($P_{tc}CO_2$ and $P_{tc}O_2$) are frequently measured together in a combination electrode.

In order to rule out burns to the skin, the monitors monitor the duration of the application of the sensor at the measurement site, request a change in the

application site and recalibration and, under some circumstances, even switch off the heating of the sensor automatically when a specified time span is exceeded. The heat output needed to maintain a constant sensor temperature is usually displayed, and its profile gives valuable information about the centralisation of the circulation, provided that the ambient temperature is kept constant.

If there is a sharp rise in the heat output, the application site should be checked especially closely for signs of heat damage. With a heating temperature of 43 °C, in the case of very small premature infants, for example, the placement of the sensor should be changed at intervals of 2–3 h.

The local overheating leads to a shift in the haemoglobin dissociation curve, which results in an

increase in both the $PtcO_2$ and the $PtcCO_2$. This is counteracted in the calculations by the oxygen consumption in the tissue, resulting in a realistic oxygen measurement which is close to the arterial values. However, due to the production of CO_2 in the heated tissue, the $PtcCO_2$ values are mostly too high. These effects can be compensated for in the calculations by in vivo correction. When the heat output varies to a large degree, arterial blood gas values must be taken continuously to check the displayed measurement values.

The sensors are attached to the skin using adhesive rings and a drop of contact solution, avoiding air pockets (Fig. 54.3). At intervals of approximately one week, the sensors must be covered with a new membrane. Calibration should be performed at least once a day.

Fig. 54.3 Transcutaneous sensor for measuring the $PtcCO_2$ in a premature infant

54.6 Measurement of the $PtcCO_2$ (Transcapnode)

The sensor attached to the skin generates a local skin temperature of $43\text{ }^\circ\text{C}$. CO_2 then diffuses from the skin – in which it has the same concentration as in the capillary terminal vascular bed of the blood – via a membrane with hydrophobic properties (silicone or Teflon) into an electrolyte solution. There, the CO_2 molecules become H^+ ions, which change the pH. This change is recorded by a pH electrode and compared with a reference electrode, and the voltage potential is proportional to the pCO_2 . A potential source of errors is the CO_2 formed in the skin itself, which is dependent on metabolic processes. Since the partial pressure difference between the

arterial and mixed venous blood is very much lower and CO_2 is better diffused than O_2 on account of their different solubility coefficients, the degree of (arterial) tissue perfusion is less crucial than in the measurement of the $PtcO_2$ (transoxode). For these reasons, the $PtcCO_2$ is frequently higher than the arterial pCO_2 . A two-point calibration is performed at fixed intervals using a special calibration gas. The transcapnode is less dependent on the measurement site, blood pressure, pH, body temperature and haematocrit, and a sensor temperature of $42\text{ }^\circ\text{C}$ is often sufficient. At 30–50 s, the response time is longer than that of transoxodes.

54.7 Measurement of the $PtcO_2$ (Transoxode)

The reliability of this method is dependent on the thickness of the skin, the measurement site and the peripheral perfusion at this site. It is also influenced by the sensor temperature selected and the fixing of the sensor. Moreover, it is unreliable at a pH of 7.0 and below, and also in cases of severe anaemia (haematocrit < 28%).

These conditions are rarely found, in contrast to systolic blood pressure values of below 32 mmHg, which are common in very small, sick, premature infants, and which then limit the reliability of the $PtcO_2$ measurement considerably. This can also be interpreted differently, however: under some circumstances, the discrepancy between the results of an arterial blood gas analysis with standard values and an unreliable $PtcO_2$ measurement with lowered values points to the beginning of a breakdown in the pe-

ripheral circulation. In premature infants with chronic lung disease (bronchopulmonary dysplasia), the measurement of $PtcO_2$ is often unreliable, probably on account of strong fluctuations in the skin perfusion.

For optimum correlation with the arterial pO_2 , a sensor temperature of $44\text{ }^\circ\text{C}$ is recommended, and in the case of small premature infants, a temperature of $43\text{ }^\circ\text{C}$ is a workable compromise between the reliability of the measurement values and the risk of heat damage. Calibration is performed with the ambient air, taking into consideration the current air pressure. After every sensor repositioning, a time span of 10–15 min is required before stable steady-state conditions are reached. The response time for acute changes in the pO_2 varies between 20 and 60 s depending on the conditions.

54.8 Monitoring the Oxygenation – Which Method?

Opinions about how the oxygen status should be monitored vary greatly from one hospital or clinic to the next. There are good arguments for various standards. The fluctuations in the oxygen saturation in premature and newborn infants, which are in any case much larger than in adults, must first be kept constant within narrow limits. Hyperoxia is dangerous in premature infants in the first instance due to the potential development of retinopathy. Chronic lung damage can also arise as a result of unnecessarily high inspiratory oxygen concentrations, however. Finally, the formation of oxygen radicals is also important for other pathophysiological processes.

Hypoxia is naturally equally unwelcome; after all, all cells in the body – but in particular those in the developing brain – are highly dependent on oxygen.

The dilemma over the narrow oxygen limits is increased by the fact that the optimum target range for the oxygenation of premature and newborn infants has

not yet been conclusively identified, and can only be defined by a method with great difficulty. It is known that the intrauterine foetus has a $p\text{aO}_2$ value of only about 30 mmHg in the arterial blood, and grows without any problems. For extrauterine life, additional oxygen is required for purely pragmatic reasons as additional organ functions (e.g. respiration), metabolic activities and also the generation of heat *initiate*. For small premature infants at risk of retinopathy, according to currently prevailing scientific opinion, the arterial $p\text{O}_2$ should not be above 60 mmHg or below 40 mmHg. It is sensible to set the limits using the $p\text{O}_2$ as, due to peculiarities in the oxygen–haemoglobin dissociation curve, the upper limit cannot be monitored exactly by means of saturation (pulse oximetry) (Fig. 54.4).

Aside from the fact that complete saturation of the haemoglobin of 100% can be dangerous for premature infants anyway, the additional oxygen dissolved in the blood must be regarded as toxic. Noninvasive monitor-

Fig. 54.4 Oxygen–haemoglobin dissociation curve (after [54.2])

Table 54.4 Advantages and disadvantages of monitoring systems for oxygen status

	Pulse oximetry	Transoxodes
Advantages	<ul style="list-style-type: none"> Fast to become operationally ready No calibration necessary Short response time Virtually no local irritation Low dependency on the circulation Suitable for all ages 	<ul style="list-style-type: none"> Measurement of the relevant variable (pO_2), Good correlation with the arterial pO_2, Few artefacts
Disadvantages	<ul style="list-style-type: none"> Unsuitable for hyperoxia monitoring Inaccuracy at < 75% saturation Movement artefacts common Sensitive to scattered light Frequent alerts 	<ul style="list-style-type: none"> Warm-up time of up to 15 min Long response time, Not sensitive to brief variations in the oxygenation Reliability limited in the case of certain pathophysiological circumstances Localised burns Labour-intensive due to frequent calibration Susceptible to faults on the part of the membrane Rigid cable

ing of the oxygen status should therefore be performed by means of transoxodes in the case of small premature infants who require an elevated inspiratory oxygen concentration. If short-term under/oversaturation is suspected, the faster-reacting pulse oximeter should be used in addition. A pulse oximeter is sufficient for premature infants who do not require extra oxygen and for mature newborn infants.

For very small premature infants with poor perfusion and very sensitive skin, it may be necessary to do without transcutaneous gas sensors (and any ECG electrodes) and to monitor exclusively using pulse oximetry. In more mature patients, movement artefacts can cause false alerts in the pulse oximetry, meaning that transoxode monitoring is more suitable. On the other hand, in patients who are increasingly mobile, the rigid ca-

bles of the transoxodes and transcapnodes are a real hindrance.

If oxygen monitoring is necessary in the case of an acute emergency, pulse oximetry should in principle initially be performed preferentially because of its fast availability, regardless of the maturity of the patient. In premature infants with severe bronchopulmonary dysplasia, pulse oximetry should again preferably be used on account of its greater degree of reliability in this patient group. If there are doubts as to the relevance of measurement values with one of the two methods for an individual patient, the alternative method should be used in addition.

The advantages and disadvantages of the two alternative methods for monitoring oxygenation are compiled in Table 54.4.

54.9 Setting Alert Limits and Limit Values

When setting limit values, it is necessary to distinguish between the target range and alert values (alert limits). The target range includes the values that are aimed for, which means that the continuously recorded values should predominantly be within this range. In contrast, the alert values specify those values which, if they are exceeded or undershot, will illicit a response from the staff by triggering an alert (stimulation of the child in the event of an apnoea, adjustment of the inspiratory oxygen concentration, etc.).

If the alert range selected is too *generous* and the recorded values only show minor fluctuations, it could

be that no alert is recorded over long periods, even though the child is mostly not within the medically based target range – which must be defined more narrowly – during this period. The setting of alert values and limit values is an important medical task in the case of neonatal patients, and while this task can sometimes be standardised, it must be carried out individually at other times. There are many studies in which the sensitivities and specificities of various alert limits for the diagnosis of hyperoxia and hypoxia have been tested in various pulse oximetry devices. These studies are recommended for more detailed study in this area and for issuing guidelines.

Every neonatal department should adapt the standards for its own devices to the patient, however, and specify individual limits. Standardisation of this nature for oxygen saturation and partial pressures for O₂ and CO₂ should be carried out on the basis of an arterial blood sample. This is best done using an existing vascular cannula: if a vasopuncture is performed at the time (and particularly if this is difficult), the child presents rapid changes in the blood gases even in the intubated state due to the bout of crying connected with the reaction to the pain. The resulting acutely elevated *p*CO₂ values and the lowered *p*O₂ values are

then still not recorded correctly as a result of the latent periods due to the noninvasive nature of the methods used (in particular transoxodes and transcapnodes) (Table 54.3).

Intraoperative Neuromonitoring

Werner Kneist, Daniel W. Kauff

Intraoperative neuromonitoring (IONM) was described as early as 1898 when facial muscles were visually assessed for activation during surgery near the facial nerve. Nowadays, it is based on the measurement of important physiological parameters for observation of the central and peripheral nervous system. The main focus of this chapter is IONM performed by the surgeon for prevention of direct nerve damage during the surgical procedure. IONM has been developed for nerve identification and observation of neural pathways during the surgical procedure (Sect. 55.1). Aside from the prevention and risk reduction of nerve damage, IONM serves as guidance for the surgeon. Nervous tissue is not able to compensate its cell death by formation of new nerve cells. Therefore, monitoring methods should reliably observe critical pathophysiological circumstances with potential for irreversible nerve damage (Sect. 55.2). Finally, IONM leads to improved surgical outcome and avoids postoperative function disturbances, maintaining patients' quality of life. Currently, several types of neuro-

monitoring systems are available and IONM is used in almost all surgical centers (Sect. 55.3).

55.1 General Principles

IONM refers to intermittent or continuous observation of functional nerve integrity. Its purpose is to prevent direct (mechanical, thermal) and indirect (blood circulatory disturbances) damage of the central and peripheral nervous system (Fig. 55.1). IONM has evolved to address risks to neural structures in a wide variety of surgeries. The field continues to grow as the benefits of neuromonitoring become apparent and as the techniques and methods used are expanded (Table 55.1).

The underlying principle of IONM for prevention of direct nerve damage is to monitor the neural pathways *crossing* the operative field. The stimulus results in neural excitations which can be recorded with suitable electrodes on innervated organs or muscles (Fig. 55.2).

IONM has several objectives (Table 55.2):

- Localization of functional neural areas or neural pathways, e.g., identification of eloquent brain areas, supporting the choice of the appropriate surgical approach in neurosurgery (intraoperative nerve mapping).
- Avoidance of neurological injury and early detection of impairment to prevent irreversible damage, e.g., monitoring of the recurrent laryngeal nerve in thyroid surgery (primary prevention).
- Intraoperative verification of nerve damage for determination of subsequent surgical steps and early postoperative therapy, e.g., in pelvic surgery a uni-

Table 55.1 Intraoperative neuromonitoring methods and scopes of application

Methods	Application
Manometry	● Pelvic surgery

Table 55.2 Objectives of intraoperative neuromonitoring

- ⇒ Intraoperative nerve mapping provides security for the surgeon
- ⇒ Primary prevention of postoperative dysfunction due to controlled nerve sparing
- ⇒ Secondary prevention of postoperative dysfunction due to early specific therapy

lateral damaged inferior hypogastric plexus might be evaluated to determine urological therapy immediately, to prevent early and long-term urinary dysfunction or impotence (secondary prevention).

55.1.1 Intraoperative Nerve Mapping

Intraoperative nerve mapping is a technique for identification, tracking, and verification of nervous tissue. This anatomic testing enables the creation of a map pro-

viding the localization of eloquent neurological areas, for instance, speech and motor function (brain) or any organ-specific neural pathways. To combine radicality and functional integrity, the surgeon uses the acquired information for the choice of an appropriate approach for tumor excision without damaging eloquent nervous tissue. Even deep neural pathways can be identified by direct electrical stimulation (intraoperative subcortical mapping) with consecutive adaption of the neurosurgical procedure.

55.1.2 Intermittent Intraoperative Neuromonitoring

Intermittent intraoperative neuromonitoring (iIONM) provides electrophysiological nerve testing in certain phases of the operation. The control of nerve function is limited to the periods of neurostimulation. It is performed with a handheld stimulation probe, enabling identification and verification of the functional integrity of different neural pathways. For each iIONM performance, the surgical procedure needs to be interrupted.

55.1.3 Continuous Intraoperative Neuromonitoring

Continuous intraoperative neuromonitoring (cIONM) provides sustained observation of selected neural pathways during the whole critical phase of the procedure

where nervous tissue is at risk for damage. The principle is to stimulate the identified nerve segments and monitor the neural pathways innervating the target organs or muscles. This presupposes great demands in terms of technique, e.g., probe design, electrodes, and methodological setup. cIONM overcomes the limitations of intermittent neuromonitoring, as it observes the *same* neural pathways and closes the gap between surgical preparation with and without monitoring. Surgery only needs to be interrupted for initial application or replacement of suitable stimulation probes in case of further areas of interest. However, there is an ongoing debate regarding the definition of cIONM concerning several aspects, e.g., continuous stimulation, repetitive stimulations in a predefined sequence of the *same* neural pathways, continuous recording, target organ or muscle fatigue, permanent application, and location of the stimulation probe.

55.2 Neuromonitoring Signals

55.2.1 Signal Recording and Processing

For IONM, the used electrodes or pressure sensors are placed in the corresponding optimal areas (e.g., target muscles or organs) to record their signal response. Neurostimulation is carried out with a stimulation probe (e.g., a handheld stimulator for iIONM). If probe fixation is needed for cIONM, a suitable probe holder should meet the following requirements:

1. Prevent probe movement
2. Avoid trauma to nervous and other tissues
3. Permit access to critical regions of the operative field.

The electrodes and the probe are connected to a multichannel box which is part of the neuromonitoring device. Stimulation parameters, e.g., currents, pulse trains, pulse duration, and event thresholds, are set (Table 55.3).

Correct electrode placement is ensured by visual checking, confirmed by impedance measurement. For the interpretation of IONM signals, recordings of signal baselines are necessary. The time from the patient's arrival in theater until exposure of the at-risk nervous tissue allows the assembly of the neuromonitoring setup, initial evaluation of signals, and multiple system checks to ensure accuracy. If signals are of poor

quality, there should be further optimization of the neuromonitoring setup. There are different troubleshooting protocols in use to cover anatomical (e.g., external branching of the nerve) and technical aspects [e.g., proper position of electrodes (main cause of equipment failure), the impedance measurement, signal baselines]. Furthermore, communication regarding anesthetic regimen (e.g., total intravenous anesthesia, anesthesia with inhalational agents) or bolus administration (e.g., muscle relaxant) is important, as certain anesthetics could affect the recorded IONM signals.

Monitoring is performed with comparisons of IONM signals made against the baseline data. When these signals are recorded on the hard drive of the device, it is necessary to print out a record, which has to be filed for future reference.

IONM signals suffer from a poor signal-to-noise ratio. Advanced signal processing is required to separate *noise* from signal for correct intraoperative assessment. The processing enables automatic analysis and extraction of the relevant signal from the raw signal. Thus, the recorded IONM signals could be visually observed during the operation on the monitor of the device, facilitating online verification of functional nerve integrity. The use of specific amplifiers and additional filter settings (e.g., frequency filters) enhances the quality of signals, for instance, in pelvic surgery for improvement of the reliability of IONM signals (Fig. 55.3).

Table 55.3 Scopes of application and stimulation parameters (examples)

Scopes	Method	Stimulation site	Recording site	Parameters (frequency, pulse duration, intensity)
Thyroid surgery	iIONM: triggered EMG	Vagal nerve, recurrent laryngeal nerve	Vocal muscle	4 Hz, 100 μ s, 1–2 mA (vagal nerve)/ 0.8–1 mA (recurrent laryngeal nerve)
	cIONM: triggered EMG	Vagal nerve	Vocal muscle	3–4 Hz, 100–200 μ s, 0.1–5 mA
Pelvic surgery	Triggered EMG	Inferior hypogastric plexus, pelvic splanchnic nerves	Internal anal sphincter	30 Hz, 200 μ s, up to 150 mA
	Intravesical pressure	Inferior hypogastric plexus, pelvic splanchnic nerves	Urinary bladder	30 Hz, 200 μ s, up to 15 mA
Spine surgery	SSEP	Lower limb: tibial posterior nerve, sciatic nerve, peroneal nerve Upper limb: median nerve, ulnar nerve	Somatosensory cortex (C1, C2, Cz, C3, C4), midline scalp (Cz'-Fz), contralateral scalp (C3'-Fz, C4'-Fz)	2.35–5.1 Hz, 200–300 μ s, 15–40 mA
	Dermatome SSEP	Dermatome field stimula- tion	Scalp electrodes	
	MEP	Motor cortex (C3/C4), alter- native C1/C2 (lower limb)	Lower limb: tibialis ante- rior, medial gastrocnemius, and extensor hallucis longus muscles, abductor hallucis Upper limb: abductor digiti minimi and abductor pollicis brevis, thenar	Interstimulus interval 1–5 ms/50–200 Hz, pulse duration 50 μ s to 2–5 s, stimulation intensity 75–500 V/25–30 mA
	DNEP			
	PERC	Consecutive cervical lamina	Sciatic nerve (popliteal fossa)	4.7–5.1 Hz, 500–700 μ s, 100–400 V
	EPI-DNEP	Spinal catheter, epidural	Sciatic nerve (popliteal fossa)	4.7–5.1 Hz, 500–700 μ s, 2–40 mA
	SP-DNEP	Spinous process (of consec- utive spinal levels within the proximal portion of the surgical incision)	Sciatic nerve (popliteal fossa)	4.7–5.1 Hz, 500–700 μ s, 100–400 V
EMG	Spontaneous EMG		Muscles innervated by corresponding nerve roots	
	Triggered EMG	Top of the pedicle screw	Appropriate muscle groups	\leq 20 mA
Skull base surgery	Triggered EMG	Nerve trunks	Corresponding muscles and muscle groups	4–4.7 Hz, 50–100 μ s, up to 1 mA

55.2.2 Signal Analysis

The interpretation of IONM signals and any recommendations regarding the consequences or intervention are the responsibility of a qualified physician (e.g., surgeon) or a clinical neurophysiologist. Intraoperatively, the observer has to differentiate true neuromonitoring signal events from artifacts, for instance, such as electric stimulation, interfering electrosurgical units or contact between surgical instruments in the operative field. The recorded IONM signals are interpreted with regard to their baseline data and must be seen in relation to the specific pre- and postoperative diagnostic nerve tests. Numerous factors influence the quality of

the recorded signals, such as use of stimulation probes and electrodes, localization, impedance of tissue, contact surface of the stimulation probe to the nerve, and stimulation parameters. In addition, mechanical and thermal phenomena, anesthetic agents, and other systematic variables may affect the IONM signal quality throughout the operation or even result in signal loss. Occurrence of any false neuromonitoring signals should be excluded, as this could be misleading and may give the surgeon a false sense of security during the procedure with a probably higher risk for nerve damage than without IONM. The absence of neuromonitoring signals during electric stimulation does not exclude the possibility that stimulation of tissue other than nervous

Fig. 55.3a–c Signal processing of internal anal sphincter activity for monitoring of pelvic autonomic nerves: **(a)** time-based electromyographic signal of the internal anal sphincter before and during bipolar electric stimulation as originally recorded, **(b)** original signal after high-pass filtering (cutoff frequency 5 Hz), and **(c)** signal after additional low-pass filtering (cutoff frequency 20 Hz); blue curve represents the mean absolute value of the amplitudes computed over windows with 5024 sample points

tissue was performed. The surgeon has to distinguish between signal loss by nerve damage and signal loss due to incorrect placement of the stimulation probe or newly occurred probe or electrode dislocation.

Standardization of IONM procedures is useful as it may help to eliminate these pitfalls, elucidate the mechanisms of neurological injuries, and reduce the rates of postoperative nerve-related dysfunctions.

55.3 Scope of Application

55.3.1 Thyroid Surgery

Recurrent laryngeal nerve (RLN) palsy is the most common and serious complication in thyroid and parathyroid surgery (Table 55.4). Since routine identification of RLN is an established technique, permanent palsy rates are reduced to less than 2% for first-time

operations. In reoperative settings (Table 55.5) or in operations for malignant disease palsy rates are higher, ranging from 2% to 20%. Bilateral RLN palsy after total thyroidectomy is a life-threatening event. It has to be taken into account that injury of the RLN is the most common reason for legal complaints in this field.

Table 55.4 Nerve-related postoperative dysfunctions

Scope of application	Nerves/structures	Postoperative dysfunctions
Thyroid surgery	Branches of vagal nerve Recurrent laryngeal nerve Laryngeal superior nerve	Dysphonia Dyspnea Dysphagia Voice alterations
Skull base, posterior fossa, and brainstem surgery	Spinal cord	Hypesthesia Hemiparesis Paraplegia Quadriplegia Coma
Skull base, posterior fossa and brainstem, and head and neck surgery	Cranial nerves CN I-XII Olfactory nerve CN I Optic nerve CN II Eye movement nerves CN III, IV,VI Trigeminal nerve CN V Facial nerve CN VII Acoustic nerve CN VIII Glossopharyngeal nerve CN IX Vagal nerve CN X Spinal accessory nerve CN XI Hypoglossal nerve CN XII	Reduced or absent smell sensation Visual loss Syndrome of superior orbital fissure Eyelid ptosis Eyeball fixation Exophthalmus Pupil dilation Low vision limitation Diplopia Trigeminal neuralgia Sensory disturbances in the face Jaw muscle paresis Activation of trigeminocardiac reflex → (transient) asystole Paralysis of the mimetic musculature Hearing reduction or loss Sensory disturbances of the palate Taste quality bitter will not be perceived Loss of gag reflex Uvular deviation Aphonia Dysphagia Shoulder drop Tongue atrophy
Spine surgery	Brachial plexus Lumbosacral plexus Spinal cord Conus medullaris Cauda equina	Paralysis of shoulder and arm muscles Pain Atrophia Paralysis of lower limb muscles Inguinal pain Lower limb sensory disturbances Hypesthesia Hemiparesis Paraplegia Quadriplegia Coma Conus syndrome Cauda syndrome
Pelvic surgery	Pelvic autonomic nerves (superior hypogastric plexus, hypogastric nerve, inferior hypogastric plexus, splanchnic nerves, neurovascular bundles)	Sexual dysfunction Bladder dysfunction Anorectal dysfunction

Mechanisms of RLN injury are compression, stretching, constriction, ligation, clipping or transection. Nerve paralysis also occurs after thermal alteration.

For more than 10 years several studies have demonstrated the benefits of IONM in thyroid surgery. IONM has been used to localize and identify the RLN, but also

Table 55.5 Rates of temporary and permanent recurrent laryngeal nerve palsy after surgery and redo surgery for benign multinodular goiter

	Moalem 2008	Thomusch 2003
Temporary palsy	1–10% TT	1.7% sT+sT
	0.9–6% sT	2.0% sT+HT
	0–22% RDS	4.5% TT
Permanent palsy	0–1.4% sT	0.8% sT+sT
	0–1.4% TT	1.4% sT+HT
	0–13% RDS	2.3% TT

sT+sT: bilateral subtotal resection, sT+HT: subtotal resection with contralateral lobectomy, TT: total thyroidectomy, RDS: redo surgery

to predict cord function and analyze the mechanism of RLN injury.

For intermittent IONM a handheld stimulation probe (generally bipolar) is used for localization and functional testing of the RLN and vagal nerve (Figs. 55.4 and 55.5). To sense posterior cricoarytenoid muscle contraction in response to ipsilateral nerve stimulation, an EMG is recorded from endotracheal surface electrodes (tubus electrodes) or from transligamentarily inserted needle electrodes.

A high negative predictive value of more than 97% means that patients with an intact IONM signal after thyroid resection generally have normal vocal cord function. Therefore, this method is superior to macroscopic assessment of RLN alone for prediction of postoperative vocal cord function.

Conversely, studies found a lower and highly variable positive predictive value of 10–90% for IONM signals. This might result in misleading information limiting the value of IONM technology.

Pitfalls associated with IONM during thyroid surgery have been reported: equipment malfunction, improper setup, misuse of anesthetic drugs, and anatomic variations of RLN. This highlights the importance of a standardized approach.

It has to be taken into account that a significant reduction of postoperative RLN palsy due to IONM is described only for redo operations.

The IONM technique needs a learning curve. However, experts in this field have hypothesized that surgical trainees and less experienced surgeons benefit from IONM as a helpful teaching aid, whereas the experienced surgeon may benefit in difficult cases.

In all operations with IONM a pre- and postoperative laryngeal examination (flexible laryngofibroscope to document vocal cord mobility) is mandatory. Trou-

bleshooting requires systematic checking of IONM equipment and neuroanatomy (Sect. 55.2.1).

During the operation a systematic stepwise IONM procedure is necessary to evaluate signals from the vagal nerve and RLN and to eliminate false IONM results. Important steps are:

1. Vagal nerve stimulation before thyroid dissection
2. RLN stimulation at initial identification
3. RLN stimulation at the end of thyroid dissection, and
4. Vagal nerve stimulation after complete thyroidectomy and hemostasis.

Loss of IONM signal is an important intraoperative decision criterion for the surgeon, especially when bilateral lobectomy should be performed. An amplitude response of less than 100 μ V or total loss of the primary normal biphasic stimulation waveform obtained during or after resection of the first thyroid lobe supports the indication of a two-stage operation to prevent bilateral RLN palsy (Fig. 55.6a,b).

Currently, surgeons are applying continuous IONM devices to overcome the limitations of unrecognized RLN palsy with intermittent IONM. Several vagal nerve electrodes (anchor, cuff, and adhesive tube electrodes) are being tested for real-time monitoring of RLN. Recent pilot studies have demonstrated the feasibility of cIONM for observation of RLN.

55.3.2 Neurosurgery

The potential postoperative dysfunctions after neurosurgical interventions are listed in Table 55.4. In the following, three major areas of neurosurgery are described.

Monitoring methods for removal of spinal cord and intradural tumors are comparable to those in spine deformity surgery such as SSEPs, MEPs, and EMG (see also Sect. 55.3.3).

In cranial surgery, neuromonitoring is used for translabyrinthine and middle fossa acoustic neurectomy and various procedures of the skull base and neck, e.g., resection of tumors of the lower cranial base, repair of aneurysms of the posterior circulation, and removal of brainstem tumors. Intraoperative mapping is performed to detect and preserve cranial nerves. The monitoring includes electric stimulation of nerve trunks and recording of different kinds of evoked potentials such as AEPs and visually evoked potentials for sensory cranial nerve monitoring and EMG methods for cIONM of

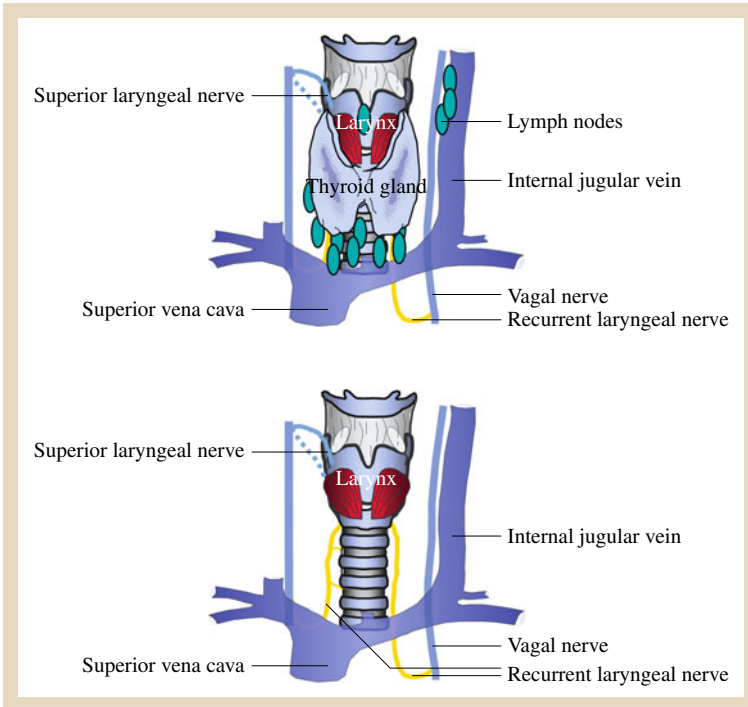

Fig. 55.4 Neuroanatomy and topography of larynx and thyroid gland

Fig. 55.5 Intraoperative neuromonitoring for identification of left recurrent laryngeal nerve (RLN) during thyroidectomy

motor cranial nerves (V, VII, IX, X, XI, XII). For signal recording, electrodes are placed in different muscles or muscle groups corresponding to the innervation pattern of the relevant cranial nerve. The orbicularis oculi and orbicularis oris muscles are suitable for facial nerve monitoring and can be observed by mechanomyogram and/or electromyogram.

Some studies have indicated increasing sensitivity and specificity with the use of transdermal intramuscu-

lar electrodes. The cochlearis nerve could be monitored by AEP, electrocochleography, and electrically evoked compound action potential. Another aspect of monitoring in skull base and brain surgery is cortical mapping. Central sulcus can be monitored by SSEP phase reversal and precentral gyrus by motor cortical stimulation.

During interventions in speech-related areas, cortical stimulation is used for speech testing throughout

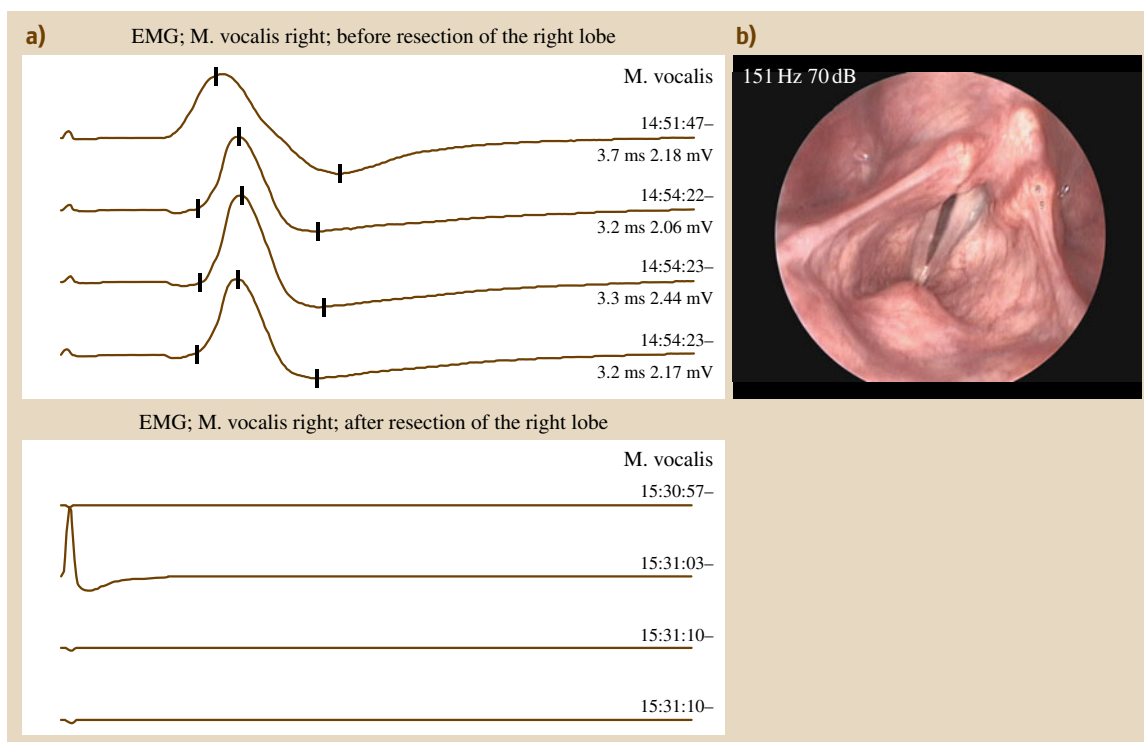

Fig. 55.6 (a) Intended thyroidectomy for benign multinodular goiter. Negative IONM result after resection of the right thyroid lobe. The surgeon decided on a two-stage operation in order not to risk bilateral vocal cord paralysis. **(b)** Post-operative laryngofibroscopy demonstrates incomplete closure of glottis. Temporary right vocal cord paralysis vanished after logopedics

the operation. If these areas are intact, the stimulation slows down speech function until speech arrest in awake patients. Visual evoked potentials are also more meaningful if raised in awake patients.

In peripheral nerve surgery, extracranial parts of motor cranial nerves could be observed, similar to intracranial parts. Important nerves are the facial nerve and vagal branches in parotis and thyroid surgery (see also Sects. 55.3.1 and 55.3.4). The monitoring is performed under electroneurography, electromyography, SSEPs, and MEPs and should ensure the control of peripheral nerve, nerve root, and plexus function. IONM aims at:

1. Identifying peripheral nerves
2. Localizing preexisting disease processes along the course of a nerve
3. Determining functional continuity across a preexisting lesion, prior to detection by other electrophysiological means

4. Determining nerve root avulsion
5. Identifying targets for nerve biopsy, and
6. Monitoring and thereby preventing damage to intact nerves during surgery.

55.3.3 Orthopedic Surgery

Perioperative neurological injury, in particular spinal cord injury, is one of the most feared complications in spinal surgery. IONM in this operative field is frequently selected for scoliosis, deformity correction, degenerative cases, instrumentation in the cervical and thoracic spine, spinal stenosis, and discectomy. There are several structures placed at risk for potential injury, including the spinal cord, nerve roots, lumbar plexus, and all relevant vascular supply to these elements. Damage to these structures could result in motor and sensory dysfunctions (Table 55.4).

Several electrophysiological modalities are currently available for monitoring various aspects of the

Fig. 55.7 Intraoperative neuromonitoring methods for spine surgery

central and peripheral nervous system, each offering a unique set of benefits, limitations, and sensitivity/specificity as diagnostic techniques. The monitoring methods in spine surgery are somatosensory evoked potentials (SSEPs), motor evoked potentials (MEPs), descending neurogenic evoked potentials (DNEPs), spontaneous and triggered electromyography (sEMG and tEMG) (Fig. 55.7). Multimodal IONM provides higher specificity and sensitivity for detecting nerve damage than any modality used in isolation.

SSEPs provide cIONM of the large fiber sensory tracts (dorsal column), which mediates tactile discrimination, vibration sensation, form recognition, and joint/muscle sensation. It does not involve the spinothalamic (pain and temperature) pathway. Upper limb SSEPs are obtained by stimulation of the median and ulnar nerve. Lower limb SSEPs are elicited by posterior tibial, peroneal, and sciatic nerve stimulation. The electrodes for signal recording are placed on the somatosensory cortex. Dermatome SSEPs are used to verify nerve root function. Data are obtained by dermatome field stimulation and recorded from the electrodes for standard SSEPs.

The MEPs monitor function of the motor tracts (corticospinal tract) which are not covered by the SSEP. They can be obtained by transcranial stimulation (electrically or magnetically) or via direct cortical stimulation. Signal recording is performed at the level of the spinal cord, nerves (e.g., spinal nerve) or muscles (e.g., tibialis anterior muscle), if stimulated transcranially or only at the level of the nerves or muscles, if cortical stimulation is carried out. MEPs have become the gold standard for IONM of the motor tracts. Recent studies have demonstrated that MEP monitoring can be performed intermittently and continuously.

DNEPs are used in all surgeries involving the thoracic spine. Different stimulation methods have been described:

1. Percutaneous stimulation via needle electrodes placed onto consecutive cervical lamina
2. Epidural stimulation with a flexible spinal catheter
3. Spinous process stimulation via needle electrodes placed in the spinous process of consecutive spinal levels within the proximal portion of the surgical incision. Data were recorded bilaterally from the sciatic nerve at the level of the popliteal fossa. Full muscle relaxant is required to prevent stimulation-induced movement and to reduce muscle artifacts.

Spontaneous EMG is primarily used to monitor nerve root function. However, it can also demonstrate subtle signs of spinal cord damage. Evoked EMG is most often used to determine if breach of the spinal pedicle wall has occurred by stimulating the pedicle screw directly or by stimulating the canal made for the screw.

Recently, it has been described that IONM could be used for identification and verification of axillary nerve function during arthroscopic shoulder stabilization.

IONM has become an important component of many types of surgery. However, a valid criticism is that scientific justification for its use does not include any blinded, placebo-controlled studies. Unfortunately, such studies can no longer be ethically performed.

55.3.4 Otolaryngology and Head and Neck Surgery

A major focus of IONM in otolaryngeal and head and neck surgery is monitoring of the facial nerve during operation for acoustic neuroma and parotidectomy. Facial nerve damage can cause cosmetic and functional morbidity diminishing patients' quality of life and resulting in medical malpractice litigation. Up to 20–70% of patients suffer from more or less pronounced postoperative facial nerve functional deficits.

Fig. 55.8 Overview of neuroanatomy and topography of the inferior hypogastric plexus illustrated by drawing (left) and cadaver dissection (right)

In general, the IONM is performed intermittently. Nevertheless, recent studies have demonstrated the feasibility of continuous monitoring of the facial nerve.

There are several methods for monitoring. One possibility is to visually observe facial movements during the surgical procedure. The assistant gives feedback to the surgeon if facial movements are evoked, for instance, electrically by neurostimulation or mechanically during dissection. Another approach is EMG of facial muscle activity. Electrodes are placed on optimal positions for recording, typically in the frontal, zygomatic, buccal, and marginal mandibular areas. Neurostimulation is carried out with a conventional stimulation probe. Both a graphic signal observed on an oscilloscope screen and an acoustic signal are generated. In general, electrophysiologic monitoring is preferred, as it is more sensitive and specific than visual observation. It enables quantification of the recorded EMG activity.

Studies have demonstrated that functional outcome could be improved by use of IONM, although the difference was not always significant. Most patients with postoperative facial palsy demonstrate good functional recovery within 1 year. However, certain patients do not show this recovery and require nerve reconstruction. Early reconstruction demonstrates better functional results than if surgery is delayed. Neuromonitoring provides intraoperative assessment of functional nerve integrity with the possibility of reconstruction in the same operation.

55.3.5 Pelvic Surgery

Autonomic nerve injury during rectal resection or other types of pelvic surgery may significantly deteriorate functional outcome and patients' quality of life. Aside from sexual and bladder disturbances, nerve damage may also affect anal sphincter function.

The efferences of the inferior hypogastric plexus contain three up to five secondary plexus innervating the pelvic organs (Fig. 55.8). Therefore, mainly damage to the different plexus segments is responsible for the different combinations of function disturbances. Despite potentially nerve-sparing operations, varying degrees of urogenital dysfunction are found in up to 32–70%, and anorectal dysfunction occurs in up to 47% of rectal cancer patients. The costs of diagnostics and treatment for short- and long-term postoperative urogenital dysfunction and incontinence are immense.

IONM of pelvic autonomic nerves could quantify and reduce the risk of such detrimental injuries. Intermittent bipolar electric stimulation of the pelvic autonomic nerves with observation of bladder motor response or penile tumescence are thus by far the most frequently used techniques for nerve identification and functional testing (Table 55.1).

IONM with assessment of penile tumescence predicts postoperative erectile dysfunction with high specificity. The low sensitivity rate of approximately 50% may be explained by preoperative impotence, influence of anesthetic procedure, and non-stimulation-related tumescence response. In particular, combined with in-

Fig. 55.9 Neuromonitoring setup for pelvic surgery

IONM in a male patient during mesorectal excision for rectal cancer [electric stimulation of pelvic splanchnic nerves (PSN)] (c)

tracavernous and intraurethral pressure observation, the method is nevertheless recommended for assessment of cavernous nerve preservation after prostatectomy and rectal resection in male patients.

In rectal cancer surgery, it has been demonstrated that the confirmation of incomplete pelvic autonomic nerve preservation is more accurate using IONM compared with macroscopic assessment by the surgeon

(sensitivity 82% versus 46%). This finding is corroborated by gynecologists, who applied IONM with observation of intravesical pressure after radical hysterectomy and obtained similar diagnostic accuracy (88%).

Recently, it has been shown in experimental studies that intraoperative verification of internal anal sphincter function by stimulation of pelvic autonomic nerves is feasible.

Moreover, it has been demonstrated in a clinical setting that the internal anal sphincter EMG response in combination with bladder manometry can be used for intraoperative mapping and monitoring of pelvic autonomic nerves (Figs. 55.9–55.11). This offers the possibility for more selective and continuous IONM with the potential for improvement of surgical technique and functional results.

Fig. 55.11 Documentation of intraoperative neuromonitoring results

55.4 Quality Management

Nerve-sparing surgery for prevention of postoperative dysfunction caused by injury to nervous tissue in the operative field is a major goal and widely established as *standard*.

However, classification or categorization of the quality of *nerve sparing* on the basis of intraoperative macroscopic assessment, functional outcome, and postoperative diagnostic testing is problematic. For this reason, nerve sparing is not generally established as a benchmark criterion.

Based on strong evidence that IONM is sensitive and specific for detecting neurologic injury during surgical procedures, it is recommended that use of such a method should be considered in operations with high risk of injury to the nervous system, especially if there are effective intervention options. In cases of detected nerve damage, there will be an undoubted benefit from IONM.

The results of intermittent IONM at the end of a surgical procedure (based upon changes from patients'

own earlier baseline IONM signals) could be used as a reference for evaluating surgical quality. Benchmarks for *controlled* nerve sparing may be drawn from the departments' own experience, from the experience of others working in the same clinical subspecialty or from professional societies and certification organizations.

The objectives of IONM are:

1. To determine what and where improvements of nerve sparing are required
2. How other surgeons/departments achieve their high rates of nerve-sparing surgical procedures, and
3. Receiving reliable information to improve the department's operative standard.

To use IONM results as a surrogate parameter for quality assessment of the surgical procedure, evidence-based protocols are needed. More prospective studies dealing with changes, cutoff values (thresholds, alarm criteria), and reference intervals of IONM signals should be performed to validate the IONM methods.

55.5 Guidelines and Legal Aspects

Professional and technical levels should be defined and could be administered by certification.

On the basis of current clinical literature and scientific evidence, IONM should be examined and evaluated

by consensus conferences and position statements promoted by scientific surgical associations.

However, at this point there are only a small number of recognized professional organizations providing

guidelines or certification specifically for the unique skills involved in IONM. Thus, guideline committees are encouraged to develop practice guidelines for IONM in the various surgical settings. The primary goals are to

1. delineate the objectives of IONM,
2. characterize the responsibilities and behaviors of the surgical team during IONM, and
3. describe methodological and ethical issues uniquely relevant to IONM.

Performance of IONM presupposes that patients have to be informed of the intent to use a neuromonitoring system with its potential to aid in localization and identification of nervous tissue and assessment of nerve function during the operation.

Interestingly, surgeons who employ IONM in their practice have been found to be less likely to have a history of a surgery-associated lawsuit. For expert assessment purposes, documentation of standardized IONM application is of utmost importance (for instance, EMG printouts of pre- and postprocedural IONM results).

Ionic Neural

56. Ionic Neural Sensing

Iasonas F. Triantis, Anna Radomska-Botelho Moniz, Kostis Michelakis, Sanjiv Sharma, Jakub Trzebinski, Belinda Garner, Amir Eftekhar

Neural disorders or malfunction can result to medical conditions such as epilepsy, Alzheimer's, chronic pain, spinal cord injury and many others, affecting the quality of life for millions of patients worldwide. Neural damage is often irreparable and when such conditions occur it is often very difficult to assess exactly the way in which neural operation is affected. Such disorders are characterised by interrelated chemical and electrical changes in the brain. At present, it is possible to monitor neural activity through the detection of electrical activity. The instrumentation required for this detection ranges from large clinical recording equipment to implantable devices. Nerve electrodes can be penetrating (needle) or non-penetrating (cuff) and depending on their shape and position they often act as spatial filters to the electrical signals they pick up due to the ionic currents involved in neural conduction. Electrical neural recordings are often severely distorted by interference from other bio-signals and vital information is lost. Moreover, trade-offs between noise and electrode dimensions impact on multi-electrode schemes. Neural amplifiers require large input dynamic range to accommodate for interference, whilst maintaining linearity, high gain and low power consumption. Although these neural recording platforms have contributed valuable insights into neuro-genic disorders and neuro-pathological studies, they mostly remain within the boundaries of research environments. Even in such environments, neural monitoring technology, as of yet, has not addressed the ionic

aspect of the neural signal, thus missing out on vital neurological information. This is almost entirely due to the conventional apparatus for ion sensing in chemical laboratories being cumbersome and inappropriate for bio-signal recording. This chapter covers some of the main nerve electrode configurations used for neural monitoring, followed by an assessment of the possible merits of monitoring the ionic aspect of neural activity. Some of the latest techniques for developing and testing ionic sensors for such an application are overviewed.

Devices for monitoring neural activity have a range of applications including diagnostics, neurophysiology and neuropathology studies, drug monitoring, and rehabilitation – through the use of the obtained signal as feedback to neurostimulation. Today, there is a mas-

sive surge in neural interfacing research, mainly due to recent advances in microelectronic and electrode technology. Various platforms are being developed for neural recording, both for the central and the peripheral nervous systems (CNS and PNS, respectively). Re-

search in the area requires a combination of expertise on microelectronics, microfabrication, biology, medicine, and often chemistry, forming a trend for interdisciplinary research. This chapter offers a brief overview of the merits of some of the most widely used neural monitoring technologies in the brain and at the periph-

ery, identifying the need for alternative approaches and it examines the merits of ionic sensing as a possible method for obtaining alternative manifestations of neuronal activity. Existing chemical sensing technologies are then assessed in light of the requirements of such an application.

56.1 Central and Peripheral Nervous System Monitoring

56.1.1 Monitoring the Brain Function

Single neurons or groups of neurons firing together in the brain generate chemical and electrical signals, of which the latter have been studied extensively through electrical measurements. Although it is possible to monitor single neuron signals by penetrating the cell membrane (intracellular monitoring through patch-clamping) [56.3], such techniques damage the cell and are only applied in basic neuroscience research that focuses on the underlying mechanisms of ion channels (Fig. 56.1a). Methods for monitoring naturally occurring or stimulation induced neural activity for clinical applications usually include measurements in the extra-neural medium, through electrodes that do not penetrate the neural membrane. Because neural conduction involves the extracellular medium, it is possible to make such measurements to detect both localized and more *global* variations in neuronal activity [56.4, 5]. Such methods are extensively used in medical diag-

nostics especially for the detection of epileptic activity prior to and during seizures. Neural recordings can be conducted *in vivo* on living tissue and *in vitro* on excised, appropriately prepared and maintained brain tissue [56.3]. *In vivo* extracellular potential recording involves monitoring potentials that relate to trains of pulses of collective activity of groups of neurons. Such techniques date back to the beginning of the 20th century. To assess large scale potential fluctuations, electro-encephalography (EEG) is used in clinical diagnostics, to record brain activity using electrodes placed across the scalp [56.6] (Fig. 56.1b). The technique has relatively low spatial sensitivity due to the tissue and bone layers located between the electrodes and the brain. In order to overcome this limitation, electrodes can be placed intracranially to gain a higher quality signal and a better definition of the location of its source. The so called electrocorticogram (ECoG) is equivalent to the EEG but with direct electrode contact on the brain surface [56.7].

Fig. 56.1 (a) Simultaneous patch clamping of multiple pyramidal neurons in a cortical brain slice (after [56.1]). (b) Typical EEG setup and seizure-related recordings (after [56.2])

Microelectrodes for Cortical Interfacing

Conventional cortical monitoring is carried out with the use of electrode arrays placed on the brain surface (epicortical electrodes, Fig. 56.2a). Recent advances in microfabrication technology have allowed the development of implantable biomedical microsystems that include thin and flexible substrates with monolithically integrated electrode arrays and circuitry, forming hybrid electronic assemblies. Bare integrated circuits (ICs) can be placed on flexible structures, which present a significant advantage in terms of biocompatibility compared to rigid structures, as they reduce scar tissue development [56.8]. To protect implantable electrodes from the influence of the biological environment, and to generate an appropriate tissue response at the implantation site, encapsulation processes can be used with materials such as parylene and silicone.

To extract more localized neural activity than that monitored through epicortical interfaces, needle microelectrodes (Fig. 56.2b) can be used to penetrate layers of the brain (but without penetrating actual neural cells) [56.2]. These provide high resolution *intracortical field potential* and access to deeper brain structures such as the hippocampus. Contrary to the flexible substrates used for epicortical interfaces, intracortical (or intracerebral) electrodes are penetrating probes usually consisting of post-processed silicon wafers with platinum-coated metal pads in vector array arrangements. Different electrode geometries built to detect bioelectric signals include three dimensional arrays [56.9], two dimensional laminar electrodes [56.10], and subcortical silicon probes [56.2]. The probes must be robust enough to penetrate both the dura and the pia mater and at the same time they must be as small as possible to minimize brain tissue damage.

In both *epicortical* and *intracortical* methods, pairs of electrodes pick up potential differences across the extracellular fluid due to the nerve-generated ionic currents flowing through it, much like measuring the potential at various points along the length of an electrical resistor while current flows through it. The materials and physical dimensions of the electrodes are extremely important for the quality of the signal because of the capacitance formed at the electrode–tissue interface. The differential signals between electrode pairs, or between each electrode and a common one acting as the physiological ground, are amplified by specifically designed neural amplifiers, described later in this section [56.11, 12].

Fig. 56.2 (a) Polyimide microelectrodes by the IBMT group at Fraunhofer Institute used for epicortical interfacing in mice (after [56.6]). (b) Intracortical probes by NeuroNexus (after [56.2])

The Need for Different Brain Monitoring Modalities

Despite the immense technological progress in the field of brain function monitoring, the EEG/ECoG methods have limitations in the insight they can offer [56.13, 14]. The main limitations of the cortical interfaces are:

- A lack of adequate localization in the presence of activity from distant brain structures when epicortical interfaces are used
- Tissue damage and high risk when intracortical electrodes are used
- Dislocation of electrodes during brain inflammation
- Severe issues with wire fragility when electronics are not embedded on the actual electrode.

In epilepsy, the so-called seizure precursor detection problem currently remains unsolved [56.13, 14]. The development of alternative monitoring methods, such as functional magnetic resonance imaging (fMRI), as well as their widespread appeal in medical diagnostics [56.15], makes a very strong case for the necessity of research into other modalities of brain activity. This will be revisited later in this chapter.

56.1.2 Peripheral Nerve Monitoring Methods

Although *action potentials* across the neural membrane are of mV order, the potentials monitored outside the nerve are a result of the ionic currents propagating along the nerves (Fig. 56.3a) scaled by the impedance of extracellular fluid. In the PNS nerve fibers located proximally to the brain or the spinal cord are bundled into groups called fascicles, that later branch out to individual organs or muscle groups. Fascicles are also grouped together initially, forming nerves. Nerves can be penetrated by needle electrodes for assessing the activity

Fig. 56.3a,b Neuron conduction. (a) *Top*: unmyelinated fiber; *bottom*: myelinated fiber. (b) A tripolar cuff electrode placed around a nerve (after [56.12])

of individual fascicles without the need to access these groups of fibers close to the particular organ they innervate. In that way surgery is minimized to a single access location that has the possibility to provide information for sensory or motor activity relating to peripheral structures located distally. However, using such needles (or *intrafascicular*) electrodes damages neural tissue and is inappropriate for chronic implantation. Implanted cuff electrodes (Fig. 56.3b) are appropriate for chronic recording of naturally occurring neural activity (electroneurogram or ENG) because they are non-invasive to the nerve and assist in reducing interference from sources outside the cuff, such as the electromyogram (EMG) generated from muscles nearby. The amplitude of the signals recorded by such electrodes placed externally to the nerves is in the order of a few microvolts [56.12, 16–19].

Characteristics and Issues of Cuff Electrodes

The conventional cuff is an insulating flexible tube typically made of silicone rubber or polyimide, with metallic (usually platinum) ring electrodes attached to its inside walls, encircling the peripheral nerve of interest [56.12, 20]. Cuffs have been extensively used in neural signal monitoring research, due to their mechanical stability and non-invasiveness to the nerve tissue [56.21]. They have demonstrated the vast potential of well performing systems for diagnostics and even more for rehabilitation, in cases of e.g. epilepsy and

spinal cord injury [56.22, 23]. Ideally, the ability of the cuff electrode (or *cuff*) to linearize the internal potential field generated by external sources allows interference to be eliminated. This is more effective when *tripolar* cuffs are used (i. e., cuffs with three equally spaced ring electrodes), in combination with appropriate amplifier configurations.

In the PNS, after decades of research, cuffs – and even more so all other electrodes – have not yet become part of mainstream healthcare practice due to their inherent limitations. The main limitations of the conventional cuffs are:

- Low ENG signal amplitude (microvolts), in the presence of up to three orders-of-magnitude greater interference from myoelectric activity of nearby muscles
- Electrical noise, which introduces constraints in both electrode and amplifier designs
- Constraints on cuff and electrode dimensions
- Poor *selectivity*, in terms of which fascicle is active inside a nerve bundle and what the direction of the signal is (sensory or motor).

Myoelectric interference rejection has been mainly addressed by the use of three-electrode cuffs in combination with appropriate amplifier schemes such as *quasi-tripole* (QT) and *true-tripole* (TT) (Fig. 56.4) [56.12]. However, their EMG cancellation effectiveness is highly

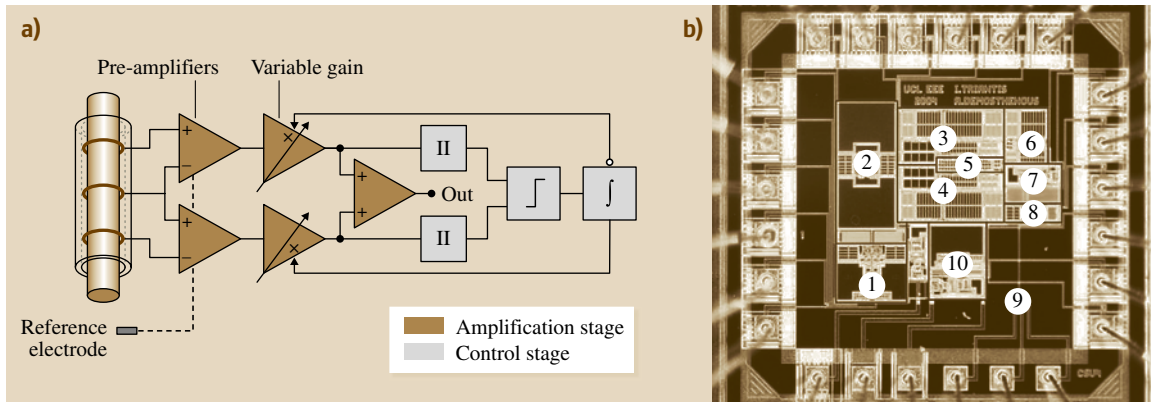

Fig. 56.4 (a) The adaptive tripole (AT) neural amplifier concept (after [56.12]). (b) AT chip microphotograph with main subcircuits numbered: (1) preamplifiers (2) band pass filters (3, 4) variable gain operational transconductance amplifiers (OTAs), (5) biasing circuitry, (6) full-wave rectifiers, (7) AT output stage, (8) feedback OTA, (9) comparator, (10) integrated integrator (after [56.12])

degraded by cuff systematic errors. These errors were given the term *cuff imbalance* by Triantis et al. [56.12], who developed the auto-adjustable *adaptive tripole* (AT) IC amplifier that minimized the effect of imbalance, significantly improving the quality of ENG recordings [56.12]. In the context of the same work, it was shown that there is still a need for greater immunity to myoelectric interference, as cuff imbalance also depends on the distance and orientation of the cuff relative to active muscles [56.17]. Thus, when different muscle groups become active, or in the presence of nearby stimulation causing an interfering stimulus artifact, the AT has to continuously adjust its EMG cancelation scheme.

The Need for Different Peripheral Monitoring Modalities

Even if EMG interference and noise factors are overcome, the quality of recordings strongly depends on the cuff having specific dimensions, sometimes making it too long for certain important implantation locations, for example, inside the dura close to the spine. Moreover, cuff electrodes are usually implanted in close proximity to the central nervous system, around large nerves. Therefore, employing ring electrodes does not offer any possibility of identifying which of these organs are active each time a signal is recorded. Various solutions have addressed this issue of *fascicle selectivity* by replacing ring electrodes with segmented multi-electrode rings. Although these approaches have indicated some degree of selectivity, they suffer from the aforementioned limitations: the small area of the electrode segments translates into higher

electrode noise relative to full ring electrodes; and amplifier configurations used in such schemes exhibit poor electromyogram (EMG) cancelation. Finally, the unavoidable increase in cuff lengths and in the number of wires connecting the cuff with the implant greatly reduces the robustness of the systems and limits the possible implantation sites.

56.1.3 Neural Amplifier Specifications

The signals provided by the electrode contacts are amplified by custom designed neural amplifiers [56.16, 24, 25] featuring high gain to raise the signal to the appropriate range for A-D conversion. Generally, the term *neural amplifier* is used to describe devices designed to amplify neural signals, irrespective of whether these are applied to the PNS or the CNS. However, the neural signal amplitude and frequency ranges are not the same in both cases, with stimulation-induced signals also exhibiting different characteristics. Thus, a device designed for a specific type of neural signals cannot be used at a different neuroprosthetic platform, even though many of the neural amplifier characteristics are similar. Neural amplifiers mainly have to deal with three typical types of neural signals:

1. Brain cortical EEG, requiring an amplifier gain range from 50 to 100 and bandwidth from 300 to 500 Hz
2. Peripheral neural signals during stimulation which require a gain range of 500 to 1000 and bandwidth of around 3 kHz

- Natural peripheral neural activity (ENG) requiring gains in the order of and bandwidth from 800 to 10 kHz.

The front-end noise of the amplifiers must be very low and care must be taken to choose the optimal technology [56.26]. Amplification is typically implemented in two stages, the first one providing low-noise pre-amplification to remove the necessity for low-noise design for the subsequent stage [56.24]. Low power

integrated circuit design is desirable for a recording system that is to be integrated into an implant [56.11, 12, 27]. As implanted devices cannot be grounded the amplifiers have to be connected to a reference electrode somewhere inside the body, usually in the vicinity of the monitoring interface. Design constraints include the need for large input dynamic range to accommodate for microvolt to millivolt signals, whilst maintaining linearity, high gain, high common-mode rejection, and low power consumption [56.12].

56.2 Chemistry of Neural Activity

Although immense progress has been achieved in technology for interfacing with and for monitoring neural signals, present day nerve recording interfaces suffer from several limitations, as mentioned previously. This calls for a more careful inspection of the fundamentals of neural conduction so as to consider alternative manifestations of neural activity. Consequently, technologies that can be utilized to obtain access to this additional information can be assessed and developed. Indeed, as nerve conduction in both the brain and the periphery is based on ionic currents, rather than on electrons, chemical sensing may be promising for an in-depth approach to neural monitoring.

56.2.1 Ionic Aspect of Brain Activity

In the CNS there are two main observable chemical variations that relate to neural operation: Variations of neurotransmitters and ions (Fig. 56.5a). Neurons receive input from other neurons through neurotransmitters – comprising of amino acids, peptides, and monoamines – and when a threshold is exceeded, they generate an ionic output, whose electrical expression is the *action potential* [56.3]. At the neuronal membrane level, the input and the output are realized by ionic currents of potassium (K^+), sodium (Na^+) (Fig. 56.5b), and chloride (Cl^-) at the axons with an additional ionic current of calcium (Ca^{2+}) at the somas. Neurotransmitters do not exclusively determine the inhibitory or excitatory activity, but actually it is the ionic milieu that regulates neural response and signalling. For example, K^+ , Cl^- ionic homeostasis was shown in [56.28] to affect neurotransmitter signalling defects in epileptic patients. Generally, variations in ionic concentrations in the brain have been observed in pathological states such as epilepsy, pain syndromes, movement disorders, and in certain psychiatric diseases [56.10].

Fig. 56.5 (a) Depiction of a neuron's synapse exchanging neurotransmitters with another (after [56.2]). (b) The main ionic components of the action potential: K^+ and Na^+ conductances (after [56.3])

Thus ionic variation is of fundamental importance to neural operation. Ionic currents change the potential of both the intra- and extracellular space. This can be measured by appropriate electrical sensing methods, however without any information on its underlying ionic composition. The flow of these ionic currents – and thus the excitability of the cells – is determined by the relatively steady ionic concentrations of the intra- and extracellular space, regulated by slower transmembrane ion pumps [56.3].

56.2.2 Ionic Aspect of Peripheral Nerve Signals

Similarly to brain neurons, the fundamental mechanism of peripheral neural activity is related to the inflow and outflow of sodium (Na^+) and potassium (K^+) ions across a cell membrane (Fig. 56.5b). When an action potential is generated, sodium (Na^+) and potassium (K^+) ions are allowed to enter or to exit the cell by their respective ion channels (gates). Under resting conditions, typical mammalian extraneural concentrations of Na^+

and K^+ are approximately 150 and 5.5 mmol, respectively, while the respective intra-neural concentrations are approximately 15 and 150 mmol [56.3].

When a cell membrane is depolarized (becomes less negative) past a certain threshold, voltage-gated sodium channels open, resulting in a great and rapid influx of Na^+ ions. The influx of Na^+ ions temporarily drives the electric potential across the cell membrane away from its resting value (approximately -75 mV in a mammalian cell) towards a more positive value. This is followed by an efflux of K^+ ions through K^+ channels resulting in a rebalancing of the membrane potential. The influx of Na^+ depolarizes the adjoining part of the membrane causing it to follow the same procedure and, therefore, the action potential propagates as a wave along the axon. During an action potential, the K^+ concentration in the immediate vicinity of the active region of the nerve increases by more than 4 mmol [56.29], i. e. it approximately doubles. The duration of each of these ionic pulses, which depend on the fiber type, are of the order of a few milliseconds [56.3].

56.3 Chemical Neural Sensing Technology and Challenges

56.3.1 Requirements for a Novel Method

Based on the previous sections, the need for a monitoring method that will discriminate between the fundamental components of neural signals makes it desirable to incorporate chemical sensors on neural interfacing platforms to allow ionic neural recording. A chemical neural monitoring platform based primarily on the measurement of K^+ and Na^+ sensing should feature micro-sensors capable of mmol sensitivity, embedded on flexible substrates. The sensors should ideally feature millisecond-order time response and sensing should be carried out without affecting neural operation. Beyond the *proof of principle* stage, such an ionic neural sensing interface should also feature acceptable longevity, depending on the application (e.g. implantability would require a life span of the order of several years) as well as biocompatibility and robustness.

56.3.2 State of the Art in Chemical Neural Recording Platforms

Before proceeding to examine the technologies available for achieving the requirements listed above for ionic sensing of neural activity, an overview of some-

what relevant concepts that have been reported in the literature is offered below, providing a very useful perspective.

In [56.30] *Strong* et al. presented a miniaturized platform including platinum electrodes on a silicon substrate with integrated front-end circuitry for sensing electrical signals as well as neurotransmitters. Even though the approach was not presented experimentally at that stage it seems very promising in terms of miniaturization and integration. However, the sensing setup proposed used a voltammetric approach (this particular sensing approach is examined along with others in the next section) resulting in a DC biasing of up to 1.6 V across the sensing electrodes. This presents a possible disadvantage affecting the neural operations that need to be monitored. The method was proposed for sensing the neurotransmitter dopamine.

Medtronic touches upon ionic sensing for biomeasurements as it reports K^+ and Na^+ ion-selective electrodes (ISEs) in a patent [56.31], where an attempt is presented to overcome the unsuitability of reference electrodes used with such sensors. These sensors are typically used for analytical chemistry applications and the reference electrodes are bulky and made of silver or silver-chloride, which is not preferred for biocompati-

ble interfacing, as it is polarizable. The patent focuses on ion measurements in blood demonstrating a technology that could be used for biointerfacing, although it is not directly suitable for miniaturization and, therefore, does not meet the abovementioned criteria for neural monitoring.

In [56.32] *Sudakov-Boreyscha* et al. presented the use of ion-sensitive field effect transistors (ISFETs – described in detail later) on brain catheter probes for the diagnosis of ischemia. The probes penetrated the skull to monitor blood pH levels. The authors focused mainly on encapsulation issues while bioelectric recordings were not mentioned. Even though the method does not focus on neural activity per se, the setup was interesting as it interfaced with the brain using a kind of sensor that can potentially have a robust miniaturized front end.

The European project, NeuroProbes [56.33], aims at recording either electrical information in the brain (mainly) or chemical information in the form of neurotransmitters. Similarly, the *Golden Brain* EU project [56.34] senses neurotransmitters using microprobes. The respective sensing methods used require DC signals between electrodes, with possible effects on neuronal operation, and the response time is in the order of tens of seconds. These projects highlight the importance of researching alternative neural monitoring forms and they proposed miniaturized interfaces. Moreover, although they do not include ionic measurements, they underscore the importance of microfabrication and portability in the relevant technologies.

56.3.3 Ionic Sensing – State of the Art and Challenges

Ion Sensors

There are three main electro-analytical methods for bioassaying chemical sensors. The first two, *coulometry* and *voltammetry*, involve current measurements and they require DC signals (voltage or current) between – or across – a pair of electrodes. The *potentiometric* configuration is the only passive method where there is practically no DC current flowing between the electrodes [56.35, 36], making it more appropriate for biointerfacing and in vivo sensing.

Conventional apparatus used for ion sensing in analytical chemistry experiments cannot be used for a miniaturized neural sensing application as it is too cumbersome and inappropriate for biosignal recording [56.37]. However, chemical sensors based on ion-sensitive field effect transistors (ISFETs) are much more able to meet the above requirements. ISFETs

are miniaturized, solid-state potentiometric transducers used predominantly for pH measurements [56.37].

Since their introduction in 1970 by *Bergveld* [56.37], ion-sensitive field effect transistors (ISFET) are today used in a wide range of sensing applications in the fields of clinical medicine, biotechnology, and the environment [56.38]. Their attractive features, such as small size, fast response time, the prospect of monolithic integration [56.39], low cost, as well as the possibility to combine them with various kinds of biologically active materials (e.g., enzymes, antibodies, DNA, and cells) make them well suited for *micro total analytical systems* (μ TAS) or *Lab-on-Chip* devices [56.40, 41]. Overall they offer cheap and portable devices for real time monitoring that could be potentially used for various biomedical and point of care diagnostic applications.

ISFETs features meet most of the requirements listed in the previous section. Even though they are mostly used for pH measurements, they can be made sensitive to specific ions. This is accomplished by deposition of appropriate ionophores [56.42], effectively replacing the transistor gate contact with a chemical membrane permeable to specific ions only [56.37, 43–46]. In that case, they are called *chemFETs* [56.37]. The response of the modified ISFET (chemFET) stems from the voltage that develops across the interface formed between the membrane and the aqueous solution, to the reversible binding of the analyte with the ion carrier. An intermediate layer is often applied to establish a reversible electron transfer pair at the ion-selective membrane–ISFET interface. Even though other types of ion sensors exist, chemFET sensors are the most suitable choice for neural monitoring because a) most of the other ion sensor types are unsuitable for this application due to their size and to their inability to be incorporated on flexible substrates, and b) ISFETs are robust [56.39], and several sensing units can be stacked on a single chip (Fig. 56.6a) [56.47].

Although ISFETs feature fast temporal response [56.37] depositing a chemical membrane on their gate to turn them into chemFETs makes them much slower because ions have now to permeate the membrane before reaching the ISFET gate. This drawback may be minimized by reducing the membrane thickness; however, this impacts on sensor robustness and lifetime. The titration diagram in Fig. 56.6b indicates how a fast and a slow ISFET-based sensor respond to step concentration changes. For reasons of cost it is desirable to fabricate ISFETs using the well established CMOS process, with silicon nitride as the sensing layer. Their power consumption can be very low when they are designed and biased in *weak inversion* oper-

Fig. 56.6 (a) CMOS ISFET pixels incorporated in an array and monolithically integrated to processing circuitry (after [56.55]). (b) Diagram of ISFET output voltage (V_{response}) corresponding to ion concentration (log) step changes vs. response time for a fast and a slow sensor

ation [56.47–53]. Several studies have described their use for detecting substances like pH, urea, alcohol, and glucose [56.54].

ISFET Fabrication in CMOS Technology

ISFETs are very closely related to the transistors found in CMOS-based processes and industrial production of stand-alone ion-sensitive probes is realized through the modification of such processes [56.2]. However, it makes perfect sense to try and accommodate the realization of ISFETs in unmodified conventional CMOS foundry processes. On the one hand, this would introduce certain drawbacks, given, for example, that an optimized dielectric layer would not be possible to achieve as all devices have to rely on the gate-oxide layer provided by the technology. Furthermore, this dielectric layer would not be able to serve as the sensing layer itself, as an inherent feature of standard CMOS technologies is that the gate-oxide is automatically covered by the polysilicon gate. On the other hand, if accommodation of ISFETs in a CMOS process could somehow be achieved, the benefits would outweigh any disadvantages. That would not only provide access to a relatively cheap and widely available method of mass manufacturing but, equally importantly, it would provide access to the monolithic implementation of all those capabilities

Fig. 56.7 Layers of an ISFET fabricated in CMOS process (after [56.55])

that come with silicon chips, including memory, logic and analog and digital signal processing, and conditioning. Indeed, *Bausells* [56.56] first demonstrated the feasibility of this idea by getting the chip's passivation layer, covering an otherwise floating CMOS-MOSFET gate, to act as the ion-sensing membrane (Fig. 56.7). Since then, this concept has found commercial applications and today a number of companies are understood to make use of this technology [56.2].

Sensor Technology Challenges

Although ISFET-based chemical detection of neural activity is a promising prospective technology, there are still several non-trivial challenges that need to be addressed, including drift and response time. ISFETs suffer from temperature dependence and long term temporal drift [56.57]. The temperature dependence is not expected to be an important issue inside the body, where temperature variation is minimal. Moreover, any temperature dependence can be eliminated using standard electronic circuit techniques, i. e. PTAT or bandgap reference [56.58]. Temporal drift is related to the capacitance at the front end of the ISFET sensing terminal, as the device is in effect a floating gate MOS transistor, with variations on the gate charge sensed with respect to an independent reference electrode. Similar issues affect all sensors that have an insulator-solution interface due to hydration effects of the insulating layer causing capacitance variations.

Post-processing steps to minimize drift involve briefly applying hydrofluoric acid on the sensing area before use or replacing the insulating layer of the sensor with one that has better properties, although this is not a choice if a standard CMOS fabrication process is used. The use of appropriate dedicated circuitry can

also improve performance of CMOS ISFETs as they can be monolithically integrated on the devices to perform drift cancelation processing. Devices that are indifferent to the target ions are often used as reference FETs (REFETs) to eliminate drift through differential connectivity [56.59]. In general, any platform for chemical detection needs to be robust and stable over time, even though this is much more important in analytical chemistry applications where absolute concentration values are needed. In bio-signal monitoring the main focus is variation monitoring, therefore, if the drift rate is much slower than the expected changes it can be filtered out by the use of AC coupling front-end circuitry involving filtering or chopping.

Irrespective to the choice of sensing technique, one of the most dominant factors in a chemical biosignal monitoring setup will be diffusion. The detection of a particular ion will greatly depend on the distance between the sensor and the source, which in this case would be the membrane of the firing neurons. Although this raises the demands for sensor sensitivity and calls for platforms that will allow very high proximity to the source, the authors expect that diffusion will also prove to be one of the beneficial factors related to electrical interfacing. Since the dominant extraneural ions are sodium and chloride, potassium or calcium specific sensors placed adequately closely to the targeted neurons will possibly benefit from diffusion, as distant sources that usually interfere with the desired measurements will mostly cause shifting of the dominant ions, while their native potassium and calcium will not reach the sensing site. Electrically, any ionic current will be picked up by the electrodes, while ion-specific measurements will only be affected by the chosen species.

Perhaps the greatest issue in ionic neural sensing will be the improvement of the sensor's response time. Bare ISFETs for pH sensing have been reported to exhibit millisecond-order response [56.37], however, with the application of ionophores on the sensing area to turn them into ion-specific chemFETs, this increases up to several minutes. Thus, reducing response time presents a major challenge. Chemistry and micro-fabrication experts that are members of the authoring group have managed to drop chemFET response times from several minutes down to several hundreds of milliseconds. Depending on the application, this could prove to be satisfactory for the envelope detection of trains of pulses or for the detection of slow global variations of e.g. potassium in the brain, which has been reported to relate to pre-epileptic states and exhibits a variation rate of hundreds of milliseconds [56.60]. Further challenges

are life span and biocompatibility. The life span is often related to encapsulation issues and degradation of ion-sensitive membranes. Commercially available devices have been reported to last several months [56.59]. Again, this may prove to be limiting for a chronic, implantable platform, however, the technology may still prove to be invaluable for intra-operative applications or for monitoring hospitalized patients. The information obtained may also be useful for an initial post-operative period for fine-tuning and calibration of electrical monitoring interfaces, assisting with adjustments that have to do with filtering, imbalance, and interference in the few weeks during which scarring tissue stabilizes. Finally, biocompatibility in terms of ill-effects to tissue due to the materials used at the front end of the sensors has been extensively researched by some of the authors of this chapter in the context of sensors of stem cell cultures, with very promising results [56.61].

Sensor Assessment

While determining the sensitivity of the sensors is quite straightforward, their response time is not so easy to assess. Shifting a sensor from a beaker to another with a different concentration can hardly assist in determining response time down to millisecond accuracy, while using a pipette to change the concentration of the solution in which the sensor is immersed involves too many parameters that mainly relate to diffusion (volume of solution, distance between pipette and sensor, stirring, or static solution – to name a few) rather than the inherent speed of the sensing membrane. As diffusion is so dominant the setup used for testing the sensing speed has to be somewhat more sophisticated, including software for modeling and, ultimately, the use of microfluidic platforms.

Due to mass limiting phenomena and ion perfusion, all sensors coated with membranes experience a lag in response time. Out of a number of approaches used to assess the influence of the membrane on the response time, incorporating a sensor into a microfluidic platform seems to be the most robust and accurate technique as it allows sensor response measurements in a highly controlled environment.

The first attempt towards integrating microfluidics and field effect transistors was reported in 1999, referred to as flowFETs. These devices were used as controlling and switching elements in microfluidic networks [56.62]. *Sharma et al.* have reported a silicon on insulator-based microfluidic device with monolithically integrated FETs for microTAS applications [56.63]. An extended gate field effect transistor (EGFET)-based bio-

Fig. 56.8 (a) Microfluidic platform developed by some of the authors, to assess single chemFET response time. (b) The flow variations inside the microfluidic channel were simulated to assess its performance (after [56.69]) ►

sensor integrated with a silicon microfluidic channel for the electronic detection of streptavidin-biotin protein complexes has been reported by Kim et al. In that instance, gold was used as the extended gate coated with self-assembled monolayers of thiols, onto which the biotin avidin complex was immobilized [56.64]. *Truman* et al. reported the use of silicon-based ISFETs for monitoring transport and chemical properties of liquids in microfluidic systems [56.65]. Reliable time-resolved ion and molecular transport sensing in chemoreceptive neurons in microfluidic channels using transistors has been demonstrated by *Jacquot* et al. [56.66]. Tetraphenylborate derivatives have been used to modify ISFETs on polymeric microfluidic devices for sensing cationic surfactants in dental rinses [56.67]. In another instance, a microfluidic chip was used for cell culture and a large transistor-based sensor array chip for direct extracellular imaging [56.68]. A literature survey does not reveal any solid state sensors integrated microfluidic device that could be used for simultaneous determination of cations. Members of the group of authors of this chapter have, therefore, proceeded to the fabrication and testing of a microfluidic platform for assessing chemFETs for biosignal sensing; the initial results of this work are very encouraging (Fig. 56.8a). The work was complemented by finite element method simulations to establish the validity of the microfluidic platform (Fig. 56.8b).

56.4 Conclusion

This chapter has presented an overview of neural sensing methods examining the prospects of an alternative method: ion sensing. The concept of ionic instead of electrical neural monitoring is theoretically very attractive, as it may serve to offer a greater insight into the underlying processes of neural activity. It may also offer increased selectivity and interference immunity due to better localization. Furthermore, the Nernstian nature of the chemical interface will offer a natural logarithmic signal companding to the monitored variations. In effect this will reduce the required input dynamic range of the front-end amplifiers and it will greatly minimize the effects of interference. For

example, the three orders of magnitude between the microvolt neural signal and the millivolt muscle interference in ENG recording platforms will translate into a factor of three between the two signals, if these were generated by the same ionic species at the same distance from the sensing surface. The benefits of such a technology are therefore evident, as the issues of signal localization and interference reduction are two of the most dominant bottlenecks in conventional neural monitoring arrangements. It is, however, equally evident that such a technology would require the sensors to be taken out of the context of analytical chemistry, which demands accurate and stable measurements of

Fig. 56.9 (a) Concept of arrays of ISFETs attached to a cuff for PNS sensing, as detailed in 56.5; (b,c) similar concepts for cortical interfaces

absolute concentration values, to a new focus where response time and miniaturization are key factors. With regards to the targeted biology itself, the brain seems to be a more realistic focus, even though peripheral nerve preparations are generally easier to use for testing and developing new interfacing technologies. This is mainly due to the ion flow reducing effects of the layers surrounding fibers inside the nerves, namely the epineurium and the perineurium [56.70]. Nerves can be treated in vitro to reduce the effects of these layers, however, this ultimately makes a non-penetrating

ion-sensing technology inappropriate for PNS interfacing, especially in vivo. Ultimately, the process of developing neural sensing modified ISFETs has huge potential in offering the enabling technology for all sorts of vital signal monitoring, mainly intraoperatively. The authors are developing relevant platforms (the concepts are shown in Fig. 56.9); they have formed an interdisciplinary group in the process of pursuing this target and are hopeful that they will create a trend of alternative monitoring concepts in the field of neuroprostheses.

Fusing Medical Engineering and Information Technology – Structure, Integration and Process Optimization

Hajo Tanck, Michael Heinlein

Integrating medical engineering and IT in a consequently and especially standardized way enables hospitals to significantly increase their efficiencies. This evolves process optimizations for medical documentation and organizational advantages within the administration of the interface used.

57.6	Résumé	1082

The combination of information technology (IT) and medical engineering (ME) is gaining more and more importance today. Years ago, only personal computers (PCs) were connected with medical devices, but nowadays systems, which consist of medical device and PC, medical devices with a complex IT infrastructure and/or medical devices with an integrated network interface, are directly integrated into IT networks. Besides creating medical findings, many systems support the medical and nursing staff in the process of medical documentation as well as in the treatment, therapy, and nursing planning. For these special fields of application, the data recorded are available for all sorts of specialized evaluations as well as scientific issues.

The integration of medical engineering into information technology of hospitals is consistent with the task of German hospitals of providing a growing quality of the treatment itself and the documentation of the

treatment process along with steadily increasing cost pressure at the same time. This is guaranteed by combining medical and administrative matters.

In times of lack of budget and staff, existing resources have to be used in the most efficient way. By integrating IT and medical engineering not only workflows are designed to be used more efficiently, but also saving potential in terms of time and money can be realized.

A complete integration is based on the semantic interoperability of the different systems; for this purpose various standards are used.

The standards for a complete integration are divided into two parts:

1. Communication between two systems (interface standards) and
2. Standards for the structure of the data that have to be transferred (data structure).

57.1 Standards of Interfaces

According to the definition, an interface is described with the help of a set of rules: standardized interfaces are mutually compatible, i.e. components or modules that support the same interface can exchange standardized data among each other. Below you will find the most important standards used in health care.

57.1.1 Health Level 7

Health Level 7 (HL7) is an international health care standard for the exchange of data. HL7 was developed by the eponymous organization; currently versions 2.x and version 3 are supported. The number 7 of the name HL7 refers to the layer 7 of the ISO/OSI reference model for communication (ISO 7498-1) and expresses that the communication is described on an application level.

In the HL7 version 2.x the following message types are supported, which are divided into segments and fields:

- ADT (admission, discharge, and transfer): patient's master data and data of their stay in hospital
- ORM (order message): request of an examination
- ORU (observation results unsolicited): transfer of findings
- DFT (detail financial transactions): transfer of performance data for accounting
- BAR (billing and accounting request): transfer of performance data according to the international classification of procedures and operations in medicine (OPS Standard)
- MDM (manage document message): document management messages

57.1.2 Digital Imaging and Communications in Medicine

Digital imaging and communications in medicine (DICOM) is an open standard for the exchange of digital images and their additional information.

The DICOM standard guarantees to standardize the format for data storage as well as the communication protocol for the exchange of data. Several working groups of the DICOM Standard Commit-

tee continue to permanently develop the DICOM standard.

Increasing numbers of manufacturers of imaging systems such as digital x-ray, magnetic resonance imaging, computed tomography, endoscopy or sonography, implement the DICOM standard in their products. This results in a high interoperability between the imaging systems and the systems for image processing and the digital image archiving as well as picture archiving and communication system (PACS).

Important DICOM services are:

- Verify – the verification, if a network node supports DICOM
- Storage – the storage of data objects
- Query/retrieve – the search of a DICOM device for objects (query) and the transmission of another DICOM device (retrieve)
- Procedure step – information about the status of examination
- Storage commitment – query, if the data transmitted have been stored
- Worklist management – data transfer between the planning system and the DICOM device, where the examination have to be performed
- Presentation state storage – transfer of information on how the image material is displayed or should be displayed
- Structured reporting storage – coded transmission of medical findings
- Hanging protocols storage – storing the presentation of image series and studies.

57.1.3 GDT

The GDT (interface for the exchange of device data) has been worked out by the Qualitätsring Medizinische Software (QMS) and is implemented as a standardized interface between IT systems and medical devices. The GDT interface is part of the standard delivery package. The data that have to be exchanged are filed in a predefined list. The file name serves to clearly identify the communication partners and reads as follows:

`{recipient-token}{sender-token}.{consecutive number}`.

The consecutive number will be incremented for every new message. Thus, it is prevented that older news will be overwritten by the reading device (client) before processing. After orderly processing the message by the client, the file in the client's exchange list is deleted by the client.

57.1.4 xDT

The xDT interface was created by order of the German Association of Statutory Health Insurance Physicians (kassenärztliche Bundesvereinigung) and contains a group of data exchange formats, which are predominantly used in private practices. The formats have a common, text-oriented syntax, where every field is

written as a line in the file and a common field directory based on XML (extensible markup language).

57.1.5 XML

XML was published by the World Wide Web Consortium (W3C) and the current version is the fifth edition. With the help of XML, a meta-language is defined. This language is the basis for creating custom-designed languages by means of structured and content restrictions, such as xDT.

A XML document consists of text characters, in the simplest case ASCII, and is therefore readable by humans. The definition does not contain any binary data that include unreadable texts.

57.2 Data Structure

The second important aspect in terms of integrating medical engineering and IT forms the issue about the content structure of medical document.

57.2.1 HL7 CDA

The HL7 clinical document architecture (CDA), based on XML, was worked out by the Health Level 7 group for the exchange and storage of clinical contents. A CDA document complies with a clinical document (e.g. a physician's letter, a findings report). CDA documents guarantee the data transfer between different systems.

57.2.2 SNOMED

The Systematized Nomenclature of Medicine (SNOMED) aims to index medical statements in a way that all content-related elements of the statement are recorded completely.

SNOMED CT contains 18 axes with 800 000 terms, which describe approximately 300 000 concepts (several terms per concept).

The German translation of SNOMED CT dates back to 2003 and has no longer been maintained.

57.2.3 LOINC

LOINC (logical observation identifiers names and codes) is an internationally acknowledged system for clearly en- and decoding examinations. The Regen-

strief Institute (Indianapolis, USA) is responsible for maintaining and documenting the LOINC database. In Germany, the DIMDI (German Institute of Medical Documentation and Information) actively promotes the implementation of LOINC and assumes the responsibility of the central data management and the information exchange with national and international institutes, project groups and industry.

LOINC is a composition of general names and identifiers for the description of examination and test results from laboratories and clinics. LOINC is not only recommended by HL7 but also by DICOM for the structured exchange of medical findings and findings data.

57.2.4 Alpha ID

The identification number for diagnoses is a continuous number identifying entries of the alphabetical list of the ICD 10-GM (International Classification of Diseases, 10th revision). With the help of the Alpha ID medical terms can be further processed electronically; the fact that the code cannot be changed due to being maintained by the DIMDI guarantees its interoperability. Due to extending the Alpha ID by terms beyond the scope of diagnoses in the future, this terminology can be used not only for encoding diagnoses.

57.2.5 Object Identifiers

For standardized exchange of medical information, an efficient software communication in health telem-

atics requires data objects, i.e. objects and messages have to be described clearly. Object identifiers (OID) are chains of number for identifying these objects and messages. In this case, objects are information units like institutions, classifications, information, documents or tables. If OID is used for standardized data exchange between software systems, the integration of the data between the systems is ensured.

57.2.6 Unified Code for Units of Measure

With the encoding system Unified Code for Units of Measure (UCUM), measuring units are shown in standardized form. If the applications for medical documentation show the SI standard unit system (international system of units), the transfer of e.g. the medication of a treatment is possible with clear measurements.

57.3 Integrating the Healthcare Enterprise

Last but not least, the Integrating the Healthcare Enterprise (IHE) serves as kind of a bridge between different standards and creates the technical framework for the implementation and verification of the standards' feasibility.

IHE reformulates requirements from experience into so-called Use Cases, identifies relevant stan-

dards, and develops technical guidelines in the so-called technical framework that enables a manufacturer to create their interfaces compliant to IHE. On the international *Connectathon* the manufacturers mutually test the interoperability of their systems and use the gained experiences to put it into practice.

57.4 Integration of Medical Devices

What does the integration of medical devices nowadays look like?

In many hospitals, medical devices of laboratories and radiology as well as single ultrasonic or endo-

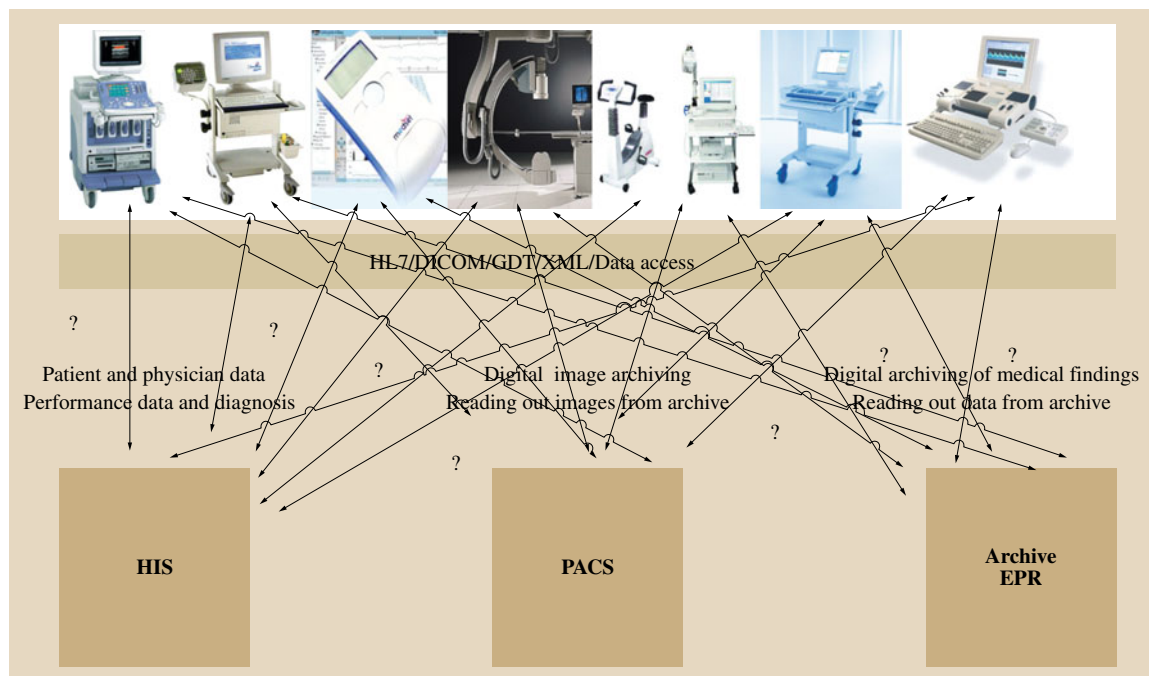

Fig. 57.1 Integration of medical devices – as of today

Fig. 57.2 Integration of medical devices into interface server

scopic devices are connected to the hospital information system (HIS). They are often equipped with a device interface and an interface for the data-receiving information system, which means a separate interface for every single supplier of medical devices is installed. Mostly, this is due to the fact that the devices used only have a GDT interface. The diagram in Fig. 57.1 clarifies the predominant interface structures in hospitals nowadays.

57.4.1 Interfaces

When technically implementing an interface of the medical device and IT network, both, IT and medical engineering are involved; however, from the organizational point of view the content-related result influences the hospital's treatment process and it is in the context of the organizational function that the content result along with the treatment process and affects the entire hospital structure.

Excursion to HL7 Communication Server

The communication of subsystems in a hospital can be optimized by the HL7 communication server. These

components assure that not every single subsystem requires an individual interface. Using a communication server benefits in reducing the number of interfaces, as not every single system has to be connected via an individual interface. This in turn, results in a more standardized and simpler communication flow as well as cost-saving, because every separate interface demands a monetary equivalent.

The data format or the HL7 version, which the individual systems use to send their messages, is absolutely random. With the help of mapping tables, the HL7 server automatically converts these formats into the format which is required by the receiving system requires. The tables will be created once when the communication server is installed. Afterwards, the interfaces are maintained directly on the communication server. If you project the HL7 communication server technique onto the integration of medical devices, Fig. 57.2 shows the resulting system environment.

57.4.2 Connecting a Medical Device

In contrast to integrating two software systems based on a HL7 communication, the connection of medical de-

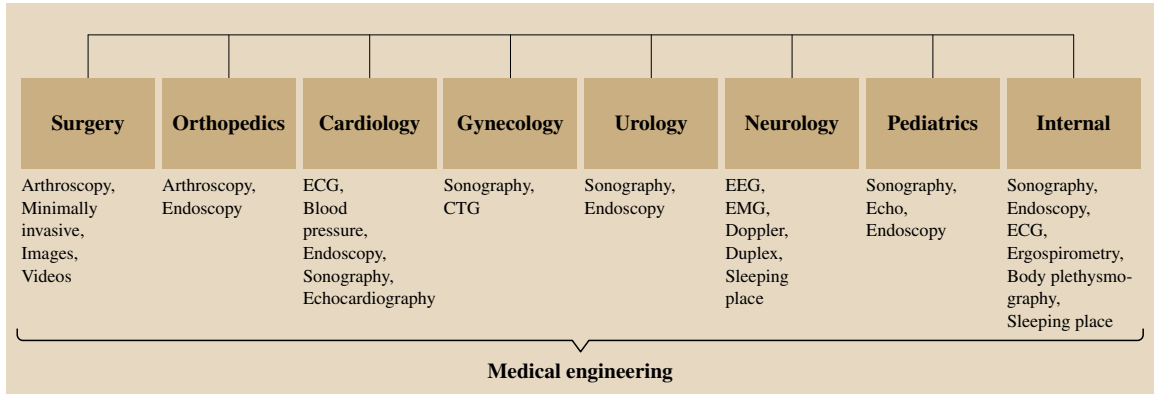

Fig. 57.3 Medical departments together with their possible medical devices and physical interfaces

VICES additionally requires that each medical device and examination result will be connected and documented. For systems that only store their data locally on the device, a physical interface has to be established for each device and workstation. If the device’s supplier additionally provides different applications, the complexity of the interface is further increased. Normally, the recorded data are data and applications of specialist departments for the purpose of medical diagnoses. Figure 57.3 points out the scope of physical interfaces required within in the context of individual integrations.

The connection of a device can be realized by means of proprietary interfaces or the standards (e.g. HL7/DICOM) as described in Sect. 57.2.

Attention should be paid to the facts that:

- There is no dependency created by the use of proprietary interfaces.
- IT and medical engineering have to mutually combine operating and change processes.
- The integration of medical products is effected according to the guidelines and
- Criteria of the MPG (MedizinProdukteGesetz – Medical Devices Law) and
- Standard interfaces for integration into existing systems are agreed upon.

Apart from that, it is important that it is not compulsory to use medical devices of in-house production and that you pay attention to the implementation of the IT safety concept when integrating medical devices; whereas the completing process of approval resulting in a risk analysis has also to be taken into consideration.

Secondly, the data sent from the medical devices will be forwarded to the different information systems

in accordance with the purpose agreed in advance. These data can be measured values, textual findings, structured medical documents, images, PDFs etc. They can also be transferred to the information system via proprietary interfaces or standard interfaces as described in Sect. 57.2.

A joint task for all responsible persons from medicine, medical engineering, IT, and administration is defining the data that has to be transferred. Often, this results in further tasks for different specialized departments managed by the respective responsible person. The following list is an example for the IT department:

1. Adaptations to the network topology (IT/ME)
2. Need for adaption to the individual IT/ME infrastructure
3. Hard-/software requirements (operating systems etc.) that have to be considered
4. Adaptation of the storage concept/long-term archiving
5. Extending the system monitoring
6. Presentation of data consistency and workflow processes (IHE).

57.4.3 Organizational Requirements for the Connection

If we consider the integration of medical devices, it is obvious that, in terms of organizational aspects, several professional groups of the hospital with overlapping responsibilities have to be involved in this process.

While the health service’s has to focus on possibilities of establishing medical diagnoses, the medical engineering will pay special attention to guarantee that the device functions without interference. The clinical

IT department is focused on the possibilities to integrate the examination results into the hospital information system, and the clinical administrative department is interested in evaluating the overall process regarding to the acquisition and consequential costs as well as the entire treatment documentation. But also the importance of the documentation possibilities will rise in the future to evaluate and justify treatment processes to cost units.

As this overall view points out, it is very important that the professional groups mentioned above work closely together. Before purchasing a device, the following sample questions have to be considered in order to satisfy the radiologic principle of *the unity of image and findings*:

- Who is responsible for process of integration with regards to the content?
- Who is responsible for technical process of integration?
- Which data should be transmitted from the medical point of view?
- Which data should be transmitted from the administrative point of view?
- Who is in charge of coordinating the specialized departments?
- Which interfaces for integration are provided by the device?
- Which interfaces support the administrative information systems?
- Do the systems that will be connected support the standards?

In addition to that, the responsible parties of a hospital have to deal with the workflow of the medical department. The convergence resulting from the integration of medical devices induces also during the use of the medical device an interference of the following aspects:

- Responsibility
- Engineering
- Organization
- Workflow/operation
- Security

57.4.4 Responsibilities

When integrating medical devices, individual responsibilities overlap during the entire cycle of operation. Especially during the operation of the medical device, it depends on the cooperation between physicians,

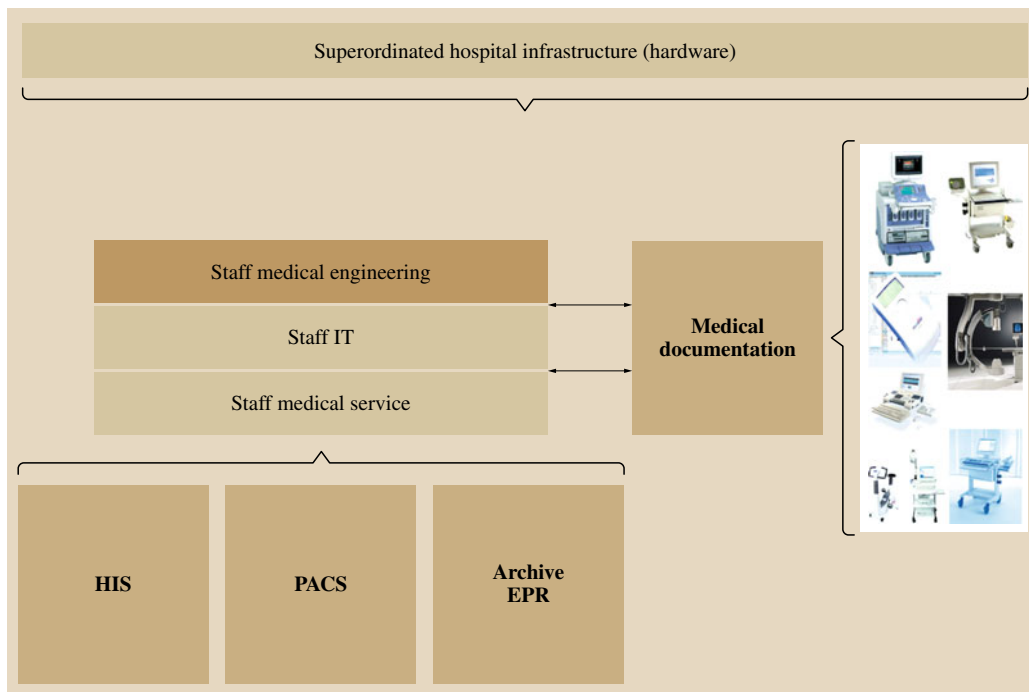

Fig. 57.4 Administrative areas of responsibility in hospitals

medical engineering and IT, whether the integration is successful or not (Fig. 57.4). The management is responsible for a secure operation by giving

clear instructions and differentiating the areas of authority each person involved has to be informed about.

57.5 Sample Integration – From Findings to Medical Documentation

The information and document structures, which have hitherto been proprietarily defined between the systems with random names for measured data, document structures, features, and/or values, are normally not interpreted by all systems to be integrated. For exchanging data the classifications and terminologies mentioned in Sect. 57.3 should be applied. Using these standards guarantees that the content transmitted is readable for all systems.

Moving from the structured medical documentation to a European- and world-wide standardized medical documentation requires this compliance and will be necessary in the near future, e.g. with regard to telemedicine. These requirements will result in a gradual removal of free-textual documentation in favor of structured documentation in hospitals. Tendencies for achieving this are the nomenclatures for structured medical documentation announced by the medical associations. To avoid that a data set is transferred randomly for technical implementation of the structured documentation, another standardized format, called HL7 CDA (Clinical Document Architecture), is already available and used successfully in numerous projects for exchanging structured documents between different institutions at home and abroad.

This success is essentially based on the following aspects:

- For mechanical processing the structured content of documents are represented in the common XML format. With the help of style sheets formats readable for humans are created.
- The XML format, i.e. that the above-mentioned structure of the features used with their relations and data types are derived from a standardized information model, the HL7 RIM (reference information model). This ensures that the content is integratively represented and processed.
- Classifications and terminologies both, internal and external of HL7, will consistently be used for all types of content such as document sections, features and ranges.

Contacting the HL7 user group you can read the implementation guideline for electronic physician letters in HL7 CDA format. With this format systems with proprietary data formats can exchange structured data processible for computers by displaying their content in HL7 CDA standard.

57.6 Résumé

To sum up it can be stated that the requirements for integrating medical engineering into the hospital's information technology do not just concern the technology and organization of the hospital. If the integration is tackled correctly, this is future-oriented and the medium-term step for a comprehensive integration of IT and medical engineering in order to use the existing resources in the most efficient way and to remain competitive. Data that so far has not or just to a limited degree been exchangeable between the systems, will no longer be available in a proprietary but standardized format. Organizational and technical issues will result in adapting safety concepts and failure scenarios to new

conditions for identifying and minimizing the risk of security gaps.

Connecting medical devices causes a displacement of resources and a cost reduction. Reasons for this are, for example, more efficient processes by avoiding media discontinuity, the reduction of the process period due to faster data transmission, the synergetic use of medical engineering and extended fields of application on the basis of existing medical products (Fig. 57.5). Therefore, an improvement in the treatment quality by e.g. faster diagnostics, shorter processing times, and a permanent availability of the treatment documentation is achieved. Physicians and patients highly satisfied with

the treatment, improved patient safety by e.g. clearly assigning patient and patient-related data, avoiding errors when transferring data and improved information of the patient and environment are further aspects.

After the fusion of medical engineering and IT, a cost-benefit analysis pointed out that there are savings of 14 000 € p.a. for an endoscopy with three workstations.

This analysis evaluates the introductory status, the increase in efficiency achieved by the users along the treatment process and the improvement potential of the entire endoscopy process. The following diagram (Fig. 57.5) describes how the process is optimized, the capacities are displaced and saved by the integration of medical engineering, the software for structured

medical documentation and the hospital information system.

The optimal integration of medical engineering and IT enables to create overall concepts instead of numerous single solutions. These concepts efficiently as well as effectively support the daily work in clinics and turn future visions of data availability into reality.

58. Communicating Medical Systems and Networks

Armin Gärtner

Part F | 58

In the last 10 years, medical devices and information technology (IT) have become inextricably connected technologically and functionally. Medical devices are no longer just connected to a personal computer (PC) in order to evaluate data but have an integrated network interface card, meaning that they can be connected directly to an IT network in order to be able to send data via the network to a server for archiving and/or further processing. The user can access this medical data for a patient at any time, in any place, and in any form. This means that the IT network in the hospital is becoming increasingly important for patient treatment and that the requirements with regard to availability, safety, and efficiency of the network are thus constantly increasing.

58.7 Future Standard IEC 80001-1	1093
References	1093

58.1 Medical Networks

Integration of a medical product into an IT network (Fig. 58.1) does not convert the IT network into a medical product.

IEC 80001-1 defines the term *medical networks* to include both active medical devices (modalities, pro-

grammable electrical medical systems (PEMS) and also network components and PCs. A medical network integrates medical devices.

The combination or integration of medical devices in IT networks as per Fig. 58.1 in the hospital

Fig. 58.1 Medical devices with a network connection

(and also other areas of the healthcare system) leads to IT networks becoming a more integral and thus more important, and also always a more highly critical, element of medical diagnostics and therapy. They therefore represent an integral part of modern patient care.

A medical network undertakes the task of relaying:

- Records of services provided, and in the private health sector, billing information,
- Image data and clinical findings, and
- Vital signs and alert data from medical devices.

For data transmission, medical devices place various demands on a network, which can be divided into three classes:

1. Transmission of a large volume of data [e.g., computed tomography (CT) series, video loops], requiring transmission rate (bandwidth).
2. Transmission of time-critical vital signs and alert data (intensive care medicine), requiring reliability.
3. Transmission of sensitive patient data, requiring safety and security.

Medical data are subject to particular requirements of

- Integrity (authenticity)
- Protection (data protection)
- Security (data transfer)
- Completeness.

A medical network must therefore ensure that these requirements are satisfied.

58.2 Requirements for Medical Networks

Medical diagnostics and therapy are today reliant on the prompt availability at any time of images, clinical findings, and other data.

Considerable problems and risks for the diagnosis and treatment of patients can therefore arise if:

- Data are not available or are incomplete.
- Data are not available promptly.
- Data such as images during an operation are suddenly no longer available.
- The transfer of vital parameters and/or alerts is not possible or is interrupted, etc.

Availability is a vital aspect of medical networks for users/operators. According to [58.1], availability is understood as meaning the fraction of time during which the application being considered or the data are available. When the availability of a service or of data is known, this value therefore gives the probability of an application and/or data being available at a particular point in time within a period of time. In hospitals, ever more applications are critical for patients and for management. A critical application or critical data transfer is defined as being an application whose failure can be associated with far-reaching consequences for the patient and the hospital.

58.2.1 Image Data in Radiology

Failure to transmit image data from a modality to an image documentation system such as a picture archiving and communication system (PACS) for storage normally

does not have any critical consequences for patient care because the modalities, such as CT equipment and ultrasound equipment, etc., can buffer the images. If, for example, the switch on a radiological IT subnetwork [local area network (LAN)] fails, then the images can usually be buffered on the modality and re-sent to the PACS once the network connection has been restored. If, however, the internal web image processing is also affected by failure or disruption of the hospital-wide network, in emergency cases such as treatment of trauma patients a alternative plan should come into effect, so that any x-ray images can be printed out using a film printer and made available to the orthopedic surgeon.

58.2.2 Intensive Care Network

Intensive care networks are traditionally set up as proprietary networks with a defined junction with the general IT network. DIN EN 60601-1 3rd defines in annex H.7.3 three safety classes for IT networks in hospitals.

Failure of an intensive care network or network components is limited in its extent to one ward and must therefore be compensated for by the staff by displaying the vital signs on the system control center monitor until network functionality is restored. Patient monitors should include the principle of first-fault safety; this means that they automatically change to an entirely acoustic and visual alert in the event of failure of the network connection to the central monitoring station.

58.2.3 Transmission of Alert Data

For various reasons, technologically orientated solutions are meanwhile being offered, which can be used to perform patient monitoring via the IT network in a hospital by connecting monitoring equipment via the network to so-called alert servers or special alert software on servers. These servers or alert software enable

alert functions and parameters to be configured, with which vital signs and/or alerts (bradycardia, etc.) can be passed on to remote display monitors or to mobile communications equipment.

The (partial) failure or disruption of an interconnected medical system of this type can have critical consequences for a patient (e.g., in the case of a bradycardia alert).

58.3 Interconnected Medical Networks

IT networks are increasingly used in hospitals to transmit also time-critical vital signs and alerts from patient monitors and other equipment. An IT network then becomes a central component of an interconnected medical system. Systems of this kind consist of a number of heterogeneous, autonomous single devices (medical and nonmedical devices) which are only capable of performing their task as a medical system as a result of networking. Within a medical network, it is possible to identify interconnected medical systems which are to be regarded as subsets of a medical network.

The functionality of such interconnected medical systems along the same lines as the medical electrical systems, in accordance with DIN EN 60601-1 3rd chapter 16, can be described and defined in the medical network as a subset.

The operator must define, evaluate, and ensure certain requirements for the reliability and the security of the system against disruptions and other influences. Software solutions which are marketed as medical products and implemented as server solutions in hospitals are a central component of such systems.

Fig. 58.2 Interconnected medical system for supplementary monitoring in the field of cardiology

The servers or alert software generally enable alert functions and parameters to be configured, with which vital signs and/or alerts (bradycardia, etc.) can be passed on to remote display monitors or else mobile communications equipment.

If electrocardiogram (ECG) alerts such as a bradycardia alert are passed on via an interconnected medical system such as this, disruption/failure can have substantial consequences for the patient if disruption/failure cannot be detected and responded to sufficiently early.

Figure 58.2 shows an example of an interconnected medical system in the field of cardiology to supplement monitoring of ambulant patients following surgery. Following surgery, the patients should be monitored using patient monitors which send vital sign alerts to a central alert server via a wireless LAN (WLAN) connection. This server or special software forwards the configurable alert messages to a telephone system, which in the event of an alert sends a message to the pager, mobile phone or digital enhanced cordless telecommunications (DECT) phone of the doctors or nursing staff.

The patient monitor and the software are marketed as individual medical devices in accordance with the medical devices directive (MDD), and the other components such as the WLAN, the hardware of the alert server, the communications system, and the mobile terminals are marketed as nonmedical devices in accordance with other directives [the low-voltage directive and the electromagnetic compatibility (EMC) and radio and telecommunications terminal equipment (R&TTE) directives].

The combination of the various components – the patient monitor as a medical device, the WLAN as transmission channel, and the PC as a nonmedical device with the alert software as a medical product and the communications system – constitutes an interconnected medical electrical system. The combination corresponds with the legal definition of a medical device system in accordance with §3 of the German Medical Devices Act [*Medizinproduktegesetz* (MPG)], because it transmits diagnostic alert data. None of the suppliers assumes responsibility for the assembly of the system and none declares conformity with the MDD 93/42/EWG.

58.4 Risk Management, DIN EN ISO 14971

Since the operator assembles this combination of a medical device system, he must carry out the process of in-house production as per §12 MPG. Every time an operator:

- Creates equipment and systems himself, without placing them on the market,
- Modifies equipment and systems in a manner not intended by the manufacturer,
- Operates equipment and systems for purposes other than the assigned purpose defined by the manufacturer, or
- Combines medical devices and nonmedical devices, without the manufacturer or manufacturers having intended this combination in the assigned purpose of the device or devices,

he produces equipment or a system in-house.

The operator must define the assembly and components of the system and evaluate them in the form of a risk analysis in accordance with DIN EN 14971. The suppliers of the individual components do not have to do this, because they only market their subcomponents as a medical device (patient monitor, alert software) or as a technical product and are neither able nor will-

ing to assume any responsibility for the signal chain created.

What the operator must do is:

- Establish the assigned purpose
- Satisfy the applicable fundamental requirements of the directive MDD 93/42/EWG
- Develop a risk management file in accordance with DIN EN ISO 14971 and if necessary even take IEC 80001-1 into consideration
- Perform a risk analysis (establish assessment criteria, analyze risks, reduce and reassess risks, e.g., availability of the server, availability and stability of the WLAN standard, etc.)
- Assess residual risks
- Incorporate experiences and observations from using the system into the risk management file.

The interconnected medical system shown by way of example in Fig. 58.2 can be used both in a complementary fashion, in parallel with monitoring of the patient by a member of staff, but also to save on on-site monitoring staff. Whatever the intention of the operator, he must in all events ensure, according to the objective of the directive MDD 93/42/EWG, that no patient comes

to any harm as a result of failure, disruption or other events during signal transmission. The risk analysis is used for this purpose and can be used to determine whether or not the risk associated with monitoring using an interconnected medical system such as this is acceptable. The risk analysis according to DIN EN 14971 therefore helps to detect dangers and risks which are not immediately recognizable and as far as possible to prevent or at least reduce these dangers and risks before they arise.

The operator must document the in-house production for every interconnected medical system, since from a legal point of view he creates a new system. This does not merely involve the legal aspects but also involves an understanding of a complex interconnected medical system by all those involved, such as the users (doctor, midwife), medical technicians, and IT staff. Risks and potential risks can be recognized and reduced prior to use by using the risk management approach according to DIN EN ISO 14971.

The operator (management) must ensure that this process is established and continued jointly by medical staff, medical technicians, and IT staff. In the event of a claim, in which a patient comes to harm as a result of a bradycardia alert not being transmitted or not being received, the operator must always demonstrate what action he took to protect the patient from risks. If he is able to account for this in the form of documentation of the in-house production, then he will at least be able to exonerate himself from the charge of gross negligence.

The operator must also decide with the users which risks exist or should be accepted with an interconnected medical system such as this. An interruption in the signal transmission or the inability to access or nonreceipt of an alert via the mobile device of the user can signify, for example, that there is no response to a bradycardia alert or that a response is not possible. The consequence of this can be the death of a patient if the user is not on site and is not notified for the reasons stated. The question is, for example, whether operators/users can and wish to accept a residual risk of one death a year and how the risk of such an event can be significantly/dramatically reduced as a result of risk analysis and measures.

It is crucial that the medical staff involved help to shape this process and accept the remaining residual risk. This can, of course, also signify that a hospital arrives at the conclusion not to perform an exemplary installation such as that of an interconnected medical system, because the residual risk is considered from the point of view of those involved to be too high or unacceptable.

When carrying out the risk analysis, the individuals involved must ask themselves which risks and potential risks exist and how these can be assessed:

- Can the signal transmission be interrupted, and where and how?
- How and when is an interruption in the signal chain detected? What do the necessary responses look like?
- Will it come down to propagation delay in the signal transmission? If so, at what level and are these acceptable or not?
- Is unidirectionality sufficient?
- Is it guaranteed that an alert verifiably reaches the receiver?
- Does the IT department have command of the correct installation and administration of the WLAN?
- How is it ensured that alert data is transmitted via the network with priority (quality of service)?
- Can excessive data traffic in peak periods impair the transmission of alert data? How is this checked and verifiably prevented?
- Can malware impair the functionality of the alert server?
- What happens during patching of the alert server at the operating system level or in cases where there is antivirus protection?
- How can the system be regularly and verifiably tested for functionality and following changes?
- Have the employees who must respond to the transmission of the alert signal been, or will they be, thoroughly and comprehensively instructed about the transmission and the complexity of the system? What happens when cover is required (holiday, illness)?
- Are the batteries in the mobile terminals always charged? Is this guaranteed and how?

58.5 Shared Networks

Traditional intensive care patient monitoring with a network and control center/central server has until

now been installed as a closed, proprietary network (Fig. 58.3). Manufacturers increasingly offer solutions

Fig. 58.3 Proprietary network in intensive care medicine

for using the existing IT network (wired or wireless) in the hospital for patient monitoring and for transferring data to the central monitoring station, under certain preconditions. Solutions of this type are described and implemented as virtualized systems or as a *shared network* form of operation. An intensive care monitoring unit can therefore use the operator-specific IT network, in other words it can share the IT network with other applications, under certain preconditions. In this context we refer to a customer support clinical network (CSCN), which is provided by the operator for the application.

Figure 58.3 shows a closed intensive care network with wired networking of the bedside monitors and the control center in the form of a so-called proprietary system, because it is frequently installed by manufacturers as a stand-alone system with its own networking.

This common solution complies with the closed network/data sharing of class C of DIN EN 60601-1 3rd (annex H7) for vital, time-critical patient data. The standard recommends using this network for all time-critical applications and processes. A network such as this is not

connected to any other network because, from the viewpoint of the standard, connection to another network could bring about uncontrollable risks. Furthermore, the standard requires that the availability must be 100% and that interruptions must be avoided and must only last for a few minutes per year.

The standard in particular defines that the responsibility must be assigned to just one individual manufacturer/system contractor, which means that a manufacturer declares conformity of the intensive care system, bears the technical responsibility for installation, and, where there is a maintenance contract, also undertakes the maintenance work.

A distinction can be made between three forms of shared network operation, using the example of intensive care networks:

- Open system with wired networking of the bedside monitors and the control center via an operator-specific network
- Open system with WLAN networking of the bedside monitors and the control center via an operator-specific WLAN

Fig. 58.4 Intensive care network in the shared network form of operation

- Open system with wired and WLAN networking of the bedside monitors and the control center via an operator-specific network (shared network).

Figure 58.4 shows the form in which *shared network* operation can be realized, using the example of an intensive care monitoring unit.

Figure 58.4 shows in principal how patient monitoring can be integrated into an existing IT network in a hospital. This means that the operator installs the network, the cabling, and the infrastructure components such as switches, or has the network, cabling, and components installed, in accordance with the specifications of the manufacturer of the patient monitoring system. For this purpose, the monitors and the control center are operated in a virtual local area network (VLAN). The intensive care network shares (shared network) the general network with other applications in order to send its patient data to the control center or to a server.

A shared network means that all users/subscribers share an installed IT infrastructure with an available, normally fixed, bandwidth (data transfer rate) in a wired or wireless network. This is usually the operator network.

This form of operation therefore results in the operator of the IT network, according to Fig. 58.4, assuming responsibility for the reliability and transmission security of the medical data and thus also for time-critical vital signs and alert data.

Manufacturers of intensive care patient monitoring do not include the operator’s IT networks in their conformity assessment procedures; they only specify requirements for the network. Conformity for integrated monitoring (shared network) is only declared by a manufacturer if:

1. The manufacturer has checked the existing IT network and has validated it for its requirements for

the transfer of data between patient monitors and the control center,

2. Any changes to the validated network have been discussed and agreed in advance with the manu-

facturer, so that he can again perform a check and validation to determine that the changes do not have any effect on the secure and real-time transfer of data.

58.6 Security Aspects of Medical Networks from a Regulatory Viewpoint

Neither the medical devices directive (MDD) 93/42/EWG nor the German Medical Devices Act (MPG) contains requirements for the properties of medical networks in hospitals.

The directive does, however, require that medical devices and medical device systems must provide a high degree of protection for patients, users, and third parties and accomplish the services specified by the manufacturer.

Paragraph 2 of the Medical Devices Operator Ordinance obliges the operator to ensure the security of interconnected medical systems and thus of medical networks.

Medical networks are now a reality in the healthcare system. The vast majority of IT networks in hospitals are implemented as wired infrastructures due to historical factors. Parts of networks or entire networks are increasingly being implemented as radio networks in the form of a WLAN based on standard 811.3. Operators of a network must define the requirements for their IT network or their medical network for the use of interconnected medical systems and assess them for risks.

The following questions from the perspective of medical technology should help with the planning and extension of medical networks.

1. How should a medical network ideally be set up and why?
2. Which medical applications run over a network? How can these applications be divided according to priority criteria?
 - Unsecured use and transmission, no authentication.
 - Secured use and transmission, not time critical.
 - Time-critical use and transmission of vital signs and alerts, etc.
3. How does the topology behave in the event of extension or upgrading of a network?
4. How is the load (average load – peak load) or the data transfer of a network calculated? Can a propa-

gation delay of time-critical data occur during peak load?

5. Which applications are subject to high requirements in terms of the availability of data exchange? What technology (redundancy, safeguarding of network components with battery back-up, uninterruptible power supply (USP), etc.) can be used to increase the availability of a network or a subnetwork?

To increase the availability of a medical network with data exchange, reliability as a result of redundant hardware and software components and greater consideration for the reliability requirements from the point of view of the user can be taken into account when setting up a medical network, for example. Redundancy is generally considered to be an essential measure in order to increase the availability of networks. In the medical sector, the term *maximum reliability* is therefore also used. The operator should therefore define, for example, which services, applications, and network components are considered critical in terms of availability in order to be able to use them redundantly in the event of a failure or malfunction.

6. What security requirements are there in terms of protection from malware?

Since medical devices and medical device systems are also infected with malware in the network, the operator, represented by the medical technicians and IT staff, must operate medical devices using antimalware software (also known as antivirus protection) and must install patch management in order to permanently update both the antimalware software and the operating system.

Manufacturers of medical devices which are integrated in a medical network must at the same time provide assistance by evaluating the protection of their devices against malware within the scope of their conformity assessment procedures and by providing the operator with details about antimalware software and regular upgrades to be used.

58.7 Future Standard IEC 80001-1

IEC 80001-1 concerns the entire medical network and the medical devices integrated therein. The future standard describes a form of risk management using technology from DIN EN ISO 14971 in order to analyze, evaluate, and if necessary reduce the risks and potential risks of integrating medical devices into an IT network and of exchanging medical data over this network.

The future standard has the objectives:

- Security in the network
- An effective network
- Data and system security
- Confidentiality
- Data integrity
- Availability of the data
- Secure interconnection of medical devices and non-medical equipment within the same network.

Irrespective of the date on which this future standard will come into force, the operator is today already obliged and well advised to analyze interconnected medical systems and the medical network for risks and potential risks (e.g., malware in the network) and to take preventive measures to increase protection against malware and reduce the dangers which arise as a result. Malware in the form of computer viruses and worms

such as the Conficker worm do not spare hospital networks and the PCs and medical devices within the network which have a network connection.

Hospital Info

59. Hospital Information Systems

Peter Haas, Klaus A. Kuhn

In this chapter, we present an overview of health information systems with a specific focus on hospitals. We start by illustrating the different dimensions of IT support from basic documentation tasks to organizational support and medical decisions. Architectural models are described, and pros and cons of existing options are discussed. Integration challenges and the role of standards are presented. Finally, the process of selecting and implementing a hospital information system is described in detail.

59.1 Background

Health care systems in many developed countries are facing significant challenges. A rise in the average age, together with an increase in chronic illnesses and thus increasing costs, losses in insurance premiums, financial problems caused by the labor market, and the universal demand for high-quality modern medical care for all citizens – irrespective of their financial situation – are resulting in fundamental questions being asked:

- How can a balance be found between the limited funds available and the demand for health care?
- How can medical progress and the latest diagnostic tests and treatments be implemented quickly and efficiently across the board?

- How can the organization of care services be made more effective and better coordinated?
- Which instruments of health reporting are needed by government in order to be able to act quickly and appropriately?

Approaches to these problems include, for example, case and disease management, managed care, and, associated with this, improved dovetailing of the different care sectors such as in-patient and out-patient rehabilitative care. Hospitals are especially affected by these approaches and will need to be involved to a major degree in their implementation, as they are responsible for a significant proportion of complex treatments and thus

also contribute essential information to the life-long treatment process of a patient and his/her continuing care.

Politicians, health insurers, medical experts, and also the general public are increasingly aware that these challenges can only be overcome with the help of health information technology. The goal is to strengthen intra and interinstitutional cooperation and to integrate the care sectors. Better access to data and knowledge is necessary to improve processes and to make decisions. Health information technology will also support the practice of evidence based medicine, characterized by Sackett et al. [59.1] as the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients.

Boundaries between hospitals and regional and national health information networks are beginning to fade, and hospital information systems (HIS) are becoming part of health information networks, leading to the replacement of the term *hospital information systems* by *health information systems* [59.2]. Likewise, institutional medical records are being integrated into interinstitutional electronic health records.

A functioning and effective network only makes sense, however, if the nodes in this network (i. e. the participating operational information systems in the health care institutions) are available and are suitable for actually setting up this network and bringing it to life. This makes it clear that a critical success factor for the further development of the health care system is to provide health care institutions with appropriate institution-

based information systems (operational information systems such as hospital information systems, medical surgery systems, emergency services information systems, etc.) and with staff with the necessary expertise.

The majority of medical information about an individual is gathered and documented in hospitals. This applies in particular to those groups mentioned initially, the chronically ill and those in old age. Essential medical procedures both of a diagnostic and therapeutic nature – which are significant also in later life and thus for further care – are performed in hospitals. The information that finds today its way into the out-patient sector is generally a brief case summary, often produced too late, which certainly helps to provide a quick overview but which is unable to answer detailed questions transparently.

It is evident that health information networks are inconceivable without well-designed and well-functioning hospital information systems, and it can even be argued that hospital information systems are the backbone of health information networks. This is also true since many problems and solutions from the microcosm of the hospital are of relevance in the macrocosm of the health IT networks. Moreover, with their EDP departments hospitals can take on the running of active network nodes for entire subregions.

In conclusion, it can thus far be determined that hospital information systems are not only a critical success factor for the respective hospital management but also collectively play a significant role in national health systems.

59.2 Necessity, Objectives, and Benefits of Comprehensive HIS

59.2.1 Necessity

The need to use comprehensive hospital information systems (HIS) is the result of four fundamental aspects:

1. The hospitals are placed under a high level of pressure with regard to their effectiveness and efficiency. This situation is manifested, among other things, in the obligations to provide proof and to communicate data, but also in complex compensation systems, for example by means of the widely used diagnosis related groups. (DRGs). Effective operational management is still only possible on the basis of a direct costing with an orientation towards medical economics and with all the necessary upstream

and downstream components. Detailed information about individual treatments are necessary for this, which can only be gathered and used via a HIS that is used across the board.

2. The translation of medical knowledge – which is made available faster than previously known by means of electronic media and the Internet – into everyday clinical work can barely be achieved without appropriate support in terms of information technology. Context-sensitive tools are required, which – ideally used during individual treatment – provide the physician, in a direct and uncomplicated form, with relevant accessible information that is present in the HIS or in corresponding medical databases or knowledge bases for the particular current patient-based problem.

3. The implementation of guidelines and the organizational coordination and streamlining by means of clinical pathways cannot be achieved effectively without corresponding supporting IT functions.
 4. It is clear from the statements made at the outset that hospital information systems play an essential role in the development of a health information network and in the care of patients as a whole. No efficient and networked health care system is feasible without high-performance hospital information systems.
- Ensure continuous quality monitoring and improvement
 - Enable information to be provided to patients, staff, and the general public
 - Improve coordination/cooperation with internal and external partners
 - Provide an electronic medical record.

Fundamental *operational objectives* – which follow these strategic objectives – are:

Against this background, the question of high strategic importance is how hospitals – which ultimately produce intangible commodities such as health, recovery and relief – handle the most important production resource for the production of these commodities, information. A critical success factor for efficient medical practice – and therefore for quality, efficiency and cost effectiveness – is the fast and comprehensive availability of up-to-date information about examinations and tests. In this respect, the availability of a high-performance hospital information system for every hospital is a fundamentally crucial factor for quality, business success, and competitiveness.

59.2.2 Objectives of Using Information Technology in Hospitals

The objectives of using IT in hospitals must – as in all fields of application – always be subordinate to and derived from the business objectives. In this respect, every hospital must establish these objectives in detail. For an overview of information management and information systems architecture, we refer to [59.3–5] and for health information systems we refer to [59.6, 7].

It is generally accepted that the following *strategic objectives* can be specified:

The use of IT in hospitals must:

- Provide extensive support for the work of the management
- Enable optimization of the revenue situation
- Create cost and performance transparency
- Enable administrative procedures to be rationalized
- Contribute towards making medical organization and decision-making processes effective
- Reduce patient throughput times (examinations, operations, in-patient hospital stays, etc.)
- Make medical organizational and decision-making processes transparent

- Safeguarding of the current modes of payment and obligations to provide proof, improve liquidity → *revenue transparency*
- Introduction of (extended) basic documentation, uniform coding software: → *transparency of patient case mix*
- Operational systems in materials management, personnel management, technology, catering, etc. → *cost transparency*
- Comprehensive optimum activity recording → performance transparency, operational transparency
- Enable direct costing/activity-based costing → *transparency in the use of resources* (personnel, equipment, etc. for case groups)
- Medical organizational and documentation systems for specialist departments → *organizational transparency, transparency of documentation*
- Documentation of treatment processes, their outcomes, and their adherence to guidelines → *transparency of health care processes needed for the improvement of quality*
- The Intranet/Internet as an information medium for the different target groups → *transparency of the hospital* (e.g. for employees, patients, and the general public).

59.2.3 Potential Benefits

The potential benefits of data processing in hospitals are wide-ranging. If we draw the analogy that a hospital information system represents the brain (in this sense the memory) and nervous system (information transmission, control, monitoring, status information) of the hospital, then the enormous significance and the potential benefit of a HIS become clear.

A hospital information system:

- Enables an overall view of patient treatment
- Contributes towards integrating the different professional groups

- Relieves the medical personnel from having to duplicate work and from administrative overhead
- Enables quick access to documentation of earlier treatment
- Enables quick access to current medical knowledge
- Enables better coordination and reconciliation, e.g. using a scheduling module, and thus prompt control and regulation of the operational processes
- Enables continuous quality monitoring
- Contributes towards an increase in the quality of treatment
- Helps to avoid unnecessary examinations and tests
- Provides information about the costs accrued and their origin
- Creates operational transparency
- Helps to save costs
- Contributes towards patient satisfaction
- Increases the attractiveness of the hospital to referring doctors, patients and the general public
- Gives a competitive advantage as a result of having a suitable range of services and a faster response to market changes
- Creates a database for research in the field of clinical epidemiology, but also for health economics.

It has been shown that information technology can reduce the rate of errors by preventing errors and adverse events, by facilitating a more rapid response after an adverse event has occurred, and by tracking and providing feedback about adverse events [59.8].

However, information processing – with its nature of being an interdisciplinary technology – only provides these benefits if implemented in a balanced and coordinated manner in all operational areas, and this, therefore, requires a complete operational IT strategy. In situations where there are limited finances, strategically controlled and coordinated gradual expansion of the HIS in a hospital, therefore, becomes particularly important.

59.3 Dimensions of IT Support

The aforementioned objectives and potential benefits can by and large only be achieved if – irrespective of the degree of distribution and the integrated component systems – all aspects of IT support in the hospital are taken into consideration within the hospital information system. Major dimensions of the support provided by IT systems in hospitals are as follows.

59.3.1 Data Processing Support

Support of the processing of data, in the sense of performing complex calculations, transformations, and data conversions. For example, ascertaining the billable DRG (diagnosis related group) from available documented clinical case details. A more clinically orientated example is the calculation of dosages, for example of infusion rates. Monitoring systems also ultimately fall into this category.

59.3.2 Documentation Support

Support of documentation by providing the relevant electronic forms and text systems in order to create documents and archiving them in electronic folders. In the area of documentation relevant for billing relating to diagnoses and procedures, more complex IT modules with thesaurus functions and checks are also used. If terminologies enabling detailed descriptions – such

as SNOMED – are not used, documentation support is limited. This limitation also affects decision support, e.g. when reminders can or cannot be generated from collected data. Semantic interoperability between information systems is likewise made more difficult.

59.3.3 Organizational Support

This includes support of organizational tasks and resource allocation planning (appointment schedules in diagnostic departments, bed management in wards), with process handling using a workflow management system, and support of treatment using clinical pathways.

59.3.4 Communication Support

This includes support of the internal communication in the form of communication of results, and also support of handover/shift changes, increasingly also communication with external partners. Communication support is closely linked to efficient documentation support and also to improved access to information. The integration of results and diagnoses in doctors' letters can, therefore, speed up the process of generating medical reports and improve the important communication between the in-patient and out-patient sectors. The communication of referrals is increasingly gaining

Table 59.1 Dimensions of IT support and examples of HIS functions

Dimension	Example
Data processing support	<ul style="list-style-type: none"> – Determining the billable DRG – Determining case-based process costs – Calculating profit margins – Calculating diagnosis-group related cost distributions – (Continually) calculating essential basic statistical measures, such as average length of stay, capacity utilization, etc. – Generating statistics and evidence (required by law)
Documentation support	<ul style="list-style-type: none"> – Billing-orientated documentation of diagnoses and procedures – Clinical diagnosis documentation – Documentation of procedures performed along with the corresponding results, e.g., the documentation relating to surgery, anaesthesia, test results and much more – Documentation of symptoms – Documentation of important incidents and events – Documentation of medication – Doctors' reports, documentation of case summaries integrated in an electronic medical record
Organizational support	<ul style="list-style-type: none"> – Appointment schedules/resource allocation planning in out-patient clinics and hospital departments – Bed management on wards – Workflow management to support the execution of examinations and generation of documents/results – Use of clinical pathways and standards of care for treatment – Monitoring of the completeness and promptness of billing documentation
Communication support	<ul style="list-style-type: none"> – Associated operational communication in the form of a service request or results confirmation (service communication, order entry/result reporting) – Transmission of case data to health insurers – Forwarding of discharge letters to the referring doctors – Internal operational email communication
Decision support	<ul style="list-style-type: none"> – Context-sensitive access to fact and knowledge bases – Clinical reminders and warnings, e.g., during order entry – Context-sensitive monitoring of test results

in importance in hospitals. When issuing referrals, reminders and warnings can be generated by checking the data.

59.3.5 Decision Support

This includes support of decision-making processes by means of operational knowledge management for

context-sensitive provision of current knowledge (e.g. access to guidelines) based on given facts (e.g. alerts in case of drug interactions, etc.). Reminders and warnings are highly relevant tools for decision support [59.8, 9].

The most important functions of HIS with respect to these dimensions of support in hospitals are shown in Table 59.1. Examples of successful HIS implementations can be found in [59.10–12].

59.4 Case Study

The intention here is to illustrate, with reference to an example of a short, fictional course of treatment in the first two days of a patient's hospital stay – and thus of an in-patient case – the fundamental aspects of support provided by HIS in terms of hospital management.

Mrs Maier – an elderly lady – is to receive an artificial hip. A date has been agreed with Mrs Maier and her GP for her to be admitted to hospital on 21 February 2011. The IT support for the organization of this starts even before the effective hospital stay, due

to anticipatory bed management and resource allocation planning – in the case study, a bed has therefore already been booked for Mrs Maier for the expected length of stay of 9 days.

If Mrs Maier then appears at the admission desk on the planned admission date, after briefly supplementing the information already present through central admissions – where the additional details necessary for billing can be found – she can then go directly to the ward, where a bed will already have been allocated to her, both

Fig. 59.1 Ward overview, including bed occupancy

in reality and also within the hospital information system (Fig. 59.1) via drag and drop. The corresponding functions with a graphical overview of bed occupancy are today realized in practically all HISs. Furthermore, double-clicking on the *bed*, demographic data, the patient's next of kin, the key caregivers, and staff also currently dealing with the patient, as well as already known critical information, are now added on the ward (Fig. 59.2).

In order to further support the treatment process, many hospitals are working on the introduction of *clinical pathways*, which determine – on a diagnosis-specific and treatment-specific basis – which procedures should be carried out in the time scale. In our case study, the corresponding pathway for a total hip replacement is as accessed for *process initialization* and uploaded into the patient's patient record. In this electronic patient record, after the allocation of the bed all the necessary procedures that are to be performed are therefore already entered automatically over time (Fig. 59.3). The fact that these are still *undone* – i. e., yet to be completed – can be seen by the status abbreviation (“r” for requested, “pl” for planned, “a” for appointment). For all special procedures in the HIS parameterization it is defined as to which types of documents/information objects (form, image, video, audio note, or report) should be recorded over all, when this procedure is finally performed. So the view of treatment process not only shows the past and future procedures over time, but also the information objects and their state (white = object still not recorded; red = object recorded, but not accessible for others than the author; green = object is entered and can be viewed by authorized users), so ev-

ery user gets an overview about state of procedures and state of information objects that have to be recorded. With a double-click on a *green* = existing information object, authorized users can take a look inside the object in a simple way. Admission to the ward is likewise already documented, and direct access to the admission data and the referral form for authorized users is possible via the “*green form*” icon in first row of the line with the procedure *patient admission*.

In the next step, the physician on duty now performs the medical history check and the clinical examination and documents the results electronically. During or after the completion of this procedure, he completes the diagnosis documentation (Fig. 59.4), which is also important for the later DRG billing and electronic transfer of billing data to the health insurance fund. Because Mrs Maier is also complaining of difficulty breathing, the doctor uses the electronic order function (Fig. 59.5) to order an additional chest x-ray, additionally to the clinical pathway. On the same afternoon, in addition to the other planned procedures in the laboratory and in the x-ray department, a corresponding chest x-ray will, therefore, also be performed. The processing in the x-ray department is done using electronic job lists, which show the planned examinations for each x-ray workstation and which are then used for activity recording. Performance data, x-ray images are, therefore, available on the ward straight after the examination has taken place and, shortly afterwards, the electronic results i. e., the radiologist's report, are also available.

The next morning, the electronic medical record appears as shown in Fig. 59.6. All of the planned procedures of the previous day have been carried out (status

Fig. 59.5 Using the electronic order function to order an additional chest x-ray, additionally to the clinical pathway

“ar” = activity recorded or “rw” = report written), and the reports and forms can now be viewed directly via a double-click on the green icons (in the figures shown in gray). As also becomes clear from the process-orientated electronic patient record, on the previous day the OT administrator scheduled the operation for 11 o’clock (“a” = appointment given). It is also evident that, in addition to the pathway procedures included, a chest x-ray was carried out at 12:38 on the previous day.

A further account of the course of treatment and the activity-based control thereof and detailed documentation by means of the HIS should be dispensed with at this point. Overall, it has become clear that process documentation is generated within a short space of time to accompany the treatment using a modern HIS, and this process documentation creates a high level of organizational transparency and transparency of documentation – everybody involved in the treatment process has access to the important information necessary for completing his or her task and is informed in real time of the status of the course of treatment. It is also important that, at the end of the in-patient treatment, all of the information is included in the case summary – the summarizing assessment – and that the details for this can be (semi)automatically taken from the electronic medical record. This is used both to promptly send the discharge

letter – potentially also in electronic form to the referring doctor – and to electronically transfer the billing information to the health insurance fund within a short space of time. For internal purposes, activity-based costing can also be carried out on the basis of the course of treatment stored in the HIS, and this activity-based costing can be used to determine the cost amounts for individual patients and diagnosis related patient groups.

On the whole, the example shows how an HIS makes the processes in hospitals more effective by supporting data processing, documentation, organization, and communication and significantly increases the clinical and administrative transparency for all those involved. Time-consuming telephone calls such as “Has Mrs Maier already been x-rayed? Where is the OT report, has it been written yet? Which services can be billed for?” are, therefore, just as much a thing of the past as the lack of economic transparency in hospital activities. HIS, therefore, supports all of the operational matters on a functional level and also supports the economic processes and the decisions on a management level. An important extension would be the transfer of de-identified data into a data warehouse.

We want to note that structured documentation of medication is needed if warnings or reminders are to be generated in the case of drug–drug interactions or contraindications. There are European countries, how-

ever, where such a structured documentation is not in widespread use. Likewise, the implementation of

decision support tools varies significantly between European countries.

59.5 Architecture and Components of HIS

59.5.1 Logical Architecture Model

Architecture models act as a reference system and thus provide a general basis for discussion and understanding for all those involved in a design and discussion process. Essentially, a distinction must be made between models from the view of the user (owner’s representation) and from the view of the computer scientist (designer’s representation). Figure 59.7 shows a logical architecture model of a hospital information system – i. e. not orientated towards technical networks, protocols and computer levels, but orientated instead towards organizational units and specific application solutions and thus towards the view of the user (owner’s representation).

The following component information systems can be identified.

The Administrative Information System

All the applications for *administration* and *logistics* are subsumed under this subsystem. If this also previously always included the patient data management system, then it becomes increasingly clear against the background of the new billing legislation that this should be regarded as an independent component, since it includes functions that are vital for all other information systems – even the medical ones.

The Patient Data Management System

This includes all of the *functions for the management of patient data that are necessary for accounting and for meeting the legal obligations to provide proof*. This includes the relevant and basic functions for the admission, discharge, and transfer of patients (ADT). Due to the current development in the legal context and the associated obligations to provide proof, the volume of previously simple administrative data has been expanded significantly with medical information (diagnoses, explanations, categories of care, diagnostic/therapeutic procedures). In this hybrid function – i. e. containing administrative data but also important medical data – the patient data management system is of particular importance. A bed management planning module can also be subsumed under this subsystem.

The Medical Information System

The medical information system includes all of the applications/information systems to support the documentation and organization of medical organizational units. On account of the various different orientations and the necessary specific functions of the individual modules for each application area, the medical information system itself can be subdivided into:

- Specialist department systems – e.g., surgical information systems, anaesthesia information systems,

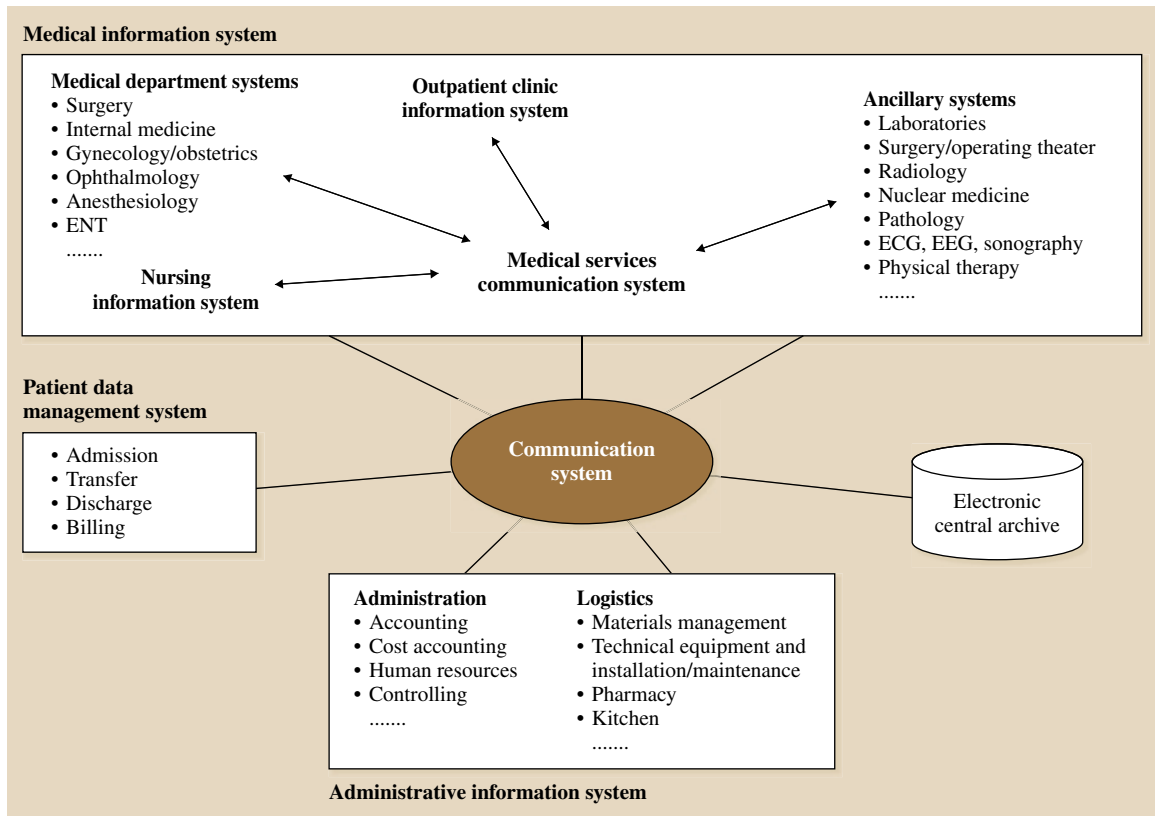

Fig. 59.7 Logical architecture model of a HIS

gynaecological information systems, etc., support the documentation of specialist medical information and also the other more subordinate purposes of documentation, such as quality management, obligations to provide evidence, billing, etc., in a specialized way within the specialist department. In addition to supporting documentation, these information systems support the medical decision-making process not only by quickly making available the most recent results by means of the service communication system, but by also allowing access to knowledge bases and electronic textbooks linked to the HIS. By means of a treatment planning module, they allow problem-based or diagnosis-based standards of care for treatment to be stored on a department-specific basis and used as a basis for planning in the case of specific treatments.

- Systems for the support of out-patient clinics – Tasks requiring specific support in out-patient clinics can be considered in particular to be the effective support of scheduling and appointment manage-

ment, the effective support of out-patient treatment processes in terms of an interdisciplinary workflow, and also the documentation of specific services and out-patient billing, which is particularly sophisticated and complex in Germany.

- Diagnostic department information systems, systems in ancillary departments such as laboratory information systems, radiology information systems, pathology systems, operative documentation systems, etc., provide integrated specialist support for organization, documentation, and communication for specific diagnostic departments (function-testing departments). In addition to the very specific documentation and special workflows, whose effective execution increases throughput, special medical technology components are also incorporated here such as the online connection of laboratory analysis equipment to the laboratory information system or of the imaging modalities to the radiology information system, etc. As in out-patient clinics, diagnostic departments in which patients are ex-

amined directly also require effective appointment management.

- The clinical information system to access and manage clinical data and to communicate with other systems. This central module manages documents such as discharge letters and coded diagnoses and procedures. It collects reports and results from ancillary systems, communicates with the ADT system, and requests services from other systems. It is often based on a central repository. It provides the typical order entry/result reporting functionality. An order entry module replaces the traditional request form with online requests on the monitor and enables orders to be booked in directly on systems of ancillary departments. The individual placing the request has the option of accessing the status of his order at any time and receives the test result quickly in electronic form at the earliest possible moment.
- Nursing information system to support the planning of nursing care, nursing records including making graphs, and nursing quality management.

Ideally, a complete electronic patient record – that is to say a paperless digital collection of all treatment documents – will be possible as a result of the interaction between these various medical information systems and their components. Often, however, electronic data and paper documents coexist. Digital archives with scanned paper documents are about to change this situation.

The Communications System

From the point of view of the user, this is understood as being the service communication system described above. On a technical level and on the basis of the topology model in Fig. 59.7, however, the communications system is to be understood as an *information processor* to link, by means of software technology, a wide range of different application systems in order to enable data communication between these application systems (e.g. between specialist department systems and laboratory and radiology systems, etc.). Technically, this component is mostly based on asynchronous messaging with an interface engine or *integration engine*. Service architectures are beginning to be used more often (e.g. enterprise service bus).

Interdisciplinary Applications

This includes *applications that are of interest for many departments/users*, such as report writing and administration, diagnosis coding, knowledge servers with

various databases such as the Red List, Medline, etc., office communication, spreadsheets, etc.; in the broadest sense, a nursing records system and a scheduling module are also interdisciplinary in character.

59.5.2 Implementation Alternative: Holistic Versus Heterogeneous

Besides the logical architecture, another important feature of hospital-wide information systems is the implementation in terms of software and hardware technology and the potential – which may also be determined along with the implementation – to distribute the solution between different components of the hardware infrastructure [59.2, 6, 7].

Holistic Information System

The software for all the system components to be found in the logical architecture model comes from one manufacturer and is based on a data model with an overall concept, meaning that the entire HIS is conceptually holistic, while the software can also be segmented in a modularized manner into components that can be operated individually in order to enable it to be better maintained and distributed (Fig. 59.8).

Heterogeneous or Best-of-Breed Information System

The software for the components listed in the logical architecture model comes from various different manufacturers who all work with their own data models and data storage. Communication and data synchronization between these systems is carried out using

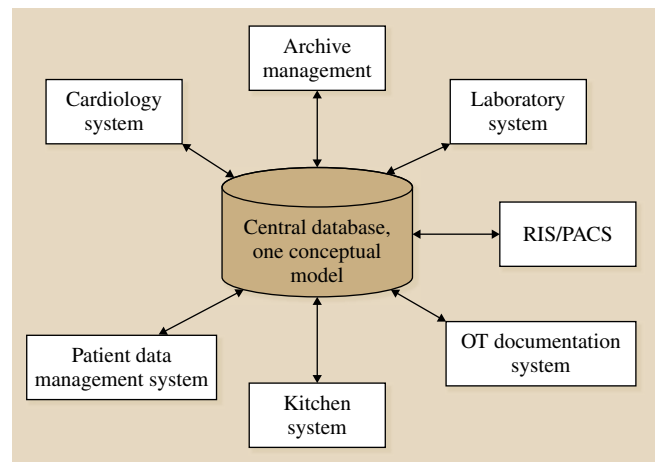

Fig. 59.8 Example of a holistic HIS

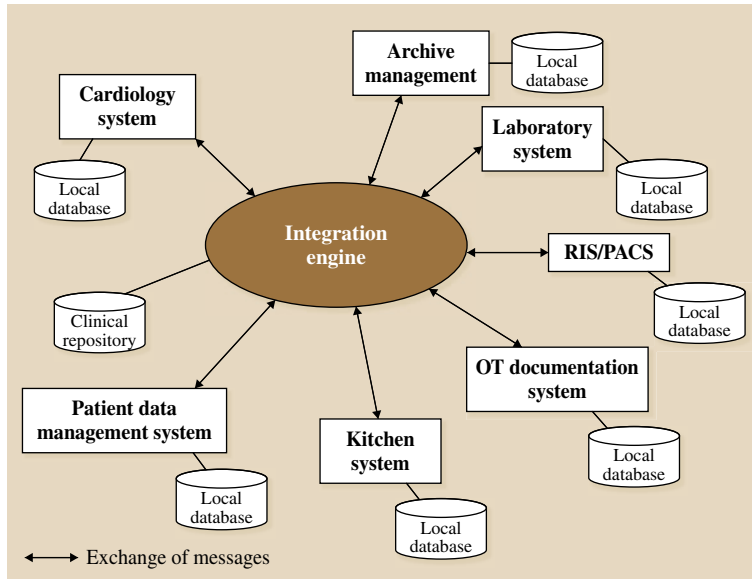

Fig. 59.9 Example of a heterogeneous HIS

Table 59.2 Advantages and disadvantages of the two approaches of a holistic and heterogeneous information system

Holistic = all applications from a single manufacturer	Best-of-breed = applications from different manufacturers
+ If necessary, one conceptual model	– Various conceptual models
+ One vendor, one contracting party	– Interface problems
+ Less maintenance required	– Various user interfaces
+ Consistent user interface	– Various data storage systems
+ No duplicated data storage	– High level of maintenance required
– Few single medical functions	+ High level of adaptation of the individual systems to the terminology, semantics, and workflow of the field of use
– Dependent on one manufacturer	

appropriate linking software, e.g., an interface engine or integration engine (Fig. 59.9). This approach is known as best-of-breed. Data from different systems are usually replicated in a common physical repository. The use of virtual repositories, i. e., of federated approaches is a less common alternative. Service oriented architecture (SOA) will play an important role in the future.

Selection of the technical specifications of the HIS determines in particular the necessary effort in terms of maintenance; the more inhomogeneous a system is, the more maintenance work is required.

Both the holistic and the best-of-breed approaches to the problem have advantages and disadvantages, which are the reverse of one another. Table 59.2 shows a comparison.

In accordance with the complex and diverse nature of hospital information systems, various different types of suppliers have developed, who for the most part can be divided into the following three categories:

1. Holistic vendors, who provide a full spectrum of solutions (e.g. a clinical information system, RIS, PACS, nursing information system, etc.) in a single, integrated system. In principle, it is not necessary to integrate further systems from other manufacturers. These solutions are generally very broad in scope but sometimes go into little depth in the specific functions. Attempts are increasingly being made to implement individualization using form generators for medical data entry and management. The basic marketing point here is the integrated solution – referred to as *holistic HIS* in Fig. 59.8. Behind the scenes it may become clear that many overall solutions do not consist of holistic software with a uniform underlying company data model, but are assembled from systems bought from different makers who communicate with one another via coupling mechanisms. Thus, the similarity to a heterogeneous approach may be higher than expected.

2. Holistic vendors who often offer a comprehensive administrative system (ERP), sometimes connected to a central clinical repository. Contrary to 1, they do not cover the full functional spectrum, and, therefore, connect any desired medical subsystems thereto in a more or less complex manner (leading to a *heterogeneous HIS* (Fig. 59.9). The shared contents such as patient data, test results, etc., must be held in multiple locations and synchronized by exchanging data records (known as communication records) between the systems involved, which is often done using a communications server.
3. Specialist suppliers, who may be called niche vendors, who – usually – provide highly competent and self-contained solutions for subareas (laboratory, radiology, hygiene, etc.) and can be integrated into heterogeneous HISs by means of data communication.

Practice has shown that the larger a hospital, the less the use of a holistic information system is able to meet the demands. This can be illustrated using an example. Whereas in a 200-bed hospital the radiology department has 2 x-ray machines and this diagnostic department can be supported using the interdisciplinary service communication module of the holistic HIS, a radiology department in a 1200-bed hospital has 16 x-ray machines and further test machines, and has a complex organization. In this case, the IT support is expediently provided using a special radiology information system with a connected picture archiving system (PACS) and an online link to the individual imaging modalities.

59.5.3 Integration Aspects of Heterogeneous HIS

With a heterogeneous approach, communication between the systems is often carried out by exchanging messages. The individual systems integrated into the HIS must, therefore, have the following functionalities:

- An import module for receiving data records
- An export module for transmitting data records
- Suitable internal database structures for storing the received data (often one central repository is used)
- Dedicated functions (programs) for displaying/processing the data received from other systems.

The resulting situation is complex, as many systems have to communicate with many other systems. Therefore, an interface engine or *integration engine* is often

used, which assumes the coordination and processing of communication between the various systems and also has the function of converting messages from a transmitting system into a format that can be processed by the receiving system.

On account of the complexity of the process of coupling heterogeneous systems in medicine and on account of the need for a solution of this kind in virtually all health care systems, development of the communication standard HL7 (health level seven) began in the 1980s. This communication standard includes a standardization of message types, i. e., a definition of syntax and semantics for the data records to be transmitted. If medical systems support this standard (both for import and export), they can then be coupled with one another with reduced effort and reduced costs. Figure 59.10 shows an example of the composition of a message type.

The current HL7 version is 3 [59.13]. It uses XML and has introduced the reference information model (RIM) and the clinical document architecture (CDA) [59.14]. The CDA Release 2.0 provides an exchange model for clinical documents (such as discharge summaries).

Because of these efforts it is conceivable that, against the background of international standards, the

integration of medical application systems from different manufacturers will become increasingly easy, even if this cannot compensate for the fact that a central entity

within the HIS is necessary for the management, and above all for the long-term archiving, of the electronic medical records.

59.6 Current Trends and Prospects

As the preceding illustrations have shown, hospital information systems are now comprehensive operational information systems for hospitals that support all aspects of the operational, tactical, and strategic dealings in hospital management. It is particularly important that the functionalities are adapted to a given degree and further developed in accordance with the changing general set-up of hospitals. This is accompanied by changes in the technical basis. We already have seen a development from 2-tier to 3-tier and n -tier client server implementations, and we see a development of the middleware layer with increasing use of SOA.

From the application perspective, we foresee changes in:

- Medical documentation
- Integration of medical technology
- Networking with external institutions
- Support for patient safety
- Decision support for doctors
- Integration of genetic data.

59.6.1 Medical Documentation

Medical documentation has become more fine-grained and process oriented, and it will become more and more paperless.

Order entry and result communication have been implemented in many hospitals, and this functionality will be developed further. The documentation of specialist departments has taken center stage as part of the drive towards a paperless hospital. This documentation for the specialist departments differs considerably between the different departments and must, therefore, be edited on the basis of the existing forms and converted into an electronic format. Interdisciplinary collaboration will be a focus, such as the interdisciplinary documentation of tumors. The implementation of fine-grained follow-up documentation is generally carried out by means of a tool – usually a forms generator – supplied by the manufacturer of the hospital information system, which enables the hospitals to implement specific documentation functions be-

yond the standard range of functions of the system supplied.

Standard terminologies are still a central challenge, and it is difficult to predict if more countries will introduce standards like SNOMED.

A relevant development towards paperless hospitals is electronic archiving. Paper-based archives will be replaced by electronic systems, comprising documents generated by computers or scanned paper records.

59.6.2 Integration of Medical Technology

The development of comprehensive paperless documentation encourages the demand for integration of information that is actually acquired by means of medical technology systems. Whereas, in the field of radiology for example, this development is largely complete as a result of the integration of modalities with PACS and radiology information systems, there are a large number of medical technology devices – such as ECG machines, EEG machines, pulmonary function testing devices, cardiac catheter measuring stations, and many more – which for the most part these days likewise record, process, and store information in digital form, but which are simply still not equipped to be interoperable such that they can communicate with other systems without any problems via standard interfaces. Considerable individual developments are still in part necessary here, but a convergence between medical technology and information technology has begun. With this integration, it is conceivable that the discontinuity between media that exists today and the distributed storage of patient medical information will increasingly be a thing of the past and that a paperless, integrated, electronic patient record, including data and documents from medical technology devices, will become available centrally in the hospital information system.

59.6.3 Health Information Networks

Hospital information systems have in the past largely been focused on assisting all aspects of the dimensions of support within a hospital which were mentioned at

the beginning of this chapter. However, the ever more intensive integration of the care sectors and the accompanying need for effective cooperation and coordination between hospitals, referring doctors, medical care centers, nursing facilities, and out-patient care services also results in a considerable requirement for electronic networking between the individual information systems of these different care providers.

In many countries, regional and national health information networks have been built or are about to be built. International standards on the terminology level (SNOMED, ICD) and on the level of structure and communication (HL7, DICOM, IHE) are of relevance in these efforts [59.6, 15].

Many hospitals have, together with their HIS-vendors, tried and pursued methods of setting up information technology networks with other institutions. So-called hospital portals are used to give referring physicians the option to access, via a secure Internet connection, selected, specially provided medical information concerning the patients referred by them and to not only view this information – usually information in the form of documents, such as reports, results and discharge summaries – but also to download this information onto their local information system at the doctor's practice and to manually integrate it into their electronic index. This is done on the basis of a sophisticated access rights system, so that every referring physician only has access to the information relating to his patients and also only with the consent of every patient.

These portals have the disadvantage, however, that doctors in private practice who cooperate with multiple hospitals may have to use portals that operate differently. As a result of this development, it therefore seems advisable that automated communication of such information be implemented on the basis of transparent interoperability between hospital information systems and systems in doctors' practices. First specifications for electronic doctors' letters and projects for the exchange of such electronic doctors' letters have since been initiated. As part of two relatively large cooperative German project initiatives (eFA, electronic case record and EPA 2015, electronic patient record), current standards for technical and semantic interoperability between hospital information systems and other information systems of care providers are being developed with a physically or purely logically central patient record infrastructure. The aim is for all care providers to be able to upload any important documents generated as part of a patient's care and also

detailed information, such as diagnoses, symptoms, and procedures, into a cross-institution electronic patient record such as this without any great difficulty, and thus to generate cross-institution transparency in the treatment process and the patients' specific situation, which will provide every member of staff involved in the patient's medical care with the important information in an effective and complete way. The informational self-determination of the patient and also the best conceivable security mechanisms must also be taken into consideration here.

For collaboration with the external systems, the hospital information systems require, on the one hand, an interoperability module that undertakes the technical communication with the external systems and health information network components and, on the other hand, require an extension of the internal function of integrated electronic mail inboxes and outboxes, by means of which users can access received documents and information and manually or automatically file them in the corresponding internal electronic patient records. Furthermore, it needs to be clear in the patient documentation which documents and information are of external origin or have been sent externally.

59.6.4 Decision Support for Health Care Professionals

Since the hospital information systems contain an increasing amount of clinical data, this clinical data provides the informational basis for decision support that has to be combined with knowledge, which may be represented in guidelines and pathways. A highly relevant example is the safety of drug therapy. If prescriptions and medication are documented in the HIS, then stored information can be used as the basis for checking interactions, and in the case of prescriptions contraindications can be checked and referred to on the basis of the documented diagnoses and other medical data. If the documentation is based on vocabularies and ontologies, advanced support can also be provided. It is then possible, for example, to specify possible treatment methods for certain diagnoses or to point towards the existence of clinical pathways or guidelines.

It has been shown that health information technology can reduce medical errors [59.8]. A review of medication-related clinical decision support in order entry systems has been provided in [59.16]. An example of a pragmatic approach to implementing best practices for clinical decision support systems can be found in [59.17].

Health information systems need, however, to be designed or implemented properly, as they may also induce medical errors [59.18]. We expect a growing focus on system design aspects [59.19].

59.6.5 Support for Patient Safety

Development in the health care system and in particular in hospitals has allowed productivity to increase more and more for doctors, too. There is often only a little time for communication about the patients when there is a change of shift, etc. More than ever, doctors are reliant on receiving optimum support in their patient-related collaboration through the hospital information system. On the whole, it is about maintaining and increasing patient safety within the framework of hospital treatments.

Patient safety means that a patient does not come to any harm during treatment and is not exposed to any potential health risks. Patient safety is taken very seriously worldwide. Reports on medical errors have occurred since 1991, leading to a better understanding of causes and the role of information technology in error reduction [59.8, 9, 20–22]. It can be assumed that, with the increasing penetration of IT into the medical areas of hospitals, the demand for patient safety to be supported by (pro)active, intelligent mechanisms in the HIS will also become ever more intense.

Risk management, together with incident reporting, will be of growing importance [59.23]. Various different facets and aspects can be presented here, such as:

- Structured risk assessment and presentation, and also constant and context-sensitive reference to existing risks for prescriptions and planning of procedures

- Documentation overview to give a brief patient-based overview of all the important and new information
- Support when performing procedures or when responding to unplanned incidents by displaying check lists
- Integrated messaging system, including active messaging using the HIS to send messages to the doctor on duty or the assigned doctor when new results arrive, if desired, depending on the type of results and with the ability to set different parameters depending on the patient
- Support with medication, right up to intelligent functions such as alternative medical treatment sites (AMTS), etc.
- Computer *integrated* radiology system (CIRS)
- Generation of clear transition reports.

59.6.6 Genomic Data

Health information technology plays an increasing role in translational medicine, which aims at transferring knowledge and techniques from basic research (from bench) to the development of new treatments (to bedside) [59.24]. One of the most significant developments will be the use of genetic and genomic data in clinical practice. This means that substantial security measures must be implemented and ethical considerations must be made in relation to the use of supporting information systems, because genetic data and dispositions concern not only the patient but also his/her relatives. The increasing use of genetic testing and the identification and use of biomarkers will open a completely new dimension for medical documentation, which requires special privacy protection and thus special protective mechanisms within hospital information systems.

59.7 Selection and Implementation of HIS

59.7.1 Preliminary Remarks

The implementation of information systems in the clinical areas of a hospital results in highly complex and sensitive operational sociotechnical systems, whose functionality only achieves the desired operational and strategic results if, once the system is implemented, all those involved find themselves in a working situation that is at the least consistent but preferably improved. It is, therefore, very important that, when preparing, se-

lecting and implementing clinical information systems, the various design dimensions of operational information systems – such as the organizational structure, process organization, documentation, technical infrastructure, and user acceptance, etc. – are taken into consideration at an early stage.

The greater the extent to which an information system is implemented in human spheres of activity, the more all of these dimensions of design need to be taken into consideration. No procurement processes should,

therefore, be entered into and no implementation of information systems should be carried out without precise knowledge of the given macroscopic and microscopic organization, without reflecting the aims of an information system in the aims and tasks of an organization and without any knowledge and consideration of users and the people affected.

The selection of a hospital information system must be conceived as a distinct project. Only in this way is it guaranteed that a reliable and safe decision will be reached. For this purpose, up to 10% of the total investment volume must be used to finance the selection process.

In order to be able to methodically come to a reliable purchase or development decision based on the particular requirements and the current state-of-the-art technology, the following phases must be gone through:

- Preparation phase (general and project-specific preliminary work)
- Project planning
- System analysis
- Drawing up an invitation to tender
- Selection
- Drafting a contract
- Acceptance and implementation
- Early operating phase.

These phases are necessary both for relatively large projects for the implementation of entire hospital information systems and also for smaller projects, e.g., the implementation of department information systems such as radiology or laboratory information systems.

Important milestones in the narrower sense are the completion of the system analysis, sending out the invitation to tender, conclusion of the contract, and putting the system into operation.

Those activities and circumstances whose implementation are seen as critical success factors in the overall process – and omission of which jeopardizes the success of DP projects or results in less than perfect solutions – are listed below in the form of check lists.

59.7.2 Project Phases and Critical Factors

Preparation Phase

A DP project generally begins with initiation of this project: recognized weak points should be remedied, statutory changes necessitate the use of data processing, resources for increasing effectiveness should be

used, an outdated system can no longer continue to be operated, etc.

The aims drawn up here are often too short-term if the selection and use of a system is only orientated towards this initial motive, and the chance to remodel the operational organization with appropriate information technology is squandered! In contrast, the use of information technology should be geared towards the operational aims – on both an organization-wide and departmental level.

It is generally assumed that guidelines for the use and procurement of DP processes already exist within the hospital. If this is not the case, these guidelines should be defined immediately. In addition to technical standards and stipulations, they can also include specifications with respect to operating and ergonomics.

Important activities in this phase are, therefore:

- If necessary, define/amend business objectives
- Fix the objectives for the use of IT (derived from the business objectives)
- If necessary, define/amend DP guidelines
- If necessary, use the DP guidelines as a basis for general standards and stipulations
- Broadly define the project idea and project objective.

Whilst, with the exception of the last activity, these involve general guidelines and standards that ideally are already defined, the last stage that is necessary is to at least describe the specifically planned project and the initial reasons behind it.

Project Planning

Project planning involves laying all the necessary foundations in order to take on the operational project work. Orientated towards the basic set-up established by the general preliminary work, *at the end of this phase clear decision-making, reporting, and documentation structures must be defined, as well as the project responsibilities and authorities.*

Irrespective of the size of the project, there should be a separation between the strategic/tactical planning/monitoring (by a project steering committee) and the operational implementation (by a project working group). As a result, an appropriate compromise can be reached between decision-makers, representatives of the various different people affected, and the individual user groups. The project working group should consist of selected representatives of the individual occupational groups, and the amount of time that they spend working in this group pro-rata should be clarified.

The following activities should be considered during project planning:

- Forming and implementing the project steering committee with:
 - Inclusion of the management
 - Inclusion of management functions from the organizational units involved
 - Involvement of the staff committee.
- Forming and implementing the project working group with:
 - Involvement of selected representatives from the project steering committee
 - Involvement of representatives of all subsequent user groups
 - Involvement of the data processing and organization department
 - Involvement of the data protection representative.
- Definition of the project objectives:
 - Strategic objectives by the project steering committee
 - Operational objectives by the project working group.

Once these two essential groups have been installed and the objectives of the project are also set, the project-based authorities and responsibilities must be defined and all those involved and affected must be informed. It is, therefore, necessary to take into account the:

- Definition of the project-based authorities and responsibilities
- Clarification of the basic setup (staff, rooms, equipment, etc.)
- Clarification of the financing framework
- Clarification of internal resources
- Clarification of external resources/inviting offers
- Initialization and setting up of project documentation
- Rough project scheduling
- Provision to those affected with initial information and information of the project-based authorities and responsibilities
- Drawing up/update of the operational DP framework.

Once this phase has been completed, all of the decisions necessary to implement the project should then be made. It is particularly important here to provide all those involved with initial information and to keep them

constantly informed. If possible, the new media should itself be used for this purpose (email with distribution lists, Intranet with corresponding project pages, etc.).

System Analysis

The selection and implementation of information systems require a high degree of operational transparency. Ultimately, for all projects for the implementation of clinical DP systems, this involves intensive migration projects that are focused on complex and sophisticated medical documentation. One of the most fundamental critical success factors for DP projects, particularly in medicine, is, therefore, the performance of a system analysis that is sufficiently detailed in terms of the knowledge and objectives of interest. It is only the results of this that generally form the basis for a definition of requirements and corresponding organizational considerations. In the past, however, it has become apparent that many hospitals at most economize on this phase – essentially on the ground work of a project – and often even entirely omit a system analysis and a definition of requirements based on the particular needs!

When carrying out the system analysis, various approaches can be used, depending on the knowledge of interest and the project objectives:

- Horizontal procedure – all of the affected operational units are examined with respect to a certain aspect (e.g. forms)
- Vertical procedure – some of the operational units of interest/all of the operational units affected are examined in detail as a whole
- Process-orientated procedure – all aspects are surveyed along defined operational (main) processes – also across organizational units.

The following activities should be performed:

- Factorial analysis
- Equipment analysis (staff, DP systems and data storage systems used, hardware and operating systems, other equipment)
- Structural analysis (rooms, network infrastructure, etc.)
- Quantity structures (numbers of cases, performance figures, etc.)
- Communication analysis
- Documentation analysis
- Organizational analysis
- Accounting analysis
- Weak-point analysis.

On account of the sophisticated and complex medical documentation and the organization, which is based heavily on the division of labor, the focus and the main costs are for the most part on:

- Documentation analysis:
 - Medical/accounting- and financial-controlling-based/legal
- Organizational analysis, including analysis of main processes:
 - Admission, discharge, transfer, emergency admission
 - Communication of orders (organizational means?, coordination?)
 - Communication of results
 - Report writing, including results
 - Internal interdisciplinary procedures (medical – administrative).

With the exception of interdepartmental process analyses, the analyses listed are generally to be performed with reference to specialist departments or based on diagnostic departments to be considered in isolation.

A weak-point analysis is often omitted for reasons of time or finance, or for political reasons. It is precisely this weak-point analysis that can be used with particular advantage to identify the possible potentials for improvement and increased effectiveness by means of a DP solution, and also to identify the requirements for a system that is to be procured. However, weak-point analysis means openly and honestly compiling, identifying, and communicating these weak points – which essentially means creating an organization quality circle and is, therefore, often bypassed.

At the end of the system analysis there is a correspondingly structured analysis documentation, which is used as the basis for all subsequent phases.

Drawing up the Functional Specifications

This phase can be split into the subphases:

- Creating the target concept
- Drawing up the functional definition of requirements
- Compiling the functional specifications.

The *target concept* (Fig. 59.11) serves the purpose of developing and defining the organizational, technical, and DP-procedural target on the basis of the results of the system analysis. This should as far as possible be done taking into consideration the design dimensions of operational information systems. This must in par-

Fig. 59.11 Influencing factors on and sources of the EDP target concept

ticular involve developing a clear projection of the final state of the project (that is to say which operational actions and process chains should be supported and which information objects are to be managed, etc.), orientated towards the operational objectives and the weak points found.

Furthermore, at this point in time it is possible, taking account of the various information sources available, both to check the strategic objectives and also to carry out a sophisticated derivation of the operation objectives of using the DP system.

The development of a target concept taking account of the factors cited above can ideally be done by moderated workshops. These workshops can be conducted both at a management level and at an operational level, and the moderator has the results of the system analysis as a background and can thus control the interactive development. The result is a target concept that has been jointly developed and accepted by all those involved, which contributes considerably towards the acceptance of the further project progression.

This target concept is then expanded further to give a *definition of requirements*, which contains all of the functional, operational, and organizational requirements for the system and is a central part of the functional specifications. The formalization and operationalization of the requirements and the expansion to include general principles for information systems are the focus of this. All of the requirements that are important for the decision and the sales agreement should be included in a structured and unambiguously worded form. The necessary additional information for sending replies must accordingly be enclosed.

The general section of the invitation to tender (introduction, terms, framework conditions) should include:

- Clear guidelines for filling out and responding to requirements

- Unambiguous eligibility requirements (e.g. minimum requirements)
- A stipulated closing date
- Names of contact people for queries
- The offer of a time-limited discussion (or alternatively a consultation)
- Envisaged time scale for the entire process
- A presentation of important parameters:
 - *Qualitative*: e.g. DP environment, interfaces, physical structure, existing cabling, etc.
 - *Quantitative*: quantity structures for numbers of cases, frequencies of examinations, number of users, etc.

Important individual activities in this phase are:

- Expand the definition of the objectives, including the business objectives and DP guidelines
- Draw up a target concept, e.g. based on questions such as:
 - Which recognized weak points should be resolved?
 - Where are the potentials to increase effectiveness?
 - Where and how can the quality of the medical work be improved by providing support?
- Define a step-by-step plan for achieving the objectives
- Set down decisive framework/boundary conditions
- Conduct a feasibility and financial viability analysis
- Form a representative definition and selection group
- Conduct market research
- Draw up a functional definition of requirements:
 - With broad inclusion of the users
 - Taking account of standards regarding structure, DP standards, etc.
 - Taking account of what is feasible and financially viable
 - Taking account of the necessary variability of the solution as a result of the target concept and definition of requirements
 - Taking account of the definition of the possible stages and timetables.
- Update the definition of the requirements for the functional specifications
- Draw up the invitation to tender on the basis of the functional specification
- Conduct the formal invitation to tender.

It is important here to ensure that the functional specifications are not too approximate but on the other

hand that they are also not set out in too much detail. The requirement, for example, for specific field lengths appears to be of little help, if not in fact counter-productive.

The catalog of requirements section is further subdivided according to various functional, technical, and strategical viewpoints. Figure 59.12 shows an example of a categorization system to which further details can be added.

The biggest weak point is often a catalog of requirements with questions/requirements that have not been formulated precisely enough or that in contrast presents too many opportunities for responses.

The following possible responses are in essence conceivable:

- Free text – Questions can be answered with comprehensive explanations (example: describe the procedure for admitting patients.). Questions of this type are strictly advised against! A comparison of the tenders and the responses is possible only with a great deal of effort, if at all, and is always dependent on interpretation.
- Although categories and explanations force a definitive answer (e.g. Is health insurance billing provided? Yes – No – Explanation: . . .), the categorized answer can often be qualified, hidden in the explanation. These types of questions become critical points in disputes within the scope of performance of a contract, if not before.
- Categories – A response is only possible on the basis of defined categories (provided – provided in part – not provided or yes/no, etc.). As a result, the assessment of the tenders and their comparison with the formal document can always be followed (no gray areas of interpretation). Moreover, it is sometimes useful and also acceptable to allow a measured value as an answer (e.g. maximum number of machines that can be connected, minimum storage space, frequency of mask changes for certain work, etc.).

Selection

Once the tenders have been received, they must be evaluated. The *evaluation of tenders* concerns both the formal part of the tender and also the parameters stated beyond the formal part of the tender. The formal part of the requirement should be weighted before the tenders are received. For each level in the requirements hierarchy, 100 points are given, for example (Table 59.1). Based on the responses by the tenderers, a total number

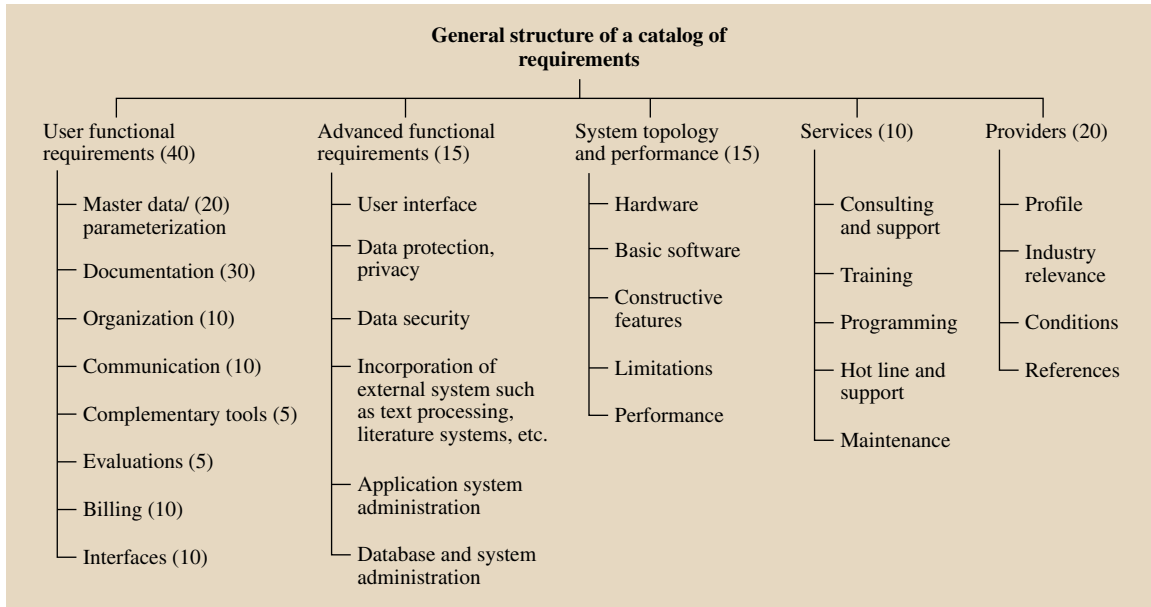

Fig. 59.12 Example of a categorization system for the catalogue of requirements with some example weightings

of points can then be calculated for the whole requirement part, which is a measure of the fulfilment of requirements. Reference should be made to the common process of cost–benefit analysis.

An important step is, after receipt of the tenders, first of all to filter these tenders so that the incomplete tenders or those that do not meet the exclusion criteria are not included in the further – more labor-intensive – selection process.

It is also necessary to go through the main stages:

- Evaluation according to the specified weightings
- Establishment of the total costs (one-off costs/running costs)
- Establishment of the costs for each point
- Establishment of the ranking (according to the absolute number of points/according to the costs per point).

The two rankings can be truly illuminating. Whereas the first ranking indicates who is offering the most in terms of function, the second indicates who will provide the most cost-effective product – irrespective of the degree to which it achieves the objectives. Depending on whether the two results correspond or differ to a vast degree, a strategic evaluation must be made with regard to available functionality and available means.

At the end of the selection process, there should be two to a maximum of three tenderers remaining, whose solutions then undergo *on-site reviews* (i. e. use in live operation) or who beforehand give in-house presentations, with all members of the project group participating. It is also helpful, for presentations at the tenderer's premises (i. e. not for on-site reviews), to specify particular case studies or cases and to allow these to be used as part of the presentation.

Important individual activities in this phase are:

- Continuation and intensification of the informal market research
- Definition of typical operational business transactions, in other words chains of medical treatment as case studies for appraisal of the solutions
- Evaluation of tenders, if necessary involving:
 - Querying, defining more precisely
 - Formal assessment and prioritization
 - Appraisal of the solutions
 - Visiting reference customers
- Informal research/validation
- Decision-making process and decision
- Putting down in writing the necessary product-related additions/amendments:
 - Clarifying ambiguities with existing modules
 - Defining the customizations/additions necessary according to the functional specifications.

Drafting a Contract

The contract should be drawn up based on the invitation to tender with the help of a professional. Faith in assurances – which in the past has all too often been tested – should be contractually translated into services owed. Consulting legal experts in the field of software law can clarify this early on and prevent disappointments. Drafting of a contract involves not only the acquisition of usage rights but also the agreement of necessary services in order to install and implement the information system. A clear definition of the division of tasks and the responsibilities is, therefore, particularly important.

Important individual activities in this phase are:

- Specification/fixing of amendments/additions
- Definition of the external range of services offered
- Definition of the contractual services: usage rights and maintenance and services
- Definition of the project of implementation
- Definition of the segregation of duties between the supplier/customer
- Definition of the responsibilities.

Acceptance and Implementation

The acceptance phase involves handover of the entire product to the customer, who then checks the product to determine whether it performs the contractually guaranteed services by means of suitable functional and quantity-orientated acceptance tests. A whole series of preliminary work is necessary in the hospital, which amounts to preparing the system for productive operation. In this respect, the work necessary for implementation of the system is necessary even before the acceptance phase, and acceptance can often only take place following a test phase in live operation because of the impracticality of testing the real operating situation.

The implementation itself can be divided into arrangement, system preparation, system adaptation and implementation, training, preparation for start-up, and start-up.

Important individual activities are as follows:

- Setting the stage technically in good time:
 - Locations and space requirements for terminals clarified?
 - Cabling sorted out from a technical and time-planning perspective?
 - Installation site for the server settled?

- Procurement of hardware, if this is not an integral part of the service owed
- Installation of a project-planning (testing) and training environment
- Definition of a training and support plan (e.g. multiplier principle)
- Gathering master data, collecting necessary documents
- Training for system operation and the project-planning group for:
 - The operating system
 - The database system
 - Application functions
- Acquiring master data (range of services, organization, employees, etc.)
- If applicable, data transfer from the existing system into a test environment, cleansing, and restructuring
 - Parametrization of functional aspects (workflow, dynamic masks, etc.)
 - Interface implementation/testing
 - Training plan for up-to-date training of all employees
 - Informing all the employees affected
 - Organization of system operation
 - Organization of first-/second-level support, fault-clearing service, call-out service
 - Installation of the entire application system (live system)
 - Quantity and load tests
 - Interface implementation/integration test
 - Setting up the production environment
 - Transfer of historic data into the production environment
- Checking all the prerequisites:
 - Have all of the necessary interfaces been implemented?
 - Are all of the interfaces functioning?
 - Has all of the master data been gathered/historic data been imported, etc.?
- Distribute user documentation.

Early Operating Phase

In the early operating phase, it is particularly important not to leave the user alone and leave the operation to run. The intended effects must now be checked with an orientation towards the target concept and, if necessary, further operational or technical system optimizations must be performed. Furthermore, user acceptance must be continuously checked in the first few weeks in order

to draw conclusions from this concerning any necessary organizational changes or the need for further training:

- Check/optimize organization
- Performance evaluation and technical system optimization
- Check correct usage
- Evaluation of user acceptance
- If necessary, conduct further training
- Checking the system functionality (functional specifications versus current status), if necessary further specification and further requirements for subsequent improvements.

59.8 Conclusion

Hospital information systems are a crucial success factor for the successful management of hospitals. The potential benefits are great, but these benefits only become accessible when the information system is used across the board. With respect to the technical architecture, the choice is between using a holistic overall system or a heterogeneous overall system that is composed of several systems.

The implementation of information systems in hospitals requires a much more cautious approach than is the case in many other sectors. This is firstly because the core tasks – namely the direct treatment and supervision of sick people, the care given to them, catering to their needs correctly, the personal contact and connection – must not be disrupted by the use of a DP system. The system as a tool must remain in the background. This is also to remove the fears of staff and patients in this sensitive environment and to prevent these fears arising. This is a serious difference from the use of data processing in most other sectors, where core tasks (e.g. dealing with accounting records, management of materials, issuing materials, etc.) are modified and changed directly by using DP systems. However, adequate involvement of the users affected in the entire process of system selection is, therefore, of particular importance.

Critical success factors for the implementation of hospital information systems are varied, and all of the activities of the project phases described above can in this respect certainly be regarded as critical success factors.

Essentially, however, the following questions must be regarded as particularly critical:

Further Influencing Factors that Are not Phase-Based

- Continually informing and identifying the management
- Continually involving and informing the employees
- Solutions provider/manufacturer
- Application system:
 - User interface/suitability of the tasks
 - Level of maintenance required
 - Flexibility/adaptability
 - User documentation
 - System documentation
 - Design of the hardware
- Plans by the manufacturer.

- Is the project objective sufficiently clearly defined (not DP for the sake of DP)?
- Have the framework conditions (financial/organizational/internal political) been settled on?
- Has a clear project organization been determined?
- Have all of the responsibilities and consequences been sufficiently defined, so that the objective can also be achieved?
- Is the management behind the project?
- Is the project adequately staffed?
- Is there a clear time schedule for the project?
- Have the employees been provided with sufficient information at an early stage?
- Does a system analysis form the basis for a target concept, which itself in turn serves as the basis for the definition of requirements?
- Is sufficient employee involvement guaranteed in the definition of requirements and the selection process?
- Are the functional specifications laid out in a sufficiently refined and realistic manner?
- Is the selection process transparent?
- Has the agreement been sufficiently worked out, and are there provisions in the event of (partial) non-performance of guaranteed services?
- Is there a clear and realistic implementation plan?
- Has sufficient training been provided?
- Has the implementation of the system in everyday operation been thought through sufficiently?
- Have all the interfaces necessary for operation been sufficiently tested?
- Is there a suitable strategy and tools for user support?

- Will checks be continuously performed to ensure correct use following implementation?
- Does the solution comply with the standards with regard to the criteria of ergonomics?

If these aspects have been given sufficient consideration, a hospital information system, which has thus been successfully implemented, can make a substantial contribution to the business success of a hospital.

60. Telemedicine in Germany

Rüdiger Klar, Ernst Pelikan

In Germany there are now many successful special applications of telemedicine. However, these projects are mostly not extendable to the whole nation because of the highly complex German healthcare system, limited funding, heterogeneous information technology (IT) standards in ambulatory and hospital care, the insufficient official electronic health card, different data protection and privacy regulations of federal and state governments, doubts of physicians and patients, as well as unequal costs and benefits for the different actors in telemedicine. The solutions of these problems are: better legal regulations for seamless interaction of ambulatory and hospital care, improved IT standards and support of the interoperability of telemedical and other healthcare IT, adaption of healthcare organization, workflow, and reimbursement for telemedicine services, and better information and education of all actors about the necessity and limits of telemedicine. There are no doubts about the benefits of telemedicine, but to achieve these advanta-

ges for the whole healthcare system in Germany will require much work, time, and good will.

Telemedicine is understood as meaning the use of telecommunications and informatics for medical applications. It is intended to improve the quality, economic efficiency, and transparency of medical care. Telemedicine uses the instruments of telematics to support communication and interaction between doctor and patient and between doctors within the framework of medical care over physical distances. Countless individual telemedical projects with often impressive solutions are increasingly being described around the world, for example ten times a year in the e-journal *Telemedicine and e-Health* [60.1] or for Germany in the annual anthology *Telemedizinführer Deutschland (Telemedicine Guide, Germany)* [60.2]. Important telemedical concepts and solutions are being developed by various scientific or practice-orientated professional societies and institutions or by industry, such as by the Deutsche

Gesellschaft für Medizinische Informatik, Biometrie und Epidemiologie (the German Society for Medical Informatics, Biometry, and Epidemiology) [60.3], the Deutsche Gesellschaft für Gesundheitstelematik (the German Society for Health Telematics) [60.4] or the Deutsche Gesellschaft für Telemedizin (the German Society for Telemedicine) [60.5], as well as by many IT firms collectively in the Bundesverband Gesundheits-IT (the Association of IT Manufacturers in Health Care) [60.6] and by various institutions such as the Zentrum für Telematik im Gesundheitswesen (the Center for Telematics in Healthcare) [60.7], the Gesellschaft für Telematikanwendungen der Gesundheitskarte (gematik – the Society for Telematics Applications of Health Cards) [60.8], and the Deutsche Institut für Medizinische Dokumentation und Information (DIMDI – the German Society for Medical Documenta-

tion and Information) [60.9] (particular mention should be made here of its endeavors to achieve semantic interoperability). European institutions are also involved, such as the European Medicine Agency (EMA) with its functions for the regulatory communication of data for pharmaceuticals [60.10]. Attempts are also being made to evaluate the benefits of telemedicine for patients and citizens, for the doctors involved, and for other staff in the healthcare system.

Even though the qualitative benefits are sometimes difficult to measure, they are still the focus of the objectives of telemedicine. In the case of common disorders such as diabetes mellitus (German Electromechanical Society (VDE): “Telemedicine saves millions in the treatment of diabetes”) [60.11] or cardiac insufficiency [60.12, 13], particularly high goals are set but are still barely reached. However, the benefits of telemedicine are already clearly discernible for a great number of other, less prevalent diseases.

The quantitative benefits of telemedicine are likewise often cited and are said, for example, for the health system in the USA in the case of electronic prescriptions, to be worth an incredible US \$27 billion per year and to avoid an additional 130 000 serious medication errors annually [60.14]. It is typical of such estimations of success, however, that the outlay for the electronic prescription system in the USA and the problems in terms of its acceptance are not mentioned. However, in Germany, at least, there are also thoroughly critical portrayals of the electronic prescription system which discuss these problems [60.15].

In the case of the many individual telemedical projects, it is striking that they are generally – at least in Germany – isolated from one another, and re-

main projects rather than products. Large-scale projects for the healthcare system are necessary to facilitate interaction between a telemedicine project and the conventional information systems as well as between different telemedicine projects. Discrepancies and system differences between a wide range of different forms of documentation must be avoided, harmonized interoperability (technical, content-related, organizational, and process-orientated cooperation) between various communication and storage technologies is necessary, the operational procedures in medical and administrative healthcare processes must be taken into consideration, and, above all, the boundaries in particular between ambulant and stationary care and the other sectors of the healthcare system must be overcome.

The introduction of the electronic health card (e-HC) began in 2006, and the associated legislation on health telematics may make an essential contribution to solving these problems for telemedicine. However, the advances made in this regard are considerably behind the original planning, and for outsiders, decisions which are barely comprehensible make this project more difficult. As a result, *increasing fatigue* is generally being observed, even among the leading protagonists of telemedicine [60.16].

The aim of this chapter is therefore to provide a critical account of the advantages of telemedicine for Germany and of its current status, but also of its limitations. Experiences with telemedicine projects at the University Medical Center in Freiburg will also be briefly discussed to illustrate our assessments by means of examples. Greater detail on the incorporation of telemedicine into health telematics in Germany as a whole can be found elsewhere [60.17].

60.1 The Peculiar Features of German Telemedicine

German telemedicine differs considerably in some aspects from telemedicine in other countries and has different – unfortunately mostly less sufficient – characteristics, at least where cross-sector projects are concerned, such as the transfer of diagnosis codes, for example, from the hospital to the Kassenärztliche Vereinigung (KV; the local state association of statutory health insurance physicians)/health insurance company, sometimes with and sometimes without additional identifiers and naturally in a different syntax. The intention here is therefore to present the most important peculiar-

ities of German telemedicine and its parameters so that the reasons for these differences also become clear.

60.1.1 Supporting Individual Projects

The introduction of new technologies into the healthcare system begins, as is completely sensible and practical, with small straightforward pilot projects. Even in the preliminary stages of a German telemedicine project back in the 1980s, for example, a radiological picture archiving and communication system (PACS) [60.18]

within a hospital information system (HIS) [60.19] was successfully tested. A lot of experience could therefore be gained with the technology and IT organization, standards of image compression and networking, and transmission of images and text, etc., and this experience is also extremely useful for expansion to a proper telemedicine system, in this case teleradiology, which extends beyond the individual care unit. Projects such as this have been and still continue to be relatively generously supported, and the specialist literature [60.2] every year describes dozens of such usually impressive projects. These projects regularly suffer from two basic problems, however.

1. They are usually only suitable for small and straightforward special applications, since for mass application in routine care they lack easy-to-handle interfaces to existing IT systems for data acquisition and data transfer. It is only in the case of special medical tasks that the additional work of redundant data processing and data control and the additional procedures are tolerated. In countries with a largely uniform IT structure for the healthcare system (as in the UK), this problem can be solved more easily, as the range of different interfaces is considerably smaller.
2. The individual projects in telemedicine rarely outgrow the care unit. Unlike the more state-controlled or centrally organized forms of healthcare provision in countries such as The Netherlands, Denmark, Sweden or Norway, the German healthcare system is fragmented, highly complex, and constructed with various heterogeneous areas of responsibility. For Germany's telemedicine system, this means that the great successes of such individual projects cannot easily be extended to the entire healthcare system. A quite considerable level of additional support is necessary, especially to expand beyond boundaries between different sectors and to integrate individual projects.

60.1.2 Legal Measures to Overcome the Disadvantages of the Fragmented Healthcare System

Even if such generous support for the integration of individual and isolated projects in telemedicine were to be awarded, this alone cannot overcome the barriers between the different sectors of the healthcare system in Germany. In order to do this, statutory and other le-

gal activities are necessary to facilitate and improve telematic communication in the healthcare system, and in the interests of the patient, good will is required from all participants to contribute with commitment and patience to the common goal of improved and more efficient care via telemedicine.

The first important steps have indeed already been made and must be continued: In order to overcome the biggest barriers in the healthcare system, namely those between the ambulant and stationary care sectors, in recent years medical care centers and integrated care have been made possible with the GKV-Modernisierungsgesetz (GKV-GMG; statutory health insurance modernization act), the GKV-Wettbewerbsstärkungsgesetz (GKV-WSG; statutory health insurance competition strengthening act), and the Vertragsarztrechtsänderungsgesetz (VÄndG; amendment to the law governing the activities of physicians in free practice) [60.20]. The medical services of doctors, nursing staff, and rehabilitation centers can now be provided and invoiced across the different sectors, centralized at specialist facilities. This makes it easier to use telemedical services across the different sectors. Initial successes show that, despite some problems and technical deficiencies, this process has been begun correctly.

Another peculiar feature in Germany is the complex and unclear cooperation between the self-administration system in the healthcare system and the governments at national level and federal state level. The intention is often for the self-administration system initially to develop collaborative plans with its – admittedly very heterogeneous – associations of the medical profession, health insurance funds, hospitals, pharmacies, rehabilitation centers, etc., in compliance with the law, but if this is not achieved within the prescribed time limit, the governmental departments must in the short term step in by means of substitute action. As a result, a great deal of time is lost, jobs are rushed leading to errors, and harmonious cooperation suffers.

60.1.3 Electronic Health Cards, Health Professional Cards, and Official Health Telematics

Applications of telemedicine focus on medical care, that is to say on the support of diagnosis and treatment over physical distances. In this respect, telemedicine should be seen as a subarea of health telematics. The planned telematics infrastructure will provide basic services which promote the interoperability of telemedical

processes. From this point of view it represents a harmonizing infrastructure which could blossom to become an integrating platform for further e-health applications. The official electronic health card (e-HC), the electronic health professional card, and the associated regulations for health telematics therefore play a crucial role in the peculiarities of the German healthcare system with respect to the legal framework conditions for telemedicine [60.8]. This involves one of the largest IT projects in the world, and cost estimate are in the region of several billions of Euros (by comparison, for the USA the costs of introducing an e-HC are estimated at US \$150 billion); 120 000 doctors in private practices, 65 000 dentists, 21 000 pharmacists, 2200 hospitals, and many other employees in the healthcare system are involved, as are naturally all of the roughly 81 million citizens with statutory health insurance and private insurance. The laws relating to this, which were passed in 2003, provided for the introduction of the e-HC as a chip card throughout Germany by 2006, which was of course impossible to achieve. As one of the first applications of telemedicine, the e-HC is intended to implement the electronic transmission of medical referrals and, in particular, prescriptions. These electronic prescriptions are intended to improve drug safety for patients (monitoring of indications and contraindications, drug interactions, questions concerning dosage, compliance, etc.), and the administration of medication should be more efficient for all those involved (doctors, doctors' assistants, pharmacists, accounting staff, etc.). Further telemedical uses of the e-HC are in electronic patient records. Significant problems and long delays in virtually all aspects of health telematics and the e-HC have by now unfortunately arisen in Germany, and it appears that an *intolerable story of the health card in Germany* [60.15] is developing. Modest approaches – such as that of Austria, for example – appear to be more successful [60.21]. Unfortunately, the basic concept for the German e-HC has also not been synchronized in advance with neighboring EU countries or brought into agreement with EU standards [60.21, 22] and also the experiences of other countries, for example, in relation to error-prone storage of the electronic prescriptions on the e-HC (one of the *blind alleys* of patients according to *Waagemann*) [60.23] instead of on servers in the health telematics network.

It must, however, be recognized that the e-HC for the first time meets a criterion that is crucial for telemedicine, namely that of unambiguous patient identification across institutions, including the possibility for authentication and signature. This makes it possible

to combine on a patient-orientated basis all of a patient's medically relevant data which accumulates at different times and in different places as part of the process of providing care and to make this data accessible to authorized individuals very quickly and in an adequately edited form. Incidentally, in the USA the absence of a *universal patient identifier* is regarded by an internationally renowned clinical journal as one of the five most important hurdles to introducing an electronic patient record and thus to telemedicine [60.24]. Without the e-HC, even if it has to be altered and expanded in some technical and functional aspects, it is not possible to successfully develop a comprehensive telemedicine system in Germany.

60.1.4 Medical Confidentiality, Data Protection, and Personal Rights

The observance of legal regulations and ethical principles relating to confidentiality in medicine, to the prevention of misuse of personal data, and in general to safeguarding of informational self-determination are essential concerns of telemedicine which necessarily are subject to an increased potential risk, as patient data from the traditional doctor–patient relationship also become potentially available elsewhere [60.25, 26].

This topic of data protection has become highly explosive in Germany. In 2007 the *Ärztetag*, the general meeting of the German Medical Association, rejected the e-HC with a significant majority as a *sociopolitical atom bomb* [60.27], mainly because of reservations regarding data protection, although the operating company responsible for introducing the e-HC, gematik [60.8], has developed a highly sophisticated technical plan for it. However, perhaps the complexity of this plan and even the easily comprehensible white paper constructed from it are a major reason for its rejection [60.28]. Educational work and risk analyses must therefore be performed in pilot projects, particularly from the point of view of the enormously important target group of the medical profession.

However, for patients too, dealing with the security technology which already has to be used to safeguard data protection sometimes seems to be difficult, inconvenient, and not very convincing. In addition, the majority of patients have not grown up with computers and many are very old, have dementia or are so seriously ill that they are hardly able to operate an e-HC with a PIN, an operating PIN or PUK, for example, or that it is barely possible to add prescription-free medication to the e-HC. Here, too, the process for access to

the telemedicine system must be designed to be user-friendly, training must be carried out, a campaign must be launched to convince users about it, and a great deal of patience is required.

Some statutory provisions and their interpretation must naturally also be considered. For example, according to the state official for data protection in North Rhine-Westphalia, emergency data on the e-HC must not be used when admitting patients to hospital. It must be reserved solely for treatment in acute emergencies. The storage of emergency data, which was planned as the heart of the e-HC, to a large extent thus loses its relevance [60.29].

60.1.5 Technical Standards

One prerequisite for successful use of telemedicine is the interoperability of the underlying components based on data and communications standards. Medical documents and structured medical data must be represented in a standardized way. In conjunction with terminology standards, semantic indexing also becomes possible. The extensible markup language (XML) represents a general technical basis for the exchange of data between computer systems, which is also suitable for standardized description of medical documents. Various specifications of standards in the healthcare system already rely on it. This includes the HL7-based clinical document architecture (CDA) [60.30], which is used as the basis for creating standards for the representation of patient-related documents in many international projects. In Germany, the AG Sciphox/HL7 has developed definitions for the doctor's letter, the letter of referral, and the hospital admission form. The preliminary work on the specification of the electronic prescription was also done on this basis. Earlier, sector-specific exchange formats for medical communication were developed in Germany. In the area of healthcare provided by statutory health insurance physicians, the xDT data storage exchange formats have become a de facto standard. Over the course of time, a full range of standards have developed which had been initiated by different organizational units. Interoperability across the boundaries between different sectors is only possible through harmonization of the previous standardization initiatives, however. Current development in Germany is also running in this direction. The local state associations of statutory health insurance physicians (KVs) in Baden-Württemberg, Bavaria, and North Rhine-Westphalia provide their doctor-to-doctor (D2D) users with the assistance of communication of doctors'

letters based on HL7 CDA release 2. The technical basis for this goes back to the VHitG initiative on *intersectoral communication*, in which companies from the software industry in the healthcare system described a guideline for implementation. The initiative is a further development of the existing specification according to HL7 CDA release 1, which is already supported in D2D.

Medical documentation as part of treatment processes is today increasingly carried out electronically in the form of electronic patient records (ePR) or electronic case records (eCR). To support communication between sectors in telemedical scenarios, a standardized architecture plays a key role for interinstitution electronic patient records. In addition to HL7 CDA as an electronic document standard, there are also a number of standards initiatives such as, for example, CEN/ISO 13606 Electronic Health Record Communication [60.31], the Standard Specification for Continuity of Care Record (CCR) from the American Society for Testing and Materials (ASTM), and the integration profile cross-enterprise document sharing (XDS) from the Integrating the Healthcare Enterprise (IHE) initiative [60.32]. An overview of these and other approaches to electronic health record (EHR) architectures can be found in *Blobel* [60.33]. It is necessary here to decide which framework architecture should be used as a basis, and in making this decision the prospect of interoperability with neighboring European countries must at least be taken into consideration in addition to national concerns. With its project to introduce the electronic health record, Austria has opted for the XDS profile and HL7 CDA as an electronic document standard for the transmission of medical results [60.21].

Because efforts towards standardization for specific implementations are at different stages of development, pragmatic initiatives are also very helpful in the interim. To accomplish harmonization for cross-project interoperable implementations, for example, for telera-diology applications, the Arbeitsgemeinschaft Informationstechnik (AGIT; German Information Technology Association) within the German x-ray society has developed a specification (<http://www.tele-x-standard.de>) for secure DICOM (digital imaging and communication in medicine) email communication, with which some manufacturers have affiliated themselves.

Project solutions existing today for telemedicine applications are barely integrated into the existing infrastructure of the primary systems of the relevant healthcare providers, but predominantly run alongside them. This has disadvantageous consequences for in-

tegration into the standard organizational processes. It is thus very desirable if a software architecture is chosen, abstracting from the specifics of primary systems via the provision of standardized services. For this purpose, an intermediate layer (middleware) must be used which provides web services for the typical requirements of telemedicine in terms of a service-orientated architecture (SOA). In this way, a standardized kit for telemedicine application can develop, which can be used to achieve service-orientated interoperability and which enables integration into the primary systems, without their specific implementations having to be known. This concept is exactly supported in the technological approach to telematics infrastructure. It would be desirable in this regard if appropriate services were provided in a defined and coordinated manner.

60.1.6 Acceptance and Benefits for Various Players in Telemedicine

As is always the case in highly complex, large-scale IT projects with extremely heterogeneous user groups and other involved players, the advantages of an IT system can hardly ever be felt equally by all those involved. For example, in the case of electronic prescriptions within the scope of the telematics project involving the e-HC and health professional card (HPC), significantly more additional effort is required by doctors than when writing conventional prescriptions (according to *Schweim* it takes 24 s instead of 2 s) [60.15]. Barely any immediate economical benefits or advantages of any other kind for the doctor can be recognized, but important advantages – in particular concerning drug safety – are expected for patients. Further improvements will certainly be found as a result of the test phases for introduction of the e-HC in different regions.

In telepathology, too, for example, 22 min are required to obtain a second opinion by means of a digital imaging and telepathology request, as opposed to 10 min for a conventional consultation request [60.34]. However, the German professional association of pathologists in 2007 described the issue of accounting as one of the barriers to telemedicine becoming established [60.35].

Radiologists have progressed slightly further in this regard, and teleradiological services can in principle be performed for emergency care without falling under the ban on remote medical treatment, but they have still not been included in the statutory health insurance catalog of standard benefits [60.36]. Our own experiences with a teleradiology project [60.37] demonstrate

that organizational integration, technical stability, and simple handling are important criteria for acceptance. However, sustainable use requires further agreements which regulate the framework conditions for the provision of services and payment for them. It would also be desirable, however, if it were no longer necessary for upgrades in the security architecture – right up to the introduction of electronic signatures for questions and treatment recommendations as part of a teleconsultation – to be implemented on a project-specific basis and therefore in an expensive way, but rather if these upgrades could be accessed as basic services of the telematics infrastructure. The health professional card, which has still not been implemented, or certain forms of electronic signature make practical use more difficult [60.38].

In this context, the fundamental problem must also be addressed, namely that telemedicine potentially compromises the doctor–patient relationship. There is the risk that, in this very personal and generally strongly desirable relationship, the computer has a distancing effect and that the face-to-face interaction, the reassuring handshake, and in general the psychosocial component of medical care suffer as a result. *Haas* [60.38] sees this as being one of the two major reasons why *in some cases the desire to use modern IT has given way to frustration*. Technically good solutions and very large future markets for IT are not enough to introduce telemedicine with lasting success and with beneficial results. From the point of view of the doctor, too, the doctor–patient relationship can be destroyed, as the patient may conceal medical data stored on the e-HC, for example. Will the patient tell the doctor about this? The doctor will therefore have to continue to keep a parallel medical history, involving extra effort and additional cost, in order to fulfill his duty of documentation (model code of medical ethics). However, he is significantly better able to research and use the information kept in the electronic medical history and, for example, to provide the patient with copies, too.

It is clear from all of the individual telemedicine projects in Germany that appreciable advantages are already being achieved, particularly for the patient. This applies in particular to teleconsultation, including obtaining a second opinion, care cooperation including transfers and referrals, telemonitoring by means of biosignal processing, treatment management for complex widespread diseases, and information for care provision for rare and high-risk diseases and emergencies. Interviews with experts and a survey within the scope of evaluation of the teleradiology projects in

Baden-Württemberg [60.39] confirm this assessment. These projects predominantly involve teleconsultations as part of stroke care and care for accident victims with head injuries [60.40]. The majority of surveyed participants affirm that teleradiology consultations increase the quality of the decision made by the attending doctor. The benefit for patients is mainly seen as being faster and more adequate care. The main aspect of this ben-

efit is the avoidance of unnecessary transportation and the fast provision of care during the night shift. The survey confirms that less time is required for diagnosis and treatment processes.

Not all of those involved are able to profit from telemedicine to the same extent. It is therefore imperative to create a win–win situation for as many of those involved in telemedicine as possible.

60.2 Consequences of the Peculiarities of the German System for Telemedicine

In an earlier account [60.17] we have already indicated some conditions for a successful telemedicine system. Taking into consideration the peculiar features of the German healthcare system mentioned above, but also on the basis of experience with individual telemedical projects and with the health telematics system which is currently being developed and the e-HC, we are now able to draw the following conclusions for telemedicine.

1. In the first instance, the current legal framework conditions must be improved on the basis of the varied and long-standing experience with individual telemedical projects, but also with the large-scale health telematics projects which are beginning. This involves in particular
 - extensive removal of boundaries between sectors in the healthcare system,
 - the option for healthcare providers to bill for telemedical services,
 - reliable financing of telemedicine as a standard benefit,
 - clarification of various concerns, particularly those of the medical profession regarding data protection,
 - harmonization with EU provisions and other international standardization authorities.
2. The technical integration of the e-HC and health telematics must be developed for telemedicine on the basis of an adequate and reliable technology. Basic telemedical care in Germany is not useful without the e-HC and health telematics system, but it still requires a telematics platform which is well designed and sufficiently well equipped.

3. This telematics infrastructure must be accessible to the tried and tested IT structure, some of which has already been in existence for decades, particularly to the IT structure of hospitals and doctors in private practice. Technical integration and migration aids must therefore be used for this purpose, such as middleware, SOA, EHR, and CDA.
4. Organizational changes, e.g., batch processing for electronic prescriptions, are already planned. More orientation towards processes rather than institution-orientated thinking, training courses about how to use telemedicine, educational work for all those involved concerning the benefits and the risks of telemedicine, and scientific monitoring to evaluate the telemedicine system – in particular in basic care – are necessary.
5. Clarification of the benefits of telemedicine must be conveyed convincingly, and the risks for patient and doctor, particularly in the psychosocial area, must be systematically reduced. Telemedicine must not have a negative impact on the personal patient–doctor relationship but must contribute towards reducing the distance between doctor and patient.

Taken as a whole, the benefits of telemedicine can no longer be disputed, even if its introduction into basic care in Germany still requires considerable expense, time, and patience. However, since – under the conditions listed here – at least five more years are still necessary to create the most important telemedical applications and introduce them across the board, work must now be continued with particular commitment, too.

61. Telemedicine Using Active Implants

Klaus P. Koch, Oliver Scholz

Telemedicine is the area of telematics that allows transfer of information, i.e., diagnostic or therapeutic data, between two locations (spatial distance) or times (temporal distance). This includes the bidirectional transmission network between patient and doctor as well as the transmission network between two doctors. Moreover, information can be transferred without material transport. In technical realizations, wired as well as wireless communication channels are used. The possibility to transmit medically relevant data has opened additional fields of application. Examples include consulting external experts during surgical interventions, transmission of physiological data/signals obtained by the patient at home, as well as distribution of data within a hospital. In the opposite direction, data should also be able to be transmitted to therapeutic devices to adapt treatment or to monitor device function. The fields of application extend, in this regard, from transfer of x-rays to forwarding of temperature values. Modern active implants normally come with a wireless communication facility to the outside world. In particular, in the latter area, energy supply to

each component also plays an important role and can be partially combined with the desired data transfer. In this chapter, the possibilities of telemedicine for the control of active implants are highlighted through a short overview of the application of telemedicine during operations and in domestic care.

Consultation of other experts during an operation is often possible only in large medical centers. With high levels

of specialization, this becomes increasingly difficult, because experts are mostly active in different centers.

61.1 Telemedicine in the Operating Theater

The application of remote data transmission offers a good, multimodal possibility to consult other experts in the short term (Fig. 61.1). Such systems also make sense for teaching and scientific exchange, for example, with live connection to an auditorium or conference hall. In modern operating theater systems, various imaging instruments such as endoscopes and ultrasound are used [61.1]. In addition to such direct diagnos-

tic devices, use of cameras to record the operative field and the operation room for meaningful representation of the operative sequence is advantageous. For control of imaging systems as well as communication and video conferencing equipment, appropriate devices must be available to the treating physician in the sterile area. This concerns in particular camera control to adjust the angle of view of the camera to

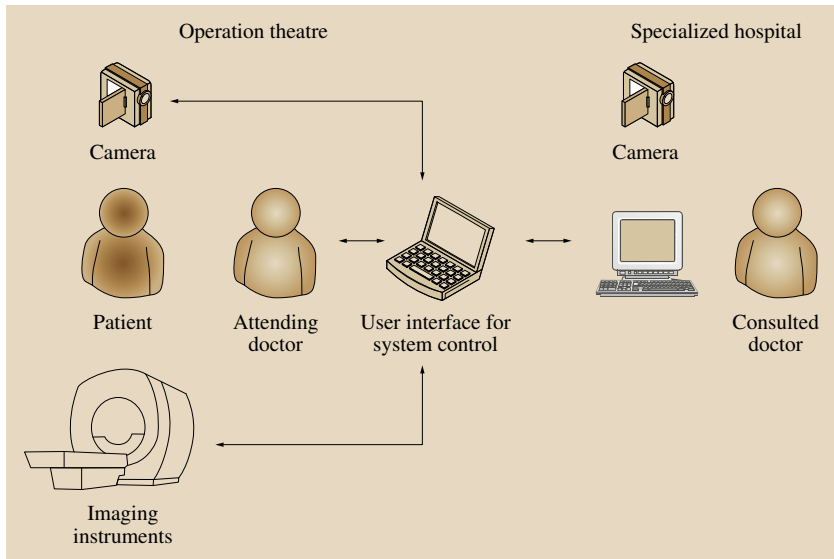

Fig. 61.1 System overview of a telemedicine-enabled operating theater

the actual operative situation. In addition, change of cameras and the link connection should be possible during surgeries from within the operating theater. Using

this technology, other experts can be consulted during complicated operations without having to move the patient.

61.2 Telemedicine in Domestic Care

For recording of medically relevant data in the home environment, a wide spectrum of devices are now available on the market, extending from devices for body temperature and weight measurement to devices to record electrocardiogram (ECG) or blood pressure. Many of these devices also have interfaces for reading out the data. When coupled to a so-called house base station, such data can be transmitted to a medical service when required. Direct point-to-point connection between doctor and patient is also a possibility, although not currently implemented. Server-based systems offer the advantage of greater availability [61.2]. Also, initial reception of the data can be done by medically trained nonmedical

staff (Fig. 61.2). In this way, the doctor can be relieved and thus the costs be reduced. To interface between the measuring instruments and the house base station, wired interfaces such as RS232 or universal serial bus (USB) as well as wireless interfaces such as Bluetooth are used. The house base station itself can use, in principle, a mobile phone or personal digital assistant (PDA) as a platform. Nevertheless, for many patient groups, simple operation is recommended, which is achieved rather by the development of a device [61.3], which may be as simple as an operating element that initiates only the data transfer. In addition, for wired connection of measuring instruments with mobile phones or PDAs, only an adap-

Fig. 61.2 Communication structure of domestic care systems

tor is possible. For the interface between the house base station and the server or medical staff, the possibilities differ mainly in terms of the interfaces available in the respective home environments, extending from telephone lines, integrated services digital network (ISDN) lines, asymmetric digital subscriber line (ADSL) connections, up to wireless global system for mobile communications

(GSM) connections. Beside the technical problems of the supply of a huge number of interfaces and the use of communication protocols with sufficient data security, legal constraints also have to be considered with regard to data protection. Beside the aspect of cost reduction, in many cases accommodation in the home environment is often more pleasant for the patient.

61.3 Implant Telemetry

In this section the application of different telemetric approaches is described using the example of implantable systems, extending from the problems of energy supply for each component to the different possibilities for data transfer. Strictly speaking, one understands by telemetry the obtaining of measured values from distant or inaccessible measuring points, requiring the transfer of values over a distance. In medical technology usage, the term “telemetry” is often used for transmission of measured data as well as control data. This can be done by wire, but also wirelessly. A simple form of contact consists in connecting implanted systems by wire through the skin (percutaneously). Nevertheless, for chronic applications, a higher risk of complications arises because of the corresponding high risk of infection or injury. Also from a cosmetic point of view, cables that enter the skin are unsightly. This explains why most active implants are wireless, i. e., passing through the skin (transcutaneous) to link with the outside world. For special applications, the percutaneous approach remains advantageous, because there are practically no restrictions on the signal and energy transfer. Therefore, technical advancements can be applied without exposing the patient to renewed surgical intervention. This is an advantage in particular during the development of new implants [61.5, 6]. For stimulation of the visual cortex, for example, 68 electrodes for use with a camera and an electronic system for stimulation of simple visual perception [61.4] (Fig. 61.3) have been implanted. Also, temporarily implanted systems can be operated effectively using such connections. Mostly the patient is under clinical care during the application time of such systems, so expert care of the percutaneous cable feed can be guaranteed.

61.3.1 Implant Telemetry by Means of Inductive Coupling

To provide energy supply to the implant, as well as to create a bidirectional interface for data transfer, in-

ductive interfaces are used. Here, the field created by an external transmitter coil passes through the receiving coil of the implant, transmitting energy to it based on the transformer principle. To send, in addition, data to the implant, the carrier wave of the transmitter can be modulated. For communication from the implant to the outside, usually the resistive load of the implant coil is modulated, causing a change in the transformer impedance and thereby the current in the external coil. The same principle can be observed in a classical transformer, in which the current in the primary circuit also depends on the load in the secondary circuit. This technique is used in cochlear implants because, in addition to the high data rate of several 100 kbit/s, the implant must be supplied with about 30 mW of power [61.7–9]. Currently, this approach is also used in the Freehand system, for stimulation of the arm musculature at carrier frequency of 10 MHz, for which as much as 90 mW is transferred [61.10]. In optimized cochlea implant systems (Medical Electronics), overall efficiency of up to 67% with transferred power of 250 mW has been achieved [61.11]. For implants with even higher power requirements, for example, ventricular assist devices, Dualis developed special inductive interfaces through which up to 50 W of power can be

Fig. 61.3 Percutaneous cable feedthrough for stimulation of the visual cortex [61.4]

Fig. 61.4 Model of an inductive interface

transferred [61.12]. Especially in cases where a high level of miniaturization is needed and only very short distances must be bridged, systems with thin-film coils applied on their own substrates can be used [61.13]. Alternatively, attempts have been made to integrate the implant coil directly onto the communication chip, e.g. for systems for measuring intracranial pressure. However, because of the small dimensions of the receiver coil, only ranges of a few millimeters can be achieved [61.14].

As an example for combined data and energy transfer through an inductive interface, a system operating at carrier frequency of 4 MHz is described in the following [61.15]. Communication from the external unit to the implant is realized through modulation of the carrier signal amplitude. For data transmission from the implant to the extracorporeal control unit, the load of the implant is modulated. Here, the transmitter oscillating circuit is modeled as a parallel connection (C_1 , L_1), and the receiver oscillating circuit as a serial connection (L_2 , C_2). The simplified description of the inductive transmission is based on a simple model of a transformer in which the coupling between the coils is determined by the real coupling coefficient k (Fig. 61.4).

The transmitter can be modeled as a linear voltage source with open-circuit voltage U_0 and internal resistance R_1 . The load on the receiver circuit due to the implant electronics is simulated by an ohmic resistance R_2 . According to the load modulation, different values are assigned to this resistance. An important index for transfer to the implant is the voltage gain A_f from the external voltage source to the load resistor in the implant [61.16, 17]. This describes the supply voltage expected at the implant U_2 as well as the transferred modulation amplitude of the carrier signal to the implant. In the applied linear model, this depends on the angular frequency ω of the carrier as follows:

$$A_f = \frac{U_2}{U_0} = \frac{i\omega k \sqrt{L_1 L_2} \frac{R_2}{1+i\omega C_2 R_2}}{(R_1 + i\omega L_1 + \frac{1}{i\omega C_1}) (i\omega L_2 + \frac{R_2}{1+i\omega C_2 R_2}) - (\omega k)^2 L_1 L_2} \quad (61.1)$$

Because the external unit should be transportable, it is battery operated, and accordingly has only a limited energy reserve. That is why the efficiency η also has to be considered during system design. The efficiency η is defined as the ratio of the active power taken up by the second side, P_2 , to the active power delivered by the voltage source, P_{tot} . In the considered case, the capacitance of the transmitter circuit has no effect on the efficiency, therefore

$$\eta = \frac{P_2}{P_{\text{tot}}} = \frac{k^2 \frac{L_1}{L_2} R_2}{k^2 \frac{L_1}{L_2} R_2 + R_1 \left(1 + R_2^2 \left(\frac{1}{\omega L_2} - \omega C_2 \right)^2 \right)} \quad (61.2)$$

The final parameter to consider is the change of the primary current ΔI on modulation of the load. This primary current depends on the ratio of the open-loop voltage to U_0 and the value of the total impedance Z_{tot} through

$$\Delta I = \frac{U_0}{|Z_{\text{tot}}(\text{with load})|} - \frac{U_0}{|Z_{\text{tot}}(\text{without load})|}$$

with $Z_{\text{tot}} = R_1 + i\omega L_1 + \frac{1}{i\omega C_1} + \frac{(k\omega)^2 L_1 L_2}{i\omega L_2 + \frac{R_2}{i\omega C_2 R_2 + 1}}$. (61.3)

To ensure safe operation of the transmission of energy as well as bidirectional data, optimization is necessary. This task should not be underestimated, due to the various system properties and their local extreme values and the different weighting of the properties. Another difficulty in this optimization lies in the range of variation of the parameters of the components of the transmission system. Thus, the coupling between the coils varies as a function of their relative position. Such problems can be alleviated by the use of intelligent positioning systems which indicate the effectiveness of the transfer to the patient. Further simplification of the positioning can be achieved by the use of permanent magnets integrated into the primary and secondary coils, which enables automatic positioning based on the

magnetic forces and independent fixation of the external coil. With all such systems, there always remains the possibility of greater variation due to movement artifacts or changing tissue layers (fat accumulation). In addition, the components themselves are subject to manufacturing tolerances and aging. In particular, aging and changes in parasitic effects are especially critical when considering systems of implanted components in contact with body liquids.

Although inductive linkage is very well suited to combined transfer of data and energy, it is sometimes used exclusively for data transfer, in particular for implants with complete titanium housing that only allows low-frequency fields to pass. This is especially useful if, as with some simple pacemakers, only a low data rate is required.

61.3.2 Implant Telemetry Employing Radio Communication

It is remarkable how implant telemetry has changed in recent years, in particular in pacemakers. Since in the beginning only a few parameters could be read or programmed, a slow inductive link was sufficient, for which a reader coil had to be placed immediately above the implantation site. To aid the *search* for the implanted device, implant manufacturers provided a means of communication. Today, such devices incorporate many more features, allowing more than battery status and heart beat to be retrieved, for example. Modern pacemakers and implantable cardioverter-defibrillators (ICDs) even record whole intracardial electrogram (IEGM) traces and store them internally. To provide a convenient means to read the large amounts of data in an acceptable time even over longer distances (2–3 m), these devices are equipped with radio interfaces. Since the titanium casing would excessively damp electromagnetic waves, an antenna is placed outside the case. In pacemakers, the antenna is usually integrated into the polymer terminal block of the electrode wires.

The problem with radiofrequency (RF) transmission from implants is the fact that body tissues impair propagation of electromagnetic waves due to their ionic conductivity. This absorption depends not only on the type of tissue through which the transmission must pass but also on the frequency used. To a good approximation, the absorption increases with increasing frequency. However, some particular frequencies are more strongly affected, in particular those at which wa-

ter molecules exhibit resonance, for instance, 2.4 GHz. Consequently, this frequency band is less suitable for implant telemetry.

Since radio waves generally propagate nearly unresisted, compared with light, strict regulations on radio traffic and channels used are necessary to avoid mutual interference or even jamming. Unfortunately, regulations differ among countries, so that it can happen that an implant of a patient cannot be read out abroad. This may occur, for instance, with implants that use the 868 MHz industrial, scientific, and medical (ISM) band, which is popular in Europe but is prohibited in the USA, where use of the 915 MHz band is instead widespread. As other devices apart from medical implants may use these unlicensed frequency bands too, definition of a RF band dedicated particularly to active medical implants and available worldwide is desirable. With the implementation of the medical implant communication service (MICS) band for wireless control and telemetry for medical implants by the International Telecommunication Union (ITU) this has been mostly achieved. Though the frequency spectrum that has been provided has to be shared with meteorological services as prime users, major problems are not expected [61.18]. In particular the overcrowded situations as experienced in the popular 2.4 GHz or 433 MHz bands (WLAN, wireless headsets, earphones, etc.) can be obviated.

The MICS frequency band lies between 402 and 405 MHz. The maximum permitted bandwidth of a MICS communication link is 300 kHz. This is sufficient to provide net transmission speeds of up to 528 kbit/s (four frequency shift keying, FSK) with Zarlink's ZL70110 transceiver chips, according to the manufacturer. An implant may initiate a communication link in emergencies only, in which case it is not required to ensure that the channel is free (listen before talk). In standard situations, only the base station may establish a connection, provided the channel is not already occupied by another link.

Presently, a number of commercially available devices already use the MICS band, e.g., implants from Medtronic and their corresponding CareLink programmer, or implants of Biotronik, St. Jude, and others. Besides pacemakers or implantable cardiac defibrillators, there exist other types of implants which make use of the MICS standard, such as implantable deep brain stimulators or blood glucose monitors. Even though not an implant in the strict sense, the camera pill from Given Imaging [61.19] transmits images taken of the gastrointestinal tract using a MICS channel.

61.3.3 Optical Transcutaneous Transmission

In cases where the transmission bandwidth of inductive links would be too low, or if one fears interference from other radio communication systems, optical transcutaneous transmission may be a viable option, provided that the skin and tissue layer to be crossed is not too thick. Examples in which this technique could be of note are, e.g., brain–computer interfaces, in which a disproportionately large amount of data [real-time multichannel electroencephalogram (EEG) recordings] has to be transmitted [61.20, 21]. Optical data transmission has also been used in fully implantable ventricular assist devices, because of the use of low-frequency magnetic fields for wireless energy transmission due to the large amount of electrical power demanded by the implant. Moreover, heavy disturbance of RF transmission channels by the operation of pumps was feared [61.22–24]. As early as the 1980s, several studies were carried out to analyze how well optical transmission suits implant telemetry [61.25]. However, transfer rates were at first rather low. Strong absorption and especially the strong dispersion due to body tissue constrained the possibilities. Nevertheless, optical transmission of data through the skin has been shown to be feasible up to 40 Mbit/s, albeit with high power demands (120 mW) and a comparatively thin skin layer (5 mm) [61.21].

One advantage of optical transcutaneous telemetry that should not be left unmentioned is the fact that the necessary components can be made very small. Indeed, manufacturers of RF transceiver chips promote their products by stating that one could implement single-chip radio solutions with them. In practice, this advantage proves to be illusionary, since additional components such as crystals, filters, and antennas are required. For optical transmission, there is no need for these devices. In place of an antenna, considerably smaller light-emitting diodes (LEDs) and photodetectors are employed. This was the main reason why, in an electrical stimulator for stimulation of the salivary glands in patients suffering from hyposalivation that had been embedded in an artificial tooth, optical transmission was used for device control [61.26]. The patient still had to open his/her mouth for successful transmission. In a more recent drug delivery system that was also embedded in a dental appliance, this was no longer necessary; here, telemetry was performed transcutaneously through the cheek [61.27]. For this, the patient was asked just to place the reader unit at the cheek, similarly to a mobile phone.

61.3.4 Energy Supply to Medical Implants

The main criteria for the choice of an implant's energy supply are the energy demands of the implant, the available space, and the possibilities to exchange the energy source. In pacemakers, primary, nonrechargeable batteries are the conventional solution. In particular, since the introduction of lithium–iodine batteries, lifespan of up to 10 years has been achieved at acceptable volume. As the active part that incorporates the battery is implanted in a subcutaneous pocket and as the distally ingrown electrode wires are attached to the active part by detachable screw locks, exchange of the active implant portion is possible with relatively low burden to the patient. The prime qualification is the very low energy consumption of pacemakers due to the low stimulation rate, the small number of electrodes, and the good coupling to the tissues. Another relevant issue is the autonomous operation of pacemakers (and deep brain stimulators, which are also powered by batteries). Both systems fulfill their role without the presence of an external control unit. Only for (de)activation or occasional adjustment of therapeutic parameters is data exchange necessary. However, battery power supply is not possible in systems with high electrode count and high stimulation rate. Examples are implants for stimulation of the upper extremities and for grasping in tetraplegics.

In implants that do not have life-sustaining functions, secondary, rechargeable batteries are already being employed; for example, Medtronic offers a neural stimulator that exhibits twice the lifespan of its primary cell-powered cousin. Recharge cycles span around 4–6 weeks. An alternative means of energy storage is utilized in implantable drug pumps. Here, energy is stored mechanically in elastic mechanical components (Medizintechnik Promedt GmbH).

To provide energy without artificial supply, there exist research activities to make use of energy prevalent in the natural environment, aiming to realize purely self-sustaining systems. These concepts can be differentiated with respect to their primary source of energy and their principle of energy conversion. Piezoelectric, capacitive, as well as electromagnetic generators belong to the class of energy converters which make use of the mechanical energy of the body. Because of the variety of locations, different possibilities of coupling exist; for example, at sinews or muscles, longitudinal forces prevail. Across joints, bending deformations can be exploited, and in body regions where pressure forces are experienced, e.g., under the sole of the foot or beneath

muscles, dynamic compression conditions may be used. The major challenge for mechanical energy converters is the encapsulation of the electric components such as the piezoceramics, which needs to be deformable. Additionally, tissue reactions induced by the mechanical loading need to be carefully analyzed. Good results are expected from thermoelectric generators due to the body's continuous production of thermal energy. However, when considering the temperature gradient that prevails at possible implantation sites and the influence of environmental temperature and clothing on this gradient, little energy conversion is achievable. Research approaches of Biophan tried to optimize thermoelectric converters for temperature differentials of 1–5 °C in order to generate electric power of up to 100 μW at 4 V_{DC} . A converter area of 2.5 cm^2 is planned. However, to date, these systems have not met with success. In principle, photovoltaic cells could be a viable option if there existed enough places on the body that are not, even intermittently, covered by clothes. Furthermore, placement of such cells close beneath the skin is problematic in humans from a cosmetic point of view.

The use of fuel cells to convert metabolic products into electrical energy is another option for harvesting body energy for energy supply to active implants. The challenges here are to protect the fuel cell from catalyst poisons, to sustain a continuous fuel supply, and to remove reaction products. Partially, this may be solved through the development of suitable membranes. Although this may solve the aforementioned problems, with time, connective tissue will still cover the membrane and thus decelerate the transport of required substances. This, in turn, limits the achievable electrical power.

Due to the limited performance of implantable energy harvesters, an energy storage component, e.g., a capacitor, will be necessary in any case. This ensures that short peaks in power demand can be handled and may also serve as a backup when, at least for short periods, the harvested power is too low to sustain the implant's operation. Besides, a special energy management circuit is required to adapt the voltage levels of the generator and the electronics.

In the 1980s, even isotope batteries employing radioactive ^{238}Pu were used to power implantable pacemakers. In the meantime these have been taken off the market because of the toxicity of the material. According to the German Radiation Protection Office, 284 patients were supplied with these kind of implants, of whom 2 were still alive in 2010.

Fig. 61.5 Example of the no return to zero (NRZ) code

61.3.5 Line Codes

To transmit a serial stream of data down a transmission line or a radio link, various coding methods are employed. These differ in their transmission properties, such as the lack of a direct current (DC) component or the incorporation of a clock signal. The lack of a DC component is required if, e.g., the data stream is sent across an inductively coupled interface, to ensure galvanic insulation. Extraction of the clock signal may become necessary for successful data transmission when transmitter and receiver are excessively desynchronized.

In the following, a few codes are presented as examples.

In the no return to zero (NRZ) code the logical symbols 1 and 0 are represented by two different voltage levels (Fig. 61.5). In case of successive 0s (or 1s), a DC component appears. Moreover, it is no longer possible to extract the clock signal.

The alternate mark inversion (AMI) code is characterized by three different voltage levels (Fig. 61.6).

Fig. 61.6 Example of the alternate mark inversion (AMI) code

Fig. 61.7 Example of the Manchester code

The logical 0 is assigned a signal level of 0 V, and a logical 1 is marked by an applied voltage level.

However, the polarity of the voltage change from one logical 1 to the next. This code allows extraction of the clock signal only during a succession of logical 1s, not from 0s.

In the Manchester code, the two logical states 1 and 0 are characterized by a polarity shift after half the symbol period (Fig. 61.7). A falling edge represents a 1, and a rising edge represents a logical 0. This ensures that the clock can always be extracted, independent of the content of the data stream. The downside of this code is that it requires a larger bandwidth, since the clock frequency is twice the bit rate.

61.4 Inclusion of Active Medical Implants in Telemedicine Systems

All major manufacturers of active implants for treatment of heart diseases now offer telemedicine services for their products, whether Merlin.net from St. Jude, Biotronik Home Monitoring, CareLink from Medtronic, etc. The Latitude system from Boston Scientific monitors not only the functions of its pacemakers but also other devices, such as a weighing scale or a blood pressure measuring device, using Bluetooth

technology. The manufacturer expects that, in this way, the comprehensive health status of the patient will be available to the treating physicians, without the need for the patient to present to the practice or clinic. A study sponsored by the industry [61.28] underpins the theory that a regular flow of comprehensive pacemaker data to hospitals reduces the risk of complications.

62. Fundamentals of Medical Image Processing

Fundamentals

Thomas M. Deserno

After some remarks to the background and terminology used, Sect. 62.3 deals with low-level image processing as far as necessary to understand the following chapters. Subsequently, the core steps of image analysis: feature extraction, segmentation, classification, quantitative measurements, and interpretation are presented in separate sections. Here, the focus is on segmentation of medical images, because this is of high relevance and, therefore, special methods and techniques have been developed in the medical application domain. In Sect. 62.9, certain aspects of medical data visualization are outlined. Many methods have been developed in this field specifically for clinical applications. Section 62.10 provides a brief summary of image communication. The electronic transmission and exchange of medical images will become more important in future for multimedia applications such as electronic patient records. Section 62.11 completes this chapter with an overview of past, present, and future challenges to medical image processing.

By the increasing use of direct digital imaging systems for medical diagnostics, digital image processing is becoming more and more important in health care. In addition to originally digital methods, such as computed tomography (CT) or magnetic resonance

imaging (MRI), initially analog imaging modalities such as endoscopy or radiography, have been equipped with digital sensors. Hence, medical image processing is becoming an inherent part of medical technology.

62.1 Background

Digital images are composed of individual pixels (this acronym is formed from the words picture and element), where discrete brightness or color values are assigned. They can be efficiently processed, objectively evalu-

ated, and made available at many places at the same time by means of appropriate communication networks and protocols, such as picture archiving and communication systems (PACS) and the digital imaging and

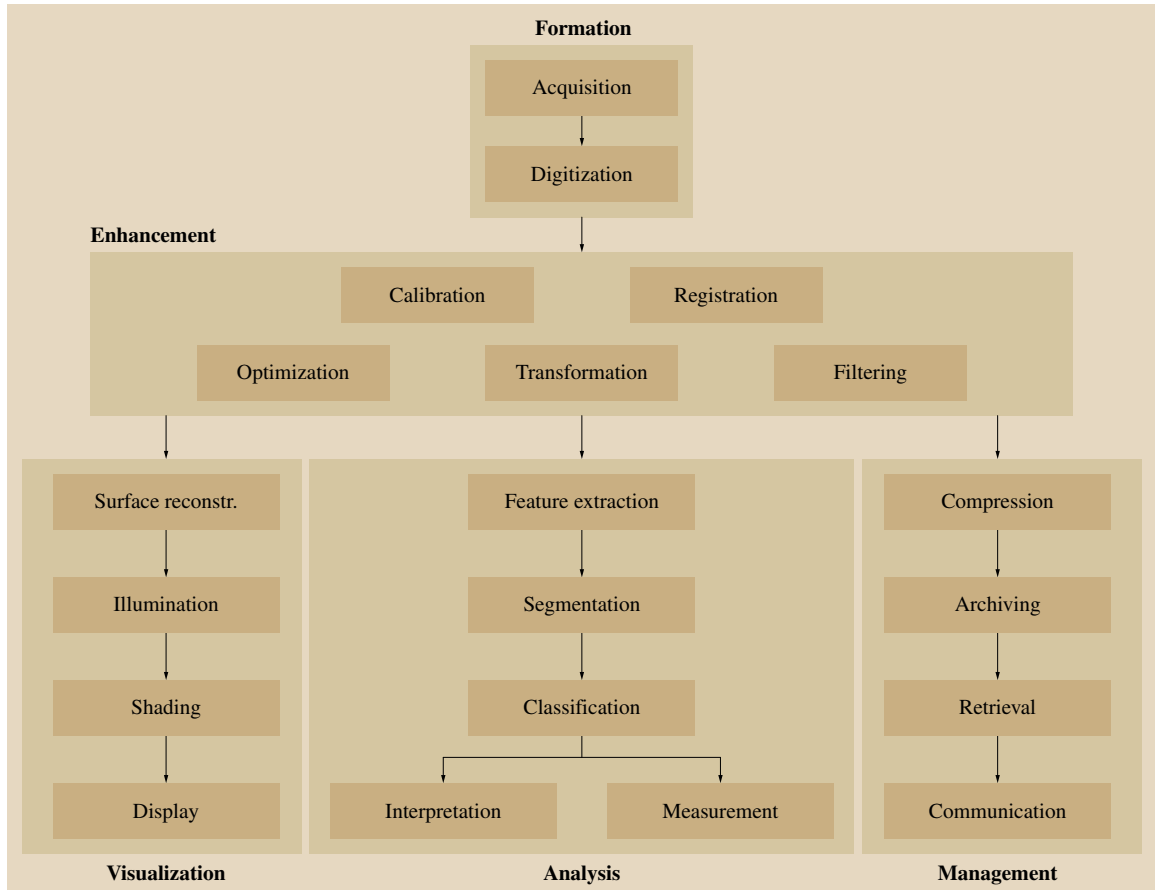

Fig. 62.1 Modules of medical image processing (after [62.1]). Medical image processing covers four main areas: image formation, analysis, visualization, and management. The algorithms of image enhancement can be assigned as pre and post in all areas

communications in medicine (DICOM) protocol, respectively. Based on digital imaging techniques, the entire spectrum of digital image processing is now applicable in medicine.

The commonly used term *medical image processing* means the provision of digital image processing for medicine. Medical image processing covers four major areas (Fig. 62.1):

1. *Image formation* includes all the steps from capturing the image to forming a digital image matrix.
2. *Image visualization* refers to all types of manipulation of this matrix, resulting in an optimized output of the image.
3. *Image analysis* includes all the steps of processing, which are used for quantitative measurements as

well as abstract interpretations of medical images. These steps require a-priori knowledge on the context and content of the images, which must be integrated into the algorithms on a high level of abstraction. Thus, the process of image analysis is very specific, and developed algorithms can be transferred rarely directly into other domains of applications.

4. *Image management* sums all techniques that provide the efficient storage, communication, transmission, archiving, and access (retrieval) of image, since an uncompressed radiograph may require several megabytes of storage capacity. The methods of telemedicine are also a part of the image management.

In contrast to image analysis, which is often also referred to as high-level image processing, low-level pro-

cessing denotes manual or automatic techniques, which can be implemented without a-priori knowledge on the specific content of images. This type of algorithm has similar effects regardless the content of the images. For example, histogram stretching of a radiograph improves

the contrast as it does on any holiday photograph. Therefore, low-level processing methods are usually available with programs for image enhancement. On this background, this chapter gives an introduction to the methods of medical image processing.

62.2 Remarks on the Terminology

The complexity of an algorithm, the difficulty of its implementation, or the computing time required for image processing plays a secondary role for the distinction between low-level and high-level processing methods. Rather, the degree of abstraction of the a-priori knowledge is important for this meaning. Although the following definitions are not standardized in the literature, they are used consistently within this chapter:

- The *raw data level* records an image as a whole. Therefore, the totality of all pixels is regarded on this level.
- The *pixel level* refers to discrete individual pixels.
- The *edge level* represents the one-dimensional (1-D) structures, which are composed of at least two neighbored pixels.
- The *texture level* refers to two-dimensional (2-D) structures. On this level, however, the delineation of the area's contour may be unknown.
- The *region level* describes 2-D structures with a well-defined boundary.
- The *object level* associates textures or regions with a certain meaning or name, i. e. semantics is given on this level.
- The *scene level* considers the ensemble of image objects in spatial and/or temporal terms.

From an iconic (concrete) to a symbolic (abstract) description of images, information is gradually reduced. Methods of low-level image processing operate on the raw data as well as pixel, edge, or texture levels, and thus at a minimal level of abstraction. Methods of high-level image processing include the texture, region, object, and scene levels. The required abstraction can be achieved by an increased modeling of a-priori knowledge. With these definitions, a particular problem in high-level processing of medical images is immediately apparent: resulting from its complex nature, it is difficult to formulate medical a-priori knowledge such that it can be integrated directly and easily into automatic algorithms of image processing. In the literature, this is referred to as the *semantic gap*, which means the discrepancy between the cognitive interpretation of a di-

agnostic image by the physician (high level) and the simple structure of discrete pixels, which is used in computer programs to represent an image (low level). In the medical domain, there are three main aspects of hindering bridging this gap:

1. *Heterogeneity of images*: Medical images display organs or body parts. Even if captured with the same modality and following a standardized acquisition protocol, shape, size, and internal structures of these objects may vary remarkably not only from patient to patient (inter-subject variation) but also among different views of a patient and similar views of the same patient at different times (intra-subject variation). In other words, biological structures are subject to both, inter- and intra-individual alterability. Thus, universal formulation of a-priori knowledge is impossible.
2. *Unknown delineation of objects*: Frequently, biological structures cannot be separated from the background because the diagnostically or therapeutically relevant object is represented by the entire image.

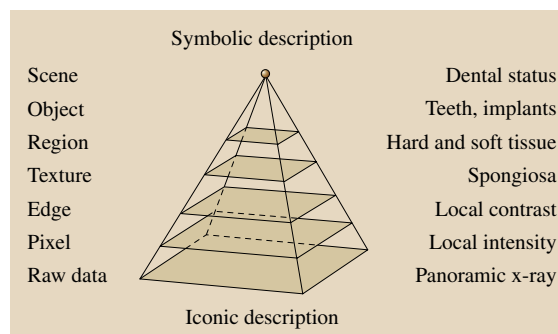

Fig. 62.2 Levels of abstraction for image processing (after [62.2]). On the pyramid's *left-hand side*, the degrees of abstraction for image processing are specified. On the *right-hand side*, the general terms are exemplified for a panoramic radiograph. At the *top*, the dental status corresponds to an abstract scene analysis, which only contains standardized information (existence and condition) on the tooth positions

Even if definable objects are observed in medical images, their segmentation is problematic because the shape or borderline itself is represented fuzzily or only partly. Hence, medically related items often can be abstracted at most on the texture level.

3. *Robustness of algorithms:* In addition to these inherent properties of medical images, which complicate their high-level processing, special requirements of reliability and robustness of medical procedures and, when applied in routine, image pro-

cessing algorithms are also demanded in the medical area. As a rule, automatic analysis of images in medicine should not provide wrong measurements. This means that images that cannot be processed correctly must be automatically classified as such and rejected. Consequently, all images that are not rejected must be evaluated correctly. Furthermore, the number of rejected images must be quite small, since most medical imaging procedures are harmful and cannot be repeated just because of processing errors.

62.3 Image Enhancement

Low-level methods of imaging processing, i. e., procedures and algorithms that are performed without a-priori knowledge about the specific content of an image, are mostly applied for pre-processing of medical images. Therefore, the basic methods of histogram transforms, convolution, and (morphological) filtering are disregarded unless required for further understanding of this text. As a special preprocessing of medical images, techniques for calibration and registration are briefly introduced.

62.3.1 Histogram Transforms

Point operations (pixel transforms) are based on the histogram of the image. Modifying the pixel values, all pixels are transformed independently from their positions in the image and their immediate neighborhood.

Therefore, these types of transforms are also referred to as point operations. The histogram shows the frequency distribution of pixel values (e.g., the gray scales) disregarding certain positions where the gray scales occur in the image. Simple pixel transforms can be defined using a histogram. For example, through the stretching of gray scales, the contrast of an image is improved (Fig. 62.3). After determining the histogram, upper and lower bounds are located, and a linear transform is applied that maps the lower bound to zero and the upper bound to the maximal gray scale (i. e., 255 for 8 bit images). If the histogram of the initial image does not contain all possible gray scales, the gray scale differences between neighbored pixels is enlarged, which results in an enhanced contrast.

Technically, those histogram transforms are computed by look-up tables. For all pixel values, the look-up

Fig. 62.3a–c Histogram stretching. A region of interest (ROI) is taken in the area of the temporomandibular joint from an intra-oral x-ray image (a). Resulting from underexposure, the spongy bone structure is displayed poorly. The associated histogram (b) is only narrow occupied (red). By stretching the histogram, the bins in the histogram are linearly pulled apart (blue) and the contrast of resulting transformed radiograph is increased (c)

Table 62.1 Look-up-table for pseudo coloring [62.3]. For each value in the range of the input image, the look-up table holds a value from the range of the output image. The color palette shown here is used for pseudo coloring keeping the original brightness progression of the input image. Pseudo coloring allows presentation of data, whose range of values exceeds the length of the RGB cube’s edges without reducing the information as results from windowing

Old gray	New pixel value			Old gray	New pixel value		
	red	gray	red		red	green	blue
0	0	0	0
1	1	0	2	246	254	244	239
2	2	0	3	247	255	245	243
3	3	0	5	248	255	245	244
4	4	1	7	249	255	246	246
5	5	1	9	250	255	247	248
6	5	2	12	251	255	249	250
7	5	2	14	252	255	251	252
8	5	3	16	253	255	251	253
9	5	4	18	254	255	253	254
...	255	255	255	255

Fig. 62.4a–f Simple templates for discrete convolution. The sliding average (a) and the binomial low-pass filter (b) cause a smoothing of the image. The binomial high-pass filter (c), however, increases contrast and edges, but also the noise in the image. The templates (a) to (c) must be normalized to make sure that range domain of values is not exceeded. The contrast filter (d) is based on integer pixel values. The convolution with (d) is, therefore, very easy to calculate. The anisotropic templates (e) and (f) belong to the family of Sobel operators. Eight Sobel masks can be generated by rotation and mirroring for direction-selective edge filtering (Fig. 62.8)

table contains a new value, which can also originate from another range of values. The example in Table 62.1 assigns each gray scale with a triple for red, green, and blue (RGB). This transform is called pseudo-coloring and is frequently used in the medical domain to enhance local contrast. Computer graphic boards may limit the number of gray scales to 256 (8 bit), but offers $256^3 = 16\,777\,216$ colors. Special algorithms are recommended for pseudo-coloring in the medical context.

62.3.2 Convolution

In contrast to point operations (histogram transforms), the considered pixel are combined with the values of their neighborhood when discrete filtering is applied. The underlying mathematical operation, i. e., convolu-

tion, can be characterized with the help of so called templates (Fig. 62.4). A *template* is a mostly small, squared mask with odd lateral length. This template is mirrored along two axes (hence the name convolution is commonly used) and positioned in one corner of the input image. The image pixels under the mask are named *kernel*. Each pair of corresponding pixel values of template and kernel are multiplied and then added together. The result is registered at the position of the mask’s center pixel in the output image. Then, the template is shifted row by row and column by column to the next positions on the input image, until all the positions have been visited, and the output image is thus completely calculated. The pixel values of the template determine the effect of the filter. If only positive values are used in the template, basically a (weighted) averaging is calculated in the local neighborhood of each

Fig. 62.5a,b Geometric distortion and brightness variations in video endoscopy (after [62.1]). With endoscopic examinations, barrel distortions are often generated, which must be corrected before the image can be analyzed quantitatively. In addition, the boundary areas in the video appear darker and blurred. Image (a) is generated with a rigid laryngoscope, which is used for the examination of the larynx. Image (b) is taken with a flexible endoscope for nasal laryngoscopy. Both endoscopes are used in clinical routine. Microscopy and other optical methods produce similar artifacts

pixel (Fig. 62.4a,b). The resulting image is smoothed and appears with reduced noise.

However, the sharpness of edges is also reduced. If the template is composed of positive and negative coefficients, the contrast in the image is intensified, and the edges are highlighted. Anisotropic (i. e., not rotationally symmetric) templates also have a preferred direction (Fig. 62.4e,f). Hereby, the contrasts can be direction-selectively strengthened.

Another approach to filtering is adapted from mathematical morphology. Although morphologic operators can also be defined to gray scale image, morphologic filtering is principally performed on binary input images, i. e., each pixel is assigned either true or false. According to a general convention, the white pixels in the binary image indicate relevant segments and the black pixels indicate the background. For printing, however, this assignment may be inverted. The binary template, which is also referred to as *structural element*, is associated to the binary image using logical operations, in particular:

- *Erosion* (based on logical AND template and binary image)
- *Dilatation* or dilation (based on logical OR template and binary image)
- *Opening* (erosion followed by dilatation using the same structuring element)
- *Closing* (dilatation followed by erosion using the same structuring element)
- *Skeleton* (e.g. by erosion with various structuring elements).

The erosion reduces the size of a segment, and the dilation leads to its enlargement. The opening removes small details on the outline of segments or the background, without affecting the total size of relevant segments. The closing is able to remove holes in the interior of a segment and smooth its contour. Here, the size of the segment is also roughly maintained. The skeleton is a path with the thickness of one pixel, which is located in the middle of the segment.

62.3.3 Calibration

If the physician intends to take quantitative measurements from an image, a careful calibration of the imaging modality is required. Both geometry (spatial domain) and brightness or color intensity (value domain) must be adapted to the modality. Calibration is device-specific but disregards the biological content captured, and thus, it is part of low-level processing methods. While reading a radiograph, calibration is made unconsciously by the radiologist. However, it must be explicitly implemented for computerized image analysis. Geometric aberration (distortions) have the consequence that relevant structures of the same size are displayed depending on the position within the image. In medicine, the positioning of the imaging device may not affect any measurements. For example, in endoscopy, resulting from the optical devices in use, so called barrel distortions originate (Fig. 62.5). Even in simple planar radiography, objects that are far away from the image plane appear larger than those located

Fig. 62.6 Unimodal registration. In dental implantology, the reference image and recall recording are taken at various times. The geometric registration with subsequent contrast adjustment enables pixel-by-pixel subtraction. In the subtraction image, bone destruction is clearly emphasized and can be segmented easily on the pixel level of features (*red*)

close to the imaging device. This must be kept in mind whenever geometric measurements in digital x-rays are made and displayed to the physicians: point distances in digital images can be converted into length measurements only under the assumption of a fixed scale, which is often not fulfilled.

In the same way, is the absolute assignment of pixel values to physical measurements is usually problematic. For example, in x-ray imaging, the linear correspondence of brightness values to the accumulated absorption coefficient of the imaged structure is possible only if an aluminum (step) wedge with known x-ray absorption properties is placed beside the object. With digital video recording, a prior white balance must be performed, so that the color values correspond to reality. However, different illumination of the same scene may still alter the colors captured.

62.3.4 Registration

Often, an absolute calibration of examination procedures is not possible or only limitedly feasible. Then, registration can be used to achieve an approximation of two or more images such that at least a change in measured dimensions can be quantified. For example, an acute inflammation turns tissue into a reddish color. Under treatment, the absolute redness of the tissue is less interesting than its relative change from the findings of previous recordings. *Single-modal registration* refers

to relative calibration of images that have been acquired with the same modality. For instance, images that have been taken from the same patient but at different points of time are adjusted in order to quantify the course of the disease. As in the field of calibration, we differ between geometric registration and color or contrast adjustment, if the registration is performed in the spatial domain or the value range, respectively. Figure 62.6 illustrates the diagnostic potential of registration in dental implantology. After registration, the appraisal of the status of peri-implant bone is significantly simplified by the subtraction of recall and follow-up recordings.

Multimodal registration is applied when the images to be compared are captured from different modalities. For example, a three-dimensional (3-D) rigid registration is illustrated as the movement of the hat on the head. These methods have a crucial meaning especially in neurology. Since tumor resection in the brain must be executed very carefully, in order to avoid damage of neighboring brain areas, functional and morphological brain images are registered to plan the procedure. While the morphological information in CT or MRI data can be adequately represented, function of areas in the brain is frequently localized using positron emission tomography (PET) or single photon emission computed tomography (SPECT). Thus, multimodal registration of functional and morphological datasets provides valuable additional information for diagnosis and therapy (Fig. 62.7).

Fig. 62.7 Multimodal registration and fusion (after [62.4]).
1. Row. T_1 -weighted MRI of a 66 year old subject with right parietal glioblastoma. *2. Row.* Corresponding PET layers after multimodal registration. *3. Row.* Fusion of registered layers to support the treatment planning. *4. Row.* The fusion of MRI with PET of the sensorimotor-activated cortex area proves that the relevant area is out of focus

62.4 Feature Extraction

In Fig. 62.1, feature extraction is defined as the first stage of intelligent (high level) image analysis. It is followed by segmentation and classification, which often do not affect in the image itself, i. e. the data or pixel level, but are performed on higher abstract levels (Fig. 62.2). Therefore, the task of feature extraction is to emphasize image information on the particular level where the following algorithms operate. Consequently, information provided on other levels must be suppressed. Thus, data reduction is executed to obtain the characteristic properties.

The schema in Fig. 62.1 is greatly simplified because many connections between the modules were left out on behalf of readability. So, for example, cascades of feature extraction and segmentation at various levels of abstraction can be realized gradually, before classification is eventually performed at a high level of abstraction. Just before classification, a step of feature extraction that is based on the region level is often performed as well. *Data-based features* depend on the joint information of all pixels. Therefore, all transforms manipulating the whole matrix of an image at once can be regarded for data feature extraction.

The most famous example of a data feature transform is the Fourier transform, which describes a 2-D image in terms of frequencies, according to their amplitude and phase. Furthermore, the Hough, wavelet, or Karhunen–Loève transforms provide possibilities of data feature extraction (see Further Reading on image processing for more details). These methods are not in the focus of research in medical image processing. In fact, these procedures are rather adapted from technical areas to medical applications.

Since *pixel-based features* depend on the values of individual pixels, all point operations that have been defined in Sect. 62.3 can be regarded as feature extraction on the pixel level. Another example was already presented in Fig. 62.6, namely, the arithmetic combination of two images. The subtraction of reference and recall images after appropriate registration in both spatial and value ranges enforces local changes in the images as characteristic pixels.

Edge-based features are defined as local contrast, i. e., a strong difference of (gray scale or color) values of adjacent pixels. Thus, the discrete convolution introduced in Sect. 62.3 can be used with appropriate

Fig. 62.8 Edge extraction with Sobel operator. The x-ray image was convolved with the eight direction-selective Sobel templates. The strong contrasts on the edges of metallic implants are further strengthened by binarization of the edge images. An isotropic edge image is obtained if, e.g., the maximum at each pixel position is chosen from the eight direction-selective subimages

templates for edge extraction. All masks for high-pass filtering amplify edges in an image. The templates of the so called Sobel operator (Fig. 62.4e,f) are particularly suited for edge extraction. Figure 62.8 exemplarily presents the result of the orientation-selective Sobel masks when applied to a dental radiograph. The edges of the metallic implants are clearly highlighted. Moreover, an isotropic Sobel-based edge image is achieved, e.g., by a linear or maximum combination of the eight subimages.

Textural features have been used in medicine for a long time. In textbooks on pathology one can read many metaphors to describe texture, such as a cobblestone-like mucosal relief, onion-like stratification of subintima, or honeycomb-like lung. As intuitive these metaphors are for people, as difficult is computational texture processing, and a variety of procedures and approaches have been developed. Texture analysis attempts to quantify objectively the homogeneity in a heterogeneous but at least subjectively periodic structure

(see the spongy bone structure in Fig. 62.3c as an example). In general, we can distinguish (i) structural approaches, which are based on texture primitives (so called *texel* or *textone*) and their rules of combinations, and (ii) statistical approaches, which describe texture by a set of empirical parameters. *Regional features* are used primarily for object classification and identification. They are normally calculated for each segment after the segmentation process. The most important parameters to be mentioned here are (i) localization-descriptive measurement such as size, position, and orientation of the major axes, and (ii) delineation-descriptive measures such as shape, convexity, and length of the border. Since the degree of abstraction on the regional level is rather high as compared to the previous levels, a-priori knowledge has already been largely integrated. Therefore, universal examples cannot be specified. In fact, the definition of regional feature extraction is strongly dependent on the respective application (Sects. 62.5.3, 62.6).

62.5 Segmentation

Segmentation generally means dividing an image into connected regions. With this definition, the production of regions is emphasized as the pre-stage of classification. Other definitions emphasize the various diagnostically or therapeutically relevant image areas and, thus, focus on the most common application of medical imaging, namely, the discrimination between healthy anatomical structures in pathological tissue. Per definition, the result of segmentation is al-

ways on the regional level of abstraction (Fig. 62.2). Depending on the level of feature extraction as an input to the segmentation, we can methodically classify pixel, edge, and texture or region-oriented procedures. In addition, there are hybrid segmentation procedures, which result from the combination of single approaches.

62.5.1 Pixel-Based Segmentation

Pixel-based procedures for segmentation only consider the gray scale or color value of current pixels, disregarding its surroundings. It should be pointed out that pixel-based procedures are not segmentation procedures in the strict sense of our definition. Since each pixel is considered only isolated from its neighborhood, it cannot be ensured that actually only connected components are obtained. For this reason, a post-processing is required, e.g., by morphologic filtering (Sect. 62.3).

Most pixel-based procedures use thresholds in the histogram of an image and employ more or less complex methods to determine this threshold, or statistical methods for pixel clustering are used.

Static thresholds can be applied if the assignment of pixel intensities is well known and constant for a certain type of tissue. A static threshold is independent of each image. For example, bone or soft tissue windows in the

Fig. 62.9 Thresholding of a CT slice. The CT slice in the area of the spine can be statically segmented because the standardized Hounsfield units (HU) allow the definition of windows for different tissue such as bone [200...3000], water [-200...200], fat [-500...-200], and air [-1000...-500]

Fig. 62.10a–e Dynamic thresholding in microscopy (after [62.5]). The microscopy of a cell culture (a) was segmented using a global threshold (b), locally adaptive (c) and pixel-adaptive (d). According to morphological post-processing for noise reduction and a connected components analysis, the final segmentation is shown in (e)

CT with static thresholds on the Hounsfield units can be realized (Fig. 62.9).

Globally adaptive thresholds result from an analysis of each image. They are exclusively used in this image. The well known method of Otsu is based on a simple object/background model. The threshold in the histogram is determined such that the two resulting classes minimize the intra-class variance of gray scale values, while the inter-class variance is maximized. For example in skeletal radiography, bone, soft tissue, and background can be seen, but the actual mean gray scale of these tissue classes may vary with respect to illumination and exposure parameters. By adopting the threshold to the image, the Otsu segmentation is able to balance this variation in imaging.

Using *locally adaptive thresholds*, the threshold is computed not only for each image individually, but also for each region within an image. In the extreme case, an individual threshold is determined for every pixel position. This is particularly necessary if the simple object to background assumption is globally invalid, for instance, because of continuous brightness gradients. For example, due to the irregularity of optical illumination, the background in microscopy imaging of cell cultures (Fig. 62.10a) runs from light shades of gray (top right) to dark shades of gray (bottom left), where also the gray scale values of the cells are located. A global threshold determined with the dynamic procedure of Otsu (Fig. 62.10b) does not separate the cells from backgrounds, although the global threshold has been determined image-individually. The locally adaptive segmentation (Fig. 62.10c) leads to a significantly improved result, but isolated block artifacts appear. These artifacts can be avoided only by pixel-adaptive thresholding (Fig. 62.10d).

Pixel clustering is another way of pixel-based segmentation. This statistical method is particularly

suitable if more than one value is assigned to each pixel and regarded in the segmentation process (e.g., color images). Figure 62.11 illustrates the isodata clustering algorithm (also referred to as *k*-means clustering) in a simple 2-D case. All pixel values are registered as data point in the 2-D feature space. Initialized by the number of segments to be obtained, the initial cluster centers are arbitrarily placed by the algorithm. Then, the following two steps are repeated iteratively until the process converges:

1. Each data point is aligned to the closest cluster center
2. Based on the current assignment, the cluster centers are re-calculated.

It can be proven mathematically that the resulting cluster centers are independent of initial positions, which may only impact the number of iterations and hence, the calculation time. However, either a fixed distance metrics (e.g., Euclidean (geometric) distance) or a data adaptive metrics (e.g. Mahalanobis distance) must be selected, which certainly impacts the clustering result. Also, the pre-defined number of cluster centers is an important parameter. If the application domain does not allow determination of the number of segments a-priori, pixel clustering can be performed for a different number of centers and the residual error of the computed model can be analyzed to determine the appropriate number of centers. Segments obtained from pixel-based analysis are usually incoherent and highly noisy (Fig. 62.9).

Therefore, post-processing is required. Noisy structures can be effectively reduced with methods of mathematical morphology. While a morphologic opening removes spread parts from the segments, holes are closed by morphologic closing (Sect. 62.3). The connected components algorithm provides each sepa-

Fig. 62.11 Isodata pixel clustering. The iterative isodata algorithm for pixel clustering is exemplified in a 2-D feature space. The number of clusters is given a-priori. After arbitrary initialization, the data points are assigned to the nearest cluster center. Then, the positions of the centers are re-calculated and the assignment is updated until the process finally converges. The final location of cluster centers is not affected by their initial position. This may only have impact on the number of iterations

rated segment with a unique reference number. In the segmentation of the cell image (Fig. 62.10); clustering provides a rough cluster of cells, which is separated from the background, although many individual cells are shown separately in the image (Fig. 62.10d). After morphological post-processing and connected components analysis, cells are separated and colored (labeled) differently according to their segment number. Now, they can be further processed as independent objects (Fig. 62.10e).

62.5.2 Edge-Based Segmentation

This type of segmentation is based on the abstract level of edges and tries to capture the objects due to their closed outline in the image. Hence, edge-based segmentation procedures are only used for such problems where objects are represented as clearly defined boundaries. As described in Sect. 62.2, this occurs rather seldom when biologic tissue is imaged. One of these special cases is a metallic implant shown in a radiograph. In general, the image processing chain for edge-based segmentation is composed of edge extraction, edge completion, and object recognition. Edge extraction is usually obtained by edge-based feature extraction, as

described in Sect. 62.4, such as generated with the Sobel filter (Fig. 62.8). The next steps of processing are binarization, to obtain only edge pixels and nonedge pixels, morphological filtering to reduce noise and artifacts, and, finally, a skeleton of the edge is computed. Tracing and closing of binary contours are the main tasks of the edge-based segmentation. Almost exclusively heuristical methods are used here. For example, one can search along some rays for connecting pieces of a contour of an object to skip the local gaps of the edge.

In practice, edge-based segmentation is often realized semi-automatically. With interactive live-wire segmentation, the user clicks on or near the edge of the object of interest, and the computer determines the exact edge location based on local gradients. Then, the computer calculates a cost function, which is again based on local gradients; for all paths (wire) to the current position of the cursor, the path with the least cost is displayed in real time (live) as the cursor is moved manually. Therefore, the metaphor live-wire is commonly used to refer to this interactive method of segmentation. If the cursor moves far from the object, the contour is lost, but if the cursor is placed near the contour again, the cost function ensures that the wire snaps back to the desired object.

Fig. 62.12a–h Edge-based interactive live-wire segmentation in MRI (after [62.6]). The user marks a starting point with the cursor (yellow) on the border between white and gray matter (a). The connection to the current cursor position is denoted with red, cf. (b) to (e). Depending on the cursor position, the contour can also jump between very different courses (d),(e). So, the user can interactively place an appropriate fix point. The fixed curve segment is shown in blue, cf. (e) to (g). In this example, only five points are manually marked to achieve a complete segmentation (h)

Finally, the user must provide only a few support points by hand and can directly verify the correctness of segmentation (Fig. 62.12). Application of such procedures can be found at computer-assisted (semi-automatic) segmentations in layers of CT data, e.g., to produce a model for surgical treatment planning.

62.5.3 Region-Based Segmentation

As an advantage of region-based segmentation, only connected segments are produced, and morphological post-processing is avoided. There are agglomerative (bottom-up), divisive (top-down), and hierarchical approaches. All approaches are based on a certain distance or similarity measure to guide the assignment of neighbored pixels or regions. Here, a variety of methods is used. The easiest is to compare the mean gray value but complex texture measures (Sect. 62.4) are also often used.

Region growing (in 3-D also referred to as volume growing) is a well known example of an agglomerative procedures. Starting from seed points, which may be placed either automatically or manually, neighboring pixels are iteratively associated to the growing areas if the distance is below a certain threshold. This process is

iterated until no more merges can be carried out. From this qualitative description, the variety and sensitivity of the parameters of such procedures are already clear. The following have a special influence on the result of agglomerative segmentation:

- The number and position of seed points
- The order in which the pixels or voxels (in analogy to the term pixel, this acronym is formed from the words volume and element) are iteratively processed
- The distance or similarity measure applied
- The threshold used to guide merging.

Therefore, agglomerative algorithms for segmentation often are affected by small shifts or rotations of the input image, in particular if x and y -axes of the image matrix are transposed, which is unwanted in medical image processing. The *divisive approach* somehow inverts the agglomerative strategy. The regions are iteratively subdivided by splitting until they are sufficiently homogeneous in terms of the chosen similarity measure. As an advantage, seed points are not required, because the first split is performed throughout the whole image. As a drawback, the dividing lines are usually drawn horizontally or vertically, and this arbitrary separation may

separate individual image objects. Therefore, a split is not usually performed as a self-standing segmentation procedure, but rather combined with a subsequent merging step (so called split & merge). Another drawback of divisive segmentation procedures is the resulting wedge-formed boundary of objects, which may require post-processing such as smoothing. A fundamental problem of pixel-based and region-based segmentation is the dualism between *over* and *under-segmentation*. For a definition of these terms, we rely on the general model of the image processing chain (Fig. 62.1). Here, segmentation is regarded as a pre-stage for classification, in which the extracted image segments are assigned to their semantic meaning. This can take the form of automatically assigning concrete terms for the segments (for example, the organ *heart* or the object *TPS implant* or, more abstract, a defect or an artifact). In any case, the segment should be related directly to an object, if automatic classification is to be possible. In this context, under-segmentation occurs if the resulting segments are composed from parts of several objects. Analogously, over-segmentation is obtained if a particular object is disintegrated into several segments. The big problem with the segmentation of medical images is that over and under-segmentation usually occur simultaneously.

Hierarchical procedures are one of the concepts to deal with the dualism between over and under segmentation. Starting on a lower resolution of the image, where it is represented with a small number of pixels only, the chance of splitting objects into more than one segment is decreased. Then, the exact outline of each segment is reconstructed on higher resolutions, where more details are contained.

62.5.4 Hybrid Segmentation Procedures

In the practice of medical image processing, hybrid approaches of segmentation have come to be of greatest importance. Here, one is trying to combine the advantages of individual (usually edge-based and region-based) algorithms without maintaining their disadvantages. Two widely used approaches, the watersheds transform and the active contour models, are exemplarily discussed in the following sections.

The *watershed transform* extends an agglomerative, regional segmentation procedure with edge-based aspects of segmentation. The numerical gray scales of a pixel are interpreted as the elevation level in a row of mountains, and crest lines are formed in the relief. If it is raining, the water drops fall onto the

mountains, flowing downhill into the valleys, and form small lakes in the local minima. During the successive flooding of the landscape, neighboring pools may be merged. The merging of pools, however, is prevented by artificial watersheds. Frequently, the watershed segmentation is applied to a gradient image rather than the original, since the water reservoirs then directly correspond with visual image regions. For segmentation of medical images, the watershed transform especially has the following advantages:

- From the region-based idea of the flooding process, continuous segments are determined inherently.
- From the edge-based approach of the watersheds, the objects are exactly delineated.
- The problem of under-segmentation is avoided, since the merging of smaller pools is prevented by the watersheds.

However, the watershed transform results in a strong over-segmentation (for example Fig. 62.13b), which must be handled appropriately before any object recognition in the image is successful. This can be done with those methods of region merging that already have been discussed. Nevertheless, over-segmentation depicts in principle the difficulty of the watershed transform.

Active contour models are based on an edge-based segmentation in consideration of region-based aspects and an object-based model of a-priori knowledge. In the medical application domain, so called snake and balloon approaches are applied for segmentation of 2-D and 3-D image data and the tracing of contours in 2-D image and 3-D image sequences, i.e. 3-D and four-dimensional (4-D) data, respectively. The contour of the objects, which is usually closely modeled, is presented by individual nodes, which are – in the simplest case – piecewise connected with straight lines forming a closed polygon. For the nodes, a scalar quality measure (e.g., energy) is calculated and optimized in the local environment of the nodes. Alternatively, adjusted forces are determined that directly move the nodes. The iterative segmentation process completes at minimal energy or if an optimum balance of forces has been found. Thus, the potential of this approach is kept in the choice of capable quality criterions (e.g., energy) or forces. The classical *snake* approach models an internal and an external quality criterion, both as undirected energy. The internal energy results from a predefined elasticity and stiffness of the contour, which is high in places of strong bends or buckling. The external energy is calculated from an edge-filtered image. The external energy is small if the contour runs along edges. The

Fig. 62.13a–g Hierarchical region merging. The skeletal radiograph of the hand (a) has been segmented at various levels of resolution, cf. (b) to (d). The initial step is obtained with the watershed transform (Sect. 62.5.4). Depending on the size of the objects, they can be localized in the appropriate level (e), approximated by ellipses (f), or visualized as nodes in a graph (g)

Fig. 62.14 Balloon segmentation of motoneuron cell membrane (after [62.7]). The frames show the balloon at different iterations. By touching the cell membrane, the strong image forces prevent further movement of the active contour. In this application, the internal forces correspond physically to a membrane. This is clearly recognizable at the adhesion border of the balloons reaching the dendrites (*bottom left*)

Fig. 62.15a,b Segmentation with a 3-D balloon model (after [62.8]). The CT of a spine (a) was segmented with a 3-D balloon. In the surface-based rendering after automatic segmentation, the prolapse is clearly visible (b). The visualization is based on Phong shading (Sect. 62.9)

idea behind this approach is an edge-based segmentation combined with the a-priori knowledge that medical or biological objects rarely have sharp bending boundaries. With an optimal weighting of energy terms, the contour course is primarily determined by the information of edges in the image. However, if the object's contour is partially covered or incompletely captured, the internal energy ensures an appropriate interpolation of the region's shape.

As simply as this approach has been formulated verbally, as difficult is its implementation. During the iteration, the number of nodes must be constantly adjusted to the current size of the contour. Furthermore, crossovers and entanglements of the moving contour must be avoided. The classical snake approach also requires an already precisely positioned starting contour, which often must be defined interactively. Then, the two steps of segmentation, i. e. localization and delineation are performed by man and machine, respectively. This concept was also applied in the first publications of this segmentation method. For contour tracking of moving

objects in image sequences, the segmentation of image at time t serves as an initial contour of iteration in image $t + 1$. After a single initialization for the image $t = 0$, the procedure runs automatically. Hence, fluoroscopy and endoscopy are suitable modalities for the application of the snake approach to track moving objects.

Balloons are based on forces rather than energies. Besides the internal and external force, an inner pressure or suction is modeled, which lets the contour continuously expand or shrink. Figure 62.14 shows the inflation movement of a balloon to segment the cell membrane, which is visualized by the synaptic boutons of contacting dendrites in a microscopy of a motoneuron. Although segmentation is done without an accurate initial contour, the balloon nestles in the course of iteration better and better to the real contour of cell membrane. Another advantage of the balloon model is that this concept is directly transferable to higher dimensions (Fig. 62.15).

In recent developments of active contour models, it has been attempted to incorporate further a-priori knowledge, e.g., in the form of anatomical models. Prototypes of the expected object shapes are integrated into the algorithm. In each iteration, the distance of the current object shape to a suitable selected prototype is modeled as an additional force on the node.

With those extensions, a break out of the active contour model is prevented also for long passages of the local object boundary without sufficient edge information. The complex and time-consuming parameterization of an active contour model for a specific application can be based on manual and also automatic reference segmentations. For the latter approach, different combinations of parameters are determined and the segmentation is performed for all cases. All resulting segmented contours are compared with the appropriate reference contour, a-priori defined as the ground truth of the training data. Then that set of parameters with the best approximation of the reference contour is selected.

62.6 Classification

According to the general processing chain (Fig. 62.1), the task of the classification step is to assign all connected regions obtained from the segmentation to particularly specified classes of objects. Usually, region-based features that capture the characteristics of the objects sufficiently abstractedly are used to guide the classification process. In this case, another feature extraction step is performed between segmentation and classi-

fication, which is not visualized in Fig. 62.1. These features must be sufficiently discriminative and suitably adopted to the application, since they fundamentally impact the resulting quality of the classifier. For all types of classifiers, we can differ supervised (trained), unsupervised (untrained) and learning classification. For example, pixel clustering, which was already introduced for pixel-based segmentation, is an unsupervised clas-

sification process. As a goal, individual objects are divided into similar groups (Fig. 62.11).
